CHURCHILL LIVINGSTONE

CONTRIBUTORS

Janis L. Abkowitz MD
Professor of Medicine, Director, Hematology Clinic, Seattle Cancer Care Alliance; Head, Division of Hematology, University of Washington, Seattle, Washington

Janet L. Abrahm MD
Associate Professor, Department of Medicine and Anesthesia, Harvard Medical School; Director, Pain and Palliative Care Program, Department of Medical Oncology, Dana-Farber Cancer Institute; Director, Palliative Care Program, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts

Charles S. Abrams MD
Associate Professor, Department of Medicine, Division of Hematology-Oncology, University of Pennsylvania School of Medicine; Attending Physician, Division of Hematology-Oncology, Department of Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Steven J. Ackerman PhD
Professor of Medicine (Hematology-Oncology), Biochemistry and Molecular Genetics, Department of Biochemistry and Molecular Genetics, University of Illinois at Chicago College of Medicine, Chicago, Illinois

Sharon Adams MT CHS
HLA Laboratory Supervisor, National Institute of Health, Warren G. Magnuson Clinical Center, Bethesda, Maryland

Adeboye H. Adewoye MD
Assistant Professor of Medicine, Boston University School of Medicine; Attending Physician, Boston Medical Center, Boston, Massachusetts

Claudio Agostinelli MD
Researcher, Bologna University School of Medicine, Bologna, Italy

Amin Alousi MD
Assistant Professor of Medicine, Department of Stem Cell Transplant and Cellular Therapy, University of Texas, M.D. Anderson Cancer Center, Houston, Texas

Claudio Anasetti MD
Professor, Department of Interdisciplinary Oncology, University of South Florida School of Medicine; Leader, Blood and Marrow Transplant Program, H. Lee Moffitt Cancer Center and Research Institute, Tampa, Florida

John Anastasi, MD
Associate Professor of Pathology, University of Chicago, Pritzker School of Medicine, Chicago, Illinois

Nancy C. Andrews MD, PhD
Dean and Vice Chancellor, Duke University School of Medicine, Durham, North Carolina

Aśok C. Antony MD
Professor, Department of Medicine, Division of Hematology-Oncology, Indiana University School of Medicine; Attending Physician and Consultant, Indiana University Hospitals; Roudebush Veterans Affairs Medical Center, Indianapolis, Indiana

Robert J. Arceci MD, PhD
King Fahd Professor of Pediatric Oncology; Professor of Pediatrics, Oncology and Cellular and Molecular Medicine, Kimmel Comprehensive Cancer Center at Johns Hopkins, Bunting-Blaustein Cancer Research Building, Baltimore, Maryland

Scott A. Armstrong MD, PhD
Assistant Professor of Pediatrics, Harvard Medical School; Attending Physician, Department of Hematology/Oncology, Children's Hospital/Dana-Farber Cancer Institute, Boston, Massachusetts

Irit Avivi MD
Senior Lecturer, Bruce Rappaport Faculty of Medicine, Technion, Israel Institute of Technology; Senior Attending Hematologist, Department of Hematology and Bone Marrow Transplantation, Rambam Medical Center, Haifa, Israel

Farrukh T. Awan MD, MS
Clinical Instructor, Clinical Fellow-Hematology Oncology, James Cancer Center, The Ohio State University, Columbus, Ohio

Aleksandar Babic PhD, MD
Instructor in Pathology, Harvard Medical School; Associate Medical Director, Adult Transfusion Service, Brigham and Women's Hospital, Boston, Massachusetts

Tiziano Barbui MD
Professor of Hematology, Scientific Director, Research Foundation, Ospedali Riuniti di Bergamo, Bergamo Italy

Giovanni Barosi MD
Director, Unit of Clinical Epidemiology and Center for the Study of Myelofibrosis, IRCCS Policlirico S. Matteo Foundation, Pavia, Italy

Robert A. Barrington MD
Postdoctoral Fellow, Department of Pathology, Harvard University Medical School and CBR Institute for Biomedical Research, Boston, Massachusetts

Kenneth A. Bauer MD
Professor of Medicine, Harvard Medical School, Boston; Chief, Hematology Section, VA Boston Healthcare System, West Roxbury; Director, Thrombosis Clinical Research, Division of Hemostasis and Thrombosis, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Linda G. Baum MD
Professor, Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California

Johanna Bendell MD
Instructor, Department of Medicine, Harvard Medical School, Assistant, Department of Medicine, Massachusetts General Hospital Cancer Center, Boston, Massachusetts

Joel S. Bennett MD
Professor of Medicine and Pharmacology, University of Pennsylvania School of Medicine; Attending Physician, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Don M. Benson, Jr. MD, PhD
Assistant Professor of Medicine, The Ohio State University; Attending Physician, Comprehensive Cancer Center, The Ohio State University Columbus, Ohio

Edward J. Benz, Jr. MD
Richard and Susan Smith Professor of Medicine, Professor of Pediatrics, and Professor of Pathology, Harvard Medical School; President and CEO, Dana-Farber Cancer Institute; Director, Dana-Farber/Harvard Cancer Center, Boston, Massachusetts

Stacey L. Berg MD
Professor of Pediatrics, Section of Hematology/Oncology, Baylor College of Medicine Houston, Texas

Nancy Berliner MD
Professor of Medicine, Brigham and Women's Hospital, Harvard Medicine School, Boston, Massachusetts

Kapil N. Bhalla MD
Director, Medical College of Georgia Cancer Center; Professor, School of Medicine, Medical College of Georgia; Vice-Dean for Cancer Research and Services, Medical College of Georgia; Chief, Clinical Cancer Services, MCG Health System, Augusta, Georgia

Nina Bhardwaj MD, PhD
Professor of Medicine, Pathology and Dermatology, New York University School of Medicine; Director, Tumor Vaccine Program, New York University Cancer Institute, New York, New York

Ravi Bhatia MD
Professor, Division of Hematology and Hematopoietic Cell Transplantation, Director, Division of Hematopoietic Stem Cell and Leukemia Research, City of Hope National Medical Center, Duarte, California

Smita Bhatia MD, MPH
Professor and Chair, Division of Population Sciences, City of Hope National Medical Center, Duarte, California

Craig D. Blinderman MD, MA
Instructor, Harvard Medical School; Co-Director, MGH Cancer Pain Clinic; Attending Physician, Palliative Care Service, Massachusetts General Hospital, Boston, Massachusetts

Catherine M. Bollard MBChB, FRACP, FRCPA
Associate Professor, Department of Pediatrics, Baylor College of Medicine; Department of Pediatric Hematology/Oncology, Texas Children's Hospital, Houston, Texas

Douglas E. Brandoff MD
Instructor in Medicine, Harvard Medical School; Attending Physician and Co-Director of Outpatient Services, Pain and Palliative Care Program, Dana-Farber Cancer Institute/Brigham and Women's Hospital, Boston, Massachusetts

Lawrence F. Brass MD, PhD
Professor of Medicine and Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Malcolm K. Brenner MD, PhD
Professor of Medicine and Pediatrics, Director, Center for Cell and Gene Therapy; Fayez Sarofim Chair, Baylor College of Medicine; Director, Center for Cell and Gene Therapy, The Methodist Hospital, Texas Children's Hospital, Houston, Texas

Gary M. Brittenham MD
James A. Wolff Professor of Pediatrics and Medicine, Columbia University College of Physicians and Surgeons; Attending Pediatrician, Children's Hospital of New York–Presbyterian, Hospital New York, New York

Robert A. Brodsky MD
Director, Division of Hematology, Johns Hopkins University School of Medicine, Johns Hopkins University, Baltimore, Maryland

Hal E. Broxmeyer PhD
Chairman and Mary Margaret Walther Professor of Microbiology and Immunology; Professor of Medicine; Indiana University School of Medicine; Scientific Director, Walther Oncology Center, Indianapolis, Indiana

Claudio G. Brunstein MD, PhD
Assistant Professor, Division of Hematology, Oncology, and Transplantation Department of Medicine, University of Minnesota, Medical School; Attending Physician, Medical Director of Unrelated Donor Transplant, University of Minnesota Medical Center, Minneapolis, Minnesota

Michael P. Busch MD, PhD
Professor of Laboratory Medicine, University of California, San Francisco, School of Medicine; Vice President, Blood Systems Research Institute, San Francisco, California

James B. Bussel MD
Professor of Pediatrics and Professor of Pediatrics in Obstetrics and Gynecology and in Medicine, Weill Medical College of Cornell University; Director, Platelet Research and Treatment Program, and Attending, Department of Pediatric Hematology Oncology, New York Hospital; Attending Pediatrician, New York Presbyterian Hospital, New York, New York

Joseph H. Butterfield MD
Professor of Medicine, Mayo Medical School, Mayo Clinic, Rochester, Minnesota

John C. Byrd MD
Professor of Medicine and Medical Chemistry, D Warner Brown Professor of Leukemia Research, The Ohio State University, Columbus, Ohio

Michael A. Caligiuri MD
Professor, The Ohio State University; Director/Chief Executive Officer, Comprehensive Cancer Center, Arthur James Cancer Hospital and Richard Solove Research Institute, Columbus, Ohio

Alan B. Cantor MD, PhD
Assistant Professor of Pediatrics, Harvard Medical School; Assistant in Medicine, Children's Hospital Boston, Dana-Farber Cancer Institute, Boston, Massachusetts

Christopher L. Carpenter MD, PhD
Assistant Professor, Department of Medicine, Harvard Medical School; Department of Medicine, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Michael C. Carroll PhD
Professor of Pediatrics and Pathology, Harvard Medical School; Senior Investigator, CBR Institute for Biomedical Research, Boston, Massachusetts

Paula M. Charuhas MS, RD, FADA, CD, CNSD
Nutrition Education Coordinator, Nutrition Program Seattle Cancer Care Alliance, Seattle, Washington

David H.K. Chui MD
Professor of Medicine, Boston University School of Medicine, Boston, Massachusetts

Douglas Cines MD
Professor, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine; Director, Coagulation Laboratory, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

David B. Clark PhD
President, Platte Canyon Consulting, Inc., Shawnee, Coloràdo

Thomas D. Coates MD
Professor of Pediatrics and Pathology, University of Southern California Keck School of Medicine; Section Head of Hematology, Children's Center for Cancer and Blood Disease, Children's Hospital Los Angeles, Los Angeles, California

Aileen C, Cohen MD PhD
Instructor of Pediatrics, Division of Hematology/Oncology, Department of Pediatrics, Stanford University School of Medicine; Attending Physician at Lucile Packard Children's Hospital, Lucile Packard Children's Hospital, Stanford, California

Désiré Collen MD, PhD
Professor Center for Molecular and Vascular Biology, University of Leuven Faculty of Medicine, Leuven, Belgium

Barry S. Coller MD
David Rockefeller Professor of Medicine, Rockefeller University School of Medicine; Head, Laboratory of Blood and Vascular Biology and Physician-in-Chief, Rockefeller University Hospital; Clinical Professor of Medicine, Mount Sinai School of Medicine, New York, New York

Elizabeth Diana Cooke RN MN ANP AOCN
School of Medicine, Hamilton, Ontario, Canada

Richard J. Creger PHARM D
Associate Professor of Medicine, Case Western Reserve University; Ireland Cancer Center, University Hospitals Case Medical Center, Cleveland, Ohio

Mark A. Crowther MD, MSc, FRCPC
Professor of Medicine (Hematology and Thromboembolism), McMaster University; Senior Research Specialist and Nurse Practitioner, Department of Nursing, Beckman Research Institute at the City of Hope, Duarte, California

Melissa M. Cushing MD
Assistant Professor, Department of Pathology and Laboratory Medicine, Weill Cornell Medical College; Assistant Director, Transfusion Medicine and Cellular Therapy, New York—Presbyterian Hospital-Weill Cornell Medical Center, New York, New York

Gary V. Dahl MD
Professor of Pediatrics, Department of Pediatric Hematology/Oncology, Lucile Packard Children's Hospital, Stanford University School of Medicine, Palo Alto, California

Richard Dahl PhD
Research Assistant Professor, University of New Mexico Health Sciences Center, Albuquerque, New Mexico

Björn Dahlbäck MD, PhD
Professor of Blood Coagulation Research, Department of Laboratory Medicine, Section of Clinical Chemistry University Hospital, Lund University, Malmő, Sweden

Alan D. D' Andrea MD
Fuller-American Cancer Society Professor, Department of Radiation Oncology, Harvard Medical School; Dana-Farber Cancer Institute, Boston, Massachusetts

Chi Van Dang MD, PhD
Professor of Medicine, Oncology, Pathology and Cell Biology, Johns Hopkins University School of Medicine; Attending Physician, Johns Hopkins Hospital, Baltimore, Maryland

Ayelet Dar PhD
Weizmann Institute of Science, Rehovot, Israel

Stella M. Davies MBBS, PhD, MRCP
Professor of Pediatrics, University of Cincinnati; Director, Blood and Marrow Transplantation Program, Division of Hematology/Oncology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Marcos De Lima MD
Associate Professor of Medicine, Department of Stern Cell Transplantation and Cell Therapy, University of Texas M.D. Anderson Cancer Center, Houston, Texas

Daniel J. De Angelo MD, PhD
Assistant Professor of Medicine, Harvard Medical School; Attending Physician, Dana-Farber Cancer Institute, Boston, Massachusetts

H. Joachim Deeg MD
Professor of Medicine, Division of Oncology, University of Washington; Member, Fred Hutchinson Cancer Research Center, Clinical Research Division, HCRC, Seattle, Washington

David De Remer PHARM D, BCOP
Clinical Assistant Professor, University of Georgia; Clinical Hematology/Oncology Pharmacy Specialist, Medical College of Georgia, Augusta, Georgia

Bimalangshu R. Dey MD, PhD
Assistant Professor of Medicine, Harvard Medical School, Massachusetts General Hospital, Bone Marrow Transplantation Program, Boston, Massachusetts

Volker Diehl MD
Professor, Department of Medicine, University of Cologne Faculty of Medicine, Cologne, Germany

Mary C. Dinauer MD, PhD
Nora Letzter Professor of Pediatrics (Hematology/Oncology) and Professor of Microbiology/Immunology and of Medical and Molecular Genetics, Department of Pediatrics, Indiana University School of Medicine; Professor of Pediatrics, Riley Hospital for Children, Indianapolis, Indiana

Angela Dispenzieri MD
Consultant, Division of Hematology, Mayo Clinic, Associate Professor of Medicine, Mayo Clinic College of Medicine; Mayo Clinic, Rochester, Minnesota

Michele L. Donato MD
Core Faculty, Touro University College of Medicine; Collection Facility Medical Director, Blood and Marrow Transplantation Program, Hackensack University Medical Center, Hackensack, New Jersey

Kenneth Dorshkind PhD
Professor, Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California

William N. Drohan PhD (Deceased)
Professor, Graduate Program in Genetics, George Washington University, Washington, District of Columbia; Vice President, STB, Ltd., Gaithersburg, Maryland, deceased-contact David B, Clark, co-author

Kieron Dunleavy MD
Metabolism Branch, National Cancer Institute, Bethesda, Maryland

Benjamin L. Ebert MD, PhD
Clinical Fellow, Department of Adult Oncology, Dana-Farber Cancer Institute and Harvard Medical School, Boston; Research Fellow, Broad Institute of Harvard and MIT, Cambridge, Massachusetts

William E. Evans PHARMD
St. Jude Endowed Chair and Professor of Pediatrics, College of Medicine, University of Tennessee; Director and CEO, St. Jude Children's Research Hospital, Memphis, Tennessee

Brunangelo Falini MD
Professor of Haematology, Director of Haematopathology, Perugia University School of Medicine; Perugia, Italy Director of Haematopathology, Monteluce Hospital, Perugia, Italy

Donald I. Feinstein MD, MACP
Professor of Medicine (Emeritus), Keck School of Medicine, University of Southern California, Attending Physician, USC/Norris Comprehensive Cancer Center, USC—University Hospital, LAC/USC Medical Center, Los Angeles, California

Adolfo A. Ferrando MD, PhD
Assistant Professor of Pediatrics and Pathology, Institute for Cancer Genetics, Columbia University, New York, New York

James L. M. Ferrara MD
Professor of Internal Medicine and Pediatrics, University of Michigan Medical School; Doris Duke Distinguished Clinical Scientist and Director, Blood and Marrow Transplantation Program, University of Michigan Cancer Center, Ann Arbor, Michigan

Eberhard W. Fiebig MD
Associate Professor of Clinical Laboratory Medicine, University of California, San Francisco, School of Medicine; Chief, Transfusion Services and Hematology, Laboratory Division, Clinical Laboratory, San Francisco General Hospital, San Francisco, California

Guido Finazzi MD
Teaching Position Professor of Hematology; Universita Milano Bicocea, Milan, Italy; Director, Transfusion Medicine Service Institution, dspedali Riuniti di Bergamo, Bergamo, Italy

Bernard G. Forget MD
Professor, Department of Internal Medicine and Genetics, Yale University School of Medicine; Attending Physician, Department of Internal Medicine, Yale-New Haven Hospital, New Haven, Connecticut

Stephen J. Forman MD
Director, Hematologic Neoplasia Program, City of Hope Comprehensive Cancer Center, Duarte, California

Bridget Fowler PHARMD
Clinical Assistant Professor, Northeastern University; Clinical Pharmacy Specialist, Pain and Palliative Case Program, Dana-Farber Cancer Institute, Boston, Massachusetts

Melvin H. Freedman MD, FRCPC, FAAP
Professor (Emeritus), Department of Pediatrics, University of Toronto Faculty of Medicine; Toronto, Ontario, Canada Honorary Consultant, Division of Hematology/Oncology, Hospital for Sick Children, Toronto, Ontario, Canada

Barbara C. Furie PhD
Professor of Medicine, Harvard Medical School; Chief, Division of Hemostasis and Thrombosis, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Bruce Furie MD
Professor of Medicine, Harvard Medical School; Chief, Division of Hemostasis and Thrombosis, Beth Israel Deaconess Medical Center, Boston, Massachusetts

David Gailani MD
Associate Professor of Pathology and Medicine, Vanderbilt University; Medical Director, Clinical Coagulation Laboratory, Vanderbilt University Medical Center Nashville, Tennessee

Lawrence B. Gardner MD
Assistant Professor of Medicine and Pharmacology, Division of Hematology, Department of Medicine, New York University School of Medicine New York, New York

Sharon M. Geaghan MD
Associate Professor, Department of Pathology and Pediatrics, Stanford University School of Medicine; Chief, Pathology, Department of Pathology, Pediatrics, Lucile Salter Packard Children's Hospital, Palo Alto, California

Adrian P. Gee PhD
Professor of Medicine and Pediatrics, Baylor College of Medicine; Technical Director, GMP Laboratories, Center for Cell and Gene Therapy, Texas Children's Hospital and the Methodist Hospital, Houston, Texas

Stanton L. Gerson MD
Professor of Medicine, Director, Case Comprehensive Cancer Center; Director, Center for Stem Cell and Regenerative Medicine, Case Western Reserve University; Director, Ireland Cancer Center, University Hospitals Case Medical Center, Cleveland, Ohio

Morie A. Gertz MD
Consultant, Division of Hematology, Mayo Clinic; Professor of Medicine, Mayo Clinic College of Medicine, Mayo Clinic, Rochester, Minnesota

Alan M. Gewirtz MD
C. Winnard Robinson Professor, Division of Hematology/Oncology, Department of Medicine, University of Pennsylvania School of Medicine; Attending Physician, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Patricia J. Giardina MD
Professor of Clinical Pediatrics, Weill Medical College of Cornell University; Attending Pediatrician, New York Presbyterian Hospital, New York, New York

D. Gary Gilliland MD, PhD
Professor of Medicine, Harvard Medicine School; Investigator, Howard Hughes Medical Institute; Senior Physician, Brigham and Women's Hospital, Boston, Massachusetts

David Ginsburg MD
James V. Neel Distinguished University Professor of Internal Medicine and Human Genetics, Howard Hughes Medical Institute, University of Michigan Ann Arbor, Michigan

Jeffrey S. Ginsberg MD, FRCPC
Professor, Department of Medicine; McMaster University Faculty of Medicine; Head, Thromboembolism Unit, Hamilton Health Sciences, McMaster Site, Hamilton, Ontario, Canada

Sergio Giralt MD
Professor of Medicine, Department of Stem Cell Transplantation and Cell Therapy, University of Texas M. D. Anderson Cancer Center, Houston, Texas

Bertil Glader MD, PhD
Professor, Department of Pediatrics, Stanford University School of Medicine, Stanford; Attending Physician, Department of Hematology/Oncology, Lucile Salter Packard Children's Hospital, Palo Alto; Attending Physician, Department of Pediatrics, Stanford University Hospital, Stanford, California

Nicola Gökbuget MD
Medical Clinic III, University Hospital of J.W. Goethe University, Frankfurt, Germany

Alfred L. Goldberg PhD
Professor of Cell Biology, Harvard Medical School; Boston, Massachusetts

Todd R. Golub MD
Associate Professor of Pediatrics, Harvard Medical School; Charles A. Dana Investigator, Associate Investigator HHMI, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Boston; Director, Cancer Program, Broad Institute of Harvard and MIT, Cambridge, Massachusetts

Stephen Gottschalk MD
Associate Professor, Departments of Pediatrics and Immunology, Center for Cell and Gene Therapy, Texas Children's Cancer Center, Baylor College of Medicine, Houston, Texas

Gregory A. Grabowski MD
Professor of Pediatrics, University of Cincinnati College of Medicine; Director, Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Steven Grant MD
Professor of Medicine, Biochemistry and Pharmacology, Virginia Commonwealth University, Associate Director for Translational Research; Massey Cancer Center, VCU Health Systems Richmond, Virginia

Xylina T. Gregg MD
Utah Cancer Specialists, Salt Lake City, Utah

Timothy C. Greiner MS, MD
Associate Professor, Department of Pathology and Microbiology, University of Nebraska College of Medicine; Medical Director, Molecular Diagnostic Laboratory, The Nebraska Medical Center, Omaha, Nebraska

John G. Gribben MD, DSc
Professor of Experiment Cancer Medicine, Barts and the London School of Medicine, Institute of Cancer; Consultant, Medical Oncology, St. Bartholomew's Hospital, London, United Kingdom

Thomas G. Gross MD, PhD
Associate Professor, Department of Pediatrics, School of Medicine, The Ohio State University; Chief, Division of Hematology/Oncology/BMT, Nationwide Children's Hospital, Columbus, Ohio

Joan Guitart MD
Associate Professor of Dermatology, Department of Dermatology, Northwestern University Medical School; Northwestern Memorial Hospital, Chicago, Illinois

Alejandro Gutierrez MD
Instructor of Pediatrics, Hematology/Oncology Department, Harvard Medical School; Dana-Farber Cancer Institute and Children's Hospital, Boston, Massachusetts

Parameswaran Nair Hari MD, MS, MRCP
Division of Neoplastic Diseases, Assistant Professor of Medicine, Medical College of Wisconsin; Assistant Scientific Director, Center for International Blood and Marrow Transplant Research, Milwaukee, Wisconsin

John Harlan MD
Professor of Medicine, University of Washington; Chief, Section of Hematology–Oncology, Harborview Medical Center, Seattle, Washington

John H. Hartwig PhD
Professor of Medicine, Harvard Medical School; Senior Biologist, Brigham and Women's Hospital, Boston, Massachusetts

Evdoxia Hatjiharissi MD
Department of Hematology, Theagenio Cancer Institute, Thessaloniki, Greece

Suzanne R. Hayman MD
Consultant, Division of Hematology, Mayo Clinic; Assistant Professor of Medicine, Mayo Clinic College of Medicine, Mayo Clinic, Rochester, Minnesota

Robert P. Hebbel MD
Regents Professor, George Clark Professor, Department of Medicine, Director, Vascular Biology Center, University of Minnesota Medical School, Minneapolis, Minnesota

Helen E. Heslop MD
Professor of Medicine and Pediatrics, Dan L Duncan Chair, Center for Cell and Gene Therapy, Baylor College of Medicine, The Methodist Hospital and Texas Children's Hospital, Houston, Texas

Katherine A. High MD
William Bennett Professor of Pediatrics, University of Pennsylvania School of Medicine, Investigator, Howard Hughes Medical Institute, Children's Hospital of Philadelphia, Attending Physician, Director, Center for Cellular and Molecular Therapeutics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Christopher D. Hillyer MD
Professor, Emory University School of Medicine, Department of Pathology and Laboratory Medicine; Director, Center for Transfusion and Cellular Therapies, Medical Director, Transfusion Services, Emory University Hospital Atlanta, Georgia

David M. Hockenberry PhD
Adjunct Associate Professor, Department of Immunology, and Associate Professor, Department of Medicine, University of Washington School of Medicine; Associate Member, Clinical Research and Human Biology, Fred Hutchinson Cancer Research Center, Seattle, Washington

Dieter Hoelzer MD
Professor of Internal Medicine, Johan Wolfgang Goethe University School of Medicine; Chief, Department of Hematology, Zentrum der Inneren Medizin, Medizinische Klinik III, Frankfurt, Germany

Ronald Hoffman MD
Albert A. and Vera G. List Professor of Medicine; Hematology/Oncology Section; Mount Sinai Cancer Institute, Department of Medicine, Cell and Gene Medicine, Mount Sinai School of Medicine New York, New York

Mary M. Horowitz MD, MS
Chief Scientific Director, Center of International Blood and Marrow Transplant Research—CIBMTR®, Department of Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Robert Hromas MD
Professor, Chief, Hematology/Oncology, University of New Mexico Health Sciences Center, Albuquerque, New Mexico

Joseph E. Italiano, Jr. PhD
Assistant Professor of Medicine, Harvard School of Medicine; Assistant Professor of Medicine, Brigham and Women's Hospital, Boston, Massachusetts

Elaine S. Jaffe MD
Chief, Hematopathology Section, Laboratory of Pathology Center for Cancer Research, National Cancer Institute, Bethesda, Maryland; Staff Pathologist, Clinical Center, National Institutes of Health, Bethesda, Maryland

Petr Jarolim MD, PhD
Assistant Professor of Pathology, Harvard Medical School; Staff Pathologist, Brigham and Women's Hospital, Boston, Massachusetts

Sima Jeha MD
Professor of Pediatrics, University of Tennessee Health Science Center, Member, Department of Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

Cassandra Josephson MD
Associate Professor, Pathology Laboratory Medicine and Pediatrics, Emory University School of Medicine, Associate Direction, Children's Healthcare of Atlanta, Blood Tissue Services, Department of Pathology, Atlanta, Georgia

Sarita A. Joshi MB BS, MD
Staff Physician, Blood and Marrow Transplantation Program, Cincinnati Children's Hospital Medical Center, Division of Hematology/Oncology, Cincinnati, Ohio

Leo Kager MD
Associate Professor of Pediatrics, Medical University Vienna; Associate Professor of Pediatrics, St. Anna Children's Hospital, Vienna, Austria

Aly Karsan MD
Professor, Pathology and Laboratory Medicine, University of British Columbia; Hematopathologist/Senior Scientist, British Columbia Cancer Agency, Vancouver, BC, Canada

Randal J. Kaufman PhD
Investigator, Howard Hughes Medical Institute, Chevy Chase, Maryland; Professor, University of Michigan, Ann Arbor, Michigan

Richard M. Kaufman MD
Assistant Professor of Pathology, Harvard Medical School; Medical Director, Adult Transfusion Service, Brigham and Women's Hospital, Boston, Massachusetts

Frank G. Keller MD
Associate Professor, Department of Pediatrics, Emory University School of Medicine; Children's Healthcare of Atlanta, Atlanta, Georgia

Geoffrey Kemball-Cook PhD
Divisional Posteraduate Administrator, Senior Scientist, MRC Clinical Sciences Center, London, United Kingdom

Craig M. Kessler MD
Professor of Medicine, Department of Medicine; Georgetown University School of Medicine; Chief, Division of Hematology, Department of Medicine, Hematology-Oncology, Georgetown University Hospital, Washington, District of Columbia

Nigel S. Key MB, ChB, FRCP
Harold R. Roberts Distinguished Professor, Chief Section of Hematology, Division of Hematology-Oncology, University of North Carolina School of Medicine; Director, Harold R. Roberts Comprehensive Diagnostic and Treatment Center, UNC Memorial Hospital, Chapel Hill, North Carolina

Arati Khanna-Gupta PhD
Lecturer, Brigham and Women's Hospital, Department of Hematology; Harvard Medical School, Boston, Massachusetts

Harvey G. Klein MD
Chief, Department of Transfusion Medicine, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland

Beate Klimm MD
Department of Internal Medicine I, University Hospital of Cologne, Cologne, Germany

Orit Kollet PhD
Weizmann Institute of Science, Rehovot, Israel

Barbara A. Konkle MD
Professor of Medicine, Pathology, and Laboratory Medicine, University of Pennsylvania, Director, Penn Comprehensive Hemophilia and Thrombosis Program, Philadelphia, Pennsylvania

Stanley J. Korsmeyer MD (Deceased)
Sidney Farber Professor of Pathology and Professor of Medicine, Harvard Medical School; Director, Program in Molecular Oncology, Department of Cancer Immunology and AIDS, Dana-Farber Cancer Institute, Boston, Massachusetts; Investigator, Howard Hughes Medical Institute, Chevy Chase, Maryland

Elizabeth F. Krakow MD, CM, FRCPC
Hematology Fellow, McMaster University; Clinical Scholar, Department of Medicine, Hamilton Health Sciences, Hamilton, Ontario, Canada

Amrita Krishnan MD, FACP
City of Hope, Duarte, California

Magdalena Kucia PhD
University of Louisville, School of Medicine, Developmental Biology Research Program, Louisville, Kentucky

Thomas J. Kunicki PhD
Associate Professor Tenure, The Scripps Research Institute, La Jolla, California, Canada

Timothy M. Kuzel MD, RACP
Professor of Medicine, Division of Hematology/Oncology, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois

Martha Q. Lacy MD
Consultant, Division of Hematology, Mayo Clinic, Associate Professor of Medicine, Mayo Clinic College of Medicine, Mayo Clinic, Rochester, Minnesota

Viswanathan Lakshmanan PhD
Research Associate, Lewis Sigler Institute for Integrative Genomics, Princeton University, Princeton, New Jersey

Wendy Landier RN, MSN, CPNP
Assistant Clinical Professor, School of Nursing, University of California at Los Angeles, Los Angeles; Clinical Director Center for Cancer Survivorship, City of Hope National Medical Center, Duarte, California

Tsvee Lapidot PhD
Professor, Weizmann Institute of Science, Rehovot, Israel

Peter J. Larson MD
Director, Global Clinical Strategy, Bayer Healthcare, Biological Products, Research Triangle Park, North Carolina

Jacob Laubach MD
Instructor of Medicine, Harvard Medical School, Dana-Farber Cancer Institute, Department of Medical Oncology, Boston, Massachusetts

Ellen F. Lazarus MD, FCAP
Visiting Scientist, Department of Transfusion Medicine, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda; Division of Human Tissue, FDA Center for Biologics Evaluation and Research, Rockville, Maryland

Stewart H. Lecker MD, PhD
Assistant Professor of Medicine, Harvard Medical School; Attending Physician, Renal Unit, Beth Israel Deaconess Medical Center, Boston, Massachusetts

William M.F. Lee MD
Associate Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Xavier Leleu MD
Hematology, CHRU-Lille, Maladies du Sang, Rue Michel Polonovski, Lille, France

Michael J. Lenardo MD
Adjunct Professor of Pathology, University of Pennsylvania School of Medicine, Philadelphia; Section Chief and Senior Investigator, Molecular Development Section, National Institute of Allergy and Infections Disease, Bethesda, Maryland

Polly Lenssen MS, RD, CD, FADA
Director, Clinical Nutrition, Children's Hospital and Regional Medical Center, Seattle, Washington

Georg Lenz MD
Center for Cancer Research, National Cancer Institute, NIH, Bethesda, Maryland

Nancy D. Leslie MD
Professor of Pediatrics, University of Cincinnati College of Medicine, Director, Metabolic Lab, Director, Clinical Operations, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Alexandra M. Levine MD
Distinguished Professor of Medicine, (Emeritus), Keck School of Medicine, University of Southern California, Los Angelcs; Chief Medical Officer, City of Hope National Medical Center, Duarte, California

David B. Lewis MD
Professor of Pediatrics and Member of the Program in Immunology, Division of Immunology and Transplantation Biology, Department of Pediatric, Stanford University School of Medicine, Attending Physician at Lucile Packard Children's Hospital, Stanford, California

Howard A. Liebman MD
Associate Professor of Medicine and Pathology, Jane Anne Nohl Division of Hematology, Keck USC School of Medicine; Attending Physician, Norris Comprehension Cancer Center Keck USC School of Medicine, Los Angeles, California

Henri Roger Lijnen PhD
Fenta Por Molecular and Vascular Biology, University of Leuven, Faculty of Medicine, Leuven, Belgium

Wendy Lim MD, MSc
Assistant Professor, Department of Medicine, McMaster University, Hamilton, Ontario, Canada

Thomas S. Lin MD, PhD
Associate Professor of Medicine, The Ohio State University, Columbus, Ohio

Michael P. Link MD
Lydia J. Lee Professor of Pediatrics, and Chief, Division of Hematology/Oncology, Department of Pediatrics, Stanford University School of Medicine, Stanford; Director, Center for Cancer and Blood Disease, Lucile Salter Packard Children's Hospital at Stanford, Palo Alto, California

Evelyn Lockhart MD
American Red Cross, Carolina Region, Charlotte, North Carolina

Mignon Loh MD
Associate Professor of Pediatrics, University of California, San Francisco, California

A. Thomas Look MD
Professor, Department of Pediatrics, Harvard Medical School; Vice Chair for Research, Pediatric Oncology Department, Dana-Farber Cancer Institute, Boston, Massachusetts

José A. López MD
Executive Vice President of Research, Puget Sound Blood Center, Puget Sound, Washington

Jaroslaw P. Maciejewski MD, PhD
Chief, Experimental Hematology and Hematopoiesis Section, Taussig Cancer Center; Staff Physician, Department of Hematologic Malignancies and Blood Disorders, Taussig Cancer Center Professor of Medicine, Cleveland Clinic Lerner College of Medicine, Case Western Reserve University, Cleveland, Ohio

Navneet Majhail MD, MS
Assistant Professor, Division of Hematology, Oncology and Transplantation, University of Minnesota, Minneapolis, Minnesota

Olivier Manches PhD
Research Assistant, New York University Cancer Institute, New York, New York

Robert Mandle PhD
Investigator, Center for Blood Research, Boston, Massachusetts

Catherine S. Manno MD
Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Associate Chair for Clinical Activities, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Simon Mantha MD
Hematologist, Laney Clinic Medical Center, Burlington, Massachusetts

Francesco M. Marincola MD
Director, Immunogenetics Program, Department of Transfusion Medicine, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland

Peter W. Marks MD, PhD
Associate Professor of Medicine, Yale University School of Medicine; Attending Physician, Yale-New Haven Hospital, New Haven, Connecticut

Steffen Massberg MD, PhD
Deutsches Herzzentrum Muenchen, Technische Universitaet Muenchen, Munich, Germany

Peter M. Mauch MD
Professor, Department of Radiation Oncology, Harvard Medical School; Senior Physician, Department of Radiation Oncology, Brigham and Women's Hospital, Boston, Massachusetts

Ruth McCorkle PhD, RN, FAAN
Florence S. Wald Professor of Nursing; Director, Center for Excellence in Chronic Illness Care; Chair, Doctoral Program, Department of Nursing, Yale University; Program Leader, Cancer Control, Yale Comprehensive Cancer Center, New Haven, Connecticut

Keith R. McCrae MD
Associate Professor of Medicine, Case Western Reserve University School of Medicine; University Hospitals of Cleveland, Cleveland, Ohio

Rodger P. McEver MD
Member and Chair, Cardiovascular Biology Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma

Philip McGlave MD
C.J. Watson Land Grant Chair in Medicine; Director, Division of Hematology, Oncology and Transplantation; Deputy Director, Masonic Cancer Center, University of Minnesota, Academic Health Center, Minneapolis, Minnesota

John H. McVey BSc, HONS, PhD
Weston Professor of Molecular Medicine, Thrombosis Research Institute, London, United Kingdom

Jay E. Menitove MD
Clinical Professor of Medicine, University of Missouri–Kansas City School of Medicine; Clinical Professor of Medicine, Kansas University School of Medicine; Executive Director and Medical Director, Administration, Community Blood Center of Greater Kansas City, Kansas City, Missouri

Giampaolo Merlini MD
Biotechnology Research laboratories, IRCCS Policlinico San Matteo Hospital, Department of Biochemistry, University of Pavia, Pavia, Italy

Ara Metjian MD
Hematology Fellow, Duke University School of Medicine, Durham, North Carolina

Anna Rita Migliaccio PhD
Professor of Medicine, Hematology Oncology Section, Mount Sinai School of Medicine, New York, New York

Jeffrey S. Miller MD
Professor of Medicine, Division of Hematology, Oncology and Transplantation, University of Minnesota Medical School, Minneapolis, Minnesota

Kenneth B. Miller MD
Director of Clinical Hematology, Bone Marrow Transplantation and Hematological Malignancy Unit, Beth Israel Deaconess Medical Center, Boston, Massachusetts

John G. Monroe PhD
Professor and Vice-Chair, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania

Michael R. Moore BSc, PhD, DSc
Professor of Medicine and Director, National Research Centre for Environmental Toxicology, University of Queensland Faculty of Medicine; Director, Queensland Health Scientific Services, Queensland Health, Brisbane, Queensland, Australia

Kari C. Nadeau MD, PhD
Assistant Professor of Pediatrics, Center of Excellence in Pulmonary Biology, Department of Pediatrics, Stanford University School of Medicine; Attending Physician, Lucile Packard Children's Hospital, Stanford, California

Vesna Najfeld PhD
Professor of Pathology and Medicine Director, Tumor Cytogenetics, The Mount Sinai School of Medicine, New York, New York

Kavita Natarajan MBBS
Assistant Professor of Medicine, Section of Hematology/Oncology, Medical College of Georgia, Augusta, Georgia

Benjamin G. Neel MD, PhD
Senior Scientist, Division of Stem Cell and Development Biology; Director, Ontario Cancer Institute, Toronto, Ontario, Canada

Anne T. Neff MD
Vanderbilt University Medical Center, Division of Hematology/Stem Cell Transplant, Vanderbilt University; Medical Director, Vanderbilt Hemostasis and Thrombosis Clinic, Medical Director, Blood Cell Collection Center, Vanderbilt University Medical Center, Nashville, Tennessee

Robert S. Negrin MD
Associate Professor of Medicine, Department of Medicine, Stanford University School of Medicine, Stanford, California

Paul M. Ness MD
Professor, Department of Pathology and Medicine, Johns Hopkins University School of Medicine; Director, Department of Transfusion Medicine, Johns Hopkins Hospital, Baltimore, Maryland

Ellis J. Neufeld MD, PhD
Associate Professor of Pediatrics, Harvard Medical School, Associate Chief, Hematology, Children's Hospital, Boston, Massachusetts

Andrea K. Ng MD, MPH
Associate Professor in Radiation Oncology, Harvard Medical School; Brigham and Women's Hospital, Dana-Farber Cancer Institute, Boston, Massachusetts

Diane J. Nugent MD
Director, Hemostasis Thrombosis Research and Proteomic Core, Children's Hospital of Orange County, Orange, California

Sarah H. O'Brien MD, MSc
Assistant Professor of Pediatrics, The Ohio State University College of Medicine; Assistant Professor of Pediatrics, Pediatric Hematology/Oncology, Nationwide Children's Hospital, Columbus, Ohio

Thalia Papayannopoulou MD
Professor, Department of Medicine, Division of Hematology, University of Washington School of Medicine, Seattle, Washington

Animesh D. Pardanani MBBS, PhD
Assistant Professor, Mayo Medical School, Consultant in Hematology, Mayo Clinic, Rochester, Minnesota

Effie W. Petersdorf MD
Professor of Medicine, Department of Medicine, Division of Oncology, University of Washington School of Medicine; Attending Physician, Seattle Cancer Care Alliance; Member, Division of Clinical Research, Fred Hutchinson Cancer Research Center, Seattle, Washington

LoAnn C. Peterson MD
Professor, Deparment of Pathology, Northwestern University Feinberg School of Medicine, Chicago, Illinois

German A. Pihan MD
Assistant Professor, Department of Pathology, Harvard Medical School; Director, Hematopathology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Stefano A. Pileri MD
Professor of Pathology, Director of the Haematopathology Unit and of the Doctorate Research Project in Clinical and Experimental Haematology anal Haemetopathology, Bologna University School of Medicine; Director of the Haematopathology Unit, ST Orsota-Malpighi Hospital, Bologna, Italy

Stefania Pittaluga MD, PhD
Staff Clinician, Hematopathology Section, Laboratory of Pathology, Center for Cancer Research; Staff Pathologist, National Institutes of Health, Bethesda, Maryland

Edward F. Plow PhD
Chair, Department of Molecular Cardiology, Cleveland Clinic Foundation/Lerner Research Institute, Cleveland, Ohio

David G. Poplack MD
Professor of Pediatrics, Section of Hematology/Oncology, Department of Pediatrics, Baylor College of Medicine, Texas Children's Cancer Center Houston, Texas

Laura Popolo PhD
Associate Professor, Universita' Degli Studi di Milano, Milano, Italy

Leland D. Powell MD, PhD
Associate Clinical Professor of Medicine, Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles; Olive View–UCLA Medical Center, Sylmar, California

Amy Pocoers MD
Instructor in Pathology, Harvard Medical School; Medical Director, Aphenesis and Infusion Services, Beth Israel Deaconess Medical Center, Boston, Massachusetts

Josef T. Prchal MD
Professor of Medicine, Department of Pathology and Genetics, University of Utah School of Medicine, Salt Lake City, Utah

Elizabeth A. Price MD
Instructor in Medicine Hematology, Division of Hematology, Department of Medicine, Stanford University School of Medicine, Stanford, California

Felipe Prosper MD, PhD
Professor, School of Medicine, University of Navarra; Co-Director, Department of Hematology and Director of Cell Therapy Area, Clinica Universîtaria De Navarra, Panflowa, Spain

Ching-Hon Pui MD
Professor of Pediatrics, University of Tenneisee Health Suenie Center; Chair, Department of Oncology, American Cancer Society Professor, St. Jude Children's Research Hospital, Memphis, Tennessee

Karen R. Rabin MD
Assistant Professor of Pediatrics, Section of Hematology/Oncology, Baylor College of Medicine, Houston, Texas

Jerald P. Radich MD
Professor, Fred Hutchinson Cancer Research Center, University of Washington School of Medicine, Seattle, Washington

Margaret V. Ragni MD, MPH
Professor of Medicine, Department of Medicine, Division of Hematology/Oncology, University of Pittsburgh School of Medicine; Director, Hemophilia Center of Western Pennsylvania, Pittsburgh, Pennsylvania

Janina Ratajczak MD, PhD
University of Louisville School of Medicine, Developmental Biology Research Program, Louisville, Kentucky

Marius Z. Ratajczak MD, PhD
Professor of Medicine, Stem Cell Institute at James Graham Brown Cancer Center, University of Louisville, Louisville, Kentucky

David J. Rawlings MD
Professor, Division of Pediatric Immunology, University of Washington, Section Head, Immunology, Seattle Children's Hospital Research Institute, Seattle, Washington

Daniel Re MD
Internal Medicine, Hematology and Medical Oncology, Centre Hospitalier Antibes Juan-les-Pins, Antibes Cédex, France

Pavan Reddy MD
Assistant Professor of Medicine, Department of Internal Medicine, University of Michigan Medical School; University of Michigan Comprehensive Cancer Center, Ann Arbor, Michigan

Mark T. Reding MD
Assistant Professor of Medicine, Division of Hematology, Oncology, and Transplantation, Department of Medicine, University of Minnesdta Medical School; Director, Center for Bleeding and Clotting Disorders, University of Minnesota Medical Center–Fairview, Minneapolis, Minnesota

Marion E. Reid PhD
Director, Immochemistry Laboratory, New York Blood Center, New York, New York

Alan C. Rigby PhD
Assistant Professor of Medicine, Harvard Medical School, Division of Molecular and Vascular Medicine, Both Israel Deaconess Medical Center, Boston, Massachusetts

A. Kim Ritchey MD
Professor Department of Pediatrics, University of Pittsburgh School of Medicine; Chief, Pediatric Hematology/Oncology, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Jerome Ritz MD
Professor of Medicine, Harvard Medical School; Medical Director, The Connell and O'Reilly Families Cell Manipulation Core Facility, Dana-Farber Cancer Institute, Boston, Massachusetts

David J. Roberts MD, PhD
Professor of Haematology, Naffield Department of Clinical Laboratory Science, University of Oxford, Consuntant Haematologist, National Health Service Blood and Transplant Oxford, United Kingdom

Aldo Roccaro MD
Dana-Farber Cancer Institute, Boston, Massachusetts

Cliona M. Rooney PhD
Professor, Department of Pediatrics and Department of Molecular Virology and Microbiology, Baylor College of Medicine; Center for Cell and Gene Therapy, Texas Children's Cancer Center, Texas Children's Hospital, Houston, Texas

Steven T. Rosen MD
Professor of Medicine, Northwestern University Feinberg School of Medicine; Director, Robert H. Lurie Comprehensive Cancer Center, Northwestern Memorial Hospital, Chicago, Illinois

David S. Rosenthal MD
Professor of Medicine, Harvard Medical School; Attending Physician, Brigham and Women's Hospital, Dana-Farber Cancer Institute, Boston, Massachusetts

Rachel Rosovsky MD
Instructor in Medicine, Harvard Medical School; Attending Physician, Massachusetts General Hospital, Boston, Massachusetts

David A. Roth MD
Assistant Vice President, Clinical Research and Development, Therapeutic Area Director, Hematology, Wyeth Research, Cambridge, Massachusetts

Jacob M. Rowe MD
Dresner Professor of Hemato-Oncology, Bruce Rappaport Faculty of Medicine, Technion, Israel; Institute of Technology; Director, Department of Hematology and Bone Marrow Transplantation, Rambam Medical Center, Haifa, Israel

Scott D. Rowley MD, FACP
Clinical Associate Professor, UMDNJ-School of Medicine, Newark, New Jersey; Chief, Adult Blood and Marrow Transplantation Program, Hackensack University Medical Center, Hackensack, New Jersey

J. Evan Sadler MD, PhD
Professor of Medicine, Professor of Biochemistry and Molecular Biophysics, Washington University School of Medicine, St. Louis, Missouri

John T. Sandlund, Jr. MD
Professor of Pediatrics, University of Tennessee College of Medicine; Member, Department of Hematology/Oncology, St. Jude Children's Research Hospital, Memphis, Tennessee

Tomo Saric MD, PhD
University of Cologne, Medical School, Group Leader, Institute for Neurophysiology, Cologne, Germany

Yogen Saunthararajah MB, BCh
Associate Professor, Cleveland Clinic Foundation, Cleveland, Ohio

David T. Scadden MD
Associate Professor, Harvard Medical School; Co-Director, Harvard Stem Cell Institute, Massachusetts General Hospital, Boston, Massachusetts

Alvin H. Schmaier MD
Chief, Hematology and Oncology, Robert W. Kellermeyer Professor of Hematology and Oncology, Case Western Reserve University, School of Medicine; University Hospitals Case Medical Center, Cleveland, Ohio

Paul I. Schneiderman MD
Clinical Professor, Department of Dermatology, Columbia University College of Physicians and Surgeons; Department of Dermatology, Columbia Presbyterian Medical Center, New York, New York

Hélène Schoemans MD
Fellow in Hematology, PhD Student, Katholieke Universiteit Leuven, Leuven, Belgium

Jeffrey R. Schriber MD, FRCP
Banner Good Samaritan Medical School, Phoenix, Arizona

Stanley L. Schrier MD
Professor of Medicine (Hematology) Active Emeritus, Department of Medicine, Division of Hematology, Stanford University School of Medicine; Stanford University Medical Center, Stanford, California

Bart L. Scott MD, MS
Assistant Professor, University of Washington, Assistant Member, Fred Hutchinson Cancer Research Center, Seattle, Washington

Montaser Shaheen MD
Adjunct Clinical Assistant Professor, Indiana University; Physician, Providence Medical Group, Terre Haute, Indiana

Sanford J. Shattil MD
Professor of Medicine and Chief, Hematology-Oncology Division, University of California San Diego; Adjunct Professor of Molecular and Experimental Medicine, The Scripps Research Institute, La Jolla, California

Mark J. Shlomchik MD, PhD
Professor, Department of Laboratory Medicine and Immunobiology, Yale University School of Medicine; Associate Director, Transfusion Service, Yale New Haven Hospital, New Haven, Connecticut

Susan B. Shurin MD
Deputy Director, National Heart, Lung and Blood Institute NIH, Bethesda, Maryland

Leslie E. Silberstein MD
Professor of Pathology; Director, Joint Program in Transfusion Medicine and Director, Center for Human Cell Therapy, Harvard Medical School, Boston, Massachusetts

Franklin O. Smith MD
Professor of Pediatrics, University of Cincinnati College of Medicine; Marjory J. Johnson Endowed Chair, Director, Division of Hematology/Oncology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Edward L. Snyder MD
Professor of Laboratory Medicine, Yale University School of Medicine; Director, Transfusion/Apheresis/Cell Processing/Tissue Bank, Yale New Haven Hospital, New Haven, Connecticut

Thomas R. Spitzer MD
Professor of Medicine, Harvard Medical School; Director, Bone Marrow Transplant Program, Massachusetts General Hospital, Boston, Massachusetts

Louis M. Staudt MD, PhD
Deputy Chief and Chief of Lymphoid Malignancies Section, Center for Cancer Research, National Cancer Institute, Bethesda, Maryland

Harald Stein MD
Professor of Pathology; Charite-University Medicine Berlin, Campus Benjamin Franklin; Director of the Pathology Department, Benjamin Franklin Clinic, Berlin, Germany

Martin H. Steinberg MD
Professor of Medicine, Pediatrics, Pathology and Laboratory Medicine, Department of Medicine, Boston University School of Medicine; Director, Center of Excellence in Sickle Cell Disease, Boston Medical Center, Boston, Massachusetts

Johan Stenflo MD, PhD
Professor of Clinical Chemistry, Department of Laboratory Medicine, Section of Clinical Chemistry, University Hospital, Malmo, Sweden

C. Philip Steuber MD
Professor of Pediatrics, Section of Hematology/Oncology, Baylor College of Medicine; Texas Children's Cancer Center, Houston, Texas

Richard M. Stone MD
Associate Professor of Medicine, Harvard Medical School; Boston, MA Director of Clinical Research, Adult Leukemia Program, Dana-Farber Cancer Institute, Boston, Massachusetts

Ronald G. Strauss MD
Professor of Pathology and Pediatrics, University of Iowa College of Medicine; Medical Director, U.I. DeGowin Blood Center, University of Iowa Hospitals and Clinics, Iowa City, Iowa

David F. Stroncek MD
Chief, Laboratory Services Section, Department of Transfusion Medicine, Warren G. Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland

Zbigniew M. Szczepiorkowski MD, PhD
Director, Transfusion Medicine Service and Cellular Therapy Center, Darmouth-Hitchcock Medical Center, Lebanon, New Hampshire

Martin S. Tallman MD
Professor, Division of Hematology/Oncology, Northwestern University Feinberg School of Medicine, Chicago, Illinois

Ayalew Tefferi MD
Professor of Medicine and Hematology, Mayo College of Medicine, Mayo Clinic, Rochester, Minnesota

Ramon V. Tiu MD
Cleveland Clinic Taussig Cancer Center, Research Scholar in Bone Marrow Failure, Cleveland, Ohio

Cameron C. Trenor III MD
Instructor in Pediatrics, Harvard Medical School; Staff Physician, Division of Pediatric Hematology/Oncology, Children's Hospital Boston, Dana-Farber Cancer Institute, Boston, Massachusetts

Steven P. Treon MD, PhD
Bing Program for Waldenström's Macroglobulinemia, Division of Hematologic Oncology; Associate Professor, Harvard Medical School Dana-Farber Cancer Institute, Boston, Massachusetts

Guido Tricot MD, PhD
Professor, Department of Medicine; Director, Utah Blood and Marrow Transplant and Myeloma Program, University of Utah School of Medicine, Salt Lake City, Utah

Edward G. Tuddenham MD
Professor of Haemophilia, University College, Director, Royal Free Hospital Haemophilia Centre, Royal Free Hospital Trust, London, United Kingdom

Catherine Verfaillie MD
Professor of Medicine, Director, Stem Cell Institute, Katholieue Universiteit Leuven, Leuven, Belgium

Elliott P. Vichinsky MD
Adjunct Professor of Pediatrics, University of California, San Francisco, School of Medicine, San Francisco; Director, Department of Hematology/Oncology, Children's Hospital and Research Center at Oakland, Oakland, California

Ulrich H. von Andrian MD, PhD
Mallinckrodt Professor of Immunopathology, Harvard Medical School, Senior Investigator Immune Disease Institute; Boston, Massachusetts

Andrew J. Wagner MD, PhD
Instruction of Medicine, Harvard Medical School; Staff Oncologist, Center for Sarcoma and Bone Oncology, Dana-Farber Cancer Institute, Boston, Massachusetts

Denisa D. Wagner PhD
Professor, Department of Pathology, Harvard Medical School; Senior Investigator, CBR Institute for Biomedical Research, Boston, Massachusetts

John E. Wagner Jr. MD
Professor and Director, Division of Hematology/Oncology and Transplantation, Department of Pediatrics, University of Minnesota, Medical School; Attending Physician, Co-Director of the Blood and Marrow Transplant Program, University of Minnesota Medical Center and Children is Hospital, Minneapolis, Minnesota

Ena Wang MD
Staff Scientist, Department of Transfusion Medicine, National Institutes of Health, Bethesda, Maryland

Theodore E. Warkentin MD
Professor, Department of Pathology and Molecular Medicine, and Department of Medicine, Michael G. DeGroote School of Medicine, McMaster University, Regional Director, Transfusion Medicine, Hamilton Regional Laboratory Medicine Program, Hamilton Health Sciences, Hamilton General Hospital Site, Hamilton, Ontraio, Canada

Michael C. Wei MD, PhD
Instructor, Division of Pediatric Hematology/Oncology, Stanford University School of Medicine; Lucile Packard Children's Hospital, Palo Alto California

Howard J. Weinstein MD
Alan R. Ezekowitz Professor of Pediatrics, Harvard Medical School; Chief, Pediatric Hematology and Oncology, Massachusetts General Hospital for Children, Boston, Massachusetts

Daniel J. Weisdorf MD
Professor, Department of Medicine, University of Minnesota Medical School; Director, Adult Blood and Marrow Transplant Program, University of Minnesota Hospitals, Minneapolis, Minnesota

Jeffrey I. Weitz MD, FRCPC, FACP
Professor of Medicine and Biochemistry, Canada, Research Chair (Tier I) in Thrombosis, Heart and Stroke Foundation of Ontario/J.F. Mustard, Chair in Cardiovascular Research, McMaster University; Director, Henderson Research Centre, Hamilton Health Sciences-Henderson Site, Hamilton, Ontario, Canada

Ilene Ceil Weitz MD
Assistant Clinical Professor of Medicine, Jane Anne Nohl Division of Hematology, Keck-USC School of Medicine; Norris Comprehensive Cancer Center, Keck-USC School of Medicine, Los Angeles, California

Gerlinde Wernig MD
Harvard Medical School; Brigham and Women's Hospital, Boston, Massachusetts

Connie M. Westhoff PhD
Adjunct Professor, Division of Transfusion Medicine, Department of Pathology and Laboratory Medicine, University of Pennsylvania; Scientific Director, American Red Cross, Philadelphia, Pennsylvania

Gilbert C. White, II MD
Professor of Medicine, Biochemistry, Pharmacology and Toxicology Associate Dean for Research, Medical College of Wisconsin; Executive Vice President for Research, Director, Blood Research Institute, Richard H. and Sara E. Aster Chair for Medical Research, Blood Center of Wisconsin, Milwaukee, Wisconsin

James S. Wiley MD, FRACP, FRCPA
Professor, Department of Medicine, Nepean Clinical School, University of Sydney; Head, Department of Haematology, Nepean Hospital, Penrith, New South Wales, Australia

Wyndham H. Wilson MD, PhD
Senior Investigator, Metabolism Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland

Thomas E. Witzig MD
Professor of Medicine, Mayo Clinic College of Medicine; Consultant, Mayo Clinic, Rochester, Minnesota

Joanne Wolfe MD, MPH
Assistant Professor of Pediatrics, Harvard Medical School, Harvard University; Director, Pediatric Palliative Care, Dana-Farber Cancer Institute and Children's Hospital of Boston, Boston, Massachusetts

Yan Yun Wu MD, PhD
Assistant Professor of Laboratory Medicine, Yale University School of Medicine; Assistant Director, Blood Bank/Apheresis/Transfusion Cellular Therapy, Yale New Haven Hospital, New Haven, Connecticut

Kai W. Wucherpfennig MD, PhD
Professor, Harvard Medical School, Professor, Dana-Farber Cancer Institute, Boston, Massachusetts

Ming Jiang Xu MD, PhD
Assistant Professor, Hematology/Oncology Section, Mount Sinai Cancer Institute, Mount Sinai School of Medicine, New York, New York

Donald C. Yee MD
Assistant Professor, Department of Pediatrics, Hematology/Oncology Section, Department of Medicine, Thrombosis Research Section, Baylor College of Medicine, Texas Children's Cancer Center and Hematology Service, Houston, Texas

Mervin C. Yoder MD
Richard and Pauline Klingler Professor of Pediatrics, Professor of Biochemistry and Molecular Biology and of Cellular and Integrative Physiology, Indiana University School of Medicine; Attending Physician, James Whitcomb Riley Hospital for Children, Indianapolis, Indiana

Jo-Anne Hertha Young MD
Associate Professor, Department of Medicine; Director, Transplant Infectious Diseases, University of Minnesota, Minneapolis, Minnesota

Neal Stuart Young MD
Chief, Hematology Branch, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, Maryland

Anaadriana Zakarija MD
Clinical Instructor, Division of Hematology/Oncology, Northwestern University Feinberg School of Medicine, Chicago, Illinois

PREFACE TO THE FIFTH EDITION

This volume represents the fifth edition of *Hematology: Basic Principles and Practice*. The initial concept for this textbook was formulated over two decades ago, and each edition of the book has evolved in response to the dramatic advances that have occurred in hematology. This evolution is a testimony to the continued energy of the editors, contributors, and readers of the book. The editorial board has incorporated scientific and diagnostic and therapeutic advances in hematology into each edition so that that the practicing hematologist, laboratory researcher, clinical researcher, student, or healthcare professional might more easily keep pace with this field and more effectively practice their craft. This text is intended to make modern hematology an exciting discipline that can be easily accessed by its diverse readership.

There have been several changes in the leadership of the book that have resulted in this fifth volume moving in new and exciting directions. Six of the editors of the previous edition, Ronald Hoffman, Edward J. Benz Jr., Sanford J. Shattil, Bruce Furie, Leslie E. Silberstein and Philip McGlave, have enthusiastically participated in the fifth edition. Remarkably, Drs. Hoffman, Benz, Shattil, and Furie have been with the book from its conception. Dr. Harvey J. Cohen, who was one of the editors of each of the previous four editions, unfortunately was not able to participate in this edition due to other responsibilities. Dr. Cohen made numerous important contributions to each of the previous editions and was an important ingredient to the success of this textbook. Each of the editors would like to express their sincere appreciation for his efforts. Dr. Cohen has been replaced by Dr. Helen Heslop from the Baylor College of Medicine in Houston, Texas. Dr. Heslop is an outstanding, internationally renowned scientist, pediatrician, and hematologist. Her participation has led to further improvements and expansion of chapters dealing with clinical immunology, pediatric hematology, pediatric stem cell transplantation, and gene therapy—additions that have substantially improved this edition.

The editorial board recognizes the pivotal role that hematopathology plays in the practice of modern hematology. This requires a close interaction between the clinician and the hematopathologist, each using their various clinical tools to serve patients with hematologic disorders. To improve the number and quality of hematopatology images in the fifth edition, we have invited Dr. John Anastasi, a well-respected hematopathologist from the University of Chicago, Pritzker School of Medicine, to join our editorial board as Hematopathology Image Consultant. Dr. Anastasi has reviewed each chapter and added or replaced photomicrographs with more illustrative images. One just has to thumb through this volume to gain a sense of the contribution that Dr. Anastasi has made to the fifth edition.

Another modification that is being implemented in this edition deals with references in each chapter. In previous editions, a significant proportion of the pages of many chapters were devoted to long lists of references. Such referencing of the literature is critical to the maintenance of the book as an academic enterprise. In order to retain this feature, a complete reference list of each chapter is provided on the Expert Consult Website that accompanies this volume. This strategy has allowed us to expand the actual number of pages devoted to useful text and to provide a short list of 20–30 general references at the end of each chapter. This modification has allowed us to maintain this textbook as a single volume. We hope that this compromise will be received in a favorable manner by our readership and that the website containing the full reference list will be accessible and useful.

Hematology: Basic Principles and Practice has become a leader among other textbooks dealing with the same subject matter. The close interaction between the members of the editorial board has, in the creation of each edition, led to novel concepts that have subsequently been incorporated into a number of other medical textbooks. As we finish this fifth edition of our book, it is important for the readership to be aware that this unique group of editors and authors will shortly begin to plan the sixth edition. These efforts and responsibilities are truly labors of love, which have provided us with enormous satisfaction. We all hope that this edition of *Hematology: Basic Principles and Practice* will not only find its way onto your bookshelf or your computer, but be your constant companion as you navigate the field of modern hematology.

Ronald Hoffman, MD
Edward J. Benz Jr., MD
Sanford Shattil, MD
Bruce Furie, MD
Leslie E. Silberstein, MD
Philip McGlave, MD
Helen Heslop, MD
John Anastasi, MD

CHAPTER 1

ANATOMY AND PHYSIOLOGY OF THE GENE

Andrew J. Wagner, Nancy Berliner, and Edward J. Benz, Jr

Normal blood cells have limited life spans; they must be replenished in precise numbers by a continuously renewing population of progenitor cells. Homeostasis of the blood requires that proliferation of these cells be efficient yet strictly constrained. Many distinctive types of mature blood cells must arise from these progenitors by a controlled process of commitment to, and execution of, complex programs of differentiation. Thus, developing red blood cells must produce large quantities of hemoglobin, but not the myeloperoxidase characteristic of granulocytes, the immunoglobulins characteristic of lymphocytes, or the fibrinogen receptors characteristic of platelets. Similarly, the maintenance of normal amounts of coagulant and anticoagulant proteins in the circulation requires exquisitely regulated production, destruction, and interaction of the components. Understanding the basic biologic principles underlying cell growth, differentiation, and protein biosynthesis requires a thorough knowledge of the structure and regulated expression of genes, because the gene is now known to be the fundamental unit by which biologic information is stored, transmitted, and expressed in a regulated fashion.

Genes were originally characterized as mathematical units of inheritance. They are now known to consist of molecules of deoxyribonucleic acid (DNA). By virtue of their ability to store information in the form of nucleotide sequences, to transmit it by means of semiconservative replication to daughter cells during mitosis and meiosis, and to express it by directing the incorporation of amino acids into proteins, DNA molecules are the chemical transducers of genetic information flow. Efforts to understand the biochemical means by which this transduction is accomplished have given rise to the discipline of molecular genetics.

THE GENETIC VIEW OF THE BIOSPHERE: THE CENTRAL DOGMA OF MOLECULAR BIOLOGY

The fundamental premise of the molecular biologist is that the magnificent diversity encountered in nature is ultimately governed by genes. The capacity of genes to exert this control is in turn determined by relatively simple stereochemical rules, first appreciated by Watson and Crick in the 1950s. These rules constrain the types of interactions that can occur between two molecules of DNA or ribonucleic acid (RNA).

DNA and RNA are linear polymers consisting of four types of nucleotide subunits. Proteins are linear unbranched polymers consisting of 21 types of amino acid subunits. Each amino acid is distinguished from the others by the chemical nature of its side chain, the moiety not involved in forming the peptide bond links of the chain. The properties of cells, tissues, and organisms depend largely on the aggregate structures and properties of their proteins. The central dogma of molecular biology states that genes control these properties by controlling the structures of proteins, the timing and amount of their production, and the coordination of their synthesis with that of other proteins. The information needed to achieve these ends is transmitted by a class of nucleic acid molecules called RNA. Genetic information thus flows in the direction DNA → RNA → protein. This central dogma provides, in principle, a universal approach for investigating the biologic properties and behavior of any given cell, tissue, or organism by study of the controlling genes. Methods permitting direct manipulation of DNA sequences should then be universally applicable to the study of all living entities. Indeed, the power of the molecular genetic approach lies in the universality of its utility.

One exception to the central dogma of molecular biology that is especially relevant to hematologists is the storage of genetic information in RNA molecules in certain viruses, notably the retroviruses associated with T-cell leukemia/lymphoma and the human immunodeficiency virus. When retroviruses enter the cell, the RNA genome is copied into a DNA replica by an enzyme called *reverse transcriptase*. This DNA representation of the viral genome is then expressed according to the rules of the central dogma. Retroviruses thus represent a variation on the theme, rather than a true exception to or violation of the rules.

ANATOMY AND PHYSIOLOGY OF GENES

DNA Structure

DNA molecules are extremely long, unbranched polymers of nucleotide subunits. Each nucleotide contains a sugar moiety called deoxyribose, a phosphate group attached to the 5′ carbon position, and a purine or pyrimidine base attached to the 1′ position (Fig. 1–1). The linkages in the chain are formed by phosphodiester bonds between the 5′ position of each sugar residue and the 3′ position of the adjacent residue in the chain (Fig. 1–1). The sugar phosphate links form the backbone of the polymer, from which the purine or pyrimidine bases project perpendicularly.

The haploid human genome consists of 23 long, double-stranded DNA molecules tightly complexed with histones and other nuclear proteins to form compact linear structures called *chromosomes*. The genome contains 3 billion nucleotides; each chromosome is thus 50 to 200 million bases in length. The individual genes are aligned along each chromosome. The human genome contains about 30,000 genes. Blood cells, like most somatic cells, are diploid. That is, each chromosome is present in two copies, so that there are 46 chromosomes consisting of approximately 6 billion base pairs (bp) of DNA.

The four nucleotide bases in DNA are the purines (adenosine and guanosine) and the pyrimidines (thymine and cytosine). The basic chemical configuration of the other nucleic acid found in cells, RNA, is quite similar, except that the sugar is ribose (having a hydroxyl group attached to the 2′ carbon, rather than the hydrogen found in deoxyribose) and the pyrimidine base uracil is used in place of thymine. The bases are commonly referred to by a shorthand notation: the letters A, C, T, G, and U are used to refer to adenosine, cytosine, thymine, guanosine, and uracil, respectively.

The ends of DNA and RNA strands are chemically distinct, because of the 3′ → 5′ phosphodiester bond linkage that ties adjacent bases together (see Fig. 1–1). One end of the strand (the 3′ end) has an unlinked (free at the 3′ carbon) sugar position, and the other (the 5′ end) a free 5′ position. There is thus a polarity to the sequence of bases in a DNA strand: the same sequence of bases read in a 3′ → 5′ direction carries a different meaning than if read in a 5′ → 3′ direction. Cellular enzymes can thus distinguish one end of a nucleic

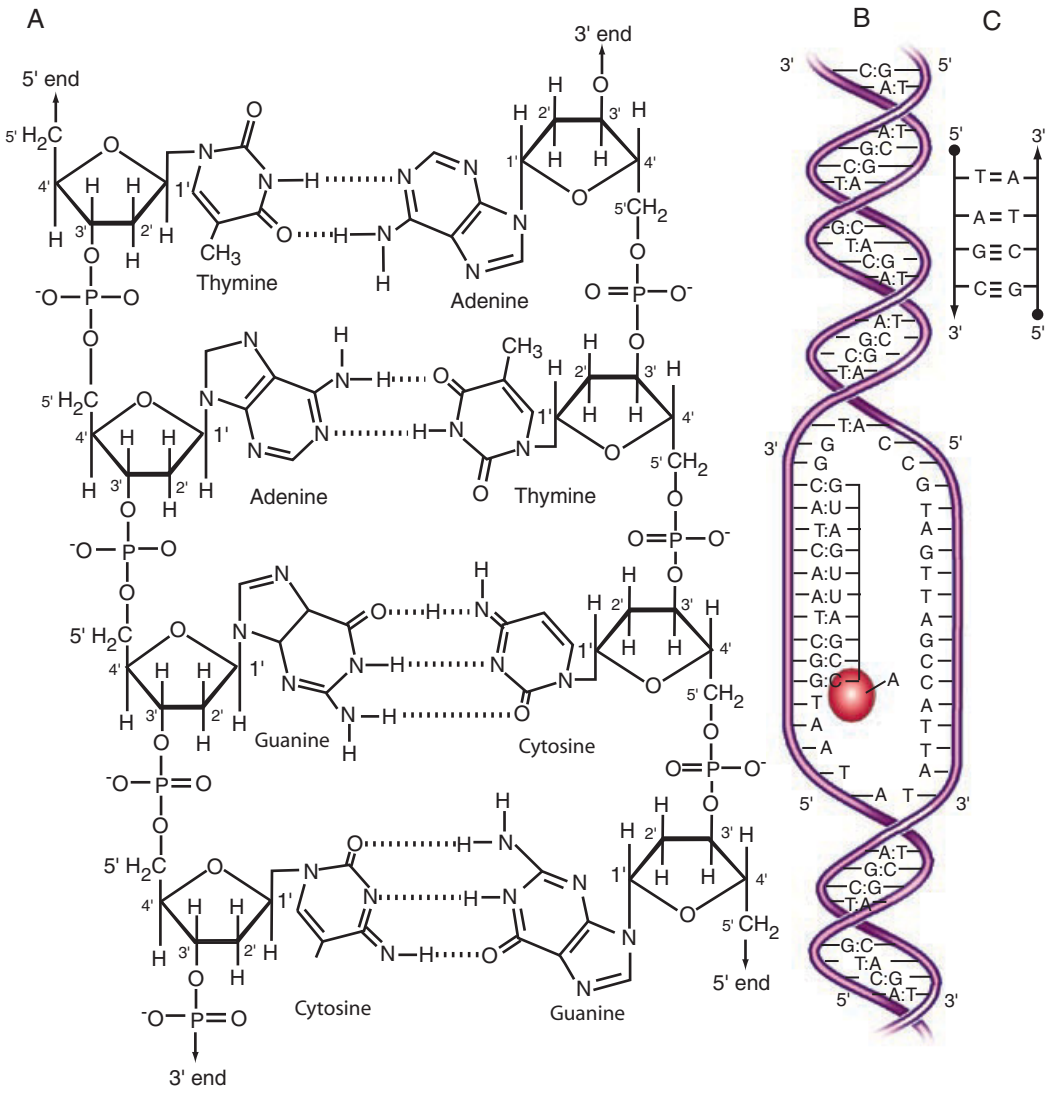

Figure 1–1 STRUCTURE, BASE PAIRING, POLARITY, AND TEMPLATE PROPERTIES OF DNA. **A,** Structures of the four nitrogenous bases projecting from sugar phosphate backbones. The hydrogen bonds between them form base pairs holding complementary strands of DNA together. Note that A–T and T–A base pairs have only two hydrogen bonds, whereas C–G and G–C pairs have three. **B,** The double helical structure of DNA results from base pairing of strands to form a double-stranded molecule with the backbones on the outside and the hydrogen-bonded bases stacked in the middle. Also shown schematically is the separation (unwinding) of a region of the helix by mRNA polymerase, which is shown using one of the strands as a template for the synthesis of an mRNA precursor molecule. Note that new bases added to the growing RNA strand obey the rules of Watson-Crick base pairing (see text). Uracil (U) in RNA replaces T in DNA and, like T, forms base pairs with A. **C,** Diagram of the antiparallel nature of the strands, based on the stereochemical 3′ → 5′ polarity of the strands. The chemical differences between reading along the backbone in the 5′ → 3′ and 3′ → 5′ directions can be appreciated by reference to part **A**. A, adenosine; T, thymine; C, cytosine; G, guanosine.

acid from the other; most enzymes that "read" the DNA sequence tend to do so only in one direction (3′ → 5′ or 5′ → 3′, but not both). Most nucleic acid-synthesizing enzymes, for instance, add new bases to the strand in a 5′ → 3′ direction.

The ability of DNA molecules to store information resides in the sequence of nucleotide bases arrayed along the polymer chain. Under the physiologic conditions in living cells, DNA is thermodynamically most stable when two strands coil around each other to form a double-stranded helix. The strands are aligned in an "antiparallel" direction, having opposite 3′ → 5′ polarity (see Fig. 1–1). The DNA strands are held together by hydrogen bonds between the bases on one strand and the bases on the opposite (complementary) strand. The stereochemistry of these interactions allows bonds to form between the two strands only when adenine on one strand pairs with thymine at the same position of the opposite strand, or guanine with cytosine; the Watson-Crick rules of base pairing. Two strands joined together in compliance with these rules are said to have "complementary" base sequences.

These thermodynamic rules imply that the sequence of bases along one DNA strand immediately dictates the sequence of bases that must be present along the complementary strand in the double helix. For example, whenever an A occurs along one strand, a T must be present at that exact position on the opposite strand; a G must always be paired with a C, a T with an A, and a C with a G. In RNA–RNA or RNA–DNA double-stranded molecules, U–A base pairs replace T–A pairs.

STORAGE AND TRANSMISSION OF GENETIC INFORMATION

The rules of Watson-Crick base pairing apply to DNA–RNA, RNA–RNA, and DNA–DNA double-stranded molecules. Enzymes that replicate or polymerize DNA and RNA molecules obey the base-pairing rules. By using an existing strand of DNA or RNA as the template, a new (daughter) strand is copied (transcribed) by reading

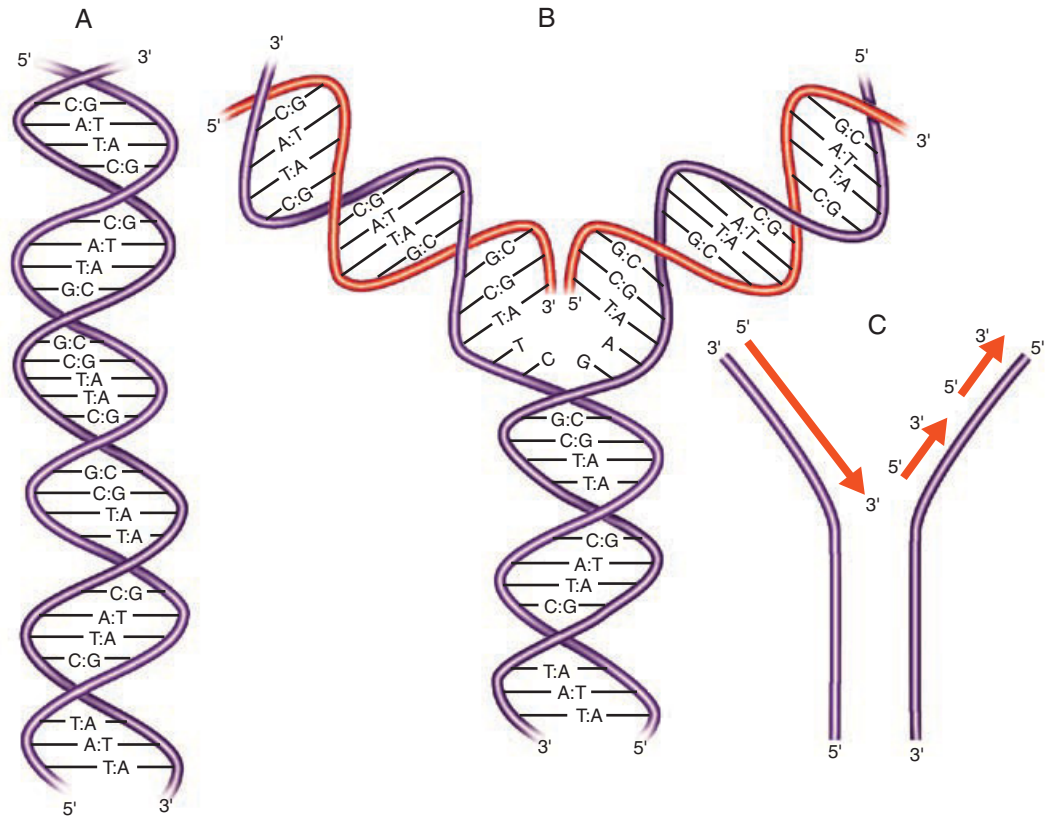

Figure 1–2 SEMICONSERVATIVE REPLICATION OF DNA. **A,** The process by which the DNA molecule on the left is replicated into two daughter molecules, as occurs during cell division. Replication occurs by separation of the parent molecule into the single-stranded form at one end, reading of each of the daughter strands in the 3′ → 5′ direction by DNA polymerase, and addition of new bases to growing daughter strands in the 5′ → 3′ direction. **B,** The replicated portions of the daughter molecules are identical to each other (*red*). Each carries one of the two strands of the parent molecule, accounting for the term *semiconservative replication.* Note the presence of the replication fork, the point at which the parent DNA is being unwound. **C,** The antiparallel nature of the DNA strands demands that replication proceed toward the fork in one direction and away from the fork in the other (*red*). This means that replication is actually accomplished by reading of short stretches of DNA, followed by ligation of the short daughter strand regions to form an intact daughter strand.

processively along the base sequence of the template strand, adding to the growing strand at each position only that base that is complementary to the corresponding base in the template according to the Watson-Crick rules. Thus, a DNA strand having the base sequence 5′-GCTATG-3′ could be copied by DNA polymerase only into a daughter strand having the sequence 3′-CGATAC-5′. Note that the sequence of the template strand provides all the information needed to predict the nucleotide sequence of the complementary daughter strand. Genetic information is thus stored in the form of base-paired nucleotide sequences.

If a double-stranded DNA molecule is separated into its two component strands, and each strand is then used as a template to synthesize a new daughter strand, the product will be two double-stranded daughter DNA molecules, each identical to the original parent molecule. This semiconservative replication process is exactly what occurs during mitosis and meiosis as cell division proceeds (Fig. 1–2). The rules of Watson-Crick base pairing thus provide for the faithful transmission of exact copies of the cellular genome to subsequent generations.

EXPRESSION OF GENETIC INFORMATION THROUGH THE GENETIC CODE AND PROTEIN SYNTHESIS

The information stored in the DNA base sequence achieves its impact on the structure, function, and behavior of organisms by governing the structures, timing, and amounts of protein synthesized in the cells. The primary structure (ie, the amino acid sequence) of each protein determines its three-dimensional conformation and therefore properties (eg, shape, enzymatic activity, ability to interact with other molecules, stability). In the aggregate, these proteins control cell structure and metabolism. The process by which DNA achieves its control of cells through protein synthesis is called *gene expression*.

An outline of the basic pathway of gene expression in eukaryotic cells is shown in Fig. 1–3. The DNA base sequence is first copied into an RNA molecule, called *premessenger RNA*, by messenger RNA (mRNA) polymerase. Premessenger RNA has a base sequence identical to the DNA coding strand. Genes in eukaryotic species consist of tandem arrays of sequences encoding mRNA (exons); these sequences alternate with sequences (introns) present in the initial mRNA transcript (premessenger RNA) but absent from the mature mRNA. The entire gene is transcribed into the large precursor, which is then further processed (spliced) in the nucleus. The introns are excised from the final mature mRNA molecule, which is then exported to the cytoplasm to be decoded (translated) into the amino acid sequence of the protein, by association with a biochemically complex group of ribonucleoprotein structures called *ribosomes*. Ribosomes contain two subunits: the 60S subunit contains a single, large (28S) ribosomal RNA molecule complexed with multiple proteins, whereas the RNA component of the 40S subunit is a smaller (18S) ribosomal RNA molecule.

Ribosomes read mRNA sequence in a ticker tape fashion three bases at a time, inserting the appropriate amino acid encoded by each three-base code word or codon into the appropriate position of the growing protein chain. This process is called *mRNA translation*. The glossary used by cells to know which amino acids are encoded by each DNA codon is called the *genetic code* (Table 1–1). Each amino acid is encoded by a sequence of three successive bases. Because there

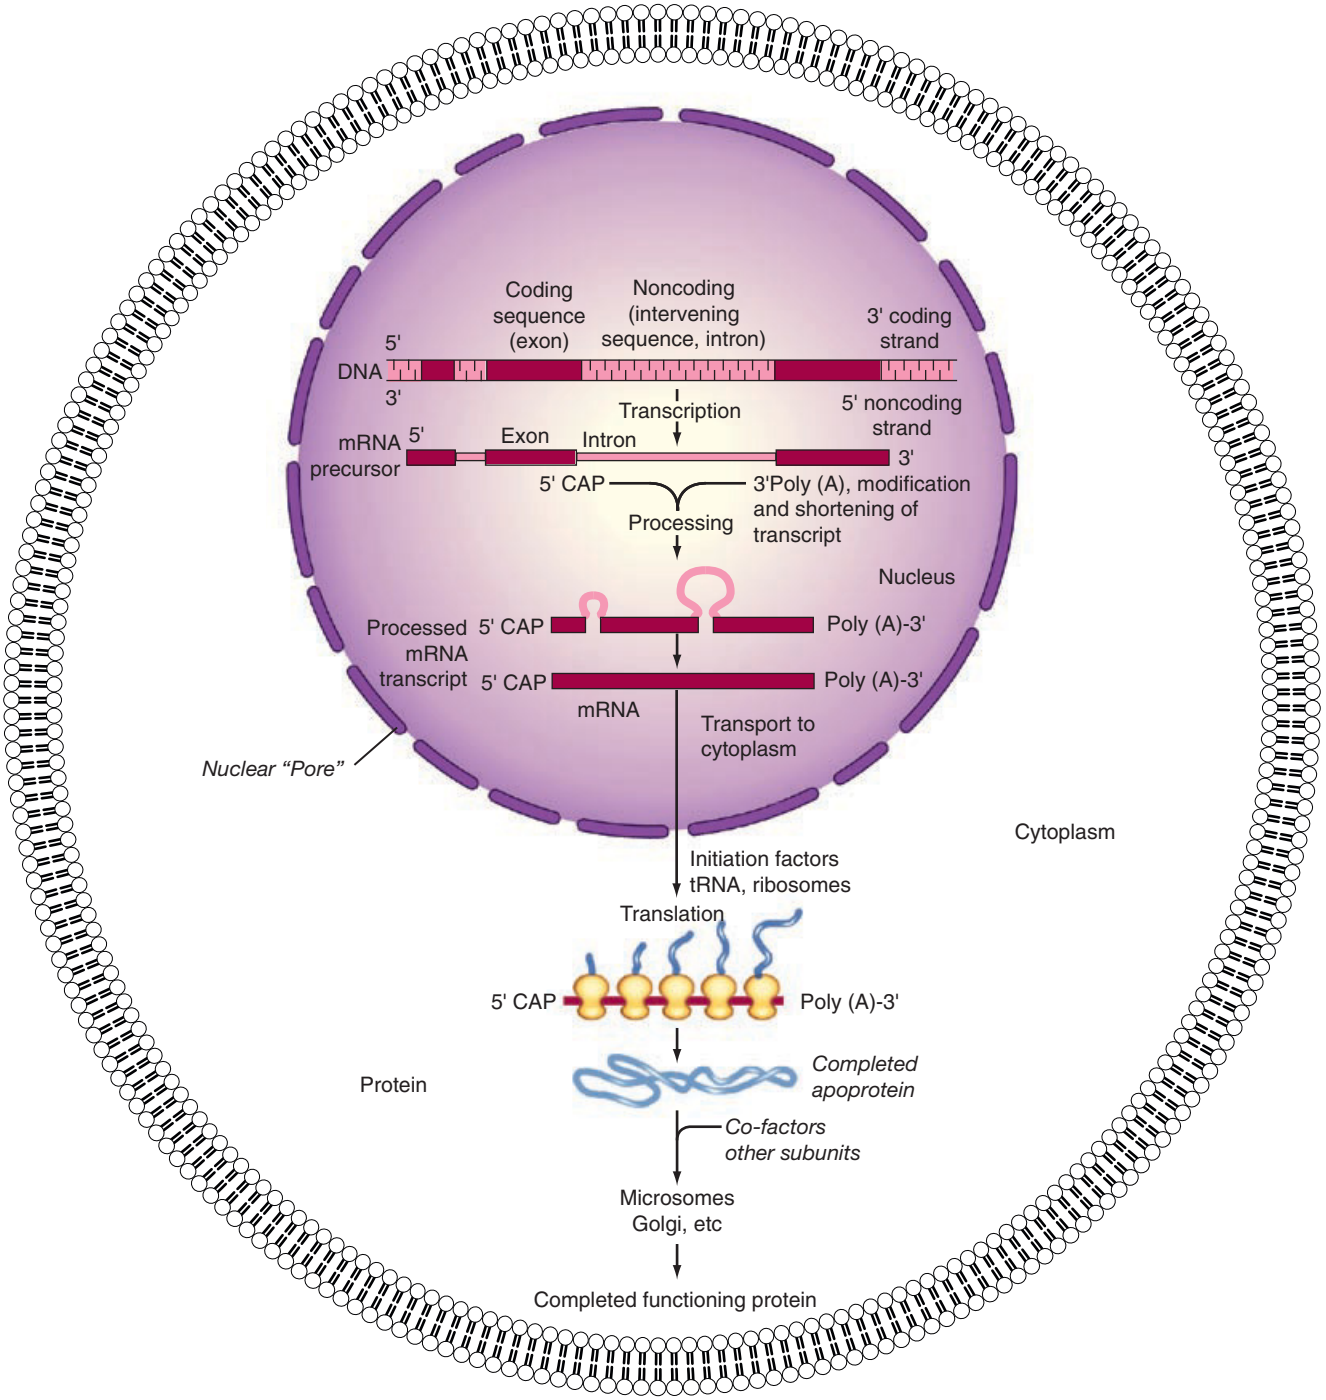

Figure 1–3 SYNTHESIS OF MRNA AND PROTEIN—THE PATHWAY OF GENE EXPRESSION. The diagram of the DNA gene shows the alternating array of exons (*red*) and introns (*shaded color*) typical of most eukaryotic genes. Transcription of the mRNA precursor, addition of the 5′-CAP and 3′-poly (A) tail, splicing and excision of introns, transport to the cytoplasm through the nuclear pores, translation into the amino acid sequence of the apoprotein, and posttranslational processing of the protein are described in the text. Translation proceeds from the initiator methionine codon near the 5′ end of the mRNA, with incorporation of the amino terminal end of the protein. As the mRNA is read in a 5′ → 3′ direction, the nascent polypeptide is assembled in an amino → carboxyl terminal direction.

are four code letters (A, C, G, and U), and because sequences read in the 5′ → 3′ direction have a different biologic meaning than sequences read in the 3′ → 5′ direction, there are 4^3, or 64, possible codons consisting of three bases.

There are 21 naturally occurring amino acids found in proteins. Thus, more codons are available than amino acids to be encoded. As noted in Table 1–1, a consequence of this redundancy is that some amino acids are encoded by more than one codon. For example, six distinct codons can specify incorporation of arginine into a growing amino acid chain, four codons can specify valine, two can specify glutamic acid, and only one each methionine or tryptophan. In no case does a single codon encode more than one amino acid. Codons thus predict unambiguously the amino acid sequence they encode. However, one cannot easily read backward from the amino acid sequence to decipher the *exact* encoding DNA sequence. These facts are summarized by saying that the code is degenerate but not ambiguous.

Some specialized codons serve as punctuation points during translation. The methionine codon (AUG), when surrounded by a consensus sequence (the Kozak box) near the beginning (5′ end) of the mRNA, serves as the initiator codon signaling the first amino acid to

†AUG is also used as the chain-initiation codon when surrounded by the Kozak consensus sequence.
‡Hydroxyproline, the 21st amino acid, is generated by posttranslational modification of proline. It is almost exclusively confined to collagen subunits.
§The codons that signal the end of translation, also called nonsense or termination codons, are described by their nicknames *amber* (UAG), *ochre* (UAA), and *opal* (UGA).

be incorporated. All proteins thus begin with a methionine residue, but this is often removed later in the translational process. Three codons, UAG, UAA, and UGA, serve as translation terminators, signaling the end of translation.

The adaptor molecules mediating individual decoding events during mRNA translation are small (40 bases long) RNA molecules called *transfer RNAs* (tRNAs). When bound into a ribosome, each tRNA exposes a three-base segment within its sequence called the *anticodon*. These three bases attempt to pair with the three-base codon exposed on the mRNA. If the anticodon is complementary in sequence to the codon, a stable interaction among the mRNA, the ribosome, and the tRNA molecule results. Each tRNA also contains a separate region that is adapted for covalent binding to an amino acid. The enzymes that catalyze the binding of each amino acid are constrained in such a way that each tRNA species can bind only to a single amino acid. For example, tRNA molecules containing the anticodon 3′-AAA-5′, which is complementary to a 5′-UUU-3′ (phenylalanine) codon in mRNA, can only be bound to or charged with phenylalanine; tRNA containing the anticodon 3′-UAG-5′ can only be charged with isoleucine, and so forth.

Transfer RNAs and their amino acyl tRNA synthetases provide for the coupling of nucleic acid information to protein information needed to convert the genetic code to an amino acid sequence. Ribosomes provide the structural matrix on which tRNA anticodons and mRNA codons become properly exposed and aligned in an orderly, linear, and sequential fashion. As each new codon is exposed, the appropriate charged tRNA species is bound. A peptide bond is then formed between the amino acid carried by this tRNA and the C-terminal residue on the existing nascent protein chain. The growing chain is transferred to the new tRNA in the process, so that it is held in place as the next tRNA is brought in. This cycle is repeated until completion of translation. The completed polypeptide chain is then transferred to other organelles for further processing (eg, to the endoplasmic reticulum and the Golgi apparatus) or released into cytosol for association of the newly completed chain with other subunits to form complex multimeric proteins (eg, hemoglobin), and so forth, as discussed in Chapter 2.

mRNA METABOLISM

In eukaryotic cells, mRNA is initially synthesized in the nucleus (Figs. 1–3 and 1–4). Before the initial transcript becomes suitable for translation in the cytoplasm, mRNA processing and transport occur by a complex series of events including excision of the portions of the mRNA corresponding to the introns of the gene (mRNA splicing), modification of the 5′ and 3′ ends of the mRNA to render them more stable and translatable, and transport to the cytoplasm. Moreover, the amount of any particular mRNA moiety in both prokaryotic and eukaryotic cells is governed not only by the composite rate of mRNA synthesis (transcription, processing, and transport) but also by its degradation by cytoplasmic ribonucleases (RNA degradation). Many mRNA species of special importance in hematology (eg, mRNAs for growth factors and their receptors, protooncogene mRNAs, acute-phase reactants) are exquisitely regulated by control of their stability (half-life) in the cytoplasm.

Posttranscriptional mRNA metabolism is complex. Only a few relevant details are considered in this section.

mRNA Splicing

The initial transcript of eukaryotic genes contains several subregions (see Fig. 1–4). Most striking is the tandem alignment of exons and introns. Precise excision of intron sequences and ligation of exons is critical for production of mature mRNA. This process is called *mRNA splicing*, and it occurs on complexes of small nuclear RNAs and proteins called snRNPs; the term *spliceosome* is also used to describe the intranuclear organelle that mediates mRNA splicing reactions. The biochemical mechanism for splicing is complex. A consensus sequence, which includes the dinucleotide GU, is recognized as the donor site at the 5′ end of the intron (5′ end refers to the polarity of the mRNA strand coding for protein); a second consensus sequence ending in the dinucleotide AG is recognized as the acceptor site, which marks the distal end of the intron (Figs. 1–4 and 1–5). The spliceosome recognizes the donor and acceptor and forms an intermediate lariat structure that provides for both excision of the intron and proper alignment of the cut ends of the two exons for ligation in precise register.

Messenger RNA splicing has proved to be an important mechanism for greatly increasing the versatility and diversity of expression of a single gene. For example, some genes contain an array of more exons than are actually found in any mature mRNA species encoded by that gene. Several different mRNA and protein products can arise from a single gene by selective inclusion or exclusion of individual exons from the mature mRNA products. This phenomenon is called *alternative mRNA splicing*. It permits a single gene to code for multiple mRNA and protein products with related but distinct structures and functions. The mechanisms by which individual exons are selected or rejected remain obscure. For present purposes, it is sufficient to note that important physiologic changes in cells can be regulated by altering the patterns of mRNA splicing products arising from single genes.

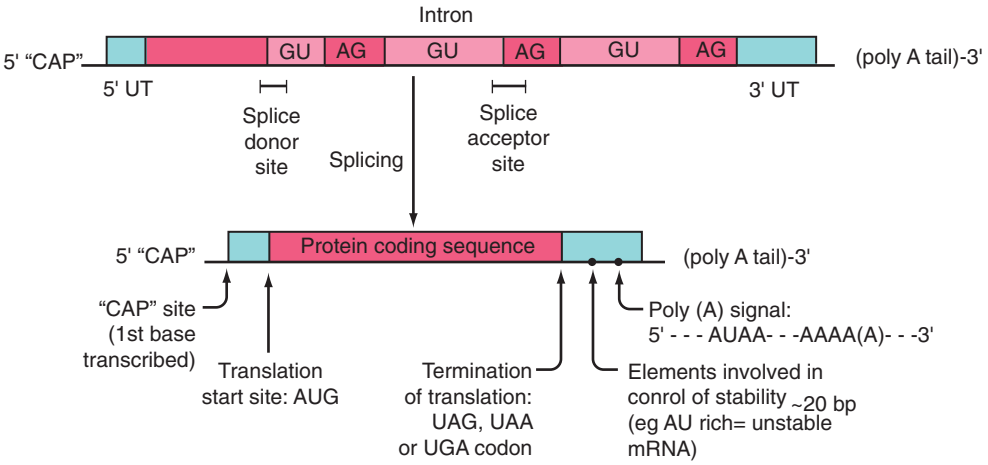

Figure 1–4 ANATOMY OF THE PRODUCTS OF THE STRUCTURAL GENE (MRNA PRECURSOR AND MRNA). This schematic shows the configuration of the critical anatomic elements of an mRNA precursor, which represents the primary copy of the structural portion of the gene. The sequences GU and AG indicate, respectively, the invariant dinucleotides present in the donor and acceptor sites at which introns are spliced out of the precursor. Not shown are the less stringently conserved consensus sequences that must precede and succeed each of these sites for a short distance.

Many inherited hematologic diseases arise from mutations that derange mRNA splicing. For example, some of the most common forms of the thalassemia syndromes and hemophilia arise by mutations that alter normal splicing signals or create splicing signals where they normally do not exist (activation of cryptic splice sites).

Modification of the Ends of the mRNA Molecule

Most eukaryotic mRNA species are polyadenylated at their 3′ ends. mRNA precursors are initially synthesized as large molecules that extend further downstream from the 3′ end of the mature mRNA molecule. Polyadenylation results in the addition of stretches of 100 to 150 A residues at the 3′ end. Such an addition is often called the poly-A tail and is of variable length. Polyadenylation facilitates rapid early cleavage of the unwanted 3′ sequences from the transcript and is also important for stability or transport of the mRNA out of the nucleus. Signals near the 3′ extremity of the mature mRNA mark positions at which polyadenylation occurs. The consensus signal is AUAAA (see Fig. 1–4). Mutations in the poly-A signal sequence have been shown to cause thalassemia.

At the 5′ end of the mRNA, a complex oligonucleotide having unusual phosphodiester bonds is added. This structure contains the nucleotide 7-methyl-guanosine and is called CAP (see Fig. 1–4). The 5′-CAP enhances both mRNA stability and the ability of the mRNA to interact with protein translation factors and ribosomes.

5′ and 3′ Untranslated Sequences

The 5′ and 3′ extremities of mRNA extend beyond the initiator and terminator codons that mark the beginning and the end of the sequences actually translated into proteins (see Figs. 1–4 and 1–5). These so-called 5′ and 3′ untranslated regions (5′ UTR and 3′ UTR) are involved in determining mRNA stability and the efficiency with which mRNA species can be translated. For example, if the 3′ UTR of a very stable mRNA (eg, globin mRNA) is swapped with the 3′ UTR of a highly unstable mRNA (eg, the c-*myc* protooncogene), the c-*myc* mRNA becomes more stable. Conversely, attachment of the 3′ UTR of c-*myc* to a globin molecule renders it unstable. Instability is often associated with repeated sequences rich in A and U in the 3′ UTR (see Fig. 1–4). Similarly, the UTRs in mRNAs coding for proteins involved in iron metabolism mediate altered mRNA stability or translatability by binding iron-laden proteins.

Transport of mRNA From Nucleus to Cytoplasm: mRNP Particles

An additional potential step for regulation or disruption of mRNA metabolism occurs during the transport from nucleus to cytoplasm. mRNA transport is an active, energy-consuming process. Moreover, at least some mRNAs appear to enter the cytoplasm in the form of complexes bound to proteins (mRNPs). mRNPs may regulate stability of the mRNAs and their access to translational apparatus. There is some evidence that certain mRNPs are present in the cytoplasm but are not translated (masked message) until proper physiologic signals are received.

GENE REGULATION

Virtually all cells of an organism receive a complete copy of the DNA genome inherited at the time of conception. The panoply of distinct

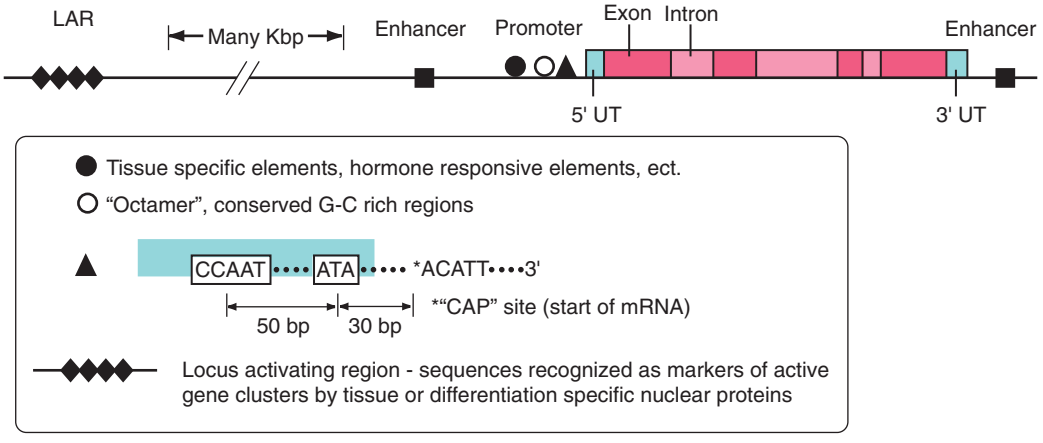

Figure 1–5 Regulatory elements flanking the structural gene.

cell types and tissues found in any complex organism is possible only because different portions of the genome are selectively expressed or repressed in each cell type. Each cell must "know" which genes to express, how actively to express them, and when to express them. This biologic necessity has come to be known as *gene regulation* or *regulated gene expression*. Understanding gene regulation provides insight into how pluripotent stem cells determine that they will express the proper sets of genes in daughter progenitor cells that differentiate along each lineage. Major hematologic disorders (such as the leukemias and lymphomas), immunodeficiency states, and myeloproliferative syndromes result from derangements in the system of gene regulation. An understanding of the ways that genes are selected for expression thus remains one of the major frontiers of biology and medicine.

EPIGENETIC REGULATION OF GENE EXPRESSION

Most of the DNA in living cells is inactivated by formation of a nucleoprotein complex called *chromatin*. The histone and nonhistone proteins in chromatin effectively sequester genes from enzymes needed for expression. The most tightly compacted chromatin regions are called *euchromatin*. Heterochromatin, less tightly packed, contains actively transcribed genes. Activation of a gene for expression (ie, transcription) requires that it become less compacted and more accessible to the transcription apparatus. These processes involve both *cis*-acting and *trans*-acting factors. *Cis*-acting elements are regulatory DNA sequences, within or flanking the genes. They are recognized by *trans*-acting factors, which are nuclear DNA-binding proteins needed for transcriptional regulation.

DNA sequence regions flanking genes are called *cis*-acting because they influence expression of nearby genes only on the same chromosome. These sequences do not usually encode mRNA or protein molecules. They alter the conformation of the gene within chromatin in such a way as to facilitate or inhibit access to the factors that modulate transcription. These interactions may twist or kink the DNA in such a way as to control exposure to other molecules. When exogenous nucleases are added in small amounts to nuclei, these exposed sequence regions become especially sensitive to the DNA-cutting action of the nucleases. Thus, nuclease-hypersensitive sites in DNA have come to be appreciated as markers for regions in or near genes that are interacting with regulatory nuclear proteins.

Methylation is another structural feature that can be used to recognize differences between actively transcribed and inactive genes. Most eukaryotic DNA is heavily methylated, that is, the DNA is modified by the addition of a methyl group to the 5 position of the cytosine pyrimidine ring (5-methyl-C). In general, heavily methylated genes are inactive, whereas active genes are relatively hypomethylated, especially in the 5′ flanking regions containing the promoter and other regulatory elements (see "Enhancers, Promoters, and Silencers"). These flanking regions frequently include DNA sequences with a high content of Cs and Gs (CpG islands). Hypomethylated CpG islands (detectable by methylation-sensitive restriction endonucleases) serve as markers of actively transcribed genes. For example, a search for undermethylated CpG islands on chromosome 7 facilitated the search for the gene for cystic fibrosis.

DNA methylation is facilitated by DNA methyltransferases. DNA replication incorporates unmethylated nucleotides into each nascent strand, thus leading to demethylated DNA. For cytosines to become methylated, the methyltransferases must act after each round of replication. After an initial wave of demethylation early in embryonic development, regulatory areas are methylated during various stages of development and differentiation. Aberrant DNA methylation also occurs as an early step during tumorigenesis, leading to silencing of tumor suppressor genes and of genes related to differentiation. This finding has led to induction of DNA demethylation as a target in cancer therapy. Indeed, 5-azacytidine, a cytidine analog unable to be methylated, and the related compound decitabine, are approved by the United States Food and Drug Administration for use in myelodysplastic syndromes, and their use in cases of other malignancies is being investigated.

Although it is poorly understood how particular regions of DNA are targeted for methylation, it is becoming increasingly apparent that this modification targets further alterations in chromatin proteins that in turn influence gene expression. Histone acetylation, phosphorylation, and methylation of the *N*-terminal tail are currently the focus of intense study. Acetylation of lysine residues (catalyzed by histone acetyltransferases), for example, is associated with transcriptional activation. Conversely, histone deacetylation (catalyzed by histone deacetylase) leads to gene silencing. Histone deacetylases are recruited to areas of DNA methylation by DNA methyltransferases and by methyl–DNA-binding proteins, thus linking DNA methylation to histone deacetylation. Drugs inhibiting these enzymes are being studied as anticancer agents.

The regulation of histone acetylation/deacetylation appears to be linked to gene expression, but the roles of histone phosphorylation and methylation are less well understood. Current research suggests that in addition to gene regulation, histone modifications contribute to the "epigenetic code" and are thus a means by which information regarding chromatin structure is passed to daughter cells after DNA replication occurs.

ENHANCERS, PROMOTERS, AND SILENCERS

Several types of *cis*-active DNA sequence elements have been defined according to the presumed consequences of their interaction with nuclear proteins (see Fig. 1–5). *Promoters* are found just upstream (to the 5′ side) of the start of mRNA transcription (the CAP). mRNA polymerases appear to bind first to the promoter region and thereby gain access to the structural gene sequences downstream. Promoters thus serve a dual function of being binding sites for mRNA polymerase and marking for the polymerase the downstream point at which transcription should start.

Enhancers are more complicated DNA sequence elements. Enhancers can lie on either side of a gene, or even within the gene. Enhancers bind transcription factors and thereby stimulate expression of genes nearby. The domain of influence of enhancers (ie, the number of genes to either side whose expression is stimulated) varies. Some enhancers influence only the adjacent gene; others seem to mark the boundaries of large multigene clusters (gene domains) whose coordinated expression is appropriate to a particular tissue type or a particular time. For example, the very high levels of globin gene expression in erythroid cells depend on the function of an enhancer that seems to activate the entire gene cluster and is thus called a locus-activating region (see Fig. 1–5). The nuclear factors interacting with enhancers are probably induced into synthesis or activation as part of the process of differentiation.

Silencer sequences serve a function that is the obverse of enhancers. When bound by the appropriate nuclear proteins, silencer sequences cause repression of gene expression. There is some evidence that the same sequence elements can act as enhancers or silencers under different conditions, presumably by being bound by different sets of proteins having opposite effects on transcription. *Insulators* are sequence domains that mark the "boundaries" of multigene clusters, thereby preventing activation of one set of genes from "leaking" into nearby genes.

TRANSCRIPTION FACTORS

Transcription factors are nuclear proteins that exhibit gene-specific DNA binding. Considerable information is now available about these nuclear proteins and their biochemical properties, but their physiologic behavior remains incompletely understood. Common structural features have become apparent. Most transcription factors have DNA-binding domains sharing homologous structural motifs (cytosine-rich regions called zinc fingers, leucine-rich regions called leucine zippers, etc), but other regions appear to be unique. Many factors implicated in the regulation of growth, differentiation, and development (eg, homeobox genes, protooncogenes, antioncogenes) appear

to be DNA-binding proteins and may be involved in the steps needed for activation of a gene within chromatin. Others bind to or modify DNA-binding proteins. These factors are discussed in more detail in several other chapters.

REGULATION OF MRNA SPLICING, STABILITY, AND TRANSLATION (POSTTRANSCRIPTIONAL REGULATION)

It has become increasingly apparent that posttranscriptional and translational mechanisms are important strategies used by cells to govern the amounts of mRNA and protein accumulating when a particular gene is expressed. The major modes of posttranscriptional regulation at the mRNA level are regulated alternative mRNA splicing, control of mRNA stability, and control of translational efficiency. As discussed elsewhere (see Chapter 2), additional regulation at the protein level occurs by mechanisms modulating localization, stability, activation, or export of the protein.

A cell can regulate the relative amounts of different protein isoforms arising from a given gene by altering the relative amounts of an mRNA precursor that are spliced along one pathway or another (alternative mRNA splicing). Many striking examples of this type of regulation are known—for example, the ability of B lymphocytes to make both IgM and IgD at the same developmental stage, changes in the particular isoforms of cytoskeletal proteins produced during red blood cell differentiation, and a switch from one isoform of the *c-myb* protooncogene product to another during red blood cell differentiation. The effect of controlling the pathway of mRNA processing used in a cell is to include or exclude portions of the mRNA sequence. These portions encode peptide sequences that influence the ultimate physiologic behavior of the protein, or the RNA sequences that alter stability or translatability.

The importance of the control of mRNA stability for gene regulation is being increasingly appreciated. The steady-state level of any given mRNA species ultimately depends on the balance between the rate of its production (transcription and mRNA processing) and its destruction. One means by which stability is regulated is the inherent structure of the mRNA sequence, especially the 3′ and 5′ UTRs. As already noted, these sequences appear to affect mRNA secondary structure or recognition by nucleases, or both. Different mRNAs thus have inherently longer or shorter half-lives, almost regardless of the cell type in which they are expressed. Some mRNAs tend to be highly unstable. In response to appropriate physiologic needs, they can thus be produced quickly and removed from the cell quickly when a need for them no longer exists. Globin mRNA, on the other hand, is inherently quite stable, with a half-life measured in the range of 15–50 hours. This is appropriate for the need of reticulocytes to continue to synthesize globin for 24 to 48 hours after the ability to synthesize new mRNA has been lost by the terminally mature erythroblasts.

The stability of mRNA can also be altered in response to changes in the intracellular milieu. This phenomenon usually involves nucleases capable of destroying one or more broad classes of mRNA defined on the basis of their 3′ or 5′ UTR sequences. Thus, for example, histone mRNAs are destabilized after the S phase of the cell cycle is complete. Presumably this occurs because histone synthesis is no longer needed. Induction of cell activation, mitogenesis, or terminal differentiation events often results in the induction of nucleases that destabilize specific subsets of mRNAs. Selective stabilization of mRNAs probably also occurs, but specific examples are less well documented.

The amount of a given protein accumulating in a cell depends on the amount of the mRNA present, the rate at which it is translated into the protein, and the stability of the protein. Translational efficiency depends on a number of variables, including polyadenylation and presence of the 5′ cap. The amounts and state of activation of protein factors needed for translation are also crucial. The secondary structure of the mRNA, particularly in the 5′ UTR, greatly influences the intrinsic translatability of an mRNA molecule by constraining the access of translation factors and ribosomes to the translation initiation signal in the mRNA. Secondary structures along the coding sequence of the mRNA may also have some impact on the rate of elongation of the peptide.

Changes in capping, polyadenylation, and translation factor efficiency affect the overall rate of protein synthesis within each cell. These effects tend to be global, rather than specific to a particular gene product. However, these effects influence the relative amounts of different proteins made. mRNAs whose structures inherently lend themselves to more efficient translation tend to compete better for rate-limiting components of the translational apparatus, whereas those mRNAs that are inherently less translatable tend to be translated less efficiently in the face of limited access to other translational components. For example, the translation factor eIF-4 tends to be produced in higher amounts when cells encounter transforming or mitogenic events. This causes an increase in overall rates of protein synthesis but also leads to a selective increase in the synthesis of some proteins that were underproduced before mitogenesis.

Translational regulation of individual mRNA species is critical for some events important to blood cell homeostasis. For example, as discussed in Chapter 31, the amount of iron entering a cell is an exquisite regulator of the rate of ferritin mRNA translation. An mRNA sequence called the *iron response element* is recognized by a specific mRNA-binding protein, but only when the protein lacks iron. mRNA bound to the protein is translationally inactive. As iron accumulates in the cell, the protein becomes iron bound and loses its affinity for the mRNA, resulting in translation into apoferritin molecules that bind the iron.

Tubulin synthesis involves coordinated regulation of translation and mRNA stability. Tubulin regulates the stability of its own mRNA by a feedback loop. As tubulin concentrations rise in the cell, it interacts with its own mRNA through the intermediary of an mRNA-binding protein. This results in the formation of an mRNA–protein complex and nucleolytic cleavage of the mRNA. The mRNA is destroyed and further tubulin production is halted.

These few examples of posttranscriptional regulation emphasize that cells tend to use every step in the complex pathway of gene expression as points at which exquisite control over the amounts of a particular protein can be regulated. In other chapters, additional levels of regulation are described (eg, regulation of the stability, activity, localization, and access to other cellular components of the proteins that are present in a cell).

SMALL INTERFERING RNA AND MICRO RNA

Recently, posttranscriptional mechanisms of gene silencing involving small RNAs were discovered. One process is carried out by *small interfering RNAs* (siRNAs): short, double-stranded fragments of RNA containing 21 to 23 bp (Fig. 1–6). The process is triggered by perfectly complementary double-stranded RNA, which is cleaved by Dicer, a member of the RNase III family, into siRNA fragments. These small fragments of double-stranded RNA are unwound by a helicase in the RNA-induced silencing complex. The antisense strand anneals to mRNA transcripts in a sequence-specific manner, and in doing so brings the endonuclease activity within the RNA-induced silencing complex to the targeted transcript. An RNA-dependent RNA polymerase in the RNA-induced silencing complex may then create new siRNAs to processively degrade the mRNA, ultimately leading to complete degradation of the mRNA transcript and abrogation of protein expression.

Although this endogenous process likely evolved to destroy invading viral RNA, the use of siRNA has become a commonly used tool for evaluation of gene function. Sequence-specific synthetic siRNA may be directly introduced into cells or introduced via gene transfertion methods and targeted to an mRNA of a gene of interest. The siRNA will lead to degradation of the mRNA transcript, and accordingly prevent new protein translation. This technique is a relatively simple, efficient, and inexpensive means to investigate cellular phenotypes after directed elimination of expression of a single gene. The

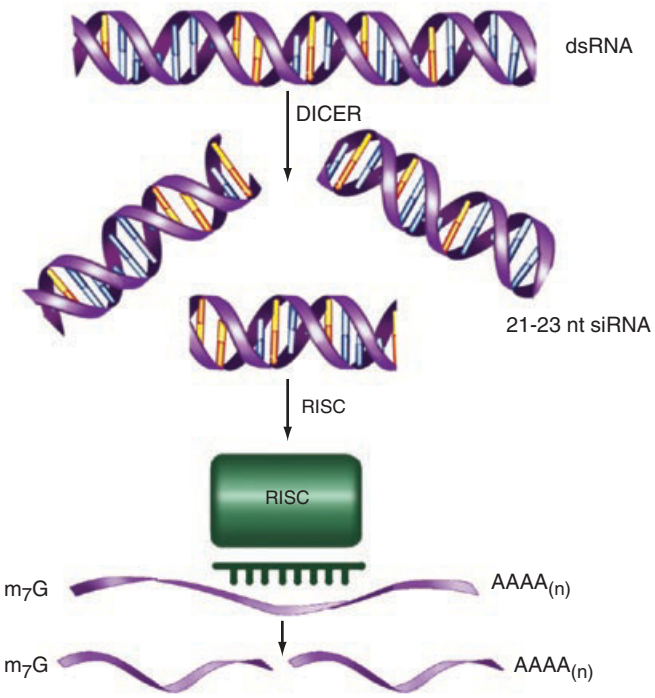

Figure 1–6 mRNA DEGRADATION BY siRNA. Double-stranded RNA is digested into 21- to 23-bp siRNAs by the Dicer RNase. These RNA fragments are unwound by RISC and bring the endonucleolytic activity of RISC to mRNA transcripts in a sequence-specific manner, leading to degradation of the mRNA. mRNA, messenger RNA; RISC, RNA-induced silencing complex; siRNA, small interfering RNA.

2006 Nobel Prize in Physiology or Medicine was awarded to two discoverers of RNA interference, Andrew Fire and Craig Mello.

Micro RNAs (miRNAs) are 22 nt small RNAs encoded by the cellular genome that alter mRNA stability and protein translation. These genes are transcribed by RNA polymerase II, and capped and polyadenylated like other RNA polymerase II transcripts. The precursor transcript of approximately 70 nucleotides is cleaved into mature miRNA by the enzymes Drosha and Dicer. One strand of the resulting duplex forms a complex with the RNA-induced silencing complex that together binds the target mRNA with imperfect complementarity. Through mechanisms that are still incompletely understood, miRNA suppresses gene expression, likely either through inhibition of protein translation or through destabilization of mRNA. miRNAs appear to have essential roles in development and differentiation, and may be aberrantly regulated in cancer cells. The identification of miRNA sequences, their regulation, and their target genes are areas of intense study.

ADDITIONAL STRUCTURAL FEATURES OF GENOMIC DNA

Most DNA does not code for RNA or protein molecules. The vast majority of nucleotides present in the human genome reside outside structural genes. Structural genes are separated from one another by as few as 1 to 5 kilobases, or as many as several thousand kilobases of DNA. Almost nothing is known about the reason for the erratic clustering and spacing of genes along chromosomes. It is clear that intergenic DNA contains a variegated landscape of structural features that provide useful tools to localize genes, identify individual human beings as unique from every other human being (DNA fingerprinting), and diagnose human diseases by linkage. A more detailed discussion of these techniques is included in Chapter 2. Only a brief introduction is provided here.

The rate of mutation in DNA under normal circumstances is approximately $1/10^6$. In other words, 1 of 1 million bases of DNA will be mutated during each round of DNA replication. A set of enzymes called *DNA proofreading enzymes* corrects many but not all of these mutations. When these enzymes are themselves altered by mutation, the rate of mutation (and therefore the odds of neoplastic transformation) increases considerably. If these mutations occur in bases critical to the structure or function of a protein or gene, altered function, disease, or a lethal condition can result. Most pathologic mutations tend not to be preserved throughout many generations because of their unfavorable phenotypes. Exceptions, such as the hemoglobinopathies, occur when the heterozygous state for these mutations confers selective advantage in the face of unusual environmental conditions, such as malaria epidemics. These "adaptive" mutations drive the dynamic change in the genome with time (evolution).

Most of the mutations that accumulate in the DNA of *Homo sapiens* occur in either intergenic DNA or the "silent" bases of DNA, such as the degenerate third bases of codons. They do not pathologically alter the function of the gene or its products. These clinically harmless mutations are called *DNA polymorphisms*. DNA polymorphisms can be regarded in exactly the same way as other types of polymorphisms that have been widely recognized for years (eg, eye and hair color, blood groups). They are variations in the population that occur without apparent clinical impact. Each of us differs from other humans in the precise number and type of DNA polymorphisms that we possess.

Like other types of polymorphisms, DNA polymorphisms breed true. In other words, if an individual's DNA contains a G 1200 bases upstream from the α-globin gene, instead of the C most commonly found in the population, that G will be transmitted to that individual's offspring. Note that if one had a means for distinguishing the G at that position from a C, one would have a linked marker for that individual's α-globin gene.

Occasionally, a DNA polymorphism falls within a restriction endonuclease site. (Restriction enzymes cut DNA molecules into smaller pieces, but only at limited sites, defined by short base sequences recognized by each enzyme.) The change could abolish the site or create a site where one did not exist before. These polymorphisms change the array of fragments generated when the genome is digested by that restriction endonuclease. This permits detection of the polymorphism by use of the appropriate restriction enzyme. This specific class of polymorphisms is thus called *restriction fragment length polymorphisms* (RFLPs).

Restriction fragment length polymorphisms are useful because the length of a restriction endonuclease fragment on which a gene of interest resides provides a linked marker for that gene. The exploitation of this fact for diagnosis of genetic diseases and detection of specific genes is discussed in Chapter 2; Fig. 1–7 shows a simple example.

Restriction fragment length polymorphisms have proved to be extraordinarily useful for the diagnosis of genetic diseases, especially when the precise mutation is not known. Recall that DNA polymorphisms breed true in the population. For example, as discussed in Chapter 116, a mutation that causes hemophilia will, when it occurs on the X chromosome, be transmitted to subsequent generations attached to the pattern (often called a framework or haplotype) of RFLPs that was present on that same X chromosome. If the pattern of RFLPs in the parents is known, the presence of the abnormal chromosome can be detected in the offspring.

An important feature of the DNA landscape is the high degree of repeated DNA sequence. A DNA sequence is said to be repeated if it or a sequence very similar (homologous) to it occurs more than once in a genome. Some multicopy genes, such as the histone genes and the ribosomal RNA genes, are repeated DNA sequences. Most repeated DNA occurs outside genes, or within introns. Indeed, 30% to 45% of the human genome appears to consist of repeated DNA sequences.

The function of repeated sequences remains unknown, but their presence has inspired useful strategies for detecting and characterizing individual genomes. For example, a pattern of short repeated DNA sequences, characterized by the presence of flanking sites recognized by the restriction endonuclease Alu-1 (called Alu-repeats), occurs approximately 300,000 times in a human genome. These sequences

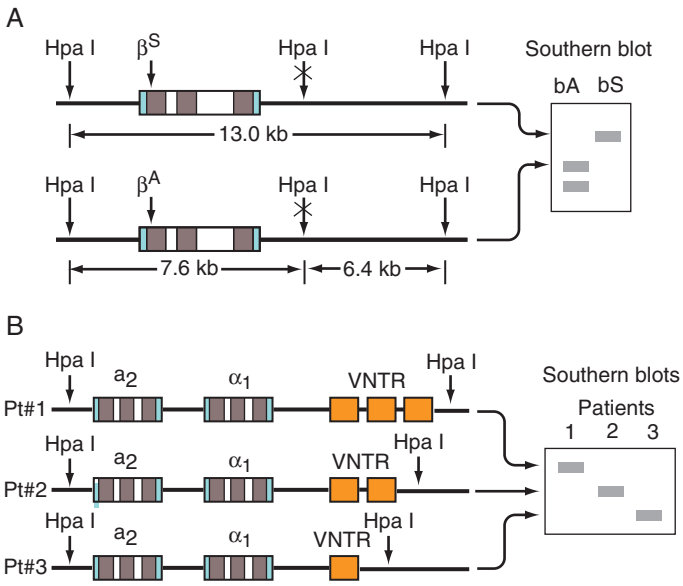

Figure 1–7 TWO USEFUL FORMS OF SEQUENCE VARIATION AMONG THE GENOMES OF NORMAL INDIVIDUALS. **A,** Presence of a DNA sequence polymorphism that falls within a restriction endonuclease site, thus altering the pattern of restriction endonuclease digests obtained from this region of DNA on Southern blot analysis. (Readers not familiar with Southern blot analysis should return to examine this figure after reading later sections of this chapter.) **B,** A variable-number tandem repeat (VNTR) region (defined and discussed in the text). Note that individuals can vary from one to another in many ways according to how many repeated units of the VNTR are located on their genomes, whereas restriction fragment length polymorphism differences are in effect all-or-none differences, allowing for only two variables (restriction site presence or absence).

are not present in the mouse genome. If one wishes to infect mouse cells with human DNA and then identify the human DNA sequences in the infected mouse cells, one simply probes for the presence of Alu-repeats. The Alu-repeat thus serves as a signature of human DNA.

Classes of highly repeated DNA sequences (tandem repeats) have proved to be useful for distinguishing genomes of each human individual. These short DNA sequences, usually less than a few hundred bases long, tend to occur in clusters, with the number of repeats varying between individuals (see Fig. 1–6). Alleles of a given gene can therefore be associated with a variable number of tandem repeats (VNTR) in different individuals or populations. For example, there is a VNTR near the insulin gene. In some individuals or populations, it is present in only a few tandem copies, whereas in others it is present in many more. When the population as a whole is examined, there is a wide degree of variability from individual to individual as to the number of these repeats residing near the insulin gene. It can readily be imagined that if probes were available to detect a dozen or so distinct VNTR regions, each human individual would differ from virtually all others with respect to the aggregate pattern of these VNTRs. Indeed, it can be shown mathematically that the probability of any two human beings' sharing exactly the same pattern of VNTRs is exceedingly small if approximately 10 to 12 different VNTR elements are mapped for each person. A technique called DNA fingerprinting that is based on VNTR analysis has become widely publicized because of its forensic applications.

Variable-number tandem repeats can be regarded as normal sequence variations in DNA that are similar to, but far more useful than, single-base-change RFLP polymorphisms. Note that the odds of a single base change altering a convenient restriction endonuclease site are relatively small, so that RFLPs occur relatively infrequently in a useful region of the genome. Moreover, there is only one state or variable that can be examined—that is, the presence or absence of the restriction site. By contrast, many VNTRs are scattered throughout the human genome. Most of these can be distinguished from one another quite readily by standard methods. Most important, the amount of variability from individual to individual at each site of a VNTR is considerably greater than for RFLPs. Rather than the mere presence or absence of a site, a whole array of banding patterns is possible, depending on how many individual repeats are present at that site (see Fig. 1–6). This reasoning can readily be extended to appreciate that those VNTRs occurring near genes of hematologic interest can provide highly useful markers for localizing that gene, or for distinguishing the normal allele from an allele carrying a pathologic mutation.

More recently, genomic technologies have made it possible to characterize single nucleotide polymorphisms in large stretches of DNA whether or not they alter restriction endonuclease sites. Single nucleotide polymorphism analysis is gaining momentum as a means for characterizing genomes.

There are many other classes of repeated sequences in human DNA. For example, human DNA has been invaded many times in its history by retroviruses. Retroviruses tend to integrate into human DNA and then "jump out" of the genome when they are reactivated, to complete their life cycle. The proviral genomes often carry with them nearby bits of the genomic DNA in which they sat. If the retrovirus infects the DNA of another individual at another site, it will insert this genomic bit. Through many cycles of infection, the virus will act as a transposon, scattering its attached sequence throughout the genome. These types of sequences are called *long interspersed elements*. They represent footprints of ancient viral infections.

KEY METHODS FOR GENE ANALYSIS

The foundation for the molecular understanding of gene structure and expression is based on fundamental molecular biologic techniques that were developed in the 1970s and 1980s. These techniques allow for the reduction of the multibillion nucleotide genome into smaller fragments that are more easily analyzed. Several key methods are outlined here.

Restriction Endonucleases

Naturally occurring bacterial enzymes called *restriction endonucleases* catalyze sequence-specific hydrolysis of phosphodiester bonds in the DNA backbone. For example, *Eco*RI, a restriction endonuclease isolated from *Escherichia coli*, cleaves DNA only at the sequence 5′-GAATTC-3′. Thus, each DNA sample will be reproducibly reduced to an array of fragments whose size ranges depend on the distribution with which that sequence exists within the DNA. A specific six-nucleotide sequence would be statistically expected to appear once every 4^6 (or 4096) nucleotides, but in reality the distance between specific sequences varies greatly. Using combinations of restriction endonucleases, DNA several hundred million base pairs in length can be reproducibly reduced to fragments ranging from a few dozen to tens of thousands of base pairs long. These smaller products of enzymatic digestion are much more manageable experimentally. Genetic "fingerprinting," or restriction enzyme maps of genomes, can be constructed by analyzing the DNA fragments resulting from digestion. Many enzymes cleave DNA so as to leave short, single-stranded overhanging regions that can be enzymatically linked to other similar fragments, generating artificially recombined, or *recombinant*, DNA molecules. These ligated gene fragments can then be inserted into bacteria to produce more copies of the recombinant molecules or to express the cloned genes.

DNA, RNA, and Protein Blotting

There are many ways that a cloned DNA sequence can be exploited to characterize the behavior of normal or pathologic genes. Blotting

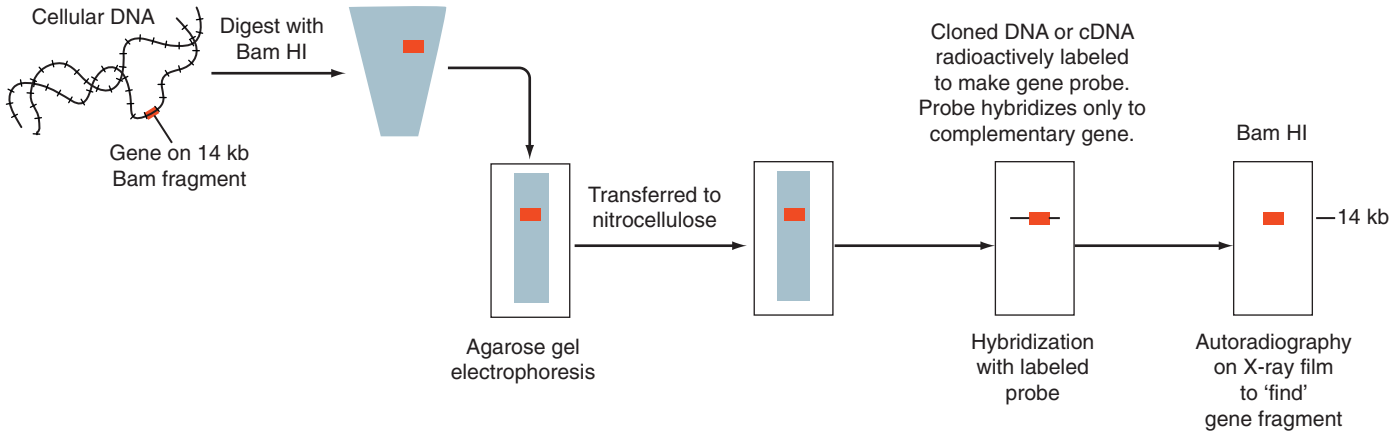

Figure 1–8 SOUTHERN GENE BLOTTING. Detection of a genomic gene (*red*) that resides on a 14-kilobase Bam HI fragment. To identify the presence of a gene in the genome and the size of the restriction fragment on which it resides, genomic DNA is digested with a restriction enzyme, and the fragments are separated by agarose gel electrophoresis. Human genomes contain from several hundred thousand to 1 million sites for any particular restriction enzyme, which results in a vast array of fragments and creates a blur or streak on the gel; one fragment cannot be distinguished from another readily. If the DNA in the gel is transferred to nitrocellulose by capillary blotting, however, it can be further analyzed by molecular hybridization to a radioactive cDNA probe for the gene. Only the band containing the gene yields a positive autoradiography signal, as shown. If a disease state were to result in loss of the gene, alteration of its structure, or mutation (altering recognition sites for one or more restriction enzymes), the banding pattern would be changed.

methods deserve special mention because of their widespread use in clinical and experimental hematology. A cloned DNA fragment can be easily purified and tagged with a radioactive or nonradioactive label. The fragment provides a pure and highly specific molecular hybridization probe for the detection of complementary DNA or RNA molecules in any specimen of DNA or RNA. One set of assays that has proved particularly useful involves Southern blotting, named after Dr E. Southern, who invented the method (Fig. 1–8). Southern blotting allows detection of a specific gene, or region in or near a gene, in a DNA preparation. The DNA is isolated and digested with one or more restriction endonucleases, and the resulting fragments are denatured and separated according to their molecular size by electrophoresis through agarose gels. By means of capillary action in a high salt buffer, the DNA fragments are passively transferred to a nitrocellulose or nylon membrane. Single-stranded DNA and RNA molecules attach noncovalently but tightly to the membrane. In this fashion, the membrane becomes a replica, or blot, of the gel. After the blotting procedure is complete, the membrane is incubated in a hybridization buffer containing the radioactively labeled probe. The probe hybridizes only to the gene of interest and renders radioactive only one or a few bands containing complementary sequences. After appropriate washing and drying, the bands can be visualized by autoradiography.

Digestion of a DNA preparation with several different restriction enzymes allows a restriction endonuclease map of a gene in the human genome to be constructed. Southern blotting has thus become a standard way of characterizing the configuration of genes in the genome.

Northern blotting represents an analogous blotting procedure used to detect RNA. RNA cannot be digested with restriction enzymes (which cut only DNA); rather, the intact RNA molecules can be separated according to molecular size by electrophoresis through the gel (mRNAs are 0.5–12 kilobases in length), transferred onto membranes, and probed with a DNA probe. In this fashion, the presence, absence, molecular size, and number of individual species of a particular mRNA species can be detected.

Western blotting is a similar method that can be used to examine protein expression. Cellular lysates (or another source of proteins) can be electrophoresed through a polyacrylamide gel so as to separate proteins on the basis of their apparent molecular sizes. The resolved proteins can then be electrically transferred to nitrocellulose membranes and probed with specific antibodies directed against the protein of interest. As with RNA analysis, the relative expression levels and molecular sizes of proteins can be assessed with this method.

Polymerase Chain Reaction

The development of the polymerase chain reaction was a major breakthrough that has revolutionized the utility of a DNA-based strategy for diagnosis and treatment. It permits the detection, synthesis, and isolation of specific genes and allows differentiation of alleles of a gene differing by as little as one base. It does not require sophisticated equipment or unusual technical skills. A clinical specimen consisting of only minute amounts of tissue will suffice; in most circumstances, no special preparation of the tissue is necessary. Polymerase chain reaction thus makes recombinant DNA techniques accessible to clinical laboratories. This single advance has produced a quantum increase in the use of direct gene analysis for diagnosis of human diseases.

The polymerase chain reaction is based on the prerequisites for copying an existing DNA strand by DNA polymerase: an existing denatured strand of DNA to be used as the template, and a primer. Primers are short oligonucleotides, 12 to 100 bases in length, having a base sequence complementary to the desired region of the existing DNA strand. The enzyme requires the primer to "know" where to begin copying. If the base sequence of the DNA of the gene under study is known, two synthetic oligonucleotides complementary to sequences flanking the region of interest can be prepared. If these are the only oligonucleotides present in the reaction mixture, then the DNA polymerase can only copy daughter strands of DNA downstream from those oligonucleotides. Recall that DNA is double stranded, that the strands are held together by the rules of Watson-Crick base pairing, and that they are aligned in antiparallel fashion. This implies that the effect of incorporation of both oligonucleotides into the reaction mix will be to synthesize two daughter strands of DNA, one originating upstream of the gene and the other originating downstream. The net effect is synthesis of only the DNA between the two primers, thus doubling only the DNA containing the region of interest. If the DNA is now heat denatured, allowing hybridization of the daughter strands to the primers, and the polymerization is repeated, then the region of DNA through the gene of interest is doubled again. Thus, two cycles of denaturation, annealing, and elongation result in a selective quadrupling of the gene of interest. The cycle can be repeated 30 to 50 times, resulting in a selective and

geometric amplification of the sequence of interest to the order of 2^{30} to 2^{50} times. The result is a millionfold or higher selective amplification of the gene of interest, yielding microgram quantities of that DNA sequence.

The polymerase chain reaction achieved practical utility when DNA polymerases from thermophilic bacteria were discovered, when synthetic oligonucleotides of any desired sequence could be produced efficiently, reproducibly, and cheaply by automated instrumentation, and when DNA thermocycling machines were developed. Thermophilic bacteria live in hot springs and other exceedingly warm environments, and their DNA polymerases can tolerate 100°C (212°F) incubations without substantial loss of activity. The advantage of these thermostable polymerases is that they retain activity in a reaction mix that is repeatedly heated to the high temperature needed to denature the DNA strands into the single-stranded form. Microprocessor-driven DNA thermocycler machines can be programmed to increase temperatures to 95°C to 100°C (203°F to 212°F) (denaturation), to cool the mix to 50°C (101°F) rapidly (a temperature that favors oligonucleotide annealing), and then to raise the temperature to 70°C to 75°C (141.4°F to 151.5°F) (the temperature for optimal activity of the thermophilic DNA polymerases). In a reaction containing the test specimen, the thermophilic polymerase, the primers, and the chemical components (eg, nucleotide subunits), the thermocycler can conduct many cycles of denaturation, annealing, and polymerization in a completely automated fashion. The gene of interest can thus be amplified more than a millionfold in a matter of a few hours. The DNA product is readily identified and isolated by routine agarose gel electrophoresis. The DNA can then be analyzed by restriction endonuclease, digestion, hybridization to specific probes, sequencing, further amplification by cloning, and so forth.

USE OF TRANSGENIC AND KNOCKOUT MICE TO DEFINE GENE FUNCTION

Recombinant DNA technology has resulted in the identification of many disease-related genes. To advance the understanding of the disease related to a previously unknown gene, the function of the protein encoded by that gene must be verified or identified, and the way changes in the gene's expression influence the disease phenotype must be characterized. Analysis of the role of these genes and their encoded proteins has been made possible by the development of recombinant DNA technology that allows the production of mice that are genetically altered at the cloned locus. Mice can be produced that express an exogenous gene and thereby provide an in vivo model of its function. Linearized DNA is injected into a fertilized mouse oocyte pronucleus and reimplanted in a pseudopregnant mouse. The resultant *transgenic mice* can then be analyzed for the phenotype induced by the injected transgene. Placing the gene under the control of a strong promoter that stimulates expression of the exogenous gene in all tissues allows the assessment of the effect of widespread overexpression of the gene. Alternatively, placing the gene under the control of a promoter that can function only in certain tissues (a tissue-specific promoter) elucidates the function of that gene in a particular tissue or cell type. A third approach is to study control elements of the gene by testing their capacity to drive expression of a "marker" gene that can be detected by chemical, immunologic, or functional means. For example, the promoter region of a gene of interest can be joined to the cDNA encoding green jellyfish protein, and activity of the gene assessed in various tissues of the resultant transgenic mouse by fluorescence microscopy. Use of such a reporter gene demonstrates the normal distribution and timing of expression of the gene from which the promoter elements are derived. Transgenic mice contain exogenous genes that insert randomly into the genome of the recipient. Expression can thus depend as much on the location of the insertion as it does on the properties of the injected DNA.

In contrast, any defined genetic locus can be specifically altered by targeted recombination between the locus and a plasmid carrying an altered version of that gene (Fig. 1–9). If a plasmid contains that altered gene with enough flanking DNA identical to that of the normal gene locus, homologous recombination can occur, and the altered gene in the plasmid will replace the gene in the recipient cell. Using a mutation that inactivates the gene allows the production of a null mutation, in which the function of that gene is completely lost. To induce such a mutation, the plasmid is introduced into an embryonic stem cell, and the rare cells that undergo homologous recombination are selected. The "knockout" embryonic stem cell is then introduced into the blastocyst of a developing embryo. The resultant animals are chimeric; only a fraction of the cells in the animal contain the targeted gene. If the new gene is introduced into some of the germline cells of the chimeric mouse, then some of the offspring of that mouse will carry the mutation as a gene in all of their cells. These heterozygous mice can be further bred to produce mice homozygous for the null allele. Such knockout mice reveal the function of the targeted gene by the phenotype induced by its absence. Genetically altered mice have been essential for discerning the biologic and pathologic roles of large numbers of genes implicated in the pathogenesis of human disease.

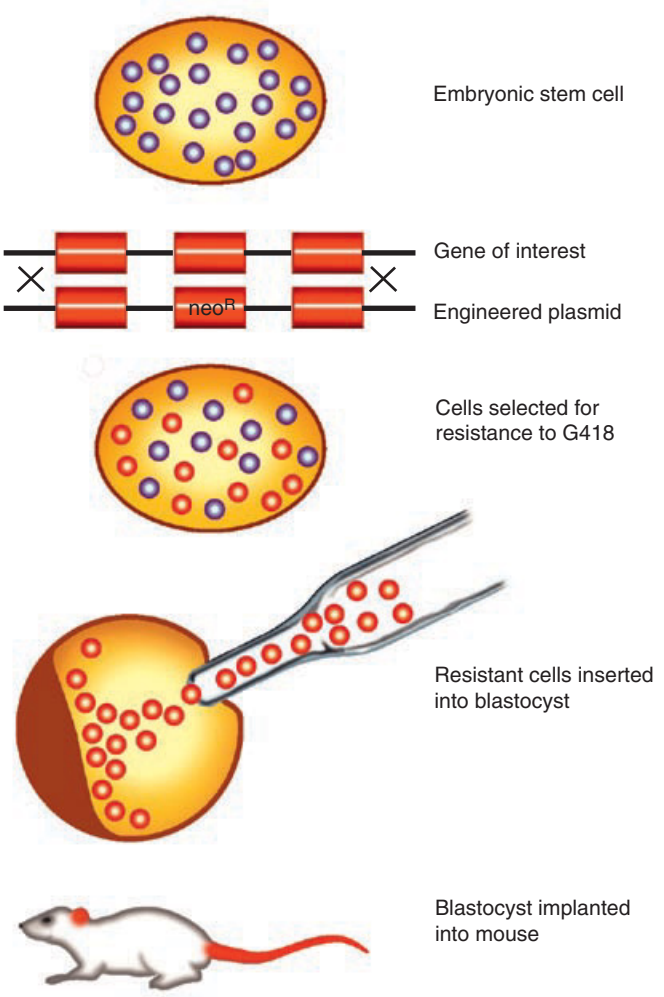

Figure 1–9 GENE "KNOCKOUT" BY HOMOLOGOUS RECOMBINATION. A plasmid containing genomic DNA homologous to the gene of interest is engineered to contain a selectable marker positioned so as to disrupt expression of the native gene. The DNA is introduced into embryonic stem cells, and cells resistant to the selectable marker are isolated and injected into a mouse blastocyst, which is then implanted into a mouse. Offspring mice that contain the knockout construct in their germ cells are then propagated, yielding mice with heterozygous or homozygous inactivation of the gene of interest.

DNA-BASED THERAPIES

Gene Therapy

The application of gene therapy to genetic hematologic disorders is an appealing idea. In most cases, this would involve isolating hematopoietic stem cells from patients with diseases with defined genetic lesions, inserting normal genes into those cells, and reintroducing the genetically engineered stem cells back into the patient. A few candidate diseases for such therapy include sickle cell disease, thalassemia, hemophilia, and adenosine deaminase-deficient severe combined immunodeficiency. The technology for separating hematopoietic stem cells and for performing gene transfer into those cells has advanced rapidly, and clinical trials have begun to test the applicability of these techniques. However, despite the fact that gene therapy has progressed to the enrollment of patients in clinical protocols, major technical problems still need to be solved, and there are no proven therapeutic successes from gene therapy. However, progress in this field continues rapidly. The scientific basis for gene therapy and the clinical issues surrounding this approach are discussed in Chapter 102.

Antisense Therapy

The recognition that abnormal expression of oncogenes plays a role in malignancy has stimulated attempts to suppress oncogene expression to reverse the neoplastic phenotype. One way of blocking mRNA expression is with antisense oligonucleotides. These are single-stranded DNA sequences, 17 to 20 bases long, having a sequence complementary to the transcription or translation start of the mRNA. These relatively small molecules freely enter the cell and complex to the mRNA by their complementary DNA sequence. This often results in a decrease in gene expression. The binding of the oligonucleotide may directly block translation and clearly enhances the rate of mRNA degradation. This technique has been shown to be promising in suppressing expression of *bcr-abl* and to suppress cell growth in chronic myelogenous leukemia. The technique is being tried as a therapeutic modality for the purging of tumor cells before autologous transplantation in patients with chronic myelogenous leukemia.

SUMMARY

The elegance of recombinant DNA technology resides in the capacity it confers on investigators to examine each gene as a discrete physical entity that can be purified, reduced to its basic building blocks for decoding of its primary structure, analyzed for its patterns of expression, and perturbed by alterations in sequence or molecular environment so that the effects of changes in each region of the gene can be assessed. Purified genes can be deliberately modified or mutated to create novel genes not available in nature. These provide the potential to generate useful new biologic entities, such as modified live virus or purified peptide vaccines, modified proteins customized for specific therapeutic purposes, and altered combinations of regulatory and structural genes that allow for the assumption of new functions by specific gene systems.

Purified genes facilitate the study of gene regulation in many ways. First, a cloned gene provides characterized DNA probes for molecular hybridization assays. Second, cloned genes provide the homogeneous DNA moieties needed to determine the exact nucleotide sequence. Sequencing techniques have become so reliable and efficient that it is often easier to clone the gene encoding a protein of interest and determine its DNA sequence than it is to purify the protein and determine its amino acid sequence. The DNA sequence predicts exactly the amino acid sequence of its protein product. By comparing normal sequences with the sequences of alleles cloned from patients known to be abnormal, such as the globin genes in the thalassemia or sickle cell syndromes, the normal and pathologic anatomy of genes critical to major hematologic diseases can be established. In this manner, it has been possible to identify many mutations responsible for various forms of thalassemia, hemophilia, thrombasthenia, red blood cell enzymopathies, porphyrias, and so forth. Similarly, single base changes have been shown to be the difference between many normally functioning protooncogenes and their cancer-promoting oncogene derivatives.

Third, cloned genes can be manipulated for studies of gene expression. Many vectors allowing efficient transfer of genes into eukaryotic cells have been perfected. Gene transfer technologies allow the gene to be placed into the desired cellular environment and the expression of that gene or the behavior of its products to be analyzed. These surrogate or reverse genetics systems allow analysis of the normal physiology of expression of a particular gene, as well as the pathophysiology of abnormal gene expression resulting from mutations.

Fourth, cloned genes enhance study of their protein products. By expressing fragments of the gene in microorganisms or eukaryotic cells, customized regions of a protein can be produced for use as an immunogen, thereby allowing preparation of a variety of useful and powerful antibody probes. Alternatively, synthetic peptides deduced from the DNA sequence can be prepared as the immunogen. Controlled production of large amounts of the protein also allows direct analysis of specific functions attributable to regions in that protein.

Finally, all of the aforementioned techniques can be extended by mutating the gene and examining the effects of those mutations on the expression of or the properties of the encoded mRNAs and proteins. By combining portions of one gene with another (chimeric genes), or abutting structural regions of one gene with regulatory sequences of another, the researcher can investigate in previously inconceivable ways the complexities of gene regulation. These activist approaches to modifying gene structure or expression create the opportunity to generate new RNA and protein products whose applications are limited only by the collective imagination of the investigators.

The most important impact of the genetic approach to the analysis of biologic phenomena is the most indirect. Diligent and repeated application of the methods outlined in this chapter to the study of many genes from diverse groups of organisms is beginning to reveal the basic strategies used by nature for the regulation of cell and tissue behavior. As our knowledge of these rules of regulation grows, our ability to understand, detect, and correct pathologic phenomena will increase substantially.

CHAPTER 2

GENOMIC APPROACHES TO THE STUDY OF HEMATOLOGIC SCIENCE

Benjamin L. Ebert, Todd R. Golub, and Scott A. Armstrong

The publication of the initial sequence of the human genome heralded the beginning of a period in biomedical research that will be heavily influenced by the field of genomics.[1] Just as molecular biology changed the face of biomedical research in the 1970s and 1980s, genomics promises a novel perspective into biological questions and human disease. Broadly defined, genomics is the study of biological processes in a manner that takes advantage of the information that has come from the sequencing of the genomes of humans and other organisms. The new technologies that have been developed allow quantitative and parallel assessment of thousands of variables in a single experiment, including mRNA expression, microRNA expression, DNA copy number, single nucleotide polymorphisms, and epigenetic modifications.

This new comprehensive approach to biology has already provided an improved understanding of a number of biological processes and disease states including hematologic malignancies. As has often been the case, the study of hematologic malignancies has proven to be an attractive training ground for the application of new technologies. Genomic analysis has progressed more rapidly in hematologic malignancies than in other diseases such as solid tumors a result of extensive knowledge about the lineage specific gene expression programs present in developing blood cells and the ability to obtain relatively pure populations of cells. Combined with the detailed characterization of recurrent chromosomal abnormalities in leukemia and lymphoma, this provides a foundation of knowledge that has aided in the interpretation of complex datasets. Finally, the development of sophisticated model systems that faithfully recapitulate human diseases represent valuable tools necessary for validation of the hypotheses that come from genomic experiments.

The massive increase in the size of datasets has subsequently led to an expansion of the field of bioinformatics, which has become a critical part of genomic experiments. The datasets generated by genomic technologies are large and potentially contaminated by experimental or biological noise. Since genomic datasets typically involve the assessment of thousands of variables in a relatively modest number of samples, analyses are prone to overinterpretation. "Traditional" clinical trials, in contrast, generally have few variables and are assessed in larger numbers of samples or patients. Genomic experiments require careful assessment of statistical significance, and validation by independent datasets or experimental systems. When carefully performed, such global genomic views provide different types of insight into disease than do narrow but deeper traditional views. In this chapter, we will outline the current technologies available for genomic analysis, describe some of the bioinformatic tools that are available, and highlight some of the applications of this technology to the study of hematologic diseases.

TECHNOLOGY PLATFORMS

Comparative Gene Expression Analysis

The most well developed and widely used genomic technology is genome-wide expression profiling. Gene expression profiling allows one to quantitatively assess the RNA expression level for thousands of genes simultaneously. The most commonly used platforms on which to perform such an analysis are DNA microarrays. A DNA microarray generally consists of a glass slide or silica wafer to which either complementary DNA (cDNA) or oligonucleotide probes are attached. The probes can be chosen based on knowledge of genes expressed in a particular cell type (eg, the "lymphochip")[2] or they can be chosen from genomic databases, which do not require previous knowledge about gene expression in a given cell type. Current microarray technology allows a density of over one million oligonucleotide probes per array. Since current estimates suggest the human genome consists of approximately 26,000 genes, we now have the capability to assess the expression of almost all genes in a given sample in a single experiment.

Oligonucleotide arrays can be generated by depositing oligonucleotides onto glass slides or directly synthesizing oligonucleotides between 25 and 60 nucleotides long on a solid support.[3–5] The most widely used oligonucleotide arrays are commercially available from Affymetrix (Santa Clara, CA). These arrays are produced by photolithographically synthesizing oligonucleotides onto a silica support. For experiments with this type of array, one labels the RNA sample of interest by first producing double stranded DNA, and then performing an in vitro transcription reaction that incorporates biotinylated nucleotides into the resulting chromosomal RNA (cRNA) (Fig. 2–1A). The labeled cRNA is then hybridized to the array, and the amount of hybridized cRNA is quantitated by a streptavidin-phycoerythrin conjugate. The major limitation of this technology is the high cost of the arrays, but their ease of use has made this technology the dominant platform for global gene expression profiling.

Alternative technologies for gene expression profiling include cDNA arrays and sequencing strategies. cDNA arrays are produced by robotic-spotting of thousands of polymerase chain reaction (PCR)-amplified cDNA clones onto glass slides.[6–8] The RNA sample of interest is then reverse-transcribed to produce cDNA labeled with a fluorescent dye (generally either Cy3 or Cy5). This labeled cDNA is then hybridized to the array in conjunction with a reference cDNA sample that is labeled with the second die (Fig. 2–1B). The relative abundance of a given RNA species in the experimental sample is then determined by comparing the intensity of the fluorescent signals from each of the dies for a given probe. The major advantage of such array technology is that once one has an appropriate cDNA library and the spotting device, they theoretically should be able to produce many arrays at a relatively low cost. In practice though, it has proven more difficult to produce high quality cDNA arrays than expected unless the center has significant expertise in such techniques.

Another method to assess genome-wide gene expression is serial analysis of gene expression (SAGE).[9] The first step in performing SAGE is to perform PCR with oligonucleotides that allow for amplification of all cDNA species within a sample. After this has been performed, high throughput sequencing is performed on many thousands of PCR amplicons and the number of unique sequences determined. This allows one to determine the number of RNA transcripts that were present in the initial sample. Therefore, SAGE is a method that counts the number of transcripts, whereas microarrays only allow one to look at the relative abundance of a given gene across two samples. The ability to compare the number of transcripts within a given sample is one of the major advantages of this technology; microarray analysis cannot do this because of the different hybridization efficiencies of different probes. The sequencing of large numbers of transcripts is expensive, so SAGE is not currently a commonly used approach to gene expression profiling. The development of single

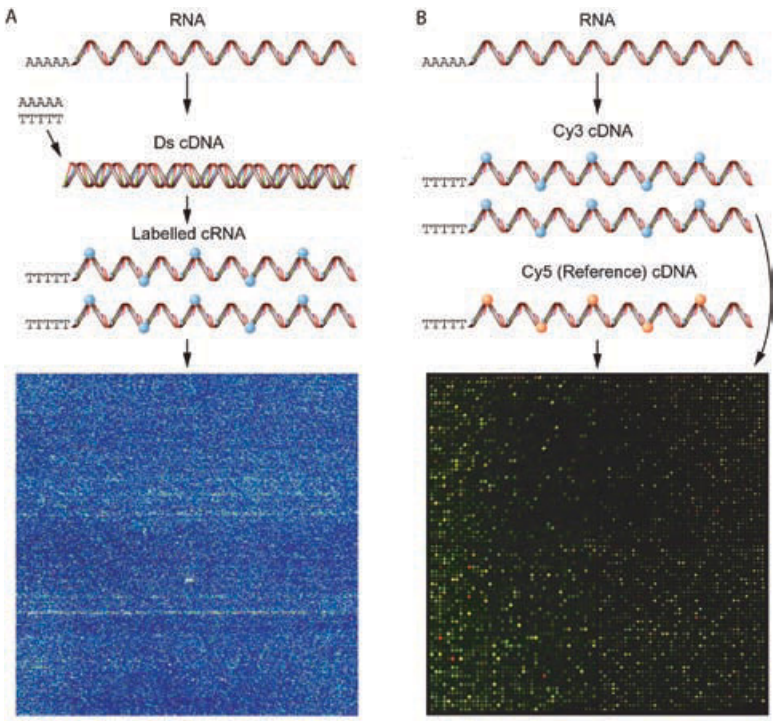

Figure 2–1 GENE EXPRESSION PROFILING USING DNA MICROARRAYS. Images from an Affymetrix oligonucleotide array (**A**) and a complementary DNA (cDNA) array (**B**). RNA labeling techniques are shown. **A,** For an Affymetrix oligonucleotide array experiment, double-stranded cDNA is first produced, and then an in vitro transcription reaction is performed with biotinylated nucleotides, to give labeled cRNA. This RNA sample is then hybridized to the array without the addition of a control sample. **B,** For hybridization to a cDNA array, Cy3- or Cy5-labeled cDNA is produced from experimental and control RNA samples. Hybridization experiments performed on cDNA arrays compare the relative amounts of a given RNA species in the labeled experimental and control samples that are hybridized to the array simultaneously.

molecule sequencing technologies, discussed below, may make a sequencing-based, high-throughput sequencing technologies may make SAGE a more attractive platform.

Analysis of MicroRNA Expression

MicroRNAs (miRNAs) are small (approximately 22 nucleotides) RNAs that do not encode for proteins, but bind to mRNA transcripts to regulate translation and mRNA stability. In *Caenorhabditis elegans*, zebrafish, and other model organisms, miRNAs play a critical role in development through regulation of translation of key proteins. In mammalian cells, a role for miRNAs has been recognized in the regulation of cellular differentiation. Not only are many miRNAs differentially expressed across hematopoietic lineages, but several miRNAs have been demonstrated to play key functional roles in hematopoietic lineage specification and differentiation.[10] Moreover, the expression or function of several miRNAs is altered by chromosomal translocations, deletions, or mutations in leukemia.[10]

Several methodologies have been developed for the detection of miRNAs. As with mRNA, individual miRNAs can be assayed by Northern blots or quantitative reverse-transcription PCR. Global miRNA profiles can be detected using microarrays or bead-based technologies using platforms that are highly analogous to the mRNA gene expression profiles.[11,12] Global miRNA profiles are sufficient to distinguish different differentiation states and can be used for the classification of cancers.[12] The expression of miRNAs is a key aspect of the complete genomic characterization of cellular states and, in some cases, may provide critical insights into the biology of the malignant transformation of hematopoietic cells.

Analysis of Changes in Gene Copy Number

Gains (amplifications) or losses (deletions) of genetic material at specific loci are recognized as playing an important role in the pathophysiology of disease. Dramatic examples of this association come from the study of inherited cancer predisposition syndromes. The most prominent example emanated from the study of families demonstrating a predisposition for development of retinoblastoma. In a landmark set of studies, it was shown that tumors from patients who inherit a mutant copy of the retinoblastoma tumor suppressor gene often contain deletions of the remaining allele.[13–16] This process has been termed *loss of heterozygosity*, and the search for genetic loci showing loss of heterozygosity in tumor samples has identified a number of genes that are involved in critical cellular processes and are important for cancer progression. Similarly, amplification of genomic loci can play an important role in oncogenesis and cancer biology. For example, amplification of the HER2/Neu oncogene in human breast cancer is associated with a poor prognosis, and HER2/Neu has been shown to be an important therapeutic target in this disease.[17,18]

The search for gains and losses of genetic material can be done using a number of techniques that require various levels of expertise, and allow assessment of genomic integrity at various resolutions. The first method developed to assess genomic integrity, *cytogenetic analysis*, is still used today, but it allows identification only of abnormalities that encompass large regions of DNA. Nevertheless, cytogenetic analysis has provided tremendous insight into the pathophysiology of disease, particularly for leukemogenesis.[19] Cytogenetic analysis remains a key part of the diagnostic workup for new cases of leukemia.

Another, more recently developed technology is that of *comparative genomic hybridization* (CGH).[20] To perform CGH analysis, tumor DNA and normal genomic DNA are labeled with different fluorescent dyes and are hybridized to a metaphase spread that is prepared in a fashion similar to that used in routine cytogenetic analysis. Gains and losses are determined on the basis of the relative fluorescence at any given location along the chromosome. Although this technique allows assessment of genomic integrity at a greater resolution than is possible with cytogenetic analysis, the resolution is still only in the 10- to 20-megabase (Mb) range. Also, CGH requires that the sample of interest has been characterized by cytogenetic analysis.

A recently developed method that has improved genomic resolution to less than 1 Mb and has all but replaced standard CGH is array CGH (aCGH).[21–23] Although this method still requires significant expertise to produce custom arrays, it allows high resolution and does not require any previous characterization such as cytogenetic analysis. Analogous to the design of gene expression microarrays, aCGH probes can be derived from oligonucleotides, cDNAs, or larger DNA fragments produced from bacterial artificial chromosomes (BACs).

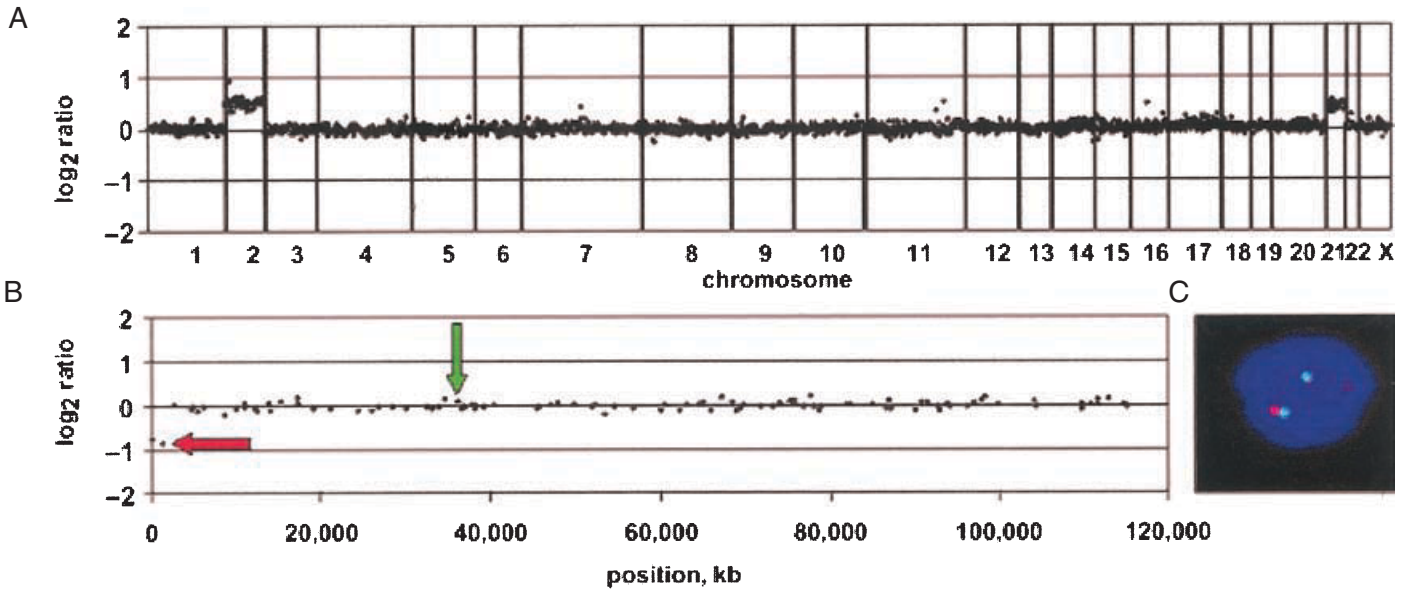

Figure 2–2 A, An example of array-based comparative genomic hybridization (CGH) performed on a cell line known to be trisomic for chromosomes 2 and 21. This technique entails comparison of fluorescence intensities of triplicate spots for each given BAC clone, represented graphically by individual spots. The data are presented for chromosomes 1p to Xq (oriented from *left* to *right*), and *bars* separate clones on different chromosomes. It is evident from the array CGH data that there are extra copies of chromosomes 2 and 21, as determined originally by FISH analysis. **B,** Array CGH data from a cell line on BACs from chromosome 9. The $\log_2$ ratio of −1 for two of the clones *(red arrow)* indicates a single-copy deletion in this region on chromosome 9. Colored arrows indicate the clones that were labeled and used to perform FISH analysis to verify the array CGH data. **C,** FISH analysis of the cell line analyzed in B using the BAC probes identified by the *colored arrows*. Note only one signal from the BAC, corresponding to the *red arrow*. BAC, bacterial artificial chromosome; FISH, fluorescence in situ hybridization. *(From Snijders AM, Nowak N, Segraves R, et al: Assembly of microarrays for genome-wide measurement of DNA copy number. Nat Genet 29:263, 2001.)*

Probes that correspond to a known location within the human genome are spotted onto glass microarrays, and the experimental genomic DNA and normal genomic DNA are labeled with either Cy3 or Cy5, as in glass slide-based microarray analysis. Relative gains or losses of genomic material are then determined on the basis of the relative Cy3 or Cy5 fluorescence at any given spot (Fig. 2–2).

Oligonucleotide microarrays designed for the detection of single nucleotide polymorphisms (SNPs) are also being widely utilized for the analysis of copy number change in tumor samples. In addition to the detection of gains and losses of chromosomal material, SNP arrays can be used to detect loss of heterozygosity in a chromosomal region that has not had a change in copy number. Unlike aCGH, in which tumor and control samples are labeled with different fluors and hybridized to the same array, a single sample is hybridized to a SNP array. SNP arrays have been utilized to identify novel genes contribute to the pathogenesis of acute leukemia.[24]

Single-Nucleotide Polymorphisms

Since the initial proposal to look for association of certain inherited diseases with common genetic polymorphisms found in the human genome,[25] linkage analysis has been a particularly successful method for identification of disease-associated genes, such as those responsible for chronic granulomatous disease and cystic fibrosis.[26,27] This method is limited, however, by the number of individuals in a family with the disease, and by the number of polymorphisms present in the region of the genome where the disease gene resides. The latter of these two problems is becoming less of an issue as the number of recognized SNPs increases. SNPs represent single nucleotides within the human genome that are polymorphic and thus constitute potential signposts in the search for linkage to a gene responsible for a given disease. Current estimates suggest that 400,000 SNPs will be required to tag each of the common haplotype blocks in the human genome. Genome-wide scans are just beginning to be performed with the approximately 2×10^6 SNPs that have been identified.[28] SNPs identified within the coding region of genes may be of particular importance, as these changes may have functional consequences and predispose carriers of these variants to the development of conditions such as thrombosis. The importance of coding-region SNPs is discussed later in the section highlighting the use of this technology. SNP analysis can be performed in a number of ways, but the most commonly used methodologies are PCR-based approaches and SNP arrays. The PCR-based approaches are the least expensive and require the least expertise, but the array-based approaches are capable of assessing thousands of SNPs simultaneously.

DIRECT SEQUENCING OF CANDIDATE GENES

The Human Genome Project helped accelerate the development of high throughput sequencing strategies. Now, high-throughput sequencing efforts are increasingly being directed towards the sequencing of cancer genomes to identify somatic mutations. Such an approach is being taken to characterize kinase mutations in cancers.[29,30] Based on the fact that kinases are frequently activated by mutation in cancer cells and that small molecule therapeutics are particularly effective against these proteins,[31] a number of groups have undertaken an effort to sequence all kinases in particular cancers. The first major discovery from such an effort was the identification of activating mutations in the serine/threonine kinase BRAF in melanoma (Fig. 2–3).[29] JAK2 mutations in polycythemia vera and other hematologic malignancies were identified by high-throughput sequencing as well as other genetic approaches. Small molecule inhibitors of BRAF and JAK2 are currently in clinical development.

Several new sequencing technologies are under development; these promise to lower the costs of sequencing by one or more orders of magnitude. Single molecule sequencing technologies either sequence a single DNA strand directly or amplify a single DNA molecule prior to sequencing.[32] By sequencing a single DNA molecule, mutations can be identified that are present in a rare subpopulation of cells. Novel sequencing technologies promise to enable the

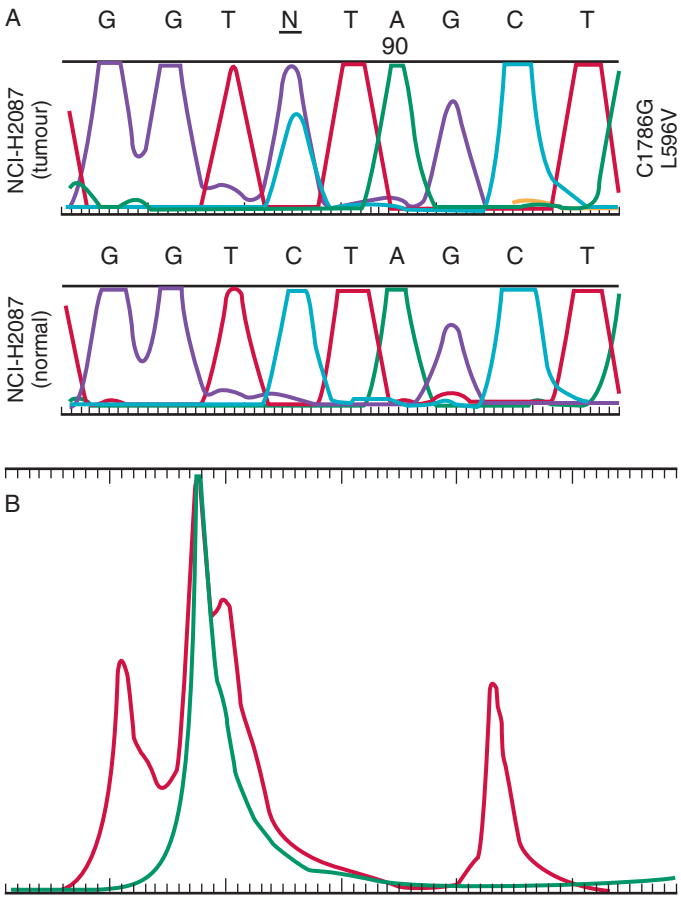

Figure 2–3 Activating mutations of *BRAF* were identified in melanoma using high-throughput DNA sequencing and heteroduplex analysis. The DNA sequencing traces are from a melanoma sample (*upper panel* in **A**) and from a normal sample (*lower panel* in **A**) for a region of the *BRAF* gene. A capillary-based heteroduplex analysis performed on normal (*green*) and cancer (*red*) DNAs from the same person is shown in (**B**). The melanoma sample has acquired a mutation that results in constitutive activation of *BRAF*. *(From Davies H, Bignell GR, Cox C, et al: Mutations of the BRAF gene in human cancer. Nature 417:949, 2002.)*

sequencing of entire genomes from biopsy specimens, allowing scientists and clinicians to catalog all of the somatic mutations present in a given sample and to correlate these mutations with phenotype and response to therapy. Moreover, the identification of novel somatic mutations may reveal important new therapeutic targets for the treatment of cancer.

SAMPLE ACQUISITION AND PREPARATION

Acquisition of the appropriate samples for a genomic experiment is arguably the most crucial step for the production of a dataset that will be rich with biological information. This is particularly true for gene expression analysis, in which a number of processes may affect the data. Since gene expression is a dynamic process that can be affected by any type of cellular manipulation, RNA abundance measurements are potentially complicated by changes that occur between the time that the biopsy is taken and the time that the RNA is isolated from the specimen. In general, the highest quality RNA is obtained if, as soon as possible after harvesting a sample, cells are dissolved in a solution such as TRIzol (Invitrogen) that inactivates RNase enzymes, and the sample is stored at −80°C (−112°F) until RNA can be extracted. Paraffin-embedded samples represent an even more difficult situation for extraction of RNA of sufficient quality for microarray analysis. Most microarray experiments require approximately 5 μg of total RNA (a few million cells) for labeling and hybridization, and thus small biopsies or rare cell populations may not produce enough RNA for standard analysis. A number of amplification procedures have been described, including those that utilize two rounds of in vitro transcription and those that take advantage of the PCR.[33]

Another extremely important, but complicated issue is the complexity of the mixture of cells present in the sample. If the goal is to assess genomic changes that represent somatic rather than germline differences, the sample needs to be enriched (often to >75%) in the cell of interest. This may not be an issue for bone marrow samples from patients with newly diagnosed leukemia, in which the number of blasts often approaches 90% or greater. But, it may become an issue if the goal is to analyze leukemia at the time of relapse. In this scenario, the relapse is often detected long before the bone marrow is completely replaced with leukemia, and thus the blasts may represent fewer than 50% of the mononuclear cells. Multiple methods are available for enrichment and selection of cells of interest from a biopsy sample including flow-cytometry, immunomagnetic bead sorting, and laser-capture microdissection.[34] All have the benefit of enrichment of the cell of interest but also increase the amount of processing time and sample manipulation. Alternatively, "contaminating" nonmalignant cells may be included in gene expression signatures as these cells may reflect the tumor environment and may therefore carry important information.[35] This is most obvious for solid tumors where the tumor stroma and infiltrating inflammatory cells likely influence the neoplastic cells, but all diseased cells exist in a complex environment and are thus no doubt influenced by their interactions. Thus, dismissing these cells as contamination must be done with caution.

BIOINFORMATICS

As the technologies described previously have become increasingly easy to use and more accessible to investigators, the rate-limiting step for turning the data thus acquired into important discoveries has become data analysis. As a result, the field of bioinformatics has become an integral part of genomic analysis. The single most difficult question that arises when genomic experiments are performed is whether the differences identified are important or are just results of measuring too many variables in too few samples and thus represent chance associations. This difficulty is further complicated because it can be difficult to separate signal from noise in genomic experiments. The issues regarding data analysis are the subjects of entire textbooks; here, we outline in broad terms two different analytic approaches: unsupervised and supervised learning.

Unsupervised Learning Approaches

Unsupervised learning approaches (often referred to as clustering) have become an important part of the discovery process in genomic analysis. This type of analysis involves grouping or separating samples based solely on the data obtained without regard to any previous knowledge that one might have had about the samples or the disease. Thus, one can obtain the predominant "structure" of the dataset without imposing any prior bias. For example, unsupervised learning approaches have been used to cluster leukemia or lymphoma samples based on their gene expression profiles with the goal of uncovering the most robust classification schemes.[36–39] Clustering algorithms can also cluster genes that have a similar expression profile in a gene expression data set. There are a number of methods for clustering genes and samples, all of which have computational strengths and weaknesses. Comparing the clustering methods is beyond the scope of this chapter, but all will identify major associations within a given data set if the signature is robust. Great care must be taken in the interpretation of clustering results because clusters with distinct gene expression profiles may be caused not only by biologically important

distinctions, but also by artifacts of sample processing. Unsupervised learning methods that have been used include hierarchical clustering[40] (freely available at http://rana.lbl.gov/), self-organizing maps (SOM)[41] (freely available at http://www.broad.mit.edu/cancer/) principal component analysis (PCA),[42] nonnegative matrix factorization (NMF),[43] and k-means clustering.[44]

Supervised Learning Approaches

Supervised learning approaches are best suited for comparing data between two or more classes of samples that can be distinguished by some known property (or class distinction) such as biologic subtype or clinical outcome. For example, to determine the gene expression differences between two leukemia subtypes with distinct genetic abnormalities, one would employ a supervised approach. The same genes might be clustered together based on the unsupervised approaches described above, but they might also be obscured by a more dominant gene expression signature that had nothing to do with the distinction of interest; if there was another major signature within the data (ie, a stage of differentiation signature) the differences that the investigator was searching for might be lost. There are a number of metrics that can be used to identify genes that are differentially expressed between two groups of samples, all of which are best suited to identify genes that are uniformly highly expressed in one group.[37,39,41] Although the different metrics may generate slightly different lists of gene expression differences, all should give comparable results if the gene expression difference is robust.

No matter which metric is used for comparison of two classes of samples, one must determine if the association is greater than what would be found by chance alone. This is particularly important when analyzing genomic datasets because one is most often assessing many more variables (>10,000) than one has samples (<500). When such an analysis is performed there will always be differential gene expression. Most methods that address this question rely on some type of permutation analysis. To determine if observed differences in gene expression are greater than random associations, the class labels that define the two groups are randomly assigned to samples and the gene expression differences of the two classes is determined. This random assignment is performed multiple times (usually 1000 or greater), and the greatest differences in gene expression identified in the randomly permuted set are compared to the differences found in the initial experiment. Given the large number of comparisons, a critical step in statistical analysis is correction for multiple hypotheses, for example by calculation of the False Discover Rate. Thus, one can determine how likely it is that the observed correlation is not a chance association.

Another common goal is the creation of a gene expression-based classifier. Most studies use a supervised approach to determine which genes discriminate the classes of interest, and then build an expression-based prediction model using these genes. Validation of classifiers can be performed using a leave-one-out cross validation scheme or, preferably, by testing the classifier in an independent dataset. Many such classifiers have been developed using machine learning algorithms such as weighted voting, k-nearest neighbors, artificial neural networks, support vector machines, nearest centroid algorithms, and decision trees.[37,41,42,45–47] While each algorithm has strengths and weaknesses, in most cases, similar results should be obtained if the gene expression differences are significant.

The statistical methods for analyzing complex genomic datasets continue to evolve, but most of the currently available methods will uncover similar structure within a dataset. But, one should keep in mind that the predominant structure within a dataset may not be the most biologically important, and identifying the more subtle structures may be obscured by other gene expression signatures. A continuing challenge is how to infer the biological importance of any such structure. Since determining the biological importance of the observed differences is a highly subjective exercise, many refer to such experiments as "hypothesis generating" experiments that require validation in model systems.

APPROACHES TO QUESTIONS IN HEMATOLOGY

The application of genomic technology has already begun to have an impact on the field of hematology, particularly in the pathogenesis and classification of leukemias. Although the potential use of genomic technologies is most obvious in the study and treatment of leukemia, application to other hematologic diseases promises to uncover new and unexpected insights. The following section summarizes some of the discoveries identified when genomic technologies have been applied to hematologic diseases and presents examples of the types of discovery that might be obtained in other hematologic diseases.

Leukemia and Lymphoma

The application of gene expression technology to the study of leukemia and lymphoma has opened new avenues, setting the stage for characterization of other cancers. The first study to use microarray-based gene expression technology to characterize a human disease compared the gene expression between acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML) samples.[41] Methods of supervised and unsupervised analyses were developed and used to show that the distinction between ALL and AML could be determined solely on the basis of gene expression. Thus, the study demonstrated that an important clinical distinction could be made using microarray-based gene expression. The first study to use gene expression-based classification to identify unique subsets of disease showed that diffuse large B-cell lymphomas (DLBCLs) could be divided into two subsets—germinal center-like and activated B cell-like tumors—having different clinical outcomes (Fig. 2–4).[37] Gene expression technology was used to gain insight into leukemias in a study that compared the gene expression profiles of 17 *MLL* (*m*ixed *l*ineage *l*eukemia)-rearranged B-precursor ALLs with those of 20 B-precursor ALLs without this rearrangement.[36] With these tumors, the presence of an *MLL* translocation is most often found in infant ALL and generally carries a poor prognosis.[48] On the basis of the significant differences in gene expression, it was hypothesized that *MLL* rearrangements specify a unique disease with features that probably contribute to the poor prognosis for this leukemia. Support for the idea that chromosome translocations specify unique subsets of ALL comes from a large gene expression study showing that all chromosome translocations found in ALL are associated with unique gene expression profiles.[39]

The presence of cytogenetic abnormalities in T-cell acute lymphoblastic leukemias (T-ALLs) is not as clearly associated with differences in outcome as it is in B-precursor ALLs; therefore, classification based on gene expression could provide needed insight. In the first study addressing this question,[49] 39 T-ALL samples were grouped with respect to high-level expression of the oncogenes LYL1, *HOX11*, and *TAL/SCL1*—genes known to be important in the pathogenesis of T-ALL.[50] Only one of the oncogenic transcription factors was highly expressed in most of the leukemia samples. Analysis of gene expression using oligonucleotide arrays suggested that LYL1-, *HOX11*-, and *TAL/SCL1*-expressing samples were arrested at the double-negative, early cortical, and late cortical stages of thymocyte development, respectively. The type of classification system also may have prognostic importance because the patients with high-level *HOX11* expression appeared to have better prognoses than those in the other groups.

Gene expression analysis of leukemias also might be used to predict response to therapy and identify important new therapeutic avenues for targeted therapies. A number of studies of hematologic malignancies have reported that gene expression-based prediction models can improve on current clinical stratification schemes.[2,38,39] If these findings can be validated prospectively and confirmed by other studies, such models will be of great clinical usefulness. Large studies are needed to determine the clinical usefulness of such analyses, and to determine if prospective gene expression-based disease stratification is feasible.

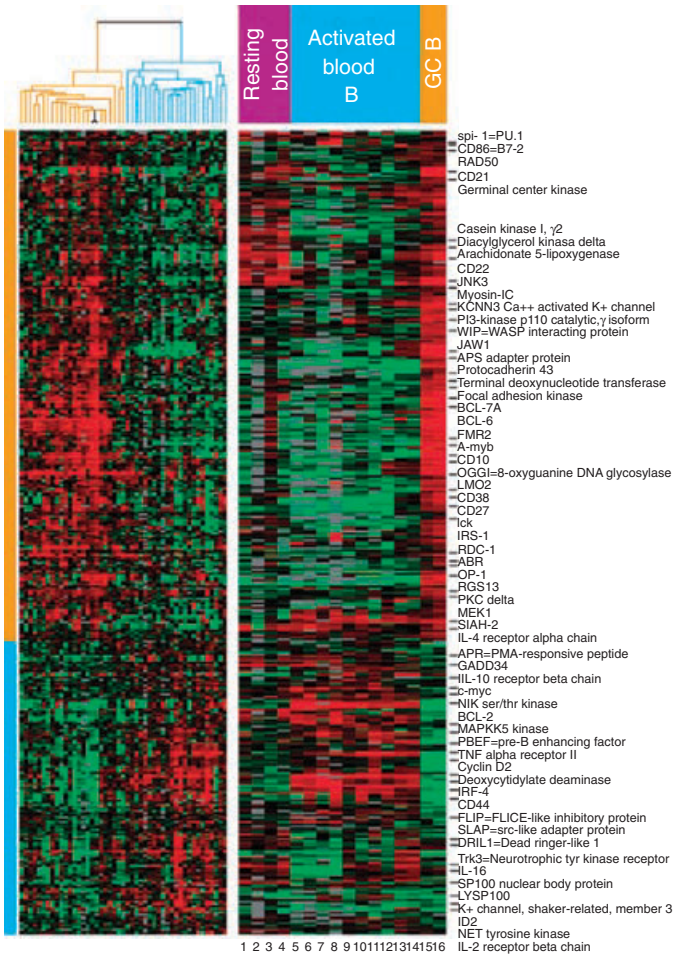

Figure 2–4 Diffuse large B-cell lymphomas (DLBCLs) classified by hierarchical clustering of genes. Gene expression in DLBCL samples was analyzed by the complementary DNA (cDNA) arrays containing approximately 17,000 genes, and the samples were clustered according to inherent differences in gene expression by hierarchical clustering. Patients with DLBCLs that had a gene germinal center-like gene expression pattern (*orange*) had a higher likelihood of survival than those with DLBCLs with an activated B cell-like expression pattern (*blue*). Each column represents a patient sample, and each row a gene. *Red* represents relative high-level expression and relative low-level expression. *(From Alizadeh AA, Eisen MB, Davis RE, et al: Distinct types of diffuse large B-cell lymphoma identified by gene expression profiling. Nature 403:503, 2000.)*

One of the most exciting potential uses of gene expression and other genomic technologies is the identification of unexpected new therapeutic avenues. In particular, gene expression analysis has the potential to identify oncogenes that are expressed to a higher level in one disease than another. High-level expression of a gene, however, does not necessarily mean anything about the function of the encoded protein. Despite this caveat, it does appear that gene expression-based comparisons can uncover important therapeutic targets in a given subset of disease. For example, when the gene expression profile of *BCR-ABL*-rearranged ALL is compared with those of other ALLs, the *ABL* gene is identified as one of the most highly expressed genes in this disease.[39] Similarly, α-*KIT* is highly expressed in gastrointestinal stromal tumors relative to other spindle cell tumors.[51] The importance of targeting *Abl* and *Kit* with the small-molecule inhibitor imatinib mesylate (Gleevec) is now well documented.[31,52] Thus, even if these molecules were not previously known to be important in these diseases, gene expression analysis probably would have identified them as such.

Along these lines, and as a result of gene expression studies (Fig. 2–5), the receptor tyrosine kinase Flt3 (*F*MS-*l*ike *t*yrosine kinase-3) has been validated as a potential therapeutic target in *MLL*-rearranged ALLs.[53] Because small-molecule Flt3 inhibitors were already being developed for the therapy of Flt3-mutated AML, the discovery of Flt3 in *MLL*-rearranged ALL prompted the initiation of clinical trials testing small-molecule Flt3 inhibitors in this disease.

Another approach that can be employed to identify potential therapeutic avenues in a given disease is to search for evidence of activation of a particular signaling pathway in the disease. This might be done by looking for high-level expression of multiple members of a pathway or by searching for a gene expression profile that is associated with activation of a particular pathway. Although analytic tools that can do this type of search in an automated fashion are still in development, activation of the nuclear factor-κB (NF-κB) pathway in activated B cell-like DLBCL was identified in this manner.[54]

Analysis of chromosome abnormalities has a long and rich history in the study of leukemogenesis. Although leukemia genomes have been studied extensively, the introduction of aCGH and SNP analysis will allow an even more thorough assessment of recurrent abnormalities in leukemia. A particularly powerful approach will be the combination of methods such as gene expression analysis and chromosome analysis by methods such as aCGH and SNP. This increase in "dimensionality" of genomic data should give an unprecedented view of the workings of a neoplastic cell. Indeed a recent study used SNP analysis to identify new recurrent genetic abnormalities in childhood leukemia that appear to be contributing to the neoplastic phenotype.[24]

Although such analyses are still in their infancy, important insights into leukemia classification and pathogenesis are beginning to be realized. Most of the discoveries await further validation in model systems, but it is clear that the addition of whole-genome expression analysis and detailed characterization of changes in DNA structure/sequence to our previous base of knowledge will provide further understanding. Finally, the development of more specific therapeutic regimens and new targeted therapeutic molecules is likely to arise from these studies. The integration of refined molecular classification and targeted therapies based on our understanding of leukemogenesis should lead to an improvement in the care of patients with leukemia.

Sickle Cell Disease

Although significant effort already has been put toward genomic analyses of diseases such as cancer, other hematologic diseases stand to benefit from such analyses. With the explosion of genomic information and the ever-increasing number of SNPs, we may now be able to begin to identify genes that modify the severity of human disease. For example, although most children with sickle cell anemia have similar genetic defects, the severity of the disease varies from individual to individual. Some patients have a predilection for the development of acute chest syndrome, stroke, or other devastating manifestations of the disease; others have a relatively benign course. Some of the genetic factors for such disease variability are known. An example is increased levels of hemoglobin F. The reason for most of the variability in disease expression, however, remains obscure. Although the cause of this variability will be multifactorial, disease modifier genes are likely to play an important role. Questions such as this can now be addressed using high-throughput SNP analysis to assess for polymorphisms that are either linked to or reside in sickle cell modifier genes. An example of an SNP that may provide information about disease severity in sickle cell disease lies within the gene encoding vascular cell adhesion molecule-1 (VCAM-1), which is associated with an increased risk of stroke.[55] Although such findings must be validated in larger studies and in models of the disease, experiments to investigate questions such as this one can be performed relatively easily and quickly. Of course, large, well-designed studies will need to be performed to take full advantage of the technology, but many centers have the clinical infrastructure to perform such studies.

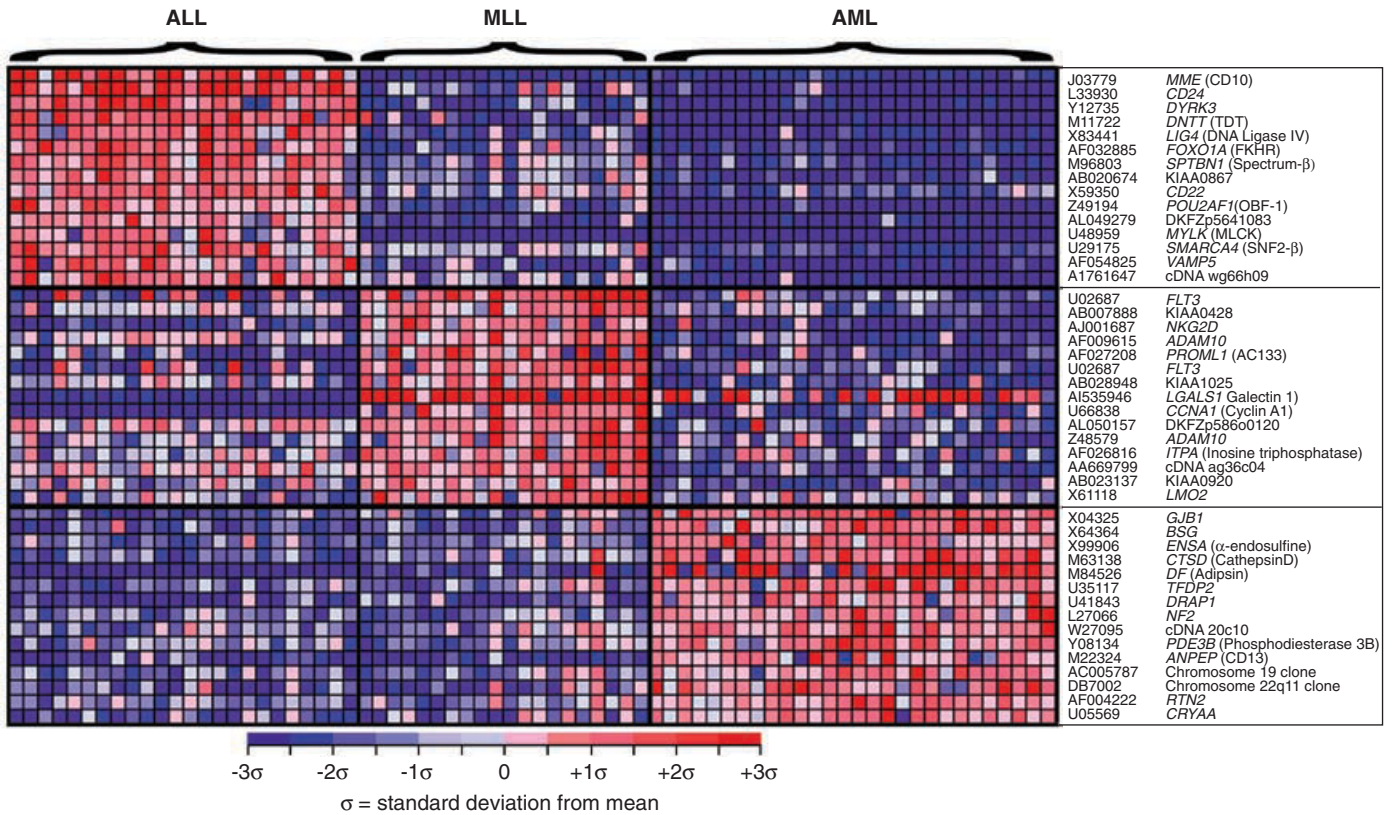

Figure 2–5 Comparison of gene expression in acute lymphocytic leukemia (ALL), *MLL*-rearranged ALL (designated MLL), and acute myelogenous leukemia (AML) samples using a supervised learning approach. Gene expression in leukemia samples was analyzed using Affymetrix microarrays (U95AV2) containing 12,600 unique probe sets. Genes that are highly expressed in one type of leukemia relative to the other two are shown. Each column represents a patient sample, and each row a gene. *Red* represents relative high-level expression and relative low-level expression. *(From Armstrong SA, Staunton JE, Silverman LB, et al: MLL translocations specify a distinct gene expression profile that distinguishes a unique leukemia. Nat Genet 30:41, 2002.)*

Thrombosis

The importance of SNPs in inherited predisposition to thrombotic episodes is well documented. The factor V Leiden and the prothrombin 20210A mutations associated with prothrombotic risk both are coding-region SNPs that predispose affected persons to venous thrombotic episodes.[56,57] Although these mutations were identified before large-scale SNP analysis, they provide evidence that further SNP analysis in persons who have experienced thrombotic episodes is likely to be of benefit. Identification of such mutations should be less time consuming because of the high-throughput nature of SNP analysis. Also, such analysis may provide insights into the mechanisms of predisposition to arterial thrombosis, stroke, and myocardial infarction in the general population.

In one such analysis, three SNPs surrounding the lymphotoxin-α gene were found to segregate with predisposition to myocardial infarction.[58] Of interest, one of the SNPs was shown to lead to increased lymphotoxin-α expression, which subsequently increased the expression of VCAM-1. A VCAM-1 polymorphism is also associated with stroke in sickle cell anemia, so this may be a particularly important association. Large follow-up studies and functional analyses are needed to validate these associations, but it appears evident that SNP analysis will provide new insights into the predisposition to thrombotic episodes.

PHARMACOGENETICS

A field that will benefit from the high-throughput technologies of genomics is that of pharmacogenetics. Pharmacogenetics encompasses the attempt to understand the clinical variability in toxicity and efficacy of particular therapeutics. The field historically has focused largely on the characterization of polymorphic variants of enzymes involved in drug metabolism. One of the earliest examples noted that an inherited deficiency in red blood cell glucose-6-phosphate dehydrogenase (G6PD deficiency) led to red cell hemolysis when affected patients were given antimalarial therapy. Since this early discovery, a number of genetic polymorphisms have been shown to modify the way a particular person responds to a given therapy. Because most drug-metabolizing enzymes are polymorphic, it is possible that a significant amount of variability in toxicity can be attributed to these polymorphisms. Drug toxicity probably represents an interplay among the multiple proteins involved in drug metabolism, proteins involved in drug clearance, and proteins that are the drug targets responsible for the toxicity; therefore, more comprehensive assessment will be required if we are to develop an understanding that can be used to predict clinical responses.[59]

Because of the complexities described earlier, the field of *pharmacogenomics* (the study of the relationship between drug effects and genome-wide variations among different people) stands to affect the manner in which we treat our patients. Studies are now under way to perform genome-wide assessment of SNPs and gene expression with a goal of correlating these changes with either toxicity or efficacy. One example of such an analysis was the correlation of gene expression with the development of secondary leukemia in patients with ALL who were given the topoisomerase II inhibitor etoposide.[39] In this study, the investigators were able to show a gene expression profile, present in lymphoblasts before treatment with etoposide, which was robust enough to predict the occurrence of the secondary leukemia. Because this study looked only at the gene expression profile of the leukemic blasts, it is not known whether this profile is the result of germline polymorphisms in some critical genes or whether it is acquired in the lymphoblasts. Despite the need for

further study, this example highlights the potential power of this type of genome-wide analysis.

Another approach is to directly assess the polymorphisms responsible for toxicity or efficacy by genome-wide SNP analysis. Such an analysis would assess the greater than 2×10^6 currently known SNPs and look for association either with response to a given drug or with toxicity. For an SNP within the coding or upstream regulatory region of a gene, the effect of this polymorphism on the gene of interest could be directly assessed.

As the technology for high-throughput genome-wide analysis continues to improve, and the types of analyses described here are performed on a large scale within the setting of carefully designed clinical trials, we should see an improvement in our ability to predict not only which drugs will be efficacious in which disease but also to identify patients who have an increased risk for severe toxicity.

CLINICAL IMPLEMENTATION

Although tremendous interest exists in how genomic views of hematologic diseases will be used clinically, most of the techniques described here are not routinely used for patient care decisions. The major reason for this limitation is the need for prospective validation of genomic studies performed to date. Furthermore, it remains uncertain whether techniques such as genome-wide gene expression analyses are feasible in the setting of routine clinical care, in view of the intricacies of sample acquisition, RNA handling, and informatic analysis described previously. Most studies performed to date have been done with rigorous controls designed to manage such variables.

The genomic discoveries that are most easily translated into clinical tests that can be used widely are those that involve assessing for polymorphisms. The best example of such translatability is the speed with which the assessment for resistance to activated protein C (factor V Leiden) began to be used clinically. Similarly, many centers can routinely test for the prothrombin 20210A mutation when assessing for predisposition to thrombosis. It is predicted that the ongoing large SNP studies will find similar polymorphism associations that can be quickly developed into useful tests.

Gene expression-based classifiers of leukemia and lymphoma represent a more difficult genomic discovery in terms of how to use this information clinically. For example, new gene expression-based classifiers of DLBCLs appear to be robust and add important information to current classification schemes. A gene expression classifier could be implemented as a multigene quantitative PCR assay, as a custom microarray that only detects the expression of key genes, or a genome-wide microarray. Clinical trials utilizing a quantitative PCR-base approach are currently underway. Whatever technology is ultimately used, most investigators believe that the information obtained by genomic studies will be incorporated into routine clinical practice in the not-too-distant future, whether or not the clinical tests are performed on the platforms used during the discovery process.

FUTURE DIRECTIONS

Genomic analysis promises to give an unprecedented view into the molecular composition of a diseased cell. These new discoveries are likely to be of both biologic and clinical importance and therefore require intense collaboration between clinical and basic scientists, so that the information gathered can be used to its full potential. Numerous studies have shown that such large-scale analysis can produce important information about disease, but an ongoing challenge is validation of hypotheses from such studies. Another current challenge is the integration of data obtained using different platforms across multiple institutions. The ability to compare genomic data sets produced by different investigators will be of great value and should help in the refinement of hypotheses. Similarly, genomic studies aimed at predicting outcome are being assessed in large prospective studies, which should provide information regarding the validity of the gene expression classifiers already developed. Finally, major effort is being put forth to develop high-throughput methods to allow rapid validation of biologic hypotheses. These studies will provide crucial tools for the future.

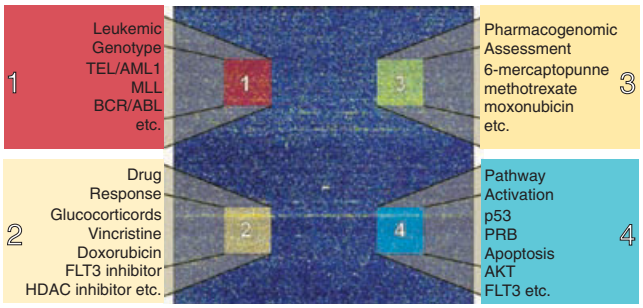

Figure 2–6 GENOMIC ANALYSIS OF LEUKEMIA IN THE FUTURE? A DNA microarray could be produced that would be able to identify molecular genetic information within the leukemia. This array could determine oncogenic mechanisms, drug resistance profiles, and the likelihood of drug toxicity. This information could then be used to develop a personalized treatment plan that would be most efficacious and least toxic for the particular type of leukemia and an individual patient.

As the ability to use genomic technologies has become more widely available, integration of multiple types of analysis has become possible. Such multicomponent analysis should lead to an ever-increasing precision and ability to focus on biologically important information. For example, analysis of a leukemia sample by gene expression, aCGH, SNP, and direct sequencing of kinases may yield clinically useful prognostic information and uncover new therapeutic avenues that might go unrecognized if any of the strategies were used alone. An important goal will be to integrate genomic information to get a complete molecular description of cancer cells: the mutations, chromosomal abnormalities, gene expression, miRNA expression, and epigenetic state of the cells that determine the clinical phenotype and response to therapy.

We can now begin to imagine a time in the near future when we will truly be able to develop personalized medicine. For example, when a patient presents to the hospital or clinic with a new diagnosis of leukemia, a sample of the leukemic cells might be taken and assessed for gene expression and SNP analysis (Fig. 2–6). From these data, the physician might learn that the patient's leukemia cells have a particular chromosome translocation, a mutant tyrosine kinase, and a gene expression profile that predicts response to certain chemotherapeutics in combination with a specific tyrosine kinase inhibitor. Also, SNP analysis might predict that the patient would have severe toxicity to one of the chemotherapeutic agents commonly used in this disease. On the basis of these data, the physician would decide to manage the patient with a combination of drugs that has the greatest likelihood of efficacy with the least toxicity.

Although this type of personalized medicine is now on the horizon, its implementation will require an intense collaboration among clinical scientists, laboratory scientists, and pharmaceutical companies. Because all of this constitutes new territory for clinicians and scientists alike, it will not be an efficient process. Also, implementation of truly personalized medicine will have to be performed in a manner that does not compromise the current standards of care. Although this may make the pace of change in clinical medicine uncertain, there is great motivation for such a change.

CHAPTER 3

PROTEIN SYNTHESIS, PROCESSING, AND TRAFFICKING

Randal J. Kaufman and Laura Popolo

Proteins are the final executers of the genetic program of a cell and are responsible for the remarkable diversity in cell specialization that is typical of metazoan organisms. To perform this role, after synthesis, proteins need to be properly folded, assembled into oligomeric complexes, and transported to their final destinations. In many cases, protein folding and processing are coupled with protein trafficking so that the targeting process is unidirectional and irreversible. Eukaryotic cells contain membrane-bound compartments, termed *organelles*, such as the mitochondria, the endoplasmic reticulum (ER), the peroxisomes, and the nucleus. Each organelle serves a particular purpose. The capacity of any organelle to fulfill its role in intracellular physiology depends on a characteristic set of protein components. This chapter briefly describes how proteins are synthesized and then focuses on their processing and delivery to appropriate destinations within the cell. An understanding of the mechanisms that catalyze protein folding, assembly, and targeting is necessary for the study of hematology and can help explain how malfunctions in these processes can cause blood disorders.

PROTEIN SYNTHESIS

Among all the biosyntheses of macromolecules occurring in a cell, protein synthesis is the most important in quantitative terms. It is a highly energy-consuming process and proceeds through a mechanism that has been conserved during evolution. Proteins are synthesized by the joining of amino acids, through peptide bonds, each of which has characteristic physical–chemical properties (see Table 3–1 for single-letter designations). Peptide bonds are created by the condensation of the carboxyl group (COOH) of one amino acid with the amino group (NH_2) of the next. The free NH_2 and COOH groups of the terminal amino acids define the amino- or N-terminal end and the carboxyl- or C-terminal end, respectively, of the resulting polypeptide chain. In many cases, multiple polypeptide chains assemble into a functional protein. For example, hemoglobin is formed by four polypeptide chains, two α-globin chains and two β-globin chains that assemble with heme, an iron-containing prosthetic group, to yield the functional protein designed to deliver molecular oxygen to all cells and tissues.

The whole process of protein synthesis is orchestrated by a large ribonucleoprotein complex, called the *ribosome*, which is composed of a large subunit of 60S and a small one of 40S (S stands for Svedberg unit, and refers to the rate of sedimentation). Eukaryotic mRNA molecules typically contain a 5′-untranslated region (5′-UTR), a protein coding sequence that begins with an AUG and ends with one of three stop codons (UAA, UAG, UGA), and a 3′-untranslated region (3′-UTR). The 5′ end carries a 7-methylguanosine forming a structure called a "cap" (m^7GpppN mRNA), whereas the 3′ end is polyadenylated. These modifications are required to protect the mRNA from degradation, for export out of the nucleus and for efficient recruitment of ribosomes for translation. Once in the cytoplasm, the 40S ribosomal subunit binds to the cap and then scans the mRNA toward the 3′ end until the translation start codon is encountered (usually the first AUG). At that time, the 60S subunit assembles with the 40S to produce an 80S ribosome. A special tRNA specific for methionine, called the initiator ($tRNA_i^{Met}$), is required for the initiation of protein synthesis at the start codon. Other charged tRNA molecules ferry amino acids to the ribosome, where they are joined together in sequence as the ribosome moves toward the 3′ end of the mRNA. The codons in the mRNA interact by base-pairing with the anticodon of the tRNAs so that amino acids are incorporated into the nascent polypeptide chain in the right order. Translation is terminated on encountering a stop codon, when the polypeptide is released. Typically, multiple ribosomes are engaged in the translation of a single mRNA molecule in a complex termed a *polyribosome* or *polysome*.

Protein synthesis is divided into three phases: initiation, elongation, and termination. Each phase requires a set of soluble proteins called initiation, elongation, and termination or release factors that are termed eIFs, eEFs, and eRFs, respectively, where the prefix *e* indicates their eukaryotic origin.

REGULATION OF mRNA TRANSLATION

There are two major general regulatory steps in mRNA translation that are mediated by the initiation factors eIF2 and eIF4. All cells regulate the rate of protein synthesis through reversible covalent modification of eIF2, a soluble factor required for the binding and recruitment of the Met-$tRNA_i^{Met}$ to the 40S subunit. eIF2 is a heterotrimeric G-protein (guanine nucleotide-binding protein) that can exist in an inactive form bound to guanosine diphosphate (GDP) or in an active form bound to guanosine triphosphate (GTP). The eIF2–GTP–Met-$tRNA_i^{Met}$ ternary complex binds to the 40S ribosomal subunit. Joining of the 60S subunit triggers hydrolysis of GTP to GDP and thus converts eIF2 to the inactive form, whereas the opposite reaction is catalyzed by a guanine nucleotide exchange factor (GEF) called eIF2B. In reticulocytes, which synthesize hemoglobin almost as a sole protein, heme starvation blocks the synthesis of α- and β-globins by activating a protein kinase, called hemin-regulated inhibitor (HRI), that specifically phosphorylates the eIF2α subunit of eIF2. The phosphorylated form of eIF2 binds more tightly than usual to eIF2B, so that eIF2B is sequestered and not available for the exchange reaction. Thus, eIF2 molecules remain in the GDP-bound form and translation of globin mRNA comes to a halt. This mechanism of translational inhibition is of more general significance because eIF2 is a target of phosphorylation by additional protein kinases that cause translational arrest in response to different conditions of cell stress, such as amino acid starvation, glucose starvation, and viral infection.

A second major control point of general protein synthesis is mediated by the eIF4 protein complex that binds the cap and uses an ATP-dependent RNA helicase activity to unwind the structural elements in the 5′ end of mRNA to make it accessible for 40S ribosome binding. The subunit that binds the cap, eIF4E, is the least abundant factor regulating translation in mammalian cells. Increased levels of eIF4E stimulate protein synthesis and can contribute to oncogenesis. The cap-binding activity of eIF4E is inhibited by the eIF4E-binding protein (eIF4EBP), which is regulated by phosphorylation by the protein kinases AKT and TOR. Because phosphorylated eIF4BP cannot bind eIF4E, eIF4EBP phosphorylation stimulates translation initiation.

The efficiency of translation can also be modulated by cellular factors that bind mRNA in a sequence-specific manner. An example of this mode of regulation is the control of iron metabolism in animal cells. Key players of this system are (a) the iron-responsive element

Table 3–1 Examples of Targeting Signals

Organelle	Signal Location*	Example
Posttranslational Uptake		
Nucleus	Internal	PKKKRKV (import; SV40 large T antigen)
		LQLPPLERLTLD (export; HIV-1 Rev)
Mitochondrion	N-terminal	MLGIRSSVKTCFKPMSLTSKRL (iron–sulfur protein of complex III)
Peroxisomes	C-terminal	KANL (PTS1, human catalase)
	N-terminal	RLQVVLGHL (PTS2, human 3-ketoacyl-CoA thiolase)
Cotranslational Uptake		
ER	N-terminal	MMSFVSLLLVGILFWATEAEQLTKCEVFQ (ovine lactalbumin)

ER, endoplasmic reticulum; HIV, human immunodeficiency virus; PTS1, peroxisomal targeting signal-type 1; PTS2, peroxisomal targeting signal-type 2, SV40, simian virus 40.

*Acidic residues (negatively charged) are in *italic* type; basic residues (positively charged) are in bold type. Amino acids: A, alanine; C, cysteine; *D*, aspartic acid; *E*, glutamic acid; F, phenylalanine; G, glycine; **H**, histidine; I, isoleucine; **K**, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; **R**, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

(IRE), a hairpin structure that is formed in the untranslated regions of the mRNAs, and (b) iron regulatory proteins (IRPs) that bind IRE. In the transferrin receptor (Tfr) mRNA and ferritin mRNA, IREs are located in the 3′-UTR and 5′-UTR, respectively. In iron-starved cells, the binding of IRPs to IREs results in the stabilization of Tfr mRNA and inhibition of translation initiation of ferritin mRNA. Conversely, when iron is abundant, IRPs have a lower affinity to IREs and as a result Tfr mRNA is degraded whereas ferritin mRNA translation is stimulated. In this manner, cells can coordinately regulate iron uptake and iron sequestration in response to the changes in iron availability.

PROTEIN SORTING

The transport of newly synthesized polypeptides to their destination requires navigation through several sorting branch points (Fig. 3–1). These sorting events are governed by sorting signals (ie, short linear sequences or three-dimensional patches of particular amino acids) and by their cognate receptors. The first sorting decision occurs after approximately 30 amino acids of the nascent polypeptide have been extruded from the ribosome. If the nascent polypeptide lacks a "signal sequence," most often found near the amino-terminal end, the translation of the polypeptide is completed in the cytosol. Then the protein can either stay in the cytosol or be posttranslationally incorporated into one of the indicated organelles (Fig. 3–1, pathways 7, 8, and 9). If the protein does contain an amino–terminal signal sequence is imported cotranslationally into the ER, from where it can be targeted to the other compartments of the secretory pathway (Fig. 3–1, pathway 1).

PROTEIN FOLDING

Proteins are not functional in the extended linear conformation in which they emerge from the ribosome. The polypeptide chain must fold into a conformation that is basically dictated by the primary structure. Although some proteins can acquire their mature three-dimensional conformation in a test tube by a self-assembly process, most polypeptides require assistance to fold. Molecular chaperones either directly assist protein folding or act to prevent aberrant interactions, such as aggregation, that can occur in a highly crowded environment, similar to the cytosol of eukaryotic cells (protein concentrations of 200–300 mg/mL). Most molecular chaperones are members of the heat-shock protein (hsp) family. Chaperones bind to short-sequence protein motifs, in many cases containing hydrophobic amino acids. By undergoing cycles of binding and release (linked to ATP hydrolysis), chaperones help the nascent polypeptide to find its native conformation, one aspect of which is hiding hydrophobic sequence motifs in the protein interior so that they no longer contact the hydrophilic environment of the cytosol. Some properly folded protein monomers are assembled with other proteins to form multisubunit complexes. The population of chaperones that assist folding and assembly in the cytosol is distinct from those that operate within the ER or mitochondria.

PROTEIN DEGRADATION

Proteins can contain mutations that prevent them from folding properly. Such misfolded proteins are marked for destruction and are degraded. In addition to carrying out the disposal of damaged and misfolded proteins, the cellular protein degradation machinery is responsible for regulating a wide array of cellular processes, including cellular differentiation, tissue development, induction of inflammatory responses, antigen presentation, and cell cycle progression through the controlled destruction of key regulatory proteins. Degradation of these molecules is achieved in two major phases. First, the molecules are tagged with a polypeptide moiety termed *ubiquitin.* Second, the tagged molecules are ferried to an ATP-dependent protease complex called the proteasome for destruction. Chapter 4 provides an overview of the ubiquitin-mediated protein degradation pathway.

SORTING FROM THE CYTOSOL INTO OTHER COMPARTMENTS

Most of the proteins synthesized on free polysomes remain in the cytosol as cytosolic or soluble proteins. These include enzymes involved in metabolic and signal transduction pathways or proteins required for the assembly of the cytoskeleton. Other proteins are imported into the organelles, including the nucleus, the mitochondrion, and the peroxisome (see Fig. 3–1).

In general, there are two types of protein trafficking. In one type, the protein crosses a lipid bilayer. The polypeptide crosses the membrane in an unfolded state through an aqueous channel composed of proteins. In the second type, the protein does not traffic across a lipid bilayer and is exemplified by trafficking into the nucleus or from the ER to the Golgi compartment. In these cases, proteins and protein complexes are transported in their folded/assembled state.

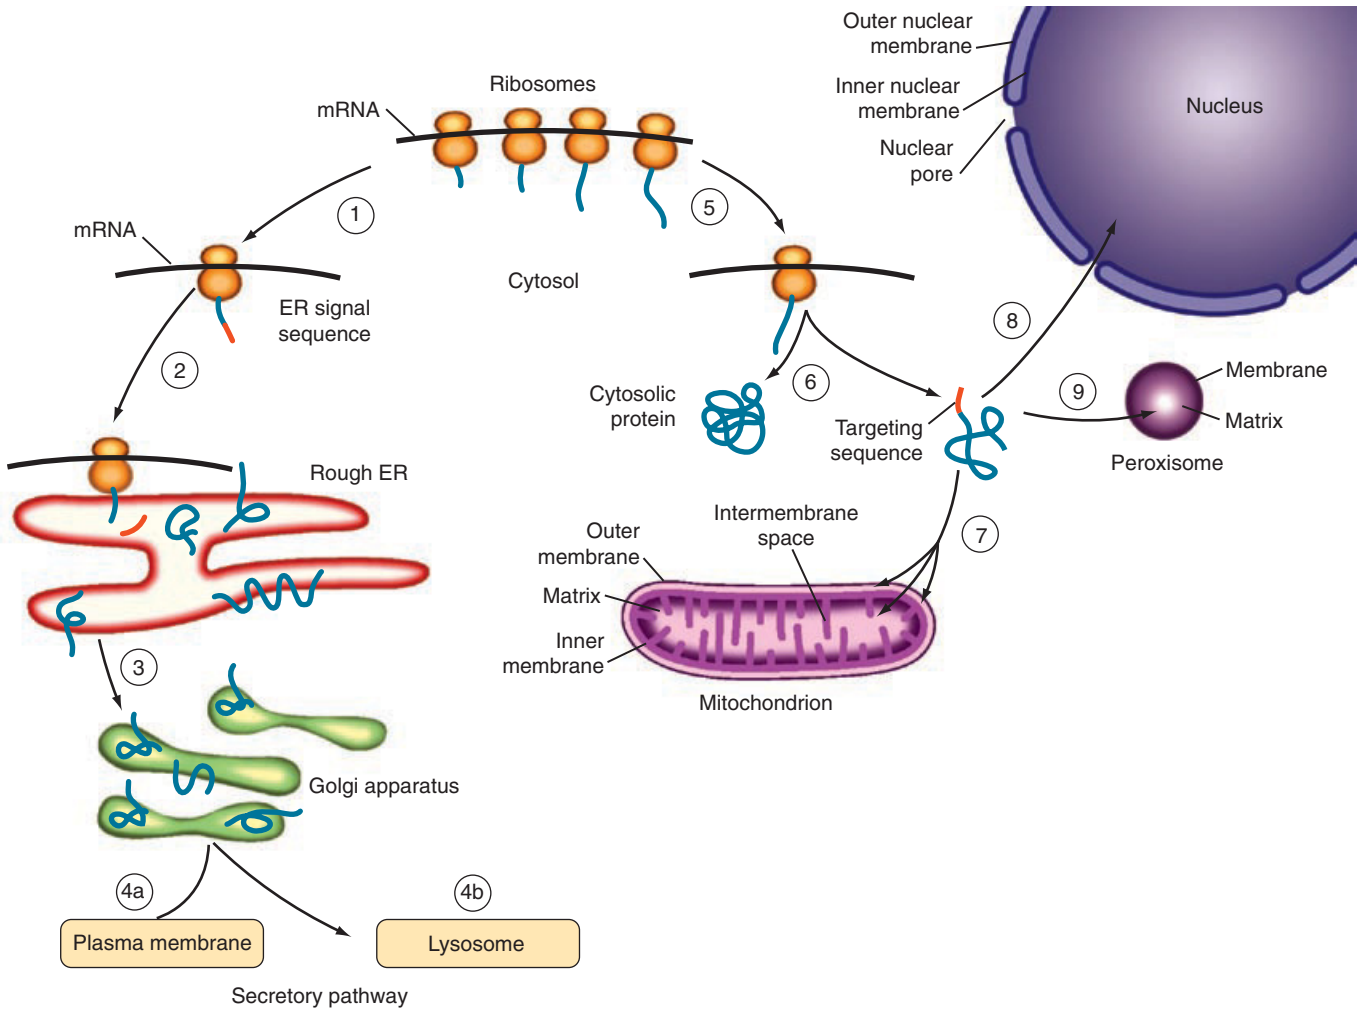

Figure 3–1 Intracellular protein trafficking.

Nuclear Proteins

The nucleus contains the genome of a cell and is bounded by a double membrane that forms the nuclear envelope (see Fig. 3–1). The outer membrane is continuous with the ER and has a polypeptide composition distinct from that of the inner membrane. Approximately 3000 nuclear pore complexes (NPCs) perforate the nuclear envelope in animal cells. NPCs are approximately 120 nm in diameter and comprise approximately 50 different proteins (nucleoporins). Although NPCs allow unrestricted, bidirectional movement of molecules smaller than 40,000 to 50,000 daltons, traversal of NPCs by larger molecules is tightly regulated.

NPCs are capable of importing and exporting molecules or complexes, provided that the molecules have an exposed nuclear localization signal or nuclear export signal (see Table 3–1). Candidates for nuclear import (ie, transcription factors, DNA repair enzymes, ribosomal proteins, mRNA processing factors, etc) or export (ribosomal subunits, mRNA-containing particles, tRNAs, etc) are transported through the NPC in association with carrier proteins, called importins, that bind their cargo on one side of the NPC and release it on the other. In contrast, other proteins called exportins bind the cargo in the nucleus and release it in the cytoplasm. A monomeric G-protein called Ran controls both the docking of carrier proteins with their cargo and the directionality of transport through cycles of GTP binding and hydrolysis. The movement of carrier proteins across the NPC requires their interaction with nucleoporins that bear phenylalanine–glycine (F–G) repeats.

The lack of a nuclear localization or nuclear export signal removal during transport through the NPC enables multiple cycles of nuclear entry and exit, which is a particularly important mechanism for regulating the activity of proteins involved in DNA and RNA metabolism.

Mitochondrial Proteins

The mitochondrion is an essential cellular compartment in eukaryotes. Although it contains a genome organized in a circular DNA molecule and an independent transcriptional/translational machinery, 98% of the approximately 1000 proteins that constitute mitochondria are encoded by nuclear DNA and are imported from the cytosol after their synthesis. A small number of proteins is encoded by mitochondrial DNA and is synthesized by ribosomes within the mitochondria.

Like nuclei, mitochondria have two membranes: an outer one that contacts the cytosol and an inner one in which reside the enzymes that synthesize ATP through reactions of the electron transport chain and oxidative phosphorylation. Where the outer membrane is permeable to small molecules and ions, the inner membrane is highly impermeable, a property essential for creating an electrochemical gradient necessary to drive the synthesis of ATP. The space enclosed by the two membranes is the intermembrane space and the space enclosed in the inner membrane is the *matrix* (see Fig. 3–1).

Translocation and sorting of nuclear-encoded proteins into the various mitochondrial subcompartments are achieved by the concerted action of translocases. Precursor proteins usually have one of two targeting signals: (a) an amino-terminal presequence that is generally between 10 and 80 amino acid residues long and forms an

amphipathic α-helix, which is rich in positively charged, hydrophobic, and hydroxylated amino acids (see Table 3–1), or (b) a less well-defined, hydrophobic targeting sequence distributed throughout the protein. The TOM complex (*t*ranslocase of the *o*uter *m*embrane) functions as a single entry point into the mitochondria. Preproteins translocate through it in an unfolded state in an N-to-C direction. After crossing the outer membrane, proteins segregate according to their signals and recognize two distinct *t*ranslocases of the *i*nner *m*embrane (TIM23 and TIM22). Presequence-containing proteins are directed to the TIM23 complex that mediates transport across the inner membrane, a process that requires the electrochemical membrane potential and the ATP-driven action of the matrix heat shock protein 70 (mtHsp70). Once in the matrix, the presequence is often cleaved by a mitochondrial processing peptidase. Proteins with internal targeting signals are guided to the TIM22 complex. Membrane insertion at the TIM22 is also dependent on the membrane potential.

Peroxisomal Proteins

Peroxisomes are membrane-bound compartments in which oxidative reactions that generate hydrogen peroxide, such as β-oxidation of fatty acids, occur. In this organelle, hydrogen peroxide is rapidly degraded by catalase to prevent oxidative reactions that have potential damaging effects on cellular structures. A single membrane surrounds the peroxisome, which encloses an interior matrix (see Fig. 3–1). This organelle lacks a genetic system and a transcriptional/translational machinery. Therefore all peroxisomal proteins are imported posttranslationally from the cytosol by proteins called peroxins.

The targeting of matrix proteins is directed by two types of peroxisomal targeting signals (PTSs). Type 1 is a carboxyl-terminal tri- or tetrapeptide (PTS1), whereas type 2 is an amino-terminal peptide of nine amino acids (PTS2) (see Table 3–1). Two cytosolic peroxins, Pex5 and Pex7, recognize PTS1 and PTS2, respectively, bind cargo proteins in the cytosol, release them into the matrix, and cycle back to the cytosol. Other peroxins are involved in the import of membrane proteins. Although the mechanism of translocation is not known, cargo proteins appear to cross the membrane in a folded state, or even as oligomers. In this regard, the process is more similar to protein import into the nucleus, although a structure similar to the nuclear pore has not been identified to date.

One consequence of the existence of two different mechanisms for protein import is that when the import of matrix proteins is defective, membrane ghosts of peroxisomes persist in the cells. In contrast, when the import of membrane proteins is impaired, neither normal peroxisomes nor membrane ghosts are present. Defects in *PEX3* underlie Zellweger syndrome, which is characterized by the presence of empty peroxisomes and abnormalities of the brain, liver, and kidney that cause death shortly after birth.

PROTEIN TRAFFICKING WITHIN THE SECRETORY PATHWAY

Proteins that enter the ER are transported toward the plasma membrane through a route that is called the secretory pathway (Fig. 3–2). Specific signals cause proteins to be retained in the ER, Golgi, or plasma membrane. Proteins may also be targeted from the Golgi compartment to lysosomes or from the plasma membrane to endosomes (Fig. 3–2, pathways 8 and 9). Initially the study of this complex protein trafficking took advantage of mutants in this pathway isolated in the lower eukaryote *Saccharomyces cerevisiae.* Many genes encoding products involved in secretion were found to be conserved from yeast to mammals, indicating the importance of this pathway for the life of a eukaryotic cell.

Transport through the secretory pathway is mediated by vesicles. Different sets of structural and regulatory proteins control the fusion of the appropriate vesicles with the target membrane. Sorting motifs dictate the selective incorporation of cargo proteins into those vesicles and their delivery to an intended destination. A major question in cell biology today is how the identity of the compartments of the secretory pathway is maintained while allowing unimpeded transit of other nonresident proteins.

Cotranslational Import and Processing of Proteins in the ER

Overview of ER Structure and Function

The ER is an extensive membranous network that extends from the nucleus and is responsible for the synthesis of the massive amounts of lipid and protein used to build the membranes of most cellular organelles. The ER comprises three interconnected domains: rough ER, smooth ER, and ER exit sites. The rough ER is so called because it is studded with bound ribosomes that are actively synthesizing proteins. Cells specialized in protein secretion, such as cells of the exocrine and endocrine glands and plasma cells, are rich in rough ER. Smooth ER lacks ribosomes, is not very abundant in most cells (except hepatocytes), and is thought to be the site of lipid biosynthesis and of cytochrome P450-mediated detoxification reactions. Finally, ER exit sites are specialized areas of the ER membrane where transport cargo is packaged into transport vesicles en route to the Golgi apparatus.

Cotranslational Import Into the ER

Nascent secretory proteins are marked for import in the ER by the presence of an amino-terminal signal sequence (see Table 3–1). This sequence has a length of approximately 15 to 30 amino acids and displays no conservation of amino acid sequence, although it contains a hydrophobic core flanked by polar residues that preferentially have short side chains in proximity to the cleavage site. As the signal sequence emerges from the ribosome, it is recognized by the signal recognition particle (SRP), a ribonucleoprotein, and this binding induces a temporary arrest in translational elongation (Fig. 3–3). The docking of ribosomes to the ER occurs by interaction of the SRP with the SRP receptor. Upon binding of GTP to both the SRP and its receptor, the ribosome and the nascent chain are transferred to the Sec61 complex, allowing translation to resume. Preproteins translocate through the Sec61 complex in an N-to-C direction. As the nascent polypeptide emerges from the luminal side of the translocon, its signal sequence is cleaved by a signal peptidase.

In the absence of specific targeting sequences, proteins that completely translocate into the ER lumen traffic through bulk flow to the cell surface. In contrast, proteins that have specific targeting signals may be localized to the lumen of the ER, the Golgi compartment, or lysosomes. Other proteins that reside in membranes of the cell contain topological sequences called transmembrane domains that consist of approximately 20 largely apolar amino acids. When a transmembrane domain enters the translocon, the polypeptide is released laterally from the Sec61 channel into the lipid bilayer.

Protein Folding in the Lumen of the ER

Protein chaperones facilitate protein folding in the ER, but amino acid posttranslational modifications such as asparagine(N)-linked-glycosylation and disulfide bond formation are also involved. Proteins start to fold cotranslationally by interaction with a host of chaperones, including the hsp70 family member BiP. In addition, there are folding catalysts that increase the rate of protein folding. For example, the proper pairing and formation of disulfide bonds is catalyzed by oxidoreductases, such as protein disulfide isomerase (PDI). In

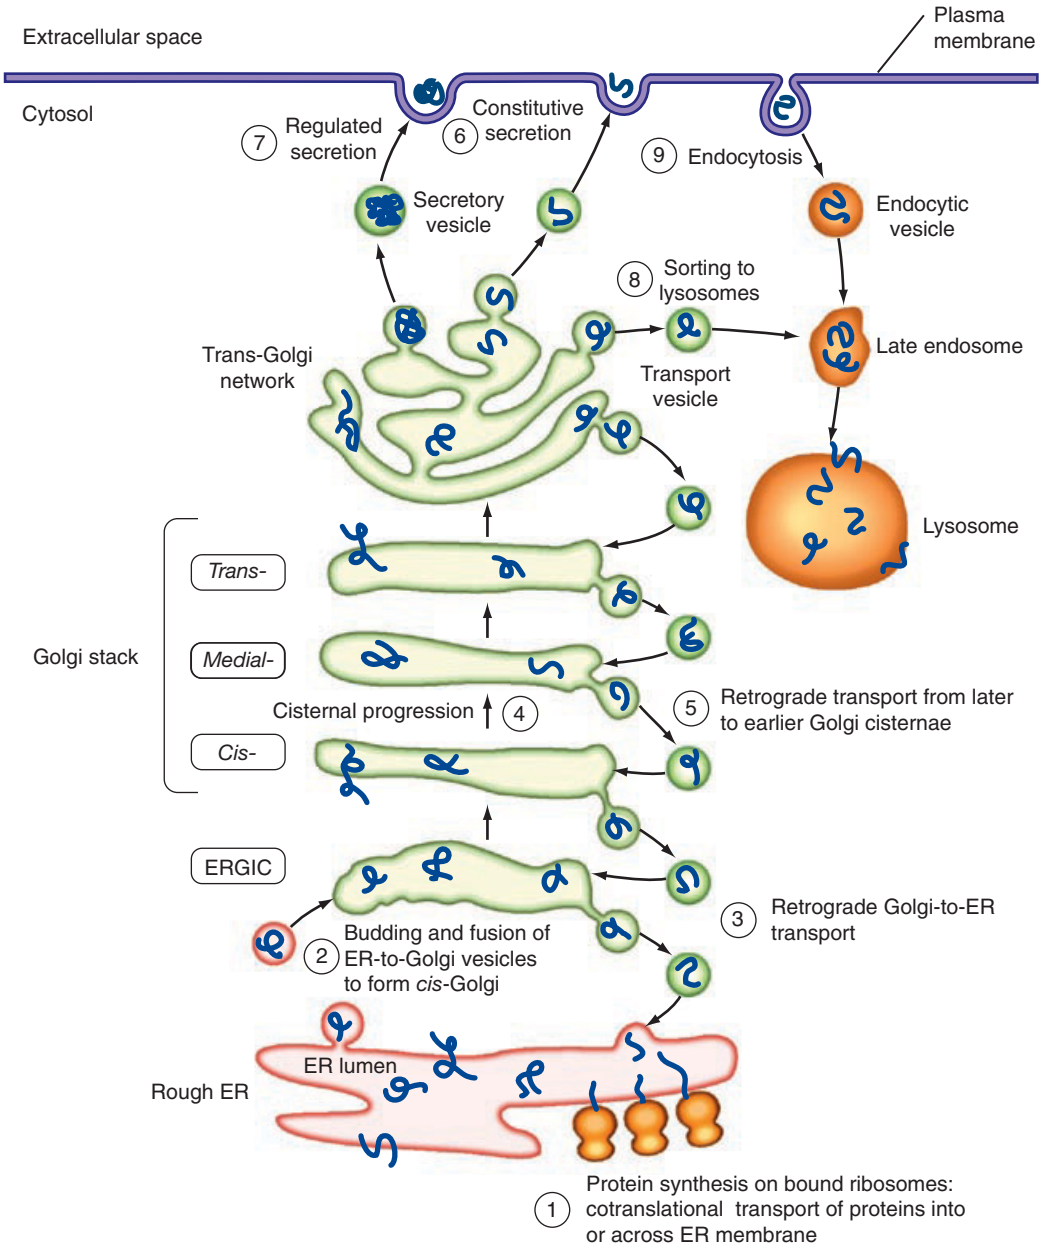

Figure 3–2 Protein trafficking through the secretory pathway. For details, see the text.

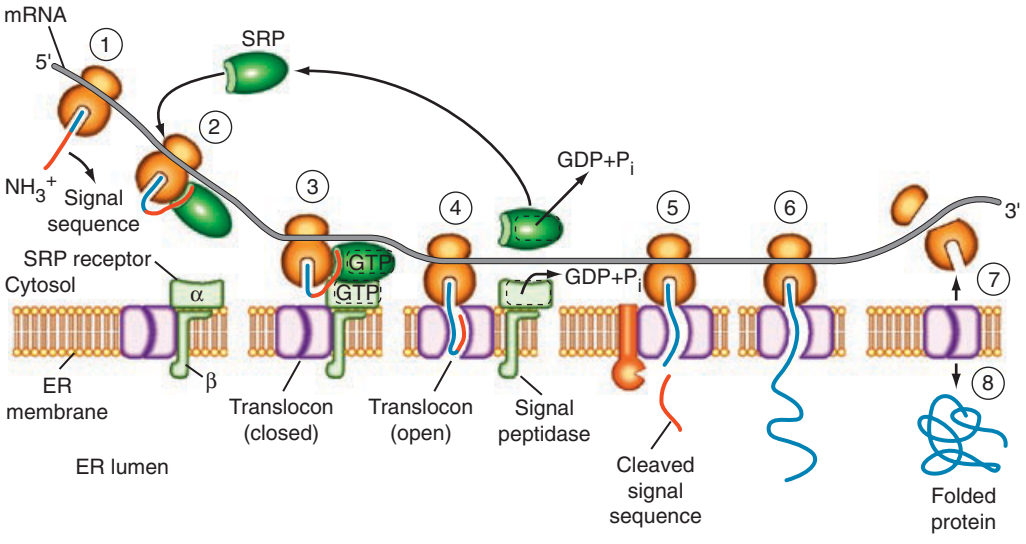

Figure 3–3 Protein translocation into the endoplasmic reticulum.

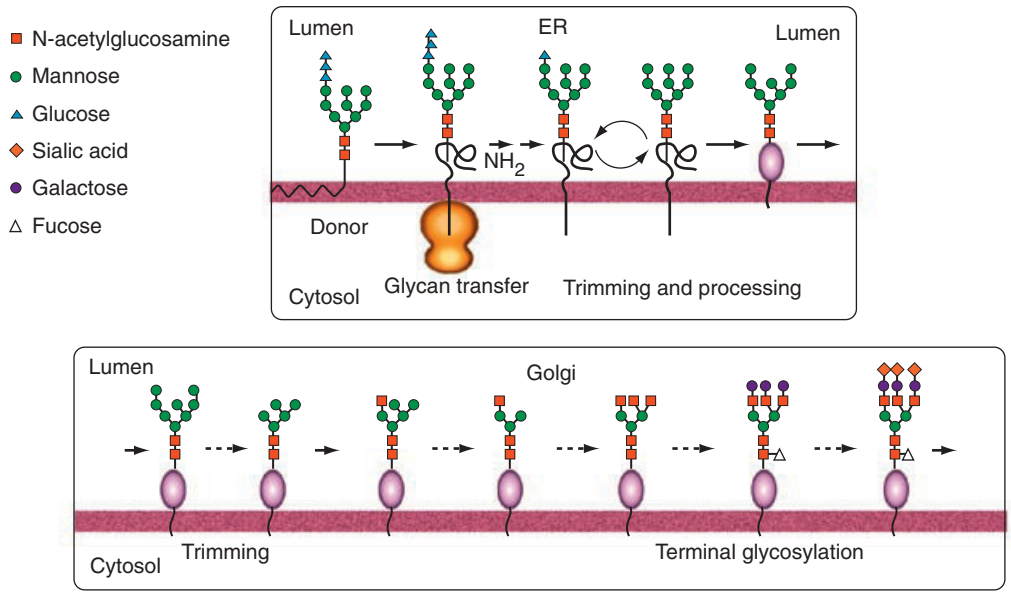

Figure 3–4 N-glycosylation of proteins. In the lumen of the endoplasmic reticulum a core oligosaccharide, $Glc_3Man_9GlcNac_2$, is transferred from a lipid-linked precursor (donor) to the asparagine residue of an N–X–S/T motif in a nascent polypeptide chain. The terminal glucoses are removed by GI and GII (see text), and cycles of reglucosylation can occur. When the protein is folded, one mannose is trimmed and the protein is transported to the Golgi. Core oligosaccharides are further trimmed by mannosidases to produce a $Man_5GlcNac_2$ unit. Further elaboration is catalyzed by glycosyltransferases, which add various sugars and create branches. Bi-, tri-, and tetraantennary chains are generated. In the figure, only one pathway of terminal glycosylation is shown. ER, endoplasmic reticulum. *(Modified from Helenius A, Aebi M: Intracellular function of N-linked glycans. Science 291:2364, 2001.)*

contrast to the highly reducing environment of the cytosol, where disulfide bonds do not typically form, the lumen of the ER is very oxidizing, so that disulfide bonds readily form. Most proteins that enter the secretory pathway are modified by N-glycosylation (Fig. 3–4). This process starts with the transfer of a core oligosaccharide from a lipid-linked donor to an asparagine residue within the consensus sequence N–X–S/T of a nascent polypeptide (X can be any amino acid except for proline). The N-linked oligosaccharide is composed of a glucose$_3$-mannose$_9$-*N*-acetylglucosamine$_2$ ($Glc_3Man_9GlcNac_2$) unit. Further processing of the terminal sugars occurs in the ER and after the polypeptide transits the Golgi compartment (Fig. 3–4).

Many blood proteins, for example, immunoglobulins, antiproteases, coagulation factors, and many membrane proteins of the cell are glycosylated. Although glycan chains are often not required for the enzymatic activity of glycoproteins, they are important for the physical properties they confer and for many physiological functions. Glycans protect proteins from protease digestion and heat denaturation, confer hydrophilicity and adhesive properties to the proteins, and mediate interaction with other proteins or receptors. A remarkable example is the hormone erythropoietin that requires a particular complex type of *N*-glycan chains for its biological function to stimulate erythropoiesis.

In recent years, several studies have revealed the importance of protein N-glycosylation in promoting folding. The addition of glycan chains may prevent aggregation or provide steric influences that affect polypeptide folding and disulfide bond formation and also mediate interaction with specific chaperones. In mammalian cells, N-linked oligosaccharides are also used as signal for monitoring protein folding. They are substrates for a complex chaperone system composed of the lectin chaperones calnexin (CNX) and calreticulin (CRT), Erp57 (an oxidoreductase), two glucosidases (GI and GII), and one folding sensor (UGT1) endowed with reglucosylation activity (UDP-glucose: glycoprotein glucosyltransferase). GI and GII remove the two terminal glucose residues to form a monoglucosylated N-linked chain (see Fig. 3–4) that is a ligand for CNX and CRT. Then another glucose residue is removed. UGT1 recognizes and reglucosylates N-linked oligosaccharides on proteins that have not completed the folding process. The addition of glucose residues allows reassociation with the CNX–CRT chaperone system for another attempt for the polypeptide to attain its proper conformation.

Destruction of Misfolded or Misassembled Proteins: ER-Associated Degradation

In the ER, proteins undergo a so-called quality control which ensures that only correctly folded proteins exit the ER. Consequently, misfolded proteins are extracted from the ER folding environment for disposal. This mode of degradation is referred to as ER-associated degradation. The destruction of proteins that undergo ER-associated degradation occurs in three major steps: (a) detection by the ER quality control machinery and targeting for ER-associated degradation, (b) transport across the ER membrane into the cytosol, and (c) ubiquitination and release in the cytosol for degradation by the proteasome. One model for misfolded protein recognition is that hydrophobic patches or sugar moieties, which remain exposed on the protein for an extended period of time, are recognized by chaperone proteins like PDI or by the CNX–CRT chaperone system. In a number of cases retrotranslocation appears to require reduction of disulfide bridges by PDI. Similarly, BiP association with substrates (eg, unassembled immunoglobulin light chains) can direct them to ER-associated degradation. If a protein remains in its unfolded state for an extended period of time, trimming of the $Man_8GlcNac_2$ occurs. The ER-resident lectin EDEM/Htm1p binds to the remaining mannose residues and assists the retrotranslocation. Proteins retrotranslocate to the cytosol through a protein-conducting channel, possibly formed by derlin and/or the Sec61 complex. On their emergence at the cytosolic face of the ER membrane, substrates targeted for degradation start undergoing ubiquitination. Tagged peptides are released into the cytosol in an ATP-dependent fashion, where they are degraded by the 26S proteasome.

The Unfolded Protein Response

The ER monitors the amount of unfolded protein in its lumen. When that number exceeds a certain threshold, ER sensors activate

a signal transduction pathway. The set of responses activated by this pathway is called the unfolded protein response (UPR). A number of cellular insults disrupt protein folding and cause unfolded protein accumulation in the ER lumen. The UPR is an adaptive response signaled through three ER-localized transmembrane proteins, PERK, IRE1, and ATF6, to limit the accumulation of unfolded protein by reducing protein synthesis, increasing the degradation of unfolded protein, and increasing the ER protein folding capacity. IRE1 is conserved in all eukaryotic cells and has protein kinase and endoribonuclease activities that, upon activation, mediate unconventional splicing of a 26-base intron from the XBP1 mRNA to produce a potent transcription factor. ATF6 is a basic leucine zipper-containing transcription factor that, upon accumulation of unfolded protein in the ER lumen, transits to the Golgi compartment, where it is cleaved to yield a cytosolic fragment that migrates to the nucleus to activate gene transcription. Finally, PERK-mediated phosphorylation of eIF2α attenuates general mRNA translation, however, paradoxically increasing translation of the transcription factor ATF4 mRNA to also induce transcription of UPR genes. If the UPR adaptive response is not sufficient to correct the protein folding defect, the cells enter apoptotic death. Activation of the UPR and defects in UPR are now known to be important factors that contribute to many disease processes ranging from metabolic disease, neurologic disease, infectious disease, and cancer.

Control of Exit From the ER

On achieving transport competence, proteins are granted access to higher-ordered membrane domains termed ER exit sites. At ER exit sites, membrane-bound and membrane-soluble proteins are concentrated into transport vesicles for trafficking to a network of smooth membranes called the ER–Golgi intermediate compartment (ERGIC; see Fig. 3–2). COPII complex, composed of *co*at *p*roteins, concentrate and package the protein cargo into vesicles. COPII binds to cargo molecules either directly, if they span the membrane, or through intermediate cargo receptors and then provides some of the force that causes vesicle budding, thereby linking cargo acquisition to vesiculation. Overall, the mechanisms involved in cargo recognition are poorly defined.

ER resident proteins are selectively sequestered in the ER both for the absence of export signals and for the presence of ER retention signals. Soluble luminal ER resident proteins are retained through a C-terminal ER tetrapeptide retention motif KDEL. Frequently, transmembrane proteins have either a C-terminal dilysine motif KKXX or an N-terminal diarginine motif XXRR, or variants thereof. However, it is more accurate to indicate ER localization signals as "retrieval motifs" because proteins bearing these signals can transiently escape from the ER into the ERGIC, from which they are returned to the ER through the retrograde vesicular transport (see Fig. 3–2).

For the KDEL motif of luminal ER proteins, a specific retrieval receptor has been identified, first in yeast and then in mammals. The KKXX motif has been shown to interact directly with the COPI-coated protein complex that is involved in retrograde transport from the ER to the Golgi. Retrograde transport also serves to replenish the vesicle components lost as a result of anterograde (forward) transport. In conclusion, selective protein exit from the ER is achieved by monitoring and regulating (a) transport competence of nascent proteins, (b) capture of cargo in transport vesicles, and (c) protein retention/retrieval for ER-localized proteins.

Receptor-Mediated Protein Transport in the Secretory Pathway

The LMAN1–MCFD2 complex is the only well-defined cargo receptor in mammalian cells. LMAN1, *L*ectin *man*nose-binding protein 1 (also referred to as ERGIC-53), is a transmembrane protein with a C-terminal cytoplasmic tail containing an endoplasmic reticulum (ER)-exit motif (two phenylalanine residues, FF). This motif allows the interaction of LMAN1 with the COPII-coat proteins. The luminal domain of LMAN1 recognizes mannose residues and binds MCFD2, a luminal protein, in a Ca^{2+}-dependent manner. Both LMAN1 and MFDC2 are required in a complex for the recruitment of coagulation factors V and VIII into specific cargo vesicles. Of interest, loss-of-function mutations in either *LMAN1* or *MCDF2* cause a bleeding disorder as a result of the combined deficiency of factors V and VIII. It has been shown that mutant forms of both LMAN1 and MFCD2 fail to recruit factor VIII into the vesicles. Thus, the deficiency of coagulation factors is caused by a block in their export from the ER. Interestingly, the LMAN1–MCFD2 complex appears to only be required for the secretion of factors V and VIII, as there are no significant reductions in any other plasma proteins.

Intra-Golgi Transport and Protein Processing

Organization of the Golgi Apparatus

The Golgi complex comprises a stack of flattened, membrane-bound cisternae that are highly dependent on microtubules for structural integrity. The stack of cisternae can be subdivided into three parts, referred to as *cis*, *medial*, and *trans*, with the *cis* and *trans* sides facing the ER and the plasma membrane, respectively (see Fig. 3–2). Both the *cis* and *trans* faces are associated with tubulovesicular bundles of membranes. The ERGIC comprises the bundle on the *cis* side of the Golgi stack and is the site where incoming proteins from the ER are sorted into those directed for anterograde or for retrograde transport. The tubulovesicular bundle at the *trans* side is the *trans*-Golgi network (TGN; see Fig. 3–2).

A major feature of the Golgi is polarity. The processing events are temporally and spatially ordered because the processing enzymes have a characteristic distribution across the Golgi stack. In the Golgi, other types of modifications also take place, for example, protein O-glycosylation, phosphorylation of oligosaccharides, and sulfation of tyrosines.

Retention of Resident Golgi Proteins

Extensive analysis has failed to reveal a clear retention motif enabling subdomain-specific retention of resident Golgi proteins. Two possible models have been proposed. One model is *retention by preferential interaction with membranes of optimal thickness*. It is based on the finding that the transmembrane domains of Golgi proteins are shorter than the transmembrane domains of plasma membrane proteins. These differences should allow a preferential interaction with the Golgi membrane lipid bilayer that is thinner than that of plasma membrane. The other model is *kin-recognition/oligomerization.* It postulates that proteins of a given subdomain of the Golgi membrane can aggregate into large detergent-insoluble oligomers as a way of minimizing lipid–protein contact. This would prevent the entry of proteins into the vesicles and thus their traffic to more distal cisternae. There is evidence in support of both models.

Protein Trafficking To and Through the Golgi Apparatus

Cargo proteins exit the ER in COPII-coated vesicles that enter the ERGIC and are ultimately delivered to the *cis*-Golgi either in vesicles or along extended tubules. However, the means whereby cargo proteins move across the Golgi complex from *cis* to *trans* remain controversial. Two models have been proposed. The vesicular transport

model contends that anterograde transport occurs in vesicles or tubules. The second suggests that there is a cisternal maturation. This alternative model proposes that Golgi cisternae are not fixed structures but move forward from the *cis* side to the *trans* side, generating an anterograde movement. As cisternae mature, resident Golgi proteins that belong to more *cis*-like cisternae must be selectively pinched off in vesicles and trafficked back to the *cis* side of the Golgi stack. This would occur by COPI-mediated retrograde vesicular transport (see Fig. 3–2). Although which of these models is correct is currently unclear, a majority of the experimental data supports the cisternal maturation model.

Sorting Events at the *Trans*-Golgi Network

Overview

The TGN is an important site of intracellular sorting, where proteins bound for lysosomes or regulated secretory vesicles are separated from those entering the constitutive pathway leading to the plasma membrane (see Fig. 3–2, pathways 6, 7, and 8). The secretion process is called exocytosis. The molecular basis for diversion of proteins into lysosomes and regulated secretory granules are described below.

Sorting Into Lysosomes

Lysosomes are acidic (pH of ~5.0–5.5), membrane-bound organelles containing numerous hydrolytic enzymes designed to degrade proteins, carbohydrates, and lipids. Soluble hydrolases are selectively marked for sorting into lysosomes by phosphorylation of their N-linked saccharides, which creates the mannose-6-phosphate (M6P) sorting signal. On arrival at the TGN, the modified hydrolase is bound by a cargo receptor, the M6P receptor (M6P-R), which delivers it first to a "late endosomal compartment," where the low pH releases the hydrolase from the M6P-R. Subsequently, the hydrolase is delivered to the lysosome, and the M6P-R is recycled to the TGN.

The motif responsible for targeting M6P-R to lysosomes is YSKV and is recognized by all three distinct adaptor protein (AP) complexes (AP-l, -2, and -3) that contribute to the delivery of cargo to lysosomes by linking cargo acquisition to vesiculation. Cargo recruitment occurs in a manner similar to that described for the COPI- and COPII-dependent vesicles, except that the cytosolic coat complex is clathrin. In addition to luminal hydrolases, lysosomes also contain a wide array of membrane proteins that are targeted to lysosomes via one of two consensus motifs: (a) YXXe, where X is any amino acid and e is any amino acid with a bulky hydrophobic side chain, and (b) a leucine-based motif (LL or LI). Trafficking of these membrane-bound proteins to lysosomes is indirect, proceeding first to late endosomes or the plasma membrane prior to their retrieval to lysosomes. Failure to accurately target lysosomal hydrolases underlies Hurler syndrome and I-cell disease.

Sorting Into Regulated Secretory Granules

In regulated secretion, proteins are condensed into stored secretory granules that are released to the plasma membrane after the cell has received an appropriate stimulus (see Fig. 3–2, pathway 7). After budding from TGN, the granule proteins are concentrated (up to 200-fold in some cases) by selective removal of extraneous contents from clathrin-coated vesicles. Mature secretory granules are thought to be stored in association with microtubules until the stimulation of a surface receptor triggers their exocytosis. One example of stimulus-induced exocytosis is the binding of a ligand to the T-cell antigen receptor complex on a cytotoxic T lymphocyte. Conjugation of a cytotoxic T cell with its target causes its microtubules and associated secretory granules to reorient toward the target cell. Subsequently, the granules are delivered along microtubules until they fuse with the plasma membrane, releasing their contents for lysis of the target cell. Following release of the granule contents, the granule membrane components are internalized and transported back to the TGN, where the granule can be refilled with cargo proteins.

Endocytic Traffic

Overview

Substances are imported from the cell exterior by a process termed *endocytosis* (see Fig. 3–2, pathway 9). Endocytosis also serves to recover the plasma membrane lipids and proteins that are lost by ongoing secretory activity. There are three types of endocytosis: (a) phagocytosis (cell eating), (b) pinocytosis (cell drinking), and (c) receptor-mediated endocytosis. Defects in endocytosis can underlie human diseases. For example, patients with familial hypercholesterolemia have elevated serum cholesterol because of mutations in the low-density lipoprotein receptor that prevents the endocytic uptake of low-density lipoprotein and its catabolism in lysosomes.

Phagocytosis

During *phagocytosis*, cells are able to ingest large particles (greater than 0.5 μm in diameter). Phagocytosis serves not only to engulf and destroy invading bacteria and fungi but also to clear cellular debris at wound sites and to dispose of aged erythrocytes. Primarily, specialized cells such as macrophages, neutrophils, and dendritic cells execute phagocytosis. Phagocytosis is triggered when specific receptors contact structural triggers on the particle, including bound antibodies, complement components as well as certain oligosaccharides. Then the polymerization of actin is stimulated, driving the extension of pseudopods, which surround the particle and engulf it in a vacuole called phagosome. The engulfed material is destroyed when the phagosome fuses with a lysosome, exposing the content to hydrolytic enzymes. In addition, phagocytosis is a means of "presenting" the pathogen's components to lymphocytes, thus eliciting an immune response.

Pinocytosis

Pinocytosis refers to the constitutive ingestion of fluid in small pinocytotic (endocytotic) vesicles (0.2 μm in diameter) and occurs in all cells. Following invagination and budding, the vesicle becomes part of the endosome system that is described below. The plasma membrane portion that is ingested returns later through exocytosis. In some cells, pinocytosis can result in turnover of the entire plasma membrane in less than 1 hour.

Receptor-Mediated Endocytosis

This is a means to import macromolecules from the extracellular fluid. More than 20 different receptors are internalized through this pathway. Some receptors are internalized continuously whereas others remain on the surface until a ligand is bound. In either case, the receptors slide laterally into coated pits that are indented regions of the plasma membrane surrounded by clathrin and pinch off to form clathrin-coated vesicles. The immediate destination of these vesicles is the endosome.

The endosome is part of a complex network of interrelated membranous vesicles and tubules termed the *endolysosomal system.* The endolysosomal system comprises four types of membrane-bound structures: early endosomes, late endosomes, recycling vesicles, and lysosomes. It is still a matter of debate whether these structures rep-

Influence of MHC-I and MHC-II Biosynthesis on Type of Antigen Presented

Peptide antigens are presented to T lymphocytes in association with either class I or class II major histocompatibility complexes (MHCs). Peptides presented by class I derive from endogenously synthesized proteins (or viruses), whereas those presented by class II derive from proteins found in the extracellular space. This results from differences in the intracellular trafficking of class I and class II MHC. Class I MHC molecules are held in the endoplasmic reticulum (ER) in association with molecular chaperones until they acquire a cytosolic peptide that is transported into the ER. In contrast, class II molecules are prevented from acquiring a peptide in the ER by an associated protein called invariant chain, which plugs the class II binding pocket. Moreover, invariant chain possesses sorting signals that divert class II molecules into the endosome–lysosome pathway, where proteolytic removal of invariant chain allows acquisition of peptides that were derived from degradation of material internalized by endocytosis. Thus, the respective roles of class I and class II molecules in presenting antigens to the immune system are dramatically influenced by their biosynthesis.

resent independent stable compartments or one structure matures into the next. The interior of the endosomes is acidic (pH ~6). Endocytosed material is ultimately delivered to the lysosome, presumably by fusion with late endosomes. Lysosomes are also used for digestion of obsolete parts of the cell in a process called autophagy.

During the formation of clathrin-coated vesicles, clathrin molecules do not recognize cargo receptors directly but rather through the adaptor proteins, which form an inner coat. The AP-2 components bind both clathrin and sorting signals present in the cytoplasmic tails of cargo receptors close to the plasma membrane. These internalization motifs are YXXϕ (where ϕ is a hydrophobic amino acid), as a most common motif, and the NPXY signal, which was first identified in the low-density lipoprotein receptor. For receptors that are internalized in response to ligand binding, the internalization signal may also be generated by a conformational change induced by the binding of the ligand. Through the specificity of the AP-2 complex, the capture of a unique set of cargo receptors is linked to vesiculation, resulting in concentration of the cargo. The coated pit pinches off from the plasma membrane by the action of a GTP-binding protein, dynamin, which forms a ring around the neck of each bud and contributes to vesicle formation. After release and shedding of the clathrin coat, the vesicle fuses with the early endosome compartment.

SPECIFICITY OF VESICULAR TARGETING

As described above, COPI- and COPII-coated vesicles transport material early in the secretory pathway whereas clathrin-coated vesicles transport material from the plasma membrane and Golgi. Coating proteins assemble at specific areas of the membrane in a process controlled by the coat-recruitment GTPases: Arf1 is responsible for the assembly of COPI coats and clathrin coats at Golgi membranes whereas Sar1p is responsible for COPII coat assembly at the ER membrane. Clathrin-coat assembly at the plasma membrane is also thought to involve a GTPase but its identity is unknown. These regulatory proteins also ensure that membrane traffic to and from an organelle are balanced.

After budding, vesicles are transported to their final destination by diffusion or motor-mediated transport along the cytoskeletal network (microtubules or actin). The molecular motors kinesin, dynein, and myosin have been implicated in this process. The vesicles undergo an uncoating process before fusion with the correct target membrane. Both transport vesicles and target membranes display surface markers that selectively recognize each other.

Three classes of proteins guide the selectivity of transport vesicle docking and fusion: (a) complementary sets of *v*esicles SNAREs, v-SNAREs (*s*oluble *N*SF *A*ssociation Protein *Re*ceptor), and *t*arget membrane SNAREs (t-SNAREs) that are crucial for the fusion; (b) a class of GTPases, called Rabs; and (c) protein complexes called tethers that, together with Rabs, facilitate the initial docking of the vesicles to the target membrane.

CONCLUSIONS

The mechanisms regulating protein synthesis, processing, degradation, and transport are under intense evaluation. Protein motifs and their cognate receptors have been identified for many intracellular sorting and processing reactions. Investigations are now directed to elucidate these processes at a molecular level by resolution of the three-dimensional structures of the proteins involved in protein processing and trafficking. The future challenge will be to find ways of exploiting this knowledge to intervene in the numerous disease states that result from errors in these processes.

CHAPTER 4

PROTEIN DEGRADATION IN CELLS

Stewart H. Lecker, Tomo Saric, and Alfred L. Goldberg

Nearly all proteins within cells and most in the extracellular space are in a state of continuous turnover, being synthesized from amino acids and then broken back down. Individual proteins in the nucleus and cytosol, as well as in the endoplasmic reticulum (ER) and mitochondria, are degraded at widely differing rates that vary from minutes for some regulatory enzymes or mutated polypeptides, to days or weeks for long-lived proteins, such as actin and myosin in skeletal muscle, and to months for hemoglobin in the red cell.

In eukaryotic cells, there are two principal systems for the complete degradation of proteins: the lysosomal system, where proteolysis occurs within membrane-enclosed vesicles, and the highly selective ubiquitin–proteasome pathway, which functions both in the cytosol and nucleus. These pathways involve very different enzymes and serve different functions in the cell. Proteolytic systems are also present in mitochondria for the degradation of organelles or proteins. One critical feature of these intracellular degradative systems is that they require metabolic energy, unlike the typical proteases that function in the extracellular space. These energy-dependent steps help ensure exquisite selectivity and allow precise regulation of the proteolytic enzymes. Other proteolytic enzymes also exist in the cytosol. A set of Ca^{2+}-activated cysteine proteases termed *calpains* appear to be activated when cell membranes are injured and cytosolic Ca^{2+} rises (eg, in muscular dystrophy). They play an important role in tissue injury, necrosis, and autolysis. Another important family of cytosolic proteases is the caspases that cleave proteins following aspartic acid residues. These enzymes, which are also cysteine proteases, are critical in the destruction of cell constituents during apoptosis. It remains unclear exactly what role the calpains or caspases play, if any, in the continuous degradation of proteins in normal cells.

WHY ARE PROTEINS CONTINUALLY TURNING OVER?

Because cells must use significant amounts of energy for new RNA and protein synthesis and protein folding (see Chapter 3), the continual destruction of cell proteins might appear to be highly wasteful. However, this process serves multiple functions that are essential for life:

1. The degradation of intracellular proteins is a highly selective and tightly regulated process. The rapid removal of many regulatory proteins (transcription factors, oncogenes, tumor suppressors) and many key rate-limiting enzymes is essential for maintaining cellular homeostasis (Table 4–1). Unlike most regulatory mechanisms, peptide bond cleavage is an irreversible process, and proteases therefore act as unidirectional biological switches. The only way that nondividing or slowly dividing cells can rapidly reduce the level of a particular protein is by proteolytic degradation, because decreases in the synthesis of a protein will not lead to a decreased protein content unless the protein itself turns over rapidly. Thus, continual protein degradation permits cells to adapt to changes in the cellular environment. For example, adaptation of the liver to fasting involves net degradation of enzymes for glycogen production, whereas synthesis of enzymes for gluconeogenesis rises.
2. Also of enormous importance in cellular regulation is that protein half-lives can vary dramatically under different conditions. Probably the most important example is the regulation of the cell cycle. Each transition between phases of the cell cycle involves programmed destruction of one of the cyclins, whose presence controls the activity of critical kinases, or of key kinase inhibitory proteins, CKIs, which prevent progression through the mitotic or meiotic cycles.

   In many cases, these degradative processes are triggered by phosphorylation of key residues, which marks them for selective degradation. Another medically important example of such regulation is in the activation of the inflammatory response. In response to the inflammatory mediators TNFα or lipopolysaccharide, the inhibitor of NFκB, IκB, is phosphorylated, leading to its rapid destruction by the ubiquitin–proteasome pathway, which allows NFκB to enter the nucleus and trigger the inflammatory response.

   In these cases, cellular responses are triggered by the conversion of a long-lived protein to one with a short half-life. In addition, several important regulatory responses proceed through stabilization of a normally short-lived protein. For example, in response to hypoxia, the very rapidly degraded transcription factor, HIF-1α, becomes stable and transcribes genes for erythropoietin, VEGF, and glycolytic enzymes. As these various examples suggest, degradation of key proteins by the ubiquitin–proteasome pathway probably regulates most cellular pathways.
3. Protein breakdown also functions as a quality control mechanism that selectively removes abnormal misfolded proteins. Such proteins may arise through mutations, biosynthetic errors (eg, premature terminations), postsynthetic damage (eg, by oxygen radicals), failure to form multienzyme complexes or to bind key cofactors, or failure of normal folding and assembly (which may be a common event in the cytosol or ER) (see Chapter 3 by Kaufman). Some of the clearest examples of protein misfolding leading to disease are the hemoglobinopathies. Some "unstable hemoglobins" demonstrate reduced heme binding and result in lower (or no) oxygen-carrying capacity. This failure of the mutant globins to fold generally leads to intracellular denaturation and rapid destruction often within minutes of synthesis. In thalassemia, mutations that reduce the levels or association of globin-α and globin-β chains lead to rapid degradation of the unassociated chains tend to be degraded in reticulocytes. Their selective degradation is noteworthy because normal hemoglobin is among the most stable intracellular proteins, lasting the life span of the red cell (in humans, ~90 days).

   The failure to degrade misfolded proteins in the cytosol and nucleus seems to account for the accumulation of intracellular inclusions in various neurodegenerative diseases (eg, Lewy bodies in Parkinson disease, τ inclusions in Alzheimer disease). Of particular medical interest in several diseases is the quality control system (termed ERAD) that catalyzes the extraction of misfolded and mutant proteins from the ER for degradation in the cytosol (see Endoplasmie Reticulum-Associated Degradation).
4. Proteins in cells also constitute a reservoir of amino acids that can be mobilized under poor nutritional conditions for generation of new proteins or for energy metabolism. When deprived of essential amino acids, all cells show a general acceleration of protein degradation, but in mammals, skeletal muscle comprises the primary mobilization pool of amino acids, and the net degradation of muscle proteins in fasting or disease provides amino acids that can be used for hepatic gluconeogenesis, direct oxidation, synthesis of acute-phase proteins, or wound repair (Muscle Protein Breakdown and Cachexia).

HIF1—controls response to hypoxia (VEGF, erythropoietin)
STAT proteins—control response to interferon
β-Catenins—critical in many cancers

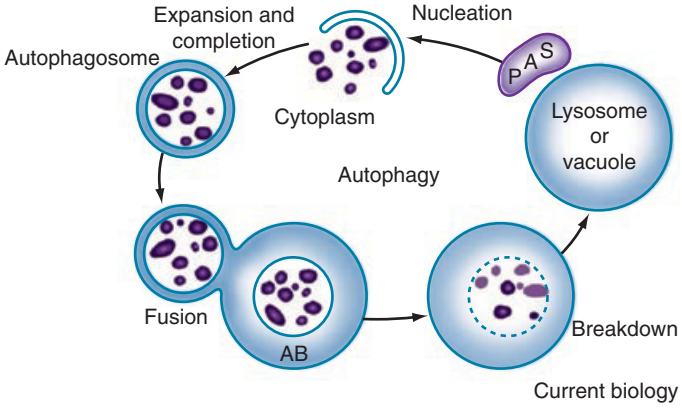

Figure 4–2 Formation of autophagic vacuoles.

5. The continuous degradation of cellular constituents is also critical for recognition of foreign proteins by the immune system. Immune surveillance against intracellular pathogens (eg, viruses and certain bacteria) or pathogens and toxins in the extracellular space (eg, bacteria) is dependent on the continual production of peptide fragments generated from cell proteins by the ubiquitin–proteasome pathway. These antigenic peptides are displayed on surface major histocompatibility complex (MHC) class I molecules, and the appearance of nonnative peptide (eg, of viral origins) triggers cytolytic T-cell responses (see below), whereas the breakdown of bacteria or viruses in lysosomes leads to the fragments' being displayed on surface MHC class II molecules, where they elicit antibody responses (Fig. 4–1).

ENDOCYTIC–LYSOSOMAL PATHWAY

Lysosomes are single membrane-bound organelles found in the cytoplasm. They were discovered by Christian de Duve and coworkers in the mid-1950s and are found in all eukaryotic cells except mature red blood cells. Most extracellular proteins (eg, plasma proteins or cytokines) taken up by receptor-mediated endocytosis are degraded in lysosomes, as are phagocytosed cells (eg, bacteria or red cells in macrophages), and most membrane proteins in all cells. In addition, lysosomes are the sites of degradation of cellular organelles, for example, mitochondria, and cytoplasmic proteins in the process of autophagy that occurs at a low rate in all eukaryotic cells but is of increased importance upon nutrient deprivation (Fig. 4–2). In this process, bits of the cytosol become surrounded by a limiting membrane to form an autophagosome or autophagic vacuole. The outer membrane of this autophagosome then fuses with the lysosome to deliver the inner vesicle to the lysosomal lumen. This process involves a highly conserved set of proteins that covalently modify membranes to promote vacuole formation. Degradation of the sequestered organelles and cytosolic material generates nucleotides, amino acids, and free fatty acids that are reutilized in macromolecular synthesis or are oxidized for energy. Autophagy is rapidly induced in cells lacking nutrients or growth factors (eg, during fasting or low-insulin states) and allows cells to rid themselves of damaged organelles or viruses (eg, during oxidative stress, infection, and accumulation of protein

aggregates). The kinase, mTOR (the target of the immunosuppression drug, rapamycin), is the major inhibitory factor that rapidly turns off autophagy during nutrient abundance and in cells activated by the IGF-1–insulin–PI-3 kinase–AKT pathway. The endocytic–lysosomal pathway also plays an important role in destroying receptor–ligase complexes (receptor "downregulation"), which helps reduce cellular sensitivity to hormones or cytokines. In addition, in specialized antigen-presenting cells (macrophages, dendritic cells, and B cells), some peptides derived from the breakdown of extracellular proteins escape complete destruction and are bound in late endosomes by major histocompatibility (MHC) class II molecules. These complexes are transported to the cell surface for presentation to T helper cells responsible for generation of humoral immune responses against nonnative proteins, for example, ones from pathogens.

There are at least 17 gene products or atg genes involved in autophagy and several are essential for viability. They encode proteins needed for the generation, maturation, and recycling of autophagosomes. These proteins are composed of four functional groups, including a protein serine–threonine kinase complex that responds to upstream signals such as TOR kinase, a lipid kinase signaling complex that mediates vesicle nucleation, two novel ubiquitin-like conjugation pathways that mediate vesicle expansion (the Atg8/LC-3 and Atg12 systems), and a recycling pathway that mediates the disassembly of Atg proteins from mature autophagosomes.

Substrates degraded in lysosomes are generally delivered by lysosomal fusion with other intracellular vesicles that are formed by endocytosis or autophagy. Endocytosis refers to the process of uptake of extracellular material or membrane proteins by invagination of the cell membrane, followed by formation of vesicles inside the cell. Before these vesicles reach the lysosomes (pH 4.5–5.0), ingested material moves from the less acidic early endosomes (pH 6.0–6.5) to the more acidic late endosomes (pH 5.0–6.0). There are three major forms of endocytosis: (a) receptor-mediated endocytosis (the specific uptake of cell surface receptors after they bind their ligands), (b) pinocytosis (the ingestion of extracellular liquid with its solute molecules), and (c) phagocytosis (the engulfing of cellular materials, including whole bacteria, apoptotic bodies, or blood cells by specialized cells such as neutrophils or macrophages). Pinocytosis and phagocytosis are nonselective bulk processes, but receptor-mediated endocytosis is a highly specific, regulated cellular process that is used, for example, by most cells for nutritional purposes to take up proteins or protein complexes (eg, lipids bound to lipoproteins, Fe^{2+} bound to transferrin), to reduce (downregulate) the levels of surface receptors after they are occupied by ligands (insulin-receptor downregulation in type II diabetes), or to internalize antigens using antibodies on the cell surface as receptors.

LYSOSOMAL PROTEOLYSIS

Lysosomes contain at least 50 different hydrolytic enzymes, which catalyze the breakdown of proteins, nucleic acids, carbohydrates, and lipids into their components. It is important that lysosomal hydrolases normally do not escape into the cytoplasm, and their isolation in this vesicular compartment is essential for protecting cells from nonspecific degradation of key cell constituents. However, during necrotic cell death, lysosomes release their contents, which helps destroy cellular constituents. Release of lysosomal enzymes outside of cells contributes to severe inflammation and the symptoms of some diseases (eg, gout) and may facilitate tumor metastases and invasiveness. Most lysosomal enzymes are optimally active at an acidic pH of 4 to 6, and the pH within this organelle is maintained acidic by a membrane hydrogen ion pump (a proton-ATPase). Thus upon release or breakage of lysosomes, these enzymes are not as destructive as within the lysosomes. Lysosomal proteases are traditionally called cathepsins, and most belong to the cysteine protease family. The most abundant lysosomal proteases are cathepsins D and L (endopeptidases) and cathepsins B and H (exopeptidases), but there are well over a dozen distinct cathepsins. The acidic milieu in lysosomes not only keeps lysosomal enzymes at their most active state, but it also helps denature protein substrates, which enhances their susceptibility to proteolytic digestion. Once the protein substrates are degraded, the products of their digestion are transported across the membrane into the cytosol, where they are further metabolized. The lack of various specific lysosomal hydrolases are associated with the accumulation of nondigested substrates in the organelle and cell enlargement, as occurs in Gaucher disease, an adult and pediatric inherited disease most common in Ashkenazic Jewish families.

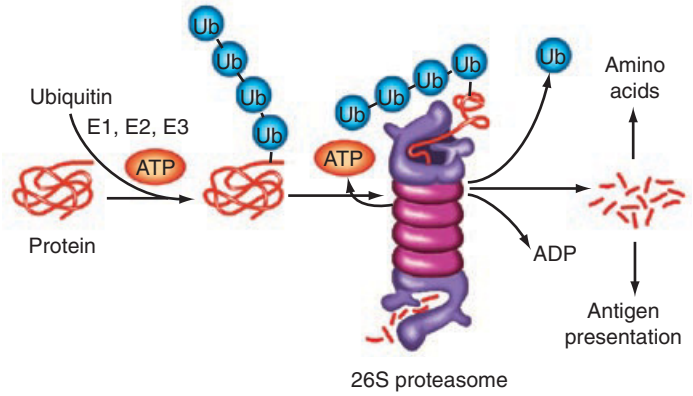

Figure 4–3 The ubiquitin–proteasome pathway.

THE UBIQUITIN–PROTEASOME PATHWAY

Most cytosolic and nuclear proteins are degraded by the highly selective ubiquitin–proteasome pathway (Fig. 4–3). This system catalyzes the breakdown of short-lived proteins that regulate a wide variety of essential cellular processes, ranging from cell cycle progression to signal transduction and gene transcription, as well as most normal long-lived proteins, which comprise the bulk of proteins in cells. In addition, it catalyzes the rapid elimination of misfolded or denatured proteins, which are continuously produced as a result of mutations, biosynthetic errors, failure of successful folding, and postsynthetic damage. The discovery of the ubiquitin–proteasome pathway resulted from the finding that the rapid breakdown of such misfolded proteins was nonlysosomal and was an ATP-dependent process, which was surprising because peptide bond cleavage per se should not require energy. Biochemical dissection of this pathway in the 1980s revealed that it consists of two ATP-dependent processes: the covalent conjugation of a small protein ubiquitin to proteins to mark them for degradation, and the hydrolysis of ubiquitinated proteins by the very large ATP-dependent proteolytic machine, the 26S proteasome (S refers to the rate of sedimentation in the ultracentrifuge in Svedberg units). The ubiquitination step provides exquisite specificity to the degradation process and regulates cellular responses. For their discovery of ubiquitin and the biochemistry of its conjugation to substrate proteins, Avram Hershko, Aaron Ciechanover, and Irwin Rose were awarded the Nobel Prize in Chemistry in 2004.

UBIQUITIN CONJUGATION

Formation of Polyubiquitin Chains

To be degraded by 26S proteasomes, most intracellular proteins must be first covalently linked to a chain of ubiquitin molecules. Ubiquitin is a 76-residue globular protein, and unlike typical peptide bonds formed on the ribosome, ubiquitin is linked to proteins via isopeptide linkages, where the C-terminal carboxyl group of ubiquitin forms an amide bond with the ε-amino group of lysine residues. Formation of a ubiquitin chain ensures that only selected substrates are degraded in a regulated manner and prevents the uncontrolled degradation of

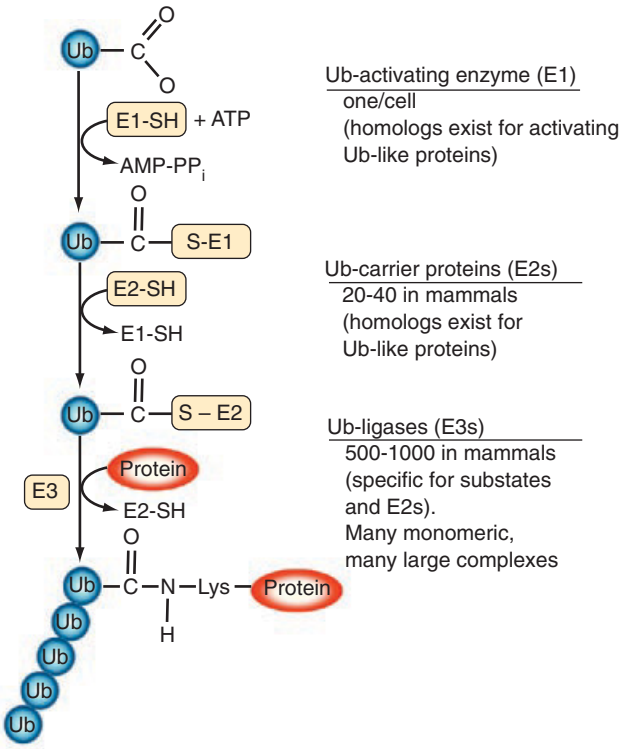

Figure 4–4 Ubiquitin conjugation to protein substrates.

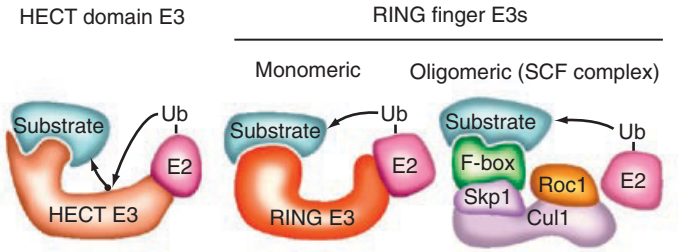

Figure 4–5 Ubiquitin protein ligases or E3s. HECT, homologous to E6-AP carboxy terminus.

other cellular proteins. Ubiquitin can also be conjugated to proteins as a monomer (rather than as a typical ubiquitin chain). This type of tagging can trigger cell surface protein internalization and targeting to the lysosome and can regulate transcription, as with the mono-ubiquitination of histones. Ubiquitin conjugation to proteins and the formation of polyubiquitin chains is mediated by the sequential action of three types of enzymes (Fig. 4–4). In this ATP-dependent process, the ubiquitin-activating enzyme (E1) initially forms a highly reactive thiolester linkage between the C terminus of ubiquitin and the thiol group in the active site of the E1. The activated ubiquitin is then transferred to a sulfhydryl group on one of the cell's 30 to 40 ubiquitin-conjugating enzymes (ubiquitin-carrier proteins or E2s).

The exquisite specificity of protein degradation is due to the large variety of the ubiquitin-protein ligases or E3 enzymes. The human genome contains between 500 and 1000 different E3s, most of which act on a small number of substrates, thus providing enormous specificity to the ubiquitination process. E3s catalyze the transfer of the activated ubiquitin from a specific E2 initially to a lysine on the target protein and subsequently to lysines present in the preceding ubiquitin, yielding a substrate-anchored chain of ubiquitin molecules. A single E2 may function with multiple E3s and a single E3 with multiple E2s to provide further specificity in a combinatorial fashion. Generally, E3s fall into two broad structural classes based on their enzymatic mechanism; some contain HECT (homologous to E6-AP carboxy terminus) domains but most catalyze ubiquitination through their RING finger domains (Fig. 4–5). Although many RING finger E3s are small monomeric proteins, many are large multisubunit complexes.

HECT domain proteins are large monomeric E3s that consist of two functionally distinct domains. The C-terminal HECT domain accepts the activated ubiquitin from the E2, by forming a thiolester linkage with ubiquitin, enabling it to be transferred to the substrate. HECT-domain E3s directly bind activated ubiquitin and are actual components of the enzymatic conjugation cascade. The prototypical member of this family is the E6-associated protein (E6AP). Lack of this enzyme causes Angelman syndrome, an inherited neurologic disorder, but E6AP is also utilized by oncogenic strains of human papilloma virus for the destruction of host p53 tumor suppressor protein.

The vast majority of E3s contain RING finger domains, which are 40- to 60-residue zinc-binding motifs that are rich in cysteine and histidine residues and facilitate transfer of the activated ubiquitin to the substrate. These E3s serve as scaffolds that bring the substrate and the E2 into close proximity but, unlike the HECT E3s, do not covalently bind the activated ubiquitin. Monomeric RING finger E3s include the oncoprotein Mdm2, a physiological regulator of p53 stability in normal cells, and c-Cbl, which catalyzes ubiquitination of certain cell surface receptors and tyrosine, and cIAP and XIAP inhibitors of apoptosis that function as oncogenes. Two E3s that are important in the processes of muscle atrophy and cachexia, Muscle Ring Finger-1 (MuRF-1) and E3α, belong to this group; E3α was the first of the E3s to be biochemically identified and recognizes protein substrates on the basis of their N-terminal amino acid. Proteins beginning with large basic or hydrophobic residues are targeted for degradation by E3α. This "N-end rule" pathway seems to be important in the destruction of protein fragments, for example, cohesins during the cell cycle, certain signaling molecules, and the enhanced protein degradation in atrophying muscle.

Another group of enzymes with ubiquitin ligase activity are small monomeric proteins that contain anomalous RING finger motifs termed *U boxes*. One important U-box-domain protein is CHIP, which catalyzes the removal of abnormally folded proteins, for example, misfolded CFTR in cystic fibrosis, mutated tau protein, and polyglutamine repeat proteins present in several neurodegenerative diseases (eg, Huntington disease). Degradation of these abnormal proteins begins when they are bound by specific molecular chaperones, Hsp70 (or its homolog, Hsc70) and Hsp90, which associate with misfolded protein domains triggering selective ubiquitination. This binding of molecular chaperones to the unfolded domains helps prevent irreversible aggregation and promotes refolding. However, if refolding is impossible (as occurs with many mutant proteins), binding to the Hsp70 or Hsp90 recruits CHIP, leading to the ubiquitination and degradation of the potentially toxic polypeptides. Interestingly, in conditions where cells accumulate large amounts of misfolded or damaged proteins (eg, during heat shock or oxidative stress), they adapt by expressing large amounts of these heat-shock proteins, ubiquitin, and certain ubiquitination enzymes. This transcriptional response (termed the *heat-shock response*) protects cells against many toxic insults and disease processes.

Other RING finger E3s contain many subunits that serve as scaffolds to bring together the substrate and an E2 conjugated to the activated ubiquitin. The largest (1.5 MDa), most complex E3 is the anaphase-promoting complex, which is essential for the ubiquitination of mitotic cyclins and other proteins involved in progression of the cell cycle. A very large group of E3s is the cullin–RING ubiquitin ligase family. The basic core of these E3s is the elongated, rigid cullin subunit. At one end of these subunits is the RING component (typically Rbx1/Roc1), which binds the E2, whereas at the other end, the substrate-interacting protein is bound, generally through an additional adaptor protein. Because of the large number of cullins and substrate-binding subunits, the same multisubunit organization can recognize and ubiquitinate a large number of diverse proteins.

The best-understood group of cullin–RING ligases are the medically important Skp1–Cul1–F-box (SCF) complexes. The F-box

protein is the subunit that binds the substrate, but it also binds to an adaptor, Skp1, through an approximately 45-amino acid F-Box motif. Substrates of SCF E3s include many key molecules that control inflammation and cell growth (eg, IκB, NFκB, β-catenin) and cell cycle-induced proteins (eg, the cyclin-dependent kinase inhibitor p27Kip1). In many cases, phosphorylation leads to the binding of substrate to the F-box subunit and subsequent ubiquitin conjugation. Regulated expression of F-box proteins can cause tissue- and disease-specific ubiquitin conjugation of target proteins. Thus the onset of the inflammatory and most immune responses involve the phosphorylation of the NFκB inhibitor, IκB, which leads to its rapid ubiquitination by the SCF family member β-TRCP and destruction in the proteasome. This step then allows NFκB to enter the nucleus and transcribe key inflammatory mediators (IL-1, Il-6, TNFα, iNOS, etc).

Other types of protein modifications can also stimulate ubiquitination. For example, under normal oxygen tension in cells, the key transcription factor, HIF-1α, which triggers expression of angiogenic genes (VEGF), erythropoietin, and glycolytic enzymes, is very short-lived. Under these conditions, a proline in HIF-1α is hydroxylated by molecular oxygen, and this single change to a hydroxyproline is recognized by the VBC–ubiquitin ligase, leading to its ubiquitination and its proteasomal destruction. The subunit in this E3 that recognizes the oxygen-modified HIF-1α is the von Hippel–Lindau (VHL) protein, and VHL mutations are associated with highly vascular tumors in the kidney, presumably due at least in part to the presence of stable, active HIF-1α. When intracellular oxygen tension falls, the HIF-1α is not modified, not recognized by VHL, and is not degraded. This response is quite important in many human cancers as it promotes angiogenesis and expression of glycolytic enzymes (a hallmark of most cancers). The VBC complex is another cullin–RING ligase, made up of Cul2 and a substrate-interacting domain made up of the VHL protein and the adaptors elonginB and elonginC. Other protein modifications that have been shown to recruit E3s include glycosylation, nitrosylation, and deacetylation. Thus, substrate modification adds another layer of regulation to the ubiquitin–proteasome pathway by integrating cell signaling and cell metabolism with the ubiquitin-conjugation degradation machinery.

DEUBIQUITINATION

Ubiquitin conjugation to cellular proteins can be reversed by deubiquitinating enzymes, which are all cysteine proteases that catalyze the disassembly of ubiquitin conjugates. Several such isopeptidases are found in the 26S proteasome, and during degradation of ubiquitin-conjugated proteins they play important roles in recycling monomeric ubiquitin. There are also many cytosolic deubiquitinating enzymes. Certain deubiquitinating enzymes also probably serve as proofreading systems, which ensures that no erroneous or inappropriate ubiquitination of substrates takes place. However, there is growing evidence that specific isopeptidases function to regulate key enzymes and to prevent their degradation (eg, isopeptidases' control of p53 longevity in the cell) by the opposing actions of E3s. In fact, mutations in certain deubiquitinating enzymes can cause neuronal degeneration and may contribute to the occurrence of cancer.

PROTEIN DEGRADATION

The 26S Proteasome

The rapid degradation of ubiquitinated proteins is catalyzed by the 26S proteasome (Fig. 4–6). This structure is found in the nucleus and the cytosol of all cells and constitutes approximately 1% to 2% of a cell's mass. The 26S particle is composed of approximately 50 subunits and is thus approximately 50 to 100 times larger than the typical proteases that function in the extracellular environment (eg, in digestion or blood clotting). Unlike such enzymes, the proteasome

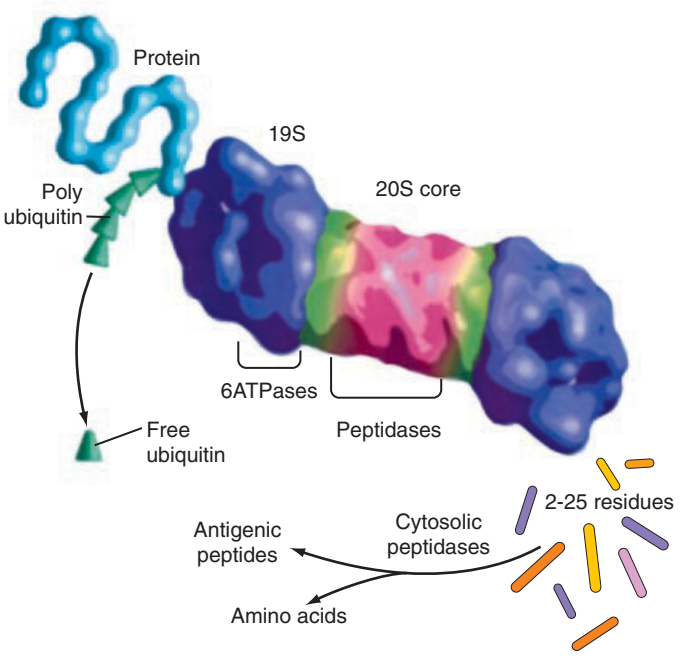

Figure 4–6 Degradation of ubiquitinated proteins by the 26S proteasome.

is a very complex proteolytic machine in which protein degradation is linked to ATP hydrolysis and substrate deubiquitination. The 26S complex is composed of the hollow cylindrical 20S proteasome, within which proteins are cleaved to small fragments, plus a 19S regulatory particle at either or both of its ends. Substrate entry is a complex ATP-dependent process catalyzed by the 19S particle. This architecture evolved to isolate proteolysis within a nano-sized compartment and thus to prevent the nonspecific destruction of cell proteins. One can view protein ubiquitination and the functioning of the 19S particle as mechanisms to ensure that proteolysis is exquisitely selective and that only certain particles and degraded molecules get translocated into the 20S.

The 20S Core Particle: The 20S proteasome is composed of four stacked rings, each containing seven homologous subunits. There are two identical outer α rings and two identical inner β rings. Three of the subunits in each inner β ring contain proteolytic active sites. The outer α rings surround the narrow openings into the 20S particle at either end, through which substrates can enter into the inner proteolytic chamber. These openings are tightly gated, and gate opening and substrate entry occur upon the association of α rings with the 19S regulatory particle. The proteasomal active sites in the β rings are confined to the interior of the cylinder where proteins are cleaved to small peptides 2 to 24 residues long. Each of the three active subunits has a different substrate preference: the "chymotrypsin-like" site cleaves preferentially after large hydrophobic residues, the "trypsin-like" site after basic amino acids, and the "caspase-like" site after acidic residues. The active-site nucleophile of these sites is the threonine hydroxyl group at the amino terminus of the β subunits.

19S Regulatory Particle: The 19S particle consists of at least 18 different subunits and associates with α rings on one or both ends of the 20S proteasome. Two functionally different substructures of this complex have been distinguished: the base and the lid. The base, which touches the α rings of the 20S core particle, contains eight polypeptides, including six ATPases in a ring-like configuration. These ATPases bind substrates and use the energy of the ATP to unfold globular protein substrates. In the ATP-bound state, these ATPases open the gate in α rings and promote rapid translocation of the unfolded substrates into the 20S core particle. The lid contains eight non-ATPase subunits, including a ubiquitin-binding subunit and two deubiquitinating enzymes. Although the lid is required for degradation of ubiquitinated proteins, much remains to be learned

about the mechanisms by which these different subunits function in recognition, binding, and disassembly of the ubiquitin chain.

Mechanism of Protein Degradation

Upon binding of the polyubiquitinated substrate to the proteasome, the substrate is unfolded in an energy-dependent manner by the action of ATPases localized in the base of the 19S particle. Conformational changes induced by ATP binding trigger opening of the gate in α rings followed by translocation of the unfolded substrate into the inner chamber of the proteasome. Successful translocation of the substrate requires removal and disassembly of the attached polyubiquitin chain by deubiquitinating enzymes attached to the 19S particle. Translocation of the substrate can occur from either its amino or carboxyl terminus, or even internally by the process in which a polypeptide loop enters the axial channel to permit initial endoproteolytic cleavage. Unlike traditional proteases, the proteasome does not simply cleave a protein and release the partially digested fragments; on the contrary, a protein substrate, once bound by the proteasome, is cut repeatedly by the six active sites until small peptides 3 to 25 residues in length are generated. This behavior ensures that partially digested proteins do not accumulate within cells. However, in several instances, the 26S proteasome degrades substrates only partially, yielding biologically active proteins, as in the generation of the p50 subunit of the transcription factor NFκB from the larger 105-kD precursor, and in the processing of some membrane-bound transcription factors. The complete process of degradation of one substrate molecule requires several hundred molecules of ATP and is completed generally in seconds (<1 min), depending on the size of the substrate. Although generally substrates must be ubiquitinated in order to be rapidly degraded, 26S proteasomes can degrade certain polypeptides in a ubiquitin-independent manner, though the physiological importance of this ubiquitin-independent degradation remains uncertain.

PROTEASOME INHIBITORS AND CANCER THERAPY

Because the proteasome's proteolytic mechanism is novel, highly specific inhibitors of its active sites have been synthesized or are found as microbial products. These inhibitors (eg, MG132, lactacystin, epoxymycin) have been widely used as research tools that have enabled investigators to discover many of the key functions of the ubiquitin–proteasome pathway. Proteasome inhibitors were initially synthesized in an attempt to develop agents that could block the excessive breakdown of muscle proteins in various cachectic states, but it was discovered that they could also block the activation of NFκB, the critical transcription factor that mediates production of many inflammatory cytokines. NFκB also has important antiapoptotic roles, which could block the death of cancer cells. Subsequently, inhibition of the proteasome was found to induce apoptosis, especially in neoplastic cells. One synthetic inhibitor, bortezomib (Velcade, PS-341), has now emerged as an important new treatment for hematologic malignancies. Bortezomib is a peptide boronate inhibitor widely used for the treatment of multiple myeloma and for mantle cell lymphoma. This agent is a potent inhibitor of the 20S proteasome's chymotrypsin-like active sites and, at therapeutic doses, it spares the other two types of active sites, thus allowing significant proteasomal protein degradation, but at a reduced rate.

Surprisingly, Bortezomib induces apoptosis in myeloma cells, even when protein degradation by the proteasome in these cells is only partially compromised. Although NFκB is antiapoptotic in all cells, myeloma cells are particularly dependent upon NFκB for production of essential autocrine growth factors (especially IL-6). In addition, plasma cells and myeloma cells require high expression of the ER chaperone system, termed the *unfolded protein response* (see Chapter by Kaufman) because they synthesize large quantities of immunoglobins. Exposure of the myeloma cells to proteasome inhibitors augments this stress response by blocking the degradation of abnormal immunoglobins by the ERAD pathway (Endoplasmic Reticulum-Associated Degradation), which activates JNK kinase and causes apoptosis. Bortezomib in combination with other chemotherapeutic agents are being currently tested against a broad range of other malignancies. Surprisingly, proteasome inhibitors also have benefits in animal models of stroke and various inflammatory disease models. The compounds appear to reduce postischemia adhesion of macrophages to ischemic endothelia and reperfusion injury. Again, the mechanism of the inhibitors seems to largely involve inhibiting the activation of NFκB.

THE PROTEASOME AND ANTIGENIC PRESENTATION

In addition to its essential roles in regulating cell growth and metabolism and in the elimination of misfolded proteins, in higher vertebrates the ubiquitin–proteasome pathway and the lysosomal–endosomal system also serve critical roles as information-gathering mechanisms for the immune system (see Fig. 4–1). The continual breakdown of intracellular proteins including foreign proteins that arise during viral or bacterial infection or with cancer, allows the immune system to screen for nonnative proteins within cells. Although the great majority of peptides generated by the proteasome during breakdown of intracellular proteins are digested within seconds to free amino acids, some escape this fate and are transported into the ER. Here, they bind to nascent MHC class I molecules and are delivered to the cell surface for presentation to cytotoxic $CD8^+$ lymphocytes. If nonnative epitopes (eg, ones derived from viruses or intracellular parasites) are presented on the cell surface, the presenting cells are quickly killed by cytotoxic ($CD8^+$) T cells. Whereas the presence of abnormal polypeptides within cells elicits cytolytic responses, foreign proteins in the extracellular space elicit antibody production. The degradation of such proteins by the endosomal–lysosomal system generates the antigenic peptides that are displayed on surface MHC class II molecules, are recognized by circulating $CD4^+$ lymphocytes, and trigger production of specific antibodies. Thus, both arms of the immune system respond to peptide fragments generated by the cell's two main proteolytic systems and are presented on surface MHC molecules.

To bind to most MHC class I molecules, antigenic peptides need to be 8 to 9 residues long; however, at least 70% to 80% of proteasome products are shorter than that length. Proteasome products longer than 8 to 9 residues (ie, with additional amino acids on their amino termini) can also be presented on MHC class I molecules after trimming in the ER. Peptides are taken up into the ER by a specific ATP-dependent peptide transporter, called TAP. Although some peptides arrive in the ER at the optimal length to bind directly to the MHC class I molecules, most contain additional N-terminal residues that are clipped off by the ER aminopeptidase 1 (ERAP1). This enzyme has the unusual ability to trim extra amino acids off the longer precursors, stopping at 8 to 9 residues, the precise length for binding to MHC molecules.

Several proteasome adaptations that enhance the efficiency of antigen presentation are evident in cells of the immune system (splenocytes, dendritic cells, or thymocytes), and in most other cells in inflammatory states. In response to the immune modifier, γ-interferon, cells express novel types of proteasomes, termed *immunoproteasomes*, that play a major role in modulating MHC class I antigen presentation. The immunoproteasomes differ because they contain three novel β subunits with peptidase activity that replace the normal β subunits containing the active sites. These specialized subunits exhibit different specificities that enable them to cleave proteins in distinct factions, so that more of the products have the correct features (eg, hydrophobic C-terminal residues) for binding to MHC class I molecules. In addition, interferon-γ induces a special proteasome-activating complex, PA28, that binds to one end of the 20S proteasome and forms a hybrid 26S particle that has a 19S complex at the other end. These hybrid particles degrade ubiquitinated proteins at normal rates, but cleave them differently, generating an even higher fraction of peptides capable of serving as antigenic precursors.

At the same time, interferon-γ can cause cells to express higher amounts of TAP (transporter associated with antigen processing), ERAP1, and MHC molecules. Presumably, antigen processing by these systems normally function well below maximal levels until activation of host's defenses is necessary. On the other hand, a number of viruses (eg, herpesviruses) have evolved sophisticated mechanisms to escape immune detection by inhibiting the uptake of proteasome products into the ER by the TAP or by promoting the degradation of MHC class I molecules from the cell surface. Interferon-γ also stimulates the lysosomal generation of antigenic peptides presented on MHC class II molecules. Thus, these two arms of the immune system increase the efficiency of immune surveillance by adaptation of the cells' two proteolytic systems.

ENDOPLASMIC RETICULUM-ASSOCIATED DEGRADATION

Newly synthesized proteins destined for secretions are translocated into the lumen of the ER and if destined to serve as components of the surface membrane, they are incorporated directly into the ER membrane. The ER contains a large set of molecular chaperones and enzymes that assist newly synthesized proteins and glycoproteins in attaining their final conformations (see Chapter 3), but sometimes, this maturation process fails, or mutations prevent proper folding. Such misfolded proteins are efficiently removed from the ER so as not to form potentially toxic aggregates by a disposal process, often called ER-associated degradation (ERAD). In this process, the misfolded proteins are retrotranslocated from the ER back into the cytosol, where they are ubiquitinated, by ER-associated ubiquitin ligases and degraded by 26S proteasomes. This export is necessary because the ER does not contain proteolytic enzymes for protein degradation. In a variety of human diseases, including cystic fibrosis and α-antitrypsin deficiency, the mutant proteins are rapidly digested by this process. ERAD is also used by some viruses (eg, cytomegalovirus) to downregulate MHC class I molecules in the ER as a means to block antigen presentation and escape the detection by the immune system. In addition, the ERAD pathway functions in the regulated degradation of critical ER-associated proteins, such as the key enzyme for cholesterol biosynthesis, HMG-CoA reductase, which is rapidly degraded when cholesterol levels are high. Also in the liver, the nascent β-lipoproteins that deliver triglycerides to peripheral tissues are rapidly degraded in the ER under conditions when lipid levels are low.

PROTEOLYSIS IN MITOCHONDRIA

As in the cytosol and nucleus, proteins in mitochondria also have widely different half-lives, and mitochondria can selectively degrade misfolded proteins, or ones damaged by free radicals. Although mitochondria as a whole can be degraded in lysosomes by autophagy, this process is nonselective and cannot account for different turnover rates of regulatory mitochondrial proteins. The matrix and the inner membrane of mitochondria contain their own autonomous proteolytic systems, which consist of several ATP-dependent proteases that belong to the AAA superfamily of ATPases (like the six 26S proteasomal ATPases). These proteasomes function independently of ubiquitin and can mediate the complete degradation of nonassembled or misfolded proteins. The matrix of mammalian mitochondria contains two kinds of soluble ATP-dependent proteases that are homologous to bacterial proteases (Lon, ClpXP) and responsible for degradation of matrix proteins. The mitochondrial inner membrane also contains two complex multimeric proteases whose catalytic sites extend into the matrix or intermembrane space. Their ATPases catalyze protein unfolding and facilitate subsequent degradation by the proteolytic sites. Substrates of these proteases are proteins located in the inner membrane, and their activity is essential for the maintenance of oxidative phosphorylation. Impaired function of these proteases has been associated with rare neurodegenerative diseases.

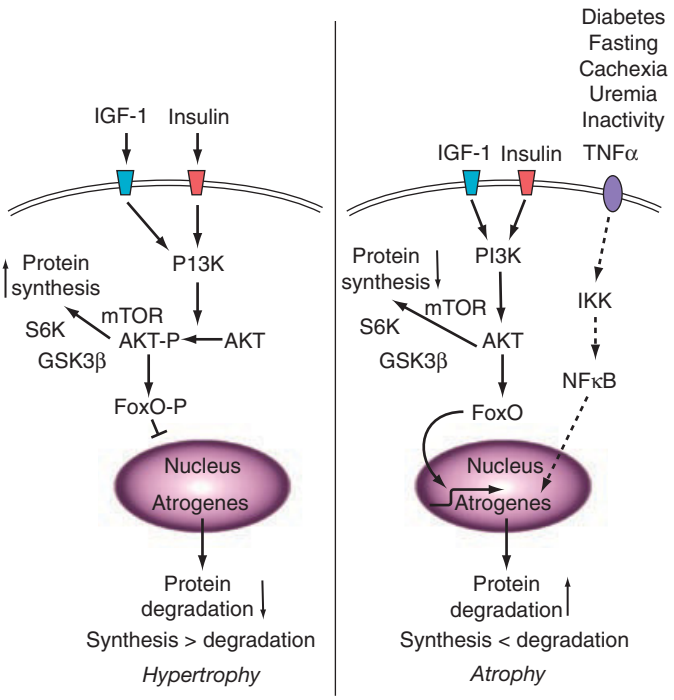

Figure 4–7 Mechanisms leading to enhanced protein breakdown, second reduced protein synthesis in atrophying muscle.

MUSCLE PROTEIN BREAKDOWN AND CACHEXIA

Muscle proteins serve as a primary protein reservoir that can be rapidly mobilized through enhanced protein breakdown to provide amino acids for hepatic gluconeogenesis and energy production. This catabolic response is marked and can be highly debilitating in many disease states, especially cancer, sepsis, untreated diabetes, and chronic renal failure. Cachexia occurs in the majority of cancer patients and may contribute to death in as many as 20% of cases, especially when the wasting process affects respiratory muscles. A similar atrophy of muscles is seen with inactivity, which in hospitalized patients is a major cause of loss of body protein stores and weaknesses. In these diverse situations, a similar series of adaptations have been found in the atrophying muscles (but not in other tissues), indicating a common cellular program that involves excessive breakdown of proteins through the ubiquitin–proteasome pathway, as well as autophagy. Microarray analyses of muscles atrophying in response to diverse diseases have identified a set of approximately 100 coordinately regulated genes, or atrogenes. These transcriptional changes include induction of ubiquitin, two atrophy-specific ubiquitin–protein ligases, proteasome subunits, and autophagy-related genes. Recent studies have established that in fasting, and in insulin-deficient (eg, diabetes) or insulin-resistant states (eg, sepsis or cancer cachexia), the general rise in proteolysis is due to decreased signaling by the PI3 kinase/AKT pathway, which in normal states is activated by insulin or IGF-1 (Fig. 4–7). When the activity of PI3 kinase is reduced, there is decreased phosphorylation and activity of the serine/threonine kinase, AKT. Activated AKT is a major stimulus of growth-related processes and, when overproduced, AKT causes muscle hypertrophy via enhanced protein synthesis and decreased protein degradation generally. The reduction in signaling by the IGF-1–PI3K–AKT pathway leads to reduced translation and protein synthesis. One of the targets of activated AKT is the forkhead family of the transcription factors (FoxO1, 3, 4); when these are not phosphorylated, they migrate into the nucleus and catalyze the transcription of certain

atrogenes, leading to excessive protein breakdown and muscle atrophy. By itself, FoxO3 can cause profound muscle wasting. There also is evidence that like FoxO factors, NFκB, if overproduced, can cause muscle atrophy specifically following muscle disuse or in cancer cachexia. These advances raise the possibility for development of rationale therapies to reduce this excessive proteolysis in these catabolic states.

OUTLOOK

This chapter hopes to make two points clear: (a) that protein degradation is an exquisitely selective, tightly regulated process that is essential in the normal control of cell division, cell metabolism, as well as immune responses, and (b) that proteolysis by the ubiquitin–proteasome pathway also is critical in the pathogenesis of multiple human diseases, especially many cancers. The recent emergence of the proteasome inhibitor, bortezomib, as a very useful treatment for multiple myeloma and mantle cell lymphoma illustrates the importance and promise of this area for pharmacologic intervention. It is likely that selective inhibitors of the activity or expression of specific ubiquitin ligases will emerge in coming years and will offer new possibilities for the treatment of specific cancers as well as cachexia.

Acknowledgments

We are grateful to Mary Dethavong, Alice Callard, and Joan Goldberg for assistance and advice in preparing this chapter and to the NIH for support of our work (grants R01 GM46147 and R01 GM51923 to A. L.G. and R01 DK62307 to S.H.L.).

CHAPTER 5

PROTEIN ARCHITECTURE: RELATIONSHIP OF FORM AND FUNCTION

Alan C. Rigby, Bruce Furie, and Barbara C. Furie

Previous chapters described how the information stored in the gene is transcribed into messenger RNA (mRNA), how the mRNA template is translated to synthesize proteins, and how newly synthesized proteins are transported to their appropriate site of function. Proteins are linear polymers made up of amino acids linked together by peptide bonds. Twenty different amino acids are incorporated into these polymers when protein is synthesized from mRNA. The features distinguishing one protein from another are determined not by the polypeptide backbone but by the different side chains of the amino acids incorporated into the protein and the sequence in which they occur. Proteins fold to form compact structures with a specific three-dimensional architecture that is determined by their unique amino acid sequences. Folded proteins have the capacity to accomplish many different tasks: formation of larger structures (as in the assembly of fibrin monomers into polymers), transport of ligands (as in the binding of oxygen by hemoglobin), catalysis of chemical reactions (as in proteolytic zymogen activation during the propagation of blood coagulation), and modulation of biologic processes (as in regulation of DNA function by DNA-binding proteins). A mutation that alters the sequence of a protein can result in failure to function either because a critical functional residue has been lost or because alterations in amino acid sequence prevent the protein from achieving its proper three-dimensional structure.

AMINO ACIDS: THE BUILDING BLOCKS OF PROTEINS

In an amino acid, the central or α-carbon atom bears four substituents: an amino group, a carboxyl group, a group of variable chemical structure (R, usually referred to as the side chain), and a hydrogen atom. The side chains of the amino acids provide each one with its distinct chemical character. The amino acids can be divided into three general classes on the basis of the properties of their side chains. *Hydrophobic* amino acids include alanine, valine, leucine, isoleucine, proline, tryptophan, phenylalanine, and methionine. The side chains of aspartic acid, glutamic acid, lysine, and arginine are charged at physiologic pH. The side chains of serine, threonine, tyrosine, histidine, cysteine, asparagine, and glutamine are considered *polar*. Additional amino acids can be found in proteins. These amino acids, for example, hydroxyproline, γ-carboxyglutamic acid, and phosphotyrosine, are formed posttranslationally by modification of one of the amino acids incorporated into a protein during translation of mRNA. Hydrogen bonds may be formed between these polar side chains and water molecules, making them adaptable to the aqueous milieu. Hydrogen bonds also may form between two polar side chains (Fig. 5–1). Glycine has as its side chain a second hydrogen atom. Histidine is unique in that it is the only amino acid whose side chain may be protonated or unprotonated, and therefore charged or uncharged, at physiologic pH. This property of the histidine side chain is functionally significant. For example, the catalytic mechanism of serine proteases, such as the enzymes in the blood coagulation cascade or the complement pathways, is dependent on the ability of a histidine residue in the active site of the enzyme to act as a general base, accepting and then releasing a proton in sequential steps of the enzymatic reaction.

NATURE OF THE PEPTIDE BOND

An amino acid becomes incorporated into a protein when the carboxyl group of one amino acid condenses with the amino group of a second, forming a peptide bond, eliminating water, and establishing the covalent link between these amino acids. The peptide bond is formed between the carbonyl carbon of one amino acid and the nitrogen of the next amino acid in the protein sequence. This process is repeated as the polypeptide chain elongates. The amino group of the first amino acid in the chain and the carboxyl group of the last are not usually modified: a protein's polypeptide chain, the main chain or backbone, is described as running from its N terminus to its C terminus. The peptide backbone is composed of the repeating unit NH—C_α—C′═O. (The carbonyl carbon of the protein backbone is referred to as C′ for ease of identification.)

The fundamental properties of the peptide bond dictate the conformation of the main chain of a protein. The chemical nature of the peptide bond (partial double bond) requires that each segment of the polypeptide chain between one C_α and the next one in the main chain be planar (Fig. 5–2). The conformation of the polypeptide backbone is thus dictated by the angles between these planar segments. The angle of rotation or torsion about the N—C_α bond (Φ, phi angle) and the angle of rotation about the C_α—C′ bond (Ψ, psi angle) are restricted because some angles of rotation would result in steric interference between the main chain and amino acid side chains. The only exceptions to these restrictions are the angles of rotation permissible for glycine residues.

DISULFIDE BRIDGES

In addition to the peptide bond, one other covalent bond between amino acid residues frequently occurs in proteins. The sulfhydryl groups on cysteine residues can be oxidized to form cystine, which contains a disulfide bond (Fig. 5–3). This reaction requires an oxidizing environment. Because the intracellular space is a reducing environment, disulfide bonds are not usually found in intracellular proteins. The disulfide bonds found in extracellular soluble and integral membrane proteins are formed in the lumen of the endoplasmic reticulum (ER), the initial compartment of the secretory pathway. Disulfide bonds form between cysteines that are members of the same polypeptide chain, probably stabilizing an already-folded polypeptide backbone. Disulfide bonds may also serve to covalently join two different polypeptide chains, for example, the heavy and light chains of immunoglobulins.

ELEMENTS OF SECONDARY STRUCTURE

The amino acid sequence of a protein is termed its *primary structure*. This structure is coded in the gene. When a number of consecutive amino acid residues have similar angles of rotation about N—C_α and C_α—C′, the main chain of the protein will assume a regular structure. Two regular protein structures, termed *secondary structures*,

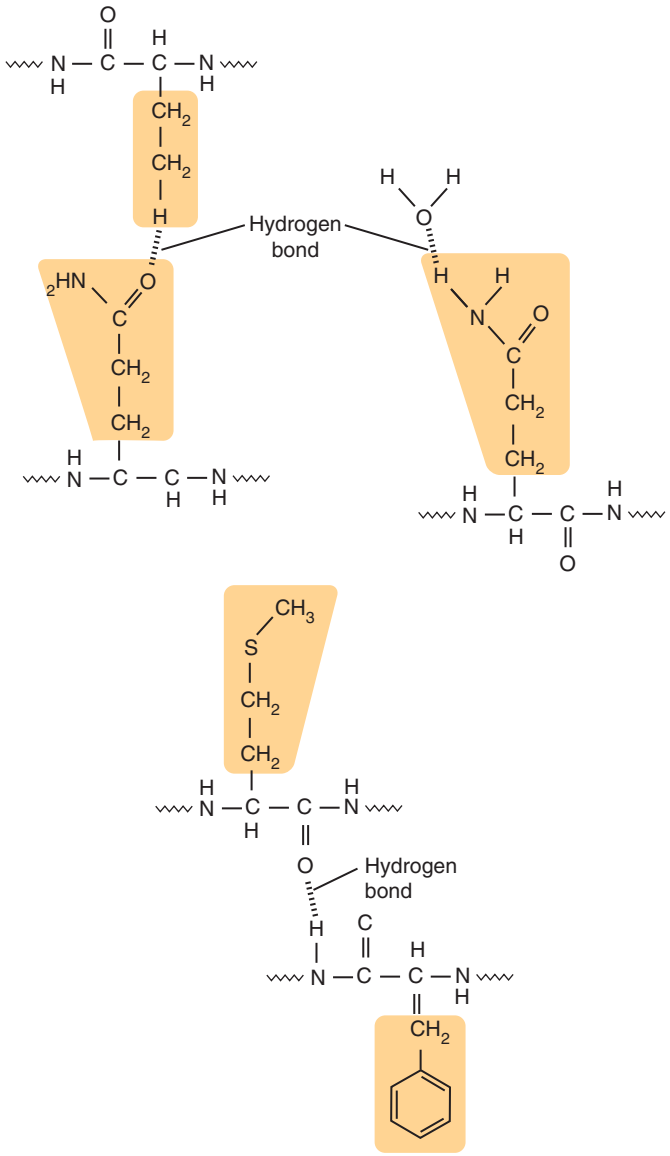

Figure 5–1 In a hydrogen bond, two electronegative atoms share a single proton. The proton is located at the normal covalent distance from the atom to which it is formally bound and at a somewhat shorter distance than the normal van der Waals contact from the other. Hydrogen bonds form in proteins between electronegative atoms in two polar side chains (shown between serine and glutamine side chains), between water and a polar amino acid side chain (shown between water and the glutamine side chain), between carbonyl oxygen atoms and amide nitrogen atoms of the protein backbone (shown between the carbonyl oxygen of a methionine residue and the amide nitrogen of a phenylalanine residue), and between polar side chains and the polypeptide backbone (not shown). Amino acid side chains are shaded.

are *α helices* and *β sheets*. A third important element of secondary structure is a *β turn*.

Formation of these secondary structures resolves a dilemma posed by the folding of a polypeptide chain by permitting formation of hydrogen bonds between the NH groups and the C′═O groups of the protein main chain. The major driving force for folding proteins in the aqueous environment is to remove nonpolar amino acid side chains from water by sequestering them in the hydrophobic core of the protein. To bring the nonpolar side chains into the hydrophobic interior of the protein, the main chain must follow. The main chain of a protein with its NH and C′═O groups is highly polar. The hydrophilic nature of the main chain is neutralized in regions of sec-

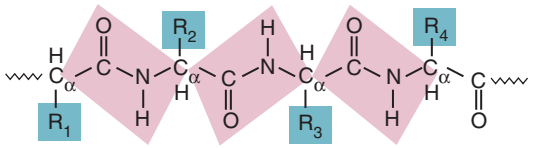

Figure 5–2 In a peptide bond, the amide nitrogen shares its lone pair of electrons with the carbonyl oxygen, lending a considerable double-bond character to the C′—N bond. As a consequence, the main chain of a protein is planar from one C_α to the next C_α. Each planar unit has two degrees of freedom; it can rotate about the N—C_α bond and about the C_α—C′ bond. The peptide bonds of the polypeptide depicted are in the trans configuration; adjacent C_α carbons and the side chains they bear are on opposite sides of the planar C′—N bond. This is the preferred configuration for most amino acids, as it minimizes steric hindrance. For proline, the trans configuration is not favored as much as for other amino acids, and the cis configuration occurs with significant frequency. The planar units of the polypeptide backbone are enclosed in gray boxes. The amino acid side chains are highlighted.

ondary structure by the formation of hydrogen bonds between its polar elements, as illustrated in Figs. 5–4 and 5–5.

α HELIX

α Helices ranging in length from 4 or 5 to 40 residues are found in compact globular proteins such as hemoglobin, whereas long rodlike proteins like the tail of the cytoskeletal protein myosin are made up of long helices twisted around each other to form coiled coils. The membrane-spanning regions of integral membrane proteins, for example, glycophorin and the α_2-adrenergic (epinephrine) receptor, are α helices of approximately 20 amino acids. An α helix is formed from a continuous sequence of amino acid residues in a protein. One turn of an α helix contains 3.6 amino acid residues, with hydrogen bonds between the carbonyl oxygen of residue n and the amide hydrogen of residue $n + 4$ (see Fig. 5–4). The distance between one turn of an α helix and the next, its pitch, is 5.4 Å. With 3.6 residues per turn, the rise per residue along the vertical axis of the helix is 1.5 Å. Theoretically, an α helix can be either right-handed or left-handed with regard to direction of "screw." In proteins, left-handed helices are rarely seen, as the side chains of L-amino acids approach

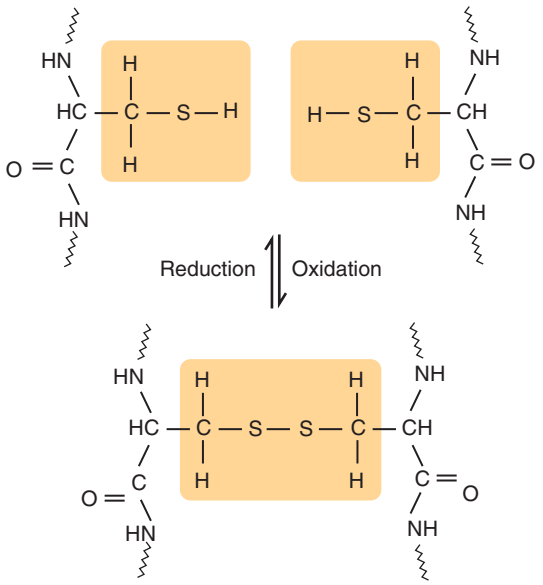

Figure 5–3 Disulfide bonds are formed between neighboring cysteine residues in an oxidizing environment. The side chains of cysteine and cystine are shaded.

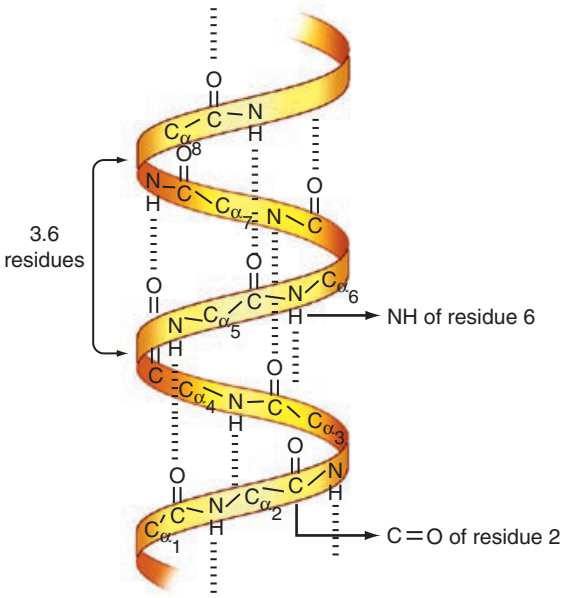

Figure 5–4 The α helix is formed from a continuous sequence of amino acids. A right-handed α helix is illustrated. The hydrogen bonds between residue *n* and residue *n* + 4, which stabilize the helix, are depicted as lines composed of stacked dashes.

the C′=O group too closely. Collagen is a notable exception: it assumes a left-handed helical conformation.

With the exception of proline, there are no strong predictors of whether or not a particular amino acid side chain is likely to be incorporated into an α helix. The last atom of the proline side chain is bonded to the main-chain nitrogen atom, preventing the nitrogen atom from participating in hydrogen bond formation. In addition, the proline side chain sterically hinders the α-helical conformation, producing a bend in the helix if it appears after the first turn.

β SHEETS

In contrast with the α helix, the β sheet is formed from several different regions of a polypeptide chain. The stretches of polypeptide, usually 5 to 10 residues long, that form the β sheet are called *β strands*. The β strands are aligned to form hydrogen bonds between the carbonyl oxygen atoms on one strand and the amide hydrogen atom on the opposite strand. If in successive β strands the amino acids are running in the same direction, amino terminal (N-terminal) to carboxyl terminal (C-terminal), then the β sheet is termed *parallel* (see Fig. 5–5A); if successive strands alternate directions, the sheet is termed *antiparallel* (see Fig. 5–3B). The hydrogen bonding pattern is distinct in the two forms of β sheet. In either case, however, the sheet appears pleated; alternate C_α groups appear above and below the plane of the β sheet. Likewise, the amino acid side chains on a β strand are alternately above and below the plane of the β sheet.

β TURNS

The β turn, the simplest and most common secondary structural element, usually contains 4 amino acids, although 3 residues are sufficient to form the turn. The turn is stabilized by a hydrogen bond between the NH of residue *n* and the C=O of residue *n* + 3. β Turns typically link successive α helices and/or β strands and generally are found on the surface of proteins exposed to the aqueous environment (Fig. 5–6).

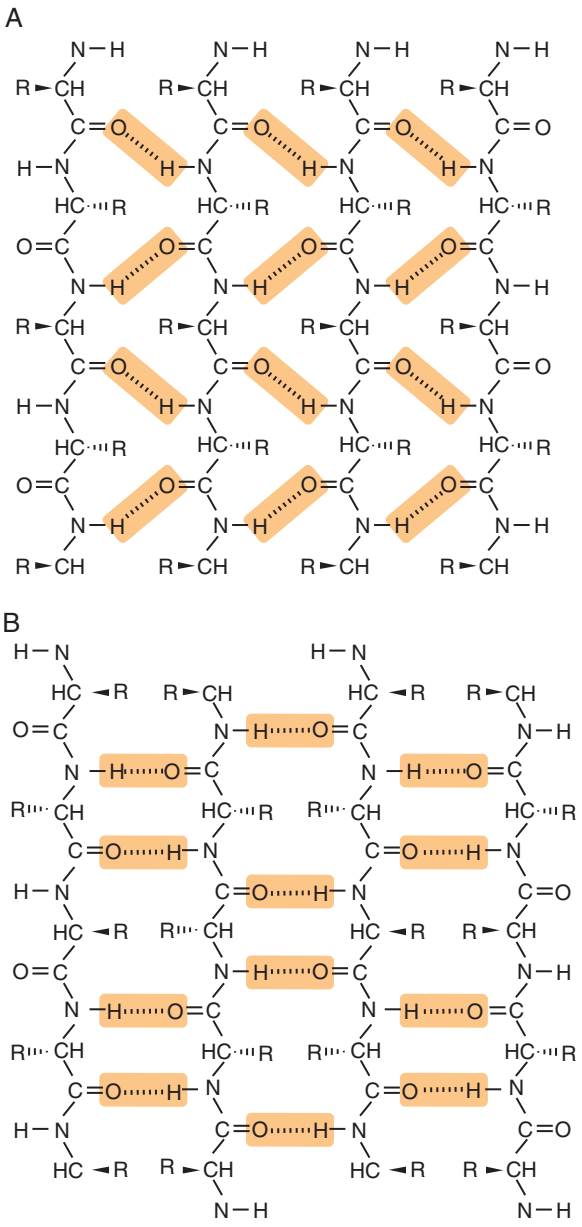

Figure 5–5 β Sheets are formed from several regions of a polypeptide chain. The strands of polypeptide assembled in a β sheet may be parallel, that is, aligned in the same direction from amino to carboxyl (N to C) terminus, or the strands may be antiparallel, that is, aligned in alternating direction from N to C terminus. **A**, Schematic drawing of a parallel β sheet. **B**, Schematic drawing of an antiparallel β sheet. The hydrogen bonds that stabilize these structures are *highlighted*.

PROTEIN TERTIARY STRUCTURE: ASSEMBLY OF SECONDARY STRUCTURES

Most proteins are made up of combinations of α helices and β sheets connected by regions of less regular structure usually termed *loops*. The α helices and β sheets pack together to form the hydrophobic core of a protein, whereas the loop regions tend to appear on the surface of the protein. Loops are stabilized by side chain-to-main chain hydrogen bonds or are extended structures that do not contain stabilizing hydrogen bonds. Comparison of homologous proteins among species suggests greater mutability of loop regions than of regions of regular secondary structure. The structures of the folded cores of the proteins are preserved during evolution, although insertions or deletions of several amino acids occur primarily in loop

regions. Protein surface loops are important determinants of a protein's functional specificity, for example, substrate recognition by enzymes or ligand recognition by adhesion molecules.

The arrangement of secondary structures within a polypeptide defines its tertiary structure. The packing of secondary structural elements into a compact, folded form brings distant parts of the polypeptide chain into close proximity. Most proteins may be assigned to one of four classes depending on the content and arrangement of secondary structure within the core of the protein. Proteins of the α class are made up primarily of α helices with connecting loop structures. Similarly, β proteins are made up of β sheets connected by loop regions. In αβ proteins, the two elements of secondary structure alternate, again connected by loops. A fourth class of proteins, α + β, incorporates both α helices and β sheets, but these elements are not arranged in an easily identifiable pattern.

Figure 5–6 shows examples of α, β, and αβ proteins.. The vesicular transport protein α-SNAP (soluble NSF attachment protein from yeast) is an α protein composed of an N-terminal twisted sheet of α-helical hairpins and a C-terminal α-helical bundle (Fig. 5–6A). It is structurally related to several other α/α proteins that are known to mediate protein–protein interactions. Homologous proteins mediate membrane fusion events in platelets and other mammalian cells. A β structure, the seven-bladed β-propeller domain, is found in integrins, adhesion proteins that mediate cell–cell interactions and intracellular signaling. This domain is illustrated in Fig. 5–6B by two seven-bladed β-propeller domains of the *Caenorhabditis elegans* homolog of the Actin interacting protein 1 (Aip1) found in yeast. Figure 5–6C shows an example of an αβ protein, a monomer of the hexameric D2 domain of *N*-ethylmaleimide-sensitive fusion protein, Nsf-D2, a cytosolic ATPase required for intracellular vesicle fusion reactions. The monomer is made up of two domains. The first contains a central five-stranded parallel β sheet flanked by α helices (an αβ domain). The second domain consists of four α helices topped by two short antiparallel β strands.

With the explosion of information on protein sequence and structure in recent years, large databases classifying proteins on the basis of structural characteristics are now available (see Databases and Related Literature at the end of this chapter).

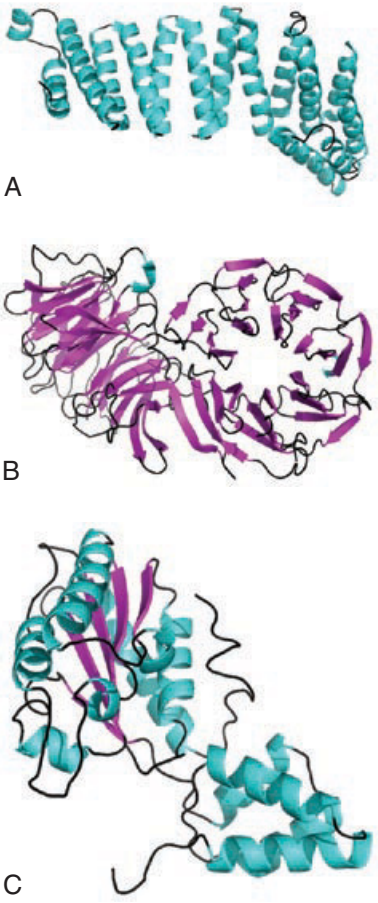

Figure 5–6 Models illustrating the three-dimensional structures of proteins composed almost exclusively of secondary structural elements. The protein backbones are illustrated using ribbon traces that make it easy to discern the elements of secondary structure. α Helices are shown as blue ribbon traces and β sheets are shown as purple ribbon traces, with arrows indicating the direction of the β strand from the N-terminal to the C-terminal. Connecting loops are indicated in black. **A**, α-SNAP (from yeast) composed of an amino (N)-terminal twisted sheet of α-helical hairpins and a carboxyl (C)-terminal α-helical bundle. **B**, Two seven-bladed β-propeller domains of the *Caenorhabditis elegans* homolog of the actin-interacting protein 1 (Aip1) found in yeast. The two β propellers are at 90° to one another. **C**, A monomer of the hexameric D2 domain of *N*-ethylmaleimide-sensitive fusion protein, Nsf-D2, is composed of two domains: a central five-stranded parallel β sheet flanked by α helices (an αβ domain) and the second four α helices topped by two short antiparallel β strands (not shown as ribbons).

PROTEIN DOMAINS

Many proteins are made up of domains. A protein domain, frequently encoded in a single exon, is a region of a polypeptide chain that can fold autonomously into a stable tertiary structure. The packing of secondary structural units into a globular or folded unit yields the tertiary structure of a domain or protein. The spatial relationship of independent domains within a protein is part of the description of its tertiary structure. The relationship between the secondary and the tertiary structure is illustrated for hemoglobin in Fig. 5–7.

During evolution, a limited number of protein domains have been used repeatedly. Related domains from different proteins share enough sequence homology to preserve the polypeptide fold but may have markedly different amino acid sequences and functions. Such domains appear to be associated with exon shuffling and duplication. Examples of proteins whose tertiary structures are built from such conserved domains abound in plasma and as components of cells within the vasculature. A demonstration of the assembly of discrete proteins from such domains is given in Chapter 118 for the proteins involved in hemostasis and fibrinolysis. These proteins incorporate, among others, epidermal growth factor (EGF)-like domains, kringle domains, and type I and type II fibronectin domains, all of which are widely distributed in mammalian proteins. The domains within a given class share a stable core structure with discrete functions determined by the nonconserved amino acids expressed on the module's surface.

Several common domain structures are illustrated in Fig. 5–8. The Src family tyrosine kinases are found in many cell types and are essential components of many signal transduction pathways. The Src homology 2 (SH2) domain is a regulatory domain that binds phosphorylated tyrosine residues in a sequence-specific manner and is found in phosphatases as well as kinases. Src-like kinases contain a second ligand-binding regulatory domain, the SH3 domain. EGF domains are common to many different classes of proteins, including blood coagulation proteins, Factors VII, IX, and X (see Chapter 118). Some of these domains contain calcium ion-binding sites. C2 domains are common to a number of phospholipid-binding proteins, including the coagulation proteins factor V and factor VIII.

Protein motifs are common arrangements of secondary structure that are incorporated into many protein domains. Motifs are characterized by highly conserved amino acid sequences and by conserved function. Examples of protein motifs are shown in Fig. 5–9. Zinc finger-containing proteins are one of the most abundant families of proteins within the eukaryotic genomes. The EF-hand is the most common calcium-binding motif. The basic leucine zipper (bZIP) motif binds to DNA. The β barrel of OmpT, an integral

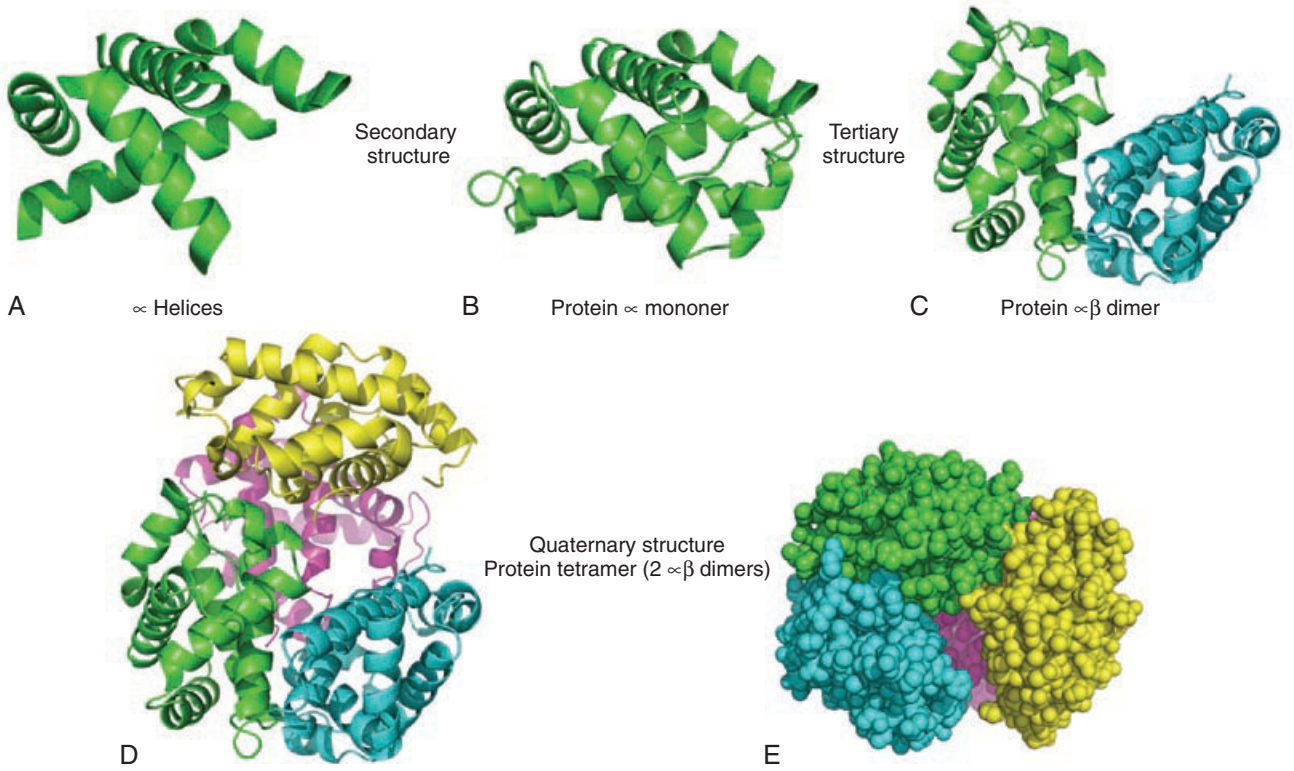

Figure 5–7 The structure of hemoglobin, made up of two α-globin chains and two β-globin chains, is used to illustrate the hierarchical nature of protein folding. Globin chains are composed almost entirely of α helices. The organization of secondary structural elements within a domain or protein defines the fold or tertiary structure, as is illustrated for the α helices (green ribbon) of an α-globin chain of deoxyhemoglobin. The spatial relationship of subunits in the assembled protein defines the protein's quaternary structure. To form a hemoglobin molecule, an α- and a β-globin chain (green and blue, respectively) assemble to form a dimer, and two αβ dimers assemble to form the hemoglobin tetramer (α chains, green and magenta; β chains, blue and yellow). A space-filling model of the hemoglobin tetramer in which the atoms are represented by spheres with radii proportional to their van der Waals radii is shown for the hemoglobin tetramer, colored as described.

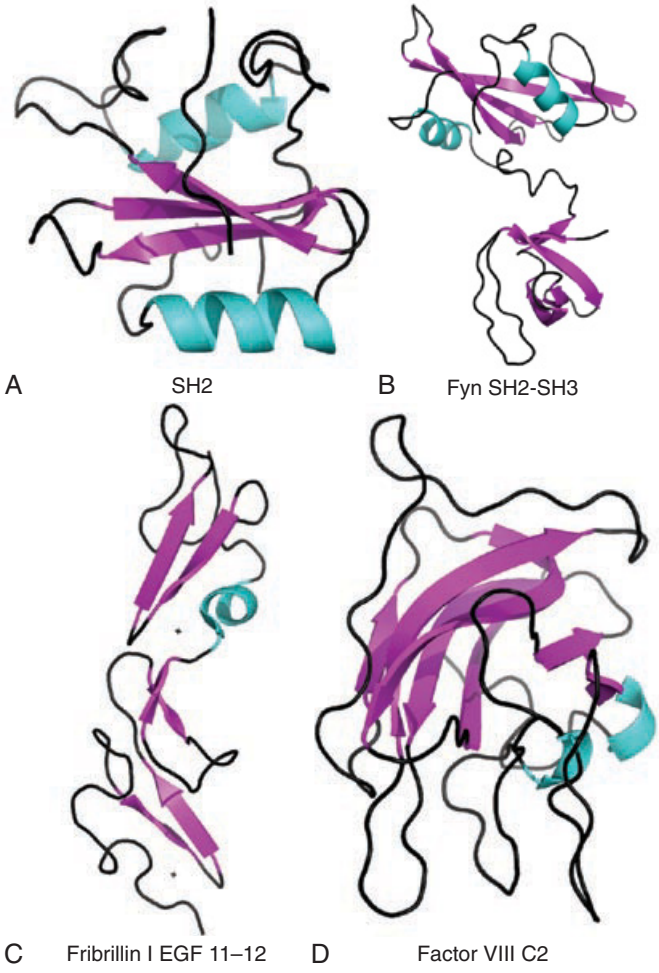

Figure 5–8 The amino-terminal SH2 domain of the tyrosine phosphatase Syp demonstrates the highly conserved central core of SH2 domains. The Src family kinases are composed of a catalytic tyrosine kinase domain preceded by two ligand-binding regulatory domains, SH3 and SH2. The backbone trace of the SH3-SH2 regulatory pair from the Src nonreceptor tyrosine kinase Fyn is illustrated with the SH2 domain oriented toward the top of the figure. Comparison of the SH2 domain of Fyn with the SH2 domain of Syp indicates differences outside the conserved SH2 core, including an additional β strand in the Fyn SH2 domain and more extensive loops in the Syp SH2 domain. These differences demonstrate that the surface topography of SH2 domains can be altered, resulting in changes in binding specificity. Fibrillin-1, a major component of connective tissue fibrils associated with Marfan syndrome, is a mosaic protein composed of 43 calcium-binding epidermal growth factor (cbEGF)-like domains. The backbone trace of calcium-bound cbEGF11–12 exhibits the linear arrangement of these domains with a single interdomain linker region. The carboxyl-terminal C2 domain of the procoagulant cofactor, factor VIII, contains critical determinants that are essential for binding to anionic phospholipids and von Willebrand factor. This structure is a β-sandwich core that possesses two solvent-exposed β turns that include the hydrophobic and positively charged residues that interact with membranes.

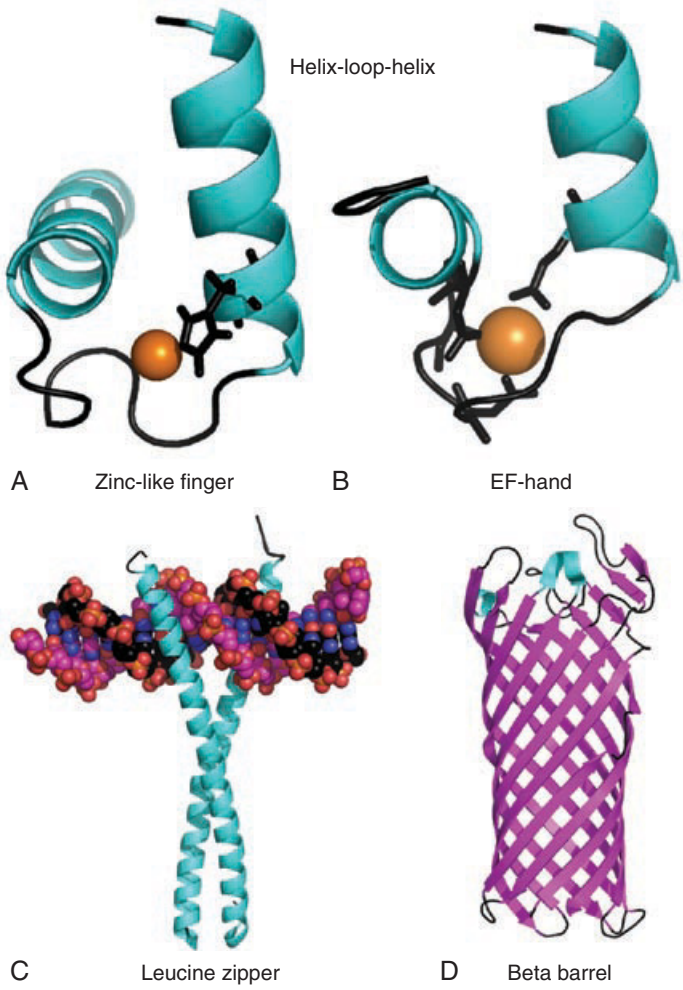

Figure 5–9 The transcriptional adaptor protein CBP contains two copies of a zinc finger motif called the *TAZ finger* that are implicated in binding to transcription factors and viral oncoproteins. The structure of the TAZ1 domain is shown. One of three bound zinc atoms is shown bound by His362, Cys366, Cys379, and Cys384. His362 is shown in black; the zinc ion is red. The most common calcium-binding motif in proteins is the EF-hand motif, which is illustrated for the calcium-bound B-chain of human psoriasin. This protein is abundant in many cell types and is upregulated in keratinocytes in psoriasis. The calcium-chelating residues of this canonical acidic helix-loop-helix motif, Asp62, Asn64, Asp66, Lys68, and Glu73, are shown in black. The calcium ion is red. The basic leucine zipper (bZIP) DNA-binding motif of GCN4 is a parallel-coiled coil. The coiled coil is oriented perpendicular to the DNA double helix, which forms numerous contacts between its major groove and the amino-terminal amino acids of GCN4. The GCN4 coiled coil is in blue. The carbons atoms of one strand of the DNA helix are black and the other purple. The 10-stranded antiparallel β barrel of OmpT of *Escherichia coli* is illustrated as a purple ribbon. The structure of OmpT is depicted with the extracellular portion of the protease that is involved in lipopolysaccharide binding oriented up.

outer-membrane protease found in *Escherichia coli*, binds to lipopolysaccharide.

QUATERNARY STRUCTURE: ASSEMBLY OF POLYPEPTIDE CHAINS

For some proteins, the functional unit is made up of more than one independently synthesized polypeptide chain. The orientation of the polypeptide chains to one another within the functional unit is termed the *quaternary structure* of a multimeric protein. A multimeric protein may be made up of identical subunits or polypeptide chains, as in glucosephosphate isomerase, a dimer of two identical polypeptide chains, or different subunits, as in hemoglobin, in which the functional protein contains two α and two β subunits. The relationship between the tertiary and the quaternary structure for hemoglobin is illustrated in Fig. 5–7. The interaction between the subunits of a multimeric protein may be stabilized by disulfide bonds between the polypeptide chains. The light and heavy chains of immunoglobulin molecules and the Aα chains, Bβ chains, and γ chains of fibrinogen are examples of such proteins.

The subunits of a multimeric protein may influence one another, as in the binding of oxygen to hemoglobin, in which the occupancy of one heme group with oxygen influences the affinity of the heme groups of the remaining three subunits for oxygen (see Chapter 33). Alternatively, the subunits of the assembled multimeric protein may provide a unique function, as in the formation of the antigen-binding site of an immunoglobulin, the complementarity-determining site being formed by the variable regions of both the heavy and light chains of the immunoglobulin molecule. Finally, there are multisubunit proteins in which each subunit has a distinct function; RNA polymerase is an example of such a protein.

Ribbon diagrams that trace the α-carbon backbone of a protein identify the fold of the protein, but they provide a misleading impression that a large amount of empty space exists within proteins. This is not the case, as most folded, globular proteins possess a hydrophobic core that is enclosed by the secondary structural elements that make up the tertiary fold. The core of globular proteins is actually densely packed with atoms contributed by both the backbone carbonyls and amine hydrogen atoms and by the atoms of the amino acid side chains, as is demonstrated by a space-filling model of the hemoglobin tetramer in which the atoms are represented by spheres with radii proportional to their van der Waals radii (see Fig. 5–7). Very little empty space remains within the core of proteins when they are in their active conformation. The cavity at the center of the assembled tetramer is filled by the four heme prosthetic groups.

CHAPTER 6

REGULATION OF CELLULAR RESPONSE

Benjamin G. Neel and Christopher L. Carpenter

INTRODUCTION AND OVERVIEW

Hematopoiesis is a dynamic process in which a small number of self-renewing stem cells generate large numbers of terminally differentiated cells, which carry out multiple essential functions. For the hematopoietic system to maintain homeostasis, cell proliferation, differentiation, adhesion, migration, and death must be carefully controlled. Small changes in this balance can lead to marked alterations in blood cell number and function, resulting in marrow failure (eg, aplastic anemia), abnormal proliferation (eg, leukemia), or defective effector cell function (eg, lymphocyte defects in autoimmunity or immunodeficiency). Understanding the regulatory systems controlling normal hematopoietic cells and delineating how these mechanisms are deranged in disease should facilitate the rational development of novel and improved diagnostic and therapeutic modalities.

Hematopoietic cells can respond to a wide range of stimuli or signals. These include *extrinsic* signals (eg, hormones, growth factors, and cytokines) and *intrinsic* (intracellular) signals that indicate exposure to toxic stimuli (eg, ionizing radiation or toxic drugs) and/or cell damage. Some hematopoietic cell signals are similar, even identical to, those acting on other cell types. For example, insulin-like growth factors (IGFs) act on hematopoietic and nonhematopoietic cells, and all cells share most elements of the DNA damage response pathway. Other signals, such as antigens and immune complexes, complement, and certain bacterial products, are more specific to hematopoietic cells. Indeed, with the possible exception of neurons, hematopoietic cells respond a greater variety of signals than any other cell type.

To react appropriately to such a diverse array of signals, cells must solve six fundamental problems: (a) most signals must be transmitted across the cell membrane; (b) detection must be sufficiently sensitive and (c) specific; (d) multiple signals must be interpreted and integrated; (e) analog signals must be converted to digital outputs; and (f) the signaling response must be terminated. The extracellular and intracellular milieus are aqueous environments separated by a hydrophobic cell membrane. Cells must have a mechanism to transmit extracellular signals across this diffusion barrier. The second problem is more general, and arises because most signals are present at very low levels. Hormones and cytokines typically act at low nanomolar or even picomolar concentrations. Likewise, white blood cells must detect and respond to extremely low numbers of invading microbes, lest the host be rapidly overcome. Cells also must recognize very low levels of DNA damage, as even one double-stranded DNA break can have disastrous consequences. Therefore, cells must be able to respond to signals with adequate *sensitivity*. A third, equally important challenge is the *specificity* of the cellular response. Hematopoietic progenitors must be able to discern a signal to proliferate from one to differentiate. Lymphocytes must distinguish foreign antigens from self, when that difference may be as small as a single amino acid in a short peptide sequence. Again, failure to achieve adequate specificity can result in serious disease. Under physiological conditions, cells are simultaneously barraged by multiple signals; hence, *signal integration* is a fourth key problem in cellular regulation. Ultimately, the cellular response consists of regulating protein expression and function. Integration of the ambient and extrinsic signals can result in fine-tuning of the cellular set point to maintain the basal state. However, when the appropriate signals are present, a change in cellular state ensues. For example, a quiescent cell is stimulated to enter the cell cycle and proliferate, or an activated lymphocyte is triggered to undergo cell death. Cellular response systems therefore must have both analog (ie, the ability to generate continuous levels of signals) and digital (ie, on–off) characteristics, and the ability to switch between these two signaling modes. Accordingly, cells must effect *analog–digital conversions*. Finally, once initiated, signals must be terminated appropriately (*signal termination*).

Cells solve these fundamental problems by means of signal transduction pathways. A typical signal transduction pathway consists of a ligand (or sometimes more than one ligand), a receptor, and a set of downstream signaling molecules (Fig. 6–1). Downstream signals converge on the nucleus to regulate transcription, RNA processing, and/or nuclear import/export, on the protein synthetic machinery to control translation, and/or on the mitochondria or various metabolic enzymes to affect cellular energetics and cell survival. Signal transduction pathways may also regulate cytoskeleton-dependent functions, such as motility or phagocytosis. Transmembrane receptors allow the cell to solve the diffusion barrier problem, and specific receptors for discrete ligands help contribute to response specificity. Downstream signaling cascades involve the formation of multiprotein complexes, phosphorylation/dephosphorylation or proteolytic cascades, and/or second messenger generation, facilitating amplification of the initial signal. Such *signal amplification* enhances the response sensitivity. Downstream signaling molecules often contain one or more small domains or *modules* (eg, SH2, SH3, PTB, PH; see below) that recognize specific *motifs* on other signaling molecules. Multiprotein complexes are assembled through these interactions. Like a molecular bar code, the combinatorial use of signaling modules and motifs contributes to specificity, amplification and efficiency of signal transmission. Signaling is terminated via several mechanisms, including degradation or posttranslational modification of the ligand, its receptor, and/or critical downstream signaling components. Many signal termination mechanisms are activated by downstream signaling pathways, thereby coupling initial pathway stimulation to its eventual inactivation. Analog-digital conversions are accomplished by signaling circuits in which pathway-stimulating and -inactivating mechanisms are regulated coordinately in opposing directions, leading to the generation of positive feedback loops.

In this chapter, we survey the types of signaling molecules found in hematopoietic cells and review the general features of their receptors and signal transduction pathways. Our goal is to emphasize the general principles that these pathways illustrate, rather than to provide a comprehensive accounting of each pathway. For details about any of the individual systems discussed, the reader is urged to consult the more detailed reviews cited at the end of the chapter.

SIGNAL DETECTION: LIGANDS AND RECEPTORS

Signals

Hematopoietic cells respond to an enormous variety of extrinsic and intracellular stimuli and generate an impressive number of signals (Table 6–1). *Extrinsic signals* important for hematopoietic cell function include proteins and peptides (eg, growth factors, hormones, cytokines, most chemokines), lipids (eg, LPA, PAF, eicosanoids),

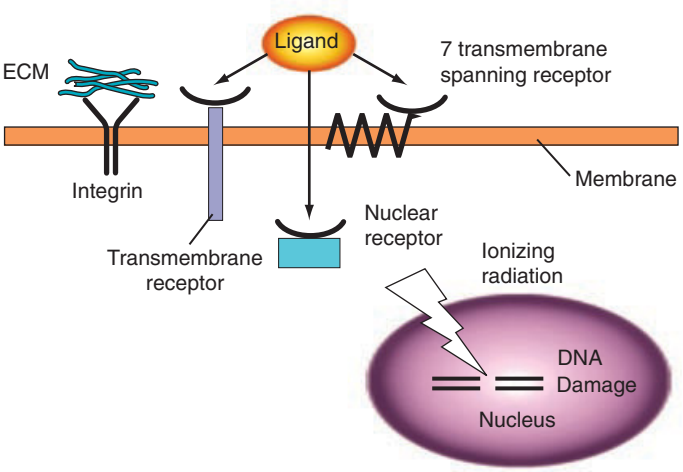

Figure 6–1 Examples of ligands and receptors. Signals can originate from fixed ligands like extracellular matrix (ECM). Soluble ligands that are not membrane permeable bind to extracellular regions of transmembrane receptors. Membrane permeable ligands bind to intracellular receptors, such as the nuclear receptor family. Signals can also originate from within the cell, such as DNA damage caused by ionizing radiation.

Table 6–1 Signals in the Hematopoietic System

Types of Ligands	Examples
Peptide/protein	
Soluble	Growth factors/cytokine
ECM	Fibronectin, collagen
Cell surface-bound	ICAM, Kit ligand
Small Organics	Thyroid hormone
Nucleotides	
Soluble	ADP
DNA	Double-strand breaks
Lipids	Eicosanoids, LPA
Gases	H_2O_2, Nitric oxide*

*Indicates function in hematopoietic system not well-defined

nucleotides (eg, ADP), and gases (eg, nitric oxide, hydrogen peroxide, and possibly superoxide). These signals can be grouped into two general classes based on their activation of two fundamentally distinct types of receptors. Signals such as steroid hormones (androgens, estrogens, glucocorticoids) and gases diffuse into the cell (*transcellular signals*) where they encounter their cognate receptors or targets. The vast majority of signals are lipid-insoluble (*extracellular signals*), however, and thus cannot transit the plasma membrane. These ligands bind to specific cell surface receptors, which transduce the signal through the membrane to the cell interior.

Extracellular signals can be further grouped into subclasses (Table 6–1). *Soluble signals* include most growth factors, hormones, chemokines, and nucleotides; as their name implies, these signals diffuse freely in the extracellular space. Often, soluble signals are further characterized based on the distance over which they act. *Endocrine* signals (classical hormones) typically act over fairly long distances. For example, IGFs are produced in the liver in response to growth hormone that, in turn, is secreted by the pituitary. *Paracrine* signals are produced by one cell and act on an adjacent one. For example, T helper lymphocytes produce cytokines that stimulate antibody production by adjacent B lymphocytes. Although the distinction is not absolute, paracrine signals are generally viewed as acting over smaller distances than endocrine signals. *Autocrine* signals are produced by, and act on, the same cell. For example, interleukin-2 is produced in response to T cell-antigen receptor activation, and stimulates further cell cycle progression of T lymphocytes. Although terms like endocrine, paracrine, and autocrine are useful, they only describe the function of a particular signal in a given physiological setting; they are not fundamental properties of a specific signal. Indeed, the same signal can act in an endocrine fashion in some contexts and as a paracrine or autocrine factor in others.

Contrasting with soluble signals are solid-state signals. Many extracellular matrix (ECM) molecules (eg, collagen and fibronectin), in addition to mediating cell–matrix adhesion, have signaling roles. Other ECM components, such as heparin sulfate proteoglycans, bind soluble growth factors. Such interactions can either concentrate or sequester the growth factor, facilitating or acting as a mechanism to localize or terminate cell signaling, respectively. Cell–cell adhesion molecules also have signaling functions. Cadherins and PECAM (platelet–endothelial cell adhesion molecule; aka CD31), among others, participate in *homotypic* interactions, in which a molecule on one cell acts as both ligand and receptor for the cognate molecule on an apposing cell. Other interactions (eg, P-selectin/PSGL-1) are *heterophilic*. Still other solid-state signals have no apparent cell adhesion function, acting only as signaling molecules. Examples include the Serrate family of ligands for Notch signal transducers. Interestingly, in the case of ephrins and Eph receptors, both heterophilic partners transduce signals into their respective cell (as well as transmitting signals to the adjacent cell), thereby muddying the distinction between "ligand" and "receptor."

Some ligands have a complex nature and/or a complicated life history. The ligands for T cell-antigen receptors (TCRs) are complexes comprising a short peptide bound to major histocompatibility complex (MHC) proteins. Epidermal growth factor family members are synthesized as transmembrane precursors, with the mature growth factor released only upon appropriate proteolytic cleavage. Although the transmembrane forms of these ligands may signal in some contexts, in others, the soluble growth factor is essential. Stem cell factor (SCF, also known as Kit Ligand), which plays an essential role in hematopoietic progenitors and mast cells, also exists in both transmembrane and soluble forms, but its transmembrane form is required for function. Wnts are secreted proteins, yet they effectively function as solid-state signal transducers because they are so tightly associated with the ECM. Still other signals, most notably TGF beta superfamily members, are secreted in a latent form that must be activated by specific proteolysis. Perhaps the most baroque example is provided by the thrombin receptor (and its relatives); here, the receptor (a G-protein coupled receptor; see below) and its cryptic ligand are contained within a single polypeptide chain. Exposure to thrombin (a protease activated during coagulation) results in cleavage of the receptor and exposure of the ligand, which then binds intramolecularly to the receptor, resulting in its activation.

Cell signals also differ in temporal quality. Most soluble signals are released only under specific conditions to enable cell–cell communication. In contrast, ECM-derived signals typically transmit continuous information about cell attachment and/or cell–cell interactions. However, solid-state signals can also be inducible. Examples include the ICAM/LFA-1 interactions that follow TCR activation and the increase in affinity of GP IIB/IIIA for its ligand fibrinogen that occurs upon platelet activation. Continuous and intermittent signaling modes probably have different cellular effects, although this issue remains poorly understood.

Finally, important signals arise from within cells. (Some investigators have termed these signals *intracrine*, but because this terminology is not in general usage, we prefer the more general *intrinsic* to refer to this type of signals.) Important examples include checkpoint pathways, which ensure orderly progression of the cell cycle, sense and repair damaged DNA, and detect and respond to cellular stresses, such as nutrient and/or energy deprivation or unfolded proteins. When activated, these pathways lead to cell-cycle arrest, which allows time for the damage to be repaired and/or cellular stress to be alleviated, or to cell death.

TABLE 6–2 Receptors in the Hematopoietic System

Types of Receptors	Examples	Types of Ligands
RTK	Insulin, Kit, Fms	Kit ligand, M-CSF
RSK	TGF-β Receptors	Activin, BMPs, TGF-β
GPCR	Thrombin receptor, CXC, CC receptors	Thrombin Chemokines
PTK-associated MIRR	Cytokine receptors BCR/TCR/FcR	Epo, Interleukins, IFN Peptide/MHC, Fc domains
TNF family	Fas, TNFR, CD40	Fas, TNF, CD40L
Notch	Notch	Delta-Serrate-LAG-2
Frizzled family	Wnt receptors	Wnts
Toll receptors	TLR1-10	Bacterial DNA, LPS
RPTP	CD45	Unknown
Nuclear receptors	AR, RAR	Testosterone, retinoids
Adhesion receptors	Integrins	Fibronectin, Collagen

AR, androgen receptor; BCR, B-cell antigen receptor; BMPs, Bone morphogenetic proteins; CC, CXC, types of chemokine receptors; CD40L, Ligand for CD40; Epo, erythropoietin; FcR, receptors for Fc portion of antibodies; GPCR, G protein-coupled receptor; M-CSF, macrophage colony stimulating factor; MIRR, multichain immune recognition receptor; RAR, retinoic acid receptor; RPTP, receptor protein-tyrosine phosphatase; RSK, receptor serine kinase; RTK, receptor tyrosine kinase; TCR, T-cell antigen receptor; TGF-β, transforming growth factor-β; TNF, tumor necrosis factor.

Receptors

Nearly all extrinsic signaling pathways begin with a ligand binding to its receptor. Signaling gases, which directly modify intracellular protein targets by nitrosylation (nitric oxide) or oxidation (peroxide, superoxide), are the exception to this general rule. Below, we briefly describe the major families of signaling receptors in hematopoietic cells (Table 6–2).

Intracellular Receptors

Intracellular receptors include those that sense DNA damage and cell cycle checkpoints, guanylate cyclase and the nuclear receptors. The checkpoint receptors are, in general, not well understood, and guanylate cyclase has little known role in hematopoietic cells, so we focus on the nuclear receptors.

The Nuclear Receptor Superfamily

The best understood intracellular receptors are members of a large superfamily of molecules that transduce signals by ligands as diverse as amino acid derivatives (eg, thyroid hormone), steroids (eg, glucocorticoids, estrogens, progesterone, androgens), vitamins (eg, retinoids, Vitamin D), xenobiotics, and fatty acids and/or their derivatives (eg, prostaglandins). Initially termed *steroid–thyroid hormone* receptors, they are now referred to as "nuclear receptors" in recognition of the wide range of signals they transduce. Unfortunately, this nomenclature also is a bit of a misnomer; some family members (eg, the progesterone receptor) bind ligand in the cytoplasm and only then move to the nucleus.

Nuclear receptors share a modular structure, consisting of domains A through E (some family members have a C-terminal extension that is termed F or E/F), which allows them to function as ligand-dependent transcription factors. Domain C is a double-stranded DNA-binding domain that binds to specific palindromic target sequences in the genome. Accordingly, nuclear receptors bind DNA as dimers, with some (eg, glucocorticoid, steroid hormone receptors) acting as homodimers, but most binding as heterodimers with a group of nuclear receptors termed RXRs (eg, thyroid hormone signals through thyroid hormone receptor/RXR heterodimers; retinoids employ retinoic acid receptor (RAR)/RXR pairs). The E (or E/F) domain functions both in ligand binding and transcriptional activation (transactivation). These two functions are coupled in a remarkable example of "induced fit." In the absence of ligand, the critical residues for transactivation are inaccessible, only to be exposed on the surface when ligand binds. The A/B domain also has a transactivation function, although this is ligand-independent. The D domain serves mainly as a hinge to join the C and E/F domains, although it also plays an important role in binding certain coregulatory molecules.

In addition to their structural similarity, nuclear receptors share the ability to bind ligand and then directly alter cellular transcription. Some data suggest that these receptors also have extranuclear functions. For example, the estrogen receptor binds to and affects the activity of the cell cycle regulatory protein cyclin D, as well as the signal transducers Src, Erk, and PI-3 kinase (see Signal Propagation: The Intermediaries). These alternative functions of nuclear receptors remain controversial and an area of active study. The ability of nuclear receptors to regulate transcription is also modified by other signal transduction pathways. For example, phosphorylation of some nuclear receptors can enhance their transactivation potential or even render them ligand-independent. Like other transcription factors, nuclear receptors transmit activation signals by means of coactivators that are associated with histone acetylase activity; phosphorylation of coactivators also can modify nuclear receptor signaling. Although ligands are known for a large number of nuclear receptors, others, known as "orphan receptors" have no known ligands. Identifying ligands remains an active area of investigation, but some nuclear receptors may not have ligands. Such molecules, of course, are not functional "receptors" (because they lack ligand-binding ability). By competing with ligand-binding family members for the same response elements, orphan receptors act as repressors and/or ligand-independent transcription factors.

Extracellular Receptors

Extracellular receptors have adopted several strategies to solve the diffusion barrier problem. *Enzyme-linked* receptors directly couple extracellular ligand binding to intracellular enzyme activation. The enzymatic activity may be intrinsic to the receptor (eg, receptor tyrosine kinases, receptor serine kinases, receptor protein-tyrosine phosphatases) or enzymes can associate noncovalently with one or more ligand-binding subunits (eg, integrins, cytokine receptors, multichain immune recognition receptors). G protein-coupled receptors (GPCRs) couple ligand binding to the activation of heterotrimeric GTP-binding proteins (G proteins). Upon activation, TNF and Toll-like receptors generate protein surfaces for the assembly of multimolecular complexes, whereas activation of members of the Notch family results in cleavage of their intracellular domain and release of a signaling fragment that translocates to the nucleus to modulate transcription. The structure of these receptor families and the initial events in receptor activation are discussed briefly below.

Enzyme-Linked Receptors

Receptor Tyrosine Kinases

Receptor tyrosine kinases (RTKs) consist of an extracellular ligand-binding domain, a transmembrane domain, and an intracellular protein-tyrosine kinase (PTK) domain. RTKs can be further grouped into subfamilies based on structural motifs found in their extracellular (ectodomains) and intracellular domains, with members of the same RTK subfamily often binding structurally related ligands. The ligands for RTKs typically are soluble proteins or peptides; examples include epidermal growth factor (EGF), platelet-derived growth factors (PDGFs), the fibroblast growth factors (FGFs) and insulin and the

insulin-like growth factors (IGFs). However, as mentioned above, some RTK ligands (eg, SCF) are cell surface proteins or have cell surface-associated forms. Indeed, the largest subfamily of RTKs, Eph receptors, respond to a number of glycerophosphoinositide (GPI)-linked or transmembrane ligands known as Ephrins. One RTK (DDR) is activated by specific subtypes of collagen, and recent data suggest that ROR is activated by certain Wnts (see below). The ligands for some RTKs (eg, ROS) remain unknown.

In the absence of ligand, most RTKs are monomers, but this is not an absolute rule. The hepatocyte growth factor (HGF) receptor (also termed Met) and its relatives, including RON, which plays an important role in the hematopoietic system, are cleaved posttranslationally to generate heterodimers. Members of the insulin receptor subfamily are heterotetramers in which the subunits are linked by disulfide bonds.

Ligands activate RTKs by promoting receptor oligomerization. Juxtaposition and activation of their (intracellular) kinase domains results, followed by cross (trans)-phosphorylation. Although for historical reasons, this process often is termed *autophosphorylation*, "trans-phosphorylation" is a more accurate description. Ligands can stimulate receptor oligomerization in a variety of ways. Some, such as PDGF, are dimeric, so that one ligand molecule binds two receptors simultaneously. Others, such as EGF, are monomers but have two receptor-binding sites that facilitate receptor dimerization. FGFs also are monomers, but they have only a single receptor-binding site. However, FGFs bind to heparin sulfate proteoglycans, which effectively oligomerize the ligand. Cell surface-bound ligands (eg, Ephrins) presumably promote RTK activation on opposing cells by clustering in localized regions of the plasma membrane.

The insulin and IGF-1 receptors are exceptions to this general scheme. These RTKs act as heterotetramers in the absence of ligand. Although their activation mechanism remains incompletely understood, most likely, ligand binding induces higher-order oligomerization and/or a conformational change that alters the orientation of the intracellular domain and leads to kinase activation. In addition, a hydrophobic residue in the juxtamembrane region of the receptor inhibits the basal activity of the IR and many other RTKs (eg, PDGFRs, Eph RTKs). Ligand binding may disrupt this autoinhibitory interaction, resulting in kinase activation.

RTK transphosphorylation occurs on multiple sites. Phosphorylation within the RTK "activation loop" locks the kinase into a high-activity conformation, and may also render it less accessible to inactivating phosphatases. Other tyrosines phosphorylated on RTKs become docking sites for *signal relay* molecules that contain SH2 (Src Homology domain-2) or PTB (phosphotyrosine-binding) domains, which are short (approximately 100 amino acid) modules that recognize phosphotyrosine (pY) within specific sequence contexts. For example, the motif pY-X-N-X (X—any amino acid), binds the SH2 domain of the signal relay molecule Grb2, whereas pY-X-X-M specifies interaction with the SH2 domains of regulatory subunit (p85) of an enzyme known as phosphoinositide-3 kinase (PI3K). Multiple proteins containing SH2 or PTB domains can assemble on an activated RTK, resulting in the formation of signaling complexes. The sequence motifs surrounding tyrosyl phosphorylation (pTyr) sites differ among RTKs. Consequently, RTKs recruit distinct combinations of signal relay molecules, providing an initial layer of specificity to RTK signaling. Although SH2 domains only bind pTyr-containing peptide sequences, some PTB domains can recognize specific motifs (NPXY) containing an unphosphorylated tyrosine.

SH2/PTB domain-containing proteins fall into two general classes: enzymes and adapters. Examples of the former include the tyrosine phosphatase Shp-2, phospholipase Cγ (PLCγ) and Ras GTPase-activating protein (RasGap). Although not enzymes per se, the SH2 domain-containing transcription factors known as Stats (Signal transducers for activating transcription) should probably be grouped within this class. Adapters lack intrinsic catalytic activity and instead serve as regulatory and/or targeting subunits for enzymes. For example, Grb2 binds the Ras guanine nucleotide exchange factor Sos, whereas PI3K p110 catalytic subunits are bound to SH2 domain-containing p85 regulatory subunits. Binding of an SH2/PTB domain-containing protein to an activated RTK can relocate an enzyme to the vicinity of its substrate (eg, PLCγ, Sos, RasGap) and/or activate the enzyme. Enzyme activation can result from binding of the SH2/PTB domain protein to its cognate pTyr motif (eg, Shp2, PI-3K). Alternatively (or in addition), many signal relay molecules are substrates for the activated RTK, and tyrosyl phosphorylation can result in enzyme activation (eg, PLCγ, Stats, and possibly Shp2).

Although this simplified paradigm applies to signaling by all RTKs, complexity abounds. For example, the EGF receptor (ERBB) family alone comprises four receptors (ERBB1–4) that respond to a large number of ligands. A single growth factor can stimulate receptor homodimerization as well as heterodimerization with other family members. ERBB3 retains the overall structure of an RTK and can bind to neuregulins (themselves, a large family of ligands). But the ERBB3 kinase domain is inactive, so that it signals *only* upon heterodimerization with an active family member (typically, ERBB2 or ERBB4). An important consequence of all of this complexity is that a single ligand can activate different signaling pathways, with distinct downstream effects, depending on which ErbB family members are expressed. For example, heparin-binding EGF-like growth factor (HB-EGF) stimulates mitogenesis but not chemotaxis when it activates the EGF receptor, but is both mitogenic and chemotactic when it activates ERBB4. Conversely, the same receptor, when stimulated by different ligands, can transduce distinct signals. Ligands may induce specific conformational changes that lead to the phosphorylation of different sets of tyrosine residues on the receptor, and consequently, phosphorylation of distinct sets of substrates. Alternatively (or in addition), the affinity of a given EGFR ligand for its receptor may influence signaling, by determining the length of time that it remains bound and thus signal duration. Finally, recent data indicate that at least some RTKs can translocate to the nucleus and have direct effects on transcription. In some cases (eg, EGFR, ERBB2, the entire receptor appears to enter the nucleus by as an yet unresolved pathway. For others (eg, ERBB4), the C-terminal tail is cleaved from the rest of the RTK and enters the nucleus in a manner somewhat analogous to that used by Notch family members (see Notch Receptors).

Receptor Protein-Tyrosine Phosphatases

Tyrosyl phosphorylation is exquisitely regulated not only by PTKs, but also by a large superfamily of protein-tyrosine phosphatases (PTPs). Like the PTKs, PTPs exist as transmembrane, receptor-like molecules and nontransmembrane (often misleadingly termed *cytosolic*) family members. Similar to the RTKs, receptor PTPs (RPTPs) have an extracellular domain(s), a single transmembrane-spanning domain, and cytoplasmic catalytic domains. The extracellular domains of many RPTPs contain fibronectin and immunoglobulin repeats, suggesting that at least some of them may recognize adhesion molecules as ligands. Several RPTPs are capable of homotypic interaction, but the ligands for most RPTPs remain either unknown or controversial. Interestingly, most RPTPs have two catalytic (PTP) domains. Although both are active in some RPTPs, in nearly all, the more the N-terminal of the two PTP domains (D1) has substantially greater activity and appears to play the major role in substrate dephosphorylation, the more the C-terminal domain (D2) is evolutionarily conserved (however, often to a greater extent than the N-terminal PTP domain), indicating that it must have an important function. Some possibilities that have been suggested for the function of D2 include substrate binding, regulation of oxidation of the D1 domain, and/or binding to certain lipids. Although at first glance, one might think that RPTPs (and other PTP superfamily members) would act to attenuate signaling initiated by PTKs, the situation is far more complicated. For example, CD45 plays both positive and negative roles in MIRR signaling (see Receptors Asscoiated with Protein-Tyrosine Kinases), keeping receptor-associated kinases inactive prior to activation but also required for activation on ligand binding.

Serine-Threonine Kinase Receptors

The transforming growth factor-β (TGF-β) receptor family, which includes receptors for TGFβ, bone morphogenetic proteins (BMPs) and activins, comprises transmembrane proteins with intrinsic serine-threonine kinase activity. Each active receptor consists of two subunits, termed Type I and Type II receptors, respectively. Signaling occurs as a result of ligand-dependent oligomerization of these receptor subunits. Type II receptors are constitutively active but do not normally phosphorylate substrates, whereas the type I receptors are normally inactive. Ligand-induced dimerization results in phosphorylation of the Type I receptor subunit by the Type II receptor, which converts the former into an active kinase. Signal propagation is dependent on the kinase activity of the Type I receptor and phosphorylation of its downstream substrates, the most important of which are the Smad family transcription factors.

Receptors Associated with Protein-Tyrosine Kinases

Three distinct families of receptors lack intrinsic enzymatic activity, but signal via associated PTKs. These include cytokine receptors, multichain immune recognition receptors (MIRRs) and integrins.

Cytokine receptors exist in several configurations, all of which associate with and signal via Janus family protein tyrosine kinases (Jaks). Some receptors, such as those for erythropoietin, prolactin, and growth hormone, combine ligand binding and signaling functions in a single transmembrane protein. Others (eg, IL3, GM-CSF, IL-5) have separate high-affinity ligand-binding and signaling subunits. Still others (eg, IL2 receptor) have a high-affinity ligand-binding subunit, and two signaling subunits, one of which also has a low affinity for ligand. The same signaling subunit can be shared by different ligand-binding subunits; for example, the IL3, GM-CSF and IL-5 receptors have different ligand binding α chains, but share a β-common (βc) chain.

The signaling subunits of cytokine receptors have two general functions: they direct association with specific Jaks and become tyrosyl phosphorylated in response to receptor stimulation. As with RTKs, ligand binding evokes Jak activation. Jaks are unusual in that besides an active kinase domain, they have an additional kinase-like domain (known as a Jak homology-2, or JH2, domain). This domain is important for regulating kinase activity, as illustrated by the association of V617F mutations (which lie in the JH2 domain) in Jak2 with nearly all cases of polycythemia vera and a significant fraction of essential thrombocythemia and myeloid metaplasia. Once activated, Jaks phosphorylate the cytokine receptor signaling subunit(s), although other PTKs also may contribute. The signaling subunits of cytokine receptors, together with their associated Jak, are the functional equivalents of RTK cytoplasmic domains. This allows analogous pTyr-dependent recruitment of signal relay molecules to the receptor. Stat family transcription factors are particularly important in cytokine receptor signaling. In addition to their DNA-binding and transcriptional-activation domains, Stat proteins contain an SH2 domain that has two functions. First, it recruits Stat monomers to the cytokine receptor, where they become tyrosyl phosphorylated. The SH2 domain on one Stat monomer then interacts with the pTyr residue on another, resulting in Stat dimers. These then translocate to the nucleus and activate specific gene expression. Cytokine receptors also activate other downstream pathways (eg, RAS/ERK P13K/AKT) in a manner similar to RTKs.

Multichain immune recognition receptors (MIRRs) include the antigen receptors on B and T lymphocytes, activating receptors on NK cells, and Fc receptors. As their name implies, these receptors tend to have several subunits (at least 2 and as many as 10 or more). At least one subunit is responsible for ligand binding and at least one other serves as the signaling subunit. Other subunits function either in receptor assembly, cell surface transport or as additional signaling subunits. MIRR signaling subunits are characterized by the presence of one or more specialized pTyr-based motifs called ITAMs (immune tyrosine-based activation motifs), which consist of two pTyr-X-X-L sequences separated by 10 amino acids.

Unlike cytokine receptors, signaling by MIRRs involves the sequential activation of Src (SFK), Syk, and Tec family PTKs. Ligand binding results in activation of one or more receptor-associated SFKs. How this occurs remains unknown. Conceivably, receptor clustering may have an effect analogous to dimerization/oligomerization by RTKs and cytokine receptors. However, some evidence, particularly for the T cell-antigen receptor (TCR) suggests that receptor-associated SFKs (eg, Lck for the TCR) are maintained in an inactive state by the adjacent receptor protein-tyrosine phosphatase, CD45. On ligand engagement, CD45 is excluded from the receptor complex, leading to SFK activation and phosphorylation of the ITAMs in the associated signaling subunits. Phosphorylated ITAMs then bind and activate Syk family PTKs (Syk or ZAP-70). The unique features of ITAMs are designed to fit optimally into the two SH2 domains of these PTKs. Activated Syk/ZAP70, in turn, phosphorylate coreceptors (eg, CD28 in T cells, CD19 in B cells) as well as adapters (eg, LAT in T cells and BLNK in B cells). Phosphorylation sites on these proteins bind signal relay molecules and activate downstream signaling. Tec family kinases (eg, Btk, Itk, Rlk) also are recruited by specific downstream adapters, activated by receptor-associated SFKs and, in turn, phosphorylate key enzymes, such as PLCγ. Thus, in MIRR signaling, three functions normally encoded on a single RTK molecule (ligand binding, kinase activation, docking site generation) are fragmented into separate receptor subunits and accessory signaling chains. Nevertheless, the same general signaling strategy applies.

Integrins, which are composed of heterodimers of α and β subunits, comprise the third group of receptors associated with PTKs. There are 18 α and 8 β subunits, allowing the generation of a large number of different heterodimers. Integrins act as both adhesion receptors and signaling molecules. Binding to an integrin requires the presence of one of two motifs, either arginine–glycine–aspartate (RGD) or leucine–aspartate–valine (LDV). These motifs typically are found in ECM molecules; hence, most integrins mediate cell–matrix adhesion and signaling. Some important integrin ligands, such as ICAM-1, are cell surface proteins. ICAM-1 is expressed on antigen-presenting cells and, by binding the integrin LFA-1, mediates cell–cell adhesion.

Activation of integrin signaling involves both ligand binding and clustering of integrins. Inactive integrins adopt a conformation in which the extracellular domains of α and β are bent, blocking ligand binding. The intracellular regions of α and β are bound to each other, preventing binding of downstream effectors. Binding of ligand to the extracellular domain separates the cytoplasmic portions of α and β, allowing them to interact with the cytoskeleton and transmit signals (outside-in signaling). Intracellular signals, such as phosphorylation, also can cause separation of the cytoplasmic domains of α and β; this can propagate in the reverse direction to open the head group and enhance ligand binding (inside-out signaling or affinity modulation). The conformational change that occurs on activation can facilitate transmembrane domain interaction, leading to cluster formation. Integrin clustering, in turn, results in increased avidity for ligand (avidity modulation).

Integrins also signal via PTKs. Integrin engagement stimulates SFKs, focal adhesion kinase (Fak), and in some cell types, the Fak relative Pyk. How this occurs is poorly understood. The so-called PBD domain of talin binds to a conserved NPXY motif in the β-integrin tail. Talin can recruit paxillin, which in turn binds Fak. Partial Fak activation and autophosphorylation appears to create a binding site for SFKs, which may phosphorylate and further activate Fak/Pyk2. However, the precise order and mechanism of activation of SFKs and Fak/Pyks during integrin signaling remains an area of controversy and active research.

G Protein-Coupled Receptors

G protein-coupled receptors (GPCRs) are by far the most numerous receptors. The human GPCR family contains nearly 700 members,

making it the second most common protein family after protein kinases. GPCRs are characterized by seven membrane-spanning domains, resulting in four extracellular and four cytoplasmic regions. GPCRs bind a large variety of ligands, including proteins and peptides, lipids, amino acids, and nucleotides. Not surprisingly, the ligand-binding regions of GPCRs are quite diverse. In the hematopoietic system, chemokine receptors probably comprise the most important group of GPCRs.

GPCRs are so named because of their associated signaling subunits, the heterotrimeric GTP-binding proteins (G proteins). Most GPCR ligands bind to the receptor extracellular domain, but others bind to the transmembrane domain or to both the transmembrane and extracellular domains. In the absence of ligand, GPCRs exist in an inactive conformation resulting from intramolecular bonds between residues in the transmembrane or juxtamembrane regions. Heterotrimeric G proteins are bound to the inactive receptor. Following ligand binding, the receptor undergoes a conformational change that stimulates an intrinsic guanine nucleotide exchange activity for the associated G protein. This catalyzes dissociation of the associated G protein into α and $\beta\gamma$ subunits (see below), either of which can then bind to and activate different downstream signaling molecules. For example, $G\alpha_s$ subunits activate adenylate cyclase, resulting in cAMP generation, whereas some $G\beta\gamma$ subunits stimulate phosphoinositide phospholipases. Many GPCRs also activate PTKs via a complex trans-activation pathway. Although the details remain controversial, this pathway appears to involve initial GPCR-activated signals that result in stimulating the cleavage and releasing the transmembrane-bound form of HB-EGF, which in turn stimulates the EGFR in an autocrine or paracrine manner.

Wnt Receptors

Wnts are a family of secreted proteins that are palmitoylated and thus relatively insoluble. They bind to extracellular matrix and can be transported by cellular extensions or lipid particles. Consequently, Wnts have properties of both solid-state and soluble signals. In the hematopoietic system, specific Wnts appear to play critical roles in stem cell homeostasis.

Wnts activate several downstream pathways by means of different receptor complexes. The canonical pathway culminates in the activation of β catenin, and is mediated by a regulatory complex comprising the Apc (adenomatous polyposis coli) tumor suppressor gene, axin, glycogen synthase kinase beta (GSK-3b), and casein kinase-1 (CK-1). In the absence of a Wnt signal, GSK-3β phosphorylates β-catenin (which is bound to the complex), promoting its degradation by the ubiquitin ligase β-TRCP. Wnts bind to primary receptors known as Frizzled proteins (relatives of *Drosophila frizzled*) which, like GPCRs, span the membrane seven times. In addition to the 10 human Frizzled family members, canonical pathway activation requires Wnt binding to the coreceptors LRP5 or LRP6, which have single membrane spanning regions and belong to the low-density-lipoprotein-related protein family. Binding results in inhibition of GSK-3β activity within the complex, a process mediated by the PDZ domain-containing adapter protein Dishelved (Dsh), and axin destabilization, which involves recruitment of axin to the LRP subunit and its phosphorylation and degradation.

Wnts also can activate noncanonical pathways. One is termed the "planar cell polarity (PCP) pathway," reflecting its key role in regulating this process during development. The PCP pathway is less well defined, but appears to involve binding to Frizzled family members (but not LRPs), Dsh phosphorylation, recruitment of Rho family small G proteins, and activation of the serine kinase JNK and downstream transcription. Wnts can also increase intracellular calcium via a second noncanonical pathway that appears to involve heterotrimeric G protein activation and phospholipase C activation. Remarkably, one Wnt family member (Wnt 5a) can bind to the receptor tyrosine kinase ROR-2, which can activate the PCP-pathway. Even more complexity is conferred by a variety of soluble receptors that modulate Wnt activity.

Notch Receptors

Notch signaling plays a critical role in cell fate determination within multiple hematopoietic lineages. Notch family receptors have a large extracellular domain, a single transmembrane domain, and a cytoplasmic domain. Their ligands (Jagged and Delta) are also transmembrane proteins expressed on the surface of adjacent cells. Activation of a Notch receptor results in a unique signal transduction mechanism. The extracellular domain of Notch is cleaved, probably by a member of the ADAM protease family, leaving the transmembrane and cytoplasmic domains intact. Following endocytosis, Notch undergoes a second proteolytic cleavage, which requires presenilin, releasing a soluble form of the receptor. This intracellular domain (ICD) fragment translocates to the nucleus and binds to a transcriptional repressor, CBF1 (the ortholog of Suppressor of Hairless in Drosophila). Binding to CBF1 relieves its inhibitory function, leading to transcriptional activation. Activation of Notch-responsive genes also requires ICD interaction with members of the Mastermind family of transcriptional coactivators. The importance of this novel signaling pathway has been vividly illustrated by mutations in Notch that result in constitutive cleavage and transcriptional activation; such mutations are found in a high percentage of T-cell acute lymphoblastic leukemia patients.

The Tumor Necrosis Factor Receptor Family

Tumor necrosis factor (TNF) family receptors (TNFRs) are single membrane-spanning proteins with a cysteine-rich extracellular ligand-binding region and a cytoplasmic tail that often contains a "death" domain. Ligand binding leads to receptor oligomerization, which is necessary to activate downstream signaling. A protein-binding surface is generated by the oligomerized receptor, leading to the recruitment of cytoplasmic proteins that form a large multiprotein complex. TNFR family members generate a least three types of downstream signals. Proapoptotic signaling is mediated via activation of a cytoplasmic protease, caspase 8, that initiates the extrinsic pathway of programmed cell death. TNFRs also can activate multiple members of the MAP kinase family of serine/threonine kinases. Some of these, in particular Jnk and possibly p38, also can have proapoptotic effects. Most TNFRs are also capable of generating survival signals. These signals depend on receptor-binding proteins known as TRAFs (TNF-associated factors) to mediate activation of the NF-κB family of transcription factors.

Whether pro- or antiapoptotic TNFR signals dominate depends on the particular cellular context as well as other signals. Some family members (eg, TRAIL) are professional death-inducers, whereas others (eg, CD30, CD40), lack a death domain and primarily generate survival signals. An additional feature of the TNFR system is the existence of so-called decoy receptors. Such receptors lack all or part of the cytoplasmic tail and thus cannot transmit a signal, but they bind and sequester ligand. Decoy receptors provide a unique mechanism for inhibiting and further regulating signaling. The pharmaceutical industry has utilized this strategy in the production of Enbrel, a recombinant soluble TNFR, which acts as a decoy receptor for TNF signals, and thus is a potent antiinflammatory agent.

Toll-Like Receptors

Toll-like receptors (TLRs), which get their name from the founding member of the family, a *Drosophila* ortholog, are expressed at particularly high levels on granulocytes and monocyte/macrophages and play critical roles in the innate immune response. Ten human TLRs have been identified. Each has a single transmembrane domain and a conserved cytoplasmic region known as the Toll/IL-1 receptor (TIR) domain. Two classes of TLRs can be defined on the basis of their extracellular domains: those with leucine-rich repeats and those with immunoglobulin domains. The most extensively studied mammalian

TLRs function to sense and respond to infection by acting as receptors for the products of microorganisms, such as lipopolysaccharide (TLR2 and TLR4) and the CpG DNA (TLR9) found in bacteria.

As for TNFRs, TLR signaling also appears to involve the formation of multimeric receptor complexes. Once activated, different TLRs recruit one or more adapters such as MyD88 and TRIM, sometimes by means of bridging adapters such as Mal (for MyD88) or TRAM (for TRIF). MyD88 recruits IRAK (interleukin-1 receptor-associated kinase) family members, which bind TRAF6 and in turn result in activation of various MAPK family members. TRIF-containing complexes promote activation of the NFκB pathway. The result is release of inflammatory cytokines, which help to activate the adaptive immune system, although some TLRs can also activate proapoptotic or prosurvival signaling pathways.

SIGNAL PROPAGATION: THE INTERMEDIARIES

Activation of a receptor usually results in transmission of signals to the cell interior. In some cases (eg, Notch or hormone receptors) receptor activation leads directly to transcriptional regulation. In other cases, receptors stimulate downstream signaling cascades that regulate many aspects of cell function. Still other receptors (eg, some RTKs, cytokine receptors, TGFβ family receptors) directly activate transcription factors (Stats, Smads) and secondary signaling cascades. Many downstream signaling pathways are shared by multiple receptors, and include protein kinases and phosphatases, small GTP-binding proteins, lipid kinases, and small molecules. This section provides an overview of these signal relay components.

Protein Kinases

Protein kinases (PKs) are divided into three classes according to the residues they phosphorylate: PTKs (some of which have been discussed above), protein serine-threonine kinases, and dual-specificity kinases, which phosphorylate serine, threonine, and tyrosine residues. Important issues in understanding the role and regulation of protein phosphorylation are how kinases phosphorylate specific substrates and sites and how phosphorylation alters protein function.

All protein kinases share the same overall three-dimensional structure, and most, if not all, shuttle between inactive and activated states. Phosphorylation of the so-called T loop serves as a general activation mechanism. The T loop forms a lip within the catalytic pocket and can occlude the active site, preventing binding of the protein substrate and/or ATP. Upon phosphorylation, the T loop undergoes a conformational change, moving out of the active site and permitting substrate access. T loop phosphorylation can be catalyzed by an upstream kinase or by kinase dimerization (eg, as in RTKs; see above).

Once activated, PKs phosphorylate specific substrates on particular sites. Specificity relies on two properties: colocalization of the kinase with the substrate and the presence of sequences in the substrate that can be phosphorylated by the kinase. Substrate motifs have been identified that in some cases, absolutely govern whether a protein will be a substrate. For example MAP kinases and cyclin-dependent kinases can only phosphorylate serines or threonines that are followed by a prolyl residue. Other kinases are slightly more promiscuous, but they too favor particular motifs as phosphorylation sites, probably because these motifs fit best into their catalytic clefts. Sequences distant from the site of phosphorylation can also mediate low-affinity association of a kinase with a substrate, which enhances both catalytic specificity and efficiency. This theme of "combinatorial control of specificity" is common to many signaling molecules and pathways.

Phosphorylation of a substrate can have two general effects: it can lead to a conformational change, thereby altering the activity of the protein, or it can create binding sites for specific domains. Examples of such binding modules are SH2 and PTB domains, which bind pTyr-containing peptides, as well as FHA domains, polo box domains, and 14–3-3 proteins, which bind phosphoserine and phosphothreonine motifs. Interaction of modules with their cognate motifs can result in the assembly of multiprotein signaling complexes.

Regulation can involve both of the above strategies. Tyrosine phosphorylation of different sites within SFKs can stimulate or inhibit their activity. Phosphorylation of a C-terminal tyrosine residue results in an intramolecular interaction between this phosphotyrosine and the SH2 domain of the SFK. This association contorts the catalytic domain, preventing substrate binding. In contrast, phosphorylation of a tyrosine in the T loop of the catalytic domain stimulates kinase activity by stabilizing the catalytic pocket in an active conformation. Once activated, SFKs can bind other phosphotyrosyl proteins via their SH2 domains; many of these proteins then serve as substrates for the SFK.

Mammalian serine-threonine kinases have been subdivided into 11 subfamilies on the basis of primary sequence homology. Kinases having significant homology often have related functions. Like tyrosine kinases, serine-threonine kinases are activated by phosphorylation of the T loop. Serine-threonine kinases also are regulated by other mechanisms. Small-molecule "second messengers" stimulate some serine-threonine kinases. Examples include cAMP and protein kinase A, calcium and diacylglycerol, and members of the protein kinase C family, and calcium and calmodulin for the calcium/calmodulin-dependent protein kinases (CAM kinases). Akt and PDK1, among others, contain Pleckstrin homology (PH) domains, which bind phosphoinositides. The Akt and PDK1 PH domains are specific for the phosphatidylinositol phosphate products of phosphoinositide 3-kinases (PI3K). Binding to PI3 lipids colocalizes PDK1 and Akt at the plasma membrane, which allows PDK1 to phosphorylate the T loop on Akt, resulting in the Akt activation. Protein–protein interactions, such as the association of cyclins with cyclin-dependent kinases, also can regulate kinase activity.

Many kinases participate in "kinase cascades." For example, activation of Raf results in phosphorylation and activation of Mek1, which in turn leads to activation of the Erk MAP kinases and, subsequently, pp90Rsk and Mnk. Kinase cascades allow cells to regulate pathway activity at multiple levels, thereby promoting signal integration. Equally important, cascades allow for remarkable levels of signal amplification, such that nanomolar or even picomolar levels of cytokines and growth factors can affect intracellular components at micromolar concentrations.

Protein Phosphatases

Protein phosphatases can activate or inactivate signaling pathways, depending on the specific sites that they dephosphorylate. Like the kinases, protein phosphatases can be classified on the basis of their substrate preference as tyrosine-, serine-threonine-, or dual-specificity phosphatases (DSPs). However, unlike kinases, which share the same general domain structure, protein phosphatases have several distinct structurally and mechanistically distinct superfamilies, which makes for a more informative classification scheme.

The PTP superfamily includes most known tyrosine-specific and dual-specificity phosphatases. PTPs are characterized by a conserved signature motif that centers on an essential cysteine residue. Catalysis by these enzymes involves the production of a cysteinyl-phosphate intermediate by this conserved residue. Although all PTP superfamily members contain a signature motif, classic PTPs, which are specific for phosphotyrosine, also contain a number of other conserved residues within a 240- to 250-amino acid PTP domain. Classic PTPs, in turn, can be subdivided into RPTPs (see above) and nontransmembrane families. All known DSPs lack a transmembrane domain, and their catalytic domains are smaller and more similar to each other than to those of the classic PTPs. In addition, some DSPs, although they can dephosphorylate artificial phosphopeptide substrates in vitro, actually target specific phosphoinositides. These include several enzymes that, when mutated, play important roles in the pathogenesis of hematopoietic and other types of disease. The best known of these is the tumor suppressor gene PTEN, which specifically targets

PI3,4P2 and PI3,4,5P43. Other examples include myotubularin and its relatives, which target PI-3P. When mutated, these enzymes can cause several types of neuromuscular disease.

Structural and enzymological studies have provided several insights into how PTPs are regulated. As indicated above, at least some RPTPs (CD45, PTPα) may be inactivated by dimerization. The nontransmembrane family members Shp1 and Shp2 (Shps) have, in addition to their PTP domains, two N-terminal SH2 domains and C-terminal tyrosyl phosphorylation sites. In the basal, inactive state, the catalytic cleft of the Shps is blocked by their respective N-terminal SH2 (N-SH2) domain. Binding of a pTyr peptide to the N-SH2 induces a conformational change that allows substrate access to the catalytic domain. This regulatory mechanism is altered by mutations in the autosomal dominant genetic disorder Noonan syndrome, about 50% of which is caused by germline mutations in various residues that comprise the N-SH2–PTP domain interface. Similar mutations occur sporadically in juvenile myelomyelogenous leukemia and CALLA+ B-cell acute lymphoblastic leukemia. In addition, tyrosyl phosphorylation of the Shp2 C-terminus has been shown to enhance Shp2 biological activity by an as yet uncertain mechanism. A more recently appreciated, potentially general, mechanism of PTP regulation capitalizes on the high reactivity of the catalytic cysteine residue in PTPs. This allows it to undergo reversible oxidation by reactive oxygen species such as hydrogen peroxide, which have recently been shown to act as second messengers in RTK and cytokine receptor signaling pathways.

PTPs act both to attenuate signals that require tyrosine phosphorylation and to activate pathways inhibited by tyrosine phosphorylation. The two Shps provide examples of each of these types of regulatory function. Shp1 functions primarily as a negative regulator of RTK, cytokine, and immune receptor signaling. Despite its strong sequence (>50% identity) and structural similarity, Shp2 acts mainly as a positive signal transducer, although it also may downregulate signaling in some contexts. As discussed above, CD45 also has both positive and negative effects on MIRR signaling.

The protein-serine/threonine phosphatases (PSPs) also comprise a large superfamily of enzymes that differ from the PTPs in catalytic mechanism, structure, and regulation. PSP catalysis utilizes an essential bound metal ion to activate water and promote dephosphorylation. Whereas PTPs typically have catalytic and regulatory functions encoded within the same polypeptide chain, most PSPs have distinct catalytic and regulatory subunits. The regulatory subunits have two general functions: they target specific PSPs to different intracellular locales and they regulate catalytic activity. Both types of subunits also can be inducibly modified by phosphorylation and/or other post-translational modifications (eg, methylation), resulting in changes in activity and/or localization.

PSPs are subdivided into families based on shared biochemical and structural features. Protein Phosphatase 1 (PP1) enzymes contain a catalytic subunit and one regulatory (targeting) subunit. With four different catalytic and approximately 50 regulatory subunits, a large number of different PP1 holoenzymes can be generated. PP2A enzymes are heterotrimers of scaffolding A, regulatory B, and catalytic C subunits. There also are a large number of possible A-B-C subunit combinations; thus, PP2A and PP1 do not each represent a single activity but rather, more than a hundred different enzymes. PP2B, better known as calcineurin, is a multimeric enzyme that, in addition, binds to calmodulin and is regulated by calcium. Calcineurin is a particularly important enzyme for immune cells, where it acts as a positive transducer of antigen receptor signals by dephosphorylating and activating NFAT (*N*uclear *F*actor of *A*ctivated *T* cells) transcription factors, and is the target of the immunosuppressant drugs cyclosporin and FK506. PP2C family members represent the final group of PSP activities. Unlike other PSPs, these enzymes tend to have a single subunit, and their regulatory mechanisms and functions are less well known.

Recently, selected members of the haloacid dehalogenase (HAD) family have been found to act as protein phosphatases. The best described of these are the Eyes absent (Eya) transcription factors, which play critical roles in developmental pathways. There is disagreement over whether Eya proteins dephosphorylate phosphotyrosine selectively or have dual-specificity phosphatase activity, and more importantly, their physiological targets remain undefined. Whether these or other HAD family members have roles in the hematopoietic system also remains to be determined.

Guanosine Triphosphate-Binding Proteins

GTP-binding proteins (G proteins) are activated by many receptors, and transmit their signals by binding to and altering the activity and/or localization of downstream effector proteins. G proteins come in two varieties: heterotrimeric and Ras-like (small). Both types use a similar signaling strategy that involves shuttling between GDP- and GTP-bound states. When bound to GDP, G proteins cannot bind effectors and are thus inactive. GTP binding leads to a conformational change that exposes an effector-binding site (often termed the *effector domain* of the G protein). Transit of G proteins from the inactive to the active state is catalyzed by guanine nucleotide-exchange proteins (GEFs). G protein inactivation is catalyzed by GTPase-activating proteins (GAPs), which stimulate their intrinsic GTPase activity (see below). The extent to which any given G protein, heterotrimeric or small, is active at any given time depends on the relative activity of its GEFs and GAPs. Most G proteins also have lipid modifications, such as farnesylation or geranylgeranylation, that promote membrane association and are required for biological activity.

Although all G proteins share this general regulatory mechanism, there are important differences between them. Heterodimeric G proteins consist of α, β, and γ subunits. Although these proteins are synthesized as individual polypeptide chains, β and γ are bound to each other extremely tightly and never dissociate within the cell; hence, they are usually referred to as βγ subunits. Mammals have 20 α subunits, 6 β subunits, and 12 γ subunits, resulting in the generation of a large number of active heterotrimers. In the GDP-bound state, the heterotrimers are stable and associate with a GPCR, which acts as a ligand-activated GEF (see above). Following activation, GTP binds the α subunit, resulting in dissociation of βγ. Both types of subunit transduces signals by binding to different types of effectors. Examples include adenylate cyclase, which is stimulated by some Gα subunits and inhibited by others, phospholipases, protein kinases, and ion channels. "Regulators of G protein Signaling" (RGS) domains have GAP activity and attenuate signaling by the α subunit. Many, if not all, RGS proteins are Gα effectors, thereby coupling signal transmission and termination in a single protein.

In contrast, Ras-like G proteins function as monomers. There are five families of Ras-like GTP-binding proteins: the Ras, Rho, Rab, Arf, and Ran proteins. The Ras and Rho families regulate cell growth, transcription, and the actin cytoskeleton; the Arfs regulate phospholipase D and vesicle trafficking; Rabs regulate vesicle trafficking; and the Ran family regulates nuclear import. Receptors do not act directly as GEFs for exchange for Ras-like G proteins. Instead, a large number of specific GEFs catalyze activation of Ras-like G proteins in response to specific cellular events. There also are multiple and specific GAPs to direct inactivation of these proteins. Ras-like G proteins have a number of downstream effectors, including protein and lipid kinases, protein phosphatases and lipases.

Phosphoinositide Kinases

Phosphoinositides (phosphorylated isoforms of phosphatidylinositol) recruit signaling molecules to intracellular membranes and some act as substrates for specific phospholipases. The regulation of the synthesis of PI-4-P and PI-4,5-P_2, the two most abundant phosphoinositides, is not well understood. PI 4-kinases synthesize PI-4-P from PI. Type I phosphatidylinositol phosphate kinases (PIPKs) phosphorylate PI-4-P at the 5 position to make PI-4,5-P_2. A related group of enzymes, the class II PIPKs, phosphorylate PI-5-P at the 4 position to make PI-4,5-P_2. PI 3-kinases phosphorylate PI, PI-4-P, and PI-4,5-P_2 at the 3-position of the inositol ring, generating PI-3-P, PI-3,4-P_2, and PI-3,4,5-P_3, respectively. Phosphoinositide levels also are

regulated by phosphatases. As indicated above, the tumor suppressor protein PTEN dephosphorylates the 3′P on PI-3,4P2 and PI-3,4,5P_3. Distinct enzymes, SHIP in hematopoietic cells and SHIP2 in other cell types, remove the phosphate from the 5 position of PtdIns-3,4–5-P_3.

Phospholipases

Three distinct types of phospholipases play important roles in cellular signaling. Phospholipases A (PLA) cleave the acyl groups from phospholipids, producing a lysophospholipid and a free fatty acid. PLA2, for example, catalyzes the first step in the production of eicosinoids by generating free arachidonic acid. Phospholipases C (PLC) cleave PI-4,5-P_2 to produce diacylglycerol and inositol trisphosphate (IP_3), both of which are second messengers (see below). Phospholipases D (PLD) hydrolyze phosphatidylcholine to produce phosphatidic acid and choline. Phosphatidic acid (PA) also can be made by diacylglycerol kinases. The function of PA is poorly understood, although it too is believed to act as a second messenger.

Small-Molecule Second Messengers

Small molecules that regulate cell signaling are generated in response to many "first messengers" that activate cell surface receptors, such as growth factors or hormones. Second messengers generally bind noncovalently to protein targets, affecting their function. The best known small-molecule signal is cAMP, the first second messenger discovered. Adenylate cyclase, activated by heterotrimeric G proteins, catalyzes the synthesis of cAMP from ATP. The primary target of cAMP is protein kinase A (PKA), which in its inactive form is a tetramer of two catalytic and two regulatory subunits. The regulatory subunits contain two cAMP-binding sites. Binding of cAMP to the first site causes a conformational change that exposes the second site; binding of cAMP to the second site dissociates the regulatory and catalytic subunits. The free catalytic subunits are active kinases that phosphorylate a variety of important intracellular targets. Although for many years PKA was thought to be the only target of cAMP in mammalian cells, other targets, including a cAMP-dependent GEF, are now known to exist.

Many activated receptors also stimulate PLCs. PLC action results in the generation of two second messengers, inositol trisphosphate (IP_3) and diacylglycerol (DAG). DAG binds to the C1 domains of members of the protein kinase C (PKC) family of serine/threonine kinases, thereby localizing this enzyme to the plasma membrane and contributing to their activation. IP3 binds to specific receptors in the endoplasmic reticulum (ER), which leads to the release of calcium from intracellular stores. Depletion of intracellular calcium stores leads to an influx of extracellular calcium via capacitative calcium channels at the plasma membrane. In unstimulated cells, cytosolic calcium is quite low (100 nM), so opening channels in the endoplasmic reticulum or plasma membrane allows calcium to flow into the cytoplasm, temporarily raising the cytoplasmic calcium to micromolar levels. Calcium returns to basal levels as a result of closing the channels and stimulation of calcium pumps. The latter include molecules that pump calcium back into the ER (SERCA), and plasma membrane-bound calcium ATPases (PMCA). Recent evidence indicates that PMCAs also can be regulated, and may be an important target of inhibitory signaling in immune cells. Calcium has many cellular effects, including directly regulating enzymatic activities, ion channels, and transcription. Specific calcium-binding domains are known, including the C2 domain and EF hands, and are found in several cell signaling molecules. In addition, calmodulin serves as a professional calcium-binding protein that regulates a number of key intracellular signaling enzymes, including CAM-kinases and calcineurin.

Eicosanoids are ubiquitous lipid signaling molecules that bind to some GPCRs and nuclear receptors. Synthesized in response to multiple stimuli, eicosanoids, unlike most second messengers, can be produced in one cell, and then both stimulate that cell and diffuse freely into nearby cells to transmit signals. Eicosanoids are produced from arachidonic acid (AA), which in turn is produced by the action of diglyceride lipases and phospholipases A on DAG and phospholipids, respectively. PLA2s cleaves the sn-2 acyl group of phospholipids to produce free AA and a lysophospholipid. The calcium-regulated form of PLA2 shows a preference for substrates containing arachidonic acid. Further metabolism of arachidonic acid results in the synthesis of prostaglandins and leukotrienes, which function as ligands for receptors. These molecules have a large array of important physiological functions, including major roles in controlling the interaction between platelets and endothelial cells. For this reason, enzymes regulating these pathways are important targets for drugs to control hemostasis and thrombosis.

EFFICIENCY AND SPECIFICITY: MULTIPROTEIN SIGNALING COMPLEXES

Effective signal transduction requires that signaling molecules find their targets rapidly and specifically. The likelihood of any two proteins coming into contact is proportional to their concentrations. Hence, diffusion is the bane of signal transmission. Even in pure aqueous solutions, diffusion rates are slow compared to the molecular dimensions of the cell and its biomolecules, and diffusion also is nonspecific and dilutes the signal. Furthermore, the intracellular milieu is closer to a proteinaceous gel than a bag of water, making diffusion-limited processes even less efficient.

To overcome this problem, most signaling occurs in complexes, more like a solid-state rather than an aqueous process. Restricting a signaling protein to a specific compartment or complex increases the local concentration of that protein and the probability that it will interact with other proteins or small molecules in the same compartment or complex. Colocalization of proteins in a signaling pathway is achieved by recruitment to the same membrane surface or organelle (eg, plasma membrane versus ER) and ultimately by protein–protein and/or protein–lipid interactions. Conversely, separating proteins or second messengers (or both) into distinct compartments can be used to turn off signaling pathways and/or to prevent gratuitous interactions.

Protein complexes can assemble on membranes by binding to specific lipids. Creating such an environment is an important function of the products of phosphoinositide kinases. For example, PI-3,4-P_2 and PI-3,4,5-P_3 colocalize the kinases Akt and PDK1, resulting in Akt activation. Other signaling molecules bind to PI4,5P2 specifically. Higher-order membrane structures, such as lipid rafts, also may direct the formation of localized signaling complexes.

Signaling molecules also can be concentrated in organelles. Nuclear localization of the NFAT transcription factors illustrates this concept. In response to antigen receptor activation, intracellular calcium rises and activates calcineurin, which dephosphorylates NFAT. Dephosphorylated NFAT binds to importins, and NFAT, along with calcineurin, is transported through nuclear pores into the nucleus. NFAT also contains a nuclear export signal (NES). Phosphorylation of NFAT leads to binding to exportin, resulting in transport to the cytoplasm and signal attenuation.

Compartmentalization also occurs on a smaller scale. Proteins involved in a sequential pathway can exist in a preformed, but inactive, complex that is activated in response to upstream signals. This strategy was first appreciated by studies of a yeast MAP kinase module composed of the Ste11, Ste7, and MAP kinases bound to the scaffolding protein Ste5. A signal activates the first kinase in the cascade, Ste20 kinase, which initiates the relay. Ste20 phosphorylates and activates Ste11, which activates the kinase cascade on Ste5. Activation of the Jnk kinase pathway in mammalian cells uses an analogous preformed complex bound to a scaffolding protein. JIP-1 (Jnk inhibitory protein) binds to MLK1, MKK7, and JNK and facilitates the activation of JNK, through colocalization with the upstream kinases. Analogous scaffolding complexes exist for, and regulate, other MAP kinase cascades. "A Kinase-Anchoring Proteins" (AKAPs) perform a related function by binding to the regulatory subunit of PKA and

targeting it to a variety of locations, including ion channels, endosomes, and mitochondria. Most AKAPs also bind other signaling molecules in addition to PKA, including phosphatases that act to terminate PKA signaling.

A common theme utilized by such signaling complexes is that of reinforcing negative feedback loops. For example, a given kinase may be colocalized with the phosphatase that inactivates its signals, and the system "wired" such that the kinase inactivates the phosphatase (eg, by directly phosphorylating it or a regulatory molecule), whereas the phosphatase dephosphorylates and inactivates the kinase. The upstream signal is designed to simultaneously activate the kinase and inactivate the phosphatase. Mathematical modeling as well as kinetic analysis indicates that such a configuration leads to switch-like behavior of the module, so that the system can oscillate between what is essentially an "off" and "on" state. Other types of pathway "wiring" can lead to more analog types of signaling.

Protein–Protein Binding Domains

The formation of multiprotein signaling complexes often involves regulated protein–protein binding (Fig. 6–2). These interactions are typically mediated by modular domains that recognize particular peptide sequences and modifications or small molecules (Table 6–3).

SH2 domains and most PTB domains bind to motifs containing pTyr residues (some PTB domains can bind to nonphosphorylated peptide motifs). All SH2 domains share a similar structure, as do PTB domains, but in an example of convergent evolution, SH2 and PTB domains have no structural similarity. PTKs and PTPs regulate the formation of SH2- and PTB-domain-containing complexes by determining the state of tyrosine phosphorylation on specific proteins. The specificity of these interactions derives from both phosphorylation of particular tyrosine residues and recognition of a motif surrounding the phosphorylated tyrosine by the SH2 or PTB domain. An example of this type of protein–protein interaction is the binding of PI3K, SHP2, and p120 RASGAP to specific phosphorylated tyrosines on the PDGFR. In addition to mediating protein–protein interactions, binding of SH2 domains to pTyr residues stimulates the enzymatic activities of such proteins as PI3K, SHP2, and SFKs. The crystal structures of many SH2 domains have been determined, revealing a pocket that binds the phosphotyrosine and a groove that determines binding specificity based on the fit of the residue's C-terminal (or, in a few cases, N-terminal) to the phosphotyrosine.

Recognition of motifs containing a phosphorylated serine provides also an important means of protein–protein interaction. Forkhead-associated domains, 14–3-3 proteins, polo boxes, and some WD40 and WW domains bind to regions of proteins containing phosphoserine. WD40 domains in F-box proteins mediate phosphorylation-dependent ubiquitination and subsequent proteolysis of some proteins, such as the inhibitor of κB (IκB).

Other domains (Src homology 3 [SH3], WW, and Ena-Vasp homology [Eva] domains) mediate protein–protein interactions by binding to proline-rich sequences. Like SH2 and PTB domains, these domains are structurally quite different. Many proteins that contain SH3 domains have proline-rich regions themselves that mediate intramolecular binding. A conformational change in such a protein could disrupt intramolecular binding and allow the SH3 domain to interact *in trans* with other proteins. Similarly, the accessibility of proline-rich regions to SH3 domains may be regulated by conformational changes that expose the proline-rich region or disrupt an intramolecular interaction. Protein phosphorylation or binding of a small G protein to its effector domain can alter such interactions, resulting in a biological response. For example, binding of the SH3 domain containing protein Nck or the small G protein Rac to WASP, the protein mutated in Wiskott–Aldrich syndrome, can disrupt an intramolecular inhibitory interaction and promote new actin polymerization.

PDZ domains recognize specific motifs in the C-termini of proteins. These domains are found in cytoplasmic proteins, and many proteins contain multiple PDZ domains. PDZ domain-containing proteins can function to aggregate transmembrane proteins, such as the ion channels. Alternatively, they can act to assemble intracellular signaling complexes. Binding of PDZ domains to their motifs can be disrupted by phosphorylation of an amino acid in or near the binding site, thereby allowing regulation of the signaling complex assembly.

TABLE 6–3 Protein–Protein Interaction Domains and Motifs

Motif	Binding Domain	Examples of Proteins Containing this Domain
pTyr	SH2	SFK, PI3K, Shp2, PLCγ
	PTB	Ship, Shc
pSer	WD40	Apaf, PP2A-alpha subunit
	14-3-3	14–3-3 proteins
	WW	Pin1*
	FHA	Rad 53
	Polo Box	Plk
Proline-rich	SH3	SFK, Grb2, PI3K, PLCγ
	WW	YAP
	EVH1	VASP, ENA, WASp
C-terminal sequences	PDZ	Disheveled, ZO-1

PI3K, phosphatidylinositol 3-kinase; pSer, phosphoserine peptides; pTyr, phosphotyrosyl peptides; SFK, Src family kinases; YAP, yes-associated protein.
*Note that Pin1 is the only known case of a pSer-specific WW domain.

Protein/Lipid-Binding Domains

Localization of proteins to membrane surfaces reduces their diffusion, increasing the probability of enzyme–substrate contact. A number of protein modules have evolved to mediate binding to specific lipids (Table 6–4). The C1 domains present in PKCs and other signaling molecules bind to DAG. Membrane recruitment of PKC is also aided by the C2 domains, which binds to anionic phospholipids in the presence of calcium. The lipid phosphatase PTEN is also targeted to

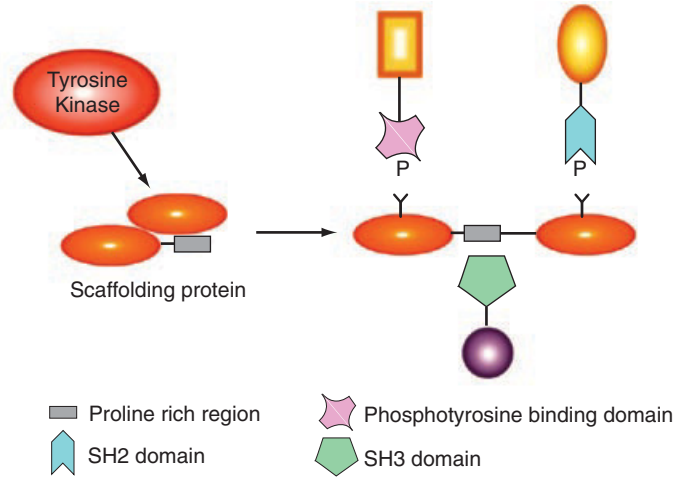

Figure 6–2 Formation of signaling complexes. Many signals are transmitted by complexes of signaling molecules that form in response to receptor activation. Scaffolding proteins are sites of complex formation. They can be activated by tyrosine phosphorylation, which allows proteins containing phosphotyrosine recognition domains (PBD and SH2 domains) to bind. Proteins that contain SH3 domains bind to proline-rich sequences, whose accessibility can be regulated. Signaling complexes solve the problem of diffusion and result in efficient transmission of signals to nearby proteins.

TABLE 6–4 Lipid-Binding Domains in Signaling Proteins

Lipid	Binding Domain
DAG	C1
PA	PX
PI-4-P	PH
PI-3-P	PX, PH, FYVE
PI-3,4-P_2	PH
PI-3,5-P_2	PH
PI-4,5-P_2	PH, Tubby, FERM, Sprouty, ENTH, ANTH
PI-3,4,5-P_3	PH

DAG, diacylglycerol; PA, phosphatidic acid.

membranes by means of a C2 domain. Several structurally unrelated domains bind to phosphoinositides. PH domains bind specifically to PI-3,4-P2, PI-3,4,5-P3, or PI-4,5P-2. PX and FYVE domains bind specifically to PI-3-P, whereas FERM domains bind PI-4,5-P_2. The physiological importance of such interactions is demonstrated by the fact that mutation of a single residue within the PH domain of the Tec family kinase BTK eliminates its ability to bind to PI3,4,5P3 and causes the disease X-linked agammaglobulinemia.

SIGNALING OUTPUTS

Signal transduction pathways regulate most aspects of cellular and organismic function. Decisions about cell division, differentiation, and death are the result of inputs from multiple signaling pathways. Similarly, metabolism, cell motility, and cell-specific functions such as antibody production are regulated by specific signaling events. Most of these outputs require changes in protein expression, which is mediated by altering transcription, translation, and protein stability.

Regulation of gene transcription is the primary outcome of many signaling pathways. Microarray studies attest to the magnitude of this effect. Addition of a single growth factor to a cell can alter the transcription of hundreds of genes. The ability to transcribe a gene is regulated at many levels, including the structure of chromatin in the region of the gene, modifications of the promoter regions, and the activity of specific transcription factors and coactivators. Signal transduction pathways affect all of these steps.

Transcription factors are stimulated by many different mechanisms (Fig. 6–3). In the simplest case, binding of ligands to the nuclear receptor family of transcription factors results in a change in conformation of the ligand-binding domain, which simultaneously results in corepressor dissociation and creates a surface for binding to coactivators. Also, as discussed above, phosphorylation of STAT family transcription factors in response to stimulation of cytokine receptors or RTKs allows them to dimerize through their SH2 domains, enter the nucleus to bind DNA, and activate transcription. TGFβ family receptors activate transcription by phosphorylating SMAD proteins on seryl residues. This promotes heterodimerization with SMAD4 and exposes the DNA-binding domain. Activated SMADs translocate to the nucleus, complex with a protein called FAST1, and bind DNA to regulate transcription.

Other transcription factors are activated by more complicated signal transduction pathways. Antigen receptor signaling leads to PLCγ activation, which, in turn, leads to an increase in intracellular calcium release and activation of calcineurin. Calcineurin dephosphorylates and activates NFAT family members, which translocate into the nucleus and activate transcription. Several immediate early genes (genes whose transcription is induced without the need for new protein synthesis) are activated by growth factors, hormones, and cytokines. A major mechanism of regulation of such genes is via Ets

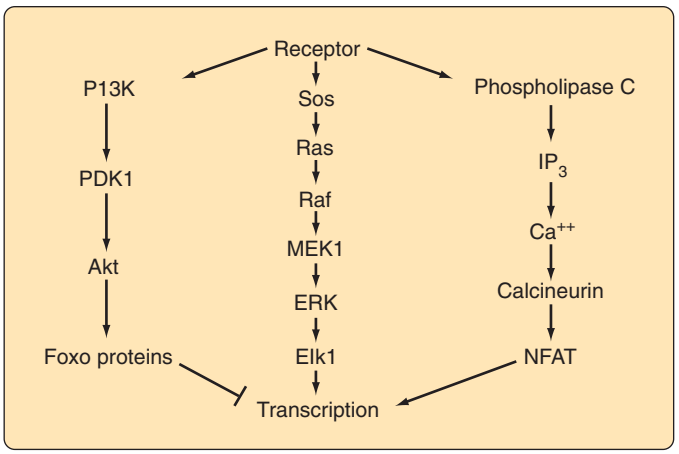

Figure 6–3 Examples of signaling pathways that regulate transcription. Transcriptional regulation is a common target of many signaling pathways and receptors often stimulate multiple pathways that can regulate common and distinct transcription factors. In the examples shown here, production of PtdIns-3,4,5-P_3 by phosphoinositide 3-kinase (PI3K) leads to the activation of the serine/threonine kinase Akt. Akt phosphorylates Foxo transcription factors, leading to their cytoplasmic sequestration and inactivation. Ras is activated by the guanine nucleotide exchange factor son of sevenless (Sos). Ras activation initiates a cascade of serine/threonine kinase activity: Ras activates Raf, Raf phosphorylates and activates Mek1, and Mek1 phosphorylates and activates Erk. Phosphorylation of the transcription factor Elk1 by Erk stimulates its activity. Increased intracellular calcium is also a common signaling event. Activation of phospholipase C leads to hydrolysis of PtdIns-4,5-P_2 and production of IP_3. IP_3 binds to its receptor, leading to intracellular calcium release and then extracellular calcium influx. Calcium activates the serine phosphatase calcineurin, which dephosphorylates NFAT proteins, allowing them to enter the nucleus and stimulate transcription.

family transcription factors such as ELK-1, which is under the control of a canonical MAP kinase cascade. Stimulation of the transcriptional activity of ELK-1 by EGF requires activation of a RAS-GEF, which leads to GTP binding and activation of RAS. RAS stimulates the kinase RAF, which in turn phosphorylates and activates MEK1. MEK1 phosphorylates and activates ERK, which translocates to the nucleus and phosphorylates and stimulates ELK-1. An analogous pathway, involving another family of MAP kinases, serves to activate the transcription factor c-JUN. In this case, receptor activation leads to activation of the MAP kinase JNK (again, via activation of the upstream kinases MEK4/7 and MEKK1, respectively), which phosphorylates c-JUN on a specific site to enhance its transcriptional activation activity. In addition to directly activating transcription factors, phosphorylation cascades can also affect the activity of coactivators and corepressors.

Messenger RNA export from the nucleus and translation also are controlled at multiple levels by cellular signaling pathways. A particularly important means of regulating translation involves the action of several protooncogene and tumor suppressor gene products. Activation of many receptors results in the activation of PI3K, which in turn activates AKT (both protooncogenes). AKT has several downstream targets, but among them is TSC2 (Tuberin), one of two tumor suppressor genes mutated in tuberous sclerosis patients. TSC2 forms a complex with the other tuberous sclerosis-associated gene, TSC1 (Hamartin); together, this protein complex inhibits the protein kinase TOR. TOR exists as part of two large protein complexes, which function to direct it to specific substrates and probably to regulate its activity. Two important targets of TOR complex 1 are p70S6 kinase (S6K) and 4EBP1. Both of these targets regulate transcription: S6K phosphorylates the ribosomal protein S6 and the RNA-binding protein SKAR, which may enhance the translation or export of specific mRNAs, respectively. 4EBP1 acts as a repressor for

the translation initiation factor eIF-4E, which binds to the Cap structure at the 5′ end of mRNAs. Phosphorylation of S6K by TOR increases its activity, whereas phosphorylation of 4EBP1 inactivates its ability to repress eIF-4E. Both of these activities can be blocked by the drug rapamycin, which binds and inhibits TOR. Although currently approved as an immunosuppressant, the recent elucidation of the details of TOR action suggests rapamycin may have antineoplastic actions as well.

Regulated proteolysis is another, increasingly appreciated mechanism of cellular regulation. Protein degradation can occur via either the proteosome or the lysosome. A common method of targeting proteins for proteolysis is the addition of the 76-amino acid polypeptide ubiquitin. Exquisitely regulated pathways control ubiquitination and deubiquitination; these, in turn are often regulated by protein phosphorylation. The type of ubiquitination determines its ultimate effect. As a general rule, polyubiquitination targets proteins to the proteosome, whereas monoubiquitination targets proteins to the lysosome. In some cases, however, monoubiquitination does not lead to lysosomal targeting, but instead alters protein function.

The NF-κB family of transcription factors provides a classic example of the interplay between phosphorylation and ubiquitination. NF-κB is sequestered in the cytoplasm by IκB proteins. A variety of receptor-mediated signaling pathways lead to the activation of a large protein complex with IκB kinase (IKK) activity. Phosphorylation of IκB causes its dissociation from NF-κB, which allows NF-κB to enter the nucleus and bind DNA. Phosphorylation of IκB also makes it a substrate for a specific ubiquitin ligase that catalyzes its polyubiquitination and degradation by the proteosome. One of the many NF-kB targets is the IκB gene, which leads to restoration of IκB levels, and resets the system.

The second major pathway of protein degradation is the lysosomal pathway, which also plays a key role in signal transduction. An early response to the stimulation of receptors is their internalization into endosomes; some evidence suggests that signaling persists at this location after endocytosis. In the case of RTKs, ligand-dependent PTK activity is necessary for endocytosis, mediated by clathrin-coated pits. After endocytosis, either receptors may either recycle to the plasma membrane or the endosomes may fuse with lysosomes, leading to degradation of the receptor. A key control of this pathway is effected by a group of monoubiquitin ligases, the Cbl proteins.

SUMMARY AND PERSPECTIVE

This brief introduction has illustrated the complexity of cellular regulation and some examples of how this regulation, when perturbed, can result in diseases of lymphohematopoietic tissues. With the completion of the Human Genome Project, most of the critical participants in cell regulation are now known, and much of the core signaling circuitry has been elucidated. The challenge for the future is to understand how these pathways are integrated to control hematopoiesis and to utilize this knowledge to develop more effective treatments for disease.

CHAPTER 7

CONTROL OF CELL DIVISION

William M. F. Lee and Chi V. Dang

Somatic cells undergo one of three general fates: They proliferate by mitotic cell division, differentiate and acquire specialized functions, or die and are eliminated. Cell proliferation is necessary for growth of the organism and ensures repletion of cells lost to terminal differentiation, cell death, or cell shedding. In the case of lymphocytes, it serves the additional function of amplifying immune responses to specific antigens. Differentiation provides the organism with a supply of cells to execute specific and specialized functions. In some cell types, such as muscle and nerve cells, differentiation and proliferation are mutually exclusive fates, and cells undergo "terminal differentiation." In other cell types, such as those of the hematopoietic lineage, proliferation may continue after cells acquire differentiated characteristics. For example, erythroblasts, myeloblasts, and megakaryoblasts are committed to particular differentiation pathways and possess lineage-specific markers yet continue to proliferate. T and B lymphocytes are fully differentiated and express antigen-specific receptors but can be induced to proliferate when appropriately stimulated. Cell death is an active process when it is initiated by the cell itself in the process known as *apoptosis* and can be as important as cell proliferation and differentiation for maintaining the integrity of the organism. It allows tissue renewal and changes in cellular composition without undesirable cell accumulation.

When the regulation of any of these three cellular processes—proliferation, death, and differentiation—goes awry and their balance becomes abnormal, the consequences to the organism are usually dire and result in either functional insufficiency or neoplasia. The relevance of these events to normal tissue function and neoplasia has led to investigations of their mechanisms and regulation at a molecular level. This chapter focuses on cell proliferation and its regulation. Cell death is discussed in Chapter 8, and differentiation of specific hematopoietic cell types is discussed in chapters focused on these cell types.

SIGNAL TRANSDUCTION AND CELL PROLIFERATION

Cells normally proliferate and differentiate and sometimes die in response to signals from their environment. Of these, cell proliferation or mitogenic signals and signaling mechanisms are the best studied and provide a paradigm for how cells respond to environmental signals in general. Cell proliferation normally is stimulated by extracellular growth factors interacting with specific receptors located at the cell surface. Signal transduction is the process by which information about growth factors at the cell surface is transmitted to the nucleus, where ultimate control of most cellular events resides. Signal transduction pathways leading to cell differentiation operate on similar principles and use similar mechanisms but produce different outcomes. A brief overview of some of the biochemical events involved in mitogenic signal transduction is provided as introduction and context for the following discussion of cell cycle regulation. A detailed discussion of signal transduction is found in Chapter 5.

Much of what is known about signal transduction is based on studies of the cellular biochemical response to mitogens such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF).[1,2] When these ligands bind to their cognate cell-surface receptors (PDGF-R and EGF-R, respectively), the receptors dimerize, activate their intrinsic tyrosine kinase activity, and catalyze the transfer of phosphate groups from adenosine triphosphate (ATP) to tyrosine residues of specific cellular proteins, including the receptors themselves (Fig. 7–1).[3] Some other types of receptors, such as the T-cell antigen receptor and CD4 and CD8 co-receptors, are not tyrosine kinases, and the tyrosine phosphorylation that they induce on ligand binding is mediated by associated nonreceptor tyrosine kinases-ZAP-70 in the case of T-cell antigen receptors and Lck in the case of CD4 and CD8.[4]

The presence of phosphotyrosines in target proteins enables them to form noncovalent complexes with proteins containing SH2 domains (Src homology region 2; defined by homology to a region in the Src retroviral oncoprotein), which are peptide domains that bind phosphotyrosine-containing peptides.[5] Thus, phosphorylation of the EGF-R and PDGF-R enables them to interact with SH2-containing proteins near or at the plasma membrane, which initiates downstream signaling events. Certain enzymes with SH2 domains, such as the γ1 isoform of phospholipase C (PLCγ1), directly associate with phosphorylated EGF-R and PDGF-R and become tyrosine phosphorylated by them, which, in the case of PLCγ1, results in enhancement of enzymatic activity. Activation of PLCγ1 catalyzes the hydrolysis of phosphatidylinositol (PIP_3) into diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP_3), both of which act as "second messengers" that launch additional actions inside cells: DAG activates protein kinase C (PKC), a kinase that phosphorylates serine/threonine residues in substrate proteins, and IP_3 induces Ca^{2+} release from intracellular stores, which in turn activates Ca^{2+}/calmodulin-dependent serine/threonine protein kinases and other Ca^{2+}-dependent events.[6]

Another signaling pathway activated when mitogen receptors bind ligand and become phosphorylated stems from activation of Ras proteins. These are low-molecular-weight guanosine triphosphate (GTP)-binding proteins that are active in their GTP-bound state but inactive in their guanosine diphosphate (GDP)-bound state. The intrinsic GTPase activity of Ras, enhanced by the presence of GTPase-activating proteins (GAPs), hydrolyzes bound GTP to GDP and maintains Ras in its inactive state.[7,8] Following EGF binding by EGF-R, two cytoplasmic proteins, Grb2 and SOS, that exist as heterodimers in unstimulated cells physically link EGF-R with Ras in a quaternary complex through binding of phosphorylated EGF-R with the SH2 domain of Grb2 and the binding of SOS to Ras. Formation of this complex activates the function of SOS as a guanine nucleotide exchange factor (GEF), resulting in the conversion of Ras-GDP to Ras-GTP and Ras activation. Activation of Ras initiates a cascade of serine/threonine kinase activation involving a trio of kinases.[9] Beginning with the association of GTP-Ras with Raf-1 (a mitogen-activated protein kinase [MAPK]), which activates the latter's serine/threonine kinase function, Raf-1 phosphorylates and activates MEK (MAPK kinase). MEK is a kinase that phosphorylates and activates MAPK, which is also known as ERK (*e*xtracellular signal-*r*egulated *k*inase). Modules composed of three sequentially activated serine/threonine kinases are a recurring motif in signaling from the plasma membrane, where Ras and Ras-like molecules reside, to the nucleus, which phosphorylated MAPK or ERK can enter.

Serine/threonine kinases activated following mitogen exposure phosphorylate diverse cellular proteins and modulate their activities.[10] Prominent among these targets are transcription factors.[11] Phosphorylation may directly alter the ability of these factors to bind DNA or

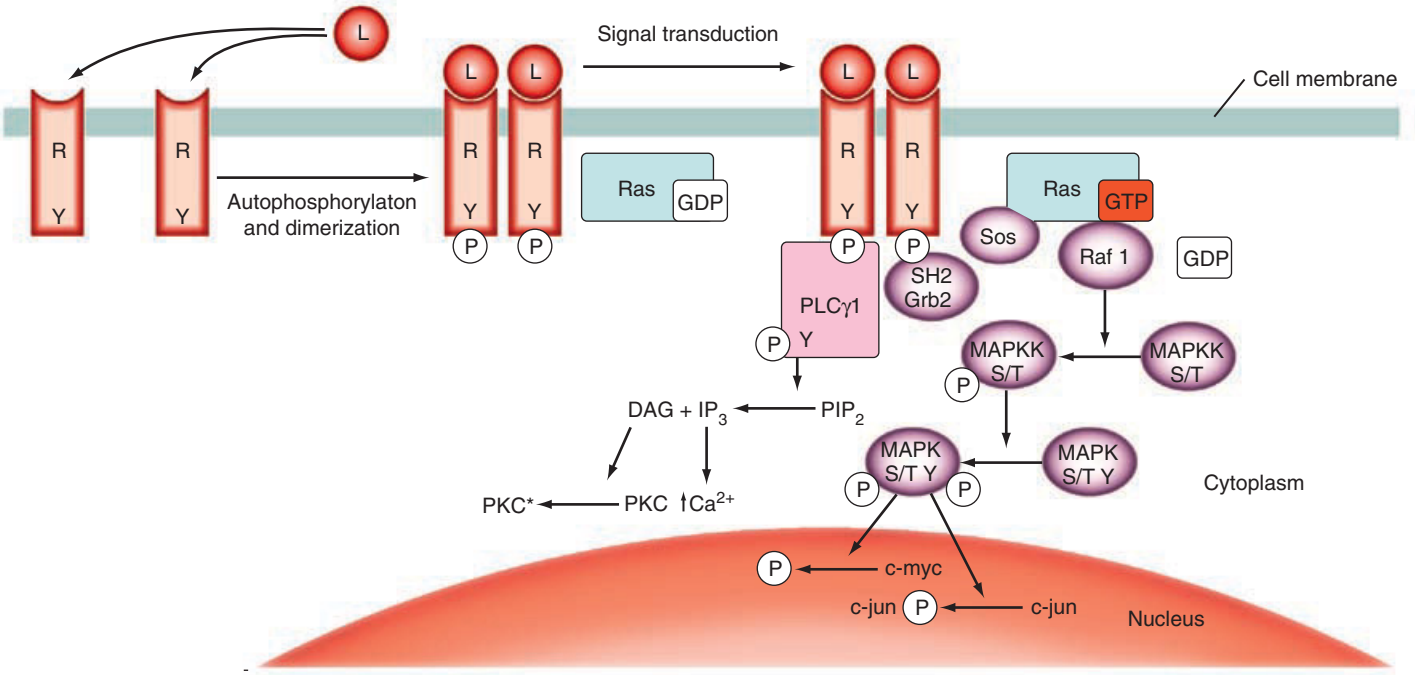

Figure 7–1 MITOGENIC SIGNAL TRANSDUCTION. Shown are signal transduction pathways activated by the binding of mitogenic ligands (L), to their cognate receptors (R) at the cell surface. Binding results in dimerization and autophosphorylation (P) of the receptors on tyrosine residues (Y). This enables them to associate with and activate specific SH2 domain-containing downstream components of the signaling pathway. In the case of phospholipase Cγ1 (PLCγ1), association leads to tyrosine phosphorylation by the receptor kinase and an enhanced ability to hydrolyze phosphoinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol trisphosphate (IP_3); in turn, DAG activates protein kinase C (PKC) and IP_3 mobilizes Ca^{2+} from intracellular stores. In the case of Grb2-SOS, association with phosphorylated receptors stimulates its ability to facilitate Ras GTP-GDP exchange; GTP-Ras activates the MAP kinase (MAPK) cascade, which eventually induces serine (S)/threonine (T) phosphorylation of nuclear proteins that modulate gene transcription. Note that MAPK is activated by serine/threonine and tyrosine phosphorylation and that both result from the activity of a single dual-function kinase, MAPK kinase. EGF, epidermal growth factor; MAP, mitogen-activated protein; PDGF, platelet-derived growth factor.

activate transcription. Alternatively, phosphorylation may indirectly activate transcription factors by inactivating an antagonist of these factors. Mitogen stimulation may result in activation of protein phosphatases that dephosphorylate specific phosphorylated residues in certain transcription factors to alter function.[12] The end result of these rapid posttranslational protein modifications is the first wave of change in cell transcription, which can occur independent of new protein synthesis. "Immediate early" is the description collectively applied to genes whose messenger RNA (mRNA) is rapidly induced by growth factor stimulation in the absence of de novo protein synthesis. Included in their number are genes encoding transcription factors. These initial changes lead to changes in expression of other transcription factor genes (which do require de novo protein synthesis) and culminate in the transcriptional reprogramming of the cell that eventually enables them to undergo DNA synthesis and cell cycling. It should not be surprising that many of the components of the mitogenic signaling pathway are oncogenic when they are inappropriately activated.[1]

Ligands other than EGF and PDGF may use different schemes for signal transduction. Neuroactive and vasoactive peptides (eg, epinephrine and thrombin) activate responsive cells through specific receptors that have seven membrane-spanning domains. These receptors are typically coupled to heterotrimeric G proteins that resemble Ras in being regulated by GTP and GDP.[7,13] These receptor-coupled G proteins are linked to effector enzymes (eg, adenylyl cyclases) that generate molecular signaling intermediates (eg, cyclic adenine monophosphate [cAMP]) on ligand binding. Steroid and thyroid hormones and retinoids can enter cells by virtue of their lipophilic nature. Their receptors are intracellularly located and able to bind sequence-specific DNA and directly modulate the transcription of responsive genes. Thus, the receptors are transcription factors whose activities are influenced by binding of the cognate hormone.[14]

Interferon signaling uses a different signal transduction paradigm. Tyrosine kinases of the Janus kinase (Jak) family associate with interferon receptor subunits. On ligand binding, association of the receptor subunits allows these Jaks to phosphorylate and activate each other and to phosphorylate the associated receptors. Specific members of the STAT (signal transducers and activators of transcription) family of latent cytoplasmic transcription factors, which have SH2 domains, dock to the receptor phosphotyrosines and become phosphorylated by Jak. Tyrosine phosphorylation allows STATs to dimerize and translocate to the nucleus, where they bind sequence-specific DNA and modulate transcription of interferon-responsive genes.[15] Signal transduction using Jak-STAT protein is used by many peptide ligands and cytokines of hematologic interest (eg, erythropoietin; interleukins IL-2, IL-3, IL-4, IL-6, and IL-12).

The signal transduction schemes outlined permit a single event, ligand-receptor interaction, to have several downstream consequences. Its multiplex, frequently cascading nature allows signal amplification and diversification but also permits their modulation and fine regulation. Signaling pathways can intersect and interact at different levels, allowing one ligand to modify the signals generated by another ligand. For example, STATs can be phosphorylated by receptor tyrosine kinases, such as PDGF-R and EGF-R, as well as by Jak, and can undergo serine/threonine phosphorylation, which modulates their transcriptional activity.[15] This allows PDGF and EGF to initiate some events usually initiated by cytokines and interferons, and the phenotypic changes brought about by cytokines and interferons may be altered in the presence of PDGF and EGF.

Transcription factors are final participants in afferent signal transduction pathways and initiators of cellular responses to these signals.[11] In general, they are sequence-specific DNA-binding proteins that modulate the expression of genes to which they bind. When these factors bind their cognate DNA sequence, they

interact with the basal transcription machinery either directly or via intermediary proteins ("coactivators" and "corepressors") to initiate, enhance, or inhibit transcription. Transcription factors have peptide domains with characteristic secondary structures that are responsible for their ability to bind DNA. Many bind DNA only as dimers, making the peptide domain responsible for dimerization essential for DNA binding.

Transcription factors use one of a number of peptide motifs to dimerize and bind DNA, among them the zinc finger, the basic region-leucine zipper (bZip), the basic region-helix-loop-helix (bHLH), and the helix-turn-helix motifs.[16] Factors that activate gene transcription generally do so because they have a distinct transcriptional activation domain that is frequently acidic in nature, glutamine rich or proline rich. Transcriptional gene regulation is highly complex, not only because of the multitude of transcription factors present in cells but also because of the ability of many factors to heterodimerize and form combinatorial pairs that have DNA-binding, transactivation, and/or regulatory properties that differ from those of the parental homodimers. A striking example is provided by heterodimers containing the Id protein, which is an HLH protein that can dimerize with selected bHLH proteins, such as the myogenic transcription factor MyoD, but that does not possess a DNA-binding basic region. Id-containing heterodimers are incapable of binding DNA, making Id a negative transcriptional regulator that inhibits the function of positive factors.

Negative gene regulation also occurs by active repression of transcription, and certain transcriptional repressors have been shown to recruit factors that bind histone deacetylases. Histones are a family of nuclear proteins that interact with DNA and organize it into higher-order structures consisting of DNA wrapped around a histone core (nucleosomes). Acetylation of histones masks their basic residues, destabilizes their interaction with DNA, "loosens" nucleosome DNA, and facilitates transcription. Deacetylation of histones, in contrast, stabilizes their interaction with DNA, which "tightens" nucleosome DNA and inhibits transcription. Reversible, regional histone acetylation, through recruitment of co-activators with acetyltransferase activity or recruitment of co-repressors with deacetylase activity, is a general mechanism by which transcription factors facilitate or repress expression of specific genes.[17]

THE CELL DIVISION CYCLE

A cell stimulated to divide passes through a series of states, defined by biochemical and morphologic criteria, collectively termed the *cell cycle* (Fig. 7–2). Passage through the cell cycle provides an ordered sequence to the complex series of events necessary for the production of two identical progeny cells. The normal cell cycle is divided into discrete and sequential phases: S, G_2, M, and G_1.

S Phase

S phase is the period of wholesale DNA synthesis during which the cell replicates its genetic content; a normal diploid somatic cell with a 2N complement of DNA at the beginning of S phase acquires a 4N complement of DNA at its end. (Recall that N = 1 copy of each chromosome per cell [haploid]; 2N = 2 copies [diploid].) The duration of S phase may vary from only a few minutes in rapidly dividing, early embryo cells to a few hours in most somatic cells. Early embryo cells generally "live off" the accumulated stores of maternal RNA and proteins present in the egg and are transcriptionally silent, whereas cells in later development and mature organisms must actively transcribe subsets of their genes to survive and maintain specialized functions. The longer time required for the latter to complete S phase probably allows these cells to coordinate DNA replication with transcription and to preserve higher-order gene and chromatin structural information that influences gene expression for transmission to progeny cells.

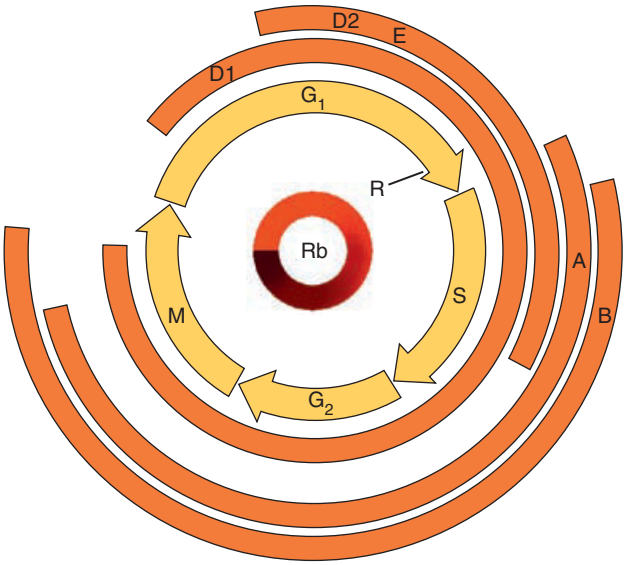

Figure 7–2 THE CELL CYCLE. The somatic cell cycle is divided into phases of DNA replication (S), mitosis (M), and the "gaps" in between (G_1 between M and S; G_2 between S and M). G_0 is not shown for the sake of simplicity but would be a side loop exiting and entering G_1. The point in late G_1 at which cells become committed to DNA replication is called the restriction point (R). The *inner circle* shows the pattern of Rb phosphorylation through the cell cycle, with the density of stippling indicating the degree of Rb phosphorylation. Places in the cell cycle where individual cyclins (A, B, D1, D2, E) appear are shown by the outer arcs.

M Phase

Mitosis, or M phase, is the period of actual nuclear and cell division during which the duplicated chromosomes are divided equally between two progeny cells. It is obvious microscopically as the period of chromosome condensation and segregation, nuclear division (karyokinesis), and physical separation of the two daughter cells (cytokinesis). A cell entering M phase has a 4N DNA content and finishes as two cells, each with an identical 2N complement of DNA. The complex sequence of changes that take place allows M to be subdivided into prophase, prometaphase, metaphase, anaphase, and telophase. *Prophase* is the period of chromatin/chromosome condensation, centrosome separation/migration to opposite poles, and nuclear membrane breakdown. The centrosomes are microtubule organization centers that eventually give rise to the bipole mitotic spindle apparatus that will separate the sister chromatids of each duplicated chromosome. During *prometaphase*, chromosomes attach to microtubules of the mitotic spindle, so that sister chromatids become attached to opposite poles. In *metaphase*, the condensed chromosomes align at the equatorial plate. The cohesive "bond" between sister chromatids of duplicated chromosomes is dissolved, allowing *anaphase*, the period of sister chromatid separation, to proceed. On reaching their poles, nuclear membranes form to envelop each of the two separated sets of chromosomes, which also begin to decondense, marking *telophase* and karyokinesis. This is soon followed by cytokinesis and exit from M.

G_1 and G_2 Phases

G_1 and G_2 phases were originally conceived of as "gaps" between the distinctive M and S phases of the cell cycle. G_1, which occupies the period or gap between M and S, is the interval between the completion of one round of cell division and initiation of the next. Its duration is the most variable, can be prolonged depending on the cell type, and is subject to regulation by environmental factors such as the availability of growth factors and nutrients. It is the period of cell

growth, and a certain increase in mass usually is required before the cell initiates the next S phase.

If cell size or mass were not regulated, S phase entry might cause cells to become progressively smaller or be at risk for DNA replication errors as a result of insufficient substrates. The mechanisms of cell size regulation are beginning to emerge from studies of yeast as well as mammalian systems.[18] Cell size regulation is intimately linked to ribosome biogenesis and nutrient-sensing systems, central to which are the phosphoinositol 3-kinase (PI3K) and target of rapamycin (TOR) pathways. Yeast mutants that generate small-size cells include mutants of the *sch9* gene, whose product is homologous to mammalian Akt/protein kinase B (PKB), and *sfp1*, which encodes a transcription factor involved in ribosome biogenesis and translation. TOR was identified as a sensor of nutrients and mediator of protein synthesis. In the setting of amino acid deprivation, for example, TOR is inactivated. Inactivation of TOR in turn decreases activated S6K, a target of TOR and a kinase that phosphorylates ribosomal protein S6 in response to proliferative signals. A decrease in TOR function also activates 4EBP, which binds to and inhibits the translational initiator eIF4E. In an intriguing line of evidence, a class of *Drosophila* small-body-size mutants, termed *Minutes*, also has been shown to be defective in ribosomal protein genes as well as in signal transduction pathways. Specifically, mutations in the *Drosophila* insulin receptor, PI3K, TOR, S6K and Akt/PKB result in the *Minut*e phenotype, whereas mutation of *Pten* (phosphatase and tensin homolog deleted on chromosome 10), which negatively regulates the PI3K and Akt/PKB pathways, produces large flies with large cells.

Remarkably, mutations in the *Drosophila Myc* gene also resulted in fewer, smaller cells and small body size, suggesting that protooncogenic *Myc* regulates size as well as cell proliferation. Because Myc pleiotropically affects gene expression, it has emerged as an integrator of cell size regulation and cell proliferation. In particular, mammalian c-Myc regulates both cyclins and *CDK* genes as well as ribosomal protein genes and genes involved in translation. Overexpression of c-Myc in lymphocytes results in both cell size increase and a detectable increase in cell proliferation. However, germline mutation of *myc* in the mouse results in small mice that have fewer but normal-sized cells. An interpretation of these observations is that mammalian cells may be less tolerant of cell size depletion than lower metazoans. In aggregate, studies from a variety of organisms indicate that cell size regulation is linked to cell proliferation, except in specialized cells that undergo endoreplication (see Specialized Cell Cycle).

As a first approximation, the amount of time a cell spends in G_1 is inversely related to its rate of proliferation. When conditions are unsuitable for proliferation (eg, because of insufficient nutrients or absence of mitogens), cells arrest in G_1, and those that are already in S, G_2, or M usually complete the round to which they have been committed and arrest only when they reach G_1 again. On the other hand, when rapid cell proliferation is mandated, as in embryos shortly after fertilization, G_1 is virtually undetectable, and there is no cell enlargement. As a result, the original mass of egg cytoplasm is partitioned among thousands of cells within a few hours without a noticeable increase in size. G_1 has been subdivided into segments and regulatory points based largely on the study of the proliferative response of cells to sequential application of different growth factors, nutrients, and metabolic inhibitors. From the standpoint of cell cycle regulation, a particularly important point in G_1 is the restriction point, or R, which occurs near the G_1-S boundary. This is the point at which cells become committed to entering S phase, regardless of subsequent availability of growth factors or essential nutrients, and is analogous to the commitment point in the yeast cell cycle called Start.

G_2 is the period or gap between S and M when cells have finished replicating their DNA, are preparing to divide, and have a 4N DNA content. For most cells entering S phase, passage through G_2 is "automatic," and the duration of G_2 is fixed except under unusual circumstances. For example, G_2 duration can be extremely short and is essentially undetectable in rapidly proliferating, early embryonic cells.

G_0 Phase

G_0 is a nonproliferative phase in which viable cells may remain for prolonged periods. Cells in G_0 have 2N DNA content and have exited the cell cycle. They may be difficult to distinguish morphologically from cells in a prolonged G_1 phase but in some cases can be distinguished biochemically, as they differ in protein and RNA metabolism. Terminally differentiated cells, such as neutrophilic granulocytes, muscle cells, and neurons, have irreversibly exited the cell cycle during the process of differentiation and are examples of cells that have irreversibly entered G_0. Other cells reversibly enter G_0 and may be induced to return to G_1 and begin cycling with appropriate stimuli. For example, hepatocytes usually are in G_0, unless partial hepatectomy induces them to proliferate to reconstitute the functional mass of the liver. Resting, antigen-specific lymphocytes are in G_0 until antigen and cytokine stimulation induces them to proliferate.

The enforced sequence G_1–S–G_2–M during normal progression through the cell cycle means that a cell must duplicate its DNA before dividing and that it must divide before duplicating its DNA again. This sequence ensures euploidy, and its enforcement maintains genetic stability. The dependence of later events in the cell cycle on successful completion of earlier events is ensured by checkpoint control mechanisms that prevent a cell that has not successfully completed one phase of the cycle from entering the next.[19,20] Certain cell types, such as megakaryocytes, become polyploid as part of their normal development and differentiation. In these cases, the normal cell division cycle script obviously is not followed: M fails to follow S, and DNA replication is allowed to repeat despite this lack of follow-through.

RB AND TRANSCRIPTIONAL REGULATION OF THE CELL DIVISION CYCLE

Progression through the different phases of the cell cycle requires successful execution of a complex series of events. Although each of these is indispensable for a cell to give rise to two identical progeny, the pivotal event during cell proliferation is the replication of its genes. Not surprisingly, therefore, entry into S phase and initiation of DNA replication constitute a highly regulated decision. Without trivializing the other processes involved in cell cycling, those preceding DNA synthesis may be viewed as ensuring that conditions warrant genome replication and preparing for it, whereas those following genome replication may be viewed as making sure that the products are apportioned correctly to progeny cells. The actual process of DNA replication requires the coordinate presence and activity of substrates for DNA synthesis (deoxynucleotide triphosphates), DNA-synthetic enzymes, mechanisms for copying template DNA, mechanisms for checking the integrity of the results and correcting defects if present, and mechanisms for deconstructing and reconstructing chromatin composition and chromosome structure. The task of replicating cellular DNA is complex, as are the enzymatic and regulatory mechanisms that carry them out. Cells entering S phase must possess the proteins and substrates necessary for DNA synthesis (acquiring substrates essentially means acquiring the relevant biosynthetic enzymes), so S phase entry can happen only in cells that have activated expression of genes encoding the needed proteins.

Studies of the Rb protein have revealed fundamental principles underlying transcriptional regulation of cell entry into S phase and DNA replication.[21] Rb is the product of the *Rb* gene, which when defective is responsible for childhood susceptibility to retinoblastoma tumors.[22] Only one functional copy of *Rb* is present in the germline of patients with familial susceptibility to retinoblastomas. Retinoblasts become transformed and proliferate uncontrollably when there is no functional Rb after the remaining good copy of *Rb* is lost or rendered nonfunctional in retinoblastoma tumor cells from these patients. This mechanism is supported by the observation that introduction of wild-type but not mutant Rb into cells without Rb causes

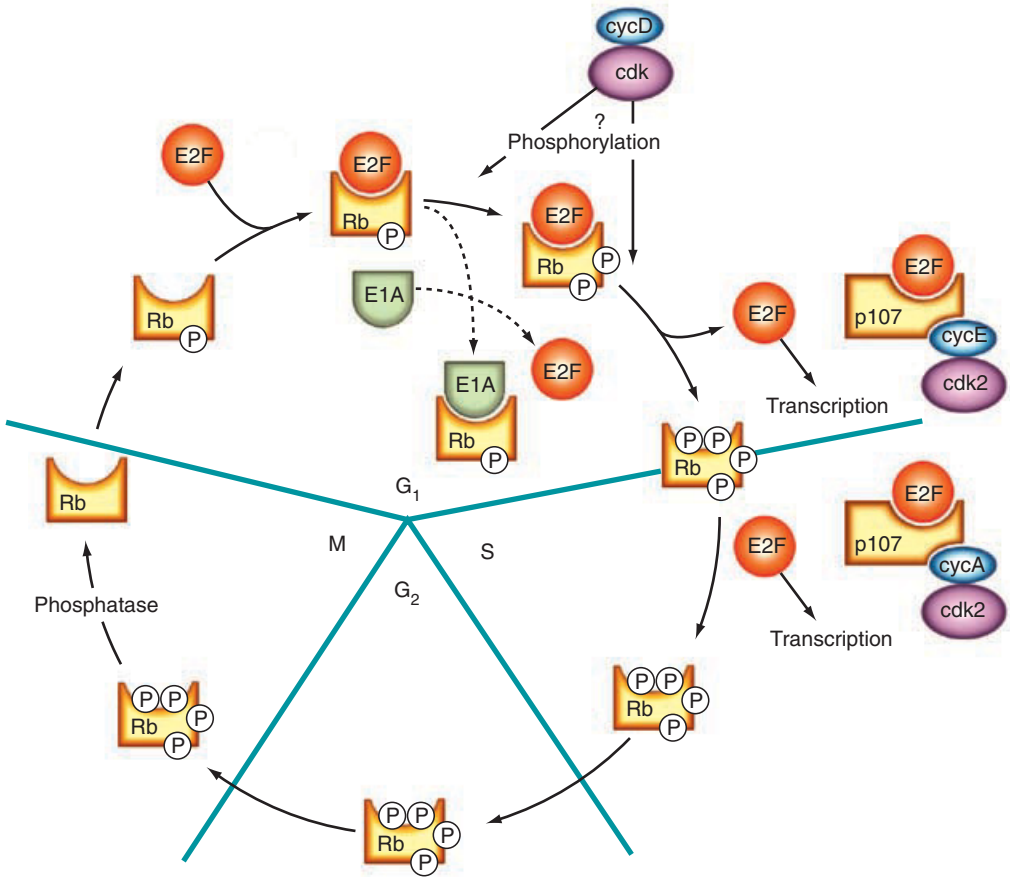

Figure 7–3 REGULATION OF THE RETINOBLASTOMA SUSCEPTIBILITY GENE PRODUCT (RB) THROUGH THE CELL CYCLE. Rb is regulated by serine/threonine phosphorylation (P) through the cell cycle. Non- or hypophosphorylated Rb present in early and mid-G_1 can bind transcription factor E2F and thereby alter or sequester its activity. In late G_1, Rb becomes hyperphosphorylated (perhaps caused by Cdk/cyclin D kinase activity), releasing E2F for transcriptional duties or formation of other complexes. Removal of phosphate groups in M restores Rb to its hypophosphorylated form. In cells transformed by adenovirus E1A, SV40 large T, or HPV E7, these oncoproteins can bind hypophosphorylated RB and displace E2F (*dashed lines*). The Rb-like p107 protein also binds E2F and is found in quaternary complexes with cyclin E/Cdk2 in G_1 or with cyclin A/Cdk2 in S phase.

them to arrest in G_1.[23] Thus, Rb can prevent cell entry into S phase, and retinoblastomas arise when retinoblast proliferation is no longer restrained by Rb.

Rb is widely expressed in normal cells and present at similar levels throughout the cell cycle, indicating that cell proliferation is not regulated primarily by levels of Rb protein. On the other hand, Rb phosphorylation changes markedly in different phases of the cell cycle. It is hypophosphorylated in early G_1, becomes progressively more phosphorylated on serine and threonine residues as cells progress through G_1 and approach S, and maintains this hyperphosphorylated state until M, at which time it is dephosphorylated and returned to its hypophosphorylated, early G_1 state.[24–26]

How Rb phosphorylation controls cell proliferation is understood in terms of Rb binding to transcription factors of the E2F family (Fig. 7–3).[27,28] Originally described as a cellular factor necessary for adenovirus E2 gene transcription, E2F proteins heterodimerize with members of the DP family of proteins to activate gene transcription. E2F-responsive genes include many that encode proteins necessary for DNA synthesis, such as dihydrofolate reductase, thymidine kinase, and others. Hypophosphorylated Rb binds E2F, rendering it transcriptionally inactive or an active repressor of E2F-mediated transcription.[29] Phosphorylation of serine/threonine residues in Rb near or at the site of E2F binding abrogates this interaction and Rb inhibition of E2F transcriptional activity. Thus, E2F activation of gene expression needed for S phase is inhibited by hypophosphorylated Rb in early G_1 and is reinstated as Rb becomes increasingly phosphorylated as cells progress through G_1. The importance of E2F activity for S phase transition is shown by the fact that its gratuitous expression can induce cells to enter S phase. In addition to p105 Rb (molecular mass of 105 kD), two related cellular proteins, p107 and p130, possess similar functional properties, such as the ability to bind E2F.[30] These two Rb-related proteins undoubtedly participate in cell cycle regulation, but their precise roles are still being defined.

The importance of hypophosphorylated Rb in control of cell cycling is underscored by the mechanisms tumorigenic DNA viruses use to deregulate proliferation of infected cells.[31] These viruses possess oncogenes that encode proteins responsible for transforming the infected cells. The E1A oncoprotein of adenovirus, E7 oncoprotein of human papillomavirus, and large T antigen of SV40 virus preferentially bind Rb in its hypophosphorylated state. These oncoproteins interact with Rb in the same molecular pocket as that of E2F, preventing Rb from binding E2F and permitting E2F to carry out its function unimpeded. Thus, transformation by these DNA tumor viruses is associated with cell cycle deregulation caused by viral oncoprotein inactivation of hypophosphorylated Rb function.

In the widely accepted model just described, the key to cell proliferation is release of E2F and other proteins important for S phase from Rb inhibition. This is solved in retinoblastoma and some other tumor cell types by inactivating both copies of the *Rb* gene and in cells transformed by DNA tumor viruses by viral oncoproteins that inactivate hypophosphorylated Rb. Solutions that cause total, irreversible disruption of normal cell cycle regulation present no problems for tumors and help explain their growth deregulation. Normal cells needing to proliferate, however, must use a solution that can be reversed when the need has been satisfied. Their solution is use of kinases that phosphorylate Rb, which results in the progressive phosphorylation of Rb seen during passage of normal cells through G_1.

The model of Rb activity derived from study of tumors and tumor cells implies that Rb is a regulatory protein dispensable for cell cycling. The phenotype of *Rb* knock-out mice[32] suggests that this view also may apply in physiologic situations and during development. $Rb^{-/-}$ embryos arise in expected numbers up to day 14 of gestation but fail to develop beyond that, with evidence of abnormal central nervous system (CNS) development and defective erythropoiesis. Their development more than halfway through gestation and grossly normal appearance up to that time indicate that Rb is

nonessential for cell proliferation, whereas the failure of CNS and erythroid development supports a role for Rb in enforcing terminal differentiation in these tissues. Neither are Rb-related p107 and p130 obligatory components of the cell cycle: Knock-out of *p107* and *p130* individually permits normal mouse development, and knock-out of the two in combination results in abnormal chondrocyte development and neonatal lethality.[30] Thus, Rb appears to provide a cell cycle braking mechanism that can be applied whenever circumstances dictate a stop to cell proliferation. Although the limited developmental abnormalities in *Rb*–/– embryos may be interpreted as suggesting that Rb has a rather tissue-restricted role in normal development, they more likely reflect the fact that the affected cell lineages require Rb regulatory intervention first. Rb is almost certainly part of a global regulatory mechanism for controlling mammalian cell proliferation based on the fact that the Rb pathway (involving cyclin D/Cdk4,6 and $p16^{INK4a}$ in addition to Rb, discussed next) is corrupted in many types of cancers originating in diverse tissues.

CYCLINS, CYCLIN-DEPENDENT KINASES, AND CELL CYCLE REGULATION

Discovery of the mechanisms responsible for Rb phosphorylation and mammalian cell cycle regulation had origins in studies in yeast and invertebrate and frog embryos and was aided by the phylogenetic conservation of the molecular mechanisms involved. Many of the molecules found to be important in yeast and nonmammalian cells, which can be experimentally manipulated and studied far more easily, have close counterparts and functional equivalents in mammalian cells.

Identification and subsequent functional analysis of the factors and cofactors involved in mammalian cell cycle regulation have led to the current view that progression through the cell division cycle is driven and regulated by the activity of serine/threonine kinases of the Cdk (*c*yclin-*d*ependent *k*inase) family. As their name implies, the activity of these kinases is under the stringent control of associated regulatory proteins called *cyclins*. These were so named because levels of the first to be described, cyclins A and B, were seen to fluctuate periodically with the cell cycle. Binding to cyclins alters Cdk structure and activates their catalytic function.[33] Numerous Cdk kinases and cyclins exist in the cell, forming combinatorial pairs with distinct activities.

Control of cyclin/Cdk activity occurs at many levels. First is the appearance and disappearance of different cyclins at specific phases of the cell cycle, which dictates the cyclin/Cdk complexes that can form in each phase. Regulation at this level is a result of highly regulated synthesis and degradation of cyclin mRNA and protein at different points in the cell cycle. A second level of regulation is afforded by posttranslational modification of Cdk kinases, which is often necessary to activate their function. A third level of regulation is provided by proteins that inhibit the activity of Cdk kinases or cyclin/Cdk complexes. The importance of regulation by Cdk inhibitors is shown by the fact that cell differentiation signals often act through them to inhibit cell proliferation and by the fact that inhibitor loss allows deregulated proliferation and promotes neoplastic transformation of some cell types. Once active, Cdk kinases phosphorylate other proteins involved in cell cycling, modulating their activity and behavior. Among their important functions is control of cell entry into S and M phases of the cell cycle.

ENTRY INTO S PHASE

The importance of decisions made in G_1 leading into S and their relevance to neoplastic cell behavior have made identification of regulatory factors involved in G_1 and the G_1–S transition a prime objective.[34] The molecular mechanisms regulating cell entry into S phase were first revealed by studies of a conditional cell cycle mutant of *Schizosaccharomyces pombe* (fission yeast) called *cdc2* (cell division cycle 2). Grown under nonpermissive conditions, these mutants arrest in G_1 or G_2 and cannot enter S or M. Cloning of the *cdc2* gene revealed that it encodes a 34-kD serine/threonine kinase. The structurally and functionally similar protein in mammalian cells, $p34^{cdc2}$, is the prototypical member of a family of Cdk kinases. The protein $p34^{cdc2}$ is Cdk1, and subsequently discovered members of this kinase family have been designated Cdk2, Cdk3, and so forth. Whereas $p34^{cdc2}$ is responsible for both the G_1–S and G_2–M transitions in *S. pombe*, in higher organisms, Cdk1 is involved only in G_2 and M phase events. Other Cdk kinases, such as Cdk2 and Cdk4, are the kinases important in G_1 and S in mammalian cells.

Identifying the cyclins important for G_1-S transition has been facilitated by the timing of their appearance (see Fig. 7–2). Cyclins A and B disappear during M and only reappear in S and are unlikely to have a role, whereas cyclins D and E are excellent candidates on the basis of timing. The candidacy of cyclins D and E is supported by their ability to functionally complement *Saccharomyces cerevisiae* (budding yeast) mutants deficient in G_1 cyclin genes (*CLN*).[35,36] D-type cyclins were independently suspected as being important when their genes turned up during the search for an oncogene involved in parathyroid adenomas[37] and for genes induced during mitogenic stimulation of macrophages.[38] Studies indicate that D-type cyclins, of which there are three (D1, D2, and D3), associate predominantly with Cdk4 and Cdk6. Cyclin E associates with Cdk2, which also can associate with cyclin A, once it appears in S phase.

Cyclin D/Cdk4,6 and cyclin E/Cdk2 are considered the kinases primarily responsible for phosphorylating Rb and allowing cells to progress through G_1, past R in late G_1, and into S phase. Several lines of evidence support cyclin D/Cdk4,6 as regulators of G_1 progression and entry into S phase: D-type cyclins appear in early G_1 and are induced by mitogenic signals; they can phosphorylate Rb; neutralization of D-type cyclins prevents cell entry into S; and overexpression of D-type cyclins can accelerate entry into S.[39,40] D-type cyclins appear to be mitogen sensors for the cell cycle, with many steps in their accumulation being sensitive to the presence of extrinsic growth factors and mitogenic signaling. The generally accepted view is that cyclin D/Cdk4,6 complexes initiate Rb phosphorylation in mid-G_1, which leads up to the subsequent complete inactivation of Rb that is needed for the G_1-S transition. Other studies, however, have raised questions about the absolute requirement for cyclin D/Cdk4,6 in the G_1-S transition.[41,42] In mitogen-stimulated cells, cyclin E appears later in G_1, peaks near the G_1/S boundary, and declines in S (see Fig. 7–2). Cyclin E/Cdk2 associates with Rb in G_1 and can phosphorylate Rb, and inhibition of Cdk2 activity blocks cell entry into S. If all of these observations are taken into account, Cyclin E/Cdk2 is probably responsible for phosphorylating Rb at additional sites in late G_1, producing a hyperphosphorylated Rb that can no longer bind E2F.

Cyclin E associates primarily with Cdk2, and the two can be found in complex with transcription factor E2F and members of the Rb family of proteins in cells in G_1. Of interest, this complex disappears as cells enter S, just as a similar complex containing cyclin A instead of E makes its appearance. Thus, cyclin A/Cdk complexes may maintain Rb in its hyperphosphorylated state past this point in the cell cycle. Cyclin A first appears at the beginning of S and declines in G_2 and M and has an expression pattern that parallels but precedes that of cyclin B (see Fig. 7–2). These data and the results of cyclin A inhibition and addition experiments[43] have led to the view that cyclin A/Cdk2 plays a major role in driving events once cells enter S phase. Later in S and G_2, cyclin A in complex with $p32^{cdc2}$ may help trigger the G_2-M transition by phosphorylating Cdc25 and initiating activation of cyclin B/$p32^{cdc2}$.

ENTRY INTO M PHASE

Studies initiated in *S. pombe cdc2* mutants, which arrest in G_1 or G_2 and do not enter S or M, led to the cloning of the evolutionarily conserved $p34^{cdc2}$ (Cdk1) serine/threonine kinase.[44] An independent line of study examining the effect of cytoplasmic extracts from mature

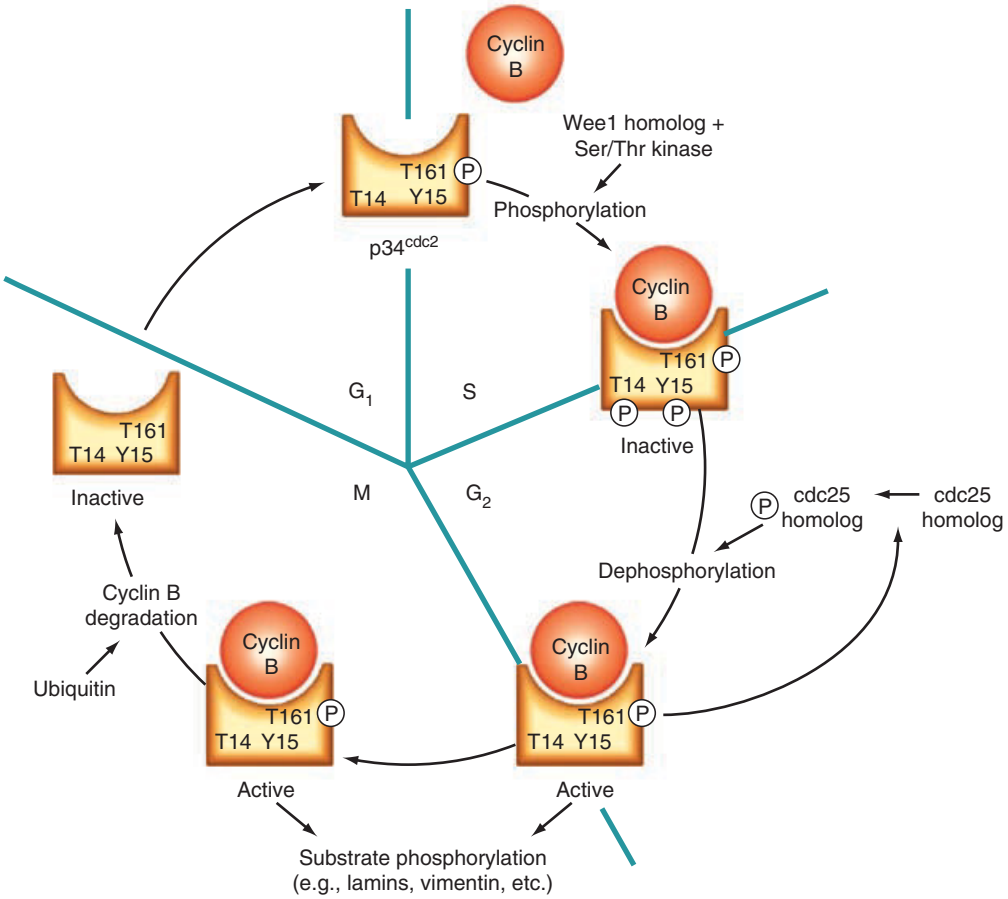

Figure 7–4 Regulation of cell entry into M by cyclin B/p34^{cdc2} or Cdk1 (maturation-promoting factor [MPF]). p34^{cdc2} kinase activity controls cell entry into M and is regulated during the cell cycle. Association with cyclin B, which first appears during S phase, is necessary for its kinase activity, and formation of the cyclin B/p34^{cdc2} or Cdk1 complex (MPF) is stabilized by phosphorylation of Thr(T)161. Accumulating MPF is maintained in an inactive state by phosphorylation of Thr14 and Tyr(Y)15, which is catalyzed by the homolog of the *Schizosaccharomyces pombe wee1* gene product and another kinase. At the G_2/M transition, MPF is activated by dephosphorylation of Thr14 and Tyr15 by the homolog of the *S. pombe cdc25* gene product. This may be a self-amplifying reaction because activated MPF can phosphorylate and activate more Cdc25. Activated MPF phosphorylates cellular substrates and brings about the biochemical changes needed for M phase. During progression through M, degradation of cyclin B generates inactive p34^{cdc2} and permits cell exit from M.

Xenopus frog eggs microinjected into immature frog oocytes showed that these extracts contain a material that induces oocytes to mature and undergo M phase changes such as nuclear membrane breakdown. After purification, the maturation-promoting factor (MPF) in these extracts was found to contain two proteins: One is p34^{cdc2}, and the other is a B-type cyclin. Cyclin B has a regulatory role in the MPF complex, shown by the fact that p34^{cdc2} exhibits kinase/MPF activity only in association with cyclin B.

Cyclin B levels increase during S and G_2 (see Fig. 7–2), and levels of cyclin B/p34^{cdc2} complex sufficient for the G_2-M transition are reached well before the onset of M. Mitosis is not prematurely triggered because the complex accumulates in an inactive form (Fig. 7–4). During S and G_2, the p34^{cdc2} complexed with cyclin B accumulates as a multiply phosphorylated protein. In mammalian cells, phosphorylation of p34^{cdc2} threonine (Thr) 161 stabilizes its association with cyclin B and is essential for activity. The kinase responsible for Thr 161 phosphorylation, CAK (*C*dk-*a*ctivating *k*inase), is itself a Cdk (designated Cdk7) that associates with a novel cyclin, cyclin H. On the other hand, phosphorylation of p34^{cdc2} Thr 14 and tyrosine (Tyr) 15 suppresses its kinase activity and keeps the cyclin B/p34^{cdc2} complex inactive. The kinase responsible for Tyr 15 phosphorylation is the homolog of the product of the *S. pombe wee1* gene.[45]

Activation of the cyclin B/p34^{cdc2} complex is the key to cell entry into M and occurs just prior to M through the action of the dual-specificity phosphatase, Cdc25, causing dephosphorylation of both Thr 14 and Tyr 15. The activities of *wee1* kinase and Cdc25 phosphatase are themselves regulated with phosphorylation, inhibiting *wee1* kinase function and enhancing Cdc25 phosphatase function. Once a little cyclin B/p34^{cdc2} is activated, it can phosphorylate Cdc25 and create a self-amplifying feedback loop that generates more active cyclin B/p34^{cdc2} from the large preexisting stock of inactive complex.

What starts this sequence of events by initially phosphorylating and activating Cdc25 is unclear. Cyclin A/Cdk complexes have been suggested as candidates because they are active before cyclin B/p34^{cdc2} activation and have MPF activity, and because inhibition of cyclin A during S prevents entry into M. However, it is unclear how cyclin A/Cdk complexes, which are abundant and active throughout S, would suddenly initiate the cascade of cyclin B/p34^{cdc2} activation that marks cell entry into M phase. Polo-like kinases (PLKs), named after polo kinase, the prototypical member of this evolutionarily conserved serine/threonine kinase family, are[46] reasonable candidates, because they too can phosphorylate and activate Cdc25 and because amplification of cyclin B/p34^{cdc2} activity does not occur until PLK becomes activated. Additionally, PLK phosphorylation of cyclin B and Cdc25 promotes nuclear localization of these proteins, enhancing nuclear accumulation of active cyclin B/p34^{cdc2} complex.[47]

Cyclin B/p34^{cdc2} can phosphorylate serine/threonine residues in many cellular proteins. Discerning its direct physiologic substrates is not simple, however, because many other kinases and cyclin/Cdk kinases are concurrently active. Candidate substrates include the lamins and vimentin, which are, respectively, nuclear and cytoplasmic proteins important for the structural organization of their compartments. These proteins undergo M phase phosphorylation and are cyclin B/p34^{cdc2} substrates in vitro. Phosphorylation of lamins is important for nuclear lamina disassembly and envelope breakdown, and phosphorylation of vimentin may cause depolymerization of vimentin intermediate filaments. If these are physiologic substrates, p34^{cdc2}/cyclin B kinase activity may initiate the structural reorganization that is essential for mitosis. PLKs, which may be phosphorylated and activated by cyclin B/p34^{cdc2}, are found at important structures and sites during M and facilitate many crucial M phase events. For example, in prophase, PLK phosphorylates cohesin and is responsible for removing most of this protein, which holds sister chromatids together following DNA replication.[48] Removal of cohesin is required for subsequent sister chromatid separation during the metaphase to anaphase transition. PLK is also needed for centrosome maturation

and separation, activation of the anaphase promoting complex (APC), and regulation of cytokinesis and mitotic exit.[49]

As M phase progresses, cyclin B/p34^{cdc2} is inactivated by degradation of the cyclin B component by means of the ubiquitin pathway. A critical factor regulating its destruction is APC, the evolutionarily conserved protein complex that is responsible for ubiquitinating cyclin B and thereby targeting it for proteosome-mediated proteolysis. Low APC activity in G_2 and early M contributes to the accumulation of active cyclin B/p34^{cdc2} at those points in the cell cycle. Later in M, APC activity increases (in part owing to PLK), initiating the process of cyclin B degradation and p34^{cdc2} inactivation. Inactivation of the cyclin B/p34^{cdc2} complex is important for cell exit from M, evidenced by the fact that recombinant cyclin B that is resistant to proteolysis induces cell arrest in M. APC is important for other events during M as well. As implied by its name, APC is critical for the transition from metaphase to anaphase, when previously duplicated sister chromatids separate.[50]

INHIBITORS OF CYCLIN-DEPENDENT KINASES

Inhibitors of Cdk and cyclin/Cdk activity impose an additional layer of complexity on cell cycle regulation.[51] These inhibitors fall into two major categories. So-called "universal" inhibitors, which include p21, p27, and p57, inhibit by binding cyclin/Cdk complexes. The second group of inhibitors, which include p16, p15, p18, and p19, are more restricted in their activity and inhibit by complexing with Cdk kinases that associate with D-type cyclins-that is, Cdk4 and Cdk6. The latter group of inhibitors are also known as INK4 because of their role as *in*hibitors of Cd*k4*.

The first inhibitor to be identified and cloned in mammalian cells was p21 (Waf1, Cip1, Sdi1), which binds several different cyclin/Cdk complexes and is the prototypical "universal" inhibitor.[52,53] The proteins p27 (Kip1) and p57 (Kip2) were subsequently identified as Cdk inhibitors with structural and functional similarities to those of p21.[54–56] The regulation of p21 expression sheds light on its function. Expression is transcriptionally induced by p53, the tumor suppressor protein activated by DNA damage (see following), and induction of p21 expression provides a mechanism for halting cell proliferation after DNA damage to allow time for damage assessment and repair.[57] The p21 protein also can be expressed in cells lacking functional p53, indicating that p53-independent pathways of expression exist. These other pathways may account for increased p21 expression in other circumstances associated with cell cycle arrest, such as senescence and terminal differentiation.

The p27 protein was originally cloned as the Cdk inhibitor associated with G_1 arrest in cells treated with transforming growth factor-β (TGF-β) or experiencing contact inhibition of growth,[54] but levels also increase in cells induced to differentiate.[58] These observations indicate that p27 often mediates the cell cycle arrest induced by extrinsic inhibitors of cell proliferation. In marked contrast with the transcriptional regulation of p21, regulation of p27 occurs post-transcriptionally, such that mRNA levels remain constant while levels of the protein change. In accordance with the ability of p21 and p27 to inhibit cyclin/Cdk activity and cell cycling, *p21* and *p27* are candidate tumor suppressor genes, but silencing or loss of these genes is very uncommon in cancers. However, decreased levels of p27 are seen in many carcinomas and often correlate with aggressive tumor histology and poor prognosis.[58] In some cancers, p27 levels are normal, but the protein is found in the cytoplasm rather than in the nucleus and thus unable to inhibit nuclear cyclin/Cdk complexes. Recent studies in breast cancer cells (reviewed by Blain and Massague[59]) showed that p27 is banished from the nucleus because of its phosphorylation by AKT, which is frequently constitutively active in these cells. Thus, although the *p27* gene is not genetically inactivated during oncogenesis and therefore cannot be formally counted as a tumor suppressor gene, p27 inhibition of cyclin/Cdk activity seems to be a major obstacle that cells may have to circumvent on their way to malignancy.

Cdk inhibitors p16 (INK4a, MTS1, Cdk4), p15 (INK4b, MTS2), p18 (INK4c), and p19 (INK4d) differ structurally from p21/p27 and have restricted Cdk specificity, binding only Cdk4 and Cdk6. The two founding members, p16 and p15, were cloned as tumor suppressor genes,[60] but both had previously been identified as cell cycle inhibitory proteins.[61,62] The p18 and p19 proteins were subsequently cloned based on homology to p16 and p15 and by protein interaction cloning.[63,64] Binding of these inhibitors to Cdk4 and Cdk6 prevents their association with cyclin D and their kinase activation. As Rb family proteins are prime targets of cyclin D/Cdk4,6 kinase and phosphorylation of these proteins is crucial for G_1 progression, inhibitors of the p16 family induce cell cycle arrest in G_1. Evidence that p16 inhibits cell proliferation by preventing phosphorylation of Rb proteins is provided by the observation that p16 overexpression inhibits proliferation only of cells containing functional Rb proteins.[65] An interesting aspect of p16 expression is its upregulation in tissues of aging mice and in cultured cells approaching proliferative senescence.[66] This finding suggests a role for p16 in limiting the proliferative potential of cells in vivo and in vitro and may reflect on its activity as a tumor suppressor.

Members of the p16 family of inhibitors unquestionably have a role in preventing oncogenic transformation in vivo. This role was originally established by the cloning of the *p16* and *p15* genes from the region of chromosome 9p21 mutated in the germline of patients with familial melanoma and in the genome of many human tumor cell lines. Their importance during oncogenesis was reinforced when it was observed that p16 knock-out mice are cancer prone[67] and by the finding that the normal *p16* and *p15* genes found in many human tumors are silenced by the epigenetic mechanism of promoter hypermethylation (reviewed by Ruas and Peters[68]). A lingering issue concerning these genes in oncogenesis stems from the fact that the 9p21 locus containing *p16* also contains the *p14ARF* (in humans) or *p19ARF* (in mice) genes.[69] Because these genes overlap, *p14/p19ARF* mRNA shares sequence with *p16* mRNA but produces a totally different protein because of translation in an *a*lternative *r*eading *f*rame (ie, ARF). This overlap also means that many inactivating mutations of *p16* (including engineered mutations in mice) also inactivate *p14/p19ARF*. Because p14/p19ARF is a positive regulator of p53 expression and a tumor suppressor protein in its own right, attribution of tumor suppressor effect to each of these two genes is difficult. The more recent results of individual knock-out of each these two genes in mice indicate that loss of either *p14/p19ARF* or *p16INK4a* predisposes mice to tumors and results in abnormal regulation of cell proliferation.[70,71]

The idea that Cdk inhibitors act simply as negative regulators of kinase activity and cell cycling and that p16/p15INK4 arrests cell cycling solely through inhibition of Cdk4,6 activity has been revised (reviewed in 1999 by Sherr and Roberts[51]). It was observed that complexes such as cyclin E/Cdk2 bound to p21/p27 were inactive but that cyclin D/Cdk4,6 complexes containing these inhibitors remained active. This suggested that the latter might sequester inhibitors while maintaining activity and prevent inactivation of Cdk2-containing complexes. Keeping cyclin E/Cdk2 active by preventing its inhibition by p21/p27 is a noncatalytic function of cyclin D/Cdk4,6 that complements and augments its catalytic function of promoting Rb hyperphosphorylation and cell cycling. In addition, p21/p27 was found to promote assembly and nuclear accumulation of active cyclin D/Cdk complexes, suggesting that the presence of these inhibitors in cyclin D/Cdk complexes may actually be facilitatory or obligatory rather than merely optional. If cyclin D/Cdk complexes are positively regulated by p21/p27 and prevent p21/p27 from inactivating cyclin E/Cdk2, the effect of p16/p15 extends beyond inhibition of Cdk4,6 complexes. In binding Cdk4,6 and preventing assembly of cyclin D/Cdk complexes, p16/p15 causes redistribution of p21/p27 onto cyclin E/Cdk2 complexes, resulting in their inactivation and an inability to hyperphosphorylate Rb. Thus, G_1 cell cycle arrest induced by p16/p15INK4 may require and be mediated by p21/p27 proteins.

CELL CYCLE CHECKPOINTS

The welfare of an organism depends on production, by its constituent cells, of normal copies of themselves during mitotic replication. If errors arise, one or both of the progeny cells develop defects in their genome that will be transmitted to successive cell generations in subsequent rounds of mitotic proliferation. Perpetuation and amplification of genetic flaws are fundamentally detrimental, and cell cycle checkpoints, which are control mechanisms that monitor and enforce proper execution of the cell division cycle, defend against development of genomic error and instability.[19]

Cell cycle checkpoints are positioned before entry into S (G_1 checkpoint), in S (S phase checkpoint), and before entry into M (G_2 checkpoint). They enforce the orderly progression of cell cycle events, such that cells must fully duplicate their DNA before they divide and divide before they duplicate their DNA again. They also check for damage sustained by genomic DNA. When problems are detected, checkpoint mechanisms interrupt cell cycling to allow correction of the problem or elimination of the defective cell. Where the mechanisms are known, cell cycling is stopped through inhibition of the cyclins and Cdk kinases that drive normal cell cycle progression. Checkpoints also exist within M, but mitotic checkpoints may exist mostly to prevent chromosome missegregation by enforcing the sequence of M phase events that distribute duplicated genetic material equally between progeny cells. The operation of checkpoints and the consequences of their failure are illustrated by yeast mutants defective in the *RAD9* gene. Although yeasts normally cannot enter M phase until their DNA is fully replicated, defects in the *RAD9* gene allow yeasts to enter M phase even if they are prevented from completing DNA replication. Affected yeasts die more rapidly, as progeny inherit incomplete or damaged genetic material.

The activity of checkpoints in mammalian cells usually is observable after they have been exposed to DNA-damaging agents, such as ionizing radiation, ultraviolet light, or certain chemotherapy agents. Checkpoint activation by these genotoxic insults results in cell division cycle arrest in G_1, S, or G_2 phase, allowing cells time to repair the fault before resuming the cycle or, if the damage is irreparable, to execute a program of programmed cell death or apoptosis. Mechanisms that detect and signal the presence of damaged cellular DNA are incompletely understood, but the ATM and ATR protein kinases are clearly important components (Fig. 7–5). ATM (*a*taxia-*t*elangiectasia *m*utated) kinase is activated by ionizing radiation and the double-strand DNA breaks it causes.[72] Defects in ATM result in cell sensitivity to ionizing radiation, defects in all DNA damage-induced cell cycle checkpoints and susceptibility of patients with ataxia-telangiectasia (AT) to cancer. The ATR (*AT* and *R*AD3-related) kinase responds to UV-induced DNA damage, to stalled intermediates of DNA replication, and to damage from ionizing radiation.

ATM and ATR, both of which bind DNA, plus other proteins with homology to proteins involved in DNA replication, are responsible for sensing damaged DNA or failed DNA replication and initiating checkpoint signaling. As ATM and ATR kinase function is activated in the process, they also transduce the signals by phosphorylating downstream effectors of the checkpoint response (reviewed by Abraham[73]). Among the recipients of ATM/ATR signaling are Chk1 and Chk2. These two structurally distinct serine/threonine kinases are phosphorylated and activated by ATM/ATR. Chk1 is regulated primarily by ATR,[74] whereas Chk 2 is regulated primarily by ATM,[75] but other factors, such as BRCA1, clearly influence their activation in response to DNA damage.[76] Once active, Chk1/Chk2 join ATM/ATR to phosphorylate and activate effectors of the checkpoint response.

Prominent among the effectors activated by these kinases is p53, the tumor suppressor protein missing or inactivated in over 50% of human cancers and an essential component of the G_1 DNA damage checkpoint. ATM/ATR directly phosphorylate p53 and indirectly promote its phosphorylation through Chk1/Chk2 phosphorylation of p53 at additional sites. The effect of this p53 phosphorylation is protein stabilization, a result that is augmented by ATM phosphorylation of the Mdm2 protein and inhibition of its ability to direct rapid p53 turnover.[77] Through this combination of mechanisms, p53 is rapidly induced following DNA damage. A transcription factor, p53 engenders cell cycle arrest by activating transcription of *p21(Waf1/Cip1/Sdi1)* and inhibiting cyclin/Cdk2 activity. The pathway leading from ATM/ATR to Cdk2 inhibition activates the G_1 DNA damage checkpoint by preventing Rb hyperphosphorylation.

Enforcement of the G_2 DNA-damage checkpoint involves Chk1 and Chk2 phosphorylation of Cdc25C, allowing this phosphatase to bind the 14–3-3σ protein and be sequestered in the cytoplasm. Excluded from the nucleus, Cdc25C cannot dephosphorylate Cdc2 and activate the cyclin B/Cdc2 complex needed for M phase entry.[78] Although signaling from ATM/ATR to Chk1/Chk2 to Cdc25C is one G_2 checkpoint mechanism, p53 also plays a role. The p53 protein induces p21 and represses cyclin B and Cdc2 gene expression, reducing levels and activity of cyclin B/Cdc2 complex.[79,80] These effects, plus effects on expression of other genes, result in p53-dependent G_2 arrest following DNA damage. As p53 induction stems from ATM/ATR activation, this pathway complements Cdc25C sequestration to provide multiple ways by which ATM/ATR activation can enact G_2 arrest.

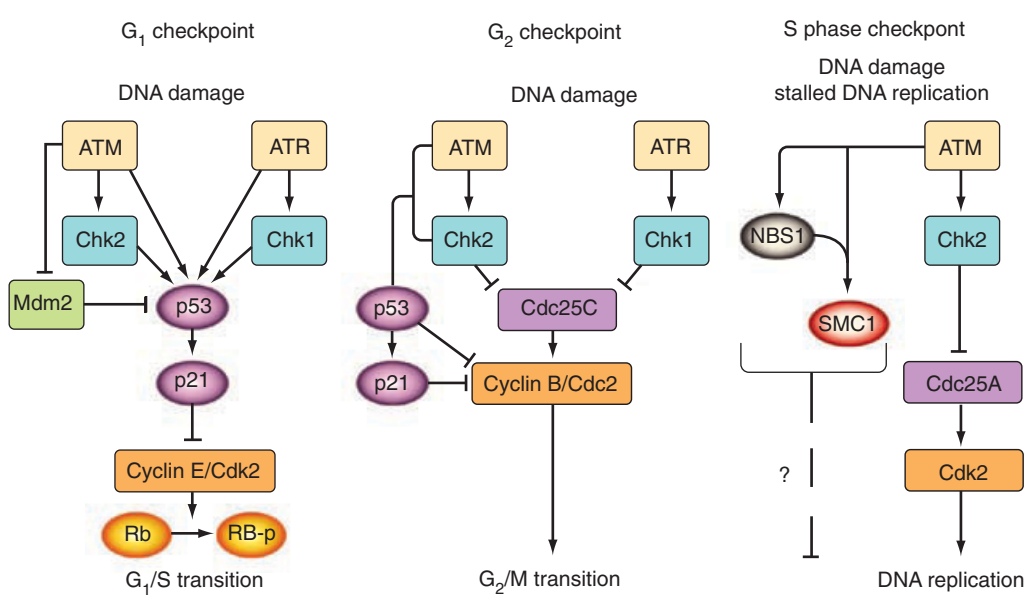

Figure 7–5 CELL CYCLE CHECKPOINTS. Pathways for activating G_1, G_2, and S phase checkpoints are shown. Arrows (Ø) designate activating interactions, and (→) designate inhibitory or inactivating interactions.

The S phase checkpoint arrests cells that experience problems after beginning DNA replication, ie, cells that are in S phase. It does not depend on p53 and is distinct from the G_1 checkpoint, which affects cells that have not yet entered S. When ionizing radiation fails to activate this checkpoint, it results in the phenomenon of radioresistant DNA synthesis (RDS), whereby cells inappropriately continue to initiate new origins of DNA replication and replicate DNA despite DNA damage. ATM plays an important role in this pathway, evidenced by the fact that AT cells display RDS. ATM activates S phase arrest via Chk2, which phosphorylates Cdc25A and accelerates its degradation. Cdc25A normally dephosphorylates Cdk2, activating this kinase and allowing it to promote assembly of replication initiation complexes at replication origins. The inability of ATM-deficient cells to downregulate Cdc25A results in their inability to curb Cdk2 activity and DNA replication in response to ionizing radiation.[81]

More recently, Chk1 also has been shown to participate in Cdc25A regulation and prevention of RDS,[82] but the mechanism of Chk1 activation in this situation remains to be clarified. In a parallel pathway of S phase checkpoint activation, ATM phosphorylates NBS1, the product of the gene mutated in Nijmegen breakage syndrome (NBS). NBS and AT resemble each other in the predisposition of patients to cancer and of their cells to chromosome instability, radiation sensitivity, and RDS. NBS1 is part of a protein complex that binds to and helps repair double-strand DNA breaks,[83,84] and its phosphorylation by ATM is important for inducing S phase arrest following DNA damage and preventing RDS. Recently, the SMC1 (*s*tructure *m*aintenance of *c*hromosomes-1) protein, which has a role in chromosome structure and DNA repair, was found to be phosphorylated by ATM following ionizing radiation exposure. Phosphorylation depended on NBS1 and was important for S phase checkpoint activation.[85,86] Although many details are still unclear, ATM/NBS1/SMC1 and ATM/Chk2/Cdc25A appear to provide parallel and cooperative pathways for S phase checkpoint activation.[87]

The importance of checkpoint mechanisms is shown by the fact that mutant yeasts defective in checkpoint genes and proteins exhibit difficulties with mitotic replication, genomic instability, and death. In mammals, the consequences of failed checkpoint mechanisms can be just as devastating. *ATR* knock-out in mice is lethal at a very early stage (7.5 days) of embryonic development, with cells cultured from the embryos exhibiting loss of genomic integrity and widespread death by apoptosis.[88] Defective checkpoint mechanisms compatible with survival beyond birth, such as loss of *ATM* or *NBS1*, must have less catastrophic consequences but nevertheless produce growth retardation and developmental abnormalities.[89–91] Because organisms deficient in ATM or NBS1 survive, the impact of these proteins on neoplasia can be seen. Deficient mice and humans are predisposed to neoplasia, especially the development of thymic lymphomas. Some humans and mice heterozygous for *ATM* mutations (carriers) also are prone to developing cancers.[92,93] This occurs when the mutant *ATM* allele produces nonfunctional protein that inhibits the function of normal ATM present in the cells (ie, exerts a dominant-negative effect).

Mutation of p53 is the single most common genetic abnormality leading to cancer and may best illustrate the importance of checkpoint effector mechanisms as safeguards against neoplasia. *P53* knock-out mice and humans heterozygous for mutated *p53* (Li-Fraumeni syndrome) have no developmental abnormalities but are predisposed to the development of a variety of malignancies. This predisposition may not be solely caused by defective p53-dependent checkpoint mechanisms, however, because p53 also has apoptosis-activating functions, and defective p53-dependent apoptotic mechanisms are known to contribute to neoplasia. The fact that p53 is important for both cell cycle arrest and apoptosis makes it almost certain that p53 plays a critical role in the cell's decision whether or not to die following genotoxic damage. In view of the fact that radiation therapy and many types of cancer chemotherapy act by damaging cellular DNA, the death or repair response of cells after genotoxic insults has impact beyond tumor development and also may influence tumor response to cancer therapy.

CELL CYCLE ALTERATIONS WITH DIFFERENTIATION

The cell cycle machinery regulates the normal proliferation of cells for both maintenance and replacement purposes. For example, blood cells, skin cells, and the gut epithelia undergo rapid turnover and require constant maintenance of the differentiated cell pools that provide specific differentiated functions. In contrast, liver, muscle, and fat cells may be replaced or expand in response to the metabolic status of the organism or to injury. Either maintenance or replacement of the differentiated cell compartment requires an orchestrated interplay between cell cycle regulation and the cell differentiation program. Although previously thought to be mutually exclusive, cell cycle progression and cell differentiation are tightly linked in the differentiation of specific cell types.

WITHDRAWAL FROM AND ENTRY INTO THE CELL CYCLE AND CELL DIFFERENTIATION

The previous paradigm for cell differentiation suggested, on the basis of studies performed with cell lines, that cell cycle progression and cell differentiation are mutually exclusive. It has become more evident, however, that cell cycle progression is inherently necessary for the differentiation of specific cell types. For example, the hematopoietic stem cell compartment is quiescent until these cells are called on by certain stresses to activate the hematopoietic differentiation program. The cell cycle inhibitors p21 and p27 participate in the regulation of hematopoietic stem cell cycle. Using mice null for either p21 or p27, transplantation experiments have revealed distinct roles for these two cell cycle inhibitors. Hematopoietic stem cells depleted of p21 proliferated, and the absolute number of stem cells doubled.[94] This unrestricted proliferation caused diminished self-renewal potential, resulting in hematopoietic failure in animals that received serially transplanted p21-null bone marrow. In contrast with the findings for p21, depletion of p27 does not affect stem cell numbers, but its absence increases progenitor cell proliferation and pool size.[95] The absence of p27, however, does not affect self-renewal potential. These findings indicate that hematopoietic stem cells differentiate through an orderly progression through the cell cycle for the generation of progenitor cells and the ensuing more differentiated lineage-specific cells.

COUPLING OF MANDATORY CELL CYCLE PROGRESSION AND CELL DIFFERENTIATION

Cell cycle progression required for cell differentiation is illustrated by a number of different systems including lymphopoiesis, myeloerythropoiesis, and adipocyte and keratinocyte differentiation. In the case of lymphopoiesis, upstream regulators of the cell cycle such as the Myc/Max and Mad/Max transcriptional regulators permit cell cycle progression of pre-B lymphocytes for their sequential differentiation down the B-lymphocyte lineage. For example, overexpression of Mad, which blocks cell cycle progression, results in the paucity of mature B lymphocytes.[96] The fact that myeloid and erythroid hematopoiesis requires several generations of differentiating cells to proliferate further supports the requirement of concurrent cell expansion and differentiation.

Perhaps one of the best-studied models of cell differentiation is the adipocyte model. In this model, specific fibroblasts are triggered to initiate the adipogenesis program through a series of cell culture manipulations, including exposure of confluent fibroblasts to specific factors such as insulin, dexamethasone, and methylisobutylxanthine. An intriguing observation is that following exposure to these differentiation-inducing agents, there is a "mitotic clonal expansion" phase that is mandatory for adipogenesis of 3T3L1 fibroblasts.[97] During this phase, preadipocytes traverse through the G_1/S checkpoint with the concurrent activation of Cdk2 activity and turnover of p27. After

several rounds of synchronous cell divisions, these cells cease to proliferate and start to express markers of adipocytes.

SPECIALIZED CELL CYCLE: ENDOREPLICATION AND DIFFERENTIATION

A special type of cell cycle progression is featured in the differentiation of cells that have high metabolic profiles required for synthesis of specific proteins, such as plasma proteins produced by hepatocytes, or for the production of platelets by megakaryocytes. Both cell types display endoreplication, or the repeated phases of DNA replication without cell division, resulting in cells that are gigantic and could have large nuclei with DNA content well over 128N.[98] Endoreplication also features prominently in specific plant and insect tissues, indicating that this mechanism is well utilized through evolution.

It stands to reason that endoreplicating cells permit G_1/S transition but have mechanisms to prevent entry into or completion of mitosis. Studies of many types of endoreplicating cells in fact support this notion. In particular, megakaryocytes endoreplicate in response to thrombopoietin with upregulation of cyclin D3. Overexpression of cyclin D3 results in increased megakaryocyte ploidy.[99] As is suspected, megakaryocyte endoreplication occurs at levels of the mitotic cyclin B/Cdk1 significantly below levels in cells that undergo cytokinesis. Similarly, mammalian trophoblasts, which also undergo endoreplication, display increased cyclins D1, E, and A, but the levels of cyclin B are diminished. These observations indicate that depending on the specific cell types, cell cycle progression may be critically required for differentiation of specialized cells.

CHAPTER 8

CELL DEATH*

David M. Hockenbery and Stanley J. Korsmeyer

Cell death is a highly organized fundamental activity that is as equivalently complex as cell division and differentiation. In the physiologic contexts of embryonic development and tissue renewal, or as pathologic responses to cell injury and infectious pathogens, cell deaths are orchestrated for multiple purposes that benefit the organism. These include maintenance of epithelial barrier function,[1] destruction of microbes,[2] immune response,[3] recycling of cellular material,[4] intercellular signaling,[5] and preservation of genomic integrity.[6] The majority of mammalian cell deaths have morphologic and biochemical features of apoptosis (Table 8–1), a self-inflicted death program encoded in the genetic material of all cells. Necrosis, an alternative mechanism of cell death, occurs in the aftermath of extreme cellular insults and could be viewed as a failure of cellular homeostasis. Although cells contain their own death apparatus, cell death in multicellular organisms is exquisitely subject to the advice and consent of neighboring cells. As might be expected, the internal cell death machinery is tightly interwoven with other essential cell pathways. Investigations of cell death have also informed our understanding of living cells, for example, the recognition that cellular remodeling shares some machinery with apoptotic cell death.[7]

PHYSIOLOGIC CELL TURNOVER

An adult human loses approximately 1011 cells/day, with skin, intestinal, and hematopoietic tissues accounting for the majority. Physiologic cell death in the adult occurs in the context of continuously (skin and intestine) or cyclically (endometrium and breast) renewing tissues. In most instances, homeostasis balances generation of new cells with loss of terminally differentiated cells. In the intestinal epithelium, for example, one stem cell per epithelial crypt asymmetrically divides to produce a daughter cell that rapidly divides, terminally differentiates (coinciding with exit from cell cycle), migrates onto the epithelium surface, and undergoes a specialized form of apoptosis that leaves behind cytoplasmic bridges that preserve epithelial barrier function, all within 2 to 3 days.

Neutrophils recruited to sites of inflammation undergo apoptosis concurrent with removal of the inflammatory stimulus.[8] Apoptotic neutrophils are unable to degranulate and are silently phagocytosed by macrophages, without stimulating an inflammatory response.[9] This clearance mechanism is specialized to apoptotic neutrophils, as necrotic neutrophils and opsonized cells trigger macrophages to secrete inflammatory cytokines. Apoptotic neutrophils also secrete anti-inflammatory cytokines, such as IL-10 and TGF-β.

Although a hallmark of apoptosis is a characteristic compaction of nuclear chromatin, enucleated cells are also subject to apoptotic processes. Biochemical evidence indicates that red blood cells (RBCs) and platelet life spans can be shortened by apoptosis. A general feature of apoptotic cells is the loss of normal asymmetry of phospholipid distribution in the plasma membrane, with accumulation of phosphatidylserine in the outer leaflet. Loss of erythrocyte and platelet viability during in vitro aging is accompanied by phosphatidylserine exposure and activation of apoptotic proteases, known as caspases. Increased phosphatidylserine exposure in erythrocyte membranes is also found in diseases characterized by shortened RBC life spans, such as sickle cell anemia.

Physiologic cell death is also a mechanism to generate a reserve production capacity for functionally mature cells. The glycoprotein hormone erythropoietin (Epo) is produced by kidney mesangial cells and stimulates excess RBC production in proportion to the demand for blood oxygen-carrying capacity. The erythropoietin receptor is expressed on committed erythrocyte precursors (CFU-E and proerythroblasts). Growth factors, in general, also generate survival signals. The primary in vivo effect of Epo is to rescue erythroid precursors from death. The Epo-responsive erythroid compartment in the bone marrow is maintained at a constant size and rate of cell proliferation under various demands (hypoxia and hypertransfusion), despite widely differing production rates of mature erythroid cells. The rationale appears to be to overproduce CFU-Es and proerythroblasts at low altitudes, with excess cells removed prior to the erythroblast stage; this scheme provides a rapidly accessible reserve under conditions of higher demand. Similar arrangements of excessive production with apoptosis of maturing cells are found in small-intestinal crypts and in spermatogenesis.

A final physiologic form for apoptosis is a mechanism for selection of specific cell phenotypes. A well-known example occurs in the immune system following clonal diversification of T- and B-lymphocyte antigen receptors by gene recombination and error-prone DNA replication. Positive and negative clonal selection to match T-cell receptors to cognate class I and class II histocompatibility antigens on accessory cells, and to eliminate receptors reacting with self-antigens, takes place in the thymus. Affinity maturation of immunoglobulin-bearing B cells takes place in germinal centers of lymphoid organs. In each case, cells run a gauntlet of near-death experiences, with death and survival signals directly linked to the binding properties of the antigen receptor on individual cells.

EMBRYOGENESIS AND SCULPTING

During development, apoptosis is extensively used to sculpt the final shape of the embryo. Regression of vestigial tails, interdigital webs, and the pro- and mesonephros are accomplished by an autophagic type of cell death with biochemical hallmarks of classic apoptosis. Certain anatomic structures, such as hollow viscus organs, are formed by apoptotic excavation of interior cell masses; the final form of other structures, such as the forebrain, is shaped by patterns of apoptotic death within neural precursor cells. A more refined example is matching the number of projecting neurons to the size of a target field, accomplished by apoptosis of surplus neurons. Excess or misdirected neurons fail to find the trophic factors produced by their designated targets.

RESPONSE TO CELL DAMAGE

One striking observation is the similarity between physiologic and pathologic cell deaths, since confirmed using biochemical and genetic approaches. Diverse forms of cellular damage trigger apoptotic death.

*This updated chapter is dedicated to the memory of Stanley J. Korsmeyer, MD, who coauthored the original version.

Table 8–1 Characteristic Features of Mammalian Cell Deaths

Apoptosis	Necrosis
Cell shrinkage and fragmentation	Cell swelling and lysis
Nuclear condensation	Karyolysis
Internucleosomal DNA fragmentation	Random DNA breaks
Loss of asymmetry of phospholipids in plasma membrane bilayer	Loss of plasma membrane integrity
Detachment and engulfment by phagocytes	Recruitment of inflammatory cells

DNA damage due to free radicals, alkylating agents, ultraviolet radiation, as well as errors of replication (eg, deficiency of nucleotide pools, topoisomerase inhibition, and mismatch errors) trigger apoptosis via the operation of cellular checkpoints. Apoptotic cell death has been associated with numerous chemical toxins and idiosyncratic drug reactions, often attacking cells prone to physiologic apoptosis.

Recently, attention has been drawn to the role of intracellular protein aggregates and misfolded proteins as a stimulus for apoptosis. Experimental expression of aggregation-prone proteins has been shown to inhibit the ubiquitin–proteasome system, leading to accumulation of multiple proteasomal substrates. Ineffective erythropoiesis in β-thalassemia major is caused by intramedullary apoptotic death of erythroblasts with aggregations of α-globin chains and the erythrocyte membrane proteins spectrin and band 4.1.

GOVERNOR OF CELL BEHAVIOR

Apoptosis also serves a tumor suppressor function to eliminate both excess and damaged cells, including those with genetic instability or DNA mutations. Cells also sense supranormal activation of dominant protooncogenes, such as myc and ras, as apoptotic signals. The list of triggers for apoptotic death seems endless. It appears that many physiologic pathways are closely monitored, with virtually any deviation from normal culled by apoptosis. For epithelia and other cell types attached to extracellular matrix and basement membranes, detachment triggers an apoptotic response, designated as anoikis. Cellular differentiation also appears to have a fail-safe apoptotic response in many lineages, such that cells that do not successfully execute a differentiation program are eliminated.

EXECUTIONERS OF APOPTOSIS

Caspases

The central effectors of apoptosis are a novel family of cysteine proteases, designated as caspases (cysteinyl aspartate-specific protease).[10,11] All caspases are aspartases with a four-residue recognition sequence P4–P1 (Fig. 8–1). Granzyme B is a serine protease involved in cytolytic T-cell killing that also recognizes aspartic acid motifs. Caspase cleavage sites often present as a single site per protein and are found in a variety of cellular proteins, leading to limited digestion of substrate proteins. Approximately 280 substrates have been identified to date.[12] These can be grouped in several categories (Table 8–2).

Although no single caspase substrate has been identified that is obligate for cell death, progress has been made in attributing the biochemical and morphologic features of apoptotic death to proteolysis of specific substrates.[13] Cleavage of structural elements of nuclear scaffolds (lamins) and cytoskeleton (actin, fodrin, and gelsolin) likely actuate membrane blebbing and packaging of chromatin and cytoplasmic material in apoptotic bodies. DNA fragmentation is mediated by an endonuclease, CAD/DFF40, activated following caspase-mediated degradation of an inhibitory binding partner, ICAD/DFF45. Detachment of apoptotic cells from adhesion surfaces

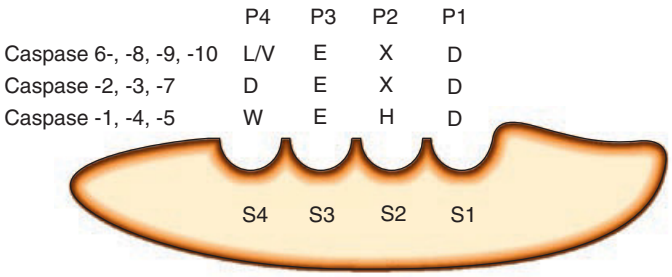

Figure 8–1 Substrate specificity of caspases is determined by the geometry of specificity-binding pockets S4 to S1, recognizing peptide side chains numbered P1 to P4 on the acyl side of the scissile peptide bond. All caspases require Asp in S1 pocket.

accompanies cleavage of proteins in focal adhesion complexes (FAKs).

Caspases also target proteins that participate in energy-consuming cell processes. A classic example is polyADP ribose polymerase (PARP), a nuclear enzyme involved in DNA repair. PARP, activated by DNA damage, consumes nicotinamide adenine dinucleotide (NAD) and ultimately adenosine triphosphate (ATP), as the source of adenosine diphosphate (ADP) ribose. Other caspase substrates are involved in DNA repair (DNA-PKcs, Rad51, MCM3, DNA, RFC140), ribosomal assembly (U1–70KsnRNP), and cell-cycle regulation (p21, p27). One rationale for this category of caspase substrates in apoptosis may be a requirement for energy in the form of ATP. Reducing cellular ATP has been reported to convert apoptosis into necrotic death, with accompanying inflammation.

In the intracellular battle between survival and proapoptotic factors, caspases can swing the advantage toward death by altering the balance of forces. The mitochondrial survival proteins, BCL-2 and BCL-XL, are subject to N-terminal cleavage by caspases. Not only does truncation eliminate their survival functions, but the shortened versions behave as proapoptotic factors experimentally. Activation of a BCL-2-family proapoptotic member, BID, also requires caspase-mediated processing to a truncated factor, tBID, that facilitates translocation to its mitochondrial site of action.

ACTIVATION OF PROCASPASES

Caspases are expressed in healthy cells as zymogens with low to absent protease activity. Strong activation happens upon proteolytic processing into large and small subunits and tetrameric assembly (dimers of heterodimers) (Fig. 8–2). Processing of procaspases occurs adjacent to aspartate residues within caspase recognition motifs.[14] Subsite specificities are distributed among caspases so that most caspase zymogens must be processed in trans by a different caspase, creating a hierarchy of proteolytic activation.[15] The remainder of the caspases have autocatalytic activity at high concentrations (induced proximity model) and are, instead, activated by the regulated assembly of self-activating complexes. Designated as initiator caspases, these zymogens are distinguished by the presence of a long prodomain that serves as a docking site for recruitment into the catalytic complex.[16] Protein associations within these complexes are built around homomeric interactions between three binding cassettes, death (DD), death effector (DED), and CARD domains.

DEATH-INDUCING SIGNALING COMPLEXES AND APOPTOSOMES

Two distinct caspase-activating assemblies are known, although additional structures are expected to be discovered (Fig. 8–3). Caspase-8 is engaged by a family of cell surface receptors known as "death receptors." These include TNF, Fas, and TRAIL (see later). Ligand binding

Table 8–2 Diversity of Caspase Substrates

Apoptosis Regulators	**Cytokines**
Bid*	Pro-IL-1β
ICAD/DFF45	Pro-IL-16
Procaspases	Pro-IL-18
Cytoskeletal Proteins	Endothelial monocyte-activating polypeptide-II*
β-Actin	**Transmembrane Receptors**

RNA Splicing	Golgin-160
Acinus	p115
Heterogeneous nuclear ribonucleoproteins	Rabaptin-5
U1–70-kDa small nuclear ribonucleoprotein	
Translation	
Eukaryotic translation initiation factor 4GI	
Death-associated protein 5	

induces trimerization of the death receptor. The cytoplasmic tail of the liganded death receptor binds to an adapter protein, FADD/MORT1, by dimerization of homologous death domains from each molecule. A second interaction domain in FADD/MORT1, a death effector domain, binds to a similar DED in the prodomain of caspase-8, leading to localized autocatalysis. The death receptor, FADD, and caspase-8 complex is known as the death-inducing signaling complex (DISC).[17]

The second assembly, the apoptosome, is specialized for activating caspase-9, which has a CARD-type prodomain. Formation of the cytoplasmic apoptosome is initiated by release of the soluble electron carrier, cytochrome c, from mitochondria. Cytochrome c binds to an adapter protein, APAF-1, which exposes its own CARD domain in an ATP/dATP-dependent process. Docking of caspase-9 initiates its autocatalytic processing. Because the prodomains of caspase-8 and caspase-9 are severed from the catalytic enzyme during processing, these initiator caspases are no longer sequestered in the complex and are dispersed to cellular substrates. Both pathways converge with proteolytic activation of caspase-3 by either caspase-8 or -9.

POSTTRANSCRIPTIONAL REGULATION

Because of their active-site cysteines, caspases are also subject to regulation by the thiol status of the cell.[18] These residues appear to be particularly susceptible to stable S-nitrosylation by nitric oxide, in the presence of reactive oxygen species (ROS) and transition metals. This is a physiologically important mechanism in the maintenance of endothelial cell survival by shear-induced stress and prolonged survival of activated neutrophils during a respiratory burst (NADPH-oxidase).[19]

NONAPOPTOTIC ROLES FOR CASPASES

Although justifiably known for their apoptotic functions, there is accumulating evidence that caspases also have roles in healthy cells.[20] Caspase-1 was originally identified as the processing enzyme for IL-1β and recently, another proinflammatory cytokine, IL-18. Caspases are also involved in negative feedback control of erythroblast

differentiation by mature erythroblasts through degradation of GATA-1.[21] Finally, several dramatic structural alterations associated with cell differentiation also apparently require transient caspase activation. Cleavage of a limited number of caspase substrates precede nuclear and chromatin changes during terminal erythroid differentiation. Caspase inhibitors also block proplatelet formation from megakaryocytes.[22] The limited caspase activation in these instances may involve some type of compartmentalization.

INHIBITOR OF APOPTOSIS PROTEINS

The only known endogenous caspase inhibitors are members of the inhibitor of apoptosis proteins (IAP) family. IAPs were originally described in insect viruses as viral proteins produced during cellular infection to block host cell apoptosis.[23] In addition to other cellular functions, certain IAPs bind to the active sites of specific caspases (3, 6, 7, and 9) to block catalytic activity or maturation of procaspases.[24] IAP proteins contain one to three BIR (baculovirus IAP repeat) domains that coordinate zinc, and one or more additional protein-interaction domains. Individual IAP proteins use different domains to occlude the substrate grooves of specific caspases. Similar proteins have been identified in yeast, flies, and worms.

Inhibitors of apoptosis proteins also function as ubiquitin E3 ligases, labeling proteins for degradation by the 26S proteasome.[25] The cIAP-1 and cIAP-2 proteins also bind to Traf-1, an adapter protein in TNF receptor signaling to NF-κB and Jun-N kinase pathways. An apoptotic response is reinforced by cIAP-mediated Traf-1 degradation, triggered when TNF binds to the TNF-RII receptor.

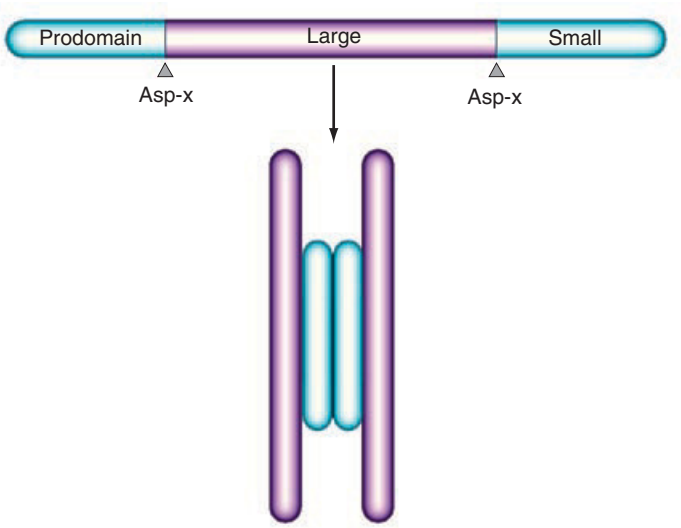

Figure 8–2 Mature caspases are formed by proteolytic processing of procaspases to divide large and small subunits and remove N-terminal peptides. Caspase substrate motifs at cleavage sites enable sequential caspase activation or, in the case of initiator caspases, autoactivation. Caspase dimers are assembled from two large and two small subunits.

SMAC/DIABLO AND OMI/HTRA2

Two proteins normally localized in the mitochondrial intermembrane space, SMAC/Diablo and Omi/HtrA2, can bind IAPs via a conserved NH_2-terminal sequence and competitively displace bound caspases.[26,27] The NH_2 terminus of active SMAC/Diablo is generated by removal of a presequence during mitochondrial import, whereas Omi/HtrA2 is a stress-activated serine protease that is cleaved by autoprocessing. Cytoplasmic translocation of SMAC/Diablo and Omi/HtrA2 during apoptosis provides an additional mechanism for caspase activation. The reaper, grim, hid, and sickle proteins in Drosophila function similarly on fly IAPs and have NH_2-terminal homology to SMAC/Diablo and HtrA2.

Inhibitors of apoptosis proteins can direct self-ubiquitination or ubiquitin ligation to caspases and reaper family proteins, suggesting that IAP complexes can flag a variety of proteins for destruction. This mechanism appears well designed for detecting differences in protein conformation and aggregation state. Although many IAPs inhibit apoptosis, only a subset is known to bind caspases. It is likely that regulation of protein stability has multiple inputs to apoptotic pathways, as found for cell-cycle control.

REGULATORS OF APOPTOSIS

The founding member of this family, BCL2, was discovered as the defining oncogene in follicular lymphomas, located at one reciprocal

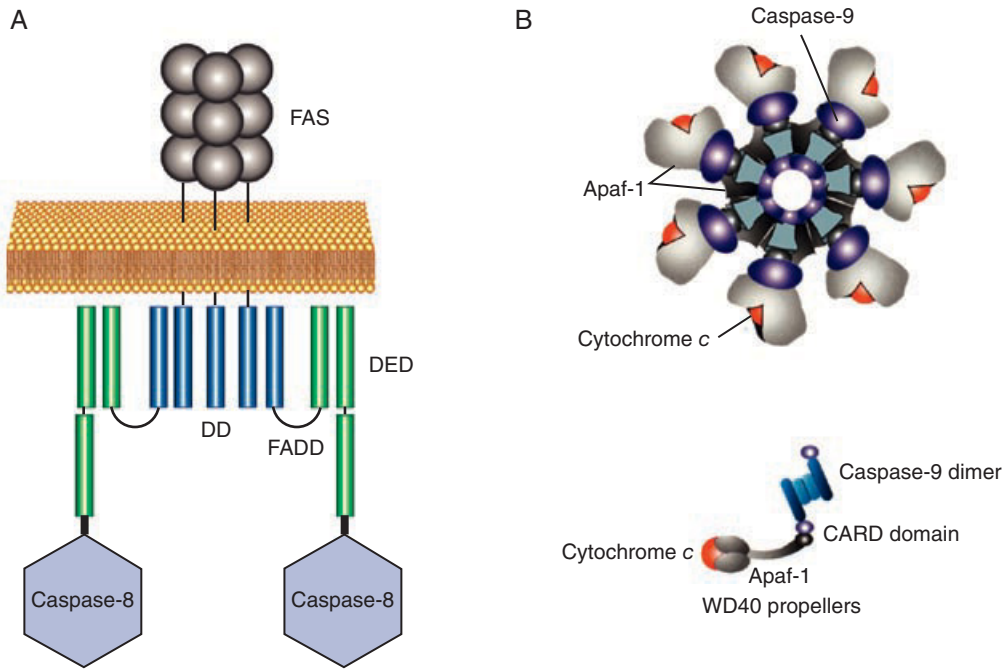

Figure 8–3 Multiprotein complexes govern activation of initiator caspases. **A**, DISC is assembled after binding of ligand (FAS) to death receptor (CD95) at cell surface. Protein interaction domains (DD and DED) mediate associations between the death receptor, initiator caspase (caspase-8), and adapter protein (FADD). **B**, Apoptosome (viewed from above) resembles seven-spoked disk, with procaspase-9 molecules bound at the hub extending above one surface, and Apaf-1 adapters aligned as spokes, presenting CARD interaction domains at the hub and WD40 propellers bound to cytochrome c at the rim. **C**, Side view of unitary cytochrome c–Apaf-1–caspase-9 association.

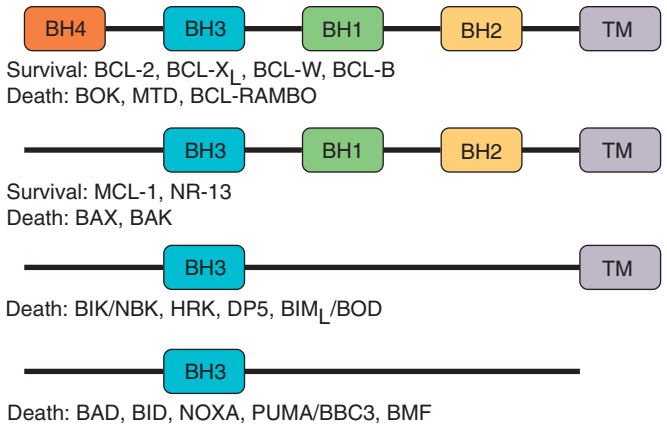

Figure 8–4 Classification of the Bcl2 family according to conserved domains. BH1–3 domains form a surface hydrophobic groove capable of binding BH3 domains of other family members. C-terminal hydrophobic sequences function to target or anchor Bcl2 family proteins to intracellular lipid membranes.

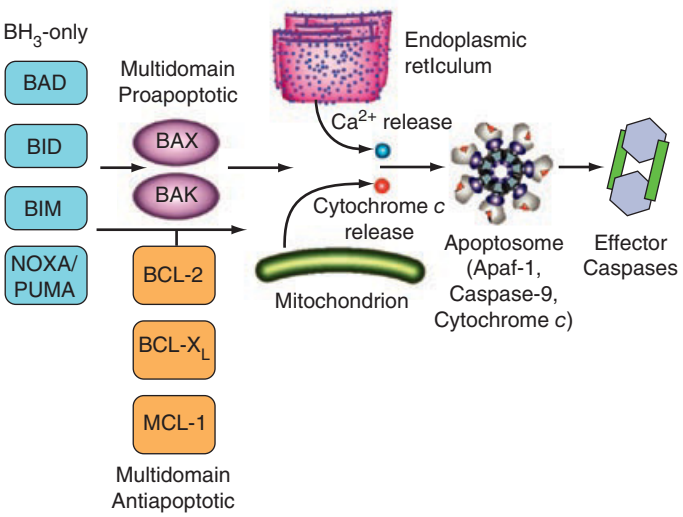

Figure 8–5 Schematic representation of the mammalian core apoptotic pathway in which a BH3-only molecule interacts with a multidomain BCL-2 member upstream of an adapter and a caspase. BH3-only BID, BIM, BAD, and NOXA/PUMA require multidomain proapoptotic BAX/BAK to initiate a cytochrome c, Apaf-1-driven caspase activation. Antiapoptotic BCL-2/BCL-XL/MCL-1 principally inhibits the activated BH3-only molecules.

breakpoint of the t(14;18) (q32;q21) chromosome translocation.[28] Cells transduced with BCL2 remained viable for extended periods in the absence of growth factors. Transgenic mice bearing a BCL2-Ig mini-gene recapitulating the t(14:18) displayed B-cell follicular hyperplasia and progressed over time to diffuse large B-cell lymphomas. The first proapoptotic BCL2 homologous protein to be identified, BAX, coimmunoprecipitated in stoichiometric amounts with BCL2. BAX-transfected cells died rapidly in the absence of growth factor and BAX was subsequently shown to be capable of directly triggering apoptosis. Since the discovery of BCL2 and BAX, the BCL2 family in mammals has expanded to 18 members, with 6 acting principally as survival factors and 12 hastening cell death in various experimental systems.[29] Homologs of BCL2 proteins exist in all metazoans studied to date and several animal DNA viruses.

BCL2 FAMILY PROTEINS

Early experiments showed that relative steady-state levels of antiapoptotic and proapoptotic BCL-2 members correlated with cellular sensitivity to death stimuli, such as growth factor withdrawal. This "rheostat" for apoptosis is manifest, in part, by differential associations between survival and death proteins.[30] The BCL-2 family is marked by the conserved homology domains, BH1–4 (Fig. 8–4). The BH1, 2, and 3 domains of the antiapoptotic proteins form a hydrophobic groove that binds to the hydrophobic face of the α-helical BH3 domain from a proapoptotic binding partner. Mutations in the pockets of antiapoptotic BCL2 members disrupt associations with proapoptotic molecules and result in strong loss of survival function.

These studies indicated that BAX and BCL2 have an agonist–antagonist relationship in apoptosis. Studies of Bcl2 and Bax gene knockout mice indicate that each protein can also function independently of the other, consistent with our current knowledge of this multigene family. The hematopoietic system of Bcl2-deficient mice develops relatively normally, but is unable to maintain cellular homeostasis with loss of lymphocytes over time. Loss of Bax disorders cell death and development of the testis and manifests as excess neurons that survived trophic factor-deprivation death. However, it is the combination of the two multidomain proapoptotic members BAX and BAK that are absolutely required to execute deaths of the intrinsic pathway.

The multidomain BCL2 family proteins are often integral membrane proteins associated with the outer mitochondrial membrane, with smaller amounts at the endoplasmic reticulum (ER) and nuclear envelope membranes. During apoptosis, the outer mitochondrial membrane becomes permeable, with release into the cytoplasm of multiple proteins normally retained within the intermembrane space.[31] One insightful approach to investigating the antiapoptotic functions of BCL2 has been to focus on its role in the mitochondrial pathway of apoptosis. The BCL2 family of pro- and antiapoptotic proteins constitutes a critical control point for apoptosis proximal to irreversible damage to cellular constituents.

A combination of genetic and biochemical studies has ordered the components of the mammalian cell death pathway. The upstream "BH3-only" family members respond to select death signals and subsequently trigger the activation of the multidomain death effectors BAX and BAK.[32–34] Multidomain, proapoptotic BAX and BAK constitute an essential gateway to the intrinsic death pathway operating both at the level of mitochondria and ER Ca^{2+} dynamics.[32,35] Activated, homo-oligomerized BAX or BAK results in the permeabilization of the mitochondrial outer membrane and the release of proteins, especially cytochrome c, which initiates a caspase cascade and contributes to organelle dysfunction. Conversely, cells protected by adequate levels of antiapoptotic BCL2 or BCL-XL bind and sequester translocated BH3-only molecules in stable complexes, preventing activation of BAX and BAK (Fig. 8–5).[33]

Structural and biophysical studies have indicated the intrinsic pore-forming capacity for several BCL2 family proteins. The tertiary structure of BCL-XL is similar to model pore-forming proteins, such as the diphtheria toxin T domain and bacterial colicins.[36] Pore-forming activities have been identified with the antiapoptotic proteins BCL-XL and BCL2, and proapoptotic BAX, BCL-XS, and BID.

Mitochondrial intramembranous homo-oligomerization of BAX and BAK is a prime candidate for a mechanism of mitochondrial outer membrane permeabilization that would release cytochrome c.[37] Whether this release is through a distinct BAX pore or some more global mechanism of membrane permeabilization is still under investigation. Recombinant BAX forms megachannels in artificial membranes (conductances 0.5–1.5 ns). Sizing approaches indicate that BAX pores have diameters up to 22 to 30 Å, and are large enough to transport cytochrome c. Hill plot kinetics indicate that a molecularity of four BAX molecules participates in the release of cytochrome c. BAX complexes ranging from 41 to 260 kd, consistent with homodimers through larger oligomers, are observed in cross-linking experiments during apoptosis. Recently, a novel high-conductance channel in the mitochondrial outer membrane has also been described

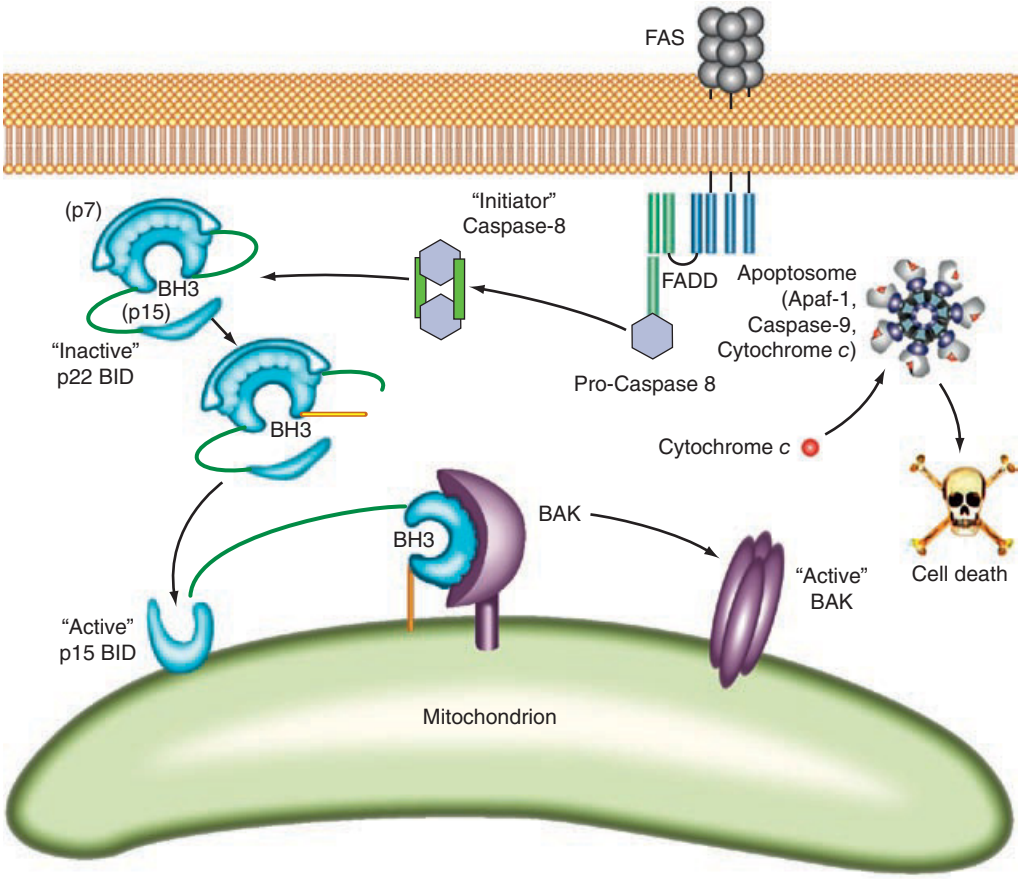

Figure 8–6 Schematic model of proapoptotic activation cascade. Proapoptotic BID to BAK integrates the apoptotic pathway from death receptors to mitochondrial release of cytochrome c.

(mitochondrial apoptosis-induced channel or MAC), coinciding with mitochondrial translocation of BAX.

Alternatively, BAX has been reported to decrease the stability of planar lipid bilayers by decreasing linear tension within the membrane, resulting in hydrophilic pores within the lipid membrane itself. The three-dimensional structure of inactive BAX revealed that its COOH-terminal tail is folded back into the BAX hydrophobic cleft formed by the BH1, 2, and 3 domains. Soon after stimulation of apoptosis, cytoplasmic BAX undergoes a conformational change, exposing an NH_2-terminal epitope, forms homodimers/oligomers, and becomes an integral mitochondrial-membrane protein (Fig. 8–6).[31]

BH3-ONLY PROAPOPTOTIC MEMBERS

The BH3-only molecules constitute the third subset of the BCL2 family and include BID, NOXA, PUMA, BIK, BIM, and BAD. These proteins share sequence homology only in the amphipathic α-helical BH3 region, which mutation analysis indicated is required in proapoptotic members for their death activity. Moreover, the BH3-only proteins require this domain to demonstrate binding to multidomain BCL2 family members. Multiple binding assays indicate that individual BH3-only molecules display some selectivity for multidomain BCL2 members. The BID protein binds proapoptotic BAX and BAK, as well as antiapoptotic BCL2 and BCL-XL. In contrast, BAD and NOXA display preferential binding as intact molecules to antiapoptotic members. However, expression of all of these members, BID, BAD, BIM, and NOXA, results in the activation of BAX and BAK. Their expression in Bax–Bak doubly deficient cells indicates that BAX and BAK are absolutely required for their induction of cell death. Comparison of wild-type with mutant BCL2, BCL-XL indicated that antiapoptotic members sequester all these BH3-only molecules in stable mitochondrial complexes, preventing the activation of BAX and BAK.

BID, the initial BH3-only protein described, is a cytosolic protein that lacks a membrane targeting sequence. Caspase-8 cleaves BID in an unstructured loop, exposing an N-terminal glycine that undergoes posttranslational (rather than classic cotranslational) N-myristoylation. Consistent with its three-dimensional structure, myristoylation enhances the translocation of a p7/myr-p15 BID complex to mitochondria, where the inhibitory p7 fragment is released exposing the BH3 domain. This lipid modification serves as a molecular switch that markedly augments the capacity of activated tBID to release cytochrome c (see Fig. 8–6).

Thus, activation of BH3-only proteins is often directed by specific apoptotic signaling pathways. Proapoptotic activity is associated with exposure of the hydrophobic face of the BH3 helix, enabling it to interact with the hydrophobic groove of multidomain dimerization partners. The specific activation mechanism for BID, a latent proapoptotic protein subject to caspase-mediated cleavage, exposes the BH3 domain.

The BAD BH3-only protein has two consensus binding sites for 14-3-3 scaffold proteins. Phosphorylation at serines 112 and 136 within the 14-3-3 binding site results in binding to 14-3-3 and cytoplasmic sequestration of BAD. Phosphorylation of BAD occurs downstream of growth factor signals and has been attributed to several kinases: protein kinase B/Akt and p70S6 kinase (Ser 136), and mitochondrial-anchored protein kinase A (Ser112). Other BH3 proteins interact with distinct extramitochondrial targets. BIM is localized to the microtubule dynein motor complex by binding to the dynein light chain, DLC1, and BMF associates with dynein light chain 2 (DLC2) in the myosin V actin motor complex.

It is interesting to consider the reasons for having multiple pro- and antiapoptotic BH proteins. In the case of the proapoptotic proteins, the large number of BH3-only members is indicative of

specialization, rather than redundancy. The emerging paradigm for BH3-only proteins is one of latent lethality requiring transcription or posttranslational modifications for activation. The unique localizations, protein associations, and mechanisms of activation for the individual proapoptotic BH3-only members BAD, BID, BIM, NOXA, and PUMA suggest that each acts as a sentinel for distinct damage signals, thereby increasing the range of inputs for endogenous death pathways.[38]

A recent development in this field is the discovery of chemical inhibitors of BCL-XL and BCL-2 that act by binding to the hydrophobic cleft.[39,40] The types of assays used to screen chemical compounds have included competitive binding with proapoptotic BH3 peptides, computational docking simulations, and BCL-XL-dependent cytotoxicity. Additionally, evidence supports a two-class model for BH3 domains in which BID-like domains are capable of activating BAX and BAK, whereas BAD-like domains sensitize by occupying the pocket of antiapoptotic members. Recently synthesized peptides corresponding to BH3-killing domains of prodeath members serve as tool compounds for the development of prototype therapeutics.[41]

APOPTOSIS PATHWAYS

To deal with the plethora of cues for apoptosis, several discrete signaling pathways are available. Much of this circuit is preformed and does not require new gene expression. Because these stimulus-specific responses funnel into a common end game involving mitochondrial disruption or activation of terminal caspases, altered expression or mutation of genes central to apoptosis can change apoptotic susceptibility to a wide range of inducers. Conversely, because the proximal stimulus-specific pathways are reasonably linear, it is possible to ablate a stimulus-specific response (eg, mutant p53, Fas/FasL). Core pathways have nonlinear, feed-forward features as well as high levels of redundancy such that complete resistance to apoptosis has not been observed.

DEATH RECEPTOR SIGNALING

Death receptors are expressed on many cell types, especially the immune system, where they function as a restraint on cell viability. The intracellular responses to death receptors appear to be more limited than for growth factors, and the cytoplasmic sequences of members of the death receptor superfamily all contain the death domain (DD 80 aa) protein-interaction motif.[42] Once clustered by receptor–ligand interaction, the DD serves to nucleate formation of an activation "machine" for initiator caspases (caspases 8, 10) with distinct protein interaction motifs in their long prodomains. This multiprotein complex has been designated as a DISC. Death receptors and proximal caspases do not bind each other directly, but through adapter connectors with docking sites for each motif. Like scaffolds in other signal transduction pathways, adapter proteins act to amplify the initial receptor signal and approximate key factors, as well as provide opportunities for flexibility and regulation of signaling circuits.

There are eight mammalian death receptors (TNF-R1, Fas, TRAMP, DR4, DR5, DR6, NGF-R, and EDA-R). The extracellular domains contain several cysteine-rich domains, forming an extended structure stabilized by disulfide bonds. Death receptor ligands share a TNF homology domain and bind as trimers to cysteine-rich domains of the corresponding receptors. All known ligands are expressed as type II transmembrane proteins and are subject to limited proteolysis, generating soluble forms. In most cases, soluble ligands are inferior to membrane-bound forms for receptor activation. Thus, cell-to-cell contacts are necessary for death-receptor signaling, justifying the characterization of subsequent apoptotic deaths as "fratricides."

In the simplest example, binding of the Fas ligand to CD95/Fas receptor triggers allosteric conformational activation of an apparently trimeric receptor. An adapter protein, FADD, binds at the Fas cytoplasmic domain using homotypic DD associations. Similarly, procaspase-8 is bound to FADD by homotypic DED interactions. The limited proteolytic activity of procaspase-8 appears to be sufficient for autoprocessing in trans of neighboring procaspase molecules. An NH_2-proximal cleavage separates the caspase-8 prodomain from the catalytic subunits, allowing untethering of active caspase-8 from the DISC and initiation of a cascade of processing effector caspases. Certain cells can bypass Bcl-2 interdiction at the mitochondria and killing by a direct route to effector caspase activation (type I cells), whereas others rely on an amplification loop in which BID cleavage triggers mitochondrial apoptosis (type II cells).[43]

Superimposed on this three-component model are additional factors that can substitute for one of the core components.[44] FLIP (FLICE/caspase-8 inhibitory protein) is homologous to caspase-8 but devoid of protease activity (the active-site cysteine is replaced). Different splice forms of FLIP retain the DED motif and either compete with caspase-8 for binding to FADD or prevent release of processed caspase-8 from the DISC. Thus, FLIP interrupts communication between Fas receptor and effector caspases, blocking apoptosis. Incorporation of FLIP in the DISC leads to the recruitment of additional factors (Rip, Trafs) that connect to signal transduction pathways involving NF-κB and ERK.

Two arenas where death receptors act physiologically involve lymphocytes. Activation-induced cell death curtails T lymphocyte immune responses through Fas receptor signaling.[45] Fas ligand and Fas are induced during T-cell activation downstream of lck and NF-κB. Engagement of Fas on one cell by Fas ligand on a second cell triggers apoptosis. Thus, the Fas–FasL system provides an upper limit on the density of activated T cells at sites of inflammation. Lymphocyte cell death is also directed by FasL expression on dissimilar cells. Fas expression on germinal center B lymphocytes appears to play a role in eliminating cells bearing self-reactive surface immunoglobulin, as mice expressing Fas only on T lymphocytes acquire high levels of autoantibodies. In this case, FasL expression on T cells delivers the fatal blow. T lymphocytes can also be eliminated by FasL expressed on nonlymphoid cell types.

Immune-privileged zones, such as the eyes and testes, can be transplanted with allogenic tissue owing to the lack of immune surveillance at these sites, enabling corneal transplants from unrelated donors without need for immunosuppression. Gld mice deficient in FasL expression do not manifest site-specific restrictions to immune responses with vigorous inflammatory responses to viral infections and allogenic cells. In place of a physical barrier to lymphocyte trafficking to immune-privileged sites, constitutive expression of FasL by interstitial and support cells in these locations effectively deletes trespassing cells.[46]

Fas expression is constitutively expressed in nonlymphoid tissues (hepatocytes, cardiac muscle, kidney epithelium); in others, it is induced during acute stress responses (UV- and gamma-radiation). FasL–Fas interactions take place during cytotoxic T lymphocyte killing, and in some circumstances, Fas has proved necessary for target cell killing.

Targeted deletions of components of the Fas signaling pathway indicate the importance of this pathway in development. Mouse knockouts for caspase-8, FADD, and FLIP die during embryogenesis with severe cardiac malformations. Although lack of normal developmental death can lead to abnormal morphogenesis, the ability of death receptors to communicate with other signal transduction pathways may have important physiologic consequences. Fas signaling in resting lymphocytes has comitogenic effects, indicating that entry to alternative signaling pathways is dependent on cell activation state and receptor density.

DNA DAMAGE

Among other types of cellular damage, alterations in DNA structure as a result of oxidation, alkylation, single- or double-strand breaks (including stalled replication forks) are notorious for triggering apoptotic pathways. Apoptosis is recognized as part of a larger DNA

damage response involving cell cycle checkpoint (control mechanisms ensuring dependency in the cell cycle) and repair pathways.[6]

The transition from repair to dismantling the cell is usually believed to involve some quantitative aspect of DNA damage, perhaps the ability to repair DNA below a certain threshold before apoptotic mechanisms kick in. Some insight into the biochemical mechanism has come from the understanding of p53 protein degradation pathways. In healthy cells, p53 has a half-life of 5 to 20 minutes, its ubiquitin-mediated degradation governed by its interactions with Mdm2. Mdm2 acts as a ubiquitin E3 ligase for p53. p53 functions as a tetrameric, sequence-specific transcription factor; thus, p53 activity is dependent on nuclear levels of p53. At early times following p53 activation, negative feedback control results from transcription of Mdm2, resulting in increased p53 degradation. However, continued stabilization of p53 inactivates another p53 target gene, the lipid phosphatase PTEN.[47] PTEN inactivates the second messenger PI(3,4,5)P3, ultimately resulting in nuclear exclusion of Mdm2 and stabilization of p53.

Several types of changes to the DNA template trigger activation of chromatin-associated kinases over long distances, probably through changes in higher-order chromatin structure. In response to DNA strand breaks, the PI(3)K-related kinase ATM phosphorylates multiple substrates, including p53, Mdm2, and the checkpoint kinase Chk2 (Cds1). Posttranslational modification of p53 at several sites leads to inhibition of Mdm2 association and transcriptional activation. Transcriptional targets of p53 include several proapoptotic BCL2 members (Bax, Noxa, Puma), death receptors (Fas, DR5), oxidation-reduction enzymes (PIG3), and APAF-1.[48] There may also be examples of p53 contributions to apoptosis that are independent of transcriptional activity, including associations of p53 with mitochondria[49] and a cytosolic E3 ligase (Parkin).

UNFOLDED PROTEIN RESPONSE

Protein stress responses are a recent addition to apoptotic pathways. These highly conserved mechanisms provide feedback fidelity control of protein folding, glycosylation, and secretory pathways in the ER. Multiple inputs (amino acid deficiency, glucose deprivation, calcium dysregulation, and proteasomal activity) trigger this pathway through their effects on ER protein folding.

In yeast models, a unique ER transmembrane protein with both serine/threonine kinase and endoribonuclease activities, IRE1, functions as a sensor for misfolded or unfolded ER proteins.[50] IRE1 kinase activity is normally suppressed by binding to the ER chaperone protein GRP78/BiP. Unfolded proteins accumulating within the ER lumen recruit GRP78/Bip away from IRE1, allowing oligomerization and autophosphorylation of IRE1. Phosphorylation stimulates IRE1 endoribonuclease activity for a specific target, the mRNA for a basic leucine zipper transcription factor, HAC1. The HAC1 transcript is constitutively expressed, but contains a nonclassic intron that inhibits translation. IRE1 removes this intron by two site-specific cleavages, and a third factor, Rlg1p, splices the remaining exons. With efficient translation of the spliced mRNA, HAC1 activates transcription of several ER chaperones.

The mammalian version of the UPR incorporates two additional features: general suppression of translation and a connection to apoptotic pathways. Inhibition of translation is accomplished using an ER transmembrane kinase, PERK, related to the dsRNA-dependent kinase PKR. PERK phosphorylates the eukaryotic initiation factor EIF2-α, inhibiting assembly of preinitiation complexes at ribosomes. The precise downstream apoptotic pathway is uncertain, but an ER-localized caspase, caspase-12, has been reported[51] to process IRE1 in response to ER stress.

ONCOGENE-INDUCED APOPTOSIS

Hyperactivity of mitogenic oncogenes, such as Myc, adenovirus E1A, and Ras triggers a common pathway of p53 accumulation via induction of the ARF tumor-suppressor gene.[52] P14ARF (or P19ARF in mice) is encoded by an alternative reading frame in the p16INK4a locus. ARF inhibits Mdm2, the p53 E3 ubiquitin ligase, and transports Mdm2 to the nucleolus, where additional ARF functions are evident. Processing of precursor rRNAs to 28S, 18S, and 5.8S rRNAs is prevented by ARF, independent of p53 or Mdm2. The proximal signals for oncogene-dependent induction of ARF are under exploration.

SURVIVAL SIGNALING PATHWAYS

Cell death has been postulated to serve as a default pathway for single cells, with a need for signals from neighboring cells for survival. The prototypical example of intercellular survival signaling is the insulin-like growth factor-1 (IGF-1)–PI(3)kinase–Akt kinase pathway.[53] Note that survival signal transduction pathways are engaged downstream of most, if not all, growth factors.

The IGF-1 receptor tyrosine kinase is autophosphorylated in trans following ligand binding. An adapter protein (insulin receptor substrate [IRS]) binds to the cytoplasmic domain of the receptor through a phosphotyrosine-binding domain. The IRS adapter is phosphorylated on tyrosines in turn, enabling the p85 regulatory subunit of PI(3) kinase to bind, and relieving inhibition of the catalytic PI(3) kinase. Phosphorylation of phosphatidylinositol in the plasma membrane yields PI3, PI4, 5P3, 4P2, and PI3P; these lipid-signaling molecules function by recruiting signaling proteins containing pleckstrin homology domains to the plasma membrane.[54] One of these, the serine/threonine kinase PDK1, activates downstream kinases, including Akt/PKB, by phosphorylating its active loop.

Several substrates for Akt/PKB and Akt-like serine/threonine kinase are implicated in cell survival. Bad and procaspase-9 are inhibited by phosphorylation. Another set of factors with proapoptotic effects inhibited by Akt/PKB-mediated serine/threonine phosphorylation are the forkhead transcription factors.[55] Phosphorylated forkhead transcription factors bind to 14–3-3 proteins and are exported from the nucleus and degraded in the cytosol. Transcriptional targets of forkhead transcription factors relevant to apoptosis include FasL and Bim. A broader role for forkhead transcription factors includes adaptation to stress and aging (mutants of the homologous DAF-16 in *Caenorhabditis elegans* have shortened life spans).

SUMMARY

Apoptosis is an evolutionarily conserved, highly regulated mechanism for maintaining homeostasis in multicellular organisms. Numerous signals are capable of modulating cell death. After a death stimulus, the signal is propagated and amplified through the activation of caspases, culminating in the ordered disassembly of the cell. The process may transpire through an intrinsic, mitochondria-dependent pathway or an extrinsic pathway—depending on the death signal and the cell type involved. The BCL2 family of proteins is situated upstream of irreversible cell damage in the apoptotic pathway, providing a pivotal checkpoint in the fate of a cell after a death stimulus. The proapoptotic molecules BAX and BAK undergo an allosteric conformational activation to permeabilize mitochondria on receipt of a death stimulus. BH3-only members connect distinct upstream signal transduction pathways with the common, core apoptotic pathway. The distribution and responsiveness of the BH3-only members suggest that they function as sentinels for recognizing cellular damage. For example, BID amplifies minimal caspase-8 activation and BAD patrols for metabolic stress after loss of critical survival factors or glucose. This model would explain how seemingly diverse cellular injuries converge on a final common pathway of cell death.

CHAPTER 9

PHARMACOGENOMICS AND HEMATOLOGIC DISEASES

Leo Kager and William E. Evans

The fundamental hypothesis pursued in genetics is that heritable genetic variation (ie, genotypes or haplotypes) translates into inherited phenotypes (eg, disease risk, drug response). On the basis of this hypothesis, the aim of medical genetics and pharmacogenomics is to understand the myriad associations between individual genotypes and specific phenotypes of *disease* or *drug response*, with the ultimate goal of better defining the risk for, or outcome of, diseases and the response to specific medications. Many seminal discoveries in medical genetics were made in the course of investigating hematologic disorders, as exemplified by the fact that the most prevalent monogenic disorders, the hemoglobinopathies, affect approximately 7% of the world's population.[1] Pharmacogenomics also has a long tradition in hematology; one of the first documented clinical observations of inherited differences in drug effects was the relationship between hemolysis after antimalarial therapy and the inherited glucose-6-phosphate dehydrogenase activity in erythrocytes.[2]

In the pregenomic era, efforts concentrated on mapping highly penetrant monogenic (mendelian) loci, for both specific diseases and drug-metabolizing pathways that influence the effects of medications.[3] Since the completion of the first draft of the human genome sequence, genome-wide approaches are being increasingly used to define markers for polygenic loci in complex diseases, identify genetic factors that modify the phenotype of a monogenic disease, and elucidate the interplay of genes encoding proteins involved in multiple pathways of drug metabolism, disposition, and effects.[3,4]

This chapter is not meant to be an exhaustive review; rather, it provides an overview of pharmacogenomics, using selected examples to illustrate its impact on the treatment of hematologic diseases. Recent reviews of the importance and potential of pharmacogenomics are available for readers seeking broader coverage of this burgeoning field.[3,5–7]

HUMAN SEQUENCE VARIATION

The genome-wide systematic identification and functional analysis of genes, their sequence variants, and related products (ie, proteins) are revolutionizing the study of disease, the development of new medications, and the optimization of drug therapy. Genetics increasingly enable clinicians to make reliable assessments of a person's risk of acquiring a particular disease, to identify drug targets, and to explain interindividual differences in the effectiveness and toxicity of medications.[3,6]

For practical purposes, the term *sequence variation* is mainly used herein.[8] *Polymorphisms* are defined as common variations in the DNA sequence. The Human Genome Project has unveiled many types of sequence variations that constitute allelic variants within the 3.2 billion base pairs of the human genetic code. Common variations include single-nucleotide polymorphisms (SNPs), insertions and deletions of nucleotides or entire genes, and variation in the number of repeats of a specific motif (mini- and microsatellites).[9,10]

SINGLE-NUCLEOTIDE POLYMORPHISMS

The most common and important inherited sequence variations are SNPs, positions in the genome where individuals have inherited a different nucleotide.[11] In diploid species such as humans, SNPs are usually biallelic. More than 1.2 million SNPs were identified in the initial sequencing of the human genome, and it is now estimated that several million SNPs exist in humans.[12] Many efforts are currently under way to catalog these variants, because a comprehensive SNP catalog would offer the possibility to pinpoint important variants in which nucleotide changes alter the function or expression of a gene that influences diseases or response to pharmacologic treatment. The main public database is dbSNP (http://www.ncbi.nlm.nih.gov/SNP/), and a rapid increase in the number of SNPs in dbSNP is driven by the HapMap project (http://www.hapmap.org/).[13]

SINGLE-NUCLEOTIDE POLYMORPHISMS AND PHENOTYPES

SNPs are present in exons, introns, promoters, enhancers, and intergenic regions. To elucidate the relationship between SNPs and phenotypes of interest, efforts have concentrated mainly on SNPs that are likely to alter the function or expression of a gene.

Only a small portion of the identified SNPs lie within coding regions, and only approximately half of those SNPs cause amino acid changes in expressed proteins. SNPs that cause amino acid changes are referred to as nonsynonymous SNPs (nsSNPs).[14] nsSNPs are the main sequence variants underlying most of the highly penetrant inherited monogenic diseases currently known, such as hemoglobinopathies. The likelihood that an nsSNP will result in disease or functional change in drug metabolism depends on the localization and nature of the amino acid change within the encoded protein. Although it is intuitively obvious that amino acid substitutions have the potential to change the function of a protein, gene expression also can be affected by SNPs positioned in regulatory sequences or intronic regions. For example, the cytosine-to-thymine nucleotide substitution in the promoter region (−159C>T) of the gene encoding CD14, an important molecule in the innate immune response, has been associated with decreased levels of soluble CD14 and increased total serum immunoglobulin E, resulting in a more severe allergic phenotype.[15] This finding demonstrates that discrete changes in genotype can amplify or damp complex biologic pathways, if those changes affect the regulation of functionally important genes.

HAPLOTYPE AND LINKAGE DISEQUILIBRIUM

The vast majority of SNPs are located in noncoding regions of the genome, which constitute a predominant amount of the human genome sequence. Most SNPs have no obvious effect on gene expression, protein function, or phenotype; however, a growing number of intronic SNPs are being linked to inherited phenotypes. Combinations of SNPs are commonly inherited together in the same region of DNA, forming haplotypes. Genome-wide haplotypes can be constructed by linkage disequilibrium (LD) analysis.[16] LD analysis is a statistical measure of the extent to which particular alleles or SNPs at two loci are associated with each other in the population, and LD occurs when haplotype combinations of alleles or SNPs at different loci occur more frequently than would be expected from random

association. SNPs and alleles of interest are presumably inherited together if they are physically close to each other (usually <50 kilobases [kb]), producing strong LD. Therefore, SNPs that are in LD with a disease phenotype or response-to-drug phenotype can *mark* the position on the chromosome where a susceptibility gene is located, even though the SNP itself may not be the cause of the phenotype. Of interest, recent investigations have demonstrated that common SNPs are also in LD with other common variants in the human genome, such as deletions.[17] In addition, studies have suggested that the human genome is organized in blocks of haplotypes with high LD that are separated by regions of low LD.[18]

Considerable debate has arisen over the best strategies for SNP-based association studies to elucidate complex diseases and drug responses.[19] Various methods (eg, polymerase chain reaction [PCR] assay, matrix-assisted laser desorption/ionization [MALDI] mass spectrometry) and study designs (eg, association studies and linkage analysis) promoting access to genetic variation have been developed, and new techniques are still emerging.[20–22]

The great majority of SNPs or haplotypes currently used as molecular diagnostics in hematology are variations that were discovered on account of their direct involvement in altering the function of encoded proteins, as opposed to anonymous SNPs, which have been identified in association studies on the basis of their LD with causative SNPs. For example, hematologists have embraced testing for informative SNPs in factor V Leiden variant as one of several parameters used to determine the appropriate duration of anticoagulant therapy after documented venous thrombosis.[23] Likewise, it is increasingly common to search for three SNPs in the human *TPMT* gene that predispose a patient to thiopurine hematopoietic toxicity upon receiving drugs such as azathioprine (AZA) or mercaptopurine (MP).[24]

GENETIC VARIATIONS INFLUENCING DRUG RESPONSE: PHARMACOGENETICS–PHARMACOGENOMICS

Until relatively recently, genetics has played little or no role in finding the right drug and the optimal dosage for individual patients. Mostly empirical approaches are used to select drug therapy, despite the fact that there is great heterogeneity in the way people respond to medications, in terms of both host toxicity and treatment efficacy. Unfortunately, for almost all medications, interindividual differences are the rule, not the exception, and these differences result from the interplay of many variables, including genetics and environment. Variables influencing drug response include pathogenesis and severity of the underlying disease being treated; drug interactions; the patient's age (ie, *developmental pharmacology*), gender, nutritional status, and renal and liver function; presence of concomitant illnesses; and other medications. In addition to these clinical variables, increasing evidence points to a substantial inherited component of interindividual differences in drug response.[3,6,25]

Clinical observations of inherited differences in drug effects were first documented in the 1950s, and the concept of *pharmacogenetics* was defined initially in 1959 by Friedrich Vogel as "the study of the role of genetics in drug response."[26] The number of recognized clinically important pharmacogenetic traits grew steadily in the 1970s; the elucidation of the molecular genetics underlying these traits began in the late 1980s and 1990s, and their translation to molecular diagnostics is well under way in the 2000s.[6] Of interest, during the last decade, the field of pharmacogenetics was *rediscovered* by the pharmaceutical industry and by a broader spectrum of researchers in academia. This rediscovery has been driven in large part by the Human Genome Project, and by the recognition that inheritance can play a major role in determining drug effects.

The study of pharmacogenetics began with the analysis of genetic variations in drug-metabolizing enzymes and how those variations translate into inherited differences in drug effects. More recently, the field has extended to genome-wide approaches to identify networks of genes that govern the clinical response to drug therapy (ie, pharmacogenomics).[5,6] The terms *pharmacogenetics* and *pharmacogenomics*, however, are synonymous for all practical purposes.[6] Overall, pharmacogenomics can be viewed as a broad strategy to establish pharmacological models by integrating information from functional genomics, high-throughput molecular analyses, and pharmacodynamics. Approaches to establish pharmacogenomic models include candidate gene analyses (which focus on the analysis of single genes or sets of functionally related genes in pathways) and genome-wide analyses. Pharmacogenomic models can be used to both maximize efficacy and reduce toxicity of existing medications, or to identify novel therapeutic targets.[27] The general field of pharmacogenomics is the subject of several recent reviews[3,5–7,27–32] and is not comprehensively addressed here. Rather, clinically relevant examples are provided to illustrate how pharmacogenomics can be used to improve current drug therapy for hematologic disorders, to prevent hematologic toxicity, and to identify novel targets for developing new therapeutic approaches.

OPTIMIZATION OF DRUG THERAPY

Most drug effects are determined by the interplay of several gene products that influence the pharmacokinetics and pharmacodynamics of medications. *Pharmacokinetics* is the study of the absorption, distribution, metabolism, and excretion (ADME) of drugs. *Pharmacodynamics* is the relationship between the pharmacokinetic properties of drugs and their pharmacologic effects, either desired or adverse. The ultimate goal of pharmacogenomics in this context is to elucidate the inherited determinants for drug disposition and response to select medications and dosages on the basis of each patient's inherited ability to metabolize, eliminate, and respond to specific drugs.[3] A model of how polygenic variables can determine drug response is illustrated in Fig. 9–1.

GENETIC VARIATIONS THAT INFLUENCE DRUG DISPOSITION

Drug Metabolism

Metabolism often includes reactions that make lipophilic drugs more water soluble and thus more easily excreted. Pathways of drug metabolism are classified as either phase I reactions, which catalyze changes of functional moieties by oxidation, reduction, or hydrolysis, or phase II conjugation reactions, which conjugate functional moieties by acetylation, glucuronidation, sulfation, or methylation. The names employed to categorize these pathways are purely historical and used for convenience.[30]

The process of metabolic reactions that inactivate drugs or prodrugs is referred to as *catabolism*; for example, cytochrome P450 enzymes catalyze the *N*-dechlorethylation of the cytostatic prodrug cyclophosphamide. However, drug metabolism also includes reactions that convert prodrugs into therapeutically active compounds; these processes are referred to as *anabolism*. Additionally, metabolic reactions can form toxic metabolites. For example, cytochrome P450 catalyzes the 4-hydroxylation of cyclophosphamide into the cytotoxic compound phosphoramide mustard, and when cyclophosphamide is activated, the urotoxic compound acrolein is formed.

Essentially all genes encoding drug-metabolizing enzymes (there are more than 30 families of enzymes in humans) exhibit genetic variations, many of which translate into functional changes in the proteins encoded.[6] Inheritance of genes containing sequence variations that alter the function of enzymes encoded can influence drug disposition and ultimately determine drug effects (either desired or adverse), if those enzymes are involved in crucial pathways of elimination or activation of the administered medication. Numerous variant enzymes have been characterized within the last decade, as reviewed elsewhere[3,30,33]; here we focus on only three relevant examples:

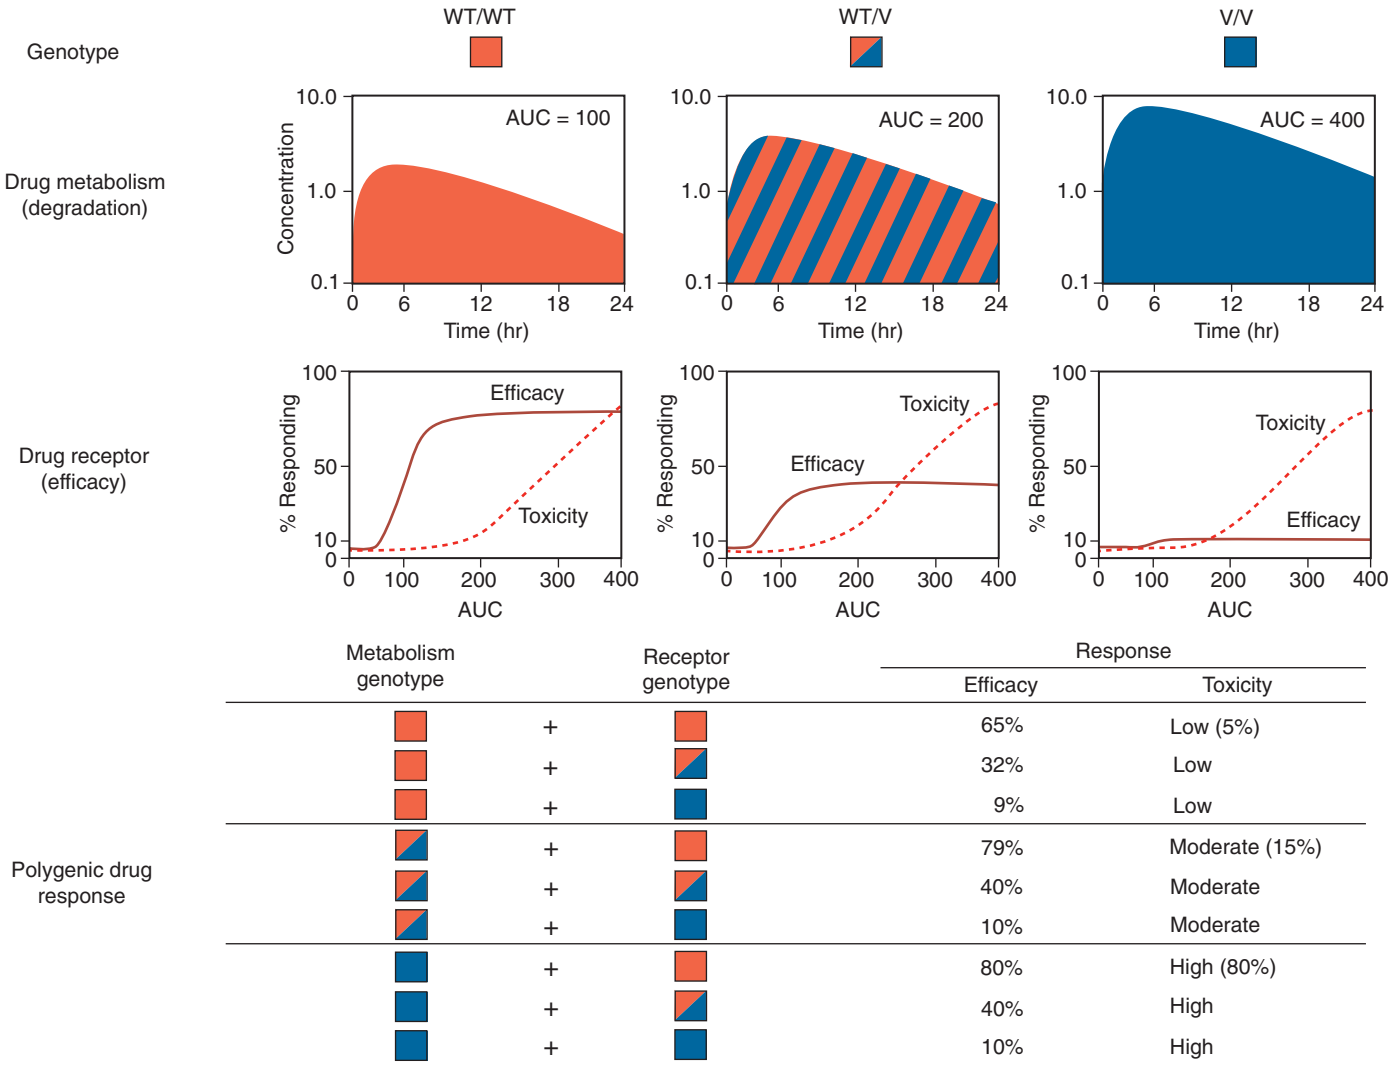

Figure 9–1 Polygenic determinants of drug response. The potential effects of two genetic variants are illustrated. One genetic variant involves a drug-metabolizing enzyme (*top*), and the second involves a drug receptor (*middle*). Differences in drug clearance (or the area under the plasma concentration–time curve [AUC]) and receptor sensitivity are depicted in patients who are either homozygous for the wild-type allele (*WT/WT*) or heterozygous for one wild-type and one variant (*V*) allele (*WT/V*), or have two variant alleles (*V/V*) for the two genetic variants. At the *bottom* are shown the nine potential combinations of drug metabolism, drug-receptor genotypes, and the corresponding drug-response phenotypes, which were calculated with data from the top. The therapeutic indexes (efficacy-to-toxicity ratios) ranged from 13 (65%:5%) to 0.125 (10%:80%).[6] *(Adapted with permission from Evans WE, McLeod HL: Pharmacogenomics—drug disposition, drug targets, and side effects. thiopurine *S*-methyltransferase (TPMT), glutathione *S*-transferases (GSTs), and cytochrome P4502C9 (CYP2C9).

Thiopurine *S*-Methyltransferase

The genetic sequence variation of *TPMT* provides one of the best and most thoroughly studied examples of a clinically important pharmacogenetic trait. During the last two decades, studies have established that variations within the *TPMT* gene locus are a major determinant of the effects of thiopurines, which are widely prescribed structural analogs of purines.[24]

The prodrugs MP and thioguanine are among the agents that constitute the backbone of treatment for childhood acute lymphoblastic leukemia (ALL). The MP prodrug AZA is used primarily as an immunosuppressant to treat autoimmune disorders and to prevent rejection reaction after solid organ transplantation.

The hydrophilic thiopurines are transported into target cells, where they undergo extensive metabolism. Metabolic reactions include anabolism to form active cytotoxic thioguanine nucleotides (TGNs) and catabolism including phase I (oxidation via xanthine oxidase) and phase II (*S*-methylation via TPMT) reactions. In hematopoietic cells such as leukemic blasts, xanthine oxidase is low or absent[34]; therefore, degradation via TPMT is the only path by which thiopurines can be inactivated. TPMT activity determines how much of these intracellular prodrugs is inactivated to methylated metabolites and how much remains available for activation to TGNs. TGNs are responsible for the efficacy in leukemic blasts and toxicity in normal hematopoietic tissues.[35,36]

TPMT activity is inherited as an autosomal codominant trait. Approximately 90% to 95% of the population are homozygous for the wild-type allele (*TPMT*1*) and have normal enzyme activity; approximately 5% to 10% are heterozygous for the polymorphism and have intermediate levels of enzyme activity; 1 in 300 persons carries two variant *TPMT* alleles that cause TPMT deficiency.[37,38] TPMT activity typically is measured in erythrocytes, because this measure correlates with the activity in other normal[39] and neoplastic tissues.[40]

Three nsSNPs account for more than 95% of the clinically relevant *TPMT variant* alleles, namely, *TPMT*2*, *TPMT*3C*, and *TPMT*3A*. The molecular defect in *TPMT*2* is a guanine to cytosine (238G>C) transversion that leads to the amino acid substitution of proline for alanine at codon 80 (Ala80Pro). The *TPMT*3A* allele contains two nsSNPs: a guanine to adenine (460G>A) transition that leads to a substitution of alanine by threonine at codon 154 (Ala154Thr) and an adenine to guanine (719A>G) transition that leads to a substitution of tyrosine by cysteine at codon 240 (Tyr240Cys). The *TPMT*3C* variant contains only the 719A>G transition.[34] The *TPMT*3B* variant is very rare; fewer than 10 cases have been reported. The *TPMT*3B* variant contains only the 460G>A transition.[24] Additionally, several other extremely rare variants, some of which have been observed in only one patient to date, have been described. These sequence variants of *TPMT* do not affect its messenger RNA (mRNA) expression; rather, they render the variant protein more susceptible to proteosome-mediated degradation,[41] and persons inheriting these alleles have a low (in heterozygotes) or undetectable (in the *variant/variant* genotype) level of TPMT activity.[41,42] Subsequent studies demonstrated that the *TPMT*3A* variant disrupts the structure of the encoded enzyme, resulting in misfolding, protein aggregation (so called *aggresome* formation) and rapid degradation of TPMT monomers and aggregates.[43,44] The prevalence of *TPMT* allelic variants differs among ethnic populations. *TPMT*3A* is the most common variant in whites, and *TPMT*3C* is the predominant variant in Asians, Africans, and African Americans.[24,44]

A subtlety worth attention in the diagnostic workup is that the existence of the very rare *TPMT*3B* variant allele makes it impossible, using conventional PCR-restriction fragment length polymorphism (PCR-RFLP) analysis, to unequivocally distinguish a *TPMT*1/TPMT*3A* genotype from a *TPMT*3B/TPMT*3C* genotype. The *TPMT*1/TPMT*3A* genotype has two nsSNPs, 460G>A and 719A>G, on the same allele and a wild-type variant on the other allele, whereas the *TPMT*3B/TPMT*3C* genotype has two nsSNPs, 460G>A and 719A>G, that reside on separate alleles. In the case of TPMT, when the nsSNPs are on the same allele, the correct genotype is *TPMT*3A/TPMT*1*; the affected person is a *TPMT* heterozygote who probably will require only modest dose reduction of thiopurine medications. In contrast, when the two nsSNPs are on different alleles, the correct genotype is *TPMT*3B/TPMT*3C*. This is an important distinction, because both the *TPMT*3B* and the *TPMT*3C* alleles, like *TPMT*3A*, encode proteins that undergo rapid degradation. Therefore, patients with a *TPMT*3B/TPMT*3C* genotype are completely TPMT deficient, which necessitates an 85% to 90% dose reduction. Because *TPMT*3B* is extremely rare and LD is so strong between the nsSNPS 460G>A and 719A>G, the assumption that such patients have a *TPMT*3A/TPMT*1* genotype, necessitating only a modest dose reduction, usually is correct.[45]

Definitive ways are available to determine the correct haplotype structure and thus genotype. However, most of these methods require either family studies, cloning and sequencing, conversion of diploid to haploid cells, or technology that is not widely available (eg, nanotubes). Recently, a relatively simple method was developed to determine molecular haplotype structure for genes like *TPMT*, in which two or more SNPs lie within approximately 30 kb in genomic DNA.[46]

Childhood ALL studies have shown that essentially all homozygous TPMT-deficient patients experience dose-limiting hematotoxicity, and some experience life-threatening hematotoxicity if given conventional doses of thiopurines. Patients with only one nonfunctional *TPMT* allele have intermediate tolerance to thioguanine therapy. Although many patients with only one nonfunctional *TPMT* allele can tolerate thiopurine therapy at essentially full doses, they are at higher risk of dose-limiting hematotoxicity than are those patients who have a wild-type *TPMT* genotype (eg, 35% cumulative risk vs. 7% cumulative risk in a study of ALL patients).[32] Furthermore, patients with no documented *TPMT* mutations *1/*1 and normal enzyme activity tolerated full-dose MP during 84% of the time of scheduled therapy; patients who were *TPMT* heterozygotes (one nonfunctional allele) tolerated this regimen for only 65% of the time; and TPMT-deficient patients (two nonfunctional alleles: *homozygous* or *heterozygous*) tolerated it only 7% of the time.[36]

In TPMT-deficient patients, the thiopurine dose must be reduced to 10% to 15% of that of conventional doses (ie, an 85%–90% dose reduction) to avoid severe hematopoietic toxicity.[34,47] At these very low thiopurine doses, TPMT-deficient patients have erythrocyte TGN levels that are comparable to (or greater than) those of "wild-type" patients given full doses. Many patients with one nonfunctional *TPMT* allele can tolerate essentially full doses of thiopurines (dependent on starting dose and other therapy), but thiopurine-intolerant heterozygous patients typically require a 50% dose reduction.[34] Multivariate analyses have demonstrated that children who have ALL and at least one *TPMT*-variant allele tend to respond well to MP therapy (ie, 75 mg/m^2/day) and may experience better leukemia control than is obtained in those who have two wild-type *TPMT* alleles.[36] However, it was observed in the same patient group that those who are treated with thiopurines and have deficient TPMT activity (ie, all patients except those with a **1/*1* genotype) are at an increased risk of epipodophyllotoxin-related acute myeloid leukemia (AML)[48] or irradiation-induced brain tumors.[49] On the other hand, a recent study from the Berlin–Frankfurt–Muenster (BFM) ALL group raised the question whether dose escalation in patients with wild-type TPMT would yield greater efficacy in protocols that routinely use lower MP doses (ie, 50–60 mg/m^2/day).[50] In this investigation, the *TPMT* genotype was linked to early ALL treatment response, which was determined by measuring minimal residual disease after induction and consolidation treatment that included a 4-week cycle of MP. Children with the **1/*1* genotype were found to have a 2.9-fold higher risk of positive minimal residual disease than did *TPMT*-heterozygous patients.[50] In contrast to *TPMT*-heterozygous patients treated at St. Jude Children's Research Hospital (more prolonged MP treatment with modestly higher MP doses; ie, 75 mg/m^2/day), for whom the risk of dose-limiting hematopoeitic toxicity is increased,[36] *TPMT*-heterozygous patients treated with lower MP doses according to BFM protocols did not have higher toxicity compared to *TPMT* wild-type patients. However, prospective MP dose adjustment (ie, reduced doses in heterozygotes) was associated with less toxicity without compromise in treatment efficacy.[51] Interestingly, in a candidate approach study in which MP doses were adjusted based on TPMT status, the efficacy of childhood ALL therapy was influenced by glutathione *S*-transferase M1 (*GSTM1*) and thymidylate synthetase (*TS*) genotypes.[52]

More than 98% concordance exists between *TPMT* genotype and phenotype, and genotyping is very reliable (90% sensitivity, 99% specificity) in identifying patients who have inherited one or two nonfunctional alleles.[53] Therefore, using the *TPMT* genotype to individualize thiopurine therapy, clinicians can now diagnose inherited differences in drug response to prevent serious toxicities (see box on Mercaptopurine Dosage Adjustment and Fig. 9–2).

Glutathione S-Transferase Polymorphisms

GSTs are ubiquitous in human organs and provide an important line of cellular defense against electrophilic genotoxic compounds. GSTs neutralize these compounds, which arise from both endogenous sources and xenobiotics (eg, anthracyclines, cisplatin), mainly by conjugating them to glutathione. In addition to their catalytic activity, certain GST isoenzymes can regulate mitogen-activated protein kinases by acting as ligand-binding proteins, or can facilitate the addition of glutathione to cysteine residues in target proteins (S-glutathionylation). The GST proteins are divided into three major families: cytosolic, mitochondrial, and microsomal GSTs.[54,55] In humans, there are currently seven subclasses of soluble cytosolic GSTs, with four major classes: GST α, GST μ, GST π, and GST θ. Three of these classes, GST μ, GST θ, and GST π, have been studied extensively in the context of pharmacogenomics and hematology/oncology.[55] Gene clusters of GST μ (*GSTM1*, *M2*, *M3*, *M4*, and *M5*) and GST θ (*GSTT1* and *GSTT2*) are located on chromosomes 1 and 22,

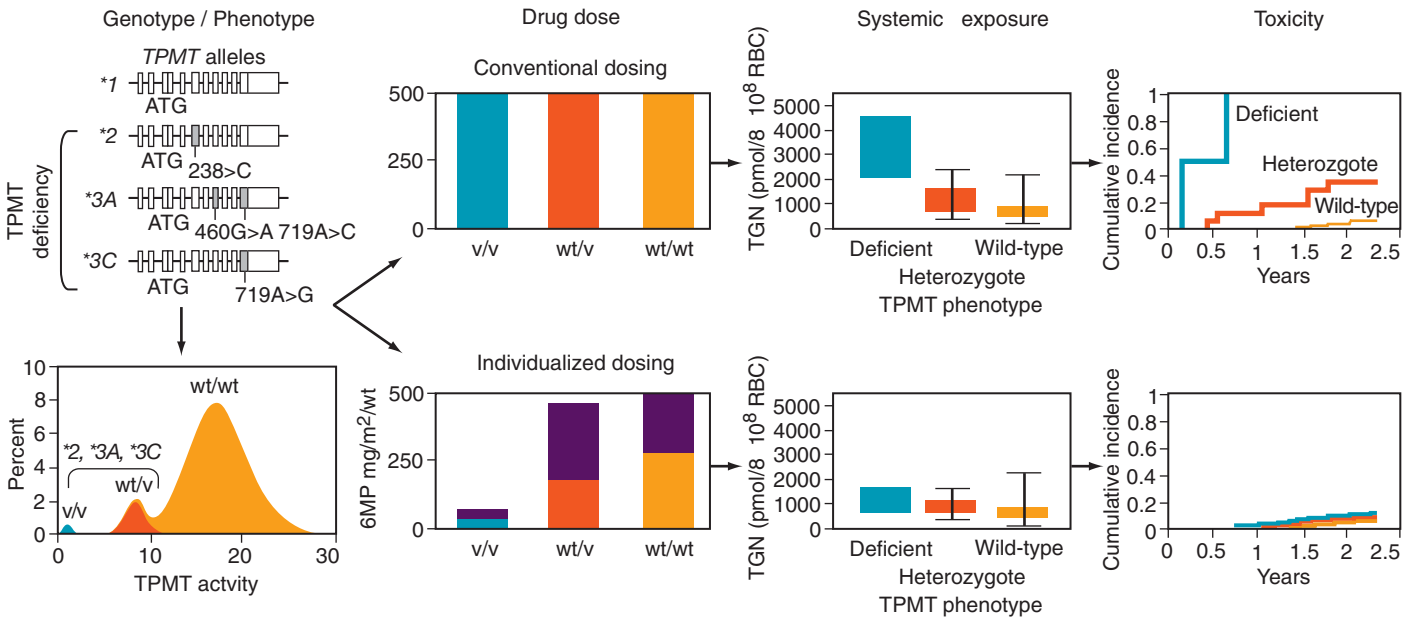

Figure 9–2 Genetic polymorphism of thiopurine methyltransferase (TMPT) and its role in determining toxicity to thiopurine medications. Under "Genotype/Phenotype" (*far left*) are depicted the predominant *TPMT* mutant alleles that cause autosomal codominant inheritance of TPMT activity in humans. As shown in the graphs under "Drug Dose," "Systemic Exposure," and "Toxicity," when uniform (conventional) dosages of thiopurine medications (eg, azathioprine, mercaptopurine [6MP], thioguanine) are administered to all patients, TPMT-deficient patients accumulate markedly higher (10-fold) cellular concentrations of the active thioguanine nucleotides (TGN), and *TPMT*-heterozygous patients accumulate approximately twofold higher TGN concentrations, which translate into a significantly higher frequency of toxicity (*far right*). As depicted in the bottom row of graphs, when genotype-specific dosages of thiopurines are administered, comparable cellular TGN concentrations are achieved, and all three TPMT phenotypes can be treated without acute toxicity. In the two graphs under "Drug Dose," the *solid* or *striped* portion of each bar depicts the mean 6MP doses that were tolerated in patients who presented with hematopoietic toxicity; the *stippled* portion depicts the mean dosage tolerated by all patients in each genotype group, not just those patients presenting with toxicity. (v, variant; wt, wild-type.) *(Reproduced with permission from Evans WE: Thiopurine S-methyltransferase: A genetic polymorphism that affects a small number of drugs in a big way. Pharmacogenetics 12:421, 2002.)*

respectively. GST π is encoded by a single locus (*GSTP1*) on chromosome 11.[56]

Some glutathione *S*-transferases (GSTs) are highly polymorphic. In most populations, approximately 50% of persons have a homozygous deletion of the gene encoding GSTM1, and approximately 25% have a homozygous deletion of the gene encoding GSTT1. These patients have the so-called *null* alleles *GSTM1*0* and *GSTT1*0*, both of which lead to absence of enzyme activity.[57] *GSTP1* also displays genetic variations within its coding region: the nsSNP 1578A>G causes an isoleucine to valine substitution at codon 105 (Ile105Val), and the 2293C>T gives rise to the replacement of alanine by valine at the amino acid position 114 (Ala114Val).[58] The enzymes encoded by the resulting variants, *GSTP1*2* (only the Ile105Val substitution) and *GSTP1*3* (both Ile105Val and Ala114Val), alter catalytic activity and thermal stability.[56] Population frequency distributions of these variants differ widely among geographic regions and ethnic groups; for example, the *GSTM1*0* type occurs more commonly in whites (50%) than in African Americans (35%).[59]

In general, it is hypothesized that patients with the *null* genotype, especially those with the *double-null* genotype (ie, *null* genotype for *GSTM1* and *GSTT1*), exhibit impaired detoxification of environmental toxins and chemotherapy. Therefore, these patients have a higher risk of primary and secondary cancers and treatment-related complications but might have a better response to chemotherapy.[60,61] Indeed, GST deficiency has been associated with increased toxicity of some anticancer drugs, and increased expression of GST has been associated with drug resistance in cell lines.[55] However, some of these results and the underlying hypothesis are challenged by results that appear contradictory.[62,63]

GST Variants and the Treatment of Acute Myeloid Leukemia

In patients receiving intensive treatment for acute myeloid leukemia (AML), the *GSTT1*0* genotype has been associated with greater toxicity and death after chemotherapy.[64,65] Because of GST's putative role in the metabolism of several cytotoxic drugs, such as anthracyclines, which are among the most important drugs used in remission induction therapy for AML, the GST deficiency caused by *null* genotypes might be expected to result in greater response to chemotherapy and higher toxicity. Consequently, a dose reduction would be indicated. However, the situation is probably more complex.

In a multivariate analysis of 106 adults with AML, persons with *GSTM1*0*, *GSTT1*0*, or *double-null* variants were found to have enhanced resistance to induction chemotherapy and a shorter survival rate. In this study, 42% of patients presented with the *GSTM1*0*, 28% with the *GSTT1*1*, and 18% with the *double-null* variant.[62] These results might be explained by the hypothesis that the deficiency of GST enzymes gives rise to higher intracellular levels of glutathione (GSH): GSH is consumed in GST-catalyzed reactions, and patients with *GST-null* genotypes have less (or no) GST to catalyze this reaction; therefore, intracellular GSH levels are higher in these patients. In addition to its role in detoxification, GSH, in high concentration, stimulates cell proliferation and inhibits apoptosis.[66,67] Accordingly, an increased level of GSH in blast cells has been associated with an increased risk of relapse in childhood ALL.[68] In a recent study on 200 adults with AML, Southwest Oncology Group investigators were unable to find associations between *GSTM1*, *GSTT1*, and *GSTA1* genotypes and treatment outcome. It was speculated that the increased

age (median 68 years, range 56–88 years) of the study population affected the results of the study; and that the extremely poor prognosis for older patients with AML may overwhelm more subtle effects of genetic variants.[69]

GST Variants and the Treatment of Acute Lymphoblastic Leukemia

GST deficiency was associated with a decreased risk of relapse of acute lymphoblastic leukemia (ALL) in a case–control study of 64 children with ALL treated on two consecutive treatment protocols designed by the Berlin–Frankfurt–Munster (BFM group (ALL-BFM 86 and ALL-BFM 90). In this study, the *GSTM1*0*, *GSTT1*0*, and the *GSTP1*B* variants conferred a decrease in the risk of relapse.[61] Additionally, the *GSTT1*0* variant conferred a reduced risk of poor cortisone response (one of the most important prognostic factors in the BFM trials) and risk of relapse.[70,71] Although central nervous system relapse tended to be less common in patients with the *GSTM*0* variant, no correlation between GST-deficient subtypes (*GSTM1*0*, *GSTT1*0*, and *double-null*) and relapse or survival was seen among 197 children who received five consecutive St. Jude Children's Research Hospital (SJCRH) protocols (Total X, XI, XII, XIIIA, and XIIIB).[59] Additionally, two studies of 710 children with ALL treated by the Children's Cancer Group and 320 children with ALL who received LAL (leucémies aiguës lymphoblastiques) protocols and the protocols developed by the Dana-Farber Cancer Institute (DFCI 87–01, 91–01, and 95–01) found no association between GST genotype (*GSTM1*0*, *GSTT1*0*, and *double-null*) and treatment outcome in childhood ALL.[63,72] Some of the observed discrepancies may be attributed to differences in study designs, number of patients, and treatment protocols. Recently, 246 children with ALL treated on the SJCRH Total XIIIB protocol were screened for 16 genetic germline sequence variants in 13 candidate genes.[52] The *GSTM1* non-null genotype (which is associated with a higher *GSTM1* expression) was significantly associated with an increased relapse rate in children with higher-risk ALL, and the risk was further increased in children carrying the thymidylate synthetase (*TS*) 3/3 genotype (which is associated with higher *TS* expression). Of interest, no genotypes were predictive for outcome in children with lower-risk ALL, which might be due to the small number of treatment failures in this cohort or that other genes are important for the lower-risk treatment protocols.[52] Overall, these data provide evidence that the identified *prognostic genotypes/phenotypes* have to be considered treatment-dependent. If confirmed, however, then dosage modifications of antileukemic medications may overcome these drug resistance genotypes in children who are treated on similar treatment protocols.

GST Variants and the Risk of Leukemia and Myelodysplastic Syndrome

GST variants have been implicated in the development of de novo ALL,[73–76] de novo AML, therapy-related AML (t-AML), and myelodysplastic syndrome (MDS) in children and adults.[56,77–80] It can be argued that the development of these diseases may be due to the limited ability of the GST variants to effectively detoxify carcinogens from the environment or cancer therapy. Results from several studies appear to be contradictory, however. For example, one multicenter study did not reveal an association of *GSTM1*0* or *GSTT1*0* variants with t-AML in the context of epipodophyllotoxin treatment[81]; another study could not find an association between *GSTT1*0* and the risk of AML[82]; and another could not find a relationship between *GSTM1*0*, *GSTT1*0*, and *double-null* variants and the risk of ALL.[64] Overall, as summarized in a recent systematic review and meta-analysis of 30 published case–control studies, it is conceivable that different *GST* genotypes may play a role in leukemogenesis.[83] However, carefully designed further studies are warranted to fully address the possible contributions of GST variants in the complex process of leukemogenesis.

GST Variants and Lymphomas

Treatment failure rates were significantly lower in a group of 169 pediatric patients with non-Hodgkin lymphoma (NHL) who had at least one *GSTM1* allele.[84] This protective effect was even more pronounced in the high-risk group (ie, patients with B-cell ALL, NHL stage IV, NHL stage III with unresected abdominal tumor, and lactate dehydrogenase activity ≥500 U/L).[84] The **2/*2* and **1/*2* genotypes of *GSTP1* were more prevalent in patients with NHL who had small tumors (<5 cm) than in those with larger tumors.[85] Additionally, a multivariate analysis of 169 patients with NHL suggested that *GSTT1*0* conferred a fourfold increase in NHL risk.[86] Although other investigators also found a 9.5-fold increased risk of gastric marginal zone lymphoma associated with the *GSTT1*0* genotype,[87] no significant correlation between *GSTT1*0* genotype and risk for NHL was observed in a large population-based case–control study (351 cases and 467 controls).[88] The discrepancy may be due to differences in study design, cohort size, and heterogeneity among NHL subtypes. Recently, the association between 15 variants in 11 metabolic genes (including *GSTP1* and *GSTM3*) and the risk of NHL was investigated in 1172 cases and 982 controls. Subjects who were heterozygous or homozygous for the cytochrome P450 gene variant *CYP1B1* V432L G allele were found to be at slightly greater risk for NHL; there was no overall association with NHL for the other gene variants examined.[89]

GST variants appear to be of interest in patients with Hodgkin disease (HD), because survivors of HD who receive combination chemotherapy and radiotherapy have an increased risk of treatment-related complications, especially second malignant neoplasms.[90] The GSTT1-null genotype was reported to be associated with a increased risk for HD,[91] and more importantly the *GSTP1*2/*2* variant (which is associated with a lower GSTP1 activity) was shown to be associated with a poor outcome in patients with advanced stage HD (IIB-IV).[92]

In conclusion, GST enzyme variants appear to be important in intracellular metabolism of drugs commonly used to treat hematologic malignancies and in the process of leukemogenesis. However, compared with the highly penetrant *TPMT* variants, *GST* variants appear to have a more complex role. Interestingly, GST variants which result in a higher expression of the genes encoded, seem to be associated with a poorer outcome in patients who receive more intense treatment; for example, for higher-risk ALL and advanced-stage HD.[52,92] Further studies are warranted to establish the importance of GST polymorphisms in determining response to treatment and the risk of leukemogenesis.

Cytochrome P4502C9

Cytochrome P4502C9 (CYP2C9) belongs to the cytochrome P450 (CYP) superfamily, a system of phase I enzymes involved in the metabolism of endogenous substances (eg, steroids, arachidonic acid, vitamin D_3) and exogenous compounds (eg, drugs, environmental chemicals, pollutants).[93] In humans, the CYP enzymes (http://drnelson.utmem.edu/CytochromeP450.html) are encoded by more than 57 genes, and the majority of genes are polymorphic.[94] Updated information regarding the nomenclature and properties of the variant alleles with links to the dbSNP database (http://www.ncbi.nlm.nih.gov/SNP/) is available at the human CYP allele home page (http://www.imm.ki.se/cypalleles/). On the basis of the composition of CYP variant alleles, individuals have been categorized into four major phenotypes: poor metabolizers (having two nonfunctional alleles), intermediate metabolizers (being deficient in one allele), extensive metabolizers (having two copies of functional alleles), and ultrarapid metabolizers (having three or more active gene copies).[94] The *CYP2* gene family, which is the largest subfamily, is encoded by more than

16 genes.[93] CYP2C9 is the principal CYP2C isoenzyme in the human liver, and it is involved in the oxidative metabolism of several clinically important drugs, including oral anticoagulants, phenytoin, and various nonsteroidal anti-inflammatory drugs. To date, numerous polymorphic alleles (*CYP2C9*1* to **30*) have been identified for the known *CYP2C9* gene, at least half of which are associated with diminished enzyme activity in vitro.[94]

The two most common *CYP2C9* variants are *CYP2C9*2* and *CYP2C9*3*. *CYP2C9*2* has a cytosine to thymine transversion at nucleotide 430 (430C>T) that encodes cysteine instead of arginine at amino acid residue 144 (Arg144Cys); *CYP2C9*3* has an adenine to cytosine transversion at nucleotide 1075 (1075A>C) that leads to the substitution of isoleucine by leucine at amino acid residue 359 (Ile359Leu).[95,96] Approximately 35% of whites have one or two of these variant alleles; the overall allelic frequency of *CYP2C9*2* is approximately 10%, and that of *CYP2C9*3* is 8%.[95,96] The **2* and **3* variants are virtually nonexistent in African Americans and Asians; 95% of these persons express the wild-type genotype (ie, extensive metabolizers).[96] Both *CYP2C9*2* and *CYP2C9*3* are important in the metabolism of the oral anticoagulants (vitamin K antagonists) warfarin, acenocoumarol, and phenprocoumon.[95,97–100]

In the United States, warfarin is widely used to prevent thromboembolic events in patients with chronic conditions such as atrial fibrillation, and the drug is prescribed to more than 1 million persons annually. A narrow therapeutic index with a risk of serious hemorrhage (1.3–2.7 per 100 patient-years[101]) and interindividual variability in response to warfarin necessitate individualization of treatment, which is based primarily on monitoring prothrombin time. Several studies have demonstrated that *CYP2C9* genotype influences warfarin anticoagulant dose requirements[95,101–105] and bleeding risks.[105] The required dose of warfarin is lowest if *CYP2C9*3* is present, as predicted by in vitro studies that compared the functional effects of the two variant alleles.[95] In addition, heterozygosity for *CYP2C9*2* significantly affects overall CYP2C9 activity.[95] Recently, a clear association between metabolic clearance of *S*-warfarin and the *CYP2C9* genotype has been demonstrated.[106]

Warfarin is a racemic mixture of *R*- and *S*-enantiomers that differ in their patterns of metabolism and in their potency of pharmacodynamic effect.[95] Although *S*-warfarin exhibits a three- to fivefold higher inhibitory effect on the target enzyme vitamin K epoxide reductase, differences in metabolism result in an approximately twofold higher plasma concentration of *R*-warfarin. It has therefore been suggested that *S*-warfarin accounts for 60% to 70% of the overall anticoagulation response and *R*-warfarin accounts for 30% to 40%.[107] A number of CYP isoforms contribute to warfarin metabolism[95]; however, 6- and 7-hydroxylation by CYP2C9 is the most important inactivation pathway of *S*-warfarin. Compared with the amount of *S*-warfarin metabolized by wild-type enzyme (encoded by the *CYP2C9*1* allele), that metabolized by the enzyme encoded by the *CYP2C9*2* variant is reduced by approximately 30% to 50%, and the amount metabolized by the enzyme encoded by the *CYP2C9*3* variant is reduced by 90%.[95] The substantial reduction in turnover seen with the *CYP2C9*3* variant may be caused by the amino acid substitution Ile359Leu within the substrate-binding site of the enzyme.[95]

It is well established that *CYP2C9* genotype is correlated with warfarin, acenocoumarol, and phenprocoumon metabolism and dose requirement, and genotyping for the more common *CYP2C9* alleles before initiation of anticoagulation therapy may help clinicians choose the appropriate initial anticoagulant treatment and determine the extent of clinical monitoring needed.[95,108] However, because interindividual variability in the dose requirement occurs within the various *CYP2C9* groups, genotyping for additional polymorphic genes that encode clotting factors, transporters, and warfarin targets could possibly further improve anticoagulation therapy. Indeed, a novel pharmacodynamic mechanism underlying warfarin resistance has been elucidated with the recent discovery of sequence variants in the warfarin target gene *VKORC1*, which encodes the vitamin K epoxide reductase complex 1.[109,110] This complex regenerates reduced vitamin K for another cycle of catalysis, which is essential for the posttranslational gamma-carboxylation of vitamin K-dependent clotting factors II (prothrombin), VII, IX, and X (Fig. 9–3). The identification of common variants in *VKORC1* has emerged as one of the most important genetic factors determining coumarin dose requirements.[111–114] Main *VKORC* haplotypes include the putative *ancestral* haplotype *VKORC1*1*, the *low-dose coumarin* haplotype *VKORC1*2*, and the *high-dose coumarin* haplotypes *VKORC1*3* and **4*. There are major differences in the distribution of *VKOCR1* haplotypes among ethnic groups, and this may explain interethnic differences in coumarin requirement. For example, the significantly higher average warfarin requirement in Africans is in line with significantly lower occurrence of the *low-dose coumarin VKORC1*2* haplotype in Africans.[112] Overall, the hereditary pharmacodynamic factor *VKORC1* explains approximately 25% of the variance in coumarin dose requirement, compared with 5% to 10% for the hereditary pharmacokinetic factor *CYP2C9* alone.[112] More recently 201 Caucasians were genotyped for sequence variants in 29 candidate genes involved in the warfarin interactive pathways, and these results combined with several nongenetic factors were tested for the association with warfarin dose requirement. By means of this systematic investigation, 62% of the variance in warfarin dose requirements in Swedish patients could be explained.[115] Clearly, prospective studies that incorporate genetic (eg, *CYP2C9* and *VKORC1*) and nongenetic factors (eg, variable intake of vitamin K) in coumarin dose calculation will be required to demonstrate the safety, cost-effectiveness, and feasibility of individualized dosing regimens.[116]

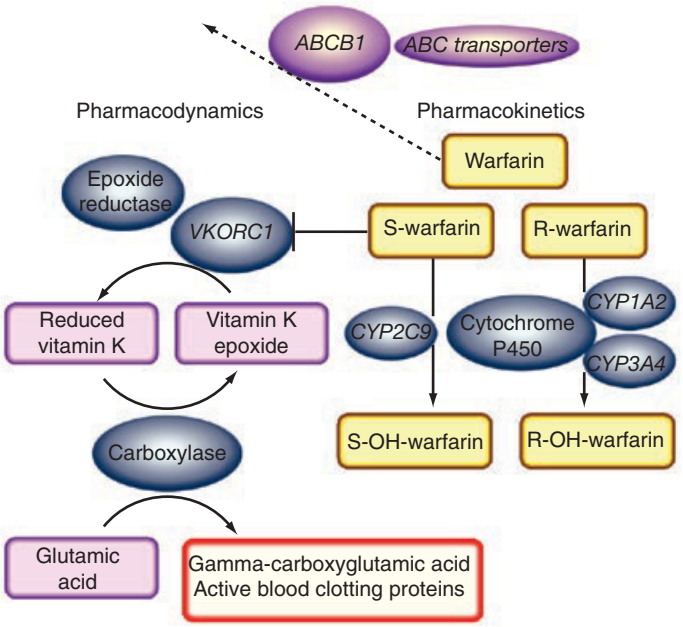

Figure 9–3 The cytochrome P450 isoenzymes *CYP2C9* (to a much lesser extent *CYP3A4* and *CYP1A2*) and vitamin K epoxide reductase complex 1 *VKORC1* genotypes influence warfarin dose requirement. The racemic mixture of *R*- and *S*-warfarin (threefold higher pharmacodynamic effect of *R*-warfarin) inhibits the reductase in the vitamin K cycle, impairing the synthesis of active vitamin K-dependent clotting factors in liver cells and causes bleeding. *R*- and *S*-warfarin are metabolized via hepatic CYP isoenzymes and there is evidence that warfarin is transported out of the liver into the bile via the ATP-dependent transporter (ABC transporter) ABCB1 (or P-glycoprotein).

DRUG TRANSPORTERS

Although passive diffusion accounts for tissue distribution of some drugs and metabolites, for more lipophilic substances and at higher drug concentrations, an increased emphasis is being placed on the role of membrane transporters. Membrane transporters move drugs

and metabolites across the gastrointestinal tract into systemic circulation and across hepatic and renal tissue into the bile and urine for excretion. They also distribute drugs into *therapeutic sanctuaries* such as the brain and testes and transport them into sites of action, such as leukemic blast cells, cardiovascular tissue, and infectious microorganisms.[5]

Adenosine Triphosphate-Binding Cassette Transporters

The most extensively studied transmembrane transporters are the adenosine triphosphate (ATP)-binding cassette (ABC) family of membrane transporters. The ABC transporters consist of P-glycoprotein MDR1, which is encoded by the multidrug-resistance gene 1 (*MDR1*) (ie, ABCB1); the six multidrug-resistance proteins (MRP1–MRP6) (ie, ABCC1–ABCC6); and other proteins such as breast cancer-resistance protein (BCRP) (ie, ABCG2) and bile salt export protein (BSEP) (ie, ABCB11).[117,118] The function, substrate specificity, and organ distribution among different transporters vary. For example, a principal function of the P-glycoprotein (MDR1) is the energy-dependent cellular efflux of numerous substrates (eg, anticancer drugs, immunosuppressive agents, glucocorticoids, bilirubin). The expression of MDR1 in many tissues, including the kidney, liver, intestinal tract, and choroid plexus, suggests that this membrane transporter plays an important role in the distribution of xenobiotics; MDR1 excretes xenobiotics and their metabolites into urine, bile, and the intestinal lumen and transports substances across the blood–brain barrier.[6] The genetic polymorphisms of the ABC transporters have been summarized,[119] and their clinical relevance in the field of hematology is being increasingly investigated.[120–122]

Although transporters like MDR1 transport various substrates and thus have rather low substrate specificity, other transporters such as the reduced folate carrier (RFC) transport only a few specific molecules and their analogs, and thus have much higher substrate specificity. Functionally important polymorphisms in transporters with high substrate specificity might be of even greater interest in pharmacogenomics than those with low specificity, because the former can affect the distribution of specific drugs.

Reduced Folate Carrier

At physiologic extracellular folate concentrations or concentrations of antifolates achieved after conventional dosages, folates and their structural analogs (eg, antifolates) enter cells mainly via the reduced folate carrier (RFC or SLC19A1), which is encoded by the *SLC19A1* gene. The antifolate drug methotrexate (MTX) is a key component in the treatment of childhood ALL. Given that passive diffusion of MTX is not of importance (ie, extracellular MTX concentrations are less than 20 μM), SLC19A1 expression and impaired SLC19A1 function appear to influence intracellular MTX accumulation and might confer cellular MTX resistance.[123,124] Gene alterations affecting the transport properties of SLC19A1 have been found in cell lines and in patient lymphoblasts.[124,125] Recently, an nsSNP (80G>A) that replaces histidine with arginine at position 27 (His27Arg) of the SLC19A1 protein has been identified.[126] The *G/G* variant correlated with lower plasma folate and higher homocysteine (Hcy) levels in healthy persons.[126]

Folate and Hcy homeostasis are affected by MTX,[127] and the nsSNP 80G>A in the *SLC19A1* gene may modulate MTX disposition and MTX effects in leukemic blast cells. This question was addressed in a study that assessed the association among the 80G>A genetic variation in *SLC19A1*, MTX plasma levels, and childhood ALL treatment outcome.[128] In this analysis, children with the *80A* variant had worse outcome after receiving MTX-containing combination chemotherapy than that noted in patients with the homozygous *80G* genotype. Additionally, patients homozygous for *80A* had higher MTX plasma concentrations than patients with other *SLC19A1* variants.[128] However, plasma concentrations of MTX are highly variable and influenced by numerous factors (eg, renal function); therefore, plasma MTX level is not a reliable indicator of SLC19A1 function. Currently, it remains unknown whether the 80G>A nsSNP confers a change in SLC19A1 function in human leukemic lymphoblasts.

The *SLC19A1*–MTX example illustrates a common problem in association studies; until causality is established through mechanistic studies, it is not possible to definitely establish the clinical importance of a given genetic variant. One can hypothesize that the association of this *SLC19A1* nsSNP and treatment outcome is caused by decreased MTX uptake into leukemic cells; however, unless it is shown that the *SLC19A1* variant causes altered transmembrane transport of MTX and/or folates, causality remains uncertain. In this regard, the amino acid change (strong to weak basic amino acid) in the first transmembrane domain (TMD1), which is caused by the 80G>A SNP, probably influences SLC19A1 transport properties; in cell lines, several alterations within the TMD1 region were shown to change the ratio of SLC19A1 affinity for MTX relative to that for other folate substrates.[129,130] Likewise, the *80A* variant transporter might have lower affinity for MTX and higher affinity for other folate substrates. However, studies in human erythroleukemia K562 cell lines showed no difference in MTX transport between the *80G* and the *80A SLC19A1* variants.[131] Therefore, additional studies are needed to elucidate the underlying mechanisms linking *SLC19A1* polymorphisms, MTX/folate transport into cells, and ALL outcomes, and these clinical findings also must be independently replicated.

The *SLC19A1* gene is located on chromosome 21, and high expression of *SLC19A1* has been correlated with higher cellular accumulation of MTX and its active polyglutamylated metabolites (MTXPG). Indeed, hyperdiploid ALL cells (ie, ALL blast cells with >50 chromosomes) almost always have extra copies of chromosome 21, and therefore have high *SLC19A1* expression and high MTXPG accumulation after MTX treatment in vivo.[124,132] Moreover, individuals with Down syndrome have germline trisomy 21, and this is associated with overexpression of a number of genes on this chromosome. However, the hypothesis that a constitutive overexpression of the *SLC19A1* gene in cells of patients with Down syndrome may explain why these individuals are more susceptible to MTX toxicity remains to be established.[124] Of interest, ALL cells carrying the *E2A-PBX1* fusion gene, which results from a t(1;19)(q23;p13.3) chromosomal translocation, have low *SLC19A1* expression and correspondingly accumulate low MTXPG levels in vivo.[132] The putative impaired MTX transport into *E2A-PBX1* ALL cells is the first chemotherapy resistance mechanism identified in this ALL subtype; and impaired MTX influx might be overcome by high-dose MTX. Notably, the clinical trials with the best treatment results for *E2A-PBX1* ALL, the St. Jude Total Therapy XIII protocol and the Berlin–Frankfurt–Muenster (ALL-BFM 90) protocol, with 5-year event-free survival rates of 89.5% ± 7.3% and 93% ± 6%, respectively, featured high-dose MTX consolidation therapy.[133,134]

Clearly, further investigations are needed to define the nature of *SLC19A1* function and MTX uptake in hematological malignancies such as acute lymphoblastic leukemia and lymphomas.

GENETIC VARIATIONS INFLUENCING DRUG TARGETS

To exert their pharmacologic effects, most drugs interact with specific target proteins such as receptors, enzymes, or proteins involved in signal transduction, cell cycle control, or other cellular events. Molecular studies have revealed that many of the genes encoding these drug targets exhibit genetic variations, which can alter the sensitivity of these targets to specific medications.[3,5,6,109] Here we focus on three that are potentially relevant in hematology.

Glycoprotein IIIa Subunit of the Glycoprotein IIb/IIIa Receptor

Platelets play a crucial role in thrombosis and the development of acute ischemic coronary artery syndromes (eg, a platelet-rich thrombus forms at the site of the ruptured atherosclerotic plaque). Inhibi-

tion of platelet function is an effective strategy in the treatment and prevention of thrombosis of arteriosclerotic origin. Three main classes of antiplatelet agents are available for clinical use: aspirin, the thienopyridines, and intravenous GPIIb/IIIa antagonists.

The glycoprotein (GP) complex GPIIb/IIIa is the most abundant platelet membrane GP; each platelet contains approximately 80,000 copies of this GP. The GPIIb/IIIa complex is believed to be the final common pathway in platelet aggregation, which is mediated by the binding of fibrinogen or von Willebrand factor. The importance of GPIIb/IIIa for thrombus formation is convincingly evidenced by clinical trials, which have successfully used intravenously administered GPIIb/IIIa antagonists to block platelet aggregation and thrombus formation.[135] In addition, aspirin inhibits epinephrine-induced platelet aggregation by inhibiting GPIIb/IIIa activation through interference with intracellular signaling events[136] and acetylation of GPIIb/IIIa molecules.[137]

Theoretically, polymorphisms that change the function of the GPIIb/IIIa receptor might influence the outcome of antiplatelet therapy and contribute to differences in drug effects. A common polymorphism of GPIIIa, *HPA-1* (*Pl(A)*), involving a thymidine to cytosine transition at nucleotide 1565 (1565T>C) results in leucine to proline substitution at position 33 (Leu33Pro) and defines the *Pl(A1)* (*HPA-1a*, Leu33) and *Pl(A2)* (*HPA-1b*, 33Pro) alleles, respectively.[138] The *Pl(A2)* allele is present in 20% to 30% of Caucasians[139] and confers a *hyperreactive* thrombocyte status in vitro (ie, these platelets have a lower threshold for activation, granule release, GPIIb/IIIa activation, and fibrinogen binding).[140] Therefore *Pl(A2)* allele carriers seem to have a higher risk for thrombotic events, for example, ischemic coronary syndromes[141,142] and restenosis after coronary stent placement.[143] Whereas there is consensus on the prothrombotic phenotype of the *Pl(A2)* sequence variant, in part disconcordant results are reported on the sensitivity of platelets to aspirin, thienopyridines, and GPIIb/IIIa antagonists as a function of the *Pl(A)* variant alleles.[140,144–148] Clearly, further studies are needed to elucidate whether the *Pl(A)* variant alters GPIIb/IIIa function and response to aspirin, thienopyridines, or intravenous GPIIb/IIIa antagonists.

IgG Fc Receptor (Subtype FcγRIIIa, CD16)

Rituximab is a chimeric anti-CD20 immunoglobulin G1 (IgG1) monoclonal antibody (mAb) directed against the CD20 antigen present on B lymphocytes. Rituximab was successfully introduced for the treatment of B-lymphoproliferative malignancies, including non-Hodgkin lymphomas (NHL, eg, diffuse large B-cell lymphoma, follicular lymphoma), Waldenstrom macroglobulinemia, and chronic lymphocytic leukemia.[149–153] This drug is associated with severe B-cell depletion from peripheral blood and lymphoid tissue, which makes it useful in autoimmune diseases such as immune thrombocytopenia, by interfering with the production of pathologic antibodies.[154] However, 30% to 50% of patients with NHL, for example, exhibit no clinical response to rituximab therapy, and the actual cause of this treatment failure is largely unknown.[149]

Besides other mechanisms, like mAb-induced apoptotic signaling via CD20[155] and complement-dependent cytotoxicity,[156] antibody-dependent cell-mediated cytotoxicity (ADCC) appears to be an important mechanism in the eradication of $CD20^+$ blast cells by rituximab, and failure in this pathway might confer drug resistance.[157] The initiation of the ADCC program requires leukocyte receptors for the Fc portion of IgG (FcγR). FcγRs link the IgG-sensitized antigens to FcγR-bearing cytotoxic cells and trigger the cell activation mechanisms.[149] Three classes of IgG Fc receptors (ie, FcγRs)—FcγRI, FcγRII, and FcγRIII—have been found in humans, and several genetic variations that influence the IgG-binding properties of these receptors have been described.[157,158]

In the FcγRIIIa (CD16) receptor, a guanine to thymine transition at position 559 of the *FCGR3A* gene (559G>T) leads to substitution of phenylalanine by valine at codon 158 (Phe158Val).[158] Of interest, this genetic variation has the same distribution in various ethnic populations.[149,158] Of the receptor molecule, the affected residue is located at the F-G loop that serves as a binding interface and is surrounded by both chains of the Fc fragments of IgG1.[159] Because the side chain of phenylalanine is hydrophobic and larger than that of valine, the genetic variation can affect the major conformation or the hydrophobicity of the surface of the binding interface; therefore, it may influence the receptor's binding properties.[159] Indeed, human IgG1 binds more strongly to natural killer (NK) cells bearing homozygous FcγRIIIa-158V receptors than to NK cells bearing homozygous FcγRIIIa-158F receptors or NK cells bearing heterozygous FcγRIIIa receptors; this difference might have a profound influence on ADCC.[157,158] Patients with follicular lymphoma,[149,150] diffuse large B-cell lymphoma,[151] and Waldenstrom macroglobulinemia,[152] whose NK cells carry the homozygous FcγRIIIa-158V receptor and who receive rituximab have a greater probability of clinical and molecular response than those patients who carry the FcγRIIIa-158F receptor, a finding that suggests that the ADCC mechanism of rituximab is more effective in the patients with homozygous FcγRIIIa-158V receptors.[149,157] However, FcγRIIIa polymorphisms were not predictive for response to rituximab in patients with chronic lymphocytic leukemia, which suggests that unlike the case with NHL, mechanisms of tumor cell clearance other than ADCC may be more important in chronic lymphocytic leukemia.[153] Interestingly, results from a recent investigation provide evidence that CD20 mAb-induced blood B cell clearance may not necessarily correlate with tissue B cell clearance.[160]

Because FcγRIIIa polymorphism is strongly associated with response to rituximab in NHL, these findings need to be considered in the development of new drugs targeting the CD20 antigen.

5,10-Methylenetetrahydrofolate Reductase

The flavin adenine dinucleotide-dependent enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR) plays a key role in folate and Hcy metabolism. MTHFR resides at a metabolic branch point directing the folate pool toward Hcy remethylation and DNA methylation, at the expense of DNA and RNA biosynthesis, by catalyzing the irreversible conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate.[161] The latter provides methyl groups for methionine synthesis from Hcy and *S*-adenosyl methionine, a common methyl donor for purine and pyrimidine biosynthesis, which is crucial for DNA methylation. Alternatively, the one-carbon unit of 5,10-methylenetetrahydrofolate is used for DNA and RNA synthesis (Fig. 9–4). Because MTHFR affects folate distribution, Hcy metabolism, and DNA methylation, genetic defects that change the activity of MTHFR have the potential to modulate disease risk and effects of medications.

Two common variations in the *MTHFR* gene, a cytosine to thymine transition (677C>T) leading to the amino acid substitution Ala222Val and an adenine to cytosine transition (1298A>C) leading to the amino acid change Glu429Ala, result in diminished enzyme activity owing to enhanced thermolability.[162] The frequencies of the 677C>T and 1298A>C alleles are similarly distributed among many ethnic groups.[162] The most extensively studied MTHFR variant contains the 677C>T nsSNP. The MTHFR enzymatic activity in persons with the homozygous *677TT* genotype (approximately 10% to 16% in white and Asian populations) is approximately 30% that of persons with the wild-type variant (*677CC*). Thus, the *TT* genotype leads to an elevated plasma concentration of Hcy, particularly in persons with low folate status.[162,163] The *TT* variant has been associated with numerous consequences, increased risk of disease (eg, cardiovascular disease, renal failure), congenital abnormalities, pregnancy complications, cancer risk, and altered drug effects (eg, MTX).[161,162] Whereas a meta-analysis published in 2002 suggested that persons with the *TT* genotype and inadequate folate status have a significantly higher risk of coronary heart disease, which is probably due to elevated Hcy levels,[164] a meta-analysis published in 2005 was unable to confirm this previous finding.[165] Nevertheless, Hcy levels can be markedly decreased in persons with the *TT* genotype by daily supplementation of folic acid (0.5 to 2.0 mg).[161] During the past decade, conflicting data have been reported on the impact of variations in the *MTHFR* gene and the risk of thromboembolic disease.[166–171] In most case–

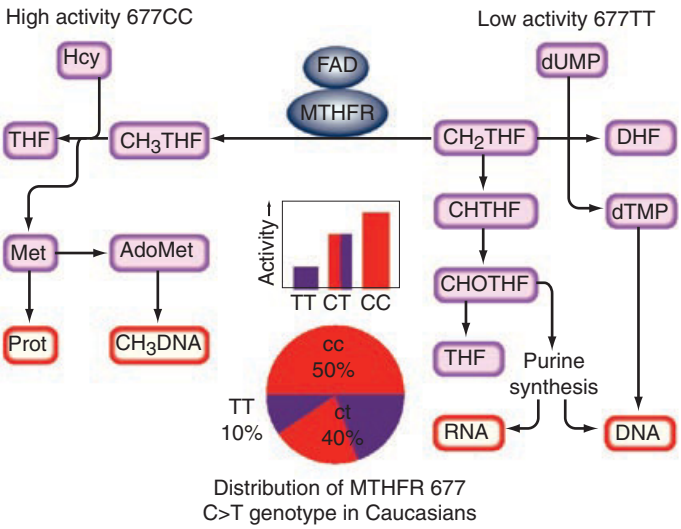

Figure 9–4 The 677C>T methylenetetrahydrofolate reductase (MTHFR) polymorphism affects the distribution between folate species used for DNA and RNA syntheses and the 5-methyltetrahydrofolate form required for homocysteine remethylation and thus protein synthesis. The pie chart in the *center* indicates the genotype prevalence often found in white populations and the associated *vertical boxes*, the relation between genotype and MTHFR activity. AdoMet, *S*-adenosylmethionine; CH_3DNA, DNA methylation; CHOTHF, formyltetrahydrofolate; CHTHF, methenyltetrahydrofolate; CH_2THF, 5,10-methylenetetrahydrofolate; CH_3THF, 5-methyltetrahydrofolate; DHF, dihydrofolate; dTMP, thymidine 5′-monophosphate; dUMP, uracil 5′-monophosphate; FAD, flavin adenine dinucleotide cofactor; Hcy, homocysteine; Met, methionine; Prot, protein; THF, tetrahydrofolate. *(Modified from Ueland PM, Refsum H, Beresford SAA, Vollset SE: The controversy over homocysteine and cardiovascular risk. Am J Clin Nutr 72:324, 2000. With permission from the American Journal of Clinical Nutrition. © Am J Clin Nutr. American Society for Clinical Nutrition.)*

control studies of the risk for venous thromboembolic disease, a leading cause of morbidity and death, no significant associations with *MTHFR* variations were observed[169–171]; therefore, it is unlikely that 677C>T and 1298A>C variants are significant risk factors for venous thromboembolic disease.

Additional examples of consequences of variations in the *MTHFR* gene are potentially relevant in hematology, namely, risk for and outcome of leukemia and MTX toxicity. Low-function *MTHFR* variants conserve intracellular folate in a cyclic pathway by shunting one-carbon groups toward thymidine and purine synthesis.[161] These variants also confer decreased *S*-adenosinemethionine synthesis, which is associated with a lower rate of DNA methylation.[172] Numerous case–control studies have evaluated the association between *MTHFR* variants and the risk of acute leukemia in both adults and children. However, in a recent meta-analysis that included the results of 13 studies, no association between the 1298A>C polymorphism and susceptibility to childhood or adult ALL was disclosed.[173] The 677C>T polymorphism in the *MTHFR* gene might contribute to risk of ALL in adults,[173] but this variant does not seem to play a major role in risk modulation in children with ALL, at least for populations with adequate folate intake.[174,175] These provocative findings require further study to fully elucidate whether a combination of unfavorable folate pathway genotypes, diet, and vitamin B status may be a key factor in susceptibility to ALL.

The response of medications that target folate metabolism (e.g., MTX) could theoretically be modulated by genetic variants of *MTHFR*. Increased toxicity (oral mucositis) was observed in patients with the 677TT genotype (decreased MTHFR activity) who received low-dose MTX as graft-versus-host disease prophylaxis after stem cell transplantation for chronic myelogenous leukemia.[176] It is hypothesized that MTX induces a more extensive folate depletion in patients who have low MTHFR activity and leads to a greater decrease in DNA synthesis and less ability to repair DNA, which results in greater damage and delayed healing.[176] Three other studies in small patient groups confirmed the potentially higher toxicity after low-dose MTX treatment in patients with the *TT* genotype, treated for ovarian cancer,[177] breast cancer,[178] and adult ALL.[179] For example, patients with the *TT* genotype had a 40-fold higher relative risk for severe (G3/G4) toxicity during low-dose MTX treatment (2.5 mg daily for 21 days) for ovarian cancer.[177] Of importance, this finding does not apply to patients receiving high-dose MTX treatment with leucovorin rescue, probably because leucovorin directly bypasses MTX-induced folate depletion to prevent MTX toxicity.[180]

Recently, the effect of the deactivating *MTHFR* allele on treatment outcome of children with ALL was assessed in the Children's Cancer Study Group ALL study CCG-1891, and it was shown that patients who carried the *MTHFR* 677C>T variant allele had significantly higher risk of relapse.[181] If these preliminary data can be confirmed, MTX dose adjustments based on *MTHFR* genotypes may help improve MTX therapy in childhood ALL.

ADVERSE DRUG EFFECTS PRESENTING AS HEMATOLOGIC DISORDERS

Adverse drug reactions (ADRs) constitute a major clinical problem, and strong evidence indicates that ADRs account for approximately 5% of all hospital admissions and increase the length of hospitalization by 2 days.[182] Although the factors that determine susceptibility to ADRs are unclear in most cases, there is increasing interest in the role of genetics[183]; therefore, the availability of a genetic test that identifies patients at risk for rare but serious adverse effects has particular appeal. Several medications whose adverse effects have been associated with variability in candidate genes and manifest predominantly as hematologic abnormalities are listed in Table 9–1. By using genome-wide analyses, gene signatures were recently identified in leukemia cells of children treated for ALL, that were associated with the development of treatment-induced AML[184] and secondary brain tumors.[185] Further investigations are necessary to confirm these data, which suggest that germline-driven gene expression across different tissues may relate to the risk of secondary malignancy following antileukemic treatment.

DRUG DEVELOPMENT

Optimizing the selection and dosage of medications is a principal goal of pharmacogenomics. Another important application is in drug development, which is evolving in parallel with improved insights into the mechanisms by which medications exert their pharmacologic effects. Such improved insights into the mechanism(s) of drug action in target cells will help elucidate mechanisms that confer drug resistance, and they will facilitate the development of strategies to further enhance efficacy. This knowledge can be used as a basis to engineer drugs that amplify treatment effects or bypass resistance mechanisms, or both. For example, identification of the mechanism underlying rituximab resistance, a genetically determined functional change in the Fc receptor domain, enables the design of more specific antibodies for patients bearing the FcγRIIIa-158F variant.[149] Indeed, in contrast to rituximab, anti-CD20 mAb with enhanced affinity for FcγRIIIa has been demonstrated to activate NK cells and ADCC effectively irrespective of FcγRIIIa polymorphism.[186]

One of the most powerful tools to study mechanisms of drug action is genome-wide analysis of gene expression profiles by means of high-density microarrays. In addition, this approach offers the opportunity to identify previously unknown drug targets. The feasibility of this method has been recently demonstrated in studies of several hematologic diseases.[187–195] For example, recent pharmacogenomic studies shed light on the biological basis of treatment failure in childhood ALL, by investigating gene expression signatures that

Table 9–1 Selected Pharmacogenetic Defects That Lead to Adverse Drug Reactions Manifesting as Hematologic Disorders

Adverse Effect	Causative Drug(s)	Altered Protein	Important Genetic Variant(s)*	Hypotheses on Pathophysiology	References
Myelosuppression	6-Mercaptopurine 6-Thioguanine azathioprine	Thiopurine-6-methyltransferase (TPMT)	TPMT*2: 238G>C; TPMT*3A: 460G>A; 719A>G; and TPMT*3C: 719A>G	In hematopoietic cells, TPMT inactivates cytotoxic thioguanine nucleotides (TGNs) by methylation. Accumulation of TGNs as a result of the functionally defective TPMT variants causes severe hematotoxicity.	See text
Myelosuppression (diarrhea)	Irinotecan (CPT-11) Active metabolite: 7-ethyl-10-hydroxycamptothecine (SN-38)	UDP-Glucuronosyltransferase (UGT) isoenzyme 1A1 (UGT1A1)	UGT1A1*28: promotor polymorphism; dinucleotide insertion in the TATA box [wild-type: (TA)6TAA] resulting in (TA)7TAA	The cytotoxic metabolite of CPT-11, SN-38, is mainly inactivated by UGT1A1. Accumulation of cytotoxic SN-38 in hematopoietic and intestinal cells is due to decreased inactivation (glucuronidation) by the variant enzyme.	References 206–208
Myelosuppression (mucositis, neurotoxicity)	5-Fluorouracil (5-FU)	Dihydropyrimidine dehydrogenase (DPD)	DPYD*2A: G to A mutation in the invariant GT splice donor site flanking exon 14 (IVS14+1G>A); leading to skipping of exon 14 during splicing	DPD is the rate-limiting enzyme in 5-FU catabolism. Skipping exon 14 during splicing renders the enzyme inactive and can, therefore, be one cause of severe 5-FU toxicity as a result of prolonged 5-FU exposure.	References 209 and 210
Venous thrombosis	Oral contraceptives	Prothrombin (FII, F2)	Factor II 20210G>A; SNP in the 3 untranslated regions (UTR) at position 20210	Factor II 20210G>A causes elevated prothrombin level, which is a risk factor for thrombosis. Oral contraceptives are an additional independent risk factor, and both (FVL) raise the risk of thrombosis	References 212–215
Venous thrombosis	Oral contraceptives	Factor V (FV, F5)	FVL: 1691G>A (in exon 10 of the FV gene) leads to Arg506Gln change lies within the activated protein C cleavage site	FVL causes activated protein C resistance, which is a thrombotic risk factor. Oral contraceptives are an additional independent risk factor, and both (+ factor II 20210G>A) raise the risk of thrombosis	References 212–215
Bleeding risk	Warfarin and other coumarin derivatives	Cytochrome P450 isoenzyme 2C9 (CYP2C9)	CYP2C9*2: 430C>T in exon 3 leads to an Arg144Cys change. CYP2C9*3: 1075A>C in exon 7 leads to an Ile359Leu change.	CYP2C9 is the most important enzyme in the catabolism of *S*-warfarin. The CYP2C9*3 allele leads to an amino acid change in the substrate-binding site, a decrease in enzyme activity (additionally seen in CYP2C9*2 allele), and an accumulation of S-warfarin, which enhances the risk of bleeding. were associated with in vitro sensitivity of diagnostic ALL cells to prednisolone, vincristine, L-asparaginase, and daunorubicin. Importantly, only few of the identified intrinsic drug resistance genes have been previously linked to drug resistance, and the identified gene expression signatures discriminated patients who were at higher risk for relapse.[193,194] Moreover, using genome-wide gene expression analyses, the FMS-like tyrosine kinase 3 (*FLT3*) gene was identified as being overexpressed in *MLL*-rearranged and hyperdiploid ALL.[189] FLT3 inhibitors have been shown to inhibit growth in cells that overexpress FLT3.[196,197] Thus, the inclusion of FLT3 inhibitors seems

Relevance to Clinical Hematology

Mercaptopurine Dosage Adjustment Based on TPMT Genotypes in Acute Lymphoblastic Leukemia

Mercaptopurine (MP) is a mainstay of treatment of childhood acute lymphoblastic leukemia (ALL). However, conventional doses of this prodrug can induce severe hematotoxicity in patients who have impaired thiopurine metabolism in hematopoietic tissues owing to less-stable thiopurine *S*-methyltransferase (TPMT) enzyme variants. The three major variant alleles (*TPMT*2*, *TPMT*3C*, and *TPMT*3A*) encoding the variant proteins can quickly be determined by commercially available Clinical Laboratories Improvement Act-certified molecular diagnostics or in special laboratories (eg, Prometheus Labs, San Diego, CA) using samples obtained from peripheral blood before MP therapy. In patients with two nonfunctional alleles (1 out of 300), MP dosage must be reduced to 10% to 15% of conventional dosages. Patients with one variant allele (5%–10% of the population) can tolerate MP at full dosage; however, in intolerant patients, a dose reduction of 50% often is required.

worthy of being investigated in the therapy of the poor prognostic ALL subtype with *MLL* rearrangements, and perhaps hyperdiploid ALL that also overexpress FLT3.[188] Most recently, a new approach was used to computationally connect disease-associated gene expression signatures (eg, ALL blast cells that are intrinsically sensitive or resistant to glucocorticoid (GC)-induced apoptosis in vitro) to drug-associated gene expression profiles (ie, the so called Connectivity Map; http://www.broad.mit.edu/cmap/)[198] in order to identify molecules that reverse a drug resistance signature.[199] This strategy builds on prior findings that small molecules can induce treatment-specific changes in gene expression in leukemia cells in vivo.[195] Indeed, the profile induced by the mTOR inhibitor rapamycin was found to match the signature of GC sensitivity in ALL cells. Moreover, it was shown that rapamycin sensitized a resistant leukemia cell line to GC-induced apoptosis via a modulation of antiapoptotic protein MCL-1.[199] This is consistent with earlier work revealing MCL-1 overexpression in steroid-resistant ALL.[193] This work suggests that GC in combination with rapamycin could be an effective approach to overcome intrinsic GC resistance in ALL, and provides evidence that such a chemical genomic approach based on gene expression might be useful to identify molecules with the potential to overcome intrinsic drug resistance in leukemia.

CHALLENGES FOR THE FUTURE

Pharmacogenomics has already been proved to be an important approach to improve drug therapy. For example, the FDA has recently approved a label for irinotecan to prevent severe hematotoxicity based on the assessment of sequence variants in the uridine diphosphate glucuronosyltransferase (UGT) 1A1 gene; ie, a reduction in the starting dose is recommended for patients homozygous for *UGT1A1*28* allele. In most occasions, however, testing for a single allele of a single gene is unlikely to provide sufficient information to establish precise pharmacogenomic models that help explain all differences in drug effects among individuals. Clearly, further progress depends on the development and refinement of strategies and methods to elucidate the inherited determinants of drug effects. For the development of strategies, a number of crucial issues must be considered; a major one is that the inherited component of drug response often is polygenic (see Fig. 9–1). Approaches to elucidate polygenic determinants of drug response include, for example, the use of anonymous SNP maps to perform genome-wide searches for genetic variants that are associated with the effects of certain drugs and the *candidate-gene strategy*. The latter is based on existing knowledge of a medication's mechanisms of action and pathways of metabolism and disposition. These approaches and their potential value and limitations have been the subjects of recent reviews.[31,200] The candidate-gene strategy offers the advantage of focusing on a manageable number of genes, and variations within, that are likely to be of importance in the pharmacokinetic and pharmacodynamic pathways of certain drugs. However, lack of knowledge of these pathways is an inherent limitation of this approach. Gene expression profiling, proteomic studies,[201] and metabonomic investigations[202] are additional evolving strategies for identifying genes and the mechanisms by which their products may contribute to drug response.

Epigenetic changes, mainly methylation, have recently been demonstrated to be implicated in the regulation of drug-metabolizing enzyme activity.[203,204] This indicates that genetic and epigenetic mechanisms may act separately or in concert to influence pharmacological effects. In addition, in hematologic malignancies like leukemias, allele-specific copy number differences exist between host cells (ie, germline genotype) and malignant cells (which often contain cytogenetic aberrations including trisomies and gene amplification). As recently documented, these differences can cause disconcordance between germline genotypes and leukemia cell phenotypes.[205] Therefore, qualitative and quantitative genomic investigations and the analysis of epigenetic factors may be necessary to establish precise pharmacogenomic models in hematologic malignancies.

In order to define valid pharmacogenetic traits, rigorous correlations between genotype and phenotype have to be established and validated. This implicates the need for well-characterized patient groups who have been uniformly treated and systematically evaluated to make it possible to estimate drug response more objectively. To this end, investigators should try to obtain genomic DNA for pharmacogenetic studies from all patients enrolled in clinical drug trials, with appropriate informed consent. Racial and ethnic differences in the frequency and nature of genetic variants also must be recognized in attempting to extrapolate research from one population to another. For example, approximately 35% of whites have variant alleles in the *CYP2C9* gene, but these variants are virtually nonexistent in African Americans and Asians. Therefore, pharmacogenomic relations must be validated for each therapeutic indication in different racial and ethnic groups, as well as in different treatment and disease contexts. Remaining cognizant of these caveats will help ensure accurate elucidation of genetic determinants of drug response and facilitate the translation of pharmacogenomics into the field of hematology.[6]

CHAPTER 10

OVERVIEW AND COMPARTMENTALIZATION OF THE IMMUNE SYSTEM

Leland D. Powell and Linda G. Baum

The human immune system is assigned the seemingly impossible role of keeping at bay the universe of pathogens seeking to invade and take advantage of the permissive conditions found in mammals for growth. It also plays a less celebrated but equally important role in the clearance of dead cells and tissues, promoting wound healing, and recognition of transformed cells. It is a complex, multilayered system that has evolved over millions of years, and early vestiges of our current immune system can be found in simple invertebrate species. The tasks assigned to it are to recognize and rapidly neutralize invading pathogens and their toxins, with minimal damage to host tissues in the process; to recognize new pathogens, including those with a high degree of likeness to the host; to discriminate between trace amounts of virulent organisms or toxins and more abundant amounts of foreign yet benign dietary or environmental structures; and to distinguish between healthy viable cells and apoptotic or necrotic cells. Disorders that are the consequence of immune underreactivity or overreactivity are found in all medical specialties. Methods of manipulating the immune system in the areas of infectious disease, transplantation biology, and tumor immunology are active frontiers of medical research.

Conceptually, the immune response may be divided into innate and adaptive systems (Table 10–1). The innate system is evolutionarily the oldest, with many components found in invertebrate species. It is a system of cells and constitutively expressed membrane-bound or soluble receptors on those cells that recognize specific pathogens without the requirement of prior exposure. Pathogen–receptor binding results in the immediate activation of specific protective humoral and cellular responses. In contrast, cells of the adaptive system do not mount an effective response on first encounter with a pathogen because of the limited numbers of antigen-specific T and B cells present in a naive host. However, recurrent infections or infections by pathogens that escape the innate immune system result in the expansion of populations of pathogen-specific lymphocytes (ie, formation of immunologic memory).

The innate and adaptive immune systems have been characterized in depth at the cellular and molecular levels. The principal goal of these systems is defense against pathogens seeking entry through one of four anatomic sites: the respiratory, gastrointestinal, and genitourinary tracts and the skin. Consequently, immune function can be fully understood only by examining the anatomy of these four entry points and their relation to lymphatics, blood vessels, and lymphoid organs. This chapter provides an introduction to the molecular and cellular components of innate and adaptive immunity with an overview of their anatomic relationships.

THE INNATE IMMUNE SYSTEM

Pathogen Recognition Receptors and Pathogen-Associated Molecular Patterns

Pathogen recognition receptors (PRRs) are proteins that recognize and bind to pathogen-associated molecular patterns (PAMPs); they are the cornerstones of the innate immune response.[1,2] PAMPs are molecular motifs common to bacteria, fungi, and some viruses but not viable mammalian cells. They frequently are characterized by a repeating pattern of hydrophobic or charged molecules. Common PAMPS include lipopolysaccharide (LPS or endotoxin of gram-negative bacteria), peptidoglycans and teichoic acids (gram-positive and negative bacteria), mannans (fungi), single or double-stranded RNA (viruses), or dsDNA (viruses or necrotic/apoptotic cells). An important feature of PAMPs is that they are derived from structures essential for the viability of the particular pathogen. Consequently, selective evolutionary pressure has not yielded organisms lacking them, which is reflected in the evolutionary endurance and invariance of the innate immune system. As such, they are ideal targets for immune recognition by a host organism, which is accomplished by the PRRs (Table 10–2). PRRs are germ-line encoded and constitutively expressed, key features that distinguish them from the adaptive immune system. PRRs may be soluble proteins found in the serum, lymphatic fluid, or cell cytosol or as type I transmembrane proteins expressed on the surface of marrow-derived effector cells. They are also found on the surface of or secreted by epithelial cells in the gut,[3] bronchial airways,[4] renal tubules,[5] uterus,[6] skin,[7] and endothelial cells in the liver.[8] As such, they are poised at the four major portals of pathogen entry.

PRRs encompass several different structural families (Table 10–2). Two PRR families—peptidoglycan receptor proteins (PGRPs) and the Toll-like receptors (TLRs)—were first identified in *Drosophila* and only later demonstrated in vertebrate organisms.[9] In flies, PGRPs help defend against gram-negative bacteria, and four PGRP homologs have been identified in the human genome.[10] In humans, 10 TLRs have been identified; their ligands include bacterial lipopeptides (TLR1, TLR2, TLR6), peptidoglycans (TLR2), LPS (TLR2, TLR4), fungal saccharides (TLR2, TLR6), ds and ssRNA (TLR3, TLR7, TLR8), flagellin (TLR5), and dsDNA and CpG DNA fragments (TLR9).[1,2,11] Although the TLRs may be the most characterized family of PRRs, other receptor families include the C-type lectins (including the mannose-binding lectin [MBL] and pulmonary surfactant proteins),[12,13] dectin-1,[14] macrophage scavenger receptors,[15,16] peptidoglycan recognition proteins,[10] NOD-like receptors (NLRs),[17] and RNA helicases.[18,19] Many of these receptors are transmembrane proteins and function as cellular receptors and activation molecules, whereas others are soluble serum proteins and function by neutralizing or inducing the opsonization of pathogens. Other PRRs are found as soluble proteins within the cytoplasm of cells, where they recognize intracellular bacterial components resulting from lysosomal degradation or the products of replicating viruses (NLRs and RNA helicases).

Consequences of PRR–PAMP Ligation: Phagocytosis, the Cytokine Response, and Priming the Adaptive Immune Response

PRR–PAMP ligation triggers immune and inflammatory responses in three stages. In the first, ligation induces clearance of pathogens or foreign molecules by monocytes, macrophages, and neutrophils. This process is initiated by pathogen binding directly to PRRs on the surfaces of these cells or the opsonization of pathogens bound by a soluble PRR. Internalized pathogens are destroyed by a combination of hydrolytic and oxidation reactions within vacuoles inside the phagocytic cells. Phagocytosis also triggers degranulation and the

Table 10–1 Human Innate Versus Adaptive Immune System

Feature	Innate	Adaptive
Response time	Hours to days	>5 Days
Expression	Constitutive	Induced by pathogen exposure
Shaped by pathogen exposure	No	Yes
Approximate number of gene products involved in direct pathogen recognition	10^2 to 10^3	10^{10} to 10^{14}
Clonal response	No	Yes
Found in invertebrate species	Yes	No

release into tissues of bactericidal or bacteriostatic molecules such as lysozyme, lactoferrin, myeloperoxidase, antimicrobial peptides, nitrous oxide, and superoxide radicals. These products are toxic to pathogens and induce a local inflammatory response that can lead to tissue injury. Other molecules released, including elastase and collagenase, participate in tissue injury and wound healing.[12,20–24]

The second stage is cytokine production. Despite the diversity of the PRRs, intracellularly they share common pathways, leading to the synthesis and secretion of proinflammatory cytokines, chemokines, and type I interferons, molecules that are essential for the initiation, amplification, and maintenance of innate and adaptive immune responses.[25] Many PRRs function by activating NF-κB, whereas others signal through the caspases, IRF3/5/7, MyD88, and other kinase cascade pathways. Cytokines may be categorized according to similarities in cell source, receptor structure, or biologic consequences.[26] In general, interleukins are produced by monocytes/macrophages, lymphocytes, or specialized or inflamed epithelial cells. They act on these and other cells to amplify the innate and initiate the adaptive immune responses. The interferons are produced by virtually all cells. Acting on T and natural killer (NK) cells, they propagate antiviral and antitumor responses. Chemokines are produced primarily by cells of the innate immune system and function dually as chemoattractants (ie, recruiting cells) and cytokines (ie, activating cells). Members of the tissue necrosis factor family mediate the sepsis response and cell death and they participate in the development of lymphoid organs. A simplified organization of some of the better-characterized cytokines by biologic effects is presented in Table 10–3, and a more detailed discussion of some cytokines can be found in Chapter 6.

The final stage is activation of the adaptive immune response. Both by the production of cytokines, which activate lymphocytes, and by the processing, transport, and presentation of antigens directly to T cells (primarily done by dendritic cells), PRRs and cells of the innate immune system are essential for the development of adaptive immune responses. The biology of T cells, B cells, and dendritic cells is discussed in detail in Chapters 11 to 14.

IMMUNE DEFICIENCY CONDITIONS DUE TO MUTATIONS IN THE INNATE IMMUNE SYSTEM

Studies in mice and in tissue culture cell lines have been instrumental in characterizing the roles of many PRRs listed in Table 10–2. Their significance to humans is established by diseases linked to naturally occurring mutations in either the PRRs or their intracellular signaling molecules.

In humans, 10 different MBL haplotypes have been identified, and serum levels may vary 1000-fold. Low MBL levels may contribute to more severe infections with encapsulated organisms in normal hosts and are associated with more significant infectious complications in immunocompromised individuals (such as patients with cystic fibrosis or chemotherapy-induced neutropenia).[27,28] Differences in MBL haplotype may contribute to responses to viral infections as well, including hepatitis B.

Within the TLR system, two classes of mutations have been identified: polymorphisms in the TLRs themselves and defects in the common intracellular signaling pathway used by the different TLRs. Two forms of ectodermal dysplasia with immunodeficiency (EDA-ID) are characterized multiple developmental abnormalities and with recurrent pyogenic infections.[29] These two disorders are due to mutations in IKKγ and IκBα—intracellular proteins essential for linking PRR–PAMP ligation to cell activation. The intracellular kinase IRAK4 is essential for the function of all of the 10 TLRs, and IRAK4 deficiency too has been identified in a small number of individuals. As with those affected by EDA-ID, these individuals are also affected by recurrent infections by gram-positive organisms. However, affected individuals become less susceptible with adulthood, likely owing to the development of the adaptive immune system.[30] Although these immunodeficiency disorders are rare, a larger number of individuals have been identified with specific polymorphisms within the TLRs. Studies using case–control methodologies have attempted to link these polymorphisms to susceptibility to specific infections (eg, invasive pyogenic infections, pulmonary tuberculosis, Legionnaire disease, or septic shock). Although some of these studies have suggested that specific TLR polymorphisms increase an individual's risk of these infections, not all studies have been in agreement.[31]

Mutations in NLRs have also been linked to specific diseases. The transcriptional activation CIITA is suggested to be an NLR on the basis of its similarity to established NLRs and TLRs, and CIITA mutations result in the bare lymphocyte syndrome, which is characterized by vulnerability to fungal, bacterial, and viral infections.[32] The NLR NOD2 functions intracellularly by binding to bacterial peptidoglycan and activating mitogen-activated protein kinases and NF-κB, and NOD2 mutations have been directly linked to both Crohn disease and Blau syndrome.[33] Polymorphisms in the TLRs and CD14 may be related to the development of asthma and other atopic disorders.[34] Single-nucleotide polymorphisms in *NOD2* correlate with complications (GVHD and transplant survival) after allogeneic bone marrow transplant.[35]

INNATE IMMUNITY AND TISSUE HOMEOSTASIS

Although PRRs and cells of the innate immune system are essential for microbial defense, they also function in normal tissue homeostasis. Specific PRRs are involved in the clearance of serum clotting factors, hormones, lysosomal hydrolases, senescent cells, and proteins and in wound healing.[34–37] The class A scavenger receptor on macrophages is involved in the internalization of oxidized low-density lipoprotein, the development of atherosclerosis, and the clearance of apoptotic T cells in the thymus.[15] Another aspect of tissue homeostasis is the surveillance against transformed or malignant cells, which involves interferon-γ (IFN-γ), γδ T cells, NK cells, and cytotoxic T lymphocytes (CTLs).

ADAPTIVE IMMUNE RESPONSE

The adaptive immune response deals primarily with the generation of T-cell receptor (TCR) and B-cell receptor ([BCR] or immunoglobulin [Ig]) diversity. The adaptive system achieves two goals not met by the innate system: generation of a receptor repertoire far more diverse than that represented by PRRs and the amplification of specific populations of pathogen-specific cells as a consequence of pathogen exposure (ie, generation of specific immunologic memory). Whereas innate immune function depends on germline-encoded molecules, the adaptive immune response arises from somatic mutations in TCR and BCR/Ig genes that occur during T- and B-cell development. This process results in a remarkable diversification and amplification of the repertoire of pathogen-specific recognition molecules (see Table 10–1).

Table 10–2 Human Pathogen Recognition Receptors

Receptor	Location	Ligands or PAMPS	Features
Toll-like receptors (TLRs) Leucine-rich protein)	Leukocytes and some epithelial cells in bronchial airways, urogenital tract, and gut	Cell wall components of gram-positive and gram-negative bacteria (peptidoglycans and lipopeptides), viral dsDNAs, ds- and ssRNAs, bacterial flagellin, and other pathogen-derived molecules	A family of 10 different proteins (TLR1–TLR10) found as transmembrane proteins on the surface of cells or internal endosomes, or as free cytosolic proteins; trigger cell activation and cytokine response
CD14 (Leucine-rich protein)	Soluble and membrane-bound forms found on monocytes, macrophages, and endothelial cells	LPS from gram-negative bacteria	Binding of LPS on the cell surface forms a complex including TLR4 that results in cytokine production and the sepsis response
Serum mannose-binding lectin (MBL) (C-type lectin)	Soluble protein found in serum and lymphatic fluid	Pathogen-derived carbohydrate structures containing mannose, fucose, or *N*-acetylglucosamine	Secreted by hepatocytes; binding to pathogen triggers complement activation and assembly of the membrane attack complex
Pulmonary surfactant proteins (C-type lectin)	Soluble proteins found extracellularly on pulmonary mucosal surfaces	Carbohydrate structures or lipid motifs on viral, bacterial, or fungal pathogens, and inhaled irritants including pollens	Secreted by alveolar type II cells and nonciliated bronchiolar epithelial cells; binding to pathogen induces opsonization and leukocyte activation (including alveolar macrophages)
Macrophage mannose receptor (C-type lectin)	Surface of monocytes and macrophages	Pathogen-derived carbohydrate structures similar to MBP	Ligand binding results in phagocytosis and monocytes/macrophage activation
NKG2 (C-type lectin)	Surface of NK cells	Carbohydrates on HLA molecules or other host molecules	Involved in recognition and destruction of virally infected or transformed host cells
Dectin-1 (C-type lectin)	Surface of macrophages, neutrophils, and dendritic cells	β-Glucan structures on fungi and plants	Binding results in cell activation, cytokine production, and internalization of pathogen
Class A scavenger receptors (SR-A I/II/III) (Scavenger receptor family)	Monocytes, macrophages, and epithelial cells	Modified low-density lipoprotein, cell wall components of gram-positive and gram-negative organisms	Phagocytosis of nonopsonized particles and macromolecules triggers macrophage activation and cytokine release; plays a role in the generation of atherosclerotic plaques and diabetic nephropathy
MACRO (Scavenger receptor family)	More restricted macrophage populations than SR-A, including alveolar, peritoneal, and thymic macrophage populations	Similar to SR-A, including silica particles	Phagocytosis of nonopsonized particles and macromolecules triggers macrophage activation and cytokine release
RNA helicases (RIG-I, Mda-5)	Cell cytoplasm	dsRNA	Bind to dsRNA produced during intracellular replication of certain classes of viruses
C-reactive proteins and Serum Amyloid P (Pentraxins)	Serum proteins	Bind to and affect clearance or activation of host proteins (C1q and DNA fragments) as well as constituents of some pathogenic organisms	Secreted by the liver during early acute phase response and influence clearance and complement activation of recognized macromolecules
Peptidoglycan recognition proteins	Soluble proteins found intracellularly in leukocyte granules or synthesized by the liver and secreted into the serum	Peptidoglycan structures	Direct bactericidal or bacteriostatic activity by interfering with bacterial peptidoglycan wall biosynthesis
NOD-LRR receptor family (NLR) (includes NOD, NALP, CIITA, IPAF, and NAIP proteins)	Soluble intracellular proteins	NOD1 and NOD2 bind bacterial peptidoglycan; PAMPs for other proteins not identified	Survey intracellular compartment for intracellular pathogens, binding to bacterial wall fragments produced either during bacteria proliferation or lysosomal degradation; ligand binding triggers activation of NF-κB inflammation pathway
$\alpha_v\beta_3$ (Integrin)	Epithelial cells	*Trypanosome cruzi*	Binding induces opsonization and cell activation
CD11b/ CD18 (also CR3) (Integrin)	Monocytes, macrophages, and epithelial cells	LPS, constituents of *Mycobacterium tuberculosis*, yeast saccharides (including zymosan)	Binding induces opsonization and cell activation
Sialic acid-binding immunoglobulin-like lectins (Siglecs)	Surface receptors on onocytes, macrophages, NK cells, and myeloid cells	Sialylated complex carbohydrates (found on endogenous proteins and some pathogenic organisms)	Role for binding and phagocytosis of pathogenic organisms proposed

Table 10–3 The Cytokines

Cytokines and Cellular Targets	Examples	Biologic Consequences
Interleukins		
Monocyte/macrophages, endothelial cells	IL-1, IL-2, IL-6, IL-10, IL-13, IL-16, TNF-α	Local inflammation, cell recruitment, hepatic acute phase reaction, sepsis response
B cells	IL-2, IL-4, IL-6, IL-7, IL-9, IL-14	Recruitment, activation, differentiation of B cells
T cells (type 1 cytokines)	IL-2, IL-12, IL-15, IFN-α/β/γ	Type 1 helper T cell (T_H1) response
T cells (type 2 cytokines)	IL-4, IL-5, IL-6, IL-10, IL-13	Type 2 helper T cell (T_H2) response
Interferons		
T cells and NK cells	IFN-α, IFN-β, IFN-γ	Upregulates activity of T cells and NK cells against virally infected cells and malignant cells
Tissue Necrosis Factors		
All cells except erythrocytes	TNF-α, TNF-β	Pyrexia, tissue hyperemia, capillary leak, sepsis/shock syndrome, enhancement of target cell effector functions, expansion of lymphoid compartments
Chemokines		
Monocytes/macrophages, granulocytes, dendritic cells, lymphocytes	MCPs, eotaxin, TARC, MDC, MIPs, RANTES, PF-4	Recruit and activate cells of innate and adaptive immune system to specific sites of pathogen exposure, inflammation, and/or tissue damage
Hematopoietic Growth Factors		
Hematopoietic cells in marrow and peripheral compartments	G-CSF, GM-CSF, M-CSF, SCF	Maintenance, growth, and differentiation of hematopoietic cells

G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MCP, macrophage/monocyte chemotactic protein; M-CSF, macrophage colony-stimulating factor; MDC, macrophage-derived chemokine; MIPs, macrophage inflammatory proteins; PF-4, platelet factor-4; RANTES, regulated on activation, normally T cell expressed and segregated chemokine; SCF, stem cell factor; TARC, thymus and activation-regulated chemokine; TNF, tumor necrosis factor.

The complex steps involved in TCR and BCR/Ig generation requires a close interplay between the innate and adaptive immune systems. A particular pathogen gaining entry through a specific anatomic site first encounters the innate defenses. The initial response, which depends on PRRs, triggers the production of cytokines that activate resident dendritic cells (DCs). DCs phagocytose and process the antigens by cleaving them into small peptides. These peptides are then presented on the DCs' surfaces bound to MHC molecules. T and B cells that recognize the processed antigens become activated and begin to divide. This antigen presentation step may occur at the site of pathogen exposure, or it may require the migration of antigen-containing DC from the point of pathogen entry through lymphatic channels to lymphoid tissues. Other consequences of the inflammatory response induced by the innate response include changes in vascular permeability, chemotaxis, and lymphocyte adhesion. These steps result in local inflammation and the recruitment of additional lymphocytes to the site of pathogen entry. DCs, B cells, and T cells are discussed in depth in Chapters 11 to 13.

CELLS OF THE INNATE AND ADAPTIVE IMMUNE SYSTEMS

Lymphocytes

The major lymphocyte subsets are B and T cells; NK cells are a specialized lymphoid population. Lymphocytes initially arise in the bone marrow and subsequently undergo maturation in peripheral lymphoid organs (ie, thymus for T cells and lymph nodes, spleen, or other lymphoid tissues for B cells). Different populations of T and B cells can be identified by unique surface phenotypes, a characteristic that has been useful in understanding normal biology and in the diagnosis of inflammatory or malignant conditions.

Mature B cells are characteristically identified by CD19 and CD20 expression. Most B cells, called B2 cells, have a $CD5^-$ phenotype and require T-cell cooperation for function. A minority population of B cells, called B1 cells, expresses CD5, does not require T-cell help, and appears to function in pleural and peritoneal immunity. Given their $CD20^+CD5^+$ phenotype, B1 lymphocytes may be the population from which chronic lymphocytic leukemia arises. B cells represent approximately 10% of the lymphocytes in the marrow or circulation but account for up to 50% of the population in spleen and lymph nodes.

After emerging from the bone marrow compartment, T cells develop further into αβ T-cell or γδ T-cell populations. The αβ T cells are the most abundant subset and include $CD3^+CD8^+$ and $CD3^+CD4^+$ T-cell populations. $CD3^+CD8^+$ T cells, which develop into CTLs, are involved in defense against virally infected or transformed cells. $CD3^+CD4^+$ T cells can be further subdivided into T_H1 cells (stimulate development of CTLs), T_H2 cells (stimulate isotype switching and antibody production in B cells), T_H17 cells (induce or enhance tissue damage secondary to autoimmune or infectious processes), or T_{reg} cells (control or limit autoimmune responses).[36–38] The γδ T cells are $CD3^+CD4^-CD8^-$ T cells that can develop in the thymus and the gut.[39] As the γδ antigen receptor on this T-cell subset is rearranged embryonically before antigen exposure, these cells may function in innate immunity. The γδ T cells represent only 1% to 5% of circulating T cells but up to 50% of the T cells in certain epithelial sites (eg, skin, intestinal tract), where their activity is influenced by local inflammation. Stimulatory and suppressive roles of γδ T cells' response to bacterial and viral infections and possibly malignant transformation have been demonstrated in experimental systems.

NK cells are a distinct lymphocyte subset and comprise approximately 10% of the circulating lymphocyte population. NK cells are identifiable by their $CD3^{-}CD56^{+}$ phenotype. They function in defense against virally infected cells and transformed cells through the generation of cytotoxic cytokines, direct cytolytic activity, and antibody-dependent cellular cytotoxicity. Pathogen recognition is accomplished through three classes of receptors, including killer-cell immunoglobulin receptors (KIRs), C-type lectins (CD94/NKG2s), and natural cytotoxicity receptors (NCRs).[40,41]

Monocytes, Macrophages, and Dendritic Cells

Monocytes develop in the bone marrow and then circulate through the blood and lymphatics with an average half-life of 1 to 3 days before migrating into tissues and maturing into macrophages.[42,43] Macrophages can be found in all tissues, particularly at points of entry for pathogens such as the skin, respiratory tract, gastrointestinal tract, and genitourinary tract. Tissue-specific macrophage populations include Kupffer cells (liver), alveolar macrophages (lung), osteoclasts (bone), microglia (central nervous system), and type A lining cells (synovia), which can be identified morphologically and by surface immunophenotype.

DCs are specialized antigen-presenting cells. Like macrophages, DCs are found at points of pathogen entry, including skin and mucosal surfaces, and locations of lymphocyte proliferation, such as germinal centers. DC biology is described further in Chapter 14.

Granulocytes

Granulocytes can be further subclassified into neutrophils, basophils, and eosinophils by the types of cytoplasmic granules that they contain. Neutrophils mature in the marrow, where 80% to 90% of the body's store of mature neutrophils resides. The recruitment of neutrophils from the marrow into the circulation and inflamed tissues can occur within hours of exposure to bacterial endotoxin. Neutrophil effector functions include phagocytosis and cytokine production, both of which are activated through PRR-, FcR-, or CR3-dependent triggering.

The basophilic leukocytes—mast cells and basophils—have several structural and functional similarities. Functionally, they are key mediators of immediate allergic and inflammatory responses, with mast cells being more predominant in tissues and basophils in circulation. Both cell types express FcεR, which induces rapid degranulation when triggered by aggregated IgE. Both cell types have granules containing histamine, platelet-activating factor, and bioactive proteoglycans. Degranulation can be rapid, producing anaphylaxis, or sustained, inducing a more sustained inflammatory response. Degranulation is also associated with leukotriene production. Differences between basophils and mast cells include the expression of receptors on basophils for IgG, C3a, and C5a and receptors on mast cells for stem cell factor, interleukin-2 (IL-2), and IL-3, and in the spectrum of cytokines produced by each cell type. Basophils and diseases related to basophils are discussed in Chapter 73.

Eosinophils are found predominantly in tissues, with a smaller fraction found in circulation. The eosinophilic granules of this subset contain hydrolytic enzymes that may be damaging to invading pathogens and host tissues. Eosinophil activation also triggers leukotriene production and the release of an array of cytokines. A role in allergic responses and defense against helminth pathogens has long been presumed according to the eosinophilia characteristic of these conditions; however, the true physiologic necessity of eosinophils has yet to be demonstrated. Eosinophils may be viewed as effector cells of the adaptive immune system, because they are acutely triggered by a B-cell product (IgE) and their development in part depends on T cells. Disorders of eosinophils are discussed in Chapter 72.

Non–Marrow-Derived Cells Involved in Immune Function

Populations of non–marrow-derived cells function in innate immunity. Renal tubular cells and epithelial cells in the gut, bronchial airways, reproductive organs, and dermis express different PRRs. In these cells, the receptors function in pathogen clearance or by triggering pathogen-dependent inflammatory responses. Bronchial airway cells secrete pulmonary surfactants and antimicrobial peptides, creating a very localized antimicrobial barrier. Liver endothelial cells use several PRRs, including the Fcγ, scavenger, and mannose receptors, to clear senescent serum proteins and pathogens. The functions of these cells dovetail with those of the leukocytes in pathogen defense and tissue homeostasis.

ANATOMY OF THE IMMUNE SYSTEM

An array of soluble mediators and a repertoire of immune cells mediate the host response to microbial pathogens, to tumors, to self-antigens in autoimmunity, and to foreign antigens in graft rejections. Where do these cells and mediators come from, and where do these interactions take place?

Immune Cell Development: Primary and Secondary Lymphoid Organs

Most immune cells or their precursors arise in the bone marrow. Bone marrow anatomy and hematopoiesis are discussed in detail in Part III of this textbook. The cellular components of the innate immune response—the neutrophils, eosinophils, basophils, and monocytes—leave the marrow as mature, functional cells. In contrast, the cellular components of the adaptive immune response leave the marrow as immature precursors (in the case of T cells) or as naive cells (in the case of B cells).

T-Cell Maturation

T-cell precursors mature into functional T cells in the thymus.[36,44,45] Thymic architecture is shown in Fig. 10–1. The thymus is composed of lymphocytes, DCs, epithelial cells, and stromal components. The thymic stroma arises primarily from the third and fourth pharyngeal pouches during fetal development, and the stroma is then populated with lymphocyte precursors emigrating from the bone marrow. The stromal meshwork of the thymus, including various types of epithelial cells, is essential for thymic development. The requirement for thymic stroma in T-cell development is demonstrated in patients with DiGeorge syndrome, otherwise known as 22q11 deletion (del22q11) syndrome. These patients have deletions of one or more genes critical for fetal development, resulting in failure of involution of the third and fourth pharyngeal pouches, and consequent absence of thymic stroma. Although DiGeorge patients have T-cell precursors in the bone marrow, they have no thymus organ and have markedly reduced numbers of mature T cells in the peripheral circulation and in tissues. As discussed in "Secondary Lymphoid Tissue", the observation that most DiGeorge patients do have small numbers of circulating mature T cells suggests that extra-thymic sites in these patients may partially substitute for the thymus in promoting T-cell maturation.

The thymus is divided histologically into two general zones, the cortex and the medulla, although these zones have microdomains where the maturing T cells, or thymocytes, are phenotypically and functionally distinct.[45–47] Thymic precursors leave the bone marrow, circulate in the blood, and selectively home to the thymus, entering the organ to populate the subcapsular cortex. At this site, TCR rearrangement begins, and maturing thymocytes move to the cortex, where continued proliferation occurs. During this phase of TCR

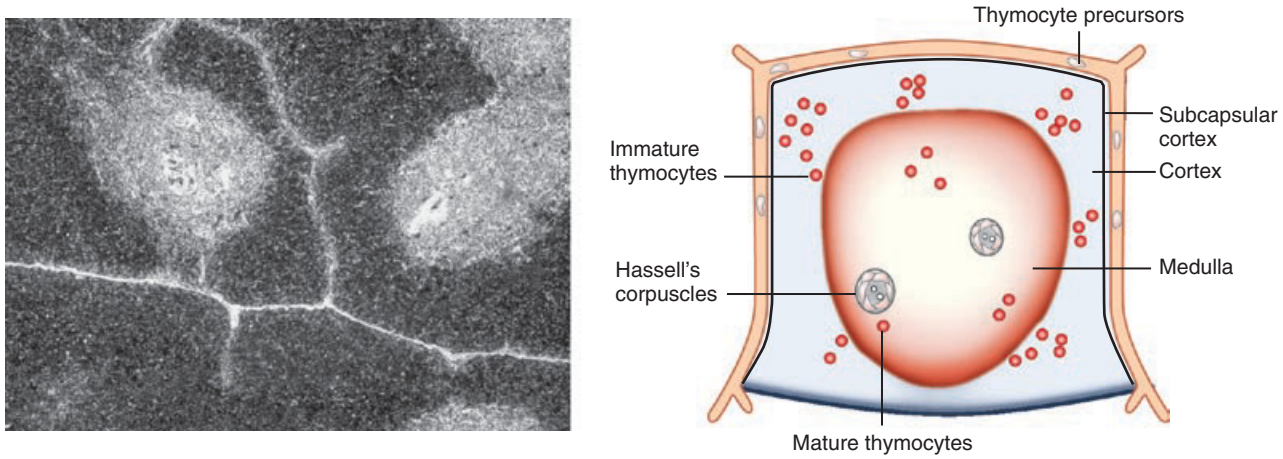

Figure 10–1 Anatomy of the thymus. The human thymus (*left*) is composed of lobules, each separated by a thin capsule. Immediately under the capsule is a narrow zone called the subcapsular cortex that surrounds the larger zone of the cortex, the darkly staining region. In the center of each lobule is the medulla, the lighter-staining region. In the medulla, nests of epithelial cells called Hassall corpuscles are visible. T-cell precursors (*right*) arising in the bone marrow migrate through the blood and enter the thymus as immature cells. During maturation in the cortex, most of the immature thymocytes fail to produce functional T-cell receptors and die. Cells that produce functional T-cell receptors are positively selected to survive and migrate to the thymic medulla. Mature, naive T cells exit the medulla to the peripheral circulation.

rearrangement and proliferation, more than 90% of the cells die in a process called *selection*. A large fraction of thymocytes fail to express a functional TCR, and these cells could never recognize antigens; these cells die of *nonselection* (ie, programmed cell death) because the cells do not receive a survival signal through a functional TCR. Of the thymocytes that do express a functional TCR, many recognize self-antigens and die through a process called *negative selection*. Negative selection is not completely understood, but involves recognition of abundant or high-affinity self-antigens that trigger robust TCR signaling, so that elimination of these developing T cells by negative selection is proposed to reduce self-reactivity and autoimmune disease. A genetic defect in presentation of self-antigens by thymic epithelial cells results in the autoimmune syndrome APECED (autoimmune endocrinopathy–candidiasis–ectodermal dystrophy).[48] Apoptotic T cells that are killed by nonselection or by negative selection are phagocytized and degraded by macrophages in the thymus. The remaining few surviving thymocytes express a functional TCR that does not appear to be autoreactive; these cells survive via a process termed *positive selection*. Positively selected thymocytes migrate to the thymic medulla, where they commit to a particular T-cell lineage (CD4 or CD8) and finally leave the thymus as functional but naive T cells.

B-Cell Maturation

In the adult, naive B cells leave the marrow and traffic to secondary lymphoid tissues, including the spleen, the lymph nodes, and the mucosa- or epithelium-associated lymphoid tissue such as Peyer patches in the small intestine. Although these tissues are critical for proper B-cell development, they are called *secondary lymphoid tissues* because these sites are also where the mature cells of the adaptive immune system encounter non-self-antigens and become activated.

B-cell maturation is described in detail in Chapter 11. Briefly, naive cells enter primary follicles in the cortex of the secondary lymphoid tissue, such as the lymph node shown in Fig. 10–2.[49] As B cells in primary follicles encounter antigens that are recognized by BCR/Ig on the cell surface, the cells begin to proliferate, and also undergo somatic hypermutation of immunoglobulin genes that results in positive selection of cells with increasing BCR affinity for antigen. Once B-cell proliferation begins, the primary follicle becomes a secondary follicle.[50] The secondary follicle has two general regions, a germinal center filled with the proliferating B cells, some T cells, macrophages, and DCs, surrounded by a mantle zone of nonproliferating B cells that have not encountered an antigen they recognize. The germinal center can be further divided into dark and light zones, depending on the stage of proliferation, as discussed below in "Systemwide Surveillance."

ENCOUNTERS WITH ANTIGEN

A primary function of the immune system is to provide protection against microbial pathogens. The most common sites for microbes to breach the protective barriers of epithelium are the skin and the respiratory, gastrointestinal, and genitourinary tracts. These tissues directly encounter the outside world, and they have evolved complex, multifaceted mechanisms for dealing with antigens.[51,52]

The local defense system is immediately activated when pathogens disrupt the epithelial barriers in these sites. These tissues are rich in components of the innate immune system, including macrophages and DCs, which perform a surveillance function in tissues. Some tissues have specialized or unique populations of macrophages and DCs (see Chapter 14), although these cells have many common features in different tissues. Macrophages provide a critical first line of defense against pathogens by directly phagocytosing microorganisms. Macrophages also send the first signals that recruit granulocytes from the circulation into the tissues (Fig. 10–3). These signals include cytokines, nitrous oxide, and leukotrienes that cause vasodilatation, endothelial cell activation, leukocyte adhesion to endothelial cells at the inflammatory site, and diapedesis of leukocytes into the tissues (see Chapter 17). The resulting exudate fluid at the site of vasodilatation is also rich in plasma proteins that participate in innate immunity, such as complement and soluble PRRs. The soluble mediators may be directly toxic to microbes or may opsonize microbes to facilitate phagocytosis and killing by granulocytes. The soluble and cellular components of the innate immune system provide the first line of defense at the tissues where pathogens invade.

These tissues contain resident lymphocytes and plasma cells. The lymphoid cells can also respond to cytokines secreted by resident macrophages, such as IL-2 that stimulates T-cell proliferation. The ability of macrophages to secrete mediators that cause vasodilatation and recruit granulocytes, as well as initiate T-cell activation, illustrates the interplay between innate and adaptive immunity in the tissues where antigens are encountered and underscores the point that the

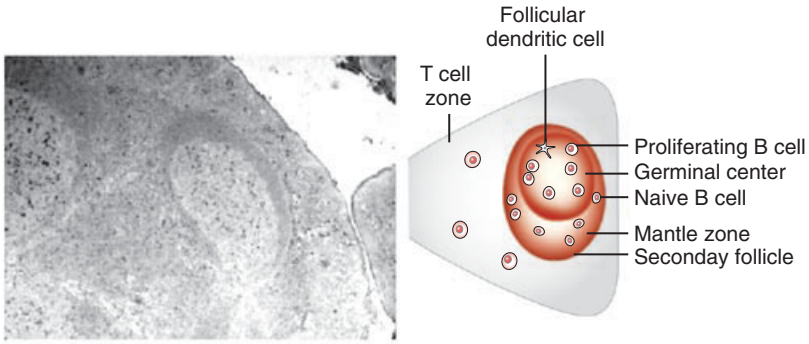

Figure 10–2 B-cell proliferation in lymph nodes. B cells primarily populate the lymphoid follicles. A section of tonsil (*left*) demonstrates a secondary follicle with a pale germinal center filled with proliferating B cells, scattered T cells, and specialized antigen-presenting cells called follicular dendritic cells (*dark staining*). The germinal center is surrounded by a darker mantle zone, populated by nonproliferating B cells. Adjacent to the follicle is the T cell-rich zone of the cortex. The schematic of a section of lymph node (*right*) demonstrates a secondary follicle with a germinal center and a mantle zone. The T cells reside primarily adjacent to the follicles. However, scattered T cells can be found in the germinal center and are typically helper T cells stimulating B-cell proliferation.

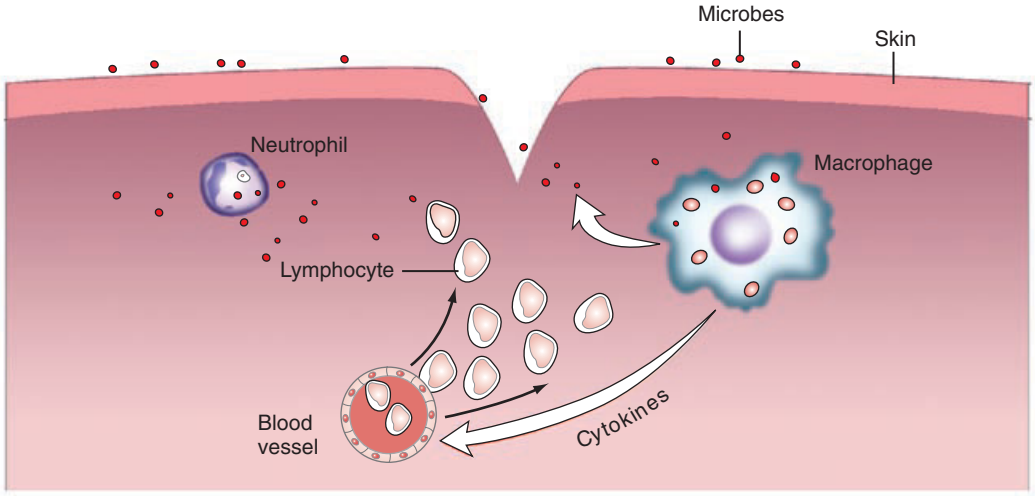

Figure 10–3 Encounters with antigen. The immune system evolved primarily to protect against invading microorganisms that penetrate the epithelial coverings of the body. In this schematic, microbes entering through a break in the skin epithelium are phagocytosed by resident macrophages as the first line of defense in innate immunity. The macrophages can secrete products that are directly microbicidal (*hatched arrow*), as well as cytokines and other mediators (*open arrow*) that cause vasodilatation and endothelial cell separation to allow influx of soluble mediators and inflammatory cells such as neutrophils and lymphocytes into the skin. Neutrophils, as a component of innate immunity, can also directly kill microorganisms, typically by releasing granular contents. Lymphocytes responding to microbial antigens proliferate and contribute to the adaptive immune response against microbes.

innate and adaptive immune systems work in concert in host defense. Resident T cells and plasma cells in the tissue can respond to antigen, with local activation of antigen-specific effector T cells and increased antibody secretion, respectively, so that the adaptive immune response is stimulated locally after pathogens are sensed by the innate immune system.

SYSTEMWIDE SURVEILLANCE: THE ROLE OF LYMPHATIC CIRCULATION

During the local inflammatory response in tissues, the exuded fluid, along with antigen-loaded DCs, T cells, and cytokines, drains from the tissues back through the lymphatic channels. Lymphatics are an essential component of the vascular system (Fig. 10–4). Even in the absence of inflammation, a fraction of the fluid component of blood leaves the capillary bed continually during circulation, because of the pressure drop between the arterial and venous sides of the vasculature. This fluid bathes the tissues, picking up antigens and cells, and drains into lymphatic channels that interdigitate in every capillary bed. At sites of inflammation, the amount of fluid and cells that drain into local lymphatics increases in response to effects on vascular tone and permeability by chemokines, lipid mediators, and oxygen radicals produced locally by activated macrophages and neutrophils. Lymphatic fluid eventually returns to the circulation by draining through the thoracic duct into the vena cava. However, before returning to the venous circulation, the lymphatic fluid travels through the secondary lymphoid tissue such as lymph nodes and spleen, which serve as sites of systemic surveillance. Signals from cells within the lymph nodes can also expand the lymphatic network, again resulting in increased drainage of DCs and antigens into the nodes.[53] The movement of lymphatic fluid through secondary lymphoid tissue is an essential component of the adaptive immune system.

Lymph node anatomy is shown schematically in Fig. 10–5; the anatomy of lymph nodes and the spleen is also discussed in Chapter 11. Fluid and cells enter the lymphatics in the tissues and travel through the lymphatics to the lymph nodes. The fluid and cells enter the lymph nodes on the convex surface through the afferent lymphatics that drain into the subcapsular sinus. Under the subcapsular sinus is the cortex of the lymph node. The cortex is composed of follicles that contain primarily B cells, along with some T cells and antigen-

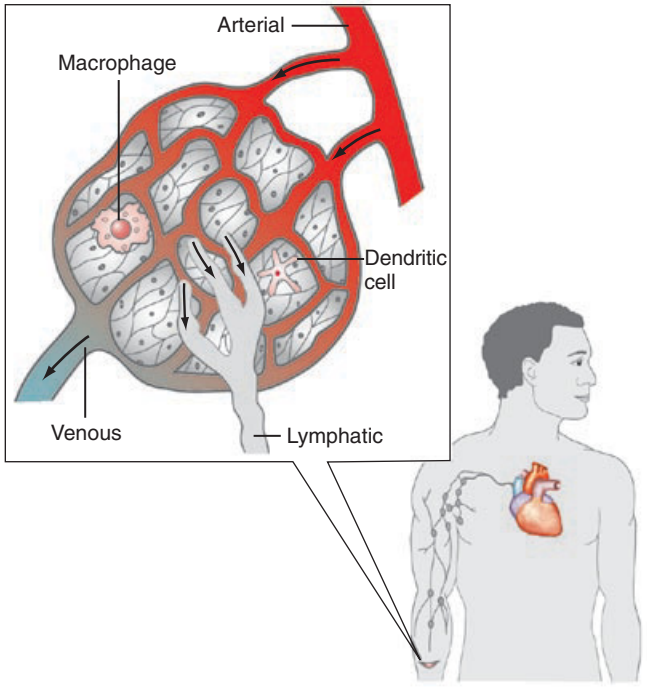

Figure 10–4 Lymphatic drainage is a critical part of immune surveillance. As shown in Figure 10–3, fluid and cells leave the vasculature at sites of inflammation. Hydrostatic pressure across the capillary bed continually drives transudation of fluid from the blood into tissues. The extravasated fluid, along with antigen-presenting cells such as macrophages and dendritic cells, collects in lymphatics (*inset*). Lymphatics drain past series of lymph nodes (*dark ovals*), affording the antigen-presenting cells the opportunity to migrate to lymph nodes and stimulate lymphocytes in the nodes. Fluid in lymphatics passing through chains of lymph nodes eventually collects in the thoracic duct, which returns the fluid to the vascular circulation by draining into the vena cava.

presenting cells, and the interfollicular zones that contain primarily T cells and additional antigen-presenting cells. Primary follicles are composed of naive B cells that are not proliferating because they have not encountered antigen recognized by BCR/Ig on the B-cell surface. Secondary follicles have a germinal center that is composed primarily of B cells that are proliferating in response to antigens presented by cells in the germinal center, and a surrounding mantle zone containing primarily quiescent naive B cells that have not encountered an antigen they recognize. The central part of the lymph node, the medulla, contains additional antigen-presenting cells, some T cells, and numerous plasma cells. Plasma cells differentiate from follicular B cells and migrate to the medulla, where most plasma cells leave the lymph node to traffic to peripheral tissues.

The germinal center can be further divided into a light zone and a dark zone.[54,55] The dark zone consists primarily of rapidly dividing immature B cells called centroblasts. In the light zone, nondividing B cells called centrocytes undergo positive selection, similar to the process described for T cells in the thymus, to select for B cells that express functional BCR/Ig. In the light zone, centrocytes interact with a unique population of DCs, called *follicular DCs*, that present antigens to B cells undergoing selection. $CD4^+$ helper T cells are also present in the light zone, providing cytokine and cell–cell contact-mediated signals important for B-cell maturation and selection. As the B cells proliferate and BCR affinity maturation occurs, the cells traffic back and forth between the dark and light zones, to continually encounter DCs and T cells that provide essential signals for B cell maturation and survival. B cells that fail this selection process (ie, do not express a functional BCR) die in the germinal center by apoptosis and are phagocytized by macrophages. Some of these cell types, such as centrocytes and centroblasts, are discussed (see Chapter 75) in the context of lymphoid malignancies.

Lymphatic fluid draining into the subcapsular sinus travels through the lymph node cortex. This movement of antigen-rich fluid delivers antigens into the B- and T-cell zones in the cortex to stimulate the proliferation of lymphocytes that recognize the antigens. Local B-cell proliferation in the lymph node further stimulates lymphatic drainage to the node.[53] In the lymph node follicles, further processing of antigens may be carried out by local antigen-presenting cells, such as the follicular DCs. The lymphatic fluid draining into the node collects through the trabecular sinuses that run through the cortex between follicles, perpendicular to the capsule, into the

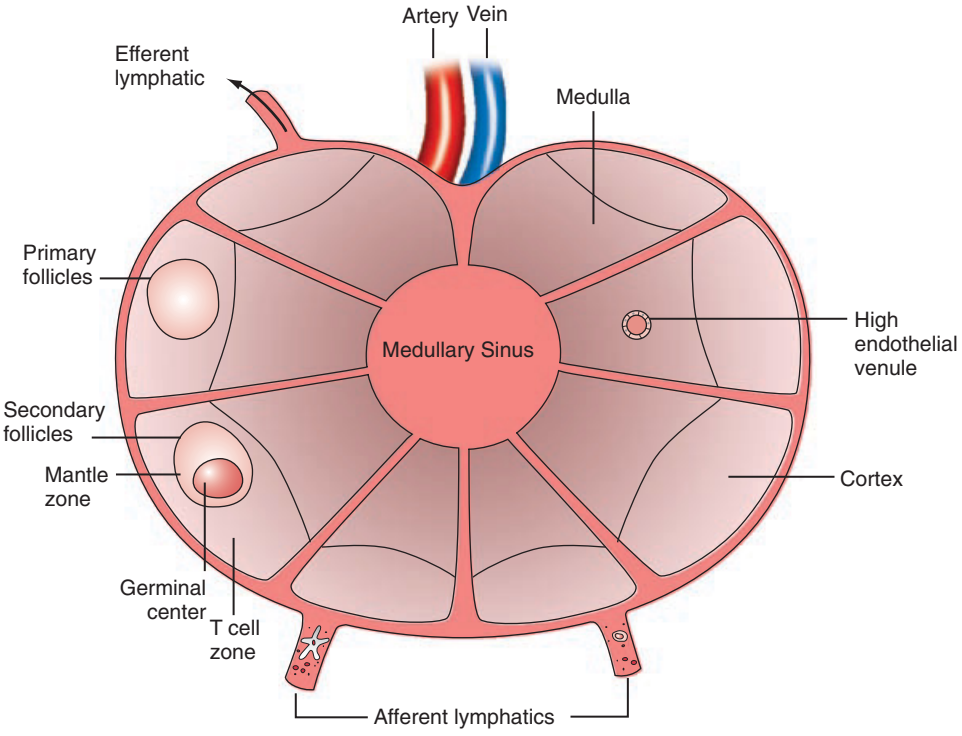

Figure 10–5 Lymph node anatomy. The lymph node is surrounded by a capsule. Afferent lymphatics draining tissues enter the node on the convex side into the capsule. Fluid and cells drain through the node and collect in the medullary sinus, where the fluid leaves the node through efferent lymphatics to rejoin the lymphatic circulation. The outer rim of the node is called the cortex and contains primary follicles composed of naive, nonproliferating B cells that have not encountered antigens and secondary follicles with proliferating B cells in the germinal center. The germinal center can be subdivided into dark and light zones. Each lymph node is supplied with blood by the arterial circulation. Arterioles expand into a meshwork of capillaries within each follicle, and venous blood drains back out of the node. Naive T cells in the peripheral circulation can exit the blood and enter the lymph node through the high endothelial venules.

medullary sinus. From the medullary sinus, the lymphatic fluid leaves the node by efferent lymphatics exiting the hilum of the node to travel through additional lymph nodes on the way to the thoracic duct. Thus, antigens and cells draining from sites of inflammation travel through chains of lymph nodes. Trace amounts of microbial proteins or toxins, together with activated monocytes/macrophages, DCs, lymphocytes, and the cytokines produced (the direct consequence of PAMP–PRR ligation), are kept in anatomic proximity, providing numerous opportunities for the antigens to encounter antigen-specific lymphocytes and stimulate the adaptive immune system.

In addition to lymphatic fluid, blood must also travel through lymph nodes, to provide oxygen and nutrients to the tissue and also to deliver new B and T cells to the tissue. Although lymphatic fluid contains lymphocytes from tissues that have already encountered antigens, lymphocytes in blood are predominantly naive T cells that have emigrated from the thymus but not yet encountered an antigen they can recognize. Arterial blood enters the lymph node at the hilum, where arterioles branch off toward each follicle. Naive T cells leave the blood to enter lymph nodes through specialized vessels called *postcapillary venules*, which arise from follicular capillary beds, and travel through the T cell-rich interfollicular zones. Naive T cells exit from postcapillary venules into the T-cell zone, and if the naive T cells encounter antigens they recognize, the cells remain in the node and proliferate. If the naive T cells do not encounter antigens they recognize, the cells drain by means of lymphatic fluid back to the blood and continue the circular route from the blood through lymph nodes to lymphatics and back to blood.

Egress of lymphocytes from lymph nodes, and from the thymus, is regulated by a specialized lipid, sphingosine-1-phosphate (S1P), that is produced in lymphoid tissues. Lymphocytes express S1P receptors that are important for facilitating lymphocyte egress from tissues into blood. Novel immunosuppressive therapeutics are being developed that are S1P antagonists; these S1P antagonists reduce release of lymphocytes from lymphoid tissues into blood.[56]

SECONDARY LYMPHOID TISSUE: COMMON AND UNIQUE ANATOMY AND FUNCTIONS

The spleen is an important site for B-cell development and for antigen presentation and stimulation of the adaptive immune system. Key differences between splenic and lymphoid anatomy are worth noting.[57] Antigens enter lymph nodes primarily by afferent lymphatics. Because the spleen has no afferent lymphatic drainage, blood enters through the splenic artery. Unlike other organs that have a closed vascular circulation in which blood travels from arterial to venous circulation through capillary beds, branches of the splenic artery penetrate into the lymphoid area of the spleen, the white pulp, and then open into marginal sinuses. From the marginal sinuses, blood filters through the parenchyma of the spleen. As lymphocytes in lymph nodes monitor lymphatic fluid for antigens, lymphocytes in the spleen monitor blood for antigens. As seen in the lymph node cortex, B cells in the splenic white pulp also form follicles, primary follicles containing naive B cells and secondary follicles with germinal centers. Surrounding the follicles are marginal zones that are populated by specialized subsets of B cells and macrophages. In the splenic white pulp, as in lymph nodes, the B- and T-cell zones are separate but contiguous.[58,59] In the splenic white pulp, the T-cell zone is found primarily surrounding a central artery, and this region is called the *periarterial lymphatic sheath* (PALS). The spleen does have efferent lymphatics, and fluid and cells that do not exit through the splenic vein collect by means of lymphatics that originate in the white pulp and drain into the lymphatic circulation.

Beyond the white pulp, the splenic artery sends additional branches into the red pulp. The red pulp contains numerous myeloid cells, including many macrophages that phagocytose unwanted components such as opsonized microbes and damaged red blood cells. The splenic red pulp is also the site of extramedullary hematopoiesis early in fetal life; extramedullary hematopoiesis in the spleen may also occur postnatally in patients with diseases in which the bone marrow is not competent to support hematopoietic cell development.

In addition to lymph nodes and the spleen, there are numerous other sites of secondary lymphoid tissue.[60] A critical part of the secondary lymphoid system is the mucosa-associated lymphatic tissue (MALT). As the name implies, the MALT is in physical proximity with the mucosa (ie, the epithelium and associated connective tissue that line the surfaces of the body). MALT is found at sites where antigens most commonly breach these epithelial barriers: the gastrointestinal, respiratory, and genitourinary tracts. In some tissues, the MALT forms relatively large structures that can be clearly distinguished histologically, such as the Peyer patches in the ileum and in the lymphoid tissue under the epithelium of the appendix. In these sites, perhaps because of the constant stimulation by microbial pathogens in the intestine, the MALT resembles lymphatic tissue in the spleen and lymph nodes, with well-demarcated primary and secondary follicles that contain primarily B cells and intervening T cell-rich zones. In other tissues, such as the genitourinary tract and the salivary glands, the microscopic anatomy of the MALT may not be as well defined as that seen in Peyer patches, but the stromal tissue underlying the epithelium contains numerous lymphocytes and antigen-presenting cells. These sites provide an additional compartment of secondary lymphoid tissue where antigens can be accumulated, processed, and presented to lymphocytes to stimulate an adaptive immune response. In addition to serving as part of the secondary lymphoid tissue, the MALT may also provide an alternative site of primary lymphoid tissue for T-cell development.[61] In support of this theory, it has been observed that children with DiGeorge syndrome, in which the thymus does not develop, do have some circulating mature T cells, although the number of T cells is greatly reduced. This suggests that the T-cell precursors emigrating from the bone marrow can mature in other sites, such as the intestine, if the thymus is absent.

Whereas the MALT constitutes a lymphoid population beneath the surface epithelium, a separate population of lymphocytes, primarily T cells, traffics directly through the epithelium in certain tissues, such as the gastrointestinal tract, on surveillance for pathogens. These intraepithelial lymphocytes (IELs) include $\alpha\beta$ T cells and $\gamma\delta$ T cells, and comprise 1 in every 5 to 10 cells in the intestinal epithelium. As the lining of the intestine is the largest organ surface area of the body, IELs are one of the largest T cell populations. These IEL T cells are comprised of different subpopulations, some of which are conventional T cells that recognize foreign antigens and some are regulatory T cells that limit the extent of an immune response and maintain immune homeostasis, a critical function in the antigen-rich milieu of the gut.[52,62]

CHAPTER 11

B-CELL DEVELOPMENT

Kenneth Dorshkind and David J. Rawlings

B cells are the subset of lymphocytes specialized to synthesize and secrete immunoglobulin (Ig). Their name derives from the finding, made in the mid-1950s, that removal of the avian bursa of Fabricius severely compromises antibody production.[1] In mammals, B-cell differentiation initiates during fetal life in various tissues, including the liver. However, during postnatal life the bone marrow is the site of B-cell production.[2–4]

The bone marrow is a primary lymphoid organ, and the generation of B cells in that tissue is referred to as *primary* B-cell production. B lymphopoiesis is dependent on the commitment of immature, multipotential hematopoietic precursors to the B-cell lineage. Subsequently, these B lineage precursors proliferate and progress through a highly regulated maturation process that culminates in the production of immature, surface Ig-expressing B lymphocytes. These newly produced, immature B lymphocytes then migrate into *secondary* lymphoid organs such as the spleen, where they undergo further maturation. These cells subsequently recirculate through the bloodstream and enter peripheral lymph nodes and spleen and are poised to respond to antigens encountered in those organs.

The aim of this chapter is to summarize B-cell development in primary and secondary lymphoid tissues. The discussion focuses initially on B-cell development during fetal and adult life and the regulation of that process by local and systemic signals. The final sections of the chapter outline B-cell development in secondary lymphoid tissues. The information presented provides a basis for understanding abnormalities of B-cell development, such as leukemia, lymphoma, and immunodeficiency states that are discussed in other chapters. Because this is a clinical textbook, the discussion preferentially focuses on human B-cell development. However, murine studies have contributed much to what is known about B-cell development, so references to the extensive literature in that species are frequent.

THE HEMATOPOIETIC HIERARCHY AND B-LINEAGE COMMITMENT

B lymphocytes, like all hematopoietic cells, are derived from hematopoietic stem cells (HSC).[5] HSC, by definition, can sustain long-term, multilineage blood cell production for the lifetime of the organism. They are able to function in this capacity because upon division they can self-renew, thereby producing additional HSC as well as more committed progenitors that ultimately give rise to myeloid and lymphoid cells.[6,7] Advances in the development of monoclonal antibodies to leukocyte cell surface antigens and achievements in flow cytometric analysis have led to isolation of these committed lymphoid and myeloid progenitors in both mouse and man (Fig. 11–1).

The *common myeloid progenitor* is an immature cell population whose downstream progeny include megakaryocyte–erythroid and granulocyte–macrophage progenitors.[8] The identification of the most immature HSC proximal lymphoid precursor is an area of active investigation. Most recent schemes of murine hematopoiesis place a cell termed the *common lymphoid progenitor*, defined in mice by its c-kit^{low} Sca-1^{low} interleukin-7 (IL-7) receptor positive (IL-7R^{+}) lineage-negative (Lin^{-}) phenotype, as the precursor from which all T and B cells arise.[9] Lin^{-} indicates that the cells lack expression of determinants present on mature myeloid, erythroid, and lymphoid lineage cells. However, an emerging view is that CLP so defined are primarily destined to generate B lineage cells and that they are downstream progeny of an earlier lymphoid-specified precursor that does not yet express IL-7R.[10]

The definition of stages of human B-cell development has recently been reviewed in depth.[3] There is general agreement that the most immature human lymphoid progenitors are included in a Lin^{-}CD34^{+} subpopulation of hematopoietic cells.[11,12] Galy and colleagues described a Lin^{-}CD34^{+}CD38^{+}CD10^{+} bone marrow cell that could generate B and T cells but whose myeloid potential was attenuated.[13] Expression of the CXCR4 chemokine receptor on Lin^{-}CD34^{+} cells also has been used to define human lymphoid precursor populations.[14] However, single cells were not manipulated in these studies, which is a prerequisite for drawing conclusions regarding a population's lineage potential.[15] Accordingly, a later study of cord blood CD34^{+}CD38^{-}CD7^{+}IL-7R^{-} cell population is of interest. Clonal analysis has demonstrated that these cells are devoid of myeloid and erythroid potential but can generate B and T cells with high efficiency.[16]

As a result of these types of studies, increasingly detailed models of hematopoiesis, as shown in Fig. 11–1, have been formulated. These schemes imply that lineage branch-points occur at precise cellular stages of development. However, the reported existence of distinct cellular intermediates that do not fit easily into these hierarchical schemes, such as those with B, T, granulocytic, and macrophage but not megakaryocytic and erythroid developmental potential, suggests that this may not be the case.[17] In addition, Fig. 11–1 indicates that commitment to a particular developmental pathway occurs as an all-or-none phenomenon, but this almost certainly does not occur. Instead, emerging evidence suggests that lineage commitment is a gradual progression. This process has been described as occurring in two phases. In the first, termed *specification*, developmental potential becomes narrowed but cells still retain multilineage potential. On the other hand, lineage *commitment* implies an inability to generate cells other than those in a specific lineage.[18]

That specification and commitment occur gradually reflects the fact that the process of activating selected genes while suppressing the expression of others takes place in a stepwise manner. In this regard, it is increasingly accepted that these evolving patterns of gene expression ultimately resulting in lineage commitment reflect the sum total effect of transcription factors expressed and the epigenetic changes that follow in developing precursors.[19,20] Genetic studies in mice in which genes controlling expression of specific transcription factors have been disrupted have made it possible to identify where within the hierarchical model of hematopoiesis expression of a particular transcription factor is critical (see Fig. 11–1).

For example, early blood cell development is dependent on *PU.1*, an Ets family member. Mice in which this gene is not expressed can produce erythroid and megakaryocytic but not monocytic, granulocytic, and lymphoid cells. As a result of this severe defect, *PU.1* knock-out mice die during embryonic development.[19–21] The developmental potential of hematopoietic cells is further narrowed toward a lymphoid fate by products of the *Ikaros* gene. Ikaros is an interesting transcription factor because rather than activating gene expression, it acts as a repressor by associating with transcriptionally silent genes in foci containing heterochromatin.[22]

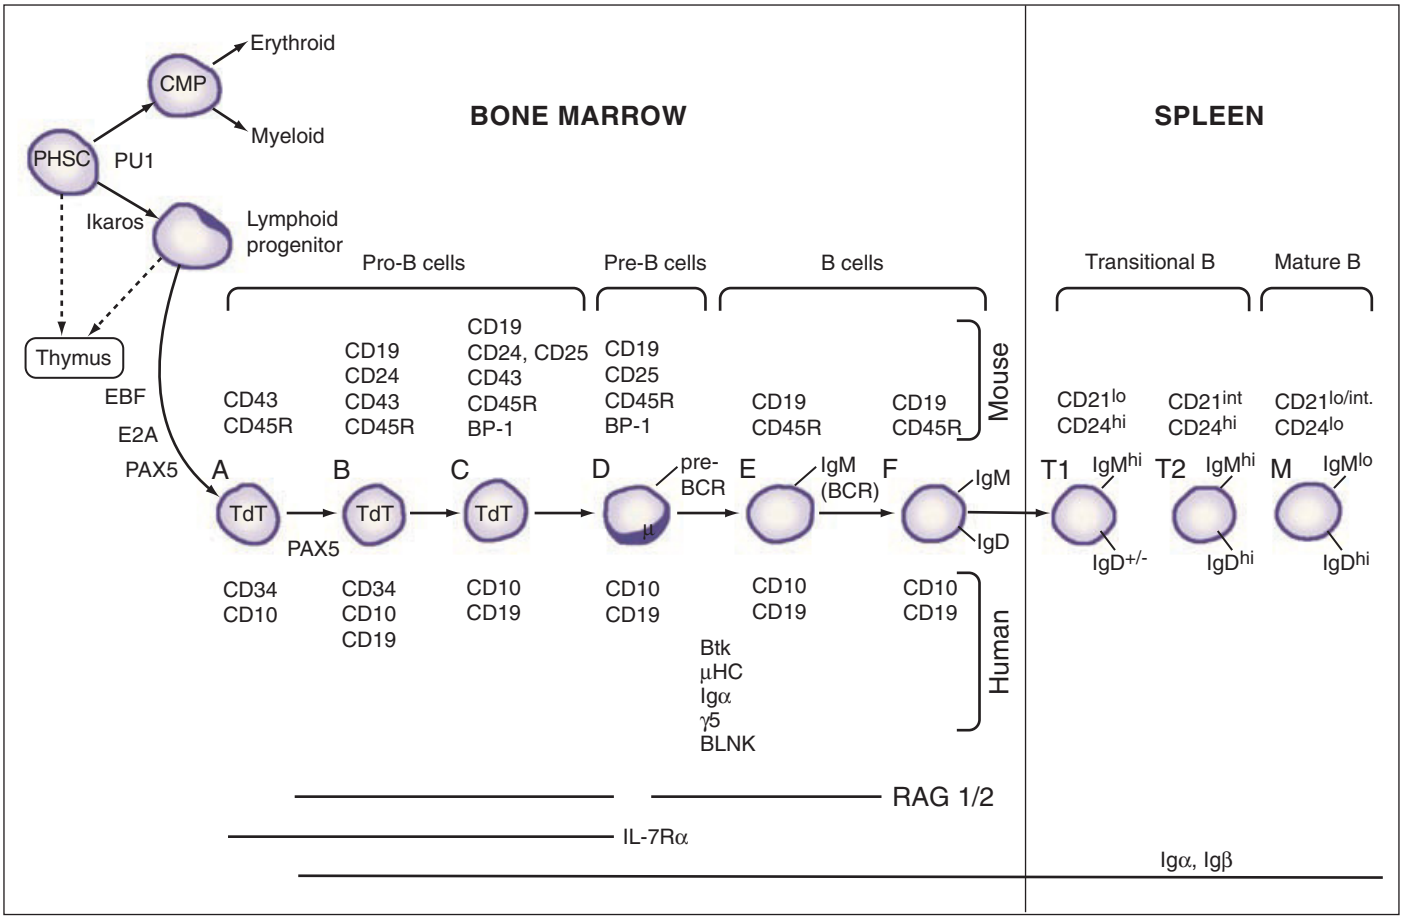

Figure 11–1 Hematopoiesis with an emphasis on B-cell development. Stages of human and murine B-cell development, and the cell surface, cytoplasmic, and nuclear determinants expressed on those cells are indicated. When comparing this scheme to others, it is important to appreciate that a uniform terminology for stages of development has not been adopted. Placement of lineage markers at various stages of development is an approximation. T1, transitional 1B cells; T2, transitional 2B cells; M, mature, naive B cells. The precise characteristics of the earliest lymphoid specified progenitor are unresolved.

T-cell, but not B-cell, progenitors can be detected in *Ikaros*-null mice, indicating that specification toward the B lineage is *Ikaros* dependent.[23] Further specification toward the B-cell lineage is dependent on expression of additional transcription factors that include early B-cell factor (EBF) and the *E2A*-encoded splice variants E12 and E47.[24–28] Each of these DNA-binding proteins regulates the expression of a variety of B-lineage target genes and induces expression of additional transcription factors that play a role in B-cell development. That EBF and E2A expression plays a critical role in B lymphopoiesis has been demonstrated by the fact that mice in which these gene products are no longer expressed exhibit an almost complete block in B-cell development at the pro-B-cell stage.

EBF- and E2A-expressing progenitors can still exhibit some myeloid potential, indicating that the expression of these DNA-binding proteins does not result in absolute commitment of cells to the B lineage. Instead, this is dependent on subsequent expression of the Pax5 transcription factor. Phenotypically identifiable B-cell precursors are present in *Pax5* knock-out mice, and when placed under appropriate conditions, they can differentiate into myeloid, T, and natural killer (NK) cells. However, if the gene encoding Pax5 is introduced into these Pax5-deficient precursors, this developmental promiscuity is no longer observed. Thus, a critical function of Pax5 is to suppress non-B lineage potential.[29,30] One way in which this is accomplished is by extinguishing expression of myeloid growth factor receptors, such as those for macrophage colony-stimulating factor. Pax5 also may inhibit the T-cell potential of lymphoid-restricted progenitors by antagonizing expression of Notch1, a cell-surface receptor whose stimulation activates signaling pathways required for commitment to the T-cell lineage.[31] Thus, Pax5-deficient pro-B cells constitute a good example of cells that have undergone specification without full commitment to the B lineage. In addition to regulating commitment to the B-cell lineage, continued Pax5 expression is necessary to maintain lineage fidelity even in relatively mature B cells.[32]

STAGES OF ADULT B-CELL DEVELOPMENT

As indicated previously, the precise characteristics of the cellular intermediates between the HSC and the most immature, B-lineage-committed progenitors are still being refined. On the other hand, there is greater certainty about the properties of B cell-committed progenitors and their downstream progeny. As a result, detailed schemes of B-cell development in mouse and human have been formulated.[2–4,33] The earliest B-lineage progenitor is termed the *pro-B cell* in both species. Ig heavy-chain gene rearrangement is under way in these cells, and if the rearrangement is successful, an Ig heavy chain of μ class is expressed in the cytoplasm. At this stage, the cells are defined as *pre-B cells*. Finally, once light-chain gene rearrangements have occurred and light-chain protein is expressed, pre-B cells mature into newly produced B lymphocytes that express the assembled Ig molecule on their surface. The designation of a cell as a B lymphocyte should be restricted to cells that express surface Ig.

Detailed phenotypic analyses of cells at various stages of pro-, pre- and B-cell development have been made, and subpopulations of cells within each compartment have been described. For example, the

pro-B-cell compartment is subdivided into pre-pro-B and pro-B stages, and protocols have been described in which up to 11 different antibody combinations are used to resolve stages within the murine B-cell developmental pathway.[34] The terminology used in this chapter is that defined originally by Hardy and colleagues[35] and is based on the differential expression of CD19, CD45R (B220), CD24 (heat-stable antigen), CD43, BP-1 IgM, and IgD (see Fig. 11–1). The ability to isolate cells on the basis of the expression of one or more of these determinants has contributed much to what is known about their molecular characteristics and how they respond to various microenvironmental and systemic signals.

Figure 11–1 shows the comparable stages of human B-cell development. The most immature B-lineage-committed pro-B cells coexpress CD10, CD34, and CD19.[36] Cells at this stage of development have initiated Ig heavy-chain gene rearrangements. CD19 can be considered to be a B-lineage-specific determinant. Once an Ig heavy-chain gene has undergone productive rearrangement and is expressed, μ heavy-chain protein is detected in the cytoplasm of pre-B cells. CD10 and CD19 are present on the pre-B-cell surface, but CD34 expression is extinguished.[37,38] Finally, productive rearrangement and expression of an Ig light-chain gene result in maturation to the surface IgM-expressing B-cell stage of development. A number of additional cell-surface determinants are expressed on developing and mature B-lineage cells and include CD20, CD21, CD22, CD24, and CD40.[39] Many of these determinants are linked to critical intracellular signaling pathways (see Chapter 14). Antibodies against the CD20 determinant (rituximab) are in widespread clinical use for the treatment of lymphoma and, increasingly, autoimmune diseases.[40]

As cells mature from pro-B cells into B lymphocytes, they pass through two critical checkpoints. The first occurs at the pro-B to pre-B-cell transition and is dependent on expression of Ig heavy-chain protein. The second occurs at the pre-B to B-cell transition, where signaling through the pre-B-cell receptor (pre-BCR) leads to expression of light-chain protein and surface expression of the mature B-cell antigen receptor (BCR).

THE PRO-B TO PRE-B-CELL TRANSITION

The expression of Ig heavy-chain protein is dependent on the functional rearrangement of an Ig heavy-chain gene. If this occurs successfully, Ig heavy-chain protein of the μ class is expressed in the cytoplasm of pre-B cells.

Organization of Immunoglobulin Heavy-Chain Genes

The genes that encode Ig heavy-chain protein are located on human chromosome 14 (Fig. 11–2).[41] The heavy-chain gene consists of distinct variable (V), diversity (D), joining (J), and constant (C) regions. The V region genes are located at the 5′ end of the Ig heavy-chain gene, and each consists of approximately 300 base pairs. These genes, which are separated by short intron sequences, are organized into seven families based on sequence homology. There are approximately 25 human D region genes located 3′ to the V region. These also are grouped into families, and at least 10 have been described in humans. Downstream of the D region are six human J region genes. Finally, 10 C region genes representing alternative Ig isotypes are arranged in tandem.[42,43]

STERILE TRANSCRIPTS

Ig heavy-chain gene rearrangement is preceded by transcription at the unrearranged heavy-chain locus. This results in the production of developmentally regulated transcripts of unrearranged Ig genes, referred to as germline transcripts, or *sterile transcripts*. Multiple species of sterile transcripts have been described, and some could conceivably encode proteins. A mechanistic link between transcription and Ig gene rearrangement has been hypothesized. For example, transcription might make unrearranged Ig genes accessible to both RNA polymerase and V(D)J recombinase, the germline transcripts could function in the rearrangement reaction, or transcription could alter structural characteristics of DNA, making the recombination signal sequences (see later) better targets for recombination.[44–46]

IMMUNOGLOBULIN HEAVY-CHAIN (H) GENE REARRANGEMENT

Subsequent to the appearance of sterile transcripts, Ig heavy-chain gene rearrangements occur. Because the coding regions of the V, D, and J region segments are separated from one another, their juxtaposition with deletion of the intervening intron must occur. The initial event during heavy-chain gene rearrangement juxtaposes a D region segment to a J_H segment. Although in theory any D region gene can join with equal frequency to any one J_H region gene, there may be preferential utilization of selected D and J_H region genes at various stages of development. Following successful D–J_H recombination, a V_H region gene rearranges to the D–J_H complex. Evidence suggests that biased usage of J_H proximal V_H genes occurs in the newly generated repertoire of neonatal mice and humans.[47] The heavy-chain C region remains separated from the rearranged V_HDJ_H complex by an intron, and this entire sequence is transcribed. RNA processing subsequently leads to deletion of the intron between the V_HDJ_H complex and the most proximal C region genes. Following translation, μ heavy-chain protein is expressed in the cytoplasm of pre-B cells.[44]

The process just described is dependent on an enzymatic machinery that deletes intronic sequences and joins coding segments of DNA.[48–50] The enzymes that mediate these functions act through recognition of recombination signal sequences that are located 3′ of each heavy-chain V region exon, 5′ of each heavy-chain J segment, and 5′ and 3′ of each heavy-chain D region gene. Figure 11–2 shows the association of these recognition sequences with the various heavy-chain exons. Each recombination signal sequence consists of conserved heptamer and nonamer sequences, separated by nonconserved DNA segments of 12 or 23 base pairs. During Ig gene recombination, these recognition sequences form loops of DNA, which in turn bring the coding exons in apposition to one another. These noncoding loops are subsequently deleted and degraded.

The expression of two highly conserved proteins, referred to as RAG-1 and RAG-2, is required for heavy- and light-chain gene recombination.[51,52] Mice[53,54] and humans[55] in whom these recombinase-activating genes (*RAG*s) are not expressed do not generate B or T cells. Results from cell-free systems that measure V(D)J recombination indicate that RAG proteins are involved in cleavage of DNA at recombination signal sequences. The RAG proteins also are needed for subsequent efficient joining of coding sequences to one another.[50] In addition to the RAG proteins, general DNA repair enzymes, and those encoded by the Ku complex of genes in particular, also play a critical role in Ig heavy-chain gene recombination.[56,57]

ALLELIC EXCLUSION

Each pro-B cell has two Ig heavy-chain genes, but only one of these encodes μ protein in any given cell. This phenomenon is known as *allelic exclusion*.[51] One theory for how this occurs is that functional Ig rearrangements are rare, so the chance that two functional rearrangements will occur in an individual cell is extremely low.[58] An increasingly accepted second model of allelic exclusion is that the expression of μ protein from a successfully rearranged allele inhibits rearrangements at the other heavy-chain allele.[59] As discussed subsequently, these signals may be mediated through the pre-BCR complex.[60] However, if rearrangements are unsuccessful at one heavy-chain locus during B-cell development, recombination will initiate at the second one. If productive, these cells will then mature into pre-B

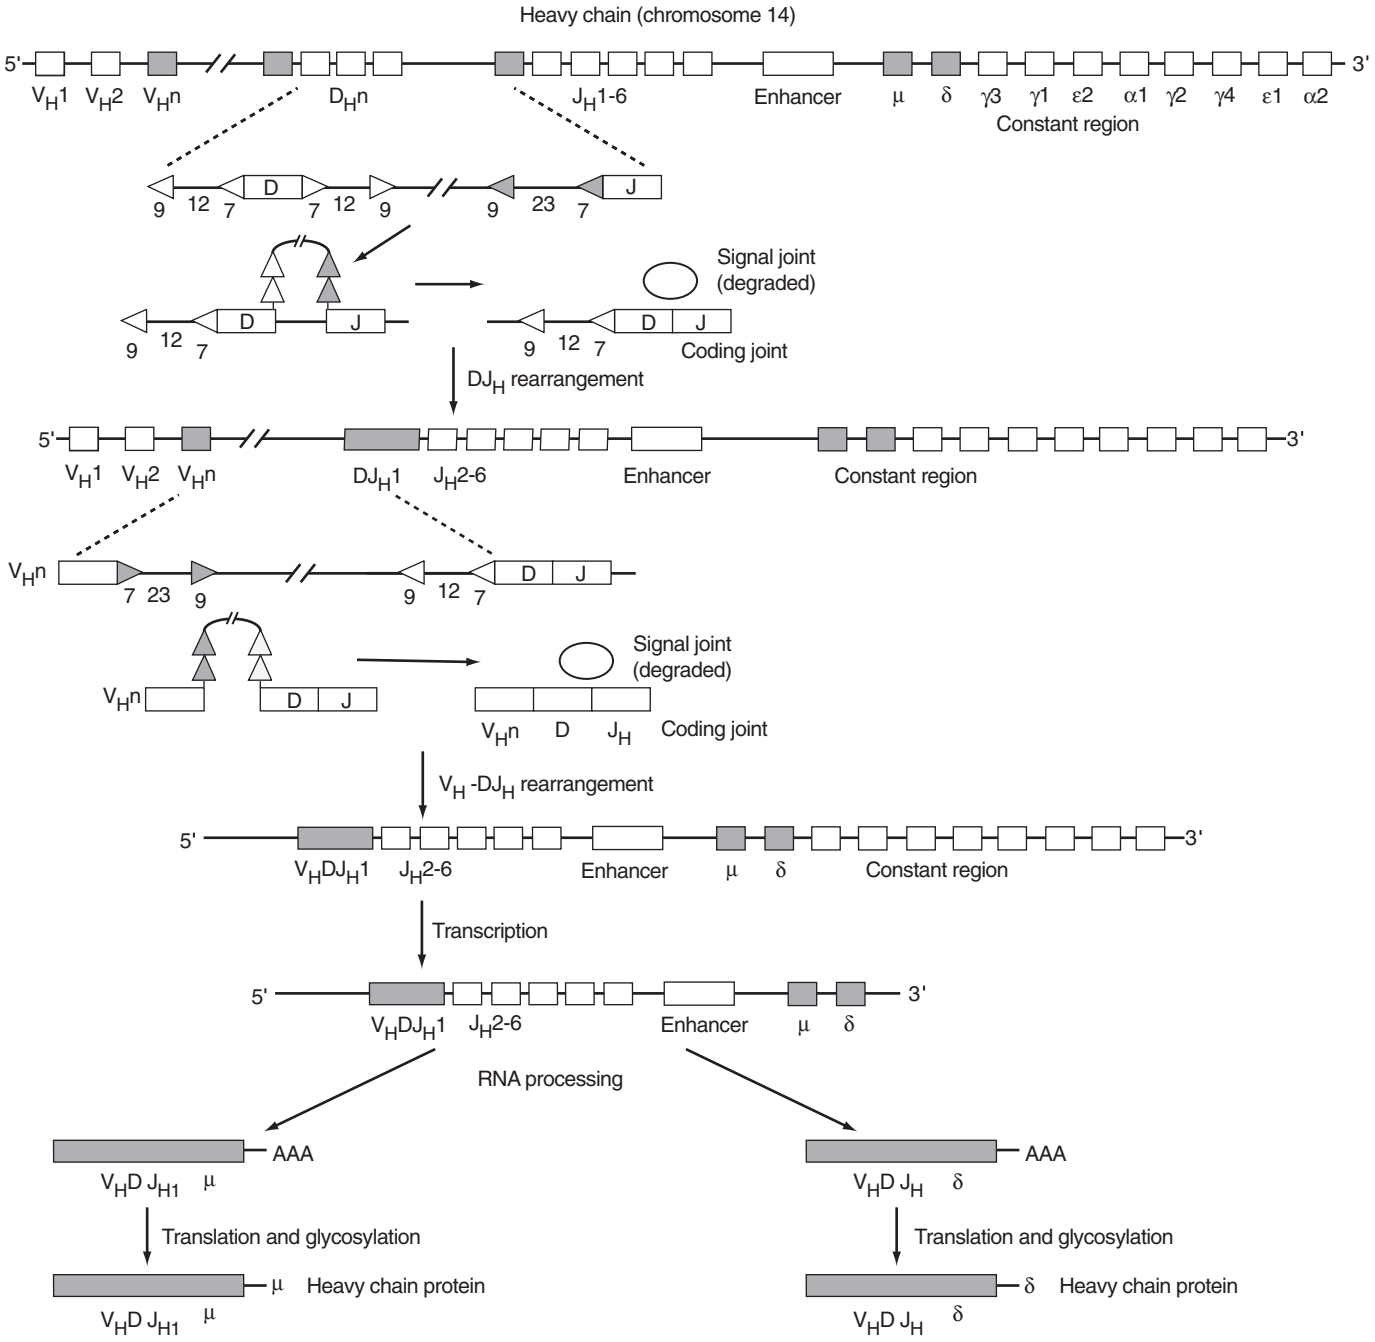

Figure 11–2 Rearrangement and expression of the human immunoglobulin heavy-chain gene. The figure shows the Ig heavy-chain gene and the signal sequences 3′ of each V region locus, 5′ and 3′ of each D region locus, and 5′ of each J region locus. These consist of heptamer and nonamer sequences separated by either 12 or 23 base pairs. During Ig recombination, a signal sequence of 12 base pairs can only join to another of 23 base pairs (the so-called 12–23 rule). As shown in the figure, initial heavy-chain gene rearrangements form coding joints between D and J regions as well as signal joints that are ultimately degraded. Subsequently, the joining of the V region gene to the DJ complex occurs. Following a successful rearrangement, the VDJ complex, the μ intron, and portions of the constant regions are transcribed. RNA processing and differential splicing results in formation of an mRNA molecule that is then translated. In the example shown, the rearranged VDJ complex and the constant region, with the μ and δ C region genes, is transcribed. Following RNA processing and translation, a particular B cell could then express μ and/or δ protein.

cells. If this rearrangement is also defective, cells will undergo apoptosis.

IMMUNOGLOBULIN HEAVY-CHAIN GENE EXPRESSION

Following the productive rearrangement of at least one heavy-chain gene, transcription of the rearranged locus occurs. Transcription is dependent on the binding of various transcription factors to specific promoter sequences located 5′ of each heavy-chain V region and one or more heavy-chain enhancer regions located 3′ of the J region genes and downstream from the C_H region genes (see Fig. 11–2).[44–46]

Many of the transcription factors that bind within these sites have been identified. These include the previously described E12 and E47 proteins encoded by the *E2A* gene. Before Ig gene rearrangement, E12 and E47 proteins may be in an inactive state owing to their heterodimeric association with another protein known as Id. In this configuration, DNA binding by E12 and E47 does not occur.[61] Thus, successful transition from the pro-B to pre-B-cell stage is dependent

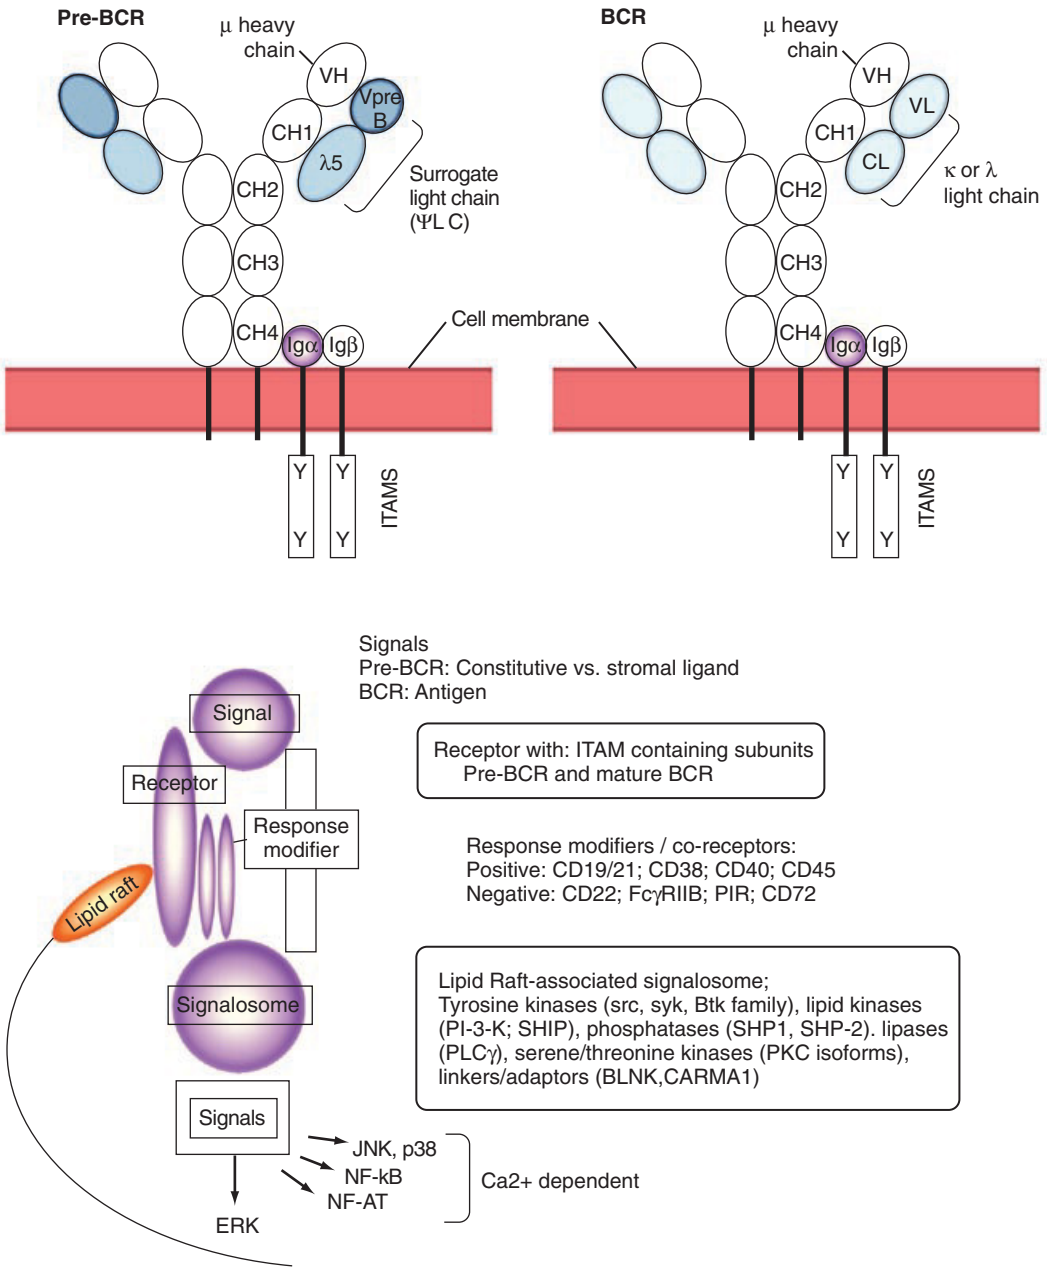

Figure 11–3 The pre-B-cell receptor (pre-BCR) and B-cell receptor (BCR) and associated signaling intermediates. **Top,** μ heavy-chain protein in pre-B cells is associated with the surrogate light chains v-pre-B and λ5 (*left*). In newly produced B lymphocytes, μ heavy chain is associated with conventional light chain (*right*). Associated with heavy chain in both pre-B and B cells are two additional transmembrane proteins, Ig-α and Ig-β, that contain immunoreceptor tyrosine activation motifs (ITAMs) critical to the signaling function. **Bottom,** Expression of the pre-BCR (or possibly its binding to a stromal ligand) or binding of antigen to the mature BCR, respectively, initiates the assembly of a lipid raft, BCR-associated "signalosome" composed of multiple signaling molecules, ultimately leading to transcriptional events that promote cell proliferation, survival, and differentiation.

on cessation of Id expression. This conclusion is consistent with the fact that mice expressing an Id transgene have a complete block in B-cell differentiation.[62]

THE PRE-B-CELL RECEPTOR

When μ heavy-chain protein is first synthesized, it associates with a chaperone protein known as Bip.[63] However, it subsequently associates on the cell surface with two additional proteins that together function in a manner analogous to that identified for conventional light chains. These proteins, referred to as Vpre-B and λ5, are noncovalently linked to one another, forming the surrogate light chain.[64,65] These proteins are encoded by genes located on chromosome 16 in mice[66] and on chromosome 22 in humans.[67] λ5 is covalently linked to the C_H1 domain of the μ heavy chain via a carboxyl-terminal (C-terminal) cysteine.[64] This μ heavy chain-surrogate light-chain complex is associated with two additional transmembrane proteins, Igα and Igβ, that together form the pre-BCR.[68] The intracellular tails of both Igα and Igβ contain immunoreceptor tyrosine activation motifs critical to the signaling function of both the pre-BCR and the BCR (Fig. 11–3, upper panel).

There has been considerable confusion regarding the stage of development at which the pre-BCR is expressed on human B-lineage cells.[33] For example, evidence has been presented that surrogate light chains are detected on pro-B cells before the expression of μ heavy-chain protein,[69] whereas other reports indicate that it is restricted to a late stage of pre-B-cell differentiation.[70] One reason for these diver-

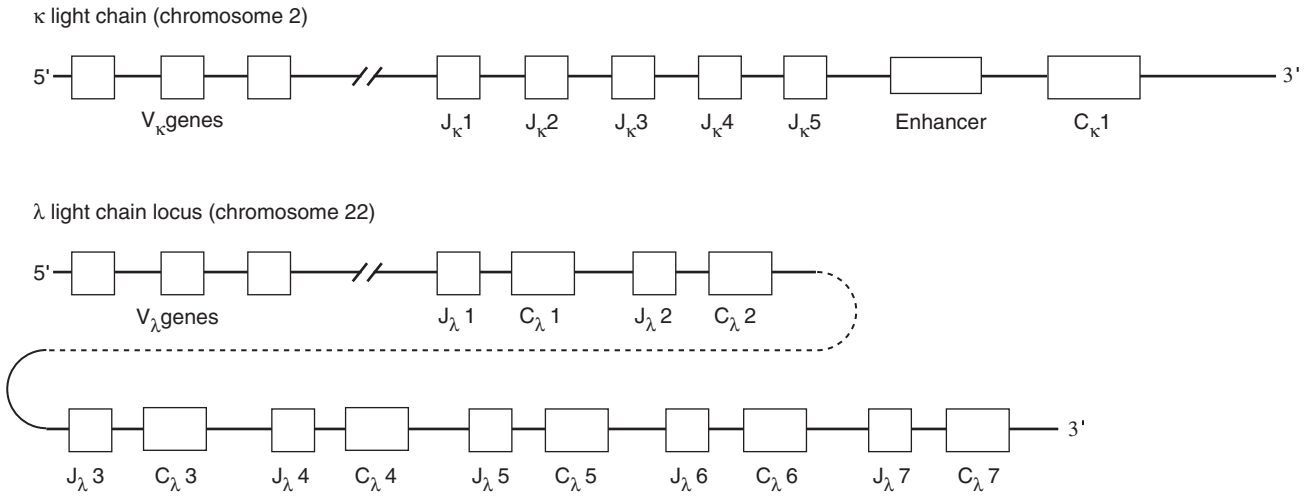

Figure 11–4 Structure of the human immunoglobulin light-chain genes.

gent findings is that different laboratories have used different antibodies to detect surrogate light chain. In addition, the target populations analyzed ranged from normal B-lineage cells to cell lines, some of which were leukemic. These issues aside, expression of the pre-BCR at the pro-B to pre-B-cell transition occurs and is critical in both mice and humans. Disruption of any pre-BCR component, including μ, Igα, and Igβ in both species leads to significant inhibition of early B-lineage development at the pro-B to pre-B-cell transition.[71,72]

One role of the surrogate light chains is to select those heavy chains that will ultimately be capable of pairing with conventional light chains. In fact, those pre-B cells that pair with surrogate light chains to form the pre-BCR have a significant proliferative advantage, thus ensuring that their numbers will increase and that they will generate progeny that will contribute to the B-cell repertoire.[73,74] Another function, as described previously, may be to mediate allelic exclusion.[60] As soon as the pre-BCR is expressed, the genes encoding RAG-1 and RAG-2 are turned off, and the previously synthesized proteins are degraded.[75] These events effectively halt further Ig heavy-chain gene rearrangements.

Lipid rafts that contain mediators of intracellular signaling such as Lyn are constitutively associated with the pre-BCR in human pre-B cells. Cross-linking of the pre-BCR leads to an increase in Lyn kinase activity, phosphorylation of the Igβ chain, and recruitment and activation within the pre-BCR complex of additional signaling intermediates including Syk, BLNK, PI3K, Btk, p85, VAV, and PLCγ2.[76] These events lead to calcium flux and activation of additional signaling cascades within the pre-B cell. Expression and signaling through the pre-BCR result in a marked growth advantage over those pre-B cells that do not express a pre-BCR.[77] A logical assumption is that these events are initiated by binding of the extracellular portion of the pre-BCR to an environmental ligand. However, no definitive pre-BCR ligand has been identified to date. Thus, precisely how these signaling events are initiated in the absence of external cross-linking ligand remains unclear, although it appears likely that constitutive signaling following pre-BCR surface expression may be sufficient.

THE PRE-B TO B-CELL TRANSITION

At some point, pre-BCR-expressing cells cease to proliferate and enter a resting phase. This change occurs coordinately with a cessation of surrogate light-chain expression, reactivation of the recombinatorial machinery, and initiation of conventional light-chain gene rearrangement. The culmination of these latter events is the expression of light-chain protein.

ORGANIZATION OF IMMUNOGLOBULIN LIGHT-CHAIN GENES

Ig light-chain protein can be encoded by the kappa (κ) or lambda (λ) genes (Fig. 11–4). Greater than 90% of murine B cells express κ protein. However, the proportions of human κ and λ proteins are more equivalent, with approximately 60% of human B cells expressing κ light-chain protein. The human κ gene is located on chromosome 2 and includes around 40 $V_κ$ region genes, clustered in up to seven families, five functional $J_κ$ region genes, and one $C_κ$ region gene.[78,79] The human λ locus is located on human chromosome 22. Approximately 30 human $V_λ$ genes exist and are grouped into 10 families. There are seven human $C_λ$ genes, four of which are functional and three pseudogenes. Each $C_λ$ gene is located 3′ of a respective $J_λ$ gene. Light-chain genes do not include D region loci.[80,81]

IMMUNOGLOBULIN LIGHT-CHAIN GENE REARRANGEMENT

Although B cells can express κ or λ light-chain protein, rearrangements initiate at the κ locus, where the initial event is the joining of a $V_κ$ segment to a $J_κ$ segment. The $V_κJ_κ$ complex remains separated from the light-chain C region by an intron, the entire complex is transcribed, and further splicing of the intron between the $J_κ$ and $C_κ$ segment results in formation of a mature $V_κ$–$J_κ$–$C_κ$ transcript. If rearrangements at the first κ allele are unsuccessful, attempts are made to rearrange the second κ gene. If this fails, the λ locus is utilized.[82,83] The regulation of light-chain gene rearrangement is similar to that for heavy-chain gene recombination. For example, the same enzymatic machinery involving the RAG proteins is necessary.

Ig light-chain gene expression is also dependent on the binding of specific transcription factors, which include nuclear factor-κB (NF-κB), to enhancer motifs. For example, an Igκ light-chain enhancer region is located downstream of the $J_κ5$ gene. Analogous to the situation in which the actions of E2A proteins are inhibited by Id, NF-κB is complexed to an inhibitory molecule, inhibitor of NF-κB (I-κB), in the cytoplasm of pre-B cells.[84,85]

IMMUNOGLOBULIN CLASS SWITCHING

At the terminal stage of primary B-cell development, newly produced B cells can express both IgM and IgD. This coexpression occurs by means of alternative processing of a primary RNA transcript. As noted previously, the rearranged V_HDJ_H heavy chain, part of the C region, and the intron separating these exons is transcribed following productive rearrangements in a cell. If the intron is spliced, resulting in association of the Cμ region with the VDJ complex, the B cell expresses IgM. Alternatively, if the Cμ exon is deleted along with the heavy-chain intron, the VDJ complex and the Cδ exon become contiguous and the B cell expresses IgD. The differential processing of heavy-chain transcripts within a single cell explains why some newly produced B cells coexpress both IgM and IgD (see Fig. 11–2).

These primary developmental events are distinguished from Ig class switching that allows the newly produced B cell to express the same VDJ complex associated with additional heavy-chain C regions other than IgM and IgD. Deletion of germline DNA resulting in re-ligation of the VDJ complex to these downstream heavy-chain C region genes, such as γ3, γ 1 γ 2b, γ 2a, ε, and α, is the mechanism by which this takes place. These DNA deletions are believed to occur at or near nucleotide sequences called *switch regions* that are located in the intron 5′ to each C_H exon. As discussed subsequently, these class-switching events are highly regulated, secondary-differentiation events that occur in spleen and lymph nodes and are potentiated by helper T cells and their secreted products.[86,87]

THE B-CELL RECEPTOR

The structure of the B-cell receptor (BCR) is similar to that described earlier for the pre-BCR, except that κ or λ, rather than surrogate light-chain proteins, is associated with the Ig heavy chain. As shown in Fig. 11–3, the BCR consists of the Ig molecule and the associated Igα and Igβ proteins that are required for initiation of the intracellular signaling cascade following binding of antigen to Ig. This requirement exists because even though Ig heavy chains span the cell membrane, their cytoplasmic carboxyl tails are relatively short. For example, the intracellular C terminus of IgM and IgD consists of only three amino acids.

Antigen engagement of the BCR initiates assembly of a lipid raft, BCR-associated "signalosome," composed of multiple signaling molecules that include tyrosine kinases, serine/threonine kinases, lipid kinases, lipases, phosphatases, and linkers and adaptors.[88–91] This signalosome mediates a cascade of intracellular signals that includes the initiation of calcium influx. Additional calcium-dependent and -independent downstream signals that include the mitogen-activated protein kinase cascade (JNK, p38, ERK) and activation of key transcription factors that include JUN, c-fos, NFAT, and NF-κB in turn mediate transcriptional events leading to cell proliferation, survival, and differentiation. The level and duration of receptor activation, and hence transcriptional output, are further modified by a series of cell surface coreceptors or "response modifiers" that bind to complement receptors on the surface of stromal cells, activated T cells, or other populations present in secondary lymphoid organs.

In addition to the critical nature of these signals in mature B cells, these signaling pathways also are crucial in developing pre-B cells. One of the best examples of this requirement is the prototypical humoral immunodeficiency known as X-linked agammaglobulinemia, first described in 1952 by Bruton.[92] X-linked agammaglobulinemia results from mutations within the gene segments that encode the nonreceptor tyrosine kinase, Btk. In males who express a defective Btk protein, pre-B-cell clonal expansion is markedly depressed and there is an almost complete loss of immature B cells in the bone marrow and in secondary lymphoid organs.[91,93] As a result, affected males develop recurrent bacterial infections early in life because of a profound decrease in circulating Ig. A nearly identical clinical phenotype also has been observed in persons with mutations in additional components of the pre-BCR signaling complex, including the μ-heavy chain, λ5, Igα, and the key B-cell adaptor protein BLNK (see Fig. 11–1).

GENERATION AND SELECTION OF THE PRIMARY B-CELL REPERTOIRE

In order for the organism to mount an effective humoral immune response, an array of immunoglobulins with unique antigen-binding specificities, together referred to as the Ig repertoire, must be generated. Several mechanisms have evolved to ensure that this occurs.

First, heavy- and light-chain proteins can be encoded by multiple germline V, J, and, in the case of the heavy chain, D region genes, and the combinatorial diversity among them is enormous.[94–96] Second, nucleotides not encoded in the germline can be added to $D–J_H$ and $V_H–DJ_H$ junctions by a nuclear enzyme known as terminal deoxynucleotidyl transferase (TdT).[97,98] Two splice variants of TdT, encoded by a single gene, have been identified, and it is the short (509-amino acid) variant that catalyzes the addition of nontemplated nucleotides at coding joints. The long (529-amino acid) form is a 3′–5′ exonuclease that catalyzes the deletion of nucleotides at coding joints. Thus, N region diversity catalyzed by TdT may be due to the coordinated activities of short and long forms of that enzyme.[99] Third, the DNA joints that form during recombination are often imprecise and can occur at any of several nucleotides in the germline. This junctional diversity has the potential to generate different amino acid sequences, resulting in added diversity of the Ig repertoire. However, out-of-frame joints that cannot be transcribed also may result.[100] Finally, somatic mutation of V region genes can occur, usually in secondary lymphoid tissues.[101,102] This latter process, which results in an increased affinity of the antibody for antigen, is discussed in more detail in the section on secondary B-cell development.

It is important to recognize that the total number of B-lineage cells in the bone marrow is far greater than the number of mature B cells that are generated.[103,104] The remarkable cell loss that occurs during the process of differentiation of pro-B cells into B lymphocytes is due to a series of selection events. First, *Ig* heavy-chain gene rearrangements are productive in approximately a third of pro-B cells. In addition, functional light-chain gene rearrangements do not occur in all pre-B cells.[105] Those cells with nonproductive *Ig* gene rearrangements undergo apoptosis and are eliminated from the marrow by resident macrophages and stromal cells.[106]

Selection events also are operative on cells that have matured to the surface IgM stage of development. As a result, although approximately 2×10^7 IgM^+ immature B cells are produced daily in murine bone marrow, only 10% to 20% of these cells survive to exit the marrow and enter the spleen as transitional B cells. Some of these surface IgM^+ cells are eliminated because they are potentially self-reactive. Such self-reactive B cells may be generated because the process of Ig gene recombination is random.

Several mechanisms have been proposed to account for the fate of such cells. In some cases, the presence of self-antigen may not activate self-reactive B cells. This scenario may result from weak B-cell affinity for the antigen, or the autoantigen may be present at an extremely low concentration. In other instances, interaction of antigen with the autoreactive B cell may result in anergy. The level of membrane Ig on such anergic B cells may be reduced up to 20-fold, the cell's ability to proliferate may be impaired, and differentiation into Ig-secreting cells may be blocked. Finally, self-reactive B cells may be clonally deleted. Clonal deletion may result from cytolysis by other cells, such as bone marrow macrophages, or autoreactive B cells may undergo a physiologic change resulting in cell death following receptor engagement.[107,108]

The recognition of self-antigen by a B cell may not necessarily result in anergy or deletion but instead may lead to *receptor editing*. In this process, rearranged κ light-chain alleles can be replaced by secondary rearrangements of upstream $V_κ$ genes to downstream,

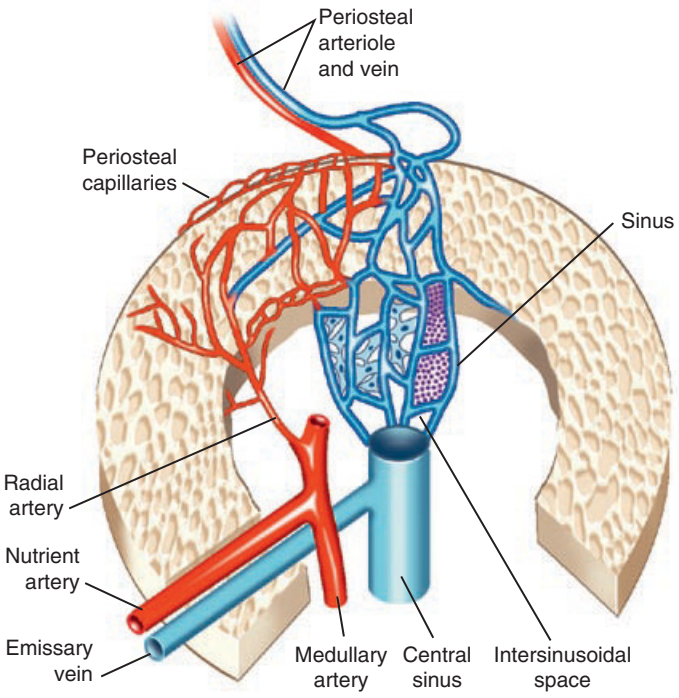

Figure 11–5 Cross section of bone showing elements of the medullary circulation, the marrow sinusoids, and the location of stromal cells. *(From Dorshkind K: Regulation of hematopoiesis by bone marrow stromal cells and their products. Annu Rev Immunol 8:111, 1990. Reprinted with permission from the* Annual Review of Immunology.*)*

unrearranged J_κ segments. These secondary rearrangements, which may delete the primary $V_\kappa J_\kappa$ complex or separate it from C_κ by inversion, are possible because of the continual presence of unrearranged V_κ regions upstream of the joined $V_\kappa J_\kappa$ coding segments.[109] Receptor editing also can occur in peripheral B cells in response to antigen stimulation, as discussed subsequently.

REGULATION OF PRIMARY B-CELL DEVELOPMENT

Hematopoiesis occurs in the intersinusoidal spaces of the medullary cavity in association with a fixed population of stromal cells. Stromal cells are largely sessile and form a three-dimensional hematopoietic microenvironment with which developing blood cells associate (Fig. 11–5).[110–112] Before 1980, little was known about how stromal cells and their secreted products regulate B-cell development. However, advances in molecular biology, the isolation of bone marrow stromal cells, and the development of long-term culture methods for growing B-lineage cells have converged in the last two decades. As a result, considerable insights into the regulation of B-cell development by extracellular signals have been obtained.

CELL–CELL INTERACTIONS

Direct contact between developing B-lineage and stromal cells can be observed on analysis of intact bone marrow or of B lymphopoiesis in long-term bone marrow cultures, and the molecular basis for these associations is being defined in both humans and mice. For example, both murine and human pre-B cells express the VLA-4 integrin that interacts with a stromal cell ligand identified as vascular cell adhesion molecule-1. VLA-4 also promotes binding to fibronectin, an extracellular matrix protein.[113–116] CD44 on developing B-lineage cells also has been implicated in mediating stromal cell–lymphocyte interactions in the mouse through binding to stromal cell-derived hyaluronate.[117] These intercellular interactions presumably would allow B cells to receive proliferative and/or developmental signals from stromal cells. It is important to appreciate that the stromal cells may not be passive populations that constitutively provide these signals. Instead, the binding of the B-lineage cell may stimulate the stromal cell in turn to produce such differentiation or growth-potentiating activities.

CYTOKINES

An additional means by which bone marrow stromal cells regulate the growth and differentiation of B-lineage cells is via the secretion of soluble mediators.[110–112] The literature describing the effects of cytokines on B-cell development is extensive, and a discussion of each one is beyond the scope of this chapter. However, the focus can be narrowed considerably when only those factors with obligate effects on B-cell development are considered.

The critical B lymphopoietic cytokine in mice is IL-7. The gene encoding IL-7 was cloned from a murine stromal cell line, and its product was identified on the basis of its ability to stimulate the proliferation of a pre-B-cell line.[118] IL-7 binds to a cell-surface receptor formed by the IL-7 receptor α chain and the common cytokine γ chain.[119,120] That IL-7 is required for murine B-cell development was demonstrated by studies showing that mice administered antibodies to IL-7 or its receptor exhibit severe lymphopenia. Subsequent analysis of IL-7 and IL-7 receptor knockout mice corroborated these studies.[121,122] These animals also exhibit a severe T-cell depletion, because IL-7 is required for thymopoiesis. Cells that have initiated Ig heavy-chain D–J_H rearrangements are particularly responsive to the growth-stimulating effects of IL-7.[2,35] However, by the time they have matured to the late pre-B-cell stage of development, responsiveness to IL-7 is lost, presumably owing to failure of cells to express the IL-7 receptor.[123] Subsequent murine studies revealed that in addition to its growth-promoting effects, IL-7 acts as a differentiation factor that potentiates the recombination of a V_H region gene segment to an already rearranged DJ_H complex.[124]

In view of these findings, it was expected that IL-7 would function in a similar manner during human B-cell development. Initial reports indicating that human $CD34^+CD19^+$ pro-B cells proliferated in response to IL-7,[125,126] albeit at a lower level than in mice, pointed to the potential for IL-7 to affect human B-cell progenitors. IL-7 is not an obligate human B lymphopoietic factor, however, as indicated by reports of patients with X-linked severe combined immunodeficiency. These patients have mutations in the gene encoding the common γ chain, which is part of the receptor for IL-2, IL-4, IL-9, and IL-15, in addition to IL-7. XSCID patients have severe defects in T-cell development, but B-cell development is normal.[127] Further substantiating the conclusion that IL-7 is not an obligate B lymphopoietic factor is that B-cell development also is normal in patients whose B-lineage cells express a mutated IL-7Rα chain.[128]

Another B lymphopoietic cytokine under current investigation is thymic stromal cell lymphopoietin (TSLP). TSLP was cloned from a murine thymic stromal cell line and has been shown to affect the growth and differentiation of B lineage cells.[129] Similar to IL-7, TSLP can stimulate pro-B-cell proliferation, and there is also evidence that TSLP can potentiate the pre-B to B-cell transition.[130] The TSLP receptor is formed by the IL-7Rα chain and another subunit related to, but not identical with, the common γ chain.[131] Utilization of the IL-7Rα chain in both IL-7 and TSLP signaling indicates that TSLP activity also is unlikely to be essential for human B-lineage development. Thus, at present, the cytokine(s) in humans that mediates the same effects as those mediated by IL-7 in the mouse remains unknown.

SYSTEMIC FACTORS

In addition to regulation by microenvironmental factors, there is a growing appreciation that systemic factors, those of endocrine origin in particular, also regulate B-cell development. For example, B-cell development in mice is dependent on the integrity of the pituitary–

thyroid axis, because mice deficient in the production of thyroid hormone or expression of the thyroid hormone receptor exhibit suppressed bone marrow B lymphopoiesis.[132] Whether or not these events also occur in human B lymphopoiesis has not been established. It also has been demonstrated that hormones can negatively affect B-cell development. In particular, increased levels of estrogens occurring during pregnancy inhibit lymphopoiesis.[133]

FETAL B-CELL DEVELOPMENT

Hematopoiesis initiates during embryogenesis.[134] Developing blood cells in mice are first detected at around day 7.5 of gestation in the murine yolk sac and in the human yolk sac at 3 weeks of gestation.[134] A long-standing model had been that HSC produced in the latter tissue subsequently seed the embryo. However, the analysis of avian chimeric embryos generated by grafting a quail yolk sac onto a chick embryo revealed that definitive blood cell development is derived from embryoid body-derived precursors.[135,136] The precise origin of intraembryonic blood cell development has been localized to the area around the dorsal aorta, developing gonads, and mesonephric kidney, which is referred to as the aorta–gonad–mesonephros (AGM) region.[137,138] The detection of human $CD34^+CD38^-$ cells with potent hematopoietic potential on the ventral endothelial wall of the dorsal aorta at day 25 of gestation is consistent with the AGM being a site in which HSC are generated.[139]

The para-aortic splanchnopleura, from which the AGM develops, appears to be the first tissue in the murine embryo that exhibits the potential to generate B lineage cells.[140] Subsequently, additional intraembryonic sites in the mouse embryo, including the fetal liver, the placenta, and the fetal bone marrow, as well as extra-embryonic tissues, such as the yolk sac, and the placenta harbor cells with the potential to generate B lymphocytes. The precise maturational state of the B-cell progenitors in these various intra- and extra-embryonic tissues is unknown, and whether or not they are produced in those sites or migrated into them from another tissue subsequent to the establishment of the fetal circulation remains unclear. Surface Ig-expressing cells develop in the fetus, and in the fetal liver in particular. For example, pre-B cells are present in that tissue by day 13 of gestation in mice, and surface IgM^+ cells are detected several days thereafter.

There are numerous parallels between murine and human fetal B-cell development. For example, pre-B cells can also be detected in human fetal liver by week 8 of gestation, and surface IgM^+ cells are present at week 9.[141] IgM-expressing cells have also been observed in additional human fetal tissues that include the omentum,[142] the peritoneal cavity, and the spleen.[143]

Many aspects of fetal B lymphopoiesis are similar to those in the adult. Thus, heavy-chain genes rearrange and are expressed before light-chain genes, and the recombinatorial machinery and transcriptional regulators of Ig gene expression are comparable. Nevertheless, murine studies suggest that the processes of fetal and adult B-cell development are not identical. One major difference between fetal and adult B-cell development is that it has been difficult to identify a fetal lymphoid committed progenitor that is devoid of myeloid potential. Instead, fetal B/T/macrophage and B/macrophage progenitors have been defined but not a lymphoid progenitor restricted only to B-cell and T-cell development.[144–146] A second difference between fetal and adult B-cell development is that the intracellular and extracellular signals that regulate growth and development are not identical. For example, although IL-7 is required for adult bone marrow B-cell development in mice, B-1 B-cell progenitors (see below) can develop in an IL-7-independent manner.[147] Also, although it has been thought that B-cell development is blocked completely in $PU.1^{-/-}$ mice, in fact fetal B-cell development occurs, and the cells produced appear to be B-1 B cells.[148] A third difference between fetal and adult B-cell progenitors is that the latter cells tend to express TdT whereas not all fetal B-cell progenitors do so.[149] Thus, the Ig repertoire of fetal-derived B cells is more restricted than that in the adult.[150] Transgenic strains of mice in which TdT is expressed during fetal B lymphopoiesis have altered immune responses to selected microorganisms.[151]

There is a growing appreciation that some fetal-derived B and T cells are functionally distinct from those produced during postnatal life. The fetal-derived cells are part of the innate immune system in contrast to lymphocytes generated during postnatal life that are effectors of adaptive immunity. Included in the former category would be natural killer (NK) cells, selected γδ T cells, some marginal zone (MZ) cells (defined below), and B-1 B cells.[152]

B-1 B CELLS

The B cells that are produced in adult bone marrow and that constitute the majority of B cells in the peripheral lymphoid tissues, such as the spleen and lymph node, are often referred to as B-2 B cells. This nomenclature serves to contrast them with a distinct population of mature B cells, referred to as B-1 B cells, that constitute around 5% of total B lymphocytes in the mouse.[152] B-1 B cells are found in multiple murine tissues that include various parts of the intestine, the spleen, and serous cavities. Approximately half of the B cells present in these latter tissues, including the pleural and peritoneal cavities, are B-1 B cells. B-1 B cells in serous cavities can be distinguished by their unusual phenotype. For example, peritoneal cavity B-1 B cells can be defined by their expression of high levels of sIgM, low levels of sIgD, and CD11b, a determinant expressed on myeloid cells ($sIgM^{high}$ $sIgD^{low}$ $CD11b^+$). B-1 B cells can be further subdivided according to the differential expression of cell surface CD5 into $sIgM^{high}sIgD^{low}CD11b^+CD5^+$ B-1a B cells and $sIgM^{high}sIgD^{low}CD11b^+CD5^-$ B-1b B cells. As noted, B-1 B cells are effectors of innate immunity and generally respond to high-molecular-weight, polymeric T-independent antigens (Table 11–1).[152,153]

Table 11–1 Characteristics of B-Cell Subpopulations

Cells	Immune Function	Phenotype	Properties	Primary Localization
B-1a	Innate Immunity	$IgM^{high}IgD^{low}CD11b^+CD5^+$ (in serous cavities)	Secretion of IgM natural antibodies	Serous cavities, spleen, gut
B-1b	Innate Immunity	$IgM^{high}IgD^{low}CD11b^+CD5^-$ (in serous cavities)	Antibody production is induced	Serous cavities, spleen, gut
MZ	Innate Immunity	IgM^+IgD^{low} (Human MZ B cells also include $CD27^+IgM^+$ unswitched memory cells)	Strong response to T-independent antigens	Splenic marginal zone
B-2 (follicular)	Adaptive Immunity	$IgM^{low}IgD^{high}$	Strong response to T-dependent antigens	Spleen and lymph nodes; recirculate

Adapted from Hardy RR, Hayakawa K: B cell developmental pathways. Annu Rev Immunol 19:595, 2001; Martin F, Kearney J: B1 cells: Similarities and differences with other B cell subsets. Currr Opin Immunol 13:195, 2001; and Martin F, Kearney JF: Marginal zone B cells. Nat Rev Immunol 2:323, 2002.

Recent observations in mice suggest that B-1a and B-1b B cells mediate distinct functions. B-1a B cells spontaneously secrete so-called IgM natural antibodies, whereas antibody production by B-1b B cells is induced following exposure to antigen. Antibodies from both subpopulations of B-1 B cells have been shown to be required for protection against pathogens such as *Streptococcus pneumoniae*.[154,155] The two types of B-1 B cells and B-2 B cells have been proposed to contribute to a "layered immune system." In this regard, the most primitive effectors would be B-1a B cells and the most highly evolved would be B-2 B cells. B-1b cells exhibit properties of both populations and may be an evolutionary link between them.[152]

The origin of B-1 B cells has been a source of considerable controversy. They have been proposed to be a separate B-cell lineage derived from a progenitor distinct from that from which B-2 B cells derive. In addition to this "lineage model," the "selection model" proposes that B-1 cells are conventional B-2 B cells whose characteristics result from selective pressures following antigen exposure.[152,156,157] Classic studies demonstrating that the transplantation of fetal liver most efficiently generated B-1 B cells whereas adult bone marrow most efficiently repopulated B-2 B cells in irradiated murine recipients provided evidence for the lineage model.[158] The recent description of a phenotypically identifiable B-1 B cell-specified progenitor produced during embryogenesis has provided strong support for the lineage model.[159]

This discussion has focused on B-1 B-cell development in mice, because very little is known about the development and role of B-1 B cells in humans. However, some B cells in patients with various autoimmune diseases have properties suggestive of a B-1 B-cell origin, and the role for this population in response to specific infectious challenges makes further studies of human B-1 B-cell development an important area of investigation.[160]

SECONDARY LYMPHOID COMPARTMENTS

Once newly produced B cells exit the bone marrow, they migrate to the spleen, where they undergo further maturation into follicular B cells or MZ B cells. In general, B cells in the follicles are poised to respond to T-dependent antigens, which, as their name implies, require help from T cells. The T cells in the spleen that provide this help are located in the periarterial lymphoid sheath (PALS; Fig. 11–6). The spleen (but not lymph nodes) contains additional B cells located at the outer limit of the splenic white pulp (Fig. 11–6). This area, known as the marginal zone, is where the MZ B cells localize, and the region also contains macrophages and dendritic cells. MZ B cells present in this region play a critical role in the response to T-independent antigens (see below). The development of these populations, known as secondary B-cell development, has been highlighted in recent studies.[161–166]

The first step in secondary B-cell development is the entry of newly arrived bone marrow immigrants into the spleen. These cells, which are now referred to as *transitional 1 (T1) B cells*, localize at the outer edge of the PALS (Fig. 11–6) that surrounds the splenic central artery. The PALS in mice is occupied by a considerable number of T cells but in humans few T cells are present in this region. T1 B cells give rise to a more mature population of splenic B cells, referred to as *T2 or follicular precursor B cells*. The T1 and T2 populations respond differentially to developmental stimuli,[163,164] and a considerable degree of selection occurs during the T1 to T2 transition. For example, T1 cells with BCR specificities for blood-borne self-antigens are deleted by negative selection. Positive selection via BCR signaling must occur, and if it does not, the T2 cells will die by neglect. The survival of T2 cells, but not T1 cells, is also dependent upon the B-cell activation factor BAFF (BLyS, TALL-1, THANK, zTNF4), which is produced by the splenic microenvironment.[165] A significant fraction of T2 cells are no longer in the G_o phase of the cell cycle, suggesting they are in a more activated state than is the case for T1 cells.

The strength of BCR-mediated signals influences the development of T2 cells. Weaker signaling through the BCR may promote entry into the MZ B-cell compartment. Signaling through Notch2 expressed on T2 cells also determines T2 cell fate. When this occurs, T2 cells are promoted to become MZ B cells, and there is a depletion of MZ B cells when this pathway is blocked.[166] Of note, human MZ B cells are clearly heterogeneous and include a large proportion of $CD27^+IgM^+$ unswitched memory B cells with somatically mutated Ig heavy chains. The origin of this cell population is unclear but is presumed to be antigen driven yet may not require T cell help. While MZ B cells in rodents appear to be a static, nonrecirculating population, cells with an identical $CD27^+IgM^+$ phenotype are clearly present in human peripheral blood as well as other lymphatic tissues. This circulating population becomes detectable in parallel with seeding of the splenic MZ (typically after 2 years of age), increases in number following exposure to polysaccharide antigens, and appears to play an essential role in the rapid response to infection with encapsulated bacteria.[161,167,168]

Strong BCR signals are critical for T2 cells to mature into a follicular B cell. It is estimated on the basis of murine studies that only 1% to 3% of splenic transitional B cells develop into mature, naive B cells.[161,163] Once mature, naive B cells are generated, they recirculate and take up residence in various lymphoid tissues that include lymph nodes, intestinal Peyer patches, and the spleen itself. Within these tissues, mature naive cells localize in clusters of B lymphocytes, and each such cluster is termed a *primary follicle* (see Fig. 11–6). Within those regions, the follicular B cells are poised to respond to antigen and undergo the germinal center reaction described below.

The molecular signals responsible for the intraorgan localization of specific B-cell populations and their migration patterns following antigenic challenge are being identified.[169–173] Proper segregation of splenic B cells in follicles and the MZ is dependent on expression of tumor necrosis factor (TNF) and lymphotoxins α and β ($LT\alpha$ and $LT\beta$). Signaling through LFA-1 and $\alpha_4\beta_1$ integrins also has been implicated in localization and retention of MZ B cells.[174,175] A related TNF family of molecules that includes B-cell activation factor (BAFF) is involved in peripheral B-cell generation, selection, and function. These molecules and their receptors may also transmit signals required for the development of stromal cells that produce chemokines required for movement of cells between different anatomic locations within secondary lymphoid organs. A role for chemokines in B-1 B-cell localization to the peritoneal cavity has also been demonstrated.[174] Further details regarding lymphocyte trafficking can be found in Chapter 16.

T-INDEPENDENT B-CELL RESPONSES

T-independent responses are elicited by polymeric antigens, such as polysaccharides, that are composed of repetitive antigenic epitopes. MZ B cells play a critical role in these responses. On antigen binding, MZ B cells undergo rapid proliferation and maturation into plasma cells that secrete low-affinity IgM.

The rapid response of MZ B cells to antigen has led to the idea that this effector population, like B-1 B cells, constitutes a key element of the innate immune response to bacterial and other selected pathogens. Because they have a low activation threshold, MZ B cells rapidly differentiate into antibody-forming cells in response to antigen. These cells secrete primarily low-affinity IgM and IgG_3 antibodies that provide a first line of defense. This response may be reinforced by B-1 B cells, whose Ig repertoire is designed for responsiveness to the polymeric antigens that characterize the T-independent response. In view of this, it is not surprising that many of the properties of MZ B cells overlap with those of B-1 B cells (see Table 11–1). However, they do not seem to be identical populations, and evidence points to a separate origin.[153,177,178]

The poor response of infants to some types of T-independent antigens correlates with the fact that the MZ is not fully formed until the age of 1 to 2 years.[178] In addition, splenectomized persons are more susceptible to infection with some bacteria, owing to the deficient antibody response to capsular polysaccharides.

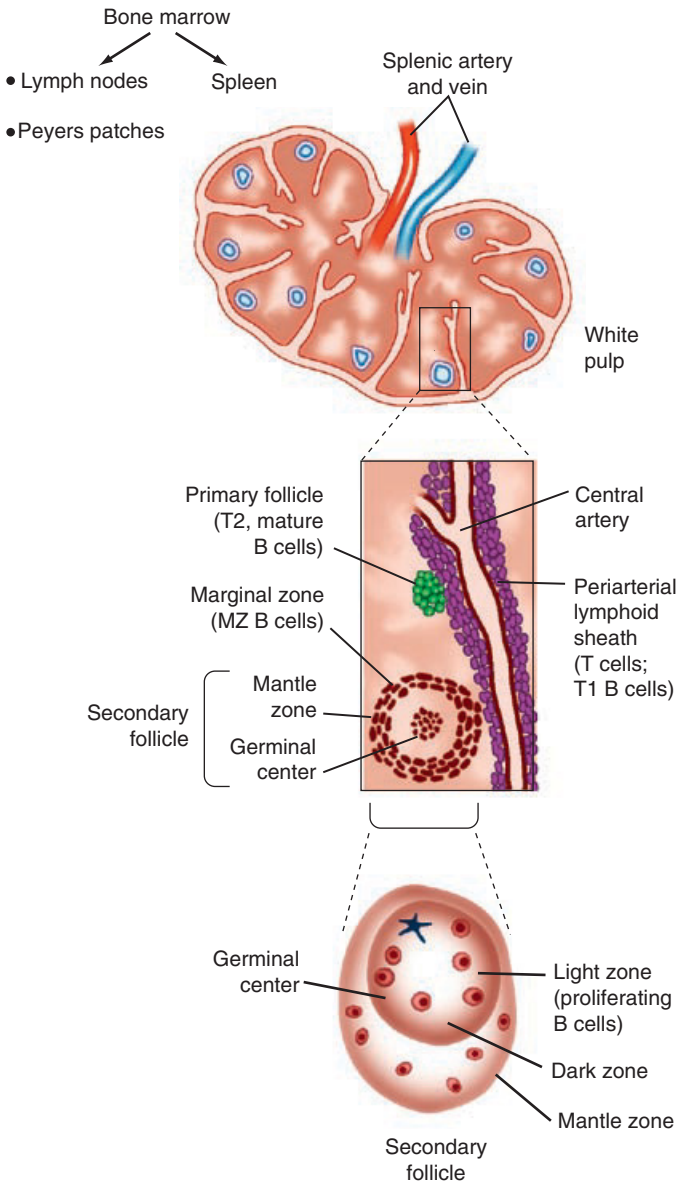

Figure 11–6 Organization of B cells in secondary lymphoid organs, with emphasis on the spleen.

T-DEPENDENT RESPONSES IN SECONDARY LYMPHOID TISSUES

Although some B cells in the MZ can respond to T-dependent antigens, most B cells that do so are the mature, naive B cells located in primary follicles. As described previously, these cells are derived from T2 B cells, and have subsequently migrated into the primary follicle. Following their binding of a T-dependent antigen (as soluble antigen or indirectly via presentation by a local antigen-presenting cell, or, alternatively, as an immune complex), mature, naive B cells in primary follicles undergo a blastogenic response. Some of these cells will immediately mature into plasma cells that secrete low-affinity IgM to provide a rapid initial response to infection.[179–181] In response to T-cell help, however, other B cells will undergo further proliferation and differentiation. The histologic appearance of the follicle changes as these events evolve. The nonresponsive B cells form an outer *mantle zone* surrounding the proliferating, antigen-responsive B cells in a central germinal center.[179,180,182,183]

Germinal center B cells are shielded from soluble antigens and are exposed only to a unique set of antigens presented by follicular dendritic cells.[184,185] Two regions can be distinguished within the germinal center of the secondary follicle. At one pole, the cycling B-cell blasts are referred to as *centroblasts* and form the *dark zone*. The other pole, referred to as the *light zone*, consists of nonproliferating cells referred to as *centrocytes*. Some of these centrocytes will go on to become plasma cells, whereas others will become memory B cells (see Fig. 11–6).[180,186,187] The end result of the germinal center reaction is the formation of plasma cells that secrete high-affinity Ig. Other germinal center B cells convert to memory B cells, which constitute approximately 40% of all B cells and are responsible for the relatively rapid response observed on secondary exposure to the same antigen.

Affinity Maturation and Lymphomagenesis

Following the initial low-affinity IgM response that helps to keep a developing infection in check, the response of B cells in the germinal centers to T-dependent antigens involves Ig class switching and selection of B-cell clones of higher-affinity antigen-binding potential. This process is known as *affinity maturation*.

Affinity maturation results in the selection of B cells estimated to have a 10-fold, or even greater, increase in antigen-binding potential.[188,189] Analysis of Ig gene sequences of pre- and post-germinal center B cells indicates that this increased affinity is secondary to changes in the genes that encode the antigen-binding domain of the Ig molecule. These genomic changes result from three types of modifications.[190] First, as described previously, B cells may undergo receptor editing. Receptor editing usually involves modifications of the existing light chain in which an upstream V region segment joins to a downstream J region gene. As a result, the genetic region encoding the originally expressed light chain is deleted. In order for this process to occur, RAG-1 and RAG-2 expression would be required. It has been proposed that B cells in germinal centers might reactivate *RAG* gene expression in order to mediate events such as receptor editing.[191] However, that this occurs has been questioned in two convincing studies.[192,193] Instead, receptor editing in splenic B cells may be limited to a small subset of recent immature bone marrow immigrants that enter germinal centers before their *RAG* gene expression has been extinguished.

Somatic hypermutation provides a second means to increase antibody affinity. During this process, single-nucleotide exchanges, deletions, and mutations are introduced into the genes encoding the antibody-binding regions of the Ig receptor. Finally, Ig class switching (see earlier) can occur. Class switching results in the replacement of the existing heavy-chain constant region by a downstream constant region gene. Recently, a B cell-specific gene that encodes activation-induced cytidine deaminase (AID), which is expressed in germinal center B cells, has been identified. AID is a putative RNA-editing enzyme that acts as a cytidine deaminase and has been shown to be indispensable for somatic hypermutation and class switch recombination.[194,195] Not all of these changes may increase antigen-binding affinity, however, and some may even result in the generation of autoreactive clones. Thus, a selection process has evolved to delete low-affinity and autoreactive transitional B cells.

Affinity maturation is dependent on signals delivered to the antigen-responsive B cells by antigen-specific T lymphocytes that migrate into the germinal center from the PALS (see Chapter 10).[196,197] T cells mediate their effects on B cells through the secretion of cytokines as well as through direct intercellular contacts, and these stimuli result in B-cell growth, differentiation, and Ig class switching. For example, CD40 is a T cell-surface glycoprotein encoded by a member of the Tumor Necrosis gene family, and its ligand is expressed on B cells.[198,199] CD40 ligand knockout mice do not form germinal centers,[200] and humans who do not express CD40 ligand suffer from X-linked hyperIgM immunodeficiency.[201] Another key T-cell costimulatory signal includes the cytokine IL-10, which is secreted by T cells in response to their activation via the "inducible costimulator" ICOS. Humans lacking expression of ICOS on T cells suffer from adult-onset common variable immune deficiency, leading to a severe deficit in generation of class-switched and memory B cells.[202]

Although the process of affinity maturation is highly efficient, one unintended consequence is thought to be the development of B-cell lymphoma. Lymphomagenesis results in part from the fact that vigorous B-cell proliferation combined with the changes at the DNA level lead to molecular alterations promoting or supporting malignant transformation. Numerous studies have assigned B-cell lymphomas to each of the normal B-cell counterparts (as described).[188] The derivation of the various lymphomas from the normal cellular counterparts and the precise genetic changes that occur in them are described in several chapters in Part VI, Hematologic Malignancies. Events that limit differentiation of immature or activated mature B cells can also promote malignant transformation. For example, disorders leading to defective pre-BCR signaling predispose to development of pre-B acute lymphocytic leukemias.[77]

AGEING AND B-CELL DEVELOPMENT

Studies of both rodents and humans have demonstrated that the quality of the immune response is diminished with age. Such declines are not incompatible with life, but they may become a factor when the individual is required to mount an immune response to a novel pathogen, respond to vaccination, or when considering the potential functional activity of bone marrow derived from older donors. Consequently, defining why aging affects the immune system is critical in order to develop strategies to augment immunity in the elderly.

One contributing factor may be that the production of B cells from HSC is severely reduced with age. For example, the frequency of CLP, pro-B cells, and pre-B cells is significantly reduced in the bone marrow of old mice. Such declines may reflect both age-related defects in HSC as well as in more differentiated lymphoid progeny. In any case, a consequence is that the reduced primary production of B cells results in a lower number of newly produced, naïve B cells that enter secondary lymphoid tissues such as the spleen. Senescence also affects mature B cells resident in peripheral lymphoid tissues. For example, in addition to an accumulation of memory B cells in the spleen of old mice, the immunoglobulins they produce are less protective because of low titer and affinity. Some of these defects may be intrinsic to the B cells while others may be secondary to age-related defects in T cells.[203] Reduced B-cell production may also predispose to alterations in B-cell tolerance. This is because reduced competition for homeostatic signals such a BAFF can lead to an increase in the survival of autoreactive B cells, which are normally outcompeted in nonlymphopenic hosts.[204,205]

CHAPTER 12

T-CELL IMMUNITY

Kai W. Wucherpfennig

CENTRAL ROLE OF T CELLS IN ADAPTIVE IMMUNITY

A fundamental understanding of the mechanisms of T cell-mediated immunity is central for an understanding of many hematological diseases. The two branches of the adaptive immune system—B cells and T cells—are specialized in recognizing pathogens in extracellular and intracellular locations, respectively. The essential receptors for B cell- and T cell-mediated immunity—antibodies and T-cell receptors—have related mechanisms for the generation of structural diversity, but distinct recognition mechanisms. Antibodies recognize soluble or cell surface-bound antigens in extracellular spaces and the enormous structural diversity among antibodies permits recognition of virtually any molecular structure: folded proteins, peptides, lipids, carbohydrates, RNA, or DNA. In contrast, T cells sense the presence of intracellular pathogens but do not make direct contact with them. Rather, short proteolytic fragments of pathogen-derived proteins are transported to the cell surface as peptide–major histocompatibility complexes (MHCs) for recognition by the T-cell receptor (TCR). TCR recognition induces clonal expansion, cytokine production, killing of infected cells and other effector functions. Furthermore, activation leads to differentiation into T-cell subsets with defined cytokine profile and function as well as establishment of a long-lived pool of memory T cells. The central role of T cells in immunity against viruses, bacteria, and fungi is illustrated by the severity of the immunodeficiency state that results from destruction of CD4 T cells by the human immunodeficiency virus (HIV).[1] Also, the slow reconstitution of T-cell populations following bone marrow transplantation is responsible for the reactivation of latent viruses, such as cytomegalovirus (CMV).[2]

MOLECULAR MECHANISM OF ANTIGEN PRESENTATION TO T CELLS

Histocompatibility and the Discovery of the Molecular Mechanisms of TCR Recognition

The discovery of the molecular mechanisms of T-cell recognition traces back to the observation that transplanted organs are accepted among identical twins, but not unrelated subjects. The discovery of histocompatibility led Dr Joseph Murray at the Peter Bent Brigham Hospital in Boston in 1954 to perform the first successful solid organ transplant between a patient with end-stage kidney disease and a healthy identical twin.[3] Preceding work had demonstrated that kidney grafts from unrelated donors could function for some time, but were invariably rejected. The major breakthrough in this field occurred several years later when immunosuppressive drugs such as 6-mercaptopurine and the 6-mercaptopurine analog azathioprine were introduced. In 1962, use of azathioprine resulted in the first successful transplant of an unrelated renal allograft, and within several years 1-year survival rates of allografted kidneys from living related donors were approaching 80% and from cadavers 65%. Dr Murray was awarded the Nobel Prize in Physiology or Medicine in 1990 for these landmark contributions.[3] These advances provided a major intellectual stimulus for the discovery of the fundamental role of MHC genes in T-cell function.

Work on the biochemistry of the MHC proteins in the 1970s in Dr Jack Strominger's laboratory at Harvard University identified two major proteins, now known as MHC class I and class II.[4] Sequencing of the proteins demonstrated that each molecule contains four extracellular domains: two membrane-distal domains that contain the polymorphic residues responsible for transplant rejection and two membrane-proximal immunoglobulin domains (Fig. 12–1).[4] Genetic characterization of the MHC locus demonstrated the presence of multiple genes for both MHC class I and class II families: the HLA-A, HLA-B, and HLA-C heavy-chain genes in the human MHC class I region and the HLA-DR, HLA-DQ, and HLA-DP genes in the MHC class II region. These genes are the most polymorphic known genes in the human genome.[5] How do the polymorphic residues contribute to their function?

MHC Molecules Present Peptides to T Cells

The key concept of "MHC restriction" of a T-cell response was established by Drs Rolf Zinkernagel and Peter Doherty through studies of cytotoxic T cells from mice infected with the lymphocytic choriomeningitis virus (Nobel Prize in Physiology or Medicine, 1996).[6,7] They tested T cells from different strains of mice infected with this virus for killing of a particular infected cell line and found that killing only occurred when the MHC haplotype of both T cells and the target cell line were matched. Two models were proposed to explain these results: a single receptor on T cells recognizes a complex formed by the MHC molecule and a viral antigen, or alternatively two receptors on T cells separately recognize MHC and viral antigen. Studies of MHC class I and class II restricted T cells converged on the same answer: MHC class I and class II molecules bind short peptides derived by proteolysis from such antigens.[8,9]

The Structure of MHC Class I Proteins

The classic publication of the crystal structure of the human MHC class I molecule HLA-A2 by Drs Pam Bjorkman, Jack Strominger, Don Wiley, and colleagues established the molecular mechanism of T-cell recognition.[10] The membrane-distal $\alpha 1$ and $\alpha 2$ domains of the heavy chain form a peptide-binding site (see Fig. 12–1). The floor of this binding site is created by a platform of eight antiparallel β strands and its sides by the two long α-helices of the $\alpha 1$ and $\alpha 2$ domains. HLA-A2 had been purified from a human EBV-transformed B-cell line and the binding site was filled with a mixture of endogenously processed peptides that were visible in the structure as extra electron density not accounted for by the HLA-A2 protein sequence. The polymorphic residues line this binding site, demonstrating that their biological role is to diversify the repertoire of peptides that can be presented to T cells in different members of a population.[11] This diversification is driven by pathogens, and individuals with rare MHC alleles can have a survival advantage compared to other members of the population because mutations in pathogens that destroy T-cell epitopes occur more frequently for peptides presented by common rather than rare alleles.[12] Transplant rejection is thus a consequence of pathogen-driven diversification of MHC genes.

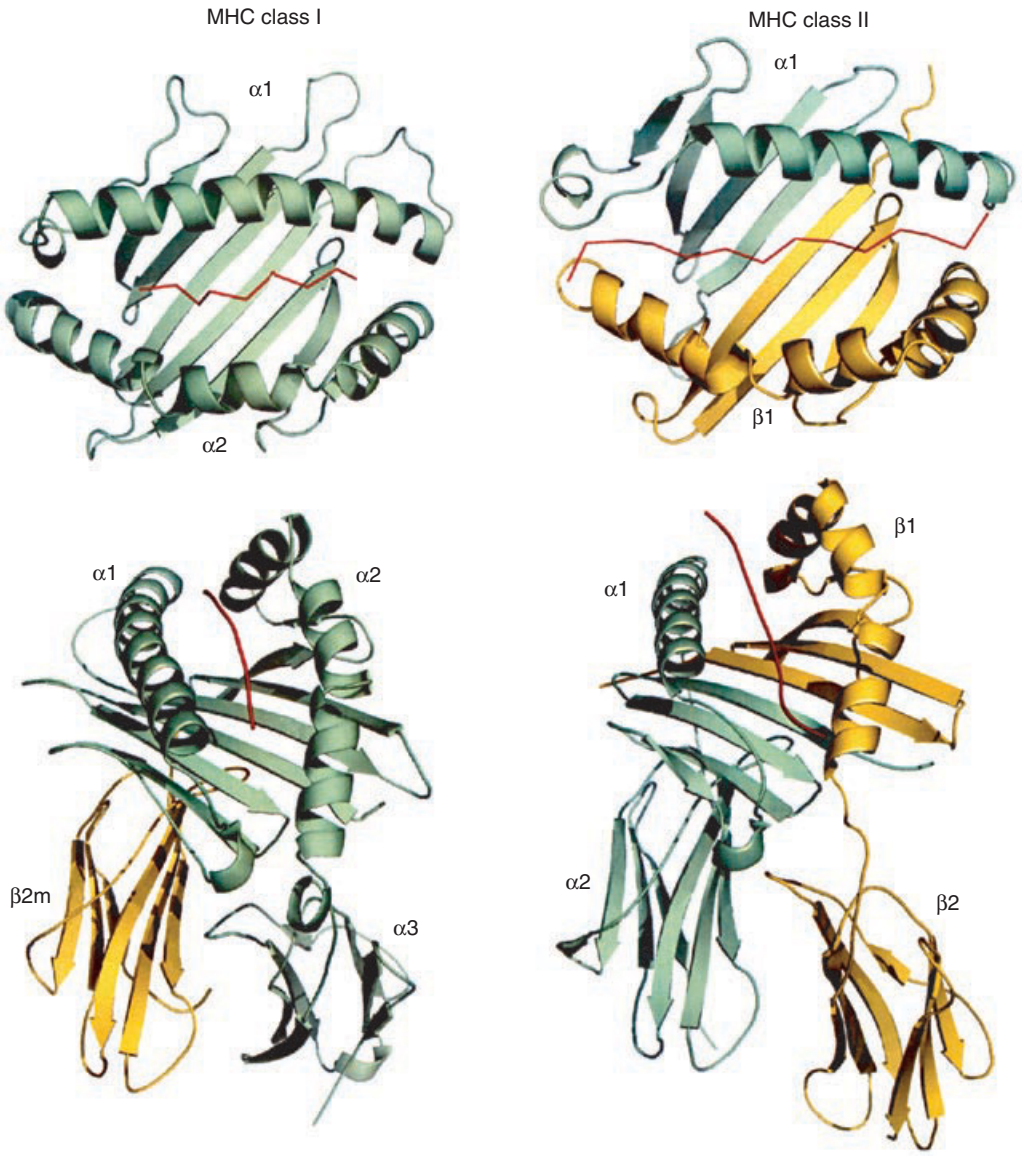

Figure 12–1 Structure of major histocompatibility complex (MHC) proteins. MHC proteins present peptides to the T-cell receptor on T cells. Peptides are bound between the two long helices of the peptide-binding site that sit atop a floor of antiparallel β strands. The α and β chains of MHC class II proteins are both membrane anchored and make equal contributions to the peptide-binding site. In contrast, only the heavy chain of MHC class I is membrane anchored and the α1 and α2 domains of the heavy chain form the peptide-binding site. The MHC class I heavy chain associates in the ER with β2-microglobulin prior to peptide binding. The MHC class II-binding site is open at both ends, permitting the binding of longer peptides compared to MHC class I proteins.

MHC Polymorphisms Determine Peptide-Binding Motifs

The polymorphic residues line six pockets (A–F) of the peptide-binding site. The A and F pockets bind the charged N and C termini of the peptide through a set of conserved hydrogen bonds.[13] The shape and surface properties of the pockets determine which amino acid residues can be accommodated and thus define the repertoire of peptides that can be presented. The majority of peptides that are bound by MHC class I molecules are 8–10 residues in length, but longer peptides have also been identified. Because the N and C termini occupy fixed positions in the A and F pockets, longer peptides "bulge" out in the center.[14] Each MHC molecule has a particular set of preferred amino acids for a given pocket, a peptide-binding motif (Table 12–1). These motifs were first elucidated by elution of peptides bound to MHC class I proteins and sequencing of these peptide pools by Edman degradation.[15] For example, HLA-A2 has a strong preference for hydrophobic amino acids at both positions 2 and 9 (L, M at position 2; V, L at position 9). In contrast, binding to HLA-B27 requires a basic residue at position 2 (R), whereas both basic (R, K, H) and hydrophobic amino acids (L, F, Y) can be accommodated by the P9 pocket.[16] Peptides that bind to HLA-A2 can thus not be presented by HLA-B27 and vice versa. Viral escape mutations that result in loss of MHC binding have been identified for HIV T-cell epitopes, such as mutation of the arginine at position 2 required for binding to HLA-B27.[17] These peptide-binding motifs have proven to be useful for the identification of T-cell epitopes from viral and tumor antigens.

Structural Differences Between MHC Class I and Class II Proteins

MHC class I proteins are expressed by most cell types and present peptides to cytotoxic T cells with the CD8 coreceptor (Fig. 12–2). In contrast, MHC class II proteins are expressed by "professional" antigen-presenting cells, such as dendritic cells, macrophages, and B cells, and present peptides to T cells that express the CD4 coreceptor.[18] The binding site for the coreceptors is located in the membrane proximal domains, the α3 domain of the MHC class I heavy chain for CD8 and the interface between the α2 and β2 domains of MHC class II proteins for CD4.[19,20] The coreceptors recruit the Src kinase Lck during TCR triggering, which phosphorylates tyrosine-based motifs in the cytoplasmic domains of the TCR–CD3 complex.[21,22]

In MHC class I proteins, the peptide-binding site is only formed by the heavy chain (α1 and α2 domains), whereas the peptide-binding groove of MHC class II proteins is created by two chains (α1 and β1 domains; see Fig. 12–1).[13,23] In contrast to MHC class I proteins, the class II-binding site is open at both ends, permitting binding of longer peptides (typically 13–20 residues).[23] Thus, the

Each MHC class I molecule has a particular peptide-binding motif that specifies the amino acid preferences for peptide side chains in the binding pockets. Motifs and examples of three T cell epitopes are shown for the human HLA-A2 and HLA-B27 proteins.

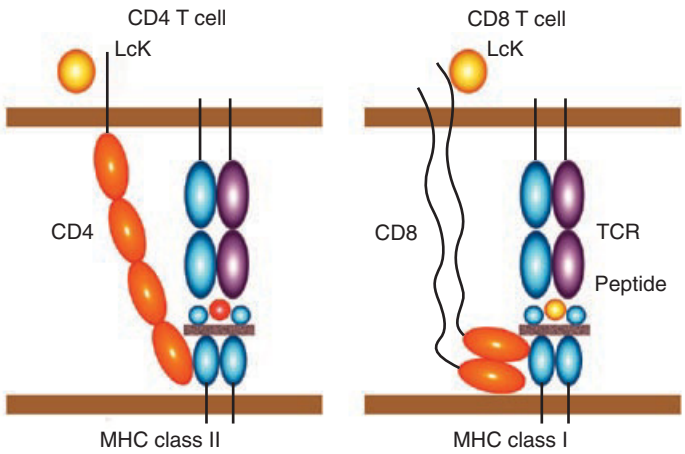

Figure 12–2 The CD4 and CD8 coreceptors bind to the membrane-proximal domains of major histocompatibility complex (MHC) class II and class I proteins, respectively. Coreceptor expression defines the CD4 and CD8 subpopulations of mature T cells. CD8 T cells recognize MHC class I-bound peptides and kill infected cells whereas CD4 T cells recognize MHC class II-bound peptides and coordinate immune responses. CD4 is a single-chain membrane protein with four extracellular Ig domains; CD8 is a homo- or heterodimer (CD8αα or CD8αβ) with an Ig domain and a long, flexible stalk segment. The coreceptors bind to the same peptide–MHC unit as the TCR: the TCR binds to membrane-distal peptide–MHC surface whereas the coreceptors bind to the membrane-proximal Ig domain(s): the CD8 dimer to the α3 domain of MHC class I proteins and CD4 to the interface between the α2 and β2 domains of MHC class II proteins. The coreceptors recruit the Src kinase Lck to the TCR during receptor activation.

peptide termini do not contribute to binding to MHC class II proteins, as described above for MHC class I. Rather, the interaction between the peptide and the MHC protein is stabilized by a set of conserved hydrogen bonds along the peptide backbone and the MHC helices.[24] These conserved interactions provide a peptide sequence-independent binding mechanism and are likely to contribute a substantial fraction of the total binding energy. In addition, pockets of the MHC class II-binding site can accommodate peptide side chains and these interactions contribute sequence specificity to the interaction. Many human autoimmune diseases are associated with particular alleles of MHC class II genes, indicating that the presentation of particular self-peptides to CD4 T cells is important in disease pathogenesis.[25] For example, susceptibility to type 1 diabetes is associated with a polymorphism at position 57 of the HLA-DQβ chain: most alleles carry an aspartic acid at this position, but diabetes-associated alleles have a noncharged amino acid at this site.[26] This polymorphism drastically alters the specificity of one particular pocket of the HLA-DQ binding site (P9 pocket) and enables the binding of certain self-peptides.[27]

Mechanisms of Peptide Generation and Loading

MHC class I and class II proteins sample distinct peptide pools in different subcellular compartments. MHC class I proteins acquire peptides in the endoplasmic reticulum (ER) that are imported from the cytosol through a dedicated peptide transporter (TAP). In contrast, MHC class II proteins traffic to endosomal/lysosomal vesicles and acquire peptides from phagocytosed pathogens. Sampling of these distinct environments is adapted to the lifestyle of the pathogens against which a T-cell response is mounted. CD8 T cells are specialized in detection of pathogens that replicate in the cytosol, viruses as well as intracellular bacteria and parasites, and kill infected cells that display pathogen-derived peptides on the cell surface. CD4 T cells are required for effective immune responses against pathogens that replicate in extracellular environments and induce the production of neutralizing antibodies by B cells, a process referred to as B-cell help (see Chapter 11).[28,29]

The MHC Class I Peptide Loading Complex

In cells infected by viruses and intracellular bacteria, pathogen-encoded proteins are synthesized by ribosomes of the host cell in the cytosol. Peptides loaded onto MHC class I proteins are generated in the cytosol by a large macromolecular complex of approximately 700 kd, the proteasome. The core proteasome is a cylindrical structure composed of four rings, each of which contains seven subunits. The two outer rings contain the α subunits and the two inner rings the catalytically active β subunits that have three different protease specificities. Proteins targeted for degradation thus have to enter the cylinder and are degraded to peptides with a length of approximately 3–22 residues (average of 13–18 residues). Proteins are targeted for proteasomal degradation by attachment of ubiquitin tags, and include misfolded and aging proteins as well as defective ribosomal prod-

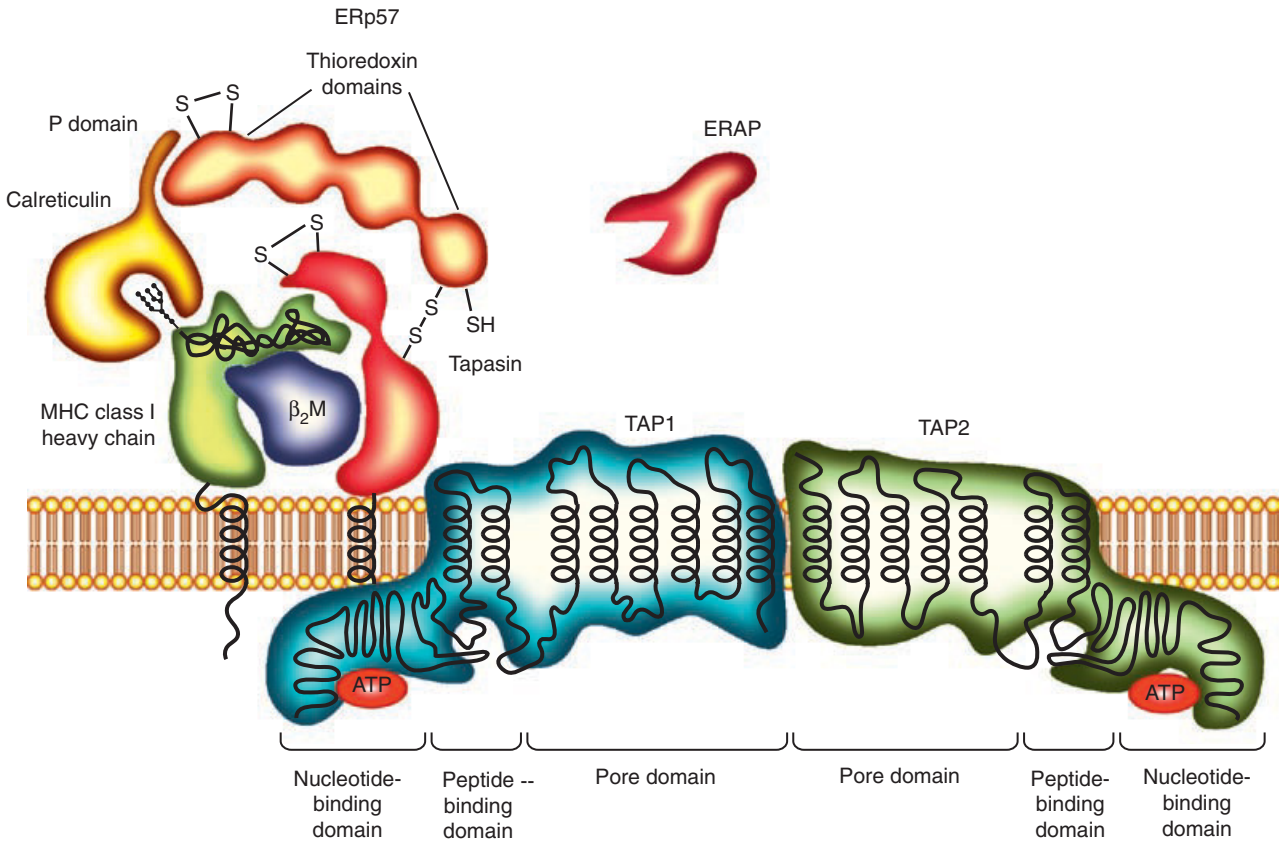

Figure 12–3 The major histocompatibility complex (MHC) class I peptide-loading complex. Peptides have a short half-life in cells owing to proteolytic attack. Translocation of peptides from the cytosol and their loading into the MHC class I-binding site is therefore tightly coordinated. The TAP peptide transporter is a heterodimer composed of TAP1 and TAP2 that uses ATP hydrolysis for transport of peptides generated in the proteasome. The tapasin protein represents the bridge between TAP and the MHC class I protein. The chaperone calreticulin and the oxidoreductases ERp57 and PDI (not shown) participate in peptide loading. The ERAP protease can trim the amino-terminal ends of peptides for an optimal fit into the MHC class I-binding site. Reprinted from *Nature Immunology*.[37]

ucts.[30] Inflammatory mediators (IFNγ and TNFα) enhance expression of immunoproteasome subunits, and the immunoproteasome can degrade proteins that have not been marked with ubiquitin, which accelerates peptide generation from recently synthesized pathogen-encoded proteins.[30,31]

It is important to appreciate that peptides have very short half-lives in cells because they are highly susceptible to degradation by proteases. Translocation of peptides into the ER and loading onto newly synthesized MHC class I molecules are coordinated by a specialized macromolecular protein complex, the MHC class I peptide loading complex (Fig. 12–3).[29] A key component of this complex is the TAP transporter that is responsible for ATP-driven translocation of peptides from the cytosol into the ER lumen.[32,33] MHC class I molecules are recruited to the TAP transporter by the tapasin protein, and this interaction is functionally important, as shown by the defect in MHC class I antigen presentation in tapasin-deficient mice.[34] Four tapasin molecules associate with one TAP transporter, and the complex thus contains four MHC proteins. The presence of four MHC proteins increases the chance that a translocated peptide will bind to one of the different MHC class I proteins (HLA-A, HLA-B, and HLA-C in humans). Three other proteins are associated with this complex: the chaperone calreticulin and the oxidoreductases ERp57 and protein disulfide isomerase (PDI). PDI catalyzes the oxidation of a critical disulfide bond between the floor of the peptide-binding groove and the α2 helix of the MHC class I protein and also transiently binds to peptides. Peptide translocation into the ER lumen, transient binding of peptide to PDI, and transfer of the peptide into the MHC class I cleft are thus closely linked.[35] Following stable binding of peptides, MHC class I molecules dissociate from the peptide-loading complex and are transported to the cell surface.

MHC class I proteins can also present peptides from extracellular pathogens and apoptotic cells by a mechanism referred to as crosspresentation. Proteins or peptides from phagocytosed pathogens or apoptotic cells are transported into the cytosol, and peptides derived from these antigens are then transported into the ER by the TAP transporter.[36,37] The crosspresentation pathway is described in detail in Chapter 14.

The MHC Class II Antigen Presentation Pathway

For MHC class I proteins, assembly and peptide loading occur in the same compartment and are closely linked processes. In contrast, MHC class II molecules assemble in the ER, but acquire peptides in a different compartment (Fig. 12–4). The invariant chain associates with recently assembled MHC class II αβ heterodimers in the ER and plays a critical role in the MHC class II pathway. Invariant chain forms a trimer and can associate with three MHC class II molecules into a nine-chain complex.[38] Invariant chain is a type II membrane protein and its N-terminal cytosolic domain bears an address code that targets the MHC class II-invariant chain complex to the endosomal–lysosomal pathway. Furthermore, the luminal domain of invariant chain protects the hydrophobic MHC class II peptide-binding site from aggregation.[39] The responsible invariant chain segment (CLIP, for class II-associated invariant chain peptide) occupies the groove in the same manner as other peptides and thus prevents binding of peptides to the MHC class II site before these molecules have reached their destination.[40] In the endosomal/lysosomal compartment, the invariant chain is degraded by a series of proteases down to the CLIP peptide segment that occupies the

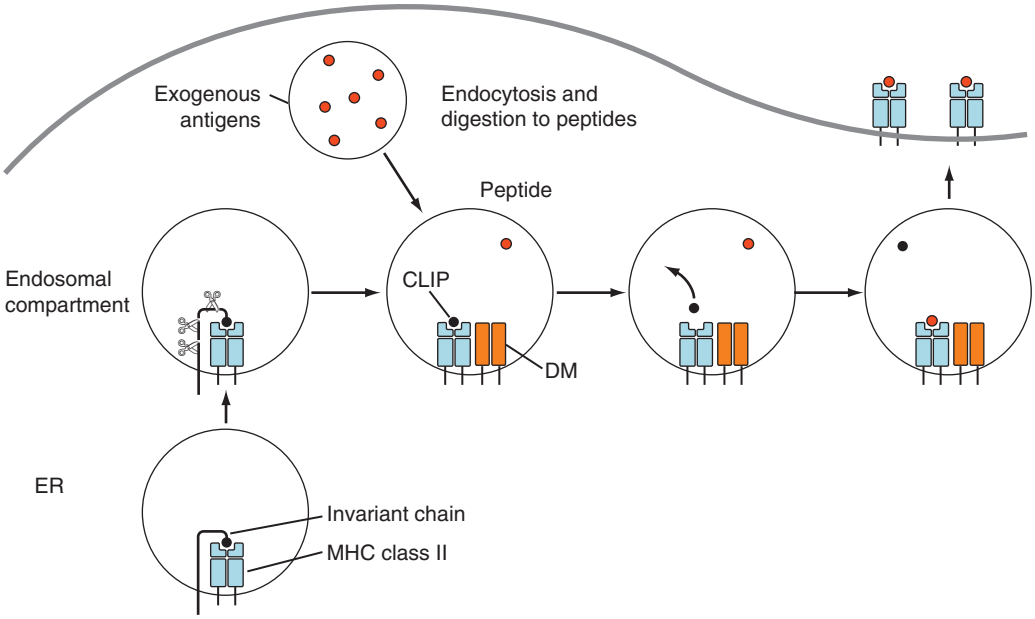

Figure 12–4 The major histocompatibility complex (MHC) class II antigen presentation pathway. MHC class II molecules assemble in the ER with the invariant chain. The class II-associated invariant chain peptide (CLIP) segment of invariant chain occupies the MHC class II groove and prevents binding of irrelevant peptides in the ER. The N-terminal cytoplasmic domain of invariant chain contains a targeting motif that directs the invariant chain–MHC class II complex to the endosomal–lysosomal compartment. In this low-pH compartment, invariant chain is proteolytically degraded down to the CLIP segment. HLA-DM binds to MHC class II–CLIP complexes and catalyzes the exchange of CLIP with peptides generated from endocytosed proteins by limited proteolysis. MHC class II-bound peptides have a long half-life at the neutral pH at the cell surface, resulting in peptide display for extended periods of time.

peptide-binding site. A critical cleavage is performed by the cysteine protease cathepsin S in bone marrow-derived antigen-presenting cells and the related cathepsin L enzyme in thymic cortical epithelial cells.[41,42]

The exchange of the invariant chain remnant CLIP with other peptides is catalyzed by the HLA-DM (DM) protein. DM is a heterodimer with sequence similarity to MHC class II proteins but cannot bind peptide.[43] Rather, it interacts with a lateral surface of MHC class II proteins and destabilizes the MHC class II-bound CLIP peptide.[44] DM also facilitates the dissociation of other peptides and this editing function favors the display of peptides at the cell surface that have a long half-life.[45] The generation of peptides and their loading occur at an acidic pH, and DM is active only in this pH range. The acidic pH in the peptide-loading compartment favors exchange, whereas the high stability of peptide–MHC complexes at a neutral pH favors long-lived display at the cell surface.[46] In fact, high-affinity peptides have exceptionally long half-lives, of several days to weeks, and the half-life of peptides is thus similar to those of the MHC proteins themselves.[47] T-cell epitopes frequently contain protease cleavage sites, and limiting proteolysis can therefore enhance presentation. Key antigen-presenting cells, such as dendritic cells and B cells, have lower levels of lysosomal proteases compared to macrophages that are specialized in rapid pathogen destruction.[48]

Presentation of Lipid Antigens by CD1 Proteins

In addition to the peptide-based surveillance system described above, T cells can also recognize pathogens depending on the recognition of lipid antigens presented by CD1 molecules. The CD1 heavy chains have sequence homology to MHC class I molecules and also assemble with β2-microglobulin. However, the CD1 genes (CD1a, CD1b, CD1c, and CD1d) are nonpolymorphic, which can be explained by the fact that microorganisms cannot readily evade recognition by modification of the lipids presented by CD1 proteins.[49] The ligand-binding site of CD1 molecules is adapted to the presentation of these ligands: it is considerably more hydrophobic than the binding site of MHC class I and class II proteins and also substantially wider.[50] Two large pockets can accommodate the two acyl chains of presented lipids whereas polar groups are positioned in the center for recognition by the TCR. The TCR shows exquisite specificity for these polar groups, such as sugar groups of glycolipids, whereas the length of the acyl chains accommodated in the pockets can vary considerably.[51] CD1 molecules acquire microbial lipid ligands in the endosomal pathway: following biosynthesis they first travel to the cell surface and are then endocytosed through recognition of a cytosolic targeting motif. Different CD1 molecules sample distinct subcompartments of the endosomal–lysosomal pathway and present different microbial lipids.[52] How do lipid groups enter the CD1 groove? Lipid loading is performed in the endosomal–lysosomal pathway by saposins, which are specialized lipid transfer proteins that extract lipids from membranes through specific interaction with their polar head groups (Fig. 12–5). The saposins A–D are generated by proteolytic cleavage of prosaposin and form small homodimers. Analogous to DM, saposins can perform editing of CD1-bound lipids and thus promote presentation of those lipids that form the most stable complexes with CD1 proteins.[53,54] Lipid antigens have been identified for *Mycobacterium tuberculosis*, including mycolic acid and glucose monomycolate, which are presented by human CD1b.[49,55]

MOLECULAR MECHANISM OF T-CELL RECOGNITION

Cloning of the T-Cell Receptor Genes

The physical identity of the TCR was a major question in immunology in the 1970s and early 1980s. Two general approaches were pursued, the generation of T cell-specific mAbs for purification and sequencing at the protein level and the isolation of T cell-specific cDNAs. The genetic studies searched for genes expressed in T cells but not B cells and that are rearranged in T cells to generate receptor diversity. The group led by Dr Mark Davis used subtractive hybridization to remove the cDNAs expressed in both T and B cells, whereas the group led by Dr Tak Mak performed differential hybrid-

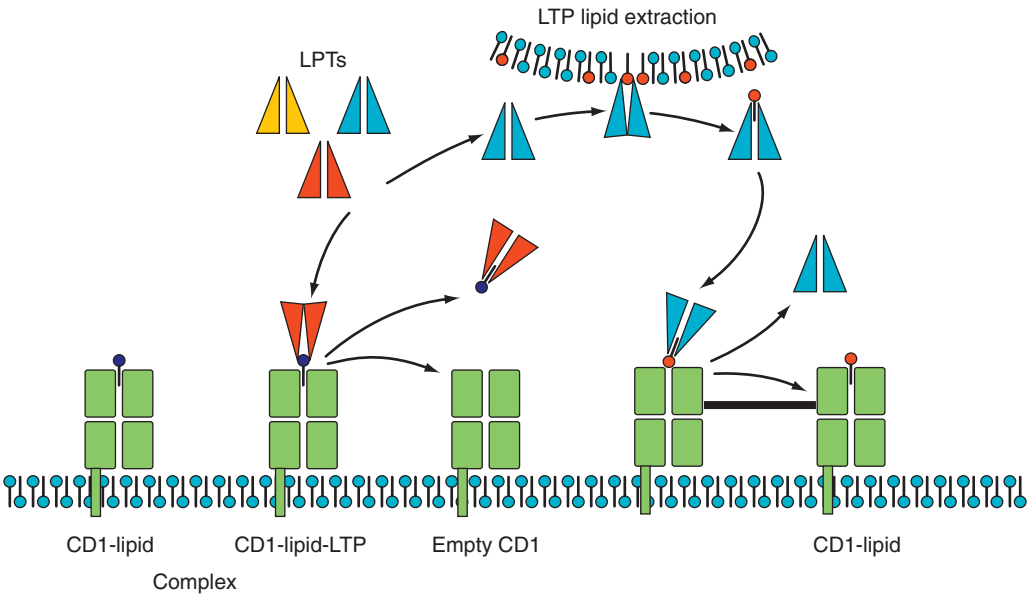

Figure 12–5 Loading of lipid antigens into the CD1 binding site by saposins. The CD1 proteins present lipid and glycolipid antigens to the T-cell receptor. CD1 molecules are targeted to the endosomal–lysosomal pathway, where they acquire exogenous lipid antigens. Lipid loading is facilitated by saposins, small homodimeric proteins that extract lipids from biological membranes. Reprinted from *Science* (53).

ization of T-cell cDNA libraries with T-cell and B-cell mRNA. These studies led to the identification of the TCR β chain in 1984, which was soon followed by isolation of the TCR α chain.[56,57] The availability of both TCR chains enabled an important experiment: transfection of both TCR chains reconstituted both peptide and MHC specificity, unequivocally demonstrating that a single receptor is sufficient for recognition of both components.[58]

These studies demonstrated that the TCR is a member of the immunoglobulin (Ig) superfamily and that each TCR chain possesses a variable and a constant domain with an Ig fold. Diversity is introduced by a molecular mechanism similar to that of antibodies, the rearrangement of variable, diversity, and joining (VDJ) segments. These junctions form the CDR3 loops that are critical for peptide recognition, as described in Structural Basis of TCR Recognition. The V domains encode the CDR1 and CDR2 loops that contribute to MHC recognition. The TCR β chain possesses greater junctional diversity than TCR α because junctions are created by the V, D, and J segments compared to only V and J segments for TCR α. However, a larger number of J segments are present in the TCR α locus, compensating for the absence of the D region.[59]

Further study by the laboratories of Drs Susumu Tonegawa and Michael Brenner led to the identification of a second TCR, the γδ TCR, which is expressed by a distinct T-cell subset.[60,61] γδ T cells have a different tissue distribution than αβ T cells, primarily the epithelial layer of the skin and the mucosal epithelium of the respiratory, intestinal, and reproductive tracts. Their anatomical distribution suggests a specialized role at sites of pathogen entry, but less is currently known about their ligands than for αβ T cells.[62]

The Signaling Subunits of the TCR

Inspection of the TCR α and β chain sequences demonstrated that the cytoplasmic tails are very short and thus not responsible for initiation of signaling. How are activation signals communicated into a T cell? Efforts to identify the TCR based on the monoclonal antibody strategy described above led to the identification of T cell-specific proteins that physically associate with the TCR, the CD3γ, δ, ε, and ζ chains (Fig. 12–6).[63] The CD3γ, δ, and ε chains each contain a single extracellular Ig domain and cytoplasmic domains with an immunoreceptor tyrosine-based activation motif (ITAM). Each ITAM contains two YxxL/I motifs with a tyrosine at the first position and an aliphatic residue (leucine or isoleucine) at the fourth position. These tyrosines are phosphorylated by Lck at an early stage of TCR triggering.[64] The CD3γ, δ and ε chains form two heterodimers, CD3γε and CD3δε. The ζ chain only has a short extracellular domain of nine amino acids, but its cytoplasmic domain is longer and carries three ITAMs. A TCR–CD3 complex is thus composed of a single TCR heterodimer, the CD3δε and CD3γε dimers as well as the disulfide-linked ζζ dimer (see Fig. 12–6).[65,66] Such a complex thus has a total of 10 ITAMs, six in the ζζ dimer and two in each CD3 dimer. The large number of ITAMs may be important for sensitive recognition of peptide–MHC complexes.

Molecular Mechanism for the Assembly of the TCR With Its Signaling Subunits

Inspection of the sequences of the TCR and its signaling subunits revealed an unusual feature: there are three basic residues in the transmembrane domains of the TCR, two in the TCR α chain and one in the TCR β chain, as well as a pair of acidic residues in the transmembrane domains of each of the dimeric signaling subunits. Mutagenesis experiments demonstrated that loss of even a single basic TCR transmembrane residue resulted in loss of surface expression, reflecting the presence of important protein–protein interactions in the membrane.[67] Further studies showed that each of the basic TCR transmembrane residues serves as an attachment site for a particular signaling module: the lysines in the transmembrane domains of TCR α and TCR β interact with CD3δε and CD3γε, respectively, whereas the arginine in the transmembrane domain of TCR α interacts with the ζζ dimer.[68] In each case, both acidic transmembrane residues are required for the interaction with a single basic residue, and the structure of the ζζ transmembrane dimer showed that the two aspartic acids form a single structural unit at the dimer interface.[69] The interaction between these basic and acidic residues stabilizes the receptor because exposure of these polar residues to the hydrophobic interior of the lipid bilayer would be energetically highly unfavorable.[68] This membrane-based assembly mechanism also serves a quality control purpose: unassembled subunits are retained in the ER and rapidly degraded.[70] Export from the ER requires masking of these polar residues at protein–protein interfaces.

Structural Basis of TCR Recognition

Each T cell expresses a distinct rearranged TCR, analogous to B cells that each express one particular BCR. The rearrangement process

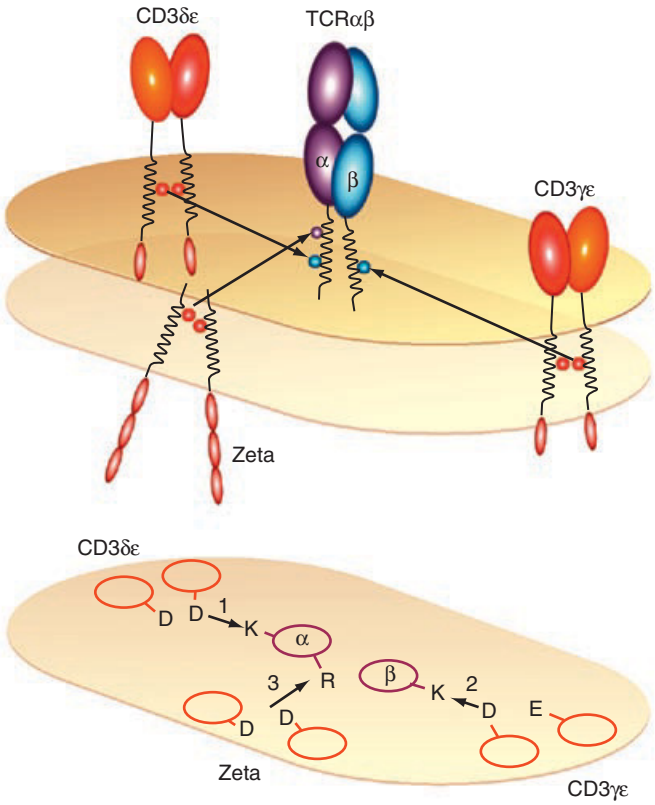

Figure 12–6 Assembly of the T-cell receptor (TCR) with its signaling subunits. The TCR heterodimer is responsible for peptide–major histocompatibility complex (MHC) recognition and assembles in the ER with three dimeric signaling modules, CD3δε, CD3γε, and ζζ. The CD3γ, δ, and ε chains have single extracellular Ig domains and a single immunoreceptor tyrosine-based activation motif (ITAM) motif in the cytoplasmic domain. The ζ chain has a short extracellular domain and a large cytoplasmic domain with three ITAM motifs. There are thus a total of 10 ITAMs in a TCR–CD3 complex that can be phosphorylated following TCR triggering. Each of the dimeric signaling modules carries a pair of acidic residues in the transmembrane domains (red circles) that interact with one particular basic residue (blue circle) in the TCR transmembrane domains. The transmembrane lysine (K) residues of TCR α and TCR β serve as the interaction sites for CD3δε and CD3γε, respectively. The ζζ dimer interacts with the transmembrane arginine (R) residue of TCR α. The lower part of the figure represents a section through the membrane that shows the three-helix interactions required for each of the three assembly steps.

generates a highly diverse TCR repertoire than can recognize virtually any MHC-bound peptide. Infection induces clonal expansion of T cells with specificity for peptides from the respective pathogen, and the maintenance of a subpopulation of these cells over many years represents the cellular basis of T-cell memory. In contrast to antibodies that can be generated against virtually any molecular shape, TCR recognition is limited to recognition of MHC-bound peptides or CD1-bound lipids. How are both peptide and MHC components recognized by the TCR? This question was answered in 1996 by the first crystal structures of TCRs bound to peptide–MHC class I complexes (Fig. 12–7).[71,72] In both structures, the TCR is centered over the peptide–MHC surface in a diagonal orientation that covers most of the MHC-bound peptide. This diagonal orientation appears to maximize the interaction with the MHC-bound peptide and positions the most variable sequence elements of the TCR, the CDR3 loops of TCR α and β chains, over the center of the MHC-bound peptide. The two CDR3 loops form a pocket in the center of the TCR surface that contacts peptide–MHC and this pocket can accommodate a side chain of the peptide. The germline-encoded CDR1 and CDR2 loops are less diverse in sequence and contact the two MHC helices. In all structures that have been determined to date, the CDR1 and CDR2 loops of the TCR α chain are positioned over the α2 helix of the MHC class I molecule, but the precise mechanism for this apparently conserved position is not yet known. The CDR1 loops can also contribute to peptide recognition: the CDR1α loop is positioned close to the peptide N-terminus and the CDR1β loop close to the peptide C-terminus. Four of the six TCR loops can thus read out the side chain specificity of the bound peptide.

Coreceptors and Costimulatory Molecules

The CD8 and CD4 molecules serve as coreceptors for MHC class I and class II restricted T cells, respectively (see Fig. 12–2). Approximately two-thirds of peripheral T cells are CD4 positive and one-third CD8 positive. The CD4 and CD8 molecules represent coreceptors because they bind to the same peptide–MHC unit as the TCR: the TCR binds to the membrane-distal peptide-binding site whereas the coreceptors engage the membrane-proximal Ig domains (see Fig. 12–2). The two coreceptors have a similar function but differ in their organization: CD4 is a single-chain membrane protein with four extracellular Ig domains, and CD8 is a dimer (CD8αβ or CD8αα) with an N-terminal Ig domain and a long extracellular stalk region that is highly glycosylated. The cytoplasmic domains of both CD4 and CD8 bind the tyrosine kinase Lck. The coreceptors thus recruit this Src kinase to the TCR for phosphorylation of the cytoplasmic ITAM domains. The coreceptors are not essential for T-cell activation but substantially increase the sensitivity of TCR activation, because lower peptide concentrations are required for coreceptor-positive T cells compared to coreceptor-loss mutants.[21]

TCR recognition is not sufficient for full T-cell activation. In fact, stimulation of T cells solely through the TCR leads to a state of unresponsiveness, referred to as T-cell anergy. Anergic T cells fail to respond to secondary stimulation with antigen-pulsed antigen-presenting cells, but retain the ability to proliferate in response to IL-2.[73] This observation led to the discovery of the costimulatory receptors, and CD28 was identified as the first member of this group. CD28 binds to CD80 and CD86 on antigen-presenting cells, and expression of these CD28 ligands is upregulated by activated dendritic cells and B cells. The cytoplasmic domains of the CD28 molecule carry a tyrosine-based phosphorylation motif that recruits the p85 subunit of phosphoinositol-3 kinase. Signaling through this receptor induces phosphorylation of c-fos and c-jun, which form the AP-1 transcription factor that binds to the IL-2 promoter. AP-1 also induces expression of the antiapoptotic Bcl-xL gene. CD28 is expressed by resting T cells and thus serves as an important costimulatory receptor of naïve T cells.[74] T-cell activation induces expression of CTLA-4, which also binds to CD80 and CD86, but induces a negative signal. CTLA-4-deficient mice die at a young age because of widespread inflammation, demonstrating the importance of this inhibitory pathway.[75] Blockade of this inhibitory pathway has shown promise in enhancing T-cell responses to tumors, in particular when the CTLA-4 antibody is administered together with a vaccine that induces an antitumor T-cell response.[76]

The inducible costimulatory receptor ICOS represents a third member of this family. In contrast to CD28, it is not constitutively expressed and serves a different function. ICOS-deficient mice have a defect in T cell-dependent antibody production by B cells, which is explained by the fact that stimulation through ICOS by ICOS-L enhances T-cell production of IL-10 and IL-4. Signaling through ICOS also stabilizes the mRNA for CD40L that interacts with the CD40 molecule on B cells.[77] These signals are critical for B-cell isotype switching and germinal center formation (see Chapter 11).

The Immunological Synapse

T-cell activation results in the formation of a highly organized structure at the interface between the interacting T cell and the antigen-presenting cell, the immunological synapse (Fig. 12–8). T cells are

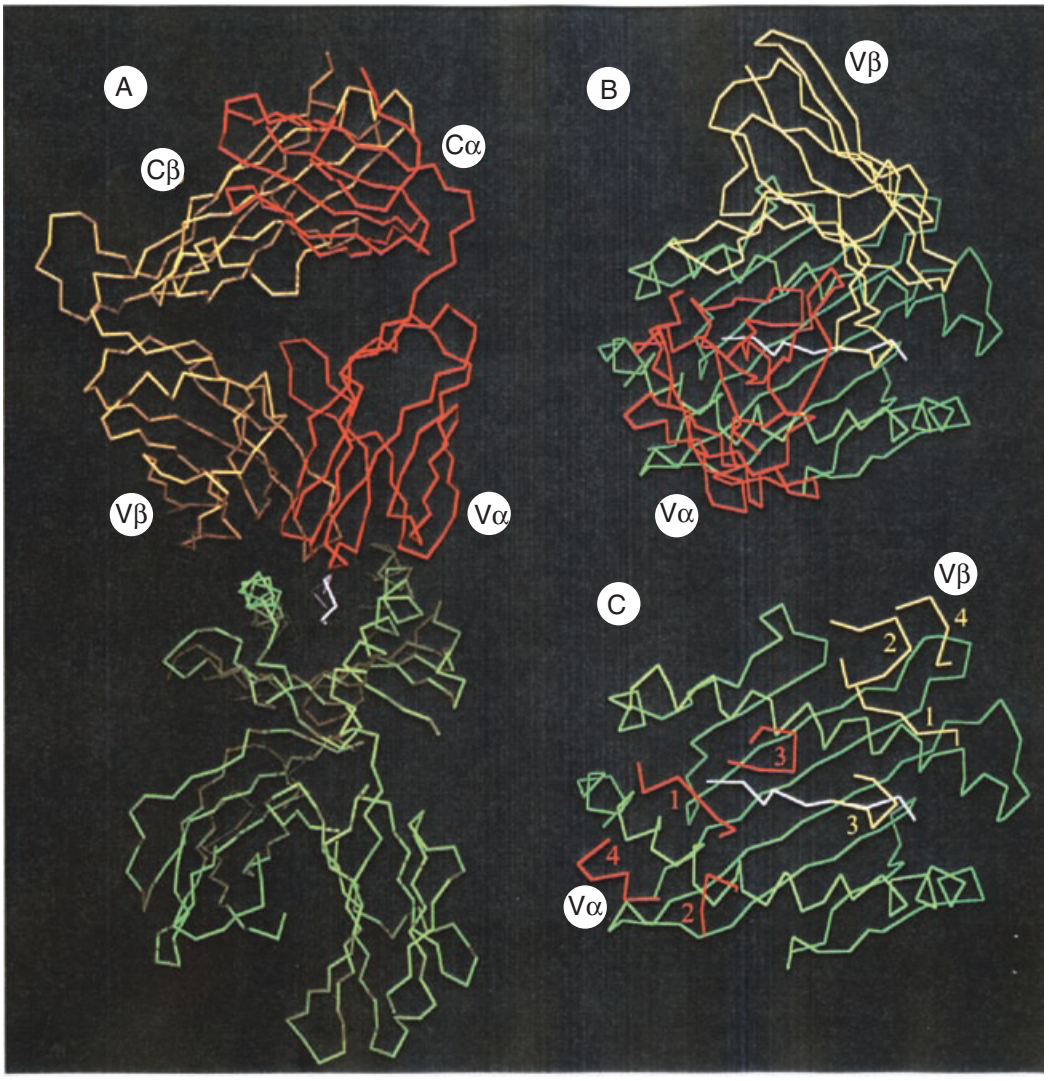

Figure 12–7 Structure of the T-cell receptor (TCR) bound to peptide–major histocompatibility complex (MHC). The TCR binds in a diagonal orientation over the surface created by the peptide and the long α helices of the MHC molecule that flank the bound peptide. This TCR position maximizes the interaction with the peptide. **A**, Overview of the complex composed of the TCR α and β chains (red and yellow, respectively) and the MHC molecule (green) with the bound peptide (white). **B**, The diagonal orientation of the TCR Vα and Vβ domains over the peptide–MHC surface, shown as a top view from the perspective of a T cell. **C**, Position of the TCR loops on the peptide–MHC surface. The hypervariable loops of the TCR α and β chains (CDR3 loops, labeled as 3) are located over the center of the peptide–MHC surface. The V-gene encoded CDR1 and CDR2 loops (labeled as 1 and 2, respectively) contact the MHC helices. The CDR1 loops can also contact the terminal segments of the peptide.

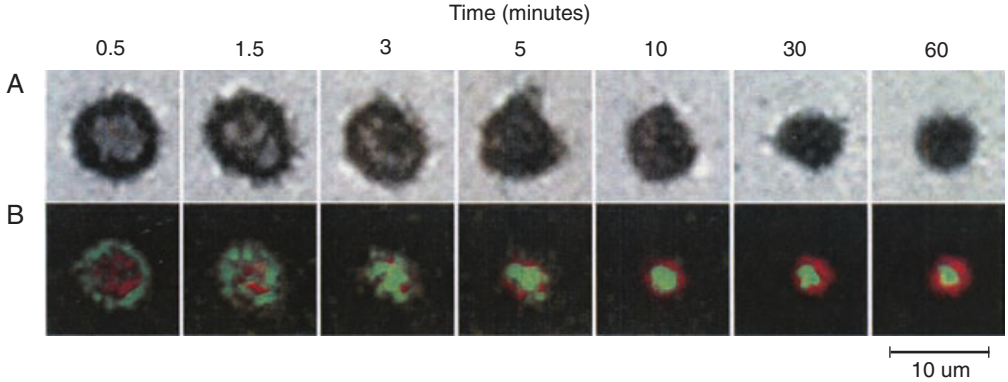

Figure 12–8 The immunological synapse. Recognition of agonist peptide–major histocompatibility complexes (MHCs) leads to the formation of a highly organized interface between the T cell and the antigen-presenting cell, termed the immunological synapse. Peptide–MHC complexes and the adhesion molecule ICAM-1 are labeled with green and red fluorophores, respectively. During initial contact, the peptide–MHC complexes (and corresponding TCRs) are located at the periphery of the interface. The peptide–MHC complexes are then transported into the center of the synapse and surrounded by a ring of ICAM-1 in the "mature" immunological synapse. The upper set of images shows the contact area of the T cell with the lipid bilayer. Reprinted from *Science*.[78]

highly motile and continuously crawl over the surface of antigen-presenting cells. Recognition of agonist peptide–MHC represents a stop signal and leads to the formation of an organized interface with the antigen-presenting cell. During initial contact, the adhesion molecule LFA-1 is located at the center of the interface and engaged TCRs at the periphery. During the next 5 to 10 minutes, this pattern reverses owing to transport of the TCR to the center. A mature immunological synapse is thus characterized by densely clustered TCRs in the center, surrounded by a ring of LFA-1 molecules.[78,79] What is the function of the immunological synapse? Analysis of early signaling events demonstrated the formation of TCR microclusters containing 10 to 20 molecules in the periphery, which are transported within approximately 2 minutes to the synapse center. These microclusters are sites of active signaling based on staining with phosphotyrosine antibodies and contain a number of signaling molecules critical for T-cell function. When these microclusters merge into the central TCR cluster, they are dephosphorylated by the CD45 phosphatase and marked for internalization and degradation by the E3 ubiquitin ligase Cbl. The central TCR cluster thus serves as the site of TCR dephosphorylation and internalization. However, microclusters are continuously formed in the periphery, resulting in sustained TCR signaling.[80]

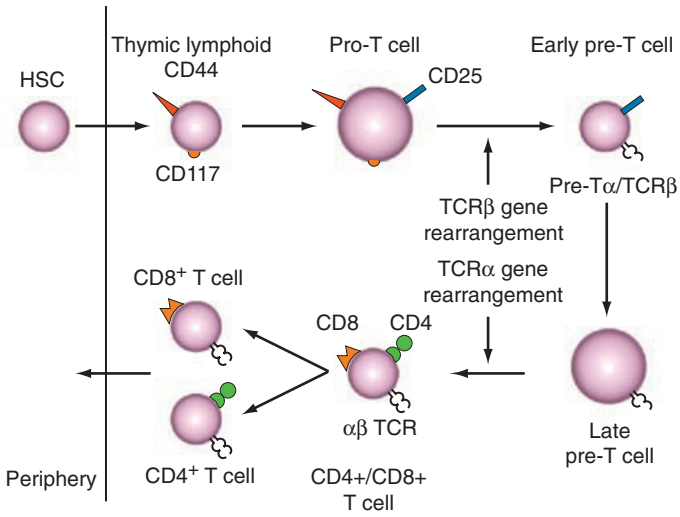

Figure 12–9 Maturation of hematopoietic stem cells in the thymus. (TCR, T-cell receptor.)

Sensitivity of TCR Recognition

Characterization of MHC-bound peptides with mass spectrometry techniques has demonstrated that a given MHC protein can bind several thousands of different peptides.[81] A given TCR has to recognize a particular peptide–MHC complex within a large number of other complexes, even though the complex of interest is present at a low density. Imaging experiments with fluorescently labeled peptides have shown that TCR recognition of only a few peptides is sufficient to induce calcium flux, and that maximum calcium flux is induced by approximately 10 to 20 peptide–MHC ligands.[82] How do T cells achieve such a level of sensitivity? A given TCR not only recognizes one particular agonist peptide–MHC complex but also other endogenous peptide–MHC complexes. The low-affinity interactions with the endogenous peptide–MHC complexes are not sufficient by themselves to trigger T-cell activation, but can amplify the signal induced by agonist peptide–MHC complexes that bind with higher affinity to the TCR.[83] The large number of ITAMs in the cytoplasmic domains of the TCR signaling subunits also contributes to the sensitivity of TCR signaling.

Mechanisms of Positive and Negative Selection of T Cells During Development in the Thymus

A system with the capability to respond to virtually any MHC-bound peptide obviously has the potential to do significant damage owing to attack on self-tissues. Elaborate mechanisms have evolved to eliminate the majority of self-reactive T cells during development in the thymus. Developing thymocytes (Fig. 12–9) first rearrange the TCR β chain, and the functionality of this rearrangement is tested by pairing with a surrogate TCR α chain, the pre-TCR α (pTα) chain.[84] The pTα chain only possesses a single extracellular Ig domain and can thus not form a TCR surface capable of recognizing peptide–MHC. However, it carries the two basic transmembrane residues required for interaction with CD3δε and ζζ and thus enables assembly of complete pre-TCR–CD3 complexes that signal constitutively when they reach the cell surface. preTCR expression prevents rearrangement of the second TCR β locus (allelic exclusion) and allows the cell to survive and rearrange the TCR α locus. Thymocytes that successfully rearrange both TCR loci become "double positive" T cells that express both the CD4 and CD8 coreceptor. Expression of an intact, mature TCR enables the first major selection step referred to as "positive selection." Positive selection requires proper engagement of peptide–MHC complexes on the surface of thymic epithelial cells, and the majority of thymocytes die at this step. The developing T cells then become CD4 or CD8 "single positive" T cells and migrate into the thymic medulla, where they face the second test, referred to as "negative selection."[85] At this stage, T cells are tested for their autoimmune potential and T cells whose TCR binds with too high an affinity to self-peptide–MHC complexes on thymic medullary thymic epithelial cells and dendritic cells die by apoptosis. Thymic medullary epithelial cells express a large variety of peripheral tissue antigens in a promiscuous manner, an unusual property that is in part controlled by the transcription factor Aire.[86] The importance of this pathway for the maintenance of tolerance is shown by the multiorgan autoimmune syndrome in both humans and mice with a defect in Aire expression.[87,88] Proper T-cell development in the thymus thus relies on TCR crossreactivity: T cells that weakly react with self-peptide–MHC complexes are positively selected whereas T cells that react too strongly are deleted. Weak recognition of thymic self-peptide–MHC complexes may set the appropriate recognition threshold for mature T cells and establish the intensity at which endogenous self-peptide–MHC complexes can amplify signaling induced by agonist peptide–MHC complexes without a resulting autoimmunity hazard.

Polyspecificity of TCR Recognition

The finding that endogenous peptides can contribute to TCR activation implies that a given TCR does not have strict specificity for a single peptide. This can be understood by considering the diversity of possible peptide sequences in a 9-mer: $20^9 = 5.12 \times 10^{11}$ sequences. For a given peptide, the precursor frequency in the naïve T-cell pool is in the range of $1:10^5$ to $1:10^7$ T cells, and comparison of the two numbers suggests that a given T cell can recognize a large number of different peptides. This conclusion is supported by experiments with peptide libraries, which demonstrated that a T-cell clone can be stimulated by peptide mixtures in which only one position carried a specified residue whereas all other positions were synthesized with amino acid mixtures. The concentration of an individual sequence in these libraries is thus far too small for activation, implying the existence of a large number of stimulatory sequences.[89] Nevertheless, T-cell activation is highly specific because minor changes in a given T-cell epitope can result in loss of recognition. The observed specificity and crossreactivity can be reconciled: T cells are specific because they recognize a very small subset of peptides but nevertheless crossreactive because the number of peptides is very large. This finding has implications for the pathogenesis of autoimmune diseases because it raises the possibility that self-reactive T cells can be activated during an infection by a cross-reactive T-cell epitope. A number of examples

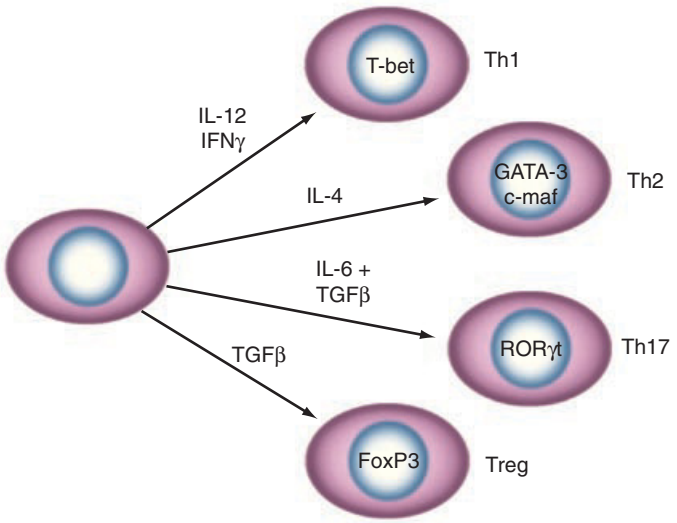

Figure 12–10 Cytokine-dependent differentiation of T cells into distinct subsets. CD4 T cells can differentiate into distinct functional subsets, IFNγ-producing Th1 cells, IL-4-producing Th2 cells, IL-17-producing Th17 cells, and regulatory T cells. The transcription factors that are required for differentiation into these subsets are indicated over the nucleus of the respective cell.

have been identified in which self-reactive T cells from patients with autoimmune diseases were activated by viral or bacterial peptides.[90] The majority of these peptides have only limited sequence similarity with the self-peptide.

T CELL-MEDIATED IMMUNE RESPONSES

CD4 T-Cell Subsets: Th1, Th2, and Th17

Activation of naïve CD4 T cells leads to their differentiation into distinct subsets, depending on the cytokine milieu, that serve specialized roles in the immune response (Fig. 12–10). Early work demonstrated that naïve CD4 T cells can differentiate into either IFNγ-producing cells (termed Th1 cells) or IL-4-producing T cells (Th2 cells).[91] Th1 cells are important in providing immunity to intracellular pathogens, such as viruses, intracellular bacteria, and parasites, whereas Th2 cells regulate immunity to extracellular pathogens through interaction with B cells. Th1 differentiation is favored by IL-12 and IFNγ produced by dendritic cells and macrophages, whereas Th2 differentiation is favored by IL-4. These cytokines also inhibit differentiation into the opposing subset: IL-4 blocks Th1 differentiation and IFNγ Th2 differentiation. The functional properties of Th1 and Th2 cells are controlled by key transcription factors, T-bet for Th1 as well as GATA-3 and c-maf for Th2 cells.[92,93] Expression of T-bet in established Th2 cells results in reversal to a Th1 phenotype, demonstrating the importance of this transcription factor in the biology of Th1 cells. These T-cell subsets also play important roles in particular disease states. For example, allergic diseases and asthma are characterized by accumulation of large numbers of allergen-specific Th2 cells that induce production of allergen-specific IgE antibodies, whereas Th1 cells can predominate in chronic inflammatory diseases.

Recent work has established the presence of another important subset of CD4 T cells that produce IL-17, a proinflammatory cytokine.[94] Such T cells play an important role in the pathogenesis of autoimmune diseases, as shown by studies in the experimental autoimmune encephalomyelitis (EAE) model of multiple sclerosis. Differentiation into this subset requires the coordinated production of two cytokines, IL-6 and TGFβ.[95] IL-23 also plays an important role in the biology of these cells: it is not required for the initial differentiation of Th17 cells, but is essential for their expansion and survival. As a consequence, IL-23-deficient mice are resistant to the induction of EAE. IL-17 induces the production of multiple chemokines and recruitment of other cells of the immune system to sites of inflammation.

CD8 T Cells

CD8 T cells play a central role in protection against infectious agents by killing of infected cells following recognition of microbial peptides presented by MHC class I molecules on the surface of target cells. Major efforts are also under way to harness tumor-specific CD8 T cells for the treatment of cancer. The main pathway for elimination of virus-infected cells is granule exocytosis (Fig. 12–11). After target cell recognition, cytotoxic granules are released into the immunological synapse formed between the killer cell and its target. The granules contain two membrane-perturbing proteins, perforin and granulysin, and a family of serine proteases known as granzymes, complexed with the proteoglycan serglycin. The perforin pore gives granzymes access to the cytosol of the target cells where they induce cell death pathways.[96]

T-Cell Expansion in Response to Infection and T-Cell Memory

The study of T-cell responses to infectious agents has been greatly advanced by the development of techniques that permit quantitative flow cytometric identification of responding T-cell populations. Particularly important has been the introduction of peptide–MHC tetramers as a tool for the visualization of T cells with defined specificity. What are tetramers? The TCR binds with low affinity to peptide–MHC and the off rate is too fast ($t_{1/2}$ of approximately 10 seconds) for TCR labeling with monomeric peptide–MHC complexes. However, the avidity of binding can be substantially enhanced by creation of multivalent ligands. Drs John Altman and Mark Davis created multivalent versions of peptide–MHC complexes by attaching a peptide tag that can be selectively biotinylated to the C-terminus of the MHC class I heavy chain.[97] This approach enables assembly of tetramers through the four biotin-binding sites of streptavidin. Fluorescent tetramers can be used to selectively label T cells with defined peptide–MHC specificity, regardless of their cytokine production profile, and to study the kinetics of T-cell expansion and contraction following viral infection.

T cells against a particular microbial peptide are present at a very low frequency in the naïve T-cell repertoire (approximately $1:10^5$ to $1:10^6$ T cells). Infection triggers massive expansion of these cells and a large fraction of all CD8 T cells can be pathogen-specific at the peak of expansion. The CD8 T-cell response against a viral pathogen can be divided into three distinct phases, as shown by infection of mice with lymphocytic choriomeningitis virus.[98] During the first phase, massive expansion of virus-specific CD8 T cells occurs and 30% to 50% of all CD8 T cells can be specific for a single immunodominant viral peptide on day 8 following infection. These T cells have classical effector properties: they can kill infected target cells by release of granules containing granzyme and perforin, produce cytokines such as IFNγ and TNFα and migrate to nonlymphoid tissues. T-cell proliferation is greatest between days 3 to 5 following infection and T cells increase in frequency approximately 500-fold (9 divisions) during this time window with an estimated doubling time of 6 to 8 hours. In the second contraction phase that follows clearance of the pathogen, 90% to 95% of these effector T cells die by apoptosis. The final phase (after day 30) represents the establishment and maintenance of CD8 T-cell memory. IL-7 provides important survival signals during effector-to-memory cell differentiation through the expression of Bcl-2. Precursors of memory CD8 T cells can be identified within the effector cell population based on high-level expression of the IL-7Rα chain. Memory CD8 T cells rapidly acquire effector function with reexposure to the pathogen and expand rapidly.

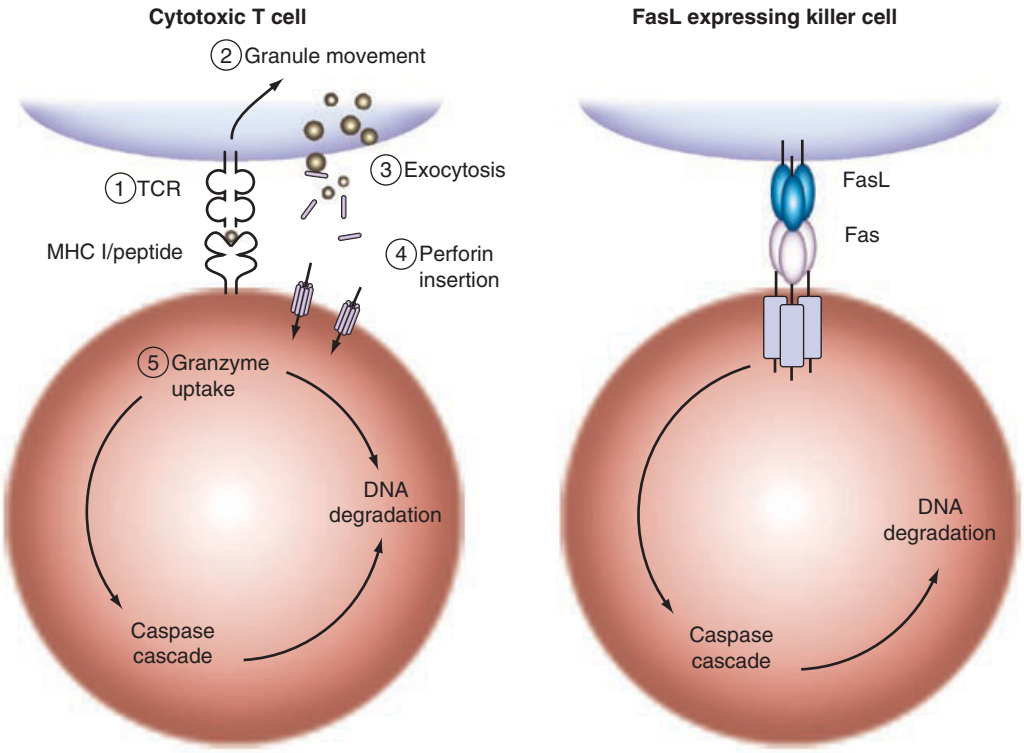

Figure 12–11 Apoptosis can be caused by granule exocytosis or Fas–Fas ligand (FasL) pathways. After the interaction of the T-cell receptor (TCR) with major histocompatibility complex (MHC) class I–peptide, granules containing perforin and granzymes localize toward the target cells and are released. Perforin inserts into the plasma membrane, and granzymes move into the target cell. Perforin and granzyme act synergistically to activate the caspase cascade, resulting in apoptosis. Binding of FasL to Fas also activates the caspase cascade, resulting in apoptosis.

Memory CD8 T cells persist for many years at relatively constant numbers owing to homeostatic proliferation that compensates for cell loss. They do not require the continued presence of antigen or expression of MHC molecules and instead depend on the cytokines IL-7 and IL-15; IL-7 promotes their survival and IL-15 induces slow homeostatic proliferation. Memory T cells and B cells provide protective immunity for decades and the rapid and specific response that is induced following reexposure to the pathogen is the basis for vaccination.[99] Vaccination enabled global eradication of smallpox, one of the major achievements of medicine in the past century.

Regulatory T Cells

How are T cell-mediated immune responses regulated? This question had posed a long-standing problem in immunology because it had been very difficult to define precise molecular markers for regulatory T cells. A major breakthrough in this field came when *FoxP3* was identified as the defective gene in a human X-linked multiorgan autoimmune disease.[100] *FoxP3* also represents the defective gene in the Scurfy mouse strain which is characterized by hyperactivation of T cells and overproduction of inflammatory cytokines. Introduction of the *Foxp3* gene into naïve T cells induces a regulatory T-cell (Treg) phenotype and program: these cells express CD25 (the IL-2R α chain), CTLA-4, and GITR and are able to inhibit the activation of other T cells.[101,102] FoxP3 thus represents a key transcription factor for Treg differentiation. IL-2 plays a critical role in the biology of these cells: Tregs do not synthesize IL-2 and instead compete with effector T cells for IL-2 present in the local microenvironment through their high-affinity IL-2 receptor. IL-2 also provides an important signal for production of IL-10 by Tregs, a cytokine that blocks Th1 and Th2 responses. These findings explain why IL-2- and CD25-deficient mice develop a severe inflammatory disease and why neutralization of IL-2 can precipitate autoimmune disease.[103,104] The definitive identification of these regulatory T cells now opens the door to the development of specific therapies for the treatment of autoimmune diseases, allergies, and transplant rejection. Tregs induce local immune suppression, and Tregs with a single specificity are therefore sufficient to inhibit a polyclonal T-cell response by both CD4 and CD8 T cells in a given organ. T cells specific for a myelin peptide could thus inhibit the local immune response in the CNS in multiple sclerosis patients without affecting immune responses at other sites. Furthermore, inhibition of Treg activity at the time of immunization may be useful for enhancement of T-cell responses against tumors.

CHAPTER 13

NATURAL KILLER CELL IMMUNITY

Don M. Benson, Jr. and Michael A. Caligiuri

INTRODUCTION

Natural killer (NK) cells are large granular lymphocytes comprising about 10% to 15% of the peripheral circulation.[1,2] First characterized by their ability to lyse targets independent of any prior activating or initiating stimuli,[3] NK cells are a critical cellular component of the innate immune system. In contradistinction to acquired immunity, the innate immune system functions as first line defense, always ready to mount an immediate antigen-independent immune response. Passive components include opsonins, lysozyme and phospholipases found at barriers between host and outside environment. Cellular components of innate immunity include neutrophils, macrophages, eosinophils, and NK cells. In addition, NK cells secrete cytokines that help to marshal and shape the innate and adaptive immune response to infection and malignant transformation. There has been a recent surge of interest in NK cells as new discoveries in both the laboratory and the clinic have characterized the crucial contributions of NK cells in shaping the early immune response.[4] NK cells play a key role in maintaining host defense as exemplified in human NK cell deficiency syndromes (which carry increased susceptibility to overwhelming viral, intracellular, and atypical mycobacterial infections),[5] and animal models of NK cell deficiency (eg, such mice are particularly susceptible to developing cancer).[6,7] The present chapter will review the current understanding of basic NK cell biology, the role of NK cells in human diseases, and the recent clinical applications of NK cells in cancer therapy.

FUNDAMENTAL BIOLOGY

NK Subsets

NK cells are phenotypically recognized by surface expression of CD56 (also called neural cell adhesion molecule, NCAM) and the absence of the T-cell specific surface antigen CD3 as well as the T cell receptor, TCR.[8,9] Based on the intensity of CD56 surface expression, two functional subsets (so called $CD56^{bright}$ and $CD56^{dim}$) of NK cells may be discriminated from one another. $CD56^{dim}$ NK cells comprise 85% to 90% of the NK cells in peripheral circulation and are potent mediators of cytotoxicity. Ten percent to 15% of NK cells in the circulation are $CD56^{bright}$ and upon activation, this subset is capable of robust cytokine and chemokine production.[2] Fig. 13–1 graphically represents the NK subsets described below, and Table 13–1 summarizes major surface antigens associated with each NK cell subset.

$CD56^{dim}$ NK Cells

$CD56^{dim}$ NK have exquisite natural cytolytic properties, being able to kill infected as well as tumor cell targets without prior sensitization.[10] They constitutively express the IL-2/15 receptor (R) β and common γ receptor chains, which together form a receptor complex through which cells may respond to stimulation by either IL-2 or IL-15.[11,12] $CD56^{dim}$ NK cells can lyse tumor cell targets through at least three distinct mechanisms. First, they can execute cytotoxicity through granule exocytosis of perforin and granzyme.[13,14] Second, cytotoxicity can be mediated through FasL and TRAIL associated with production of cytokines including IFN-γ, TNF-α, and GM-CSF.[15] Third, $CD56^{dim}$ NK cells can mediate antibody dependent cytotoxicity (ADCC) via the high density surface expression of CD16 (the FcγRIII receptor).[2,16] Freshly isolated, unstimulated $CD56^{dim}$ NK cells have intrinsically greater cytotoxicity against NK-sensitive targets such as the K562 cell line in vitro, compared to the $CD56^{bright}$ NK cells.[17]

Other antigens are differentially expressed by $CD56^{dim}$ NK cells and provide insight into their functional role in the immune response. For example, $CD56^{dim}$ NK cells also exhibit relatively high surface density expression of killer immunoglobulin-like receptors (KIR). NK cell KIR expression appears important in preventing autoimmunity and in surveying against malignant transformation.[16,18]

Both $CD56^{dim}$ and $CD56^{bright}$ NK cells express modest levels of the chemokine receptor CXCR3. However, in contrast to $CD56^{bright}$ NK cells, $CD56^{dim}$ NK cells display relatively abundant surface expression levels of CXCR1, CXCR4, and CX_3CR1.[19] CXCR1 binds IL-8, CXCR4 binds SDF-1. These cytokines are associated with local inflammatory response, for example, IL-8 levels are increased in the setting of acute viral infections,[20] and IL-8 and SDF-1 levels are increased with solid[21,22] and hematopoietic malignancies.[23,24] Thus, expression of these chemokine receptors allow NK cells to traffic to local areas of inflammatory response to mediate antiviral and antitumor activity.

$CD56^{bright}$ NK Cells

$CD56^{dim}$ NK cells, with their relatively high density expression of FcγRIII, NKR and KIR, constitutive cytolytic granules and limited proliferative capacity, likely represent the more cytotoxic subset of human NK cells. $CD56^{bright}$ NK cells, conversely play more of an immunoregulatory role. $CD56^{bright}$ NK produce a multitude of cytokines and chemokines, have a relatively high proliferative capacity, reside primarily in the parafollicular T cell rich region of secondary lymphoid tissue (SLT), and have modest cytolytic granules, KIR and FcγRIII expression (Table 13–1).[10] $CD56^{bright}$ NK cells are unique among cytotoxic effector cells in constitutive expression of the high affinity IL-2Rαβγ complex, making them responsive to picomolar concentrations of IL-2 released by activated T cells in the parafollicular T cell rich region of SLT.[25] As noted, $CD56^{bright}$ NK cells comprise only about 10% of the circulating NK population, but predominate almost to the exclusion of the $CD56^{dim}$NK subset in SLT.[2,26] This likely results from their selective expression of a number of receptors that assist in homing cells to and retaining cells in SLT (eg, CCR7 and CD62L).[10]

The ability of $CD56^{bright}$ NK cells to produce an abundant variety of cytokines and chemokines compared to the $CD56^{dim}$ subset likely relates more to the differential expression of both negative and positive regulators of cytokine/chemokine production and less to constitutive expression of cytokine-activating receptors. For example, $CD56^{bright}$ NK cells have little or no expression of two negative regulators of cytokine/chemokine production, namely SHIP-1 and HLX,[27,28] whereas $CD56^{dim}$ NK lack constitutive expression of a positive regulator of cytokines called SET.[29]

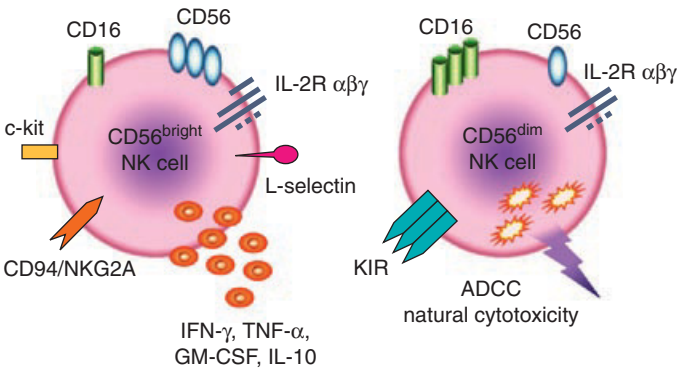

Figure 13–1 Simplified cartoon representation of natural killer cell subsets: CD56^{bright} cells have immunoregulatory function whereas CD56^{dim} cells have cytolytic function. ADCC, antibody-dependent cellular cytotoxicity; GM-CSF, granulocyte/macrophage-colony stimulating factor; IFN, interferon; IL, interleukin; KIR, killer immunoglobulin receptor; R, receptor; TNF, tumor necrosis factor. *(Adapted from Cooper MA, Fehniger TA, Caligiuri MA: The biology of human natural killer cell subsets. Trends Immunol 22:633, 2001.)*

The target cell on the left is spared, whereas the target cell on the right is lysed. *(Adapted from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: new biology and insights into the graft-versus-leukemia effect. Blood 100:1935, 2002.)*

NK DEVELOPMENT

A series of studies over the past 12 years has demonstrated that IL-15 is required for NK cell development in mouse and humans,[30,31] but until recently, there has been little known about where human NK cells develop. As with B cells and T cells, human NK cells are derived from CD34(+) hematopoietic stem cells in bone marrow (BM), however NK cell precursors in human BM have not been identified, suggesting that maturation may occur elsewhere.[2,32] Freud et al recently identified a CD34^{dim}CD45RA(+)$\alpha_4\beta_7{}^{bright}$ cell to be the only CD34(+) subset in SLT. Found within the parafollicular T cell rich region of SLT in the same region as the CD56^{bright} NK cell, this CD34^{dim}CD45RA(+)$\alpha_4\beta_7{}^{bright}$ cell can differentiate into a CD56^{bright} NK cell in the presence of IL-15.[22] With evidence for a CD34(+) NK precursor and CD56^{bright} NK cell in the same region within SLT, Freud et al next hypothesized that NK cells may develop in SLT and thus developmental intermediates should be identifiable. Indeed, four novel, discrete populations representing four stages of NK cell development were subsequently found in situ within the same parafollicular region of SLT, each characterized by their differential expression of CD34, CD117, and CD94.[33] As development proceeds along this continuum, cells acquire the ability to secrete cytokines (eg, interferon-γ),?display natural cytotoxicity, and lose the ability to differentiate into dendritic cells (DC) and/or T cells. Although not yet proven, this orderly development in SLT from a CD34(+) subset to CD56^{bright} NK cells suggests that CD56^{dim} NK cells represent a terminally differentiated NK stage that follows CD56^{bright} NK development and exit into the periphery. The abundance of CD56^{dim} NK cells in blood versus SLT, their loss of both CD117 (c-kit) expression and proliferative capacity, along with their acquisition of KIR, FcRγRIII, and cytolytic granules are all consistent with this notion, yet direct evidence to support this is currently not available.[2]

Table 13–1 Human Natural Killer Cell Subsets Display Different Repertoires of Surface Antigens*

Antigen	CD56^{dim}	CD56^{bright}
CD16 (FcγRIIIa)	+++	–/+
KIR	+++	–/+
CXCR1	+	–
CXCR3	++	–
CX3CR3	+	–
CXCR4	++	–
CD94	–	++
NKG2A	–/+	+
NKG2D	+	+
c-kit	–	+
CCR7	–	++
CD2	++	+++
CD62L (L-selectin)	+	++
CD44	+	++

NK RECEPTORS

How NK cells recognize infected or neoplastic targets from normal self has been an intense area of research for over two decades.[34] NK cells, as opposed to B and T lymphocytes, do not undergo clonotypic gene rearrangement in order to express antigen receptors; however, through the expression of a complex repertoire of surface molecules, NK cells may efficiently determine nonself from self and rapidly initiate an appropriate response. NK cell receptors may be activating or inhibitory—in other words, binding of the receptor to its ligand expressed on a target cell either activates or suppresses a functional NK response towards the target. Such receptors fall into three general categories: those which are members of the immunoglobulin-like superfamily (KIR), one type which belongs to the C-type lectin receptor (CLR) superfamily,[35] and finally so-called natural killer cell specific receptors (NKR). The complex function of these receptor subsets is still a matter of intense research; however, a model by which NK cell receptors KIR may recognize particular features of MHC class I alleles (eg, HLA-A,[36] HLA-B,[37] HLA-C[38]) or recognize other surface antigens on target cells has been developed.[40] Fig. 13–2 is a simplified, schematic representation of what we currently understand regarding the ability of NK cells and their receptors to survey the immune system.

KIR

KIRs provide one method by which NK cells recognize self from nonself to mediate the appropriate cytotoxic response. There are currently 15 KIRs identified on chromosome 19q13.4.[18,39,40] Structurally, KIRs contain two or three extracellular immunoglobulin like domains and recognize MHC Class I proteins.[18,36,37] KIRs may be either inhibitory or activating, a functional feature associated with the intracellular tyrosine-based motif of the molecule.[18] All of this information may be deduced for a particular receptor through the nomenclature used to identify KIRs. The number of Ig-like domains (2 or 3) is expressed, eg, KIR2D or KIR3D and the length of the intracytoplasmic tail (ie, a long [L] inhibitory tail or a short [S] activating tail) is also incorporated, eg, KIR2DL or KIR2DS. A suffix numeral follows the identification of some KIR to represent polymorphic forms of each receptor; for example, KIR2DS2 and KIR2DS3, each indicating a polymorphic form of an activating KIR that bears the same extra extracellular domains. HLA-C is particularly important in KIR-mediated self/nonself recognition because many well-described KIR have ligand specificity for HLA-C associated antigens. For example, the inhibitory receptor KIR2DL1 (CD158a) recognizes Group 2 HLA-C Asn77Lys80 (HLA-Cw2, w4, w5, w6 and related alleles), and the inhibitory receptors KIR2DL2 and KIR2DL3 recognize Group 1 HLA-C Ser77Asn80 (HLA-Cw1, w3, w7, w8 and related alleles).[40] Activating receptors KIR2DS1 and KIR2DS2 recognize the same Group 2 and Group 1 antigens as the inhibitory counterparts; however, generally, inhibitory receptors bind with greater avidity or attraction for a corresponding HLA antigen than activating receptors.[41] Complementary activating and inhibitory KIRs recognize the same cognate extracellular domains on target cells; thus if an NK cell expresses both activating and inhibitory KIR for an identical ligand, the cell will generally be inhibited from killing.

Understanding of KIRs continues to expand. The KIR family is likely not all inclusive for human classical type I HLA allotypes, for instance, only one inhibitory KIR directed against HLA-A (KIR3KL2) and none towards HLA-B alleles have been found.[40] Additionally, specific KIRs may have particular roles in maintaining host immunity in unique settings. For example, KIR2DL4 recognizes the nonclassical HLA-G molecule that is only expressed on fetal extravillous trophoblasts that invade the maternal decidua during pregnancy.[42] Controversy surrounds the exact nature of this KIR; however, KIR2DL4 is likely not clonally distributed as other KIRs but is present on the surface of most mature NK cells.[43] Interestingly, despite having an inhibitory intracellular signaling moiety, KIR2DL4 serves to promote IFN-γ secretion but not cytolytic activity.[43] It is possible that this KIR functions to facilitate immune tolerance to the developing fetus.[44]

C-Type Lectin Receptors

C-type lectin receptors (CTLRs), located on human chromosome 12p.12.3, share a common subunit (CD94) covalently bonded to one of four closely related gene products of the NKG2 family.[45,46] CTLR represent a second type of NK cell receptor mediating killing and include NKG2A (and splice variant B), NKG2C, NKG2E (and splice variant H), and NKG2F.[46] NKG2D, which does not bind CD94 and shares little sequence homology to other NKG2 proteins, is discussed in next paragraph. All but one of the CTLRs are activating and expressed on NK cells as well as cytotoxic T lymphocytes. CD94/NKG2A is inhibitory and is expressed on NK cells as well as cytotoxic T lymphocytes where they serve to regulate CD8(+) T cell antiviral responses.[47] CD94/NKG2A specifically recognizes the nonclassical HLA-E Class I molecule.[48] Interestingly, HLA-E specifically presents leader peptides from other HLA receptor antigens; thus, sensitivity to HLA-E provides a mechanism for NK cells to sense functional overexpression of class I MHC molecules on cell surfaces. As with KIR, binding between CD94/NKG2A and HLA-E is more avid than binding of activating CTLRs to other epitopes, however, unlike KIR, the target antigens for activating and inhibitory CTLR are not the same.[49]

NKG2D is a CTLR, however, it has only modest sequence homology with other members of the NKG2 family and does not associate with CD94.[48] NKG2D exists as a homodimer and does not have inherent signaling capability, but rather signals via the PI3K pathway as recruited through $DAP10^{Wu}$ or KAP10.[50] This unique signal transduction arrangement renders NKG2D signaling privileged from inhibitory, intracellular intermediaries that modulate signal transduction of other CTLR systems. NKG2D is constitutively expressed on all NK cells, $\gamma\delta$ T cells, and CD8(+) T cells.[51]

NKG2D mediates killing of cellular targets expressing two antigens associated with viral or neoplastic transformation.[40,52] First, *M*HC class *I c*hain-related antigens (MIC) are a family of proteins whose expression correlates with heat shock and viral and neoplastic transformation.[51,53] MICA and MICB expression are under control of promoter elements similar to that of heat shock proteins and have been shown to be upregulated in the setting of CMV infection as well as in a number of epithelial and hematologic malignancies.[53,54] Second, UL16 *b*inding *p*rotein (ULBP) serves as a ligand for NKG2D. UL16 is a type I transmembrane protein ubiquitously expressed in the setting of CMV infection.[55] UL16 binds MICB and two other proteins, ULBP-1 and ULBP-2.[56] (These latter proteins have α1 and α2 domains but lack an α3 domain as MIC and MHC class I molecules have; furthermore, they are expressed via a glycosylphosphatidyl inositol (GPI)-anchor and thus have no requirement for β_2 microglobulin.) In binding MICB, ULBP-1 and ULBP-2, CMV-produced UL16 counteracts cell surface expression of these NKG2D ligands, thus providing a mechanism of immune evasion from NK cell surveillance and cytotoxicity.[57] In similar fashion, some human tumors downregulate expression of NKG2D ligands or release soluble forms of such (eg, MICA or ULBPs), as a mechanism of immune escape from NK cells.[58–60] Although ULBPs are expressed more ubiquitously than MIC proteins, some tissues with high mRNA levels express no protein, implying important posttranscriptional control of these antigens.[56] Interestingly, IL-15 stimulation enhances the NK cell NKG2D-mediated response to tumors expressing ULBP.[61]

Other Activating NK Receptors

A third family of NK receptors that mediate cell killing are called natural cytotoxicity receptors (NCR).[54,62] In addition to NKG2D, NCR comprise an important family of activating NK cell receptors involved in the process of target recognition and elimination. NCR include three receptors called NKp46 and NKp30 which are exclusively and constitutively expressed on NK cells, and NKp44 which is expressed after IL-2 stimulation on NK and some $\gamma\delta$ T cells.[54,62,63] Infectious, pathogen-specific ligands for NCR have been identified, eg, NKp46 and NKp44 recognize and engage virus specific hemagglutinin and hemagglutinin-neuraminidase.[64] This provides a mechanistic understanding of how NK cells can target and eliminate cells infected with influenza and parainfluenza virus, for example, although such target cells have not downregulated MHC class I expression.[64] Conversely, endogenous ligands for NCR remain to be identified.[65,66]

THE ROLE OF NK CELLS IN HUMAN DISEASE

NK cells are implicated in an increasingly important role in the immune response to, and in some cases the pathogenesis of, human disease. NK cell deficiencies are rare, however, such conditions provide insight into the role NK cells play in response to infectious pathogens, autoimmune disorders and development of malignancy. For instance, observations gleaned from the study of patients with qualitative or quantitative deficiencies in NK cells have allowed a more complete understanding of this lymphocyte subset's contribution to immunity. Selective NK cell deficiency has not been associated with a particular Mendelian disorder[67]; however, a number of recent studies have shed new light on the genetic mechanisms responsible for proper NK development and function. Many syndromes

Table 13–2 Human Disorders Characterized in Part by Natural Killer Cell Deficiency*

Disease	Gene	Protein	Cell count	Cytotoxicity	ADCC	Cytokine Response
X-linked SCID	IL2Rg	Common g chain	Low/absent	Low/absent	n/a	Reduced
Autosomal recessive severe combined immunodeficiency	JAK3	Janus kinase 3	Low/absent	Low/absent	n/a	n/a
Bloom syndrome	BLM	Bloom helicase	Normal	Low	n/a	Normal
Chediak-Higashi syndrome	LYST	Lysosome trafficking regulator	Normal	Absent	Absent	Reduced

Common variable immunodeficiency	TACI	TNF receptor family member	Low	Low/normal	Low/normal	Normal

Adapted from Microbes & Infection 4:1545, 2002.[70]

have been linked to increased susceptibility to infection while others may predispose to autoimmune disease as discussed below.

NK Deficiency Syndromes Linked to Increased Infectious Risks

The first gene directly implicated in NK deficiency was FCGR3A which codes for FcγRIIIa (CD16) expressed on NK cells. A "T ◊ A" substitution at position 230 leads to coding of a lysine residue at position 48, normally a histidine. Although the protein expressed appears phenotypically normal, patients present with increased susceptibility to severe and disseminated herpes simplex virus (HSV) infections.[68] Other patients present with progressive Epstein-Barr virus and varicella infections.[69] Patients have variable deficits in NK cytotoxicity and responsiveness to cytokine stimulation. Population studies have subsequently suggested that the H48 allele may be necessary but not sufficient to produce clinical disease.[70]

Clinical examples of patients entirely lacking any $CD56^+$ lymphocyte subsets have been reported. The first report was a young female patient who presented with life-threatening varicella infection. She subsequently developed cytomegalovirus pneumonia and cutaneous HSV infection. Analysis of her lymphocyte subsets demonstrated a striking and selective absolute absence of $CD56^+$ or $CD16^+$ cells.[5] The patient went on to develop aplastic anemia and expired from complications of stem cell transplantation.[70] A second patient has been reported presenting with disseminated *M. avium* who went on to die of disseminated varicella.[71] Other patients have been described with an isolated deficiency of $CD56^+/CD3^-$ lymphocytes but with normal or even increased populations of $CD56^+/CD3^+$ cells. One such patient presented with severe, recurrent human papilloma virus related condylomatous disease.[72] Although the genetic mechanisms of these diseases remain unknown, they serve to highlight the functional role of NK cells in providing immunity towards a spectrum of infectious pathogens.

NK cell deficiencies have been described as a component of other disease processes affecting multiple hematopoietic and immune lineages, lending some indirect support that this innate immune effector cell is an important component of the immune network. The genetic deficiencies responsible for many of these disorders have been described and can be found in Table 13–2.

The Role of NK Cells in Autoimmunity

Interestingly, NK cells have been implicated in both the regulation and pathogenesis of autoimmune disorders. For example, in a murine experimental autoimmune encephalomyelitis (EAE) model of multiple sclerosis in which disease is induced with myelin oligodendrocyte glycoprotein (MOG), NK depletion leads to enhanced T cell response to MOG. Similarly, in human multiple sclerosis, NK cells have been implicated in the maintenance of disease remission.[73] NK cells have also been shown to control inflammation in an experimental model of autoimmune colitis.[74] NK cells may exert this effect through recognition and elimination of T cells activated against autoantigens.[75]

There are also examples of NK cells promoting autoimmune disorders. For instance, experimental evidence supports the idea that NK cells may promote development of type 1 diabetes mellitus through targeted elimination of pancreatic islet β-cells following viral infection.[76] Other studies suggest that NK cells can promote humorally mediated autoimmune diseases such as myasthenia gravis through potentiation of autoreactive B-cells.[77] Synoviocytes of patients with rheumatoid arthritis (RA) have been shown to express abnormally high levels of MICA, the previously described ligand for NKG2D.[78,79] In fact, NK cells are present in acute RA joint effusions and may perpetuate this autoimmune inflammatory response.[80]

Finally, polymorphisms in receptors expressed on NK cells as well as other immune cell subsets have been implicated in the pathogenesis and progression of autoimmune disease. For example, a T ◊ G substitution at position 559 in the FcγRIIIA (CD16) gene leads to a phenylalanine to valine substitution at residue 176 of the FcγRIIIA protein.[81] Although the receptors are expressed similarly on the cell membrane, the V/V homozygous state is associated with a higher affinity for IgG binding than the F/F state. The low binding state

(F/F) is associated with lupus nephritis.[82] Others have confirmed this observation by genetic linkage studies in patients with systemic lupus erythematosis.[83] Another polymorphism in the FcγRIIIA receptor (158V/F) has been associated with RA in certain ethnic groups.[84] This mutation may also be associated with development of subcutaneous rheumatoid nodules in patients with established RA.[84] As CD16 expressed on a number of immune cells, the specific role of NK cells contributing to pathology is unclear; however, as discussed below, these polymorphisms have also been linked to response to enhanced response to monoclonal antibody therapy of cancer.

THE THERAPEUTIC POTENTIAL OF NK CELLS

T lymphocytes depend on recognition of tumor-specific antigens to affect antitumor immune response, an approach limited by our inability to identify such targets for the vast majority of nonviral neoplasms. NK cells, on the other hand, have long been recognized as being capable of anti-tumor rejection independent of such tumor antigens. As the understanding of how NK cells identify and eliminate targets has advanced, novel roles for the application of NK in clinical anti-cancer therapy have been defined. Three general approaches have been developed.

First, direct infusion of NK cells into patients with therapeutic intent has been performed.[85] This strategy has developed based on observations such as that in the allogeneic peripheral blood stem cell transplant (PBSCT) setting, where higher doses of transplanted NK cells have been associated with better outcomes as evidenced by reductions in posttransplant infections as well as reduction in non-relapse mortality.[86] Several studies have shown this approach to be safe and associated with at least a modicum of effectiveness in the autologous setting.[87,88] At least one trial evaluating direct NK cell infusion has been reported in the allogeneic setting, correlating successful transfer and expansion of haploidentical NK cells with hematologic remission of leukemia.[89]

Second, NK cells have been successfully expanded in vivo in patients with cancer through the exogenous administration of recombinant human cytokines, such as low, intermediate or high-dose IL-2.[90–94] The tumor nonspecificity of these strategies is being explored by concomitantly administering a tumor-specific monoclonal antibody whose Fc portion can bind to CD16 expressed on the cytokine-expanded NK cells, thus initiating a process called antibody-dependent cellular cytotoxicty.[93,95,96]

A third methodology under development to enhance the anti-tumor response of NK cells is based on the emerging understanding of KIR biology.[97] Over 20 years ago, an inverse relationship was reported between expression of MHC Class I molecules on target cells and the ability of NK cells to kill such targets successfully.[34] As this "missing self" model was further characterized, three principal, common HLA-Class I allele specificities were identified that serve as ligands for three specific NK cell inhibitory KIR receptors. These have been termed: "Group 1" HLA-C alleles expressing Asn80 (eg, HLA-Cw1, w3, w7, w8, and related alleles), "Group 2" HLA-C alleles expressing Lys80 (eg, HLA-Cw2, w4, w5, w6, and related alleles), and HLA-Bw4 alleles (eg, HLA-B27). As one's NK receptor repertoire, including inhibitory KIRs, is dictated during development by the HLA class I genotype, ultimately every NK cell expresses at least one inhibitory KIR specific to self HLA Class I molecules.[18] Moreover, allogeneic targets sensitive to NK cytotoxicity are identified by their lack of self MHC class I inhibitory KIR ligands.

These principles have been applied in a number of therapeutic settings. Perhaps most dramatically, Velardi and colleagues have demonstrated an impressive improvement in survival following allogeneic stem cell transplantation based therapy for patients with acute myeloid leukemia.[98] Donor-versus-recipient NK cell alloreactivity has been shown to contribute to enhanced survival in this setting, as well as improved engraftment, and protection against graft-versus-host-disease.[99] In a series of patients receiving haploidentical grafts, 68% of patients without NK-alloreactivity had relapsed disease, whereas only 15% of patients with NK-alloreactivity relapsed with a median follow-up of 4 years.[99] Similarly, KIR-mismatch has been shown to improve outcome after reduced-intensity chemotherapy followed by allogeneic stem cell transplantation in multiple myeloma patients.[100,101] Fig. 13–3 shows how mismatching KIR epitopes facilitates NK mediated tumor cytotoxicity in a haploidentical setting.

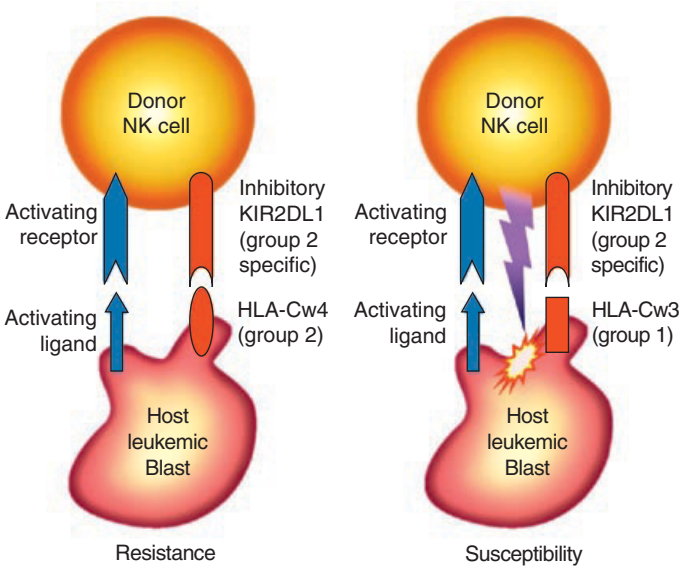

Figure 13–3 Simplified cartoon representation of haplotype mismatched allogeneic stem cell transplant for acute myeloid leukemia: proper MHC class I mismatch can lead to donor natural killer (NK) cell killing host leukemic blasts. As the HLA-C ligand binds to the NK cell inhibitory killer immunoglobulin-like receptor (KIR) on the left, the inhibitory signal interrupts the activation signal, and no killing occurs. However, when the HLA-C ligand does not bind the NK inhibitor KIR on the right, no inhibitory signal is sent, and tumor killing occurs. *(Adapted from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: new biology and insights into the graft-versus-leukemia effect. Blood 100:1935, 2002.)*

Others have extended on these transplantation-based findings by manipulating the relationship between NK receptors and MHC Class I receptors through the means of monoclonal antibodies. For example, a murine model lends support to the notion that tumor expression of MHC Class I molecules become engaged by inhibitory NK cell receptors and thus mediate NK tolerance.[102] When antibody fragments were introduced to disrupt this ligand-receptor interaction, increased NK cytotoxicity and decreased tumor growth were observed. Furthermore, adoptive transfer of murine NK cells pretreated with an antibody to block inhibitory NK receptor expression into leukemia-bearing mice led to enhanced survival as compared to transfer of untreated NK cells. These findings support the notion that blocking inhibitory NK receptors may be beneficial in increasing the efficacy of cancer immunotherapy.[102] In fact, anti-KIR antibodies are nearing Phase 1 clinical trials in humans. Fig. 13–4 demonstrates this principle.

In complementary fashion, other approaches have sought to enhance activating NK receptors, such as NKG2D. One group has created a novel bivalent protein (ULBP2-BB4) which recognizes NKG2D and CD138, a protein overexpressed in a number of malignancies, including multiple myeloma. Although such an approach is limited by knowledge of particular tumor antigens, the concept of enhancing NK function was demonstrated in this model through increases in NK cytokine secretion as well as abrogation of tumor cell growth in the presence of the molecule.[103]

Finally, the use of monoclonal antibodies directed against tumor cell antigens has significantly advanced treatment of some malignancies. For example, treatment with the monoclonal, IgG, chimeric anti-CD20 antibody rituximab has been shown to improve survival of patients with non-Hodgkin lymphoma. As discussed, genotypic, single nucleotide polymorphisms in the FcγRIIIA (CD16) receptor

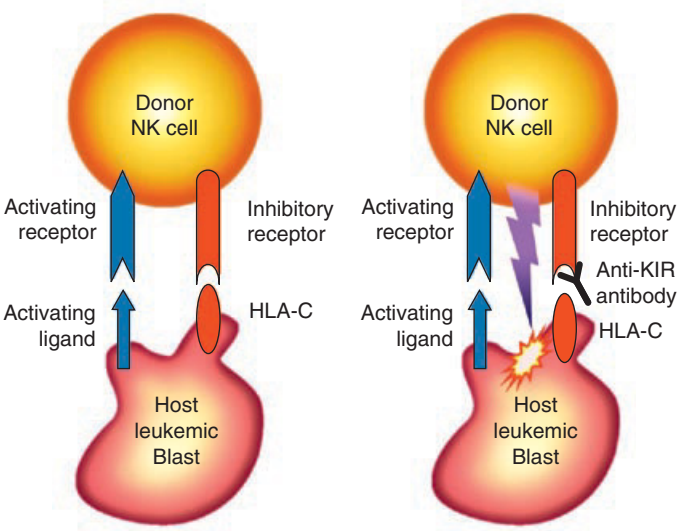

Figure 13–4 Simplified cartoon showing the general equilibrium between activating and inhibitory signaling which favors no killing as shown on the left. However, the introduction of an antibody to the inhibitory receptor tips this balance towards activation and elimination of the target cell, as shown on the right. *(Adapted from Farag SS, Fehniger TA, Ruggeri L, et al: Natural killer cell receptors: new biology and insights into the graft-versus-leukemia effect. Blood 100:1935, 2002.)*

expressed on NK cells and other immune cells may convey functional differences in the receptor that have clinical consequences. Patients with the V/V homozygous state at residue 176 have a higher affinity for the Fc portion of the rituximab, and these patients show enhanced clinical response to the antibody.[104] Such a finding supports the notion that enhanced ADCC function in CD16-bearing cells, including NK cells, is one key mechanism of action of rituximab and suggests that antibody mediated cancer therapies could be advanced by enhancing NK cell numbers and cytotoxic potential in vivo.

CONCLUSIONS

NK cells are a critical cellular component of innate immunity. Rapid secretion of powerful immunomodulatory cytokines and chemokines support the role of NK cells as "first responders" to immune insults, facilitating mobilization and tailoring of the innate and adaptive immune response. Potent natural cytotoxicity, unrestricted by classical antigen presentation, and costimulation required for adaptive immune cells, suggest that NK cells have an important, complementary role to that of cytotoxic T lymphocytes, which provide antigen-specific cytotoxicity and lasting memory. Further understanding of the functional differences between $CD56^{dim}$ and $CD56^{bright}$ subsets, their cytotoxicity and cytokine receptor expression, and their developmental biology will certainly shed more light on the therapeutic potential for NK cells in the pathogenesis, prevention, and treatment human disease.

CHAPTER 14

DENDRITIC CELL BIOLOGY

Olivier Manches, Viswanathan Lakshmanan, Zbigniew M. Szczepiorkowski, and Nina Bhardwaj

INTRODUCTION

Dendritic cells (DC) are a sparsely distributed population of bone marrow derived mononuclear cells that exist in an "immature" form in virtually all tissues in the body.[1] DC serve as professional antigen presenting cells (APC) with an extraordinary capacity to stimulate naïve T lymphocytes (as well as B, NK, and NK-T cells) and initiate primary immune responses. In their immature state DC detect and capture "danger signals" originating from microorganisms or their macromolecular constituents in their resident tissues. Upon encountering such danger signals DC undergo a complex series of events leading to their "maturation."[1] Maturation of DC is characterized by migration of DC to draining lymph nodes and processing and presentation of antigens in the context of antigen presenting molecules such as major histocompatibility complex (MHC) and CD1 to naïve T, B, and NK cells. This chapter attempts to provide a snapshot of our current understanding of DC function as well as their potential clinical applications as immunotherapeutic agents in diseases such as cancer, HIV and autoimmunity.[2]

DENDRITIC CELL SUBSETS AND DEVELOPMENT

Extensive research has demonstrated that DC exist in many "flavors."[3,4] However, our understanding of DC differentiation and the different DC subsets is complicated by the heterogeneity of data, obtained from in vitro human and mouse studies, and in vivo animal studies and limited in vivo human studies. The generation of functionally distinct DC subtypes follows two generally accepted models: (a) the *functional plasticity model* postulating the existence of a single DC lineage possessing functional plasticity, and (b) the *specialized lineage model* postulating the existence of multiple DC lineages displaying functional diversity.[5] Both models assume four stages of DC development namely hematopoietic precursors, DC precursors (pre-DC), immature DC (imDC), and mature DC (mDC) (Fig. 14–1). It is likely, however, that elements of both models are involved in DC subset development. In this short chapter we concentrate on human DC with little reference to murine models. Readers are encouraged to seek additional information in several comprehensive reviews.[5–14]

Most studies on the developmental origin of human DC subsets have used in vitro culture systems. DC precursors and imDC, similar to other cell types in the immune system, are continuously produced in a steady rate and pathogen independent manner from CD34+ hematopoietic stem cells (HSC) within the bone marrow. Fms-like tyrosine kinase-3 ligand (Flt-3-L) and GM-CSF, represent the key DC growth and differentiation factors.[15] The CD34+ HSC differentiate into hypothetical common lymphoid progenitors (CLP) and common myeloid progenitors (CMP) in the bone marrow. Subsequently CMP differentiate into CD34+CLA+ and CD34+CLA– populations (CLA, skin homing receptor cutaneous lymphocyte-associated antigen), which give rise to phenotypically distinguishable CD11c+CD1a+ and CD11c–CD1a+ immature DC, respectively.[16] The former migrate into the skin epidermis and differentiate into Langerhans cells, while the latter localize to skin dermis and other tissues, and become interstitial imDC.[17] The human Langerhans cell DC subset has distinct markers, including the presence of Birbeck granules, the expression of CD1a, and langerin, a member of the C-type lectin family of receptors involved in the uptake of pathogens.[18]

The CD34+ hematopoietic progenitor cells (HPC) and blood monocytes are commonly used as precursor cells for generating DC in culture in vitro for both research and immunotherapeutic purposes. HPC are treated with c-kit ligand and tumor necrosis factor (TNF) α that yield subsets of myeloid DC including Langerhans cells. Monocytes, obtained by simple adherence of HPC to plastic, when exposed to a combination of GM-CSF and IL-4, yield imDC that are comparable to some degree to tissue interstitial DC. Maturation of these different DC can be induced by the addition of various stimuli.

The pre-DC subset expresses several myeloid markers including CD11b, CD11c, CD13, CD14, and CD33, indicating that they may derive from a CMP. In contrast to the blood "myeloid DC" derived from CMP, which we will refer to here as conventional DC (cDC), the "plasmacytoid DC" contain "lymphoid" mRNA transcripts for pre-T α chains, germ line IgK, and Spi-B and are also called interferon (IFN) type I producing cell (IPC). These latter cells display distinct plasma cell morphology, contain abundant endoplasmic reticulum, and express CD4 and high levels of the IL-3αR, but lack myeloid antigens including CD11c and most lineage markers. Plasmacytoid DC are found in peripheral blood, thymus, and many lymphoid tissues. The production of extraordinarily high levels of IFN type 1 by pDC is unique to this cell type and may be important for initiating a strong antiviral innate response and promote maturation of bystander CD11c+ cDC to protect them from the cytopathic effect of viruses.[18–21] It is hypothesized that human cDC and pDC have evolved to recognize and respond to different pathogens in unique ways, owing to their complementary expression of receptors for "pathogen associated molecular patterns" (see Antigen Acquisition section), capacity to secrete either IFN type I or IL-12, antigen presentation, and migration into secondary lymphoid organs. As mentioned, pDC secrete high amounts of IFN-α upon viral infection, but no IL-12, and display poor antigen capture and presentation capacity. Upon activation, pDC differentiate into cells bearing similar characteristics to activated cDC, ie, with a dendritic morphology, high expression of MHC class II molecules, and the capacity to prime naïve T cells,[22,23] but express low levels of CD11c and lack typical myeloid markers. The functional properties of these latter pDC-derived DC is still to be investigated thoroughly,[24] although they may differ from cDC especially in their *cross-presentation*[25] or T cell skewing capacities. Thus, DC derived from pDC upon culture with IL-3 and activation by CD40-L preferentially prime naïve CD4+ T cells towards a Th2 profile, whereas DC derived from pDC by viral/TLR stimulation prime towards a Th1 profile in an IFN-α dependent and IL-12 independent pathway.[20] Upon activation, immature cDC migrate through afferent lymph from nonlymphoid tissues to the T cell rich areas of lymph nodes. Plasmacytoid DC, which also migrate into T cell areas of secondary lymphoid tissues, do so through high endothelial venules (HEV) of lymph nodes and marginal zone of the spleen likely using CCR7 and CD62-L.[26] Both activated blood cDC and pDC can migrate in response to lymph node homing chemokines (CCL19 and CCL21) through expression of CCR7. Although cDC can be found in virtually every peripheral tissues as well as in lymphoid organs, pDC seem to display a more restricted

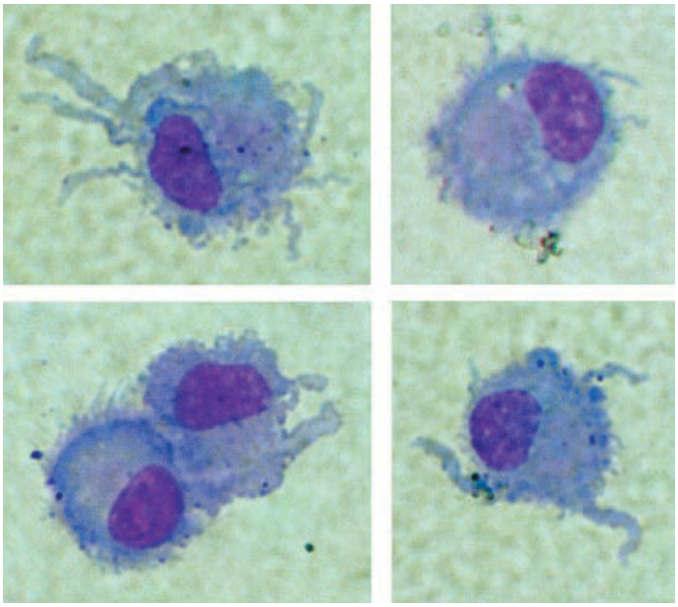

Figure 14–1 Examples of monocyte-derived mature dendritic cells are shown. The mononuclear cells were enriched by adherence, cultured with IL-4 and GM-CSF for 6 days, and underwent maturation with IL-1, IL-6, TNF-α, and PGE2 for 24 hours.

distribution. They can be found mostly in the T cell area of lymphoid organs (lymph node, tonsils, spleen, thymus, bone marrow, and Peyer patches), blood and some peripheral tissues (liver, nasal mucosa). Although cDC and pDC express a similar array of chemotactic receptors (such as CCR2, CCR5, CXCR2, CXCR4), pDC do not respond to a number of inflammatory chemokines. However, they accumulate in inflamed tissues, such as in systemic lupus erythematosus (SLE) or contact dermatitis, probably through their expression of ChemR23 and CXCR4.

This division of dendritic cells into cDC and pDC subsets is likely to be an oversimplified view of DC heterogeneity. For example splenic DC are heterogenous with regard to expression of CD4, CD11b, and CD11c, whereas most of the thymic DC are CD11c+ but lack other myeloid markers thereby not fitting into either of the classical categories of cDC and pDC in blood.[27] Recently, a new subset of pDC was discovered in mice, which presented functional features of both NK cells and conventional pDC, highlighting the functional diversity of DC.[28,29]

The developmental origin of pDC and cDC is still debated, as pDC and cDC can be derived from both CLP and CMP, suggesting that pDC and cDC may arise during hematopoiesis from progenitors with already distinct and restricted lineage potential.[30] It seems that cDC differentiation is dependent on the transcription factor Ikaros, whereas pDC development is dependent on the Ets family transcription factor SpiB, and probably PU.1. A recent study in mice described the conversion of bone marrow pDC into cDC upon viral infection, again highlighting the complexity and plasticity of DC development.[31]

The migration of myeloid DC and plasmacytoid DC precursors from the bone marrow can be increased by administration of Flt-3-L up to 50-fold for pre-DC and 15-fold for pDC.[32,33] G-CSF is also known to increase the number of pDC in the circulation. With the advent of newer technologies it has also become feasible to generate large numbers of DC subsets in vitro.

THE CONCEPT OF MATURATION

In their resting state, imDC are primed to acquire antigens in situ through a variety of receptors and mechanisms. Upon encountering pathogens or other "activating stimuli," DC undergo a complicated series of phenotypic and functional changes referred here to as "activation" and "maturation," respectively.[1] The process of DC activation is an intricate differentiation process under tight control and closely associated with antigen acquisition. It is induced by various stimuli (Table 14–1) or danger signals (eg, signs of pathogenic infection or cell injury), including cytokines (eg, IFN type I, TNF-α, and IL-1), microbial products (eg, lipopolysaccharide (LPS), flagellin, intracellular products (eg, heat shock proteins), growth factors (eg, thymic stromal lymphopoietin [TSLP]), immune complexes and T cell molecules (eg, CD40). The process of activation is characterized by upregulation of adhesion and costimulatory molecules such as CD54, CD80, CD86, MHC class I and II molecules, cytokines (eg, TNF-α, IL-12, IL-18) and chemokines (eg, RANTES, MIP-1 α, IP-10). The latter enable the recruitment of T cells, monocytes and other DC into the local environment. In their mature state, DC express markers, which distinguish them from imDC such as CD83 (a molecule involved in thymic T cell selection and DC-DC interactions) and DC-LAMP, a lysosomal protein. Maturation also changes the migratory properties of DC. They express CCR7 and acquire responsiveness to the chemokines CCL19 and CCL21 that are expressed in the T cell areas of lymph nodes where mature DC generate immune responses. Concomitantly, DC lose their receptors for CCL3, CCL4, and CCL5, which are produced in sites of inflammation, reduce their capacity for phagocytosis, macropinocytosis, antigen uptake, and processing; but acquire potent immunostimulatory ability through enhanced T-DC immune synapse formation, production of immunoproteosomes and upregulation of unique DC specific costimulatory molecules such as B7-DC.[34] However, although increased expression of costimulatory molecules and migration to secondary lymphoid organs often correlates with their capacity to prime CD4 and CD8 immunity, activated DC may also induce tolerization of T cells, as when CD4+ T cell help is missing[35,36] or on activation by inflammatory cytokines in the absence of TLR engagement,[37] and can potentially induce the generation of regulatory T cell (Treg). Some stimuli, such as TSLP, can induce phenotypic maturation of DC without concomitant secretion of proinflammatory cytokines such as IL-12, IL-6, TNF-α, or IL-1.[38] Therefore, DC maturation is more appropriately used in a functional

Table 14–1 Agents That Cause DC Maturation

Agent Property	Molecules
Stimulatory agents	TNF family members (TNFα, CD40L, FasL, TRANCE); TLR ligands (dsRNA, LPS, imiquimod, CpG ODNs); Growth factors [thymic stromal lymphopoietin (TSLP)]; Interferons (IFNα); Adhesion molecules [CECAM-1, (CD66a)]; Costimulatory molecules [LIGHT, B7-DC]; Receptors [FcR via Ag-Igs; TREM-2 via Dap-12]; Viruses/microbes (Influenza, bacteria, bacterial products); Chemokines (MCP, MIP1α, RANTES, IP10, IL-8, MDC, TARC); Chemokine receptors (CCR7 and loss of CCR2 and CCR5)
Inhibitory agents	Drugs (Rapamycin, FK506, Cyclosporin A, Dexamethasone, IVIg); Chemokines (IL-10); Viruses (EBV, vaccinia, canarypox, HSV); Others (β2 microglobulin)
Survival signals	CD40 L, TRANCE, B7-DC, BcL-2
Cell-cell interaction	Activated Cells [CD4 and CD8 cells (via CD40L)]; NK cells, NK-T cells; Vδ1+, γδ T cells

Maturation is a complex process tightly linked to antigen acquisition and the surrounding micro-environment. See text for more details.

Table 14–2 Antigen Recognition and Uptake Receptors Expressed by DC

Receptor	Antigenic Ligand
C type lectins (DC-SIGN, MMR, DEC-205)	Mannosylated molecules, viruses, bacteria, fungi
FcγR (CD32, CD64)	Immune complexes, antibody-coated tumor cells
CD1 a, b, c, d	Biphosphonate moieties in *Mycobacterium tuberculosis*, BCG and *Listeria monocytogenes*; Lipid and glycolipid foreign and self-antigens
Integrins (αVβ5, CR3, CR4)	Opsonized antigens, apoptotic cells
Scavenger receptors (CD36, LOX-1)	Opsonized antigens, apoptotic cells, heat shock proteins
Toll-like receptors (TLR) and other Pattern recognition receptors (PRR)	TLR 2–8 (myeloid DC) peptoglycans, endotoxin, flagellin; TLR 7 (plasmacytoid DC) bacterial DNA; RIG-I, MDA5, PKR, NOD proteins
Heat shock proteins receptor (HSP-R; CD91)	Heat shock proteins
Aquaporins	Fluids

The table lists some of the receptors expressed by DC that are involved in antigen acquisition.
The antigen receptor repertoire dictates that range of antigens captured by the DC.
Ligation of some of these receptors induces DC maturation.

sense, with mature DC being defined as able to prime naive T cell responses. What makes a phenotypically activated DC capable of priming instead of tolerizing a T cell appears multifactorial and dependent on such factors as the state of the microenvironment and the DC subset in question, although this remains to be clearly defined.

ANTIGEN ACQUISITION

Immature DC sample their environment through several mechanisms, including micropinocytosis, macropinocytosis, receptor mediated endocytosis, and phagocytosis. They display an array of surface receptors, which facilitate acquisition of antigens and pathogens, and at the same time induce differentiation into activated DC. An important class of receptors is the pattern recognition receptors (PRR), which recognize pathogen-associated molecular patterns (PAMP) expressed by many microorganisms. PRR serve as an important link between innate and adaptive immunity as they directly mature DC while also inducing the production of a variety of cytokines and chemokines. PRR consist of several groups of receptors including secreted (eg, MBL, CRP, SAP, LBP), cell-surface (eg, CD14, MMR, MSR, MARCO),[39] and intracellular molecules (eg, RIG-I and MDA5, which are RNA helicases involved in the recognition of nucleic acids upon viral infection; NOD receptors, which recognize peptidoglycan subcomponents or other bacterial molecules; inflammatory caspases, such as caspase-1 and caspase-5, which form an intracellular complex with NALP1 or NALP2 and 3 called the inflammasome that recognize bacterial RNA and other danger signals and induce the production of the proinflammatory cytokines IL1β and IL-18) (Table 14–2). Toll-like receptors (TLR), which constitute another group of PRR, are expressed by imDC, and mediate activation by microbial components such as peptidoglycan, LPS, flagellin, and unmethylated CpG DNA motifs. Ligation of the TLR results in the activation of Rel family members, in particular the transcription factor NF-κB, c-Jun-terminal kinase (JNK) and p38 MAP kinase, leading to the initiation of the maturation process.[40,41] TLR are unevenly distributed among DC, with myeloid DC expressing TLR 2, 3, 4, 5, 8 and plasmacytoid DC strongly expressing TLR 7 and 9 (Table 14–3). Another important feature of some TLR is their capacity to induce secretion of IFN type I for antiviral defense and immune regulation. cDC express TLR3 and 4, mediating recognition of viral double stranded RNA and LPS respectively, and on triggering secrete low amounts of IFN-β through a signaling pathway utilizing the adaptor TRIF and the transcription factor IRF3. Although cDC can also induce IFN type I through RIG-I and MDA-5 upon viral infection, pDC seem to rely mostly on a specialized MyD88-dependent signaling pathway, allowing them to secrete very high amounts of IFN-α upon triggering of TLR7 and 9. This is due to their constitutive high expression of IRF7, a crucial IFN-α gene transcription factor, and to a specialized spatiotemporal regulation of TLR7 and 9 signaling, allowing IRF7 to interact with MyD88 docked onto TLR in the endosomal membrane.[42]

Table 14–3 Toll-Like Receptors Expressed by DCs

mDC	pDC	Ligand(s)
TLR1	TLR1	?
TLR2		Peptidoglycan (*S. aureus*); Lipoproteins and lipopeptides from several bacteria; Glycophopshotidylinositol anchors from *T. cruzi;* Lipoaminomannan from *M. tuberculosis;* Zymosan (yeast)
TLR3		Double-stranded RNA e.g. poly I:C
TLR4		LPS+MD-2, taxol, hsp 60 (?), heparan sulfate (?), RSV, fibronectin
TLR5		flagellin (*S. typhimurium, Listeria*)
TLR6	TLR6	? / Undergoes dimerization with TLR2
	TLR7	Imiquimod (Aldara), R-848 (resiquimod), single-stranded RNA
TLR8	TLR8	Imiquimod (Aldara), R-848 (resiquimod), single-stranded RNA
	TLR9	CpG ODNs, DNA from bacteria and viruses, chromatin-IgG complexes
	TLR10	?

TLRs can form heterodimeric receptor complexes consisting of two different TLRs or homodimers (as in the case of TLR4). The TLR4 receptor complex requires supportive molecules (MD-2) for optimal response to its ligand lipopolysaccharide (LPS). A common feature of the TLR recepors is the cytoplasmic TIR domain that serves as a scaffold for a series of protein-protein interactions which result in the activation of a unique signaling module consisting of MyD88, interleukin-1 receptor associated kinase (IRAK) family members and Tollip, which is used exclusively by TIR family members. Subsequently, several central signaling pathways are activated in parallel, the activation of NF-kB being the most prominent event of the inflammatory response. Recent developments indicate that in addition to the common signaling module MyD88/IRAK/Tollip, other molecules can modulate signaling by TLRs, especially of TLR4, resulting in differential biological responses to distinct pathogenic structures. TLR2 is also involved in cross-presentation.

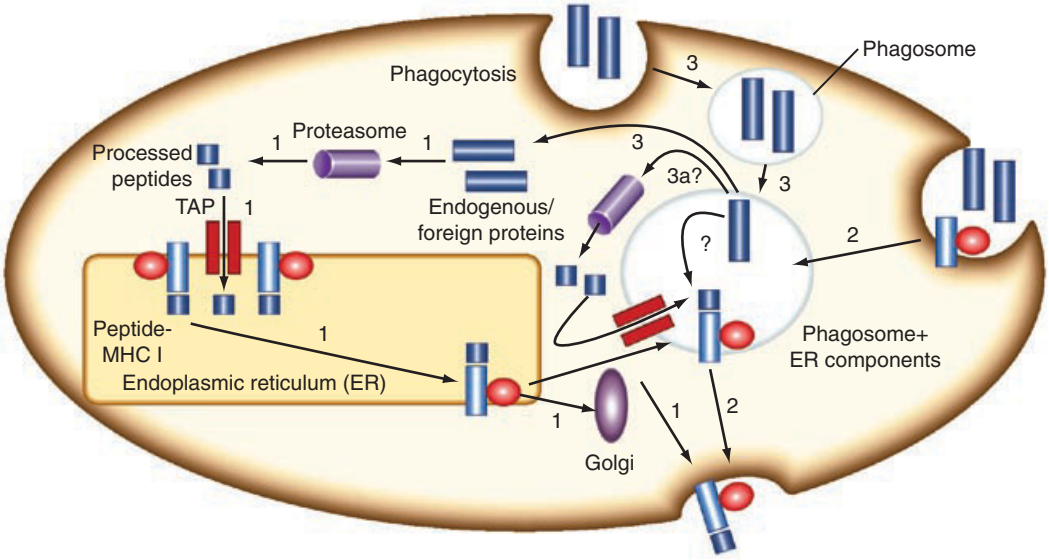

Figure 14–2 PATHWAYS FOR MHC CLASS I PRESENTATION. The classical pathway for MHC class I presentation (1) involves degradation of endogenous or viral antigens into peptides by the proteasome, followed by transport into the endoplasmic reticulum (ER). After further trimming in the ER, the peptides are loaded onto newly synthesized MHC class I molecules and the peptide-MHC class I complexes are transported to the plasma membrane. Two main pathways of cross-presentation (2,3) have been described, which allows presentation of exogenous antigens in association with MHC class I molecules. Antigens endocytosed or phagocytosed can be cleaved into peptides by proteases and loaded onto recycling MHC class I molecules within the same phagosome or on the cell surface (vacuolar pathway) (2). Alternatively, antigens may escape from the phagosome and enter the cytosol (phagosome-to-cytosol pathway) (3) to be processed via the classical MHC class I pathway. It has been suggested recently that elements of ER can be associated with phagosomes, allowing transfer of antigens into the cytosol by the ERAD pathway and degradation by the phagosome-associated proteasome (3a). The importance of each pathway (2,3) for cross-presentation in vivo and the precise mechanisms and location of antigen processing in each model are under investigation.

C-type lectins are calcium-dependent carbohydrate-binding proteins with a broad range of biological functions, many of which are involved in immune responses. They are well represented on dendritic cells and include the following: DC-SIGN, responsible for binding of HIV-1, HIV-2, simian immunodeficiency virus, Ebola viruses, dengue virus, *Candida* species, *Leishmania* species; BDCA-2, potentially responsible for delivering tolerogenic signals; BDCA-4/neuropilin-1, capable of binding VEGF; langerin, responsible for uptake and processing of antigens in Langerhans cells; DEC-205 (CD205) involved in the uptake and processing of antigens in MIIV (vesicles enriched for MHC class II molecules and proteases such as the cathepsins that mediate antigen processing and MHC class II peptide complex formation), and generation of tolerogenic signals; and macrophage mannose receptor (MMR), involved in the processing of microbial organisms.

Other receptors expressed by DC include FcR involved in cross-presentation of immune complexes and antibody opsonized dead cells; integrins such as $\alpha V\beta 5$, scavenger receptors CD36, and Mer-family tyrosine kinases for phagocytosis of apoptotic cells and Lipoxygenase-1 (LOX-1) or CD91 for uptake of HSPs; complement receptors which play a role in uptake of opsonized microbes and apoptotic cells; receptors for viruses (eg, CD4, CCR5, and CXCR4 for HIV, and CD46 for measles virus), and the CD1 family of receptors which activate CD4, CD8, $\gamma\delta$T cells, and NK-T cells through binding and processing of antigens such as sphingolipids, sulfatides, glycosphingolipids GPI-anchored mucin-like glycoproteins (GPI mucins), glycoinositolphospholipids (GIPLs), and their phosphatidylinositol moieties. Altogether, these various receptors provide substantial avenues for DC to efficiently capture multitudes of antigens in their environment.

Antigen capture is tightly coupled to DC activation and antigen presentation, and triggering of TLR or exposure to inflammatory cytokines first induces a transient increase in the macropinocytic uptake, followed by a near complete downregulation of the uptake process. Furthermore, it has been suggested that TLR engagement also enhances microbe-loaded phagosome maturation, potentially discriminating between nonimmunogenic antigens (apoptotic cells) and microbial antigens at the antigen processing level.[43]

ANTIGEN PROCESSING

Dendritic cells have a remarkable ability to process and present antigens restricted by MHC and CD1 molecules. The processing is tightly associated with DC activation.

MHC Class I Antigen Presentation (Endogenous Route)

The process of antigen processing and presentation to CD8+ T cells begins with degradation of proteins synthesized within the cytoplasm, either as mature proteins or as neosynthesized defective proteins (defective ribosomal products or DRiPS), into oligopeptides by the ubiquitin-proteasome pathway. Misfolded proteins are also a source of antigenic peptides after retrotranslocation from the ER to the cytosol through the ER-associated degradation pathway (ERAD). Subsequently, aminopeptidases cleave N-terminal precursors into peptides of appropriate length for presentation on MHC class I molecules. Antigen processing via this route is regulated through activation of the catalytically active subunits of the proteasome, the PA28 proteasome activator and leucine aminopeptidase, which are upregulated by IFN.[44] Mature DC in particular, express immunoproteosomes containing the active site subunits LMP2, LMP7 and MECL-1, which can enhance antigen processing.[45] After transport into the endoplasmic reticulum through the transporter associated with antigen processing (TAP) (Fig. 14–2), long peptides are further trimmed by ER aminopeptidase-1 (ERAP-1) to 8-mer or 9-mer peptides for loading onto MHC class I molecules.

DC also have the capacity to acquire antigens exogenously and process them for presentation on MHC class I molecules. This phe-

nomenon, referred to as cross-presentation allows the immune system to recognize antigens which are not otherwise presented or which may not access DC directly (eg, tumor cells, viruses). DC can acquire such antigens in the form of apoptotic cells, necrotic cells, antibody opsonized cells, immune complexes, and heat shock proteins (intracellular chaperones for antigenic peptides which are released by necrotic cells).[46] DC even acquire antigens via phagocytosis of particles released from intracellular vesicles (referred to as exosomes).[47] Finally, DC may even nibble bits of live cells to acquire antigens.[48] Mechanistically, cross-presentation may involve cathepsin-S dependent processing of antigenic peptides within the endocytic/phagocytic vacuole and subsequent binding to recycling MHC class I molecules within the same organelle (vacuolar pathway) (Fig. 14–2).[49] Alternatively, the antigens may be transferred from the endocytic vacuole to the cytoplasm, followed by processing by the proteasome and loading onto newly formed MHC class I molecules (phagosome-to-cytosol pathway), with a possible recruitment of the endoplasmic reticulum machinery for antigen processing and MHC class I loading (Fig. 14–2).[50–53] Activation of DC through TLR triggering or exposure to fever-like temperatures induces transient formation of large poly-ubiquitinated protein aggregates called dendritic cell aggregosome-like induced structures (DALIS), the role of which might be to temporarily concentrate and store endogenous antigens to reduce self-antigen presentation.[54,55] This phenomenon of cross presentation is especially efficient in, if not unique to, DC as compared to other antigen presenting cells.

MHC Class II Antigen Presentation (Exogenous Route)

Assembly of MHC class II molecules, which present antigen in the form of short peptides to CD4+ T lymphocytes, occurs in the endoplasmic reticulum of DC. Once assembled, these MHC class II molecules are transported to specialized compartments in the lysosomal system involved in the processing of exogenous antigens. These include MIIV which are protease rich compartments containing newly synthesized MHC class II molecules. Epidermal DC or Langerhans cells contain cytoplasmic tubules with internal striations called Birbeck granules. Birbeck granules are rich in langerin (CD205), a C-type lectin necessary for granule formation and possibly for capture of pathogens.[56] Once endocytosed by imDC, antigens are partially retained within lysosomes. Upon receiving a maturation signal, the pH of lysosomes decreases to less than 5 (owing to the activation of a vacuolar H+ ATPase). Concomitantly there is antigen degradation due to activation of proteases such as cathepsins. Cystatin C, a protein which blocks the activity of cathepsin S, is also degraded, thereby allowing the degradation of invariant chain peptide (Ii chain), which normally blocks access of antigenic peptides to MHC class II molecules. These changes occur in late endosomes and lysosomes (the MIIV compartment). Once antigenic peptide is bound to MHC class II molecules, they exit the lysosomes through the formation of long tubular structures, which simultaneously deliver costimulatory molecules such as CD86 to the cell surface.[57,58]

Dendritic cells handle internalized antigens in a specialized way unlike other phagocytic cells such as macrophages which degrade most of the internalized material, leaving only limited amounts of antigenic peptides for presentation onto MHC molecules. On the contrary, internalized antigens in cDC are preserved for longer times, thereby allowing their transport by maturing DC to secondary lymphoid organs, where actual presentation occurs. Mature DC display higher levels of proteolysis than imDC, allowing appropriate degradation of the antigens for loading onto MHC molecules. These differences are accounted for by several features unique to DC, such as low levels of lysosomal proteases in immature stages as compared to macrophages, expression of protease inhibitors (cystatin C), regulation of lysosomal pH (and hence activity of proteases) by regulation of the acidifying V-type H+ ATPase activity and consumption of H+ upon reaction with superoxide radicals generated by NADPH oxidase NOX2 in maturing DC.[59] During maturation, trafficking of MHC class II molecules to the surface is dramatically increased, probably due to degradation of Ii chain (containing endosome-lysosome targeting signal) in acidic compartments, leading to transport of MHC class II via the constitutive secretory pathway to the cell membrane.

T CELL ACTIVATION

T cell activation systematically requires three signals. Signal 1 is generated by the T cell receptor (TCR) after engagement by a peptide-MHC complex on the antigen-presenting cell. Signal 2 or costimulatory signals, determines qualitative and quantitative elements of T cell activation and differentiation and is required for priming of naïve T cells. Signal 3 specifies the type of response to be mounted, inducing either Th1 or Th2 differentiation in CD4 T cells, or promoting a regulatory phenotype. MHC/peptide, costimulatory molecules, and other signaling/adhesion molecules promote DC contact with T cells via formation of an *immunological synapse* that determines the duration and strength of signals transduced to T cells leading to their subsequent activation. The minimum time for productive interaction between naïve T cells and DC is 6 to 30 hours, with lesser time periods required for memory T cell activation.[60,61] Although only a few peptide-MHC complexes (<10) are sufficient to trigger calcium fluxes in T cells,[62] only mature DC can prime naïve CD4 and CD8 T cells.[63] Remarkably, relatively few peptide-MHC complexes (<200) are necessary on mature DC to activate T cells. Compared to other antigen-presenting cells such as B cells and monocytes, DC are up to a thousandfold more efficient in activating T cells.[64]

Costimulatory molecules include the CD80 and CD86 members of the B7 family which ligate to CD28 on T cells and members of the TNF family, such as CD40 (Table 14–4).[12] Notably one new member of the B7 family, B7-DC, is unique to DC, and stimulates naïve T cells highly efficiently.[65] Other molecules play inhibitory roles upon encountering their receptor on T cells. For example, PDL1 on DC interacts with PD1 on T cells to downregulate T cell responses.

Table 14–4 Co-Stimulatory Molecules Involved in the Interaction between DC and T Cells (Signal 2)[8]

Dendritic Cell	T Cell	Signal
B7 Family		
B7-1(CD80)/B7-2(CD86)	CD28	Activating
B7-1(CD80)/B7-2(CD86)	CTLA4	Inhibitory
B7-H1(PDL1)/B7-DC(PDL2)	?	Activating
B7-H1(PDL1)/B7-DC(PDL2)	PD1	Inhibitory
B7-H2 (B7h; B7PR1; ICOSL)	ICOS	Activating
B7H3	?	Activating
B7H4 (B7S1; B7x)	?	Inhibitory
TNF Receptor Family		
4–1BBL	4–1BB	Activating
CD27L	CD27	Activating
OX40L	OX40	Activating
LIGHT	LIGHT-R	Activating
Cytokines		
IL-2	IL-2R	T cell proliferation
IL-12	IL-12R	T cell proliferation
IL-18		

T cell activation requires two signals. The T-cell receptor interaction with a peptide-MHC complex (Signal 1) is accompanied by Signal 2 delivered by one of the mechanisms listed in this table. Formation of the immunological synapse between a DC and a T cell determines the fate of the lymphocyte. The number of identified co-stimulatory molecules responsible for Signal 2 is increasing steadily.

ICOS-L is present on both DC and B cells and is critical for germinal center formation and immunoglobulin class switching.

Signal 3 determines the skewing of the T cell response such that T cells may terminally differentiate towards either IFN gamma producing CD4+ T cells (Th1 cells), which eradicate intracellular pathogens (bacteria or viruses), or into Th2 cells producing IL-4, IL-5 and IL-13, which promote elimination of extracellular infections.

Additionally, cytokines like IL-12 for Th1 or IL-4 for Th2 differentiation are crucial determinants of initiation and/or amplification of Th responses. It has been suggested that DC express the Notch ligands Delta or Jagged under Th1 or Th2 conditions respectively, and that these ligands promote differentiation of naïve T cells towards one or the other Th profile.[66] Thus, factors and pathogens, which stimulate DC maturation and IL-12 production, promote Th1 responses (eg, *Escherichia coli*), whereas inducers of IL-4 production prime Th2 responses (*Porphyromonas gingivalis*).

Furthermore, Th1 polarizing capacity of DC is dependent on a number of variables that include the expression of certain transcription factors, the microenvironment, exposure to various maturation stimuli, the kinetics of maturation, and antigen dose. For example, expression by DC of the transcription factor T-bet which controls IFN-γ expression in CD4+ T cells appears to be required for optimal development of Th1 responses.[67] Epithelial DC in the respiratory tract may by default induce Th2 responses upon production of factors such as TSLP by epithelial cells.[38] The duration of DC activation and antigen dose also determines the direction of T cell skewing. Prolonged activation causes IL-12 depletion and results in "exhausted DC."[34] DC presenting low amounts of antigen skew towards Th2 whereas high doses skew towards Th1, which in turn is dependent upon the maturation state of the DC and consequences of environmental exposure.[68,69]

Recently, a new lineage of effector CD4 T cell was discovered.[70] Named Th17 due to their characteristic secretion of IL17 without IFN-γ or IL-4 secretion, this lineage of cells is implicated in several chronic inflammatory disorders. The IL-12 family member IL-23, and TGFβ have been implicated in the generation of Th17 cells, but the precise role of DC in the formation of these cells remains to be determined.[70] LPS-stimulated DC secrete inflammatory cytokines, notably IL-6, and in combination with TGFβ seem to divert differentiation of Treg into Th17 cells.[71,72]

It is important to note that T cell priming is dependent upon mDC, as immDC may induce immunosuppressive or Treg.[73,74] In fact, antigen presentation by immDC in vivo is an important pathway by which tolerance is maintained at both the CD4 and CD8 T cell level, either through the induction of Treg or through the deletion of autoreactive T cells.[75] Nevertheless, recent data suggest that in some conditions, mDC can also induce the generation of CD4+ CD25+ Treg.[76,77]

CD8+ T cells[78] and generation of effective CD8 memory cells in turn requires CD4 T cell help.[78–80] This help is provided through activation of DC via CD40L-CD40 interactions and the production of cytokines such as IL-2, although some studies have suggested that when cytotoxic T lymphocyte precursor frequencies are high, priming of CD8 T cell responses may be CD4 T cell independent. In these cases though, memory generation is likely to be hampered due to the absence of IL-2 during priming,[81] and primed T cells may commit fratricide through expression of TRAIL,[82] or become functionally tolerant upon receiving signals through the inhibitory receptor PD-1.[83]

Evidence is accumulating that pDC, which were believed to play a role only in the innate immune response due to their ability to produce high levels of IFN type I, can present viral and tumor antigens to initiate both CD4+ and CD8+ T cell responses.[84,85] Plasmacytoid DC mature in response to certain viral infections (eg, influenza and HIV) thereby providing an important link between innate and adaptive arms of the immune response. Like their myeloid counterparts, however, pDC display plasticity, even inducing immunosuppressive responses depending upon their microenvironment or the stimuli they are exposed to.[86] The role of pDC in antiviral responses, autoimmunity and transplant tolerance is discussed below.

B CELL ACTIVATION

In addition to affecting T cell function, DC can also influence B cell proliferation, isotype switching and plasma cell differentiation.[87] DC produce factors that activate and induce B cell proliferation (B-Lys and APRIL).[88] Furthermore, DC stimulate antibody responses in a T cell-independent manner against polysaccharide antigens. The initial interactions between B cells and DC occur in the T cell area of lymph nodes and in the germinal centers of lymph nodes and/or splenic red pulp. Importantly, antigen exposed cDC possess a specialized non-degradative pathway, which allows to present internalized antigens in their native state for the engagement of BCR on B cells. This is mediated by endocytosis of antigenic immune complexes through the inhibitory Fc receptor FcγRIIB and recycling of the endocytic vesicle to the surface without antigen degradation.[89] The follicular DC, which are present in germinal centers of lymph nodes and which constitute a different class of DC, participate in the maintenance of B cell memory by formation of multiple antigen-antibody complexes and continuous stimulation of B cells. The antigen-antibody complexes may remain in the lymph node for an extended period of time (up to months or years).

NK CELL ACTIVATION

The interactions between DC and NK cells are complex and further underscore a role of DC as a link between innate and adaptive immunity.[8] Direct interactions between NK cells and mature DC can result in NK cell activation as well as the potentiation of their cytolytic activity, and conversely, NK cells can induce further DC maturation. NK cells and DC can form an immune synapse, probably helping directional and confined secretion of cytokines as well as facilitating receptor-ligand interactions on one another. Activated NK cells induce DC through both cell contact (involving NKp30) and TNF-α and IFN-γ secretion. In turn, activated DC secrete IL-12/IL-18, IL-15, and IFN-α/β, which enhance IFN-γ secretion, proliferation, and cytotoxicity of NK cells. In some conditions, NK cells can lyse DC through NKp30, although mature DC are protected from cytolysis. This might represent a form of "cellular editing" whereby immature and tolerogenic DC are cleared by NK cells in the course of an ongoing immune response.[90]

It is thus possible that DC and NK cells play complementary roles in sensing pathogens such that DC could be the first to detect microbes through their expression of PRR (TLR, NOD proteins), whereas NK may get activated in the absence of overt inflammation but in the presence of ligands for activating NK-cell receptors, such as in the settings of tumors (which frequently lose MHC class I expression and/or express NKG2D ligands, such as MIC-A/B). In both situations, either DC or NK cells could create an inflammatory environment and induce the integrated activation of other cell types. Thus, in mice, infection by murine cytomegalovirus induces pDC to secrete high levels of IFN-α/β, whereas CD8α+ DC are the major producers of IL-12, and resistance to the virus is associated with expansion of Ly49H+ NK cells, driven by IL-12/IL-18.

The interaction between NK cells and DC is likely to take place early during the course of an immune response. This allows DC to exploit the ability of NK cells to kill tumor or virus/parasite infected cells and to cross-present this material to T cells.[91]

ACTIVATION OF OTHER ELEMENTS OF THE IMMUNE SYSTEM

DC have proven to be quite versatile in their ability to interact with many constituents of the immune system. For example, they can activate NK-T cells by presentation of the synthetic ligand alpha-galactosyl ceramide on CD1, inducing the production of cytokines such as IFN-γ and resistance to tumors.[92] CD1 restricted γ δ T cells, which respond to microbial antigens from *Mycobacterium tuberculosis* and other organisms, induce maturation of resting DC, and induce

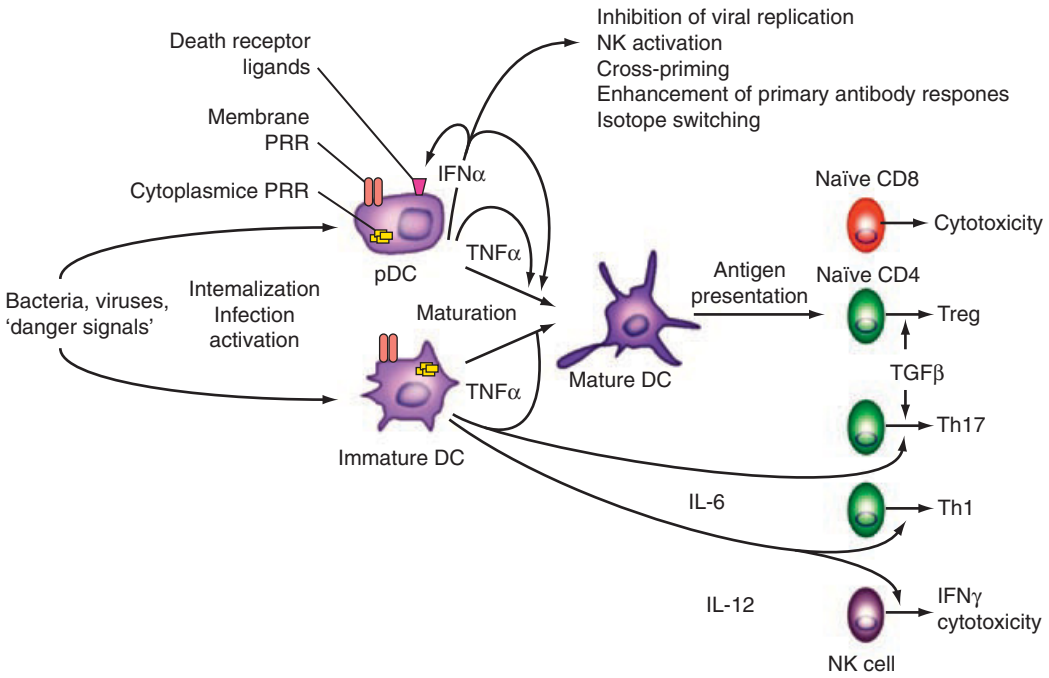

Figure 14–3 DENDRITIC CELLS LINK INNATE AND ADAPTIVE IMMUNITY. Through the expression of pattern-recognition receptors (PRR), like Toll-like receptors, dendritic cells act as sensors of pathogen intrusion. Upon signaling by PRR, they secrete cytokines and express receptors allowing stimulation of the innate immune system. IFN-α or IL-12 stimulate NK cell activation, while also inducing the expression of death-receptor ligands (TRAIL) on dendritic cells, harnessing them for direct killing of infected cells. They take up antigens through direct infection or phagocytosis, undergo a complex program of maturation by up-regulating the expression of costimulatory and MHC molecules, migrate to the secondary lymphoid organs, and stimulate naïve T cells. They secrete cytokines skewing the type of response induced, towards Th1, Th2, Treg, or Th17 differentiation, inducing the generation of cytotoxic CD8 T cells, or participating in the generation of antibody responses.

IL-12 production. This pathway and the IFN-γ secretion by activated γδ T cells, provide the immune system with a source of activated APC, which can polarize Th1 responses.[93]

In summary, the influence of DC on other cell types of the immune system is broad and integrative (Fig. 14–3). Future studies will ascertain the interplay between the myriad of host cells and the innate and adaptive immune response.

TOLERANCE AND AUTOIMMUNITY

DC play a pivotal role in the balance between immunity and tolerance. DC are important in the induction of both central and peripheral tolerance. In the former, DC play a role in deletion of autoreactive T cells in the thymus. In the latter, imDC in their steady state induce T cell deletion, anergy and/or generation of regulatory T cells, which interfere with IL-2 production and proliferation of effector T cells against self.[94] Regulatory T cells are CD4+ or CD8+ in nature, express CD25, CTLA-4 and the transcription factor Foxp3 (a member of the forkhead transcription factor family). These cells exert their tolerogenic effects either via cell contact or through release of immunosuppressive cytokines such as IL-10[95] or TGF-β, preventing proliferation and/or cytotoxicity of activated CD4 or CD8 T cells, and can also inhibit TLR-mediated maturation of cDC, but not pDC.[96] It was recently suggested that a subset of human thymic DC, upon activation by TSLP from epithelial cells of Hassall corpuscles, positively selects CD4+ Treg in the thymic medulla, thereby playing a central role in the generation of naturally occurring Treg.[97] How might DC in peripheral tissues induce tolerance is an open question. One report suggests that uptake of antigens via receptors such as DEC-205, a member of the C type lectin family, can induce T cell deletion and/or generation of antigen-specific Treg.[98]

DC may also be *actively* rendered *tolerogenic* via a number of mechanisms. Resting imDC acquire self-antigens through phagocytosis of apoptotic bodies formed as a consequence of physiological cell turnover. In the absence of a maturation signal, these DC induce tolerance to such self-antigens.[99] Some studies have suggested that ligation of specific receptors on DC such as complement receptors CR3 and CR4[100] by apoptotic cells inhibit their maturation[100] thereby ensuring the delivery of a tolerogenic rather than stimulatory signal. Others include MER, CD91/calreticulin and CD36/αvβ5. External factors such as steroids, IL-10 and/or TGF-β may also compromise DC immunostimulatory function by inhibiting their full maturation.[101] For example, DC isolated from tumor environments are poorly immunostimulatory due to the presence of immunosuppressive cytokines or the induction of costimulatory molecules such as PDL-1 which deliver negative signals.[102] Moreover, there may exist distinct tolerogenic DC subsets. A particular DC subset was recently identified in normal mice that were CD11c-low/CD45RB high), secreted IL-10 after activation, and induced tolerance through induction of Treg.[103] Recently in mice, pDC have been shown to induce tolerance against a vascularized cardiac allograft, upon administration of a tolerizing regimen.[104] After capturing pDC alloantigens from the graft, they migrated to peripheral lymph nodes and induced specific Treg.[104]

Recently, production of indoleamine 2,3 dioxygenase (IDO) has been proposed to account for some of the tolerogenic potential of DC.[105] IDO is an enzyme, which degrades the indole moiety of tryptophan and other molecules, and induces the production of immunoregulatory metabolites known as *kynurenines*. Local depletion of tryptophan and increase in proapoptotic kynurenines affects T cell proliferation and survival. Induction of IDO in DC has been postulated as one means by which deletional tolerance occurs. This is compounded by the observation that Treg may directly act on DC via CTLA-4-B7 interactions to promote IDO production.[105] Moreover, expression of death inducing ligands such as FasL may render DC capable of killing activated T cells.[98,106] Altogether, these properties of DC make them attractive candidates for inducing tolerance in the setting of transplantation or autoimmunity. Indeed, injection of antigen pulsed immature DC in vivo induces antigen specific IL-10-

producing CD8+ T regulatory cells which supplant their IFN-γ producing effector cell counterparts.[74,107]

DC are also believed to be important for the induction or chronic phase of autoimmune diseases. IFN-α produced by pDC are thought to contribute to the autoimmune response in SLE.[108,109] Plasmacytoid DC can be activated through TLR7 and 9 by immune complexes containing RNA and DNA respectively from dead cells, and induced to secrete high amounts of IFN-α. This can further promote the differentiation of monocytes into activated cDC thus enhancing presentation of self-antigens, increasing the cytotoxicity of CD8 and NK cells, and promoting plasma cell differentiation and subsequent generation of pathogenic autoantibodies. A role of cDC during disease onset is also strongly suggested in arthritis, multiple sclerosis, diabetes and atherosclerosis.[110–112] The similarity between outcomes of microbial infection and autoimmunity suggests that TLR or PRR triggered by microbial molecules on DC induce their maturation and secretion of cytokines and chemokines. This may cause DC to upregulate presentation of self-antigens in such instances as apoptosis or necrosis induced directly by pathogens or antimicrobial immune response. Endogenous ligands such as extracellular matrix breakdown products (heparan sulfate and hyaluronate), molecules released from necrotic cells (high-mobility group box 1 protein-HMGB1, uric acid, or even endogenous nucleic acids), fibronectin and heat-shock proteins, which can activate TLRs on cDC, may also contribute to the generation of autoimmune responses.[113]

SUBVERSION OF DENDRITIC CELL FUNCTION BY PATHOGENS AND TUMORS

Several pathogens have evolved different mechanisms to inhibit DC functions, allowing them to downregulate specific immune responses, and hence persist in the host. Numerous viruses, such as measles, vaccinia, herpes simplex, smallpox, and lymphocytic choriomeningitis virus, can impair antigen presentation by infected cells through different mechanisms. Thus, the human cytomegalovirus induces downmodulation of MHC class I or class II molecules, and can inhibit activated T cells through secretion of a virally encoded IL-10 homolog. Directly targeting DC allows viruses to impair the generation and quality of the antiviral immune responses. In mice, the murine cytomegalovirus has been shown to trigger paralysis of infected DC, preventing them from secreting IL-12 or IL-2 upon TLR4 triggering, impairing their capacity to mature, eventually rendering them unable to prime an effective T cell response.[114] Some viral products interfere with IFNα secretion pathways, such as the E6 oncoprotein of human papillomavirus, inhibiting trans-activation of IRF3 or IRF7, or NS3/4A inhibiting RIG-I and MDA5-mediated activation of IRF3.

It is now well documented that in HIV infected patients, not only the number of pDC and cDC in blood is reduced, but also that cDC are less efficient at stimulating primary T cell responses, and may generate IL-10 secreting T cells with a potential regulatory role. DC may be the first cells to encounter HIV in mucosal tissues and may mediate the spread of virus to CD4+ T cells in lymphoid organs. Indeed, cDC can mediate transinfection of CD4+ T cells, through the formation of an *infectious synapse*, carrying the virus with or without infection of the DC itself. DC express the coreceptors CD4, CCR5, CXCR4, and the C-type lectin DC-SIGN necessary for binding and/or entry of HIV, albeit at lower levels than CD4+ T cells, although the expression of DC-SIGN remains to be firmly demonstrated. HIV can infect DC, but its replication is not as efficient as in CD4+ T cells. The viral envelope protein gp120 can bind to CD4 and C-type lectins like DC-SIGN and mannose receptor, but the contribution of each receptor to binding and internalization may vary depending on the particular type of DC encountered by HIV. Thus, although DC are not the main reservoir of HIV, the virus can "highjack" DC to mediate its spread to CD4+ T cells from mucosal tissues to lymphoid organs. Nevertheless, although cDC only get minimally activated by HIV, pDC can get infected and be strongly activated by HIV causing them to secrete high amounts of IFNα and other antiviral molecules. This can inhibit the replication of HIV in CD4+ T cells, suggesting that the two subsets play different and opposing roles during HIV infection. However, pDC may also function to down regulate the response by secreting TRAIL.[115,116]

Tumors also evolve mechanisms to negate the functionality of DC. For example, the number of cDC (but not pDC), is reduced in blood of cancer patients and these numbers of DC are restored upon surgical removal of the tumor, indicating a systemic defect orchestrated by the tumor cells. Moreover, increased numbers of imDC are found in blood and tumor tissue, also displaying an impaired response to activation stimuli. A subset of immature myeloid cells, comprising of immature macrophages, DC, granulocytes, and myeloid cells at early stages of differentiation, accumulate in the secondary lymphoid organs and tumors of tumor-bearing mice and presumably humans. These *myeloid suppressor cells* are endowed with suppressive activity towards antitumor T cells through various mechanisms such as regulation of arginine metabolism and release of oxygen reactive species. It seems that tumors impair early myeloid, and in particular DC, differentiation at a systemic level by secreting soluble factors such as VEGF, M-CSF, IL-6, IL-10. Many tumors constitutively express activated STAT3, a transcription factor partially implicated in the production of these cytokines, the constitutive activation of which also impairs the secretion of proinflammatory cytokines. STAT3 is also responsible for abnormal differentiation of hematopoietic precursor cells, suggesting that inhibition of its activity may be a promising route towards restoring DC function in cancer.

IMMUNOTHERAPEUTIC STRATEGIES AND CLINICAL TRIALS

The last decade has seen an increasing interest in clinical applications of DC, harnessing the growing knowledge about DC biology. It is becoming apparent that any effective vaccine must activate and induce antigen presentation by DC, the most potent cells at stimulating T cell immunity. A number of clinical trials (mostly Phase I and II) have been completed describing the use of DC in cancer immunotherapy (eg, non-Hodgkin lymphoma, malignant melanoma, multiple myeloma, prostate cancer, renal cell carcinoma, breast cancer) and in the immunotherapy of human pathogens such as HIV. Most of these studies have relied on monocyte derived DC while a few have used DC prepared from CD34+ HPC. A critical issue is the antigen delivery to the DC, the nature of the antigen and the vehicle for delivery probably being decisive. DC can be pulsed with defined antigens, in the form of HLA-binding antigenic peptides or whole proteins, or the whole assortment of tumor antigens upon phagocytosis of dying or opsonized autologous tumor cells. Artificial fusion of dendritic cells with tumor cells allows the generation of hybrid cells with characteristic of dendritic cells, but also expressing the whole set of tumor antigens as well. Because autologous tumor cells are not always available from patients with advanced disease, allogeneic tumor cells of the same histological origin expressing shared tumor antigens are also used for loading DC.

DC themselves can also be genetically modified through transfection. However, DC are terminally differentiated nondividing cells and difficult to transfect. Methods using RNA electroporation, and infection by recombinant viruses (lentivirus, poxvirus, herpes virus, and adenoassociated virus) lead to foreign transgene expression in DC. Another strategy is to target DC in situ, using antibodies recognizing DC-specific molecules, such as DEC-205, as demonstrated in mouse models.[117]

Because the activation state of antigen-presenting DC is a determining factor in shaping the ensuing immune response, genetic engineering of DC or triggering activating receptors also allows to enhance their secretion, migration, and antigen presentation capacity. Thus, DC can be activated by artificial TLR ligands (eg, R848, which is a ligand for TLR7, unmethylated CpG oligonucleotides, which are

ligands for TLR9, or inflammatory cytokines, such as IL-1β, IL-6, TNF-α) that can be used in a clinical setting to activate DC before injection, or even in vivo.[118] DC can also be transfected for immunostimulatory molecules, like cytokine genes (eg, IL-2, IL-12), or inhibitory siRNA for molecules dampening DC activation (eg, SOCS1).

It is likely that to achieve significant clinical responses upon vaccination for cancer, combining DC vaccination with other strategies will improve the therapeutic outcome. For example, some strategies aim at depleting or inactivating Treg (using a toxin targeting CD25, a molecule expressed by Treg, or cyclophosphamide), alleviating T cell anergy (using antagonistic CTLA-4), differentiating myeloid suppressor cells into nonimmunosuppressive cells (by injection of retinoic acid derivative ATRA), common γ chain cytokines such as IL-7, which have potent effects on T cell survival and function, or adoptive immunotherapy of in vitro activated T cells.[119,120] Finally, it seems that irradiation of the tumor tissue conditions it for enhanced migration of antigen-presenting cells and T cells, augments MHC class I expression on tumor cells, as well as induces apoptotic cells death, thus augmenting delivery of tumor antigens to DC.[121–123] Thus far, DC vaccines have not met the desired endpoints in clinical studies (ie, tumor regression) despite clear evidence that DC vaccination can induce measurable cellular or humoral immune responses in cancer patients.[124–127] In a recent Phase III trial, vaccination of stage IV melanoma patients by DC loaded with multiple peptides could not be demonstrated to be more effective than the standard chemotherapy treatment.[128] However, the optimal DC type, optimal maturation signal(s), mechanism of antigen delivery, nature of antigen, frequency of immunization, and route of administration still remain to be determined. Furthermore, it may be that only a subset of patients may be able to respond to DC vaccination, or in the case of advanced stage cancer patients, to any vaccination. In our opinion, DC immunotherapy will be most efficacious when coadministered with an adjuvant and when tumor burden is low. The timing of vaccination is probably also crucial, and frequent immunizations may dramatically improve the clinical efficacy.[129] In the setting of HIV infection, a recent study in a small group of chronically infected individuals showed that vaccination with DC loaded with chemically inactivated virus allows stabilization and even suppression of viral load for an extended period of time without any other treatment.[130] Vaccination with DC holds great promise in cancer and infectious diseases, but its potential is likely to be best exploited in combination with other strategies manipulating other arms of the immune system.

Although DC are considered the most potent cells in inducing T cell responses, they can also function as tolerizing cells, a function that can be harnessed against autoimmune diseases and in a transplantation setting. Thus it is possible to differentiate in vitro maturation-resistant imDC, or differentially activated DC, using biological agents such as IL-10, TGF-β, or the fusion protein CTLA-4-Ig, and pharmacological agents such as corticosteroids, cyclosporine, rapamycin, mycophenolate mophetil, vitamin D3, or prostaglandin E2. The clinical relevance of some of these strategies is being evaluated. Another way to dampen pathologic immune responses is to use antagonists for TLR or other innate immune sensor participating in amplifying damaging responses. Thus, since the role of DNA-immune complexes has been established as important in the etiology of SLE, synthetic inhibitory oligodeoxyribonucleotides have been developed, that can prevent and/or inhibit activation through TLR9 on pDC and B cells, and block SLE in animal models. Finally, significant challenges remain with respect to DC based immunotherapy ranging from applicability of preclinical models to humans to regulatory and funding hurdles.

SUMMARY

Dendritic cells (DC) are a sparsely distributed population of bone marrow derived mononuclear cells that exist in an immature form in virtually all tissues in the body. DC serve as professional antigen presenting cells with extraordinary capacity to stimulate naïve T lymphocytes (as well as B cells, NK cells, and NK-T cells) and initiate primary immune response. They link innate and adaptive immunity and are responsible for activation and inhibition of effector cells. Their clinical applications in cancer, transplantation, and chronic virus infections are under investigation.

CHAPTER 15

REGULATION OF ACTIVATION OF B AND T LYMPHOCYTES

John G. Monroe and Michael J. Lenardo

OVERVIEW

The immune system is composed of different cell types that perform specialized regulatory and effector functions in an orchestrated manner to achieve immunity. Compartmentalization and subspecialization of these cells allow for enormous flexibility in the response to specific types of pathogens. Lymphocytes constitute the effector cells of the adaptive antigen-specific immune response. They are the cells responsible for the characteristics that we often associate with the immune system—namely, memory, specificity, and tolerance to self-antigens. Lymphocytes can be subdivided into two general subpopulations: B lymphocytes and T lymphocytes. B lymphocytes are responsible for antibody production, whereas T lymphocytes are the mediators of cellular immunity: cytotoxic T-lymphocyte responses, delayed-type hypersensitivity, graft-versus-host reactions, and other cellular immune reactions. A secondary role for B lymphocytes is in the major histocompatibility complex (MHC) class II antigen presentation to CD4-expressing T lymphocytes, as discussed in Chapter 12.

Immune responses involve powerful and sometimes destructive mediators that have important effects on normal physiology and anatomy. Therefore, lymphocytes are normally in a quiescent state and only those needed are called forth, or activated, in a particular immune response. Activation includes the initiation of biochemical and metabolic processes that trigger changes in gene expression programs leading to the coordinated production of internal, cell-bound, and soluble proteins that enable the lymphocytes to carry out protective immune functions. The programs of genes expressed differ between B and T cells as well as their subsets and this dictates their distinct immune functions. A crucial effect of these genetic programs is to induce clonal proliferation of the lymphocytes that have been activated. As described throughout this chapter, an elaborate set of positive and negative controls govern the gene-activating signals and thus the levels of the potent mediators and cellular offspring produced.

Activation of lymphocytes requires a means to detect antigens, an immense diversity of molecular structures (termed *epitopes*) on infectious agents or tumor cells that are the targets of immune response. As postulated as long ago as 1900 by Ehrlich[1] and confirmed by numerous studies since then, lymphocytes express clonally distributed receptors on the cell surface that facilitate antigen recognition and serve as signaling molecules to initiate the activation of these cells. Extensive investigation has shown these receptors to be transmembrane protein complexes on the cell surface that link antigen recognition events to the intracellular signaling apparatus. The structure of the antigen-binding component, and hence the specificity of the B- and T-lymphocyte antigen receptors, are determined by a complex recombination process that operates on a large variety of gene segments encoding these regions (see Chapters 11 and 12). The variable regions, which are the amino terminal regions of the receptor proteins that bind antigen, are assembled by mixing and matching assorted genetic segments, thereby generating an enormous diversity of antigen recognition sites. As a consequence of this potential variability, the number of antigenic epitopes that can be recognized has been theoretically calculated to exceed 10^{11}. Because the specificity is determined at the genetic level, the progeny and effector cells derived from a B or a T lymphocyte after antigen activation maintain in many circumstances the identical antigen specificity of the original responding cell. This process ensures the clonality of the immune response. A specific exception to this rule is the somatic hypermutation of the B-lymphocyte antigen receptor gene that occurs during germinal center reactions.[2,3] This alters the DNA sequence of the gene so as to introduce new amino acids in the antigen-combining regions of the receptors, thereby refining it specifically or creating it anew.

For B lymphocytes, antigen recognition and binding is mediated by a surface form of immunoglobulin (sIg). Other proteins that are noncovalently associated with sIg are responsible for generating signals that inform the antigen-bound B lymphocyte to respond. This multimeric protein complex is called the B-cell antigen receptor (BCR) and has separate antigen recognition and signaling components. This compartmentalization of function allows B lymphocytes to maintain maximum diversity in their antigen recognition capability and at the same time trigger identical responses. Along similar lines, the T-cell antigen receptor (TCR) also is a complex of antigen recognition and signal transducer proteins. The largest class of T lymphocytes uses a dimeric protein composed of two disulfide-linked α and β chains as their receptor for antigen recognition (α/β TCRs). A more restricted class of tissue-associated T lymphocytes use separately encoded genome (γ) and delta (δ) receptor chains for antigen recognition ($\gamma\delta$ TCRs).

Although the BCR and, as you will see later, the TCR as well are sufficient for antigen binding and signal initiation, other surface proteins called *coreceptors* can regulate the strength of antigen binding as well as the level of signals generated by this binding. These coreceptor molecules regulate the sensitivity of the antigen receptors for generating activation signals and also play a role in how certain antigens interact with B and T lymphocytes. Coreceptors CD4 and CD8 define the major subsets of T cells and also augment TCR interactions with antigenic peptides in the context of major histocompatibility complex (MHC) class II and class I molecules, respectively, expressed on antigen-presenting cells (APCs). By contrast, the MHC does not influence BCR-dependent interactions, because these receptors can bind native antigen. Distinct B cell-specific coreceptors, including CD22 and the CD19–CD21 complex, regulate BCR signaling. As is discussed in more detail later, CD22 likely modulates receptor sensitivity under defined conditions and CD19–CD21 may regulate responses to specific forms of antigen.

Antigen binding by BCRs or TCRs on fully mature B and T lymphocytes is necessary but not sufficient to generate complete activation responses. Both types of lymphocytes require signals generated through secondary cell-surface proteins called *costimulatory molecules*. For T lymphocytes, signaling through the CD28 coreceptor is required for gene induction controlling growth factor production and proliferation. B lymphocytes require CD40 costimulatory signaling for antibody production and optimal clonal expansion. Finally, for both types of lymphocytes, soluble cytokines amplify and modify the activation responses and determine the effector functions of these cells. Finally, it should be noted that B lymphocytes can be activated in some cases independently of the BCR. B lymphocytes express Toll-like receptors (TLRs) on their surface and in their cytoplasm that recognize common molecular structures or patterns associated with pathogens but not normally expressed by humans and other mammals. Using biochemical pathways different from those used to initiate BCR-induced activation, binding of these pattern-

recognition receptors to pathogen-associated molecules triggers the B lymphocyte independently of the BCR. TLRs are described in more detail in Chapter 10 and will not be mentioned further here. Likewise, T cells can also be activated independently of TCR. In this case signals generated through CD2 or the GPI-linked protein Thy-1 can trigger proliferation although the significance of this mechanism of T-cell activation is at present unknown.

This chapter discusses how antigen-induced lymphocyte responses are initiated and the way that the gene-activating signals generated through these receptors are regulated. The focus is on (a) the mechanism and role of the antigen receptor-induced activation signals, (b) the degree to which these signals are necessary for lymphocyte-mediated immune responses, and (c) how they can be modified to adapt the response to different pathogens.

B LYMPHOCYTES

B lymphocytes are the primary effector cells of the antibody-mediated immune response and are APCs for activated and, in some circumstances, resting T lymphocytes. They constitute the cells necessary for the humoral arm of the immune system because the antibody they produce can travel through the blood and lymph (the humor) and have effects at distant sites from the B cells that produced them. Also, humoral immunity can be transferred by serum without cells—a procedure sometimes used as a clinical intervention. Antigen recognition and triggering are accomplished by the BCR expressed on the surface of mature, immunocompetent B lymphocytes. Following antigen binding, the BCR-antigen complex is endocytosed, and protein antigens are processed and re-presented as peptides on the B-lymphocyte surface in association with class II MHC antigens. These peptide–MHC class II complexes are recognized by CD4 T cells. This interaction activates the T cells (see later section on T-lymphocyte activation), and these activated T cells in turn deliver activation and differentiation signals to the B lymphocyte. In this context, the antigen-specific B and T lymphocytes can be viewed as communicating with each other, each providing cues to the other to increase levels of activation and effector cell commitment. This stepwise process makes available multiple levels of regulation, providing the immune system with critical checkpoints to ensure that the appropriate magnitude and effector function are achieved. In addition to its role as a recognition structure and as a mechanism for antigen capture, the BCR also serves as the initiating signaling complex for B cell activation.

B-LYMPHOCYTE ANTIGEN RECEPTOR

The antigen recognition structure of the BCR is a surface form of immunoglobulin (sIg). The basic monomeric structure of sIg is identical to that of the monomeric subunit of the secreted form of this molecule. Each monomer possesses two light-chain proteins (IgLC) disulfide-coupled to two disulfide-linked heavy-chain (IgHC) proteins. The surface and membrane forms of immunoglobulin differ from the secreted form with respect to the carboxyl (C) end of the heavy-chain proteins. Surface immunoglobulin includes additional amino acid residues, comprising a spacer, a transmembrane region, and a cytoplasmic region. The carboxyl-terminal (C-terminal) end of the membrane form is encoded by two additional exons that differ for each immunoglobulin isotype. For sIgM and sIgD, the cytoplasmic region is composed of only three amino acids, whereas IgG and IgA are more extensive, comprising 28 and 14 amino acids, respectively. The reason for the more extensive cytoplasmic domain for IgG and IgA is not established; in IgG, however, this region may be important for optimal expansion of isotype-switched B lymphocytes in the germinal center.[2] In addition the secreted forms of Ig can exist as multimers of the Ig monomeric structure. Such is the case for IgA and IgM. The light chains are linked to the N-terminal domain of the heavy chains and thereby contribute directly to the enormous variability in antigen-binding specificities between individual B lymphocytes. The primary sequence of the heavy- and light-chain variable regions that associate to form the antigen-combining site determines the antigen specificity of a particular B-lymphocyte clone. Importantly, the diversity created by expressing unique antigen recognition elements on every newly created B lymphocyte results in an extremely large repertoire of antigen-reactive B lymphocytes within an individual. Therefore, at any given time an individual has the potential to recognize and react to an enormous universe of potential pathogens that might break through the normal physical barriers of the body.

There are molecularly distinct isotypes of immunoglobulin (IgM, IgD, IgG, IgE, IgA) that all function as antigen receptors on B lymphocytes. These arise from switching of gene segments in the carboxyl-terminal region of the Ig heavy chain via a process called "class switching." For the most part, only one isotype is expressed at any given time. A single exception to this rule occurs in the case of IgM and IgD, which can be coexpressed on resting mature follicular B lymphocytes. For isotypes other than IgM and IgD (ie, IgG, IgA, and IgE), genetic mechanisms similar to those involved in variable region gene rearrangement (see Chapter 11) make it genetically impossible to coexpress these other isotypes.

A genetic process involving the rearrangement of the exons that encode heavy- and light-chain variable regions determines the amino acid sequence of the variable region. Through a process involving stochastic selection of variable region segments, random nucleotide additions, and junctional diversity, the DNA sequence of a rearranged BCR gene has only a 1 in 10^9 to 10^{12} chance of being identical to any other BCR rearrangement. Because this genetic process occurs without antigen selection, the intrinsic antigen specificity of the B lymphocytes produced is quasi-random and highly varied, enhancing the likelihood of clones responsive to new foreign antigens. Although this potential diversity can never be realized in the immune system of a single individual within a group of individuals, it provides a tremendous advantage to a population of individuals because it ensures that the potential exists in the population to respond to a nearly infinite spectrum of antigens. In addition, 2 to 3 million new B lymphocytes are generated daily so that the diversification process constantly generates new specificities and affinities for potential pathogens. This survival advantage must be balanced, however, against the likelihood that many of the BCRs produced may be reactive to self-antigens. Although it is not discussed here, the immune system has evolved mechanisms to identify and remove self-reactive B and T lymphocytes from the repertoire based in part on signals generated through their BCRs.[3–6]

As already mentioned, the BCR exists as a protein complex in the plasma membrane of the B lymphocyte, as illustrated in Fig. 15–1. IgM and IgD are the isotypes expressed on resting B lymphocytes with no prior history of antigen-induced activation (naive or virgin B lymphocytes). However, the short cytoplasmic domain of sIgM or sIgD (three amino acids) is unable on its own to couple cross-linking by antigen to intracellular signal transducers. Consequently, in order to initiate activation signals, sIg exists noncovalently associated with a disulfide bond-coupled heterodimer of two proteins, Igα (CD79a) and Igβ (CD79b).[7,8] These proteins are products of the *mb-1* and *B29* genes, respectively, and constitute the signaling components of the BCR.[9,10] Furthermore, expression of Igα and Igβ is necessary for surface expression of membrane immunoglobulin (mIg).

Igα and Igβ are structurally similar transmembrane proteins with a single immunoglobulin superfamily domain in the N-terminal extracellular portion and a long C-terminal intracytoplasmic domain. As first noted by Reth,[11] within these cytoplasmic domains are regions homologous to other immunologic signaling molecules, such as the γ, ε, and δ chains of the CD3 complex (see later) and the high-affinity IgE receptor β and γ chains in mast cells. These motifs contain two tyrosines (Y) in a pattern of YXXL/I(X 6–8)YXXL/I, where X represents any amino acid. For the BCR and the TCR (see later), it has been shown that these tyrosine-containing motifs—immunoreceptor tyrosine-based activation motifs (ITAMs)—are necessary and largely sufficient for signal transduction.[12] The tyrosines associated with ITAMs are significant because they represent substrates for tyrosine

phosphorylation by specific kinases and subsequent docking sites for intracellular signaling molecules, as discussed later.

The earliest detected BCR-triggered event is the activation and phosphorylation of tyrosine-specific kinases, particularly those belonging to the Src, Syk, and Tec families of protein tyrosine kinases (PTKs). The phosphorylation of tyrosines in the Igα and Igβ ITAMs after BCR cross-linking provided the first clue that PTKs were involved in transmembrane signaling. Phosphorylation of these proteins is believed to be accomplished by specific PTKs that exist in noncovalent association with the BCR in an inactive form in resting B lymphocytes. Clustering of the BCR signaling complex, as occurs after binding to multivalent antigen or antigen aggregates, activates the receptor-associated PTKs and the subsequent phosphorylation of the Igα and Igβ ITAM-associated tyrosines. This process facilitates recruitment of signaling proteins containing phosphotyrosine-binding Src homology-2 (SH2) domains, as diagrammed in Fig. 15–2. The reader is also referred to several reviews for more details on the regulation of these processes.[13–15] SH2 domains interact with phosphotyrosine residues with characteristic specificities. A common theme for molecules intimately involved in signal transduction is their modular construction, associating different discrete protein–protein interaction domains with domains mediating enzymatic activity. These interaction domains facilitate not only recruitment of enzyme substrates, as in the case of kinases, but also direct the spatial localization of these multiprotein signaling complexes to receptors such as the BCR and TCR.

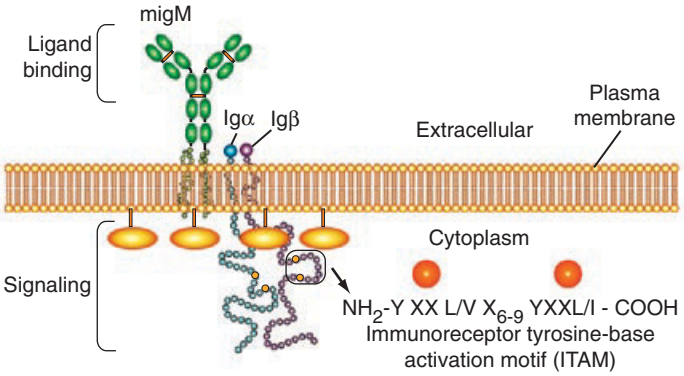

Figure 15–1 Composition of the B lymphocyte (B-cell) antigen receptor complex (BCR) on resting B lymphocytes. Shown are heterodimers of Igα and Igβ in noncovalent association with the membrane form of IgM (mIgM). Also illustrated are BCR-associated Src-family tyrosine kinases because they are believed to associate with the complex in the resting state. These kinases are tethered to the cytoplasmic side of the plasma membrane by a short myristoylated sequence and in noncovalent association with Igα and Igβ by the amino-terminal (N-terminal) portion of the kinase. The specific association of each kinase with either Igα or Igβ is not known and is illustrated here only for convenience. The diagram reflects the known stoichiometric relationship that exists between the number of Igα/Igβ heterodimers and the mIg monomer. The consensus sequence of the immunoreceptor tyrosine-based activation motif (ITAM) associated with Igα and Igβ is depicted.

B-lymphocyte receptor-associated PTKs identified so far are Lyn, Blk, Fyn, and, in a few reports, Lck.[16–18] All are members of the Src family, which is defined by a conserved arrangement of protein–protein interaction domains (Fig. 15–3) as well as a kinase domain and sites for autoregulation by phosphorylation.[19] Kinases of the Src family each have a myristoylation sequence at the N terminus, tethering the kinases to the plasma membrane. Some of these, such as Lyn, also are palmitoylated, which, as discussed later, may influence their association with specific compartments within the plasma membrane. Adjacent to the myristoylation sequence is a unique amino acid sequence that differs for each member of the Src family kinases. This region may be responsible for interactions with the unphosphorylated Igα/Iγβ complex in resting B lymphocytes.[20] At the C terminus of the unique region is a single Src homology-3 (SH3) domain that mediates protein–protein interactions by recognition of proline-rich motifs. C-terminal to the SH3 domain in the protein is the SH2 domain.

For all Src family kinases, the enzymatically active kinase domain is at the C terminus of the protein. All of these family members also share common regulatory mechanisms. One tyrosine residue, near the C terminus of the protein, negatively regulates kinase activity (see Fig. 15–3). If this site is phosphorylated, the enzyme is inactivated, thereby providing a mechanism to turn off the response. Dephosphorylation alters the conformation of the kinase to induce full activity. In B lymphocytes, this inhibitory phosphorylation event is mediated by the Csk tyrosine kinase. This kinase is structurally related to the Src family kinases, containing single SH2 and SH3 domains near the N-terminus of the molecule. Csk is functionally unique, however, in its substrate specificity. The main function of Csk kinase is to phosphorylate Src family kinases, at their C-terminal negative regulatory tyrosines.[21] Thus, the principal function of Csk is to maintain the BCR in the inactive state in the absence of antigen and possibly to downmodulate signaling once antigen is no longer present. Conversely, initiation of signaling requires dephosphorylation at this site.[19] Dephosphorylation is believed to be mediated by coclustering of CD45 (see later) with the aggregated BCR complex. The mechanism by which phosphorylation and dephosphorylation

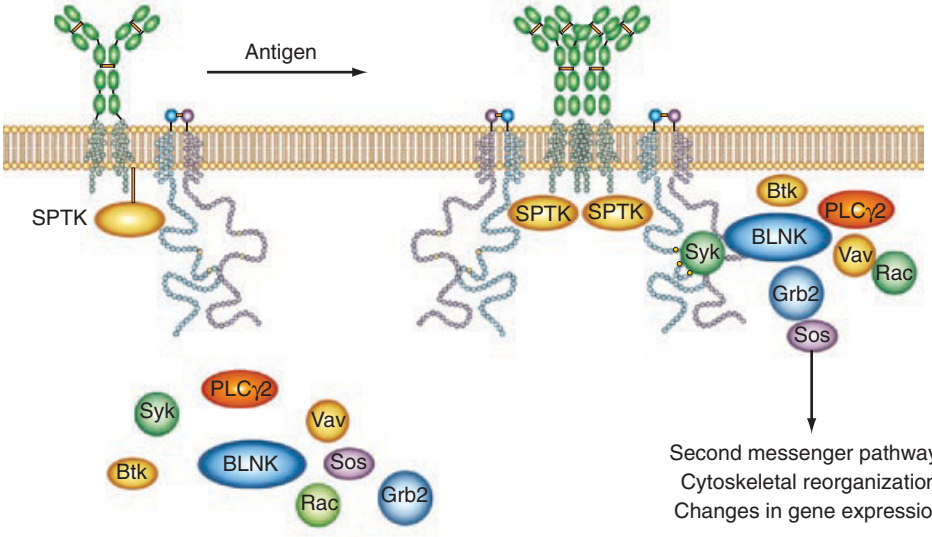

Figure 15–2 Illustrated is the signaling complex formed as a consequence of antigen-induced clustering of B-cell receptor (BCR) complexes. Shown are examples of cytoplasmic signaling effector proteins that are recruited subsequent to the Src kinase-mediated phosphorylation of the Igα/Igβ immunoreceptor tyrosine-based activation motifs (ITAMs). Although this diagram depicts only a selection of the many protein–protein interactions that occur following BCR aggregation, the example serves to illustrate the central role for adapter proteins in the organization of these signaling complexes; B-cell linker protein (BLNK) is used as the example in this figure. Ig, immunoglobulin; PLCγ2, phospholipase Cγ2; SPTK, Src protein tyrosine kinase.

are believed to regulate kinase activity for the Src family protein tyrosine kinases is illustrated in Fig. 15–3.

Subsequent to the initial wave of PTK activation mediated by the BCR-associated kinases, there follows activation of a second set of distinct PTKs. Two of these kinases play unique and critical roles in B-lymphocyte activation: Bruton tyrosine kinase (Btk), which is a member of the Tec PTK family, and Syk. As the name implies, Btk activity is associated with Bruton immunodeficiency. Accordingly, mutations in Btk have been shown to be responsible for X-chromosome-linked B-lymphocyte immune defects in mice and humans.[22–24]

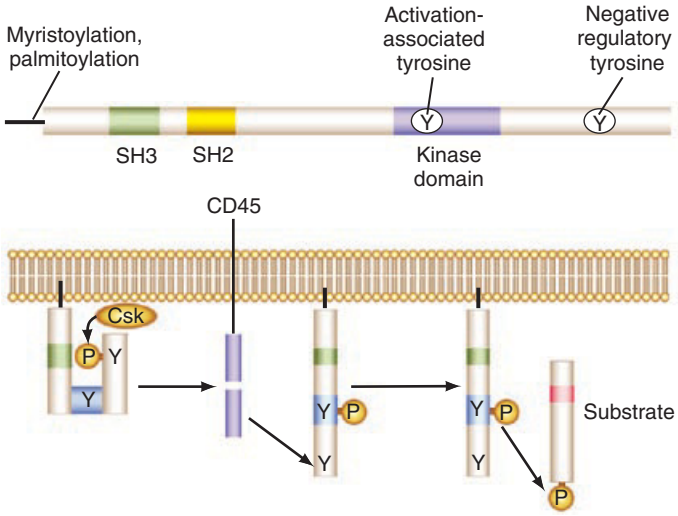

Figure 15–3 Top panel, The modular structure of protein tyrosine kinases belonging to the Src family. Each member of this family contains SH3 and SH2 domains for protein–protein interactions, a kinase domain, and two tyrosine residues that are involved in the regulation of the activity for these proteins (as diagrammed in *bottom panel*). **Bottom panel,** Regulation of the activity of the Src-family protein tyrosine kinases. Illustrated is the model accounting for decreased activity as a consequence of Csk-mediated phosphorylation of the carboxyl-terminal (C-terminal) tyrosine, which then interacts with the SH2 domain (*shaded*) of the kinase, resulting in an inaccessible kinase domain (*cross-hatched*). Cross-linking of the B- or T-lymphocyte receptor is believed to cluster CD45 and the receptor-associated Src family tyrosine kinases. CD45-associated phosphatase-catalyzed dephosphorylation of the C-terminal tyrosine results in an open configuration in which the kinase domain-associated tyrosine is phosphorylated by adjacent tyrosine kinase molecules. This phosphorylated tyrosine serves as a docking site to position substrate proteins near the catalytic domain of the kinase. P, phosphate group; Y, tyrosine.

The Syk kinase bears homology to the zeta-associated protein (ZAP-70; with an Mr of 70,000) PTK that is associated with the ζ chain of the TCR complex (see later).[12] Both ZAP-70 and Syk contain tandem SH2 domains at the N-terminal end of the protein, and a kinase domain in the C-terminal region.[25,26] Syk kinase also is activated and tyrosine phosphorylated following BCR cross-linking, although with slower kinetics than for the Src family PTKs.[27] Src kinase-mediated phosphorylation of the Igα/Igβ ITAMs creates phosphotyrosine docking sites to recruit Syk through its tandem SH2 domains (Fig. 15–4). This docking, coupled with Syk phosphorylation by Src kinases, activates the tyrosine kinase activity of Syk. One of the most immediate substrates of Syk is the cytoplasmic adapter protein BLNK (*B*-cell *link*er protein; also called SLP-65). BLNK is an example of a rapidly expanding family of intermediate signal-transducing proteins called *adapters*.[28] Adapters lack inherent enzymatic activity but function by recruiting and physically organizing other signal-transducing enzymes. In the case of BLNK, it is phosphorylated on at least five tyrosines by Syk. These phosphotyrosines then interact with the SH2 domains of Btk, PLCγ2, Vav, and potentially other signaling proteins. By so doing, adapters such as BLNK can spatially arrange signaling proteins into organized complexes termed *signalosomes*. The stability of the signalosome and thus the duration of the signal relies entirely on the continued phosphorylation of Igα, Igβ, and BLNK. As a consequence, the strength and duration of BCR signals are critically dependent on the balance of tyrosine kinase and phosphatase activities proximal to the assembled signaling complex.

B-LYMPHOCYTE INTRACELLULAR SIGNALING

Antigen-induced B-cell activation can be separated into two categories depending upon the degree to which antigen–BCR engagement alone is sufficient. Thymus-dependent antigens require secondary signals from activated T cells (as will be discussed later) in addition to BCR signaling for activation of proliferation and IgM secretion, whereas for thymus-independent antigen responses T-cell help can augment BCR-induced responses but are not absolutely required. In either case, following the initiation and transmembrane transduction of BCR signals, the signals are amplified, propagated, and translated by the B lymphocyte into appropriate responses. Many of the events are common to T lymphocytes as well. The linkage of antigen receptor-initiated signals to changes in gene expression necessary to alter the activation state and effector capabilities of the lymphocyte occurs through the generation of cytoplasmic second messengers. All defined second messenger pathways linked to the BCRs and TCRs are triggered by the initial PTK phosphorylation events. As will become evident, the initial two PTK steps are followed by activation of either serine/threonine-directed protein kinases or phosphatases. These pro-

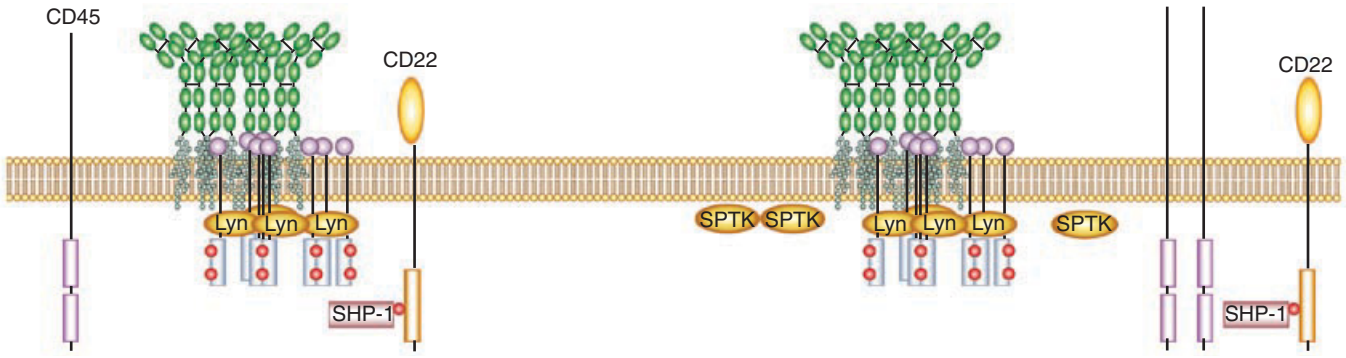

Figure 15–4 Diagram showing the inclusion of the antigen-mediated multimerized B-cell receptor (BCR) into the liquid-ordered plasma membrane compartments (ie, rafts, GEMs, or DIMs; see text) (depicted in *green*). Illustrated here is the proposed model whereby raft compartmentalization excludes negative regulatory protein tyrosine phosphatase complexes (ie, CD45 and CD22/SHP-1) from the multimerized BCR complexes and concentrates positive regulators of BCR signaling (Src protein tyrosine kinases [SPTKs]) to enhance signaling through the antigen-aggregated receptor. DIMs, detergent-insoluble membranes; GEMs, glycosphingolipid-enriched membranes.

teins are directed at the activation of transcription factors that preexist in the resting lymphocyte but in an inactive state.[14]

Three major second messenger pathways have been linked to BCR-mediated signaling. The first is the phosphatidylinositol (PI) hydrolysis pathway, which is initiated by the activation of phospholipase Cγ2 (PLCγ2). In B lymphocytes, Syk and Btk tyrosine kinase activities phosphorylate PLCγ2 to activate its lipase activity, thereby initiating this signaling pathway. The preferred substrate of active PLCγ2 is a plasma membrane phospholipid, phosphatidylinositol-4,5-bisphosphate (PIP_2). PLCγ2 lipolysis of PIP_2 yields inositol-1,4,5-triphosphate (IP_3) and diacylglycerol, each of which in turn generates two second messengers, increasing cytoplasmic free Ca^{2+} and stimulating a serine/threonine protein kinase called protein kinase Cβ (PKCβ), respectively. The rise in intracellular free Ca^{2+} concentration probably triggers a number of changes in cellular physiology; however, at a minimum, it activates calcineurin, an inducible cytoplasmic serine/threonine phosphatase. Calcineurin activity is required for the activation responses of B and T lymphocytes through its ability to activate the nuclear factor of activated T lymphocytes (NFAT).[29] Although the precise role of PKCβ in B-lymphocyte activation is not fully understood, it is critical for normal B-lymphocyte development, survival, and BCR-induced proliferative responses to T cell-independent antigens.[30,31]

Another second messenger pathway linked to BCR signaling is the phosphatidylinositol 3′-kinase (PI3K) pathway. This pathway is initiated by PTK-mediated phosphorylation of the regulatory subunit that induces the enzymatic activity of PI3K.[32,33] Activated PI3K phosphorylates inositol phospholipids converting, in one case, PIP_2 to PIP_3. Although PI3K is important in growth factor-mediated signaling and is known to be activated by BCR-mediated signaling,[34,35] its role in B-lymphocyte responses is not completely clear. One described consequence of PI3K activity is the ability of the PIP_3 product to activate a unique isoform of protein kinase C, PKCζ.[36] PI3K appears to activate another kinase, S6K, which has been shown to facilitate the progression of stimulated cells through the cell cycle.[37–39] An additional downstream kinase that is stimulated by PI3K is Akt (also known as protein kinase B, PKB), which phosphorylates and inhibits the activity of GSK3, another serine/threonine kinase that negatively regulates the transcription factor NFAT.

The third network of regulatory proteins activated by BCR signaling are the small GTPase (or G) proteins of the Ras pathway.[40] In its active state, p21 Ras binds guanosine triphosphate (GTP) and can activate Raf-1, a serine/threonine kinase. Activated Raf-1 is able to phosphorylate and activate mitogen-activated protein kinase kinase (MAPKK), a tyrosine and serine/threonine protein kinase that can then activate mitogen-activated protein kinase (MAPK). MAPKs can in turn phosphorylate and activate transcription factors such as components of activator protein-1 (AP-1), thereby inducing their activity in the nucleus, ultimately leading to specific gene activation. Ras activity is controlled by a number of modulator proteins, which either negatively regulate by promoting GTP hydrolysis to guanosine diphosphate (GDP) or positively regulate by promoting the exchange of bound GDP for GTP. Guanine nucleotide exchange factors (GNEFs) include Vav and Sos, which promote Ras activity. Localization of these Ras regulators is achieved by a number of SH2 domain- and SH3 domain-containing proteins.[41] One such protein, Grb-2, binds to Sos through its SH3 domain.[42] Grb-2 consists of two SH3 domains that flank a single SH2 domain. The Grb-2 SH2 domain binds phosphorylated tyrosines of activated receptors, thereby connecting these to the Ras pathway.[43] The Grb-2 SH2 domain also can bind to phosphorylated Shc, a protein that is phosphorylated by antigen receptor cross-linking in B lymphocytes.[40,44] Nagai and colleagues[44] showed that Src family kinases and the Syk kinase were important for Shc phosphorylation. The Vav protein is expressed only in cells of hematopoietic origin. Vav is tyrosine phosphorylated and GNEF activity is stimulated following BCR cross-linking.[45,46] Deficiencies of Vav in B lymphocytes cause a reduction in the number of peripheral B lymphocytes and the inability to proliferate in response to BCR signaling.[43,47] Downmodulators of Ras such as the Ras-GTPase activating protein (ras.GAP) are inactivated by tyrosine phosphorylation in B cells after antigen receptor stimulation.[48]

In addition to these second messenger pathways, studies of both BCR and TCR signaling (see later) have unveiled other pathways that play more specific activation functions by initiating alterations in cytoskeletal organization and motility. Although we generally describe these pathways as linear sequences of events that operate in parallel, there is considerable cross-talk between them. This cross-talk adds a level of regulation and complexity that makes it difficult to assign a particular pathway to a specific downstream activation-associated event.

Our understanding of the distribution of proteins and lipids in the plasma membrane of immune system cells has changed dramatically over the past several years. We now appreciate that the plasma membrane is compartmentalized into highly liquid-ordered and -disordered regions rather than a homogeneous structure with free diffusion of proteins and lipids.[49,50] The liquid-ordered compartments are enriched in glycosphingolipids and cholesterol.[49] The BCR (and TCR) complex exists predominantly in the liquid-disordered compartments in resting B (and T) lymphocytes.[51,52] Antigen-induced oligomerization is accompanied by the redistribution of the receptor into the liquid-ordered compartments, as diagrammed in Fig. 15–4. These compartments are known as glycosphingolipid-enriched membranes (GEMs), detergent-insoluble membranes (DIMs), or rafts. Rafts are enriched for certain molecules, including myristoylated or palmitoylated Src kinases and PIP_2. The current model for rafts in signal transduction envisions that inclusion of the BCR into rafts provides an environment rich in positive-signaling molecules. Moreover, there is evidence that rafts selectively exclude specific negative regulators of sustained antigen-receptor signaling, such as CD45 and CD22 (discussed in more detail in the subsequent sections). It appears likely that the regional organization on a nanometer scale may be dynamically assembling and dissolving in response to the signaling state of the cell. Thus, the raft concept posits that compartmentalization of oligomerized BCR promotes the ability to sustain a signal and may even enhance, or be required for, assembly of the signalosome. Although attractive conceptually, this remains an area in which there is considerable debate.

The above discussion implies that antigen-induced BCR stimulation causes activation signals in B lymphocytes. This is mainly true for mature follicular and marginal zone B lymphocytes. However, BCR expressing immature B cells in the bone marrow or transitional immature B cells in the spleen are not activated by BCR engagement. Rather, BCR signaling in these B lymphocytes triggers negative responses, resulting in induced apoptotic cell death.[53] Thus, BCR signaling, or at least the cell fates that it triggers, is developmentally regulated. These BCR-triggered negative responses may contribute to the elimination of self-reactive B lymphocytes and immunologic tolerance to self-antigens (see Chapter 18).[53] Finally, it is important to consider data that indicates that to some degree the BCR can signal independently of antigen recognition and receptor aggregation. This signaling has been termed *tonic signaling* to indicate that it represents a basal level of constitutive signaling through the BCR. Little is known about the molecular processes involved in initiating and regulating tonic signals. However, tonic signaling is important in BCR-dependent B-lymphocyte development and survival in peripheral organs such as the spleen.[54]

B-CELL RECEPTOR CORECEPTOR MOLECULES

Positive Regulators of B-Cell Receptor Signal Transduction

Although the BCR is capable of initiating an activation response, its ability to do so is influenced by the selective recruitment of coreceptor molecules by antigen. One of these coreceptors is the CD19–CD21 complex. CD19 is a cell-surface glycoprotein specifically expressed on all B cells. This transmembrane protein has a large (comprising

238 to 242 amino acids) intracellular domain containing nine tyrosine residues. Coligation of CD19 with the BCR dramatically affects the dose response of mature-stage B lymphocytes to antigen by enhancing the BCR signal.[55] The cytoplasmic tail of CD19 interacts with the PI3K p85 regulatory subunit and the Fyn and Lyn tyrosine kinases.[56,57] These interactions as well as the fact that the nine cytoplasmic-region tyrosines are rapidly phosphorylated after BCR cross-linking argue that the CD19 cytoplasmic domain is crucial for signaling. Of particular relevance, although the BCR itself may be capable of triggering the PI3K pathway, optimal triggering occurs through signals initiated by CD19.[58] Loss of CD19 results in impaired preBCR-dependent development, attenuated early BCR signaling, and impaired responses to antigen in vivo.[58,59]

On mature B lymphocytes, CD19 exists on the cell surface as a complex consisting of the complement receptor CD21 as well as Leu-13 and TAPA-1 (*t*arget of *a*nti*p*roliferative *a*ntibody-1) (ie, CD81).[60,61] Each protein brings a unique function in the complex. CD19, with its extensive intracellular domain, is a substrate for tyrosine kinases and can associate with a variety of intracellular signaling proteins. CD21 links this complex with the BCR by binding antigens that are associated with components of the complement cascade. In so doing, CD21 drags CD19 and its cytoplasm-associated signaling molecules into the BCR complex. Thus, this coreceptor enhances the BCR signaling by antigen–complement complexes bound by the B lymphocyte. The roles of TAPA-1 and Leu-13 are less clear, but both mediate homotypical cell adhesion, so they could facilitate cell–cell interaction during the immune response. More recently, it has been suggested that TAPA-1 may stabilize the BCR in lipid raft compartments, thereby sustaining antigen-induced signals under conditions where the CD19–CD21 coreceptor is engaged.[62] Figure 15–5 is a diagram of the BCR–CD19–CD21 coreceptor interaction, illustrating enhanced signaling by an antigen–complement bridge.

Another BCR coreceptor is CD45, which is an abundant, highly glycosylated, leukocyte-specific cell-surface protein. It is estimated to constitute 10% of the total cell-surface glycoprotein in B cells.[63,64] CD45 protein isoforms of various sizes occur on different lymphocyte cell types and on the same cell types during development and differentiation. This variation is due to alternative splicing of three or four exons that encode the N-terminus of the protein. The highest-molecular-weight isoform of the molecule (B220), containing all of the alternately spliced exons, is found primarily on B lymphocytes. The cytoplasmic domain of the CD45 protein contains an active phosphatase domain important for dephosphorylation of a regulatory tyrosine located at the C-terminal end of src kinases during BCR signaling.[12] Dephosphorylation of this tyrosine residue is necessary for full enzymatic acitivity. B-lymphocyte lines as well as B cells from mice lacking CD45 show defects in early BCR-mediated signal transduction.[65] B lymphocytes from mice lacking CD45 are severely compromised in their ability to proliferate in response to BCR cross-linking, although they are able to proliferate in response to the mitogen lipopolysaccharide (LPS).[66] B lymphocytes from CD45-deficient mice showed severe functional defects.[67,68] The population of high-density, IgM^{low}/IgD^{high} B lymphocytes was greatly diminished and B cells exhibited defective extracellular calcium flux, but normal release of calcium from intracellular stores in response to BCR cross-linking. Thus, CD45 expression is necessary for optimal antigen receptor signaling and normal B-lymphocyte development. Whether or not CD45 is a part of the actual signaling complex and therefore functions as a legitimate coreceptor is still unclear. Because of the abundance of the CD45 protein, it might be expected that its association with the BCR may be random and interaction between BCR, CD45, and src kinases may occur even in the absence of antigen. If so, one could predict that signals would be initiated independently of antigen at individual BCR complexes. This stochastic process may in fact represent the mechanism by which tonic signals are generated.[54] Nonetheless, it remains to be established how these tonic signals are terminated to control B-lymphocyte activation in the absence of antigen engagement. Finally, one argument for sufficiency of proximity for CD45 action is that transfection of only the cytoplasmic domain of CD45 in CD45-deficient B lymphocytes restored antigen receptor signaling.[69,70] The tyrosine phosphatase activity of CD45 suggests that it could inhibit the BCR signal by counteracting the antigen-induced ITAM phosphorylation. In this context, CD45 is observed to be excluded from lipid rafts and thus sequestered away from BCR complexes once signals have been initiated.[71,72]

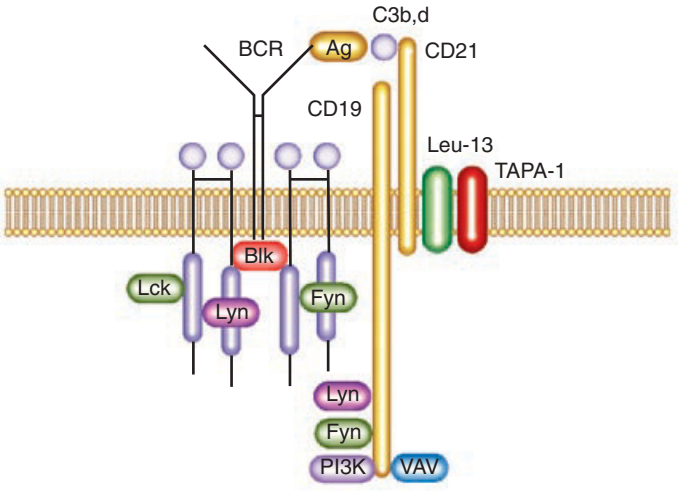

Figure 15–5 Model for antigen–complement C3b,d-mediated coaggregation of the B-lymphocyte receptor (BCR) and the CD19–CD21 coreceptor complex. Coclustering mediated by simultaneous binding of BCR and CD21 serves to recruit the CD19-associated signaling proteins to the BCR signaling complex. As discussed in the text, this is believed to enhance the signal that is generated by BCR aggregation. Ag, antigen; PI3K, phosphatidylinositol 3-kinase; TAPA-1, target of antiproliferative antibody-1.

Negative Modulators of B-Cell Receptor Signal Transduction

The activity and strength of signals generated by the BCR are also tuned or modulated by negative coreceptors. It was observed many years ago that the treatment of B lymphocytes with anti-Ig antibodies that lack the Fc portion of the molecule led to B-lymphocyte proliferation, whereas anti-Ig antibodies with the Fc region intact did not.[73] Furthermore, intact anti-Ig antibodies fail to trigger the signaling pathways leading to PI hydrolysis that is observed when BCR is cross-linked with anti-Ig that does not contain the Fc portion.[74] This effect was presumed to be due to the co-cross-linking of Fc receptors (FcR) with the sIg receptor complex on B lymphocytes. This dual signal would downmodulate a B-lymphocyte response late in an immune reaction, if B lymphocytes encounter an antigen that has been coated with secreted antibody. As illustrated in Fig. 15–6, simultaneous FcR and BCR stimulation would send a signal to shut down production of a specific antibody.

The FcR expressed by B lymphocytes is FcgRIIB1. The region of its cytoplasmic domain that is necessary and sufficient for FcR-negative signaling is a 13-amino acid immunoreceptor tyrosine-based inhibition motif (ITIM). A single tyrosine residue contained in this motif is critical for inhibition of BCR-induced Ca^{2+} flux.[75] Many other transmembrane proteins expressed predominately in hematopoietic cells such as CD22 (see later) and pair immunoglobulin-like receptor B (PIRB), as well as T-lymphocyte cell-surface proteins (see later), also harbor ITIMs. ITIMs interact with protein and lipid phosphatases that can block signaling.[76] In particular, the FcR ITIM is responsible for the interaction of this protein with the SHP-1 and SHIP-1 cytoplasmic phosphatases.[77] The tyrosine residue contained within the putative ITIM is inducibly phosphorylated, and interacts with these phosphatases through their tandem SH2 domains. Tyrosine phosphatase recruitment to the BCR complex allows

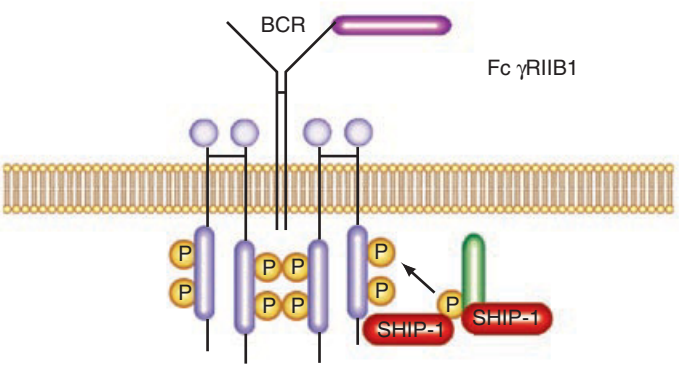

Figure 15–6 Model illustrating modulation of B-lymphocyte receptor (BCR) signal transduction by FcγRII B1. Antigen (*black*)–antibody complexes cocluster the BCR and the FcR. The latter positions the cytoplasmic phosphatases SHP-1 and SHIP-1 in the proximity of the Igα and Igβ ITAMs, thereby dephosphorylating them (note "faded" P) and downregulating their ability to recruit SH2-containing signal transduction proteins. ITAMs, immunoreceptor tyrosine-based activation motifs.

dephosphorylation of key tyrosine residues in the cytoplasmic domains of Igα and Igβ, and other signaling molecules such as CD22 and molecules associated with it. SHIP-1 is a lipid phosphatase whose activity results in the dephosphorylation of PIP_3 to PIP_2. Because PIP_3 is necessary to initiate the PI3K pathway (see earlier), FcR/SHIP-1 association will inhibit BCR signaling.

CD22 also serves as a negative coreceptor in early BCR signal transduction. CD22 can be coimmunoprecipitated with sIg from B-lymphocyte lysates made in mild detergent, and cross-linking the BCR with anti-Ig leads to phosphorylation of the CD22 cytoplasmic domain.[78–80] CD22 is a single transmembrane-spanning glycoprotein that contains seven immunoglobulin superfamily domains in its extracellular region.[81] A ligand for CD22 has not been defined, although the CD22 extracellular domain can bind sialic acid residues on a variety of proteins and the ectodomain of CD22 is necessary for some but not all of its inhibitory function.[82,83] The intracellular domain of CD22 contains six tyrosine residues, which can be substrates for tyrosine kinases. These two observations led to the inclusion of CD22 into some models of the BCR complex. It seems more likely, because not all sIg has CD22 associated with it,[78] that CD22 only associates transiently with the BCR during an immune reaction. Then, the phosphorylated tail of CD22 brings SH2-containing signaling proteins into the BCR complex, where they can then affect other receptor components. For example, the CD22 cytoplasmic tail associates with a tyrosine-specific phosphatase, protein tyrosine phosphatase 1C SH2-containing tyrosine phosphatase (PTP1C, also known as SHP-1).[82,84] SHP-1 is physically associated with the BCR in resting B cells, where it could dephosphorylate the ITAMs of Igα and Igβ. As depicted in Fig. 15–7, explanation of CD22 enhancement of BCR signaling is that in secondary lymphoid organs, sequestration of CD22 is accomplished by the association of B lymphocytes with sialic acid-modified proteins on the surface of T lymphocytes or stroma. This may involve directed movement of CD22–ligand complexes or, rather, physical displacement of the relatively large CD22 ectodomains as the B lymphocyte and associated cell become physically close.[85] In either model, phosphorylation of the tyrosines in CD22 will partition SHP-1 away from the BCR, thereby enhancing the tyrosine phosphorylation of the Igα/Igβ ITAMs. Other transmembrane proteins that contain ITIMs, including CD72 and CD5, may also modulate BCR signaling by this mechanism.[86,87]

The presence of positive- and negative-acting coreceptors indicates that BCR-mediated signaling is a tightly regulated process. TCR signaling is similarly modulated by coreceptors (eg, CD4, CD8, CD2). The functions of these coreceptors suggest that BCR signaling is not optimal through cross-linking sIg molecules alone but involves a complex orchestration of receptor and coreceptor molecules into a large complex, each element of which brings along associated proteins. A minimum-response threshold is reached by the accumulation of a critical concentration of enzymes and modulators at the cytoplasmic face of the BCR complex and its coreceptors leading to B-lymphocyte activation. However, when sIg is extensively cross-linked (ie, by anti-Ig antibody or by multivalent antigens), a requirement for coreceptor engagement may not be evident.

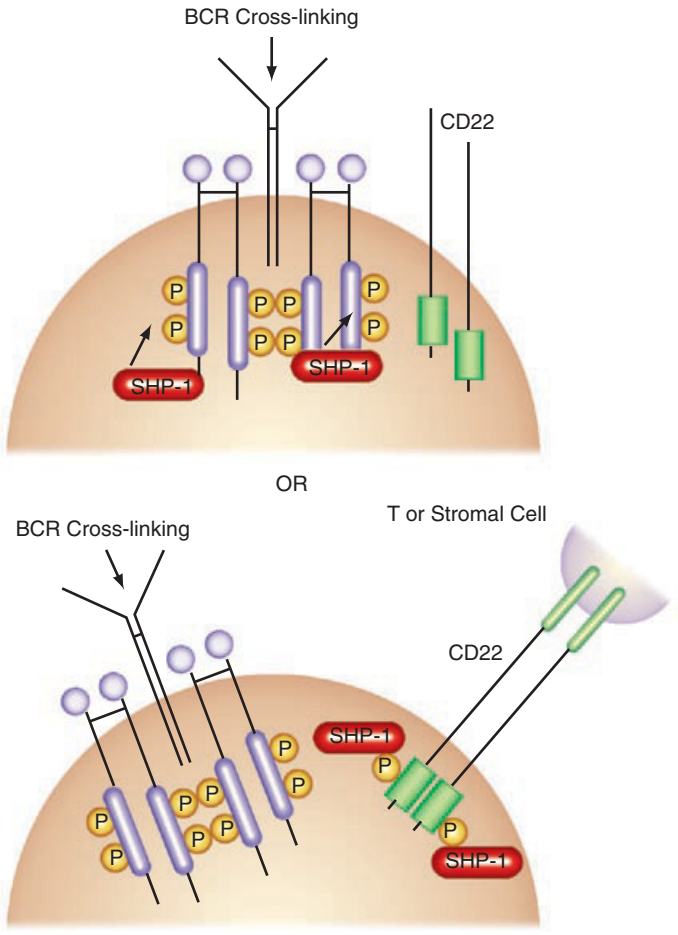

Figure 15–7 One hypothetic model to account for the ability of CD22 clustering to enhance B-lymphocyte (B-cell) receptor (BCR) signal transduction. In the resting B lymphocyte, the cytoplasmic phosphatase SHP-1 is in proximity to the complex either associated with CD22 or perhaps independent of it. In either case, SHP-1 functions to maintain dephosphorylation of the Igα- and Igβ-associated immunoreceptor tyrosine-based activation motifs (ITAMs), thereby decreasing the ability of the receptor to generate signals. Simple cross-linking of the BCR by antigen activates Src family kinases, leading to ITAM phosphorylation as well as tyrosine phosphorylation of the cytoplasmic domain of CD22. Phosphorylated CD22 recruits SHP-1. However, in this instance it is still in the vicinity of the BCR, so SHP-1 can still downmodulate BCR signal transduction through ITAM dephosphorylation. In contrast, in environments where T lymphocytes or stromal cells expressing sialylated proteins are present, CD22 and its associated SHP-1 are sequestered away from the BCR (see text for potential mechanisms). As a consequence, antigen-induced signals through the BCR would be expected to be stronger when antigen is encountered in appropriate anatomic niches or in the presence of T-helper cells.

SECONDARY COSTIMULATORY SIGNALS FOR B-LYMPHOCYTE ACTIVATION

The preceding discussion focused on the process by which antigen through the BCR initiates activation signals in mature, immunocompetent B lymphocytes. However, by themselves, these signals are

usually insufficient to promote clonal expansion and antibody secretion. For these processes, secondary signals provided by $CD4^+$ antigen-specific T lymphocytes are necessary. Thus, a humoral immune response involving antibody production usually requires the integration of T- as well as B-lymphocyte activation. Secondary signals for B-lymphocyte activation come in two forms: (a) physical contact between B and T lymphocytes and (b) soluble cytokines secreted by antigen-activated T lymphocytes. CD40 on the surface of resting and stimulated B lymphocytes is the primary receptor for cell contact-mediated secondary signals. CD40 is a 48-kd transmembrane protein belonging to the tumor necrosis factor (TNF) receptor family.[88] CD154 (CD40 ligand), homologous to TNF itself, is induced on antigen-activated $CD4^+$ T lymphocytes and binds to CD40 on nearby B cells. This promotes B-lymphocyte survival and facilitates their proliferation.[88,89] Agents that block CD40–CD154 interactions greatly impair the ability of activated T lymphocytes to interact with and drive B-lymphocyte proliferation. In humans, a genetic deficiency of CD154 causes X-linked hyper-IgM syndrome. Patients with this disorder can make IgM responses to T lymphocyte-independent antigens but fail to generate T lymphocyte-dependent B-lymphocyte responses to protein antigens. Even with T lymphocyte-independent antigens, switching to other Ig isotypes is absent.[90–93] Thus, although BCR signals can initiate B-lymphocyte activation, costimulation through CD40 is necessary for effector-level responses by these cells.

It is generally held that B-cell activation without T-cell costimulation results in an abortive activation response followed by B-lymphocyte death and elimination from the immune cell repertoire.[5,94] This may be the mechanism for deletion of self-reactive mature B lymphocytes. Engagement by self-antigens would provide BCR signals, but the necessary costimulatory signals by antigen-specific T lymphocytes would be absent.

Resting B lymphocytes express CD40, and there is experimental evidence that CD40 triggering together with certain cytokines can activate the B lymphocyte in the absence of BCR signaling. This form of activation could have adverse effects in an immune response, because it could allow activation of B lymphocytes with antibody specificities irrelevant to the pathogen or, worse, of autoreactive B lymphocytes. However, CD40 stimulation does not usually occur in vivo without prior BCR engagement on resting B lymphocytes. The ability of B cells to productively interact with T cells depends on molecules such as MHC class II and B7 that are upregulated after BCR stimulation (see next section).

In addition to CD40–CD154 interactions, other surface ligand-receptor pairs mediate physical interactions between the B and the T lymphocytes. These interactions are diagrammed in Fig. 15–8. Some of these pairs function as signaling molecules; others, such as intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated molecule-1 (LFA-1), are adhesion molecules that increase the strength of the B lymphocyte–T lymphocyte interaction and may also generate signals of their own.

Besides costimulatory signals generated through direct B lymphocyte–T lymphocyte contact, various T lymphocyte-derived cytokines facilitate ongoing regulation of the initial B cell-activation response. Although not completely defined in all cases, certain cytokines have well-characterized effects on the B cell response.[95] For example, interleukin (IL)-4 facilitates isotype switching to IgG1 and IgE, whereas tumor growth factor-β (TGF-β) results in switching to IgA. IL-4 can also augment the early stages of BCR-induced activation, whereas IL-5 may maintain clonal expansion. Because they do not require cell–cell contact for their function, cytokine-mediated effects on B-lymphocyte activation probably are limited to previously antigen- and CD40-activated cells. In this manner, they probably enhance and modify the responses to specific pathogens.

A research area of great recent interest is the involvement of TLRs in costimulation of B cells under specific situations when antigens are associated with certain pathogens. This selectivity comes from the fact that TLR ligands are specific products of microorganisms. As can be deduced from chapters that deal with these receptors and their role in the innate immune system in more detail, the engagement of TLRs during an antigen-specific B-lymphocyte response bridges the innate and adaptive immune systems.

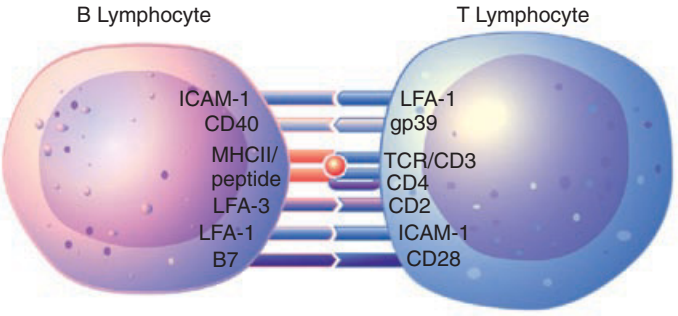

Figure 15–8 Receptor–ligand pairs contributing to association-dependent secondary signals for B- and T-lymphocyte activation. These interactions illustrate the tremendous level of communication between the B and the T lymphocytes during a lymphocyte-mediated immune response. Expression of some of these proteins is enhanced or their signaling capabilities are activated as the B- and T-lymphocyte activation responses proceed. In this way, there is continued reinforcement with checkpoints to ensure that the immune response continues to be appropriate. ICAM, intercellular adhesion molecule; LFA, leukocyte function-associated antigen; MHCII, major histocompatibility complex class II.

T LYMPHOCYTES

T lymphocytes provide the cellular arm of the immune system and characteristically exert effects in situ. There are two main T-cell subsets: those with CD4 surface coreceptors (CD4 T cells) and those with CD8 surface coreceptors (CD8 T cells). CD4 T cells are called helper T cells (T_H) because they help, that is, regulate, immune responses. CD8 T cells are chiefly cytotoxic T cells (CTLs) that directly kill virally infected or transformed cells. These immune responses result from genetic programs initiated by antigen recognition at the cell surface and transmitted to the nuclear genes by an elaborately regulated signaling apparatus (for reviews, see refs 96 and 97). T cells use a structurally unique cell-surface receptor, the TCR, to recognize specific antigen. However, unlike B cells, which recognize foreign antigens in their native conformations, T cells protect against intracellular pathogens and typically recognize a peptide determinant (epitope) or lipid derived from the pathogen. These peptide epitopes or lipids must be bound to an MHC molecule and presented as the antigen on the surface of an APC, such as a dendritic cell or B cell. Most T_H cells utilize the CD4 coreceptor to recognize antigenic peptides displayed on MHC class II molecules, whereas CTLs use the CD8 coreceptor to recognize peptide bound to MHC class I molecules. Lipids typically are presented on the nonclassical, nonpolymorphic MHC molecule CD-I and may involve a special class of αβ-NK T cells with limited TCR diversity.

T-LYMPHOCYTE ANTIGEN RECEPTOR

The antigen-binding component of most TCRs is a heterodimer composed of two glycoproteins, the α chain of 40 to 44 kd and the β chain of 47 to 54 kd, that are selectively expressed on T cells (αβ T cells).[97] The α and β chains are encoded by unique rearranging gene loci resembling Ig gene loci. Enroute to the cell surface, these chains noncovalently associate with nonpolymorphic transmembrane signaling proteins, the CD3γ, δ, ε proteins and the η and ζ chains to form an 8-chain cell-surface TCR holocomplex (Fig. 15–9). Approximately 5% of T cells express γ and δ antigen-binding chains derived from another pair of rearranging gene loci (γδ T cells). The antigen-binding TCR chains have a structural domain called the immunoglobulin fold characteristic of the immunoglobulin gene superfamily which includes immunologically important proteins

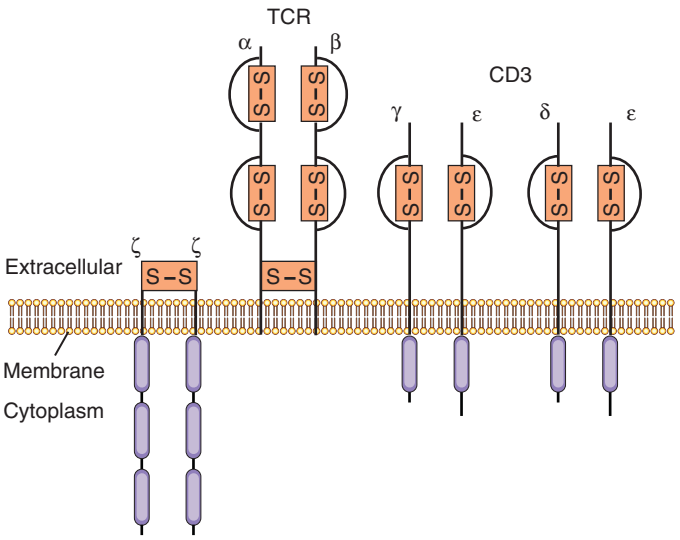

Figure 15–9 Composition of the T-lymphocyte (T-cell) antigen receptor (TCR) complex. Shown are the nonpolymorphic members (CD3γ, δ, ε, and ζ chains) in association with the ligand-binding polymorphic TCR α and β chains. Also illustrated are the immunoreceptor tyrosine-based activation motifs (ITAMs) (*shaded ovals* in the cytoplasmic domains of the CD3 complex and the ζ chain) that are tyrosine phosphorylated on receptor cross-linking and are responsible for the recruitment of other signaling molecules to the TCR complex. S–S, disulfide bonds.

such as Ig, CD4, CD8, and MHC class I and class II molecules.[98] The N-terminal domain of the extracellular portion of each ligand-binding TCR chain contains the polymorphic region that binds antigen in a way that resembles Ig.[99–101] Generally, a unique pair of TCR is expressed by any given T cell and its progeny (constituting a T cell clone), although a fraction of T cells expresses two different α chains of TCRs conferring distinct antigenic specificities.[102] Clonal diversity is generated by variation in the primary amino acid sequence of the TCR (clonal variation) resulting from the specific rearrangement of TCR genetic elements.

The genetic diversification process involves reassortment of TCR gene segments using essentially the same molecular machinery as for Ig genes. Human genetic defects in the V(D)J recombination proteins artemis or recombination activating genes (RAG)-1 or -2 cause severe defects in T (and B) lymphocyte development.[103] TCR genes have variable (V), diversity (D), joining (J), and constant (C) segments as separate genetic elements encoding the antigen-combining portion of each TCR subunit.[100] There are various numbers of V, D, and J segments in the genome that are highly polymorphic, whereas the constant region is invariant and does not contribute to antigen specificity. Each ligand-binding chain contains just one representative family member from each gene segment (V, J, and C for TCR α and γ, and V, D, J, and C for TCR β and δ). Diversity is achieved by the independent, random reassortment of V, D, and J segments that together create the potential for an enormous number of distinct TCRs. Superimposed on this is a process known as *N region addition*, whereby nucleotides not encoded in the germline DNA segments are added at V–D and D–J junctions by terminal deoxynucleotide transferase (TdT).[104,105] Finally, because both chains of the TCR ligand-binding complex contribute to antigen specificity, diversity is increased by the heterodimeric combination of two TCR ligand-binding chains. Although antigen receptor diversity generation is similar in B and T cells, somatic hypermutation of the rearranged TCR gene in peripheral lymphoid organs occurs only rarely if at all.[106] Importantly, the recombination process utilizes slowly evolving elements in the germline-encoded gene segments that predetermine certain range of specificities that function productively within an antigen environment, both internal and external, that the species has encountered during its evolution. However, it also randomly generates new specificities by nucleotide additions and deletions, giving it more adaptive potential. This is perhaps an essential function of the adaptive immune system in an environment of rapidly and continuously evolving threats from emerging infections.

Intracellular signals from the TCR are conveyed by the CD3 polypeptide chains. The C-terminal intracytoplasmic portions of the polymorphic TCR chains are quite small, ranging from 5 to 11 amino acids—a strong indication that they have no intrinsic signaling capacity.[107,108] However, the CD3 polypeptides have long cytoplasmic tails with obvious signaling motifs (ITAMs). Since the CD3 proteins are needed for receptor surface expression and signal transmission, the functional TCR is often called the TCR–CD3 complex (see later). The CD3γ, δ, and ε proteins are 20- to 26-kd structurally related polypeptides (not to be confused with the polymorphic, ligand-binding chains TCR γ and δ).[109,110] The other nonpolymorphic signaling component(s) include the structurally distinct ζ chain and, in the mouse, the η-chain.[111] The significance of the murine η-subunit is uncertain, however, because of the lack of an obvious human analog, its poor conservation across species, and no clear function.[111,112] The stoichiometry of the TCR–CD3 complex reveals four dimers, a disulfide-bonded ligand-binding heterodimer (TCR αβ or γδ), noncovalently coupled to one each of CD3εγ and CD3εδ heterodimers, and a disulfide-linked ζ–ζ homodimer to form an octamer (see Fig. 15–9).

T cell activation is initiated after TCR aggregation by the antigen-laden APCs (see Chapter 12). The resulting biochemical cascade culminates in a coordinated program of gene expression leading to effector functions (eg, cytokine production, proliferation, acquisition of cytotoxicity). Clustering of multiple TCRs on a given T cell apparently potentiates the interaction, because the affinity of individual TCRs with antigen–MHC complexes is low. Coreceptors such as CD4 and CD8 also help by increasing the TCR-antigen-MHC association and recruiting other signaling molecules into the activation complex. The earliest observed biochemical event following TCR cross-linking is tyrosine phosphorylation of the CD3 chains on ITAM motifs (ITAMs are described in the section above on BCR signaling) (Fig. 15–10).[113–115] The CD3γ, δ, and ε components each have one ITAM, whereas each ζ monomer contains three. Two Src-like kinases $p56^{lck}$ (Lck) and $p59^{fyn}$ (Fyn) are involved in phosphorylating CD3ζ[1].[116–120] Gene knockout mice show that Lck plays a more important role than Fyn in T-cell maturation and TCR signaling. Both kinases localize to the plasma membrane by a myristoylation modification. Further associations of Lck with CD4 and CD8 (see later) and Fyn with TCR components promote the phosphorylation of ζ.[121] Phosphorylation of the ζ chain by src family kinases is a pivotal event leading to recruitment of a second family of tyrosine kinases that includes ZAP-70 and Syk. N-terminal tandem SH2 domains in ZAP-70 and Syk bind the phosphotyrosines in the ζ-ITAMs, leading to further phosphorylation events by these kinases (see Fig. 15–10).[122,123] ITAM phosphorylation and the association of ZAP-70 is critical for TCR signaling. In fact, experimental proteins containing ITAMs fused to the transmembrane and extracellular domains of unrelated proteins can, upon cross-linking, transduce signals that mimic early and late signal transduction events characteristic of the intact TCR.[124] It is believed that this reflects essential features of TCR signaling: bringing the surface signaling proteins together so that they can cross-phosphorylate each other and form a scaffold to recruit cytoplasmic signal transducers through phosphotyrosine–SH2 domain associations.

Various inherited immunodeficiencies illustrate the vital role of the invariant TCR components in immunity.[103,125] Genetic deficiency of either CD3δ or CD3ζ severely impairs the development of both αβ and γδ T cells, leading to severe infections.[103,126] Inborn deficiencies of CD3ε and CD3γ are less devastating but still have an adverse effect on T-cell development and immune function. Finally, patients with mutations in ZAP-70 lack peripheral $CD8^+$ T cells and TCR signaling is defective in peripheral $CD4^+$ T lymphocytes, but ostensibly normal in the CD4 thymic precursors, in which Syk kinase compensates.[127,128]

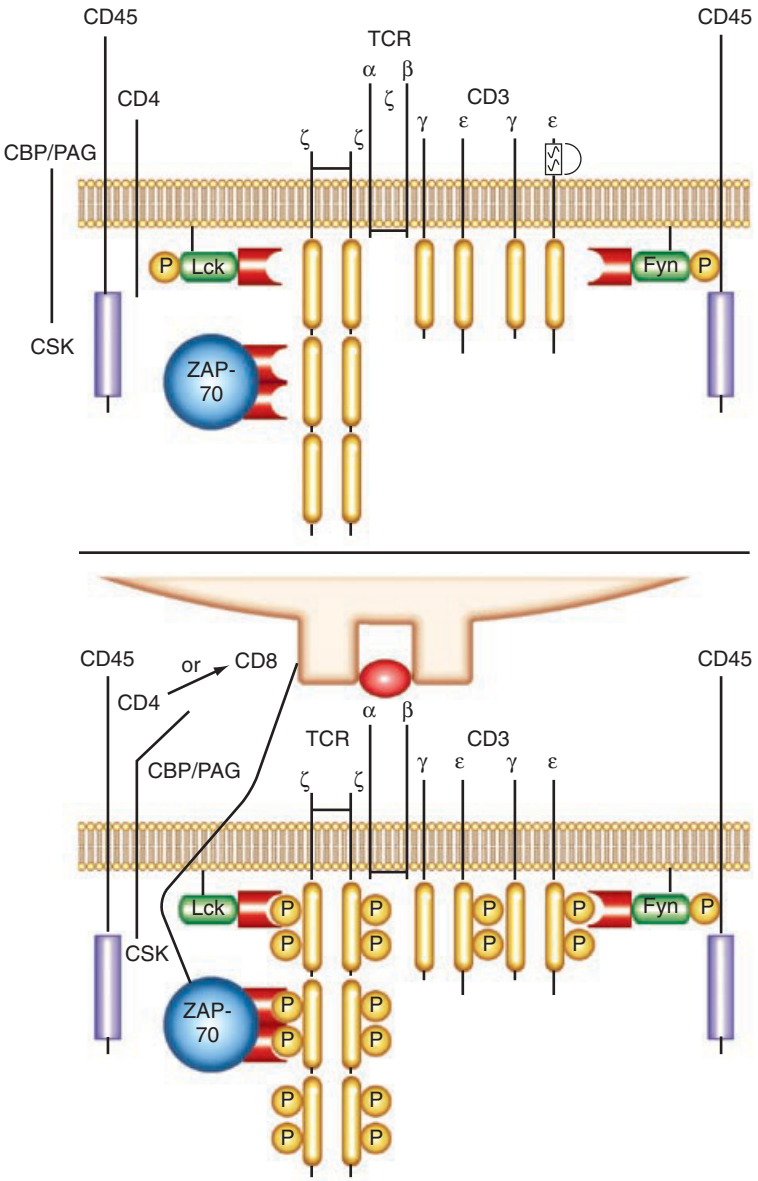

Figure 15–10 The T-cell receptor (TCR) complex and coreceptor molecules in resting and antigen-activated T cells. In the resting T cell, the TCR complex, the CD4 coreceptor, and CD45 are not associated with the membrane. The tyrosine kinase Lck is found associated with CD4, and low levels of the tyrosine kinase Fyn are believed to associate with the TCR complex. However, neither enzyme is activated, because of basal phosphorylation at a negative regulatory site. On receptor ligation, CD45 and CD4 are recruited into the receptor complex. CD45 is believed to be responsible for dephosphorylating the negative regulatory tyrosines on Lck and Fyn (note the *light-colored* P). Activation of Lck or Fyn is believed to lead to phosphorylation of the CD3 complex and the ζ chain, allowing for the association of zeta-associated protein-70 (ZAP-70) via its tandem SH2 domains and its subsequent activation. P, phosphate group.

T-CELL INTRACELLULAR SIGNALING

The initial phase of TCR signaling is completed once ZAP-70 is activated. The secondary signaling events that follow parallel those described for B lymphocytes (vide supra), including: (a) increased intracellular calcium levels and activation of PKC and NFAT as a consequence of PLCγ1 activation, (b) activation of the Ras pathway, (c) activation of PI3K (Fig. 15–11), and (d) NF-κB activation. These culminate in the production of IL-2 and other cytokines. There are two additional T cell-specific tyrosine kinases, RLK and ITK, from the Tec kinase family also involved.[129] Tec kinases can phosphorylate PLCγ1 and modulate downstream effects on Ca^{2+}, the actin cytoskeleton, and T-cell subset accumulation in the periphery. Moreover, PKC-θ has emerged as a crucial early step in the activation process to drive downstream gene regulatory events (see below).

Activation of these three distinct pathways occurs in parallel with lateral integration via cross-talk between them. They are linked by intermediate signaling molecules known as *adapter* proteins, which mediate protein–protein or protein–lipid interactions. As scaffolds, adapters regulate T-cell activation by organizing signaling assemblies and eliminating certain proteins by degradation. The discovery of adapters suggests that lymphocyte activation signals are transmitted by large multifunctional protein complexes that shift in composition and location rather than a series of individual proteins talking to one another in a linear chain. There are several T-lymphocyte adapters that are roughly analogous to the BLNK protein in B cells (see Fig. 15–11): LAT (*l*inker for *a*ctivated *T* lymphocytes), SLP76, Gads, Grb2, and Vav. LAT is a transmembrane protein that contains numerous tyrosine residues in its intracellular domain that are phosphorylated by ZAP-70.[130] These phosphotyrosines recruit Grb2, ITK, PLCγ1, PI3K, and Gads typically through SH2 domain associations. SLP76 can simultaneously bind Gads and PLCγ1, which links SLP76 with LAT. Both LAT and SLP76 are intimately involved in activation of PLCγ1 and therefore have critical roles in T-cell activation. Indeed, mice deficient for one or more of these proteins have defective TCR signaling which prevents thymocyte maturation.[131–133] Another key function of T-cell adapter proteins is to link TCR signaling to cytoskeletal rearrangements. Tyrosine-phosphorylated SLP76 associates with Vav, which activates the GTPases Rac and Rho that control the actin cytoskeleton.[134] These GTPases regulate Wiskott–Aldrich syndrome protein (WASP), which is important for cytoskeletal organization.[135] Gene knockouts in mice show that Vav and WASP play critical roles in T-cell activation and associated cellular changes, perhaps acting in part through the movement of lipid rafts and the immunologic synapse formation (see later).[136–139]

As in B cells, PLCγ1 activation causes hydrolysis of PIP_2, resulting in a rise in intracellular Ca^{2+} levels and PKC activation, which are considered second messengers of T cells. Signaling by increased intra-

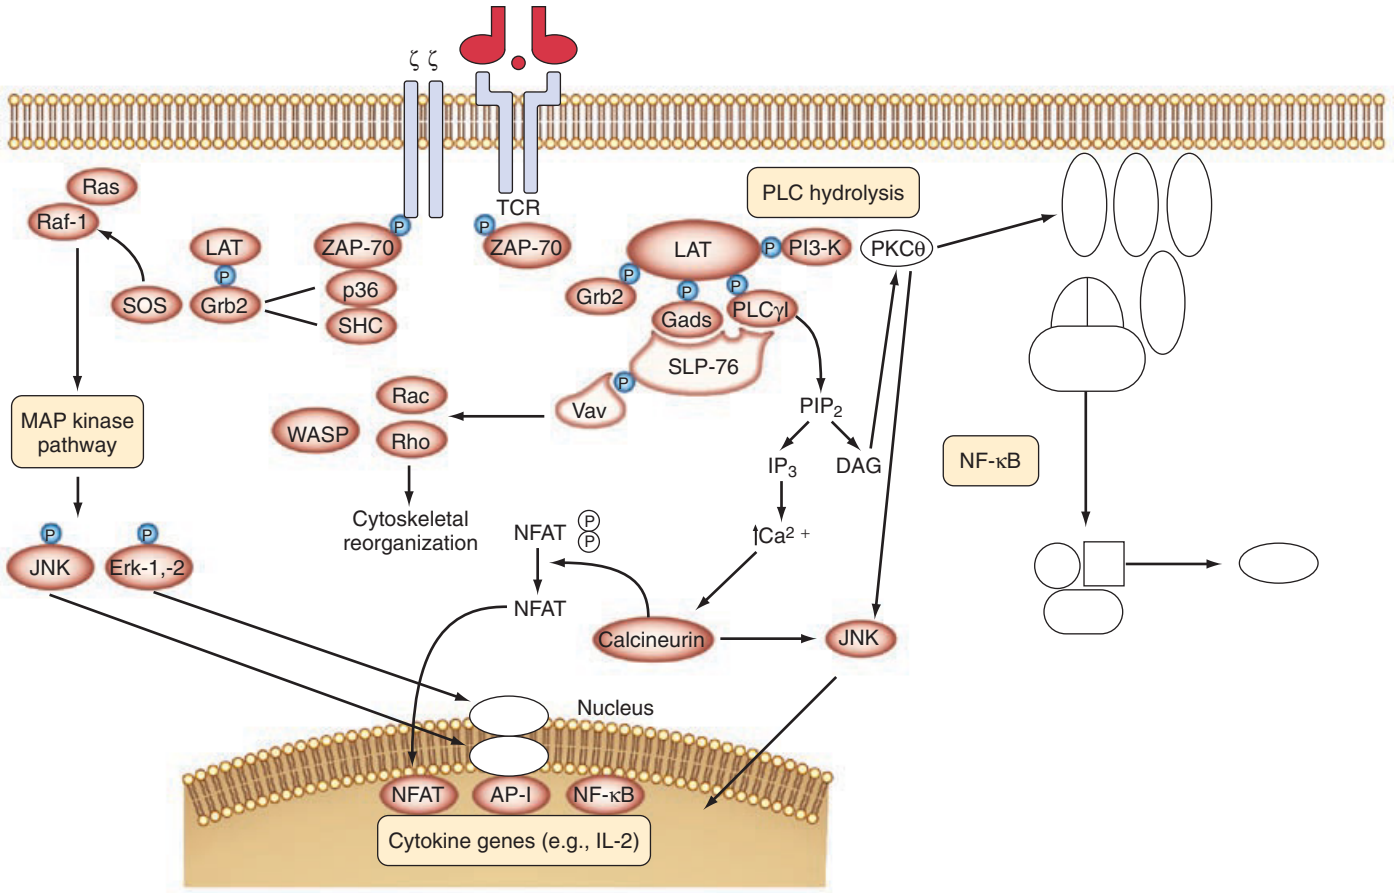

Figure 15–11 Intracellular signal transduction pathways in activated T cells. Ligand binding of the TCR leads to phosphorylation of CD3ζ molecules, a process involving Lck and Fyn. This permits recruitment and activation of ZAP-70. One pathway of downstream signaling is mediated by activation of phospholipase C (PLC) and subsequent activation of protein kinase C (PKC) and a rise in intracellular calcium concentration. Adapter proteins such as LAT, Grb2, Gads, and SLP-76 are critical linkers of CD3ζ and ZAP-70 phosphorylation to inositol phospholipid hydrolysis. Through interactions with Vav, WASP, and the Rac and Rho GTPases, these adapter proteins also serve to link TCR signaling to cytoskeletal rearrangements, which are important for complete T-cell activation. In parallel, TCR stimulation also activates the Ras–Raf–MAPK pathway. Adapter proteins such as LAT, Grb2, and Shc help activate the guanine nucleotide exchange factor SOs to mediate this effect. Together, MAPK activation and inositol phospholipid hydrolysis activate Jnk kinases, Erk kinases, and NF-κB, leading to induction of a series of genes, typified by the encoding cytokines, that characterize the T-cell response. AP-1, activator protein-1; DAG, 1,2-diacylglycerol; IL, interleukin; IP_3, inositol-1,4,5-triphosphate; LAT, linker for activated T lymphocyte; MAP, mitogen-activating protein; NF-κB, nuclear factor-κB; NFAT, nuclear factor of activated T lymphocytes; PI3K, phosphatidylinositol 3-kinase; PIP_3, phosphatidylinositol-4,5-triphosphate; WASP, Wiskott–Aldrich syndrome protein; ZAP-70, zeta (chain)-associated protein.

cellular Ca^{2+} levels is blocked by the immunosuppressive drugs cyclosporine and FK506, which prevents key activation events, especially IL-2 gene transcription.[124,140] Cyclosporine and FK506 bind to distinct proteins, collectively referred to as immunophilins, that form complexes to inhibit a calcium/calmodulin-dependent serine phosphatase calcineurin.[141] Calcineurin's role in TCR-initiated signal transduction is to dephosphorylate and promote nuclear localization of a subunit of the transcription factor NF-AT. NF-AT is a DNA-binding protein and gene activator that is required for IL-2 transcription.[142] Interestingly, T-cell activation can be triggered by the combination of phorbol myristate acetate (PMA) and ionomycin, which are pharmacologic inducers of PKC and Ca^{2+}. This is an oft-used experimental procedure for studying T-cell responses.[96,97,140]

TCR signaling also involves activation of Ras-related G proteins, which causes downstream activation of MAPK pathways (see earlier).[143] Ras activation in T cells involves the guanine nucleotide exchange factor SOS, which is linked to the TCR by the adapter protein Grb2 associated with other adapter proteins, such as p36 or Shc.[144] Stimulation of Ras induces various serine/threonine kinases, leading to the activation of two MAPKs, Erk-1 and Erk-2, among other targets. These kinases are critical for the phosphorylation of transcription factors, including components of the AP-1 complex, that are required for the activation of IL-2 and other genes. In addition to *ras* gene products, other G proteins (small signaling GTPases) expressed in T cells may contribute to TCR-induced signal transduction. For instance, the adapter Crk is linked to the nucleotide exchange factor C3G, which serves to activate the G protein Rap-1. Furthermore, members of the Rho family (Rac and Cdc42) of G proteins may regulate the activation of Jnk, an MAPK, in T cells.[144] These molecules reveal the linkage between the fully assembled adapter complexes and the transcriptional control complexes responsible for the TCR-induced gene activation program.

Although PI3K is activated after TCR engagement, the initial stimulatory effect of antigen is actually quite weak. In T lymphocytes, PI3K is only optimally stimulated after engagement of the costimulatory molecule CD28[144] and after activation by cytokines, such as IL-2, whose receptors contain the common γ chain, γ_c (see later). PI3K may principally participate in T-lymphocyte coreceptor function as discussed next.[145]

The induction of the transcription factor NF-κB is a principal event in the genetic program of T-cell activation because of the many genes it induces through the interplay of DNA-binding complexes.[146,147] Through the activation of PI3K and PLC, the PKC-θ isoform translocates to the cell membrane and becomes active following phosphorylation by Lck.[148] The activated PKC-θ then causes assembly and activation of a triprotein complex containing CARMA-

1, Bcl-10, and MALT-1 (CBM complex), which is essential for NF-κB activation (note that B cells use a different isoform, PKC-β, for this purpose). Stimulation of this pathway causes phosphorylation and activation of the I-κB kinase (IKK) complex composed of IKKα, β, and γ, which, in turn, phosphorylates the inhibitor of κB (I-κB). This leads to I-κB ubiquitination and degradation, which liberates cytoplasm-bound NF-κB to travel into the nucleus and activate specific genes by binding to their promoters and enhancers. Surprisingly, an essential biochemical connection between the CBM complex and IKK is caspase-8.[149] Deficiency of caspase-8 leads to severe immunodeficiency in humans by thwarting NF-κB in T, B, and NK lymphocytes.[150]

T-CELL RECEPTOR CORECEPTOR MOLECULES

The CD4 and CD8 coreceptors define two subsets of αβ T cells and are not expressed on γδ T cells. These transmembrane proteins enhance TCR signal transduction by (a) increasing the affinity of the TCR complex for its MHC–peptide ligand and (b) by recruiting signaling molecules, such as Lck, to the signal complex (see Fig. 15–10). CD4 and CD8 increase TCR affinity for MHC-antigenic peptide complexes by forming a physical bridge by associating with the TCR and MHC molecules.[151] Although the expression of CD4 and CD8 was originally believed to identify functional T-cell subsets (T_H cells being $CD4^+$ and CTLs being $CD8^+$), these functional associations are not mutually exclusive. CD4 CTLs have been described and CD8 cells secrete cytokines that may help immune responses in important ways. Coreceptor expression correlates mainly with the MHC molecule recognized by the TCR: MHC class II for $CD4^+$ T cells and MHC class I for $CD8^+$ T cells. There is also a subset of peripheral αβ T cells that lack CD4 and CD8, called double-negative T cells, that are normally less than 1% but may expand greatly and cause severe autoimmune disease in the autoimmune lymphoproliferative syndrome.[152]

CD4 and CD8 are structurally different. CD4 is a single-chain, type I transmembrane glycoprotein whose extracellular portion contains four immunoglobulin-like domains. By contrast, CD8 is a heterodimer composed of two disulfide-linked type I membrane-spanning glycoproteins, CD8α and CD8β, that each contain a single immunoglobulin-like extracellular domain.[152] Despite these differences, CD4 and CD8 serve analogous coreceptor functions by linking TCRs to MHC class II and I molecules, respectively. The extracellular portion of CD4 binds to a monomorphic element on the β2 domain of MHC class II molecules,[153] a site that is structurally similar to the CD8-binding domain on the MHC class I a3 membrane-proximal domain.[153–155] Coreceptor binding to these monomorphic MHC regions does not sterically interfere with TCR binding to the polymorphic, peptide-binding groove. Indeed, the ability of the coreceptor and the TCR to coengage the same MHC–peptide complex is critical for facilitating TCR-mediated signal transduction.[156]

CD4 and CD8 augment TCR signaling by providing an intracytoplasmic docking site for the Src family kinase Lck. CD4 may be a stronger coreceptor, as it binds more Lck than CD8. In addition, CD4 cross-linking can increase the enzymatic activity of Lck, which is not observed after CD8 cross-linking.[157] CD4 and CD8 interact with a Cys–XX–Cys motif in the N-terminal region of Lck through a Cys–X–Cys motif found in their cytoplasmic tails. During antigen recognition by the TCR, coengagement of the TCR and coreceptor molecules helps draw the coreceptor molecules into the TCR complex, thereby bringing Lck into the signaling complex and enhancing tyrosine phosphorylation of intracellular substrates. Once substrates such as the CD3 components are phosphorylated, the SH2 domain of Lck can interact with the phosphorylated ITAMs, anchoring the coreceptor to the activated TCR complex and further promoting coreceptor function.[158] The importance of CD4 and CD8 in T-cell activation depends on the affinity of the TCR for its peptide–MHC ligand. High-affinity ligands seem to generate enough signal through the TCR to activate T cells without a need for CD4 or CD8 coreceptors, whereas relatively lower-affinity ligands require CD4-CD8 interactions for optimal T-cell stimulation. This difference may be due to the number of TCRs engaged or the duration of engagement, or both.[159]

As in B cells, CD45 also functions as a coreceptor for TCR signaling. CD45 is a highly abundant transmembrane phosphatase required for efficient TCR signaling.[160] In CD45-deficient mice, few mature T cells develop, and those produced have poor TCR responses.[66] CD45 is believed to dephosphorylate the C-terminal inhibitory phosphotyrosine of Lck and Fyn, thereby turning on these kinases.[161] CD45 also has been described to act as a negative regulator of cytokine receptor signaling by dephosphorylating Janus kinases (JAKs), which are important signal transducers through cytokine receptors.[162] Thus, TCR signaling involves an orchestrated addition and removal of regulatory phosphates. There is no known ligand for the extracellular domain of CD45 raising a long-standing question as to whether it is a legitimate coreceptor.[66] However, CD45 has been shown to associate constitutively with the TCR, and expression of the cytoplasmic domain alone in CD45-deficient T cells is sufficient to reconstitute efficient TCR signaling.[69,70,163,164] Mice deficient for CD45 have low T-cell production and those that are produced have defective signaling. Humans with recessive deficiencies of CD45 have defects in T and NK cells leading to severe immunodeficiency.[103] Specific functions have not been ascribed to the various spliced isoforms of CD45, although it has been reported that antibodies against the CD45RB isoform selectively upregulate cytotoxic T cell-associated antigen-4 (CTLA-4).[14,165,166]

LIPID RAFTS AND THE IMMUNOLOGIC SYNAPSE

The plasma membrane of T cells appears to contain highly lipid-ordered compartments termed *lipid rafts* that are selectively enriched in activation molecules, including the TCR–CD3 complex and its attendant signaling molecules. Rafts may provide a membrane structure on which relevant molecules can be mobilized by the cytoskeleton and recruited to the point of T cell–APC contact.[167–169] A huge temporally and spatially regulated assembly of over 20 proteins, termed the *immunologic synapse*, forms where the two cells touch. Synapse formation begins with a central cluster of adhesion molecules (eg, LFA-1) surrounded by a ring of TCRs engaged by MHC (Fig. 15–12). Within 5 to 15 minutes, this orientation reverses, forming the mature synapse. This bull's-eye structure consists of a central supramolecular activation cluster (cSMAC) containing TCRs and their associated signaling machinery, surrounded concentrically by a peripheral SMAC (pSMAC)-containing integrin and adhesion molecules, such as LFA-1 and associated cytoskeletal proteins.[168,170] Synapse formation evidently does not require a live APC, because they are observed when T cells come into contact with artificial phospholipid bilayers containing antigen–MHC complexes. The immunologic synapse, which takes minutes to form, is not a prerequisite for initial TCR signaling, since tyrosine phosphorylation of CD3 proteins and ZAP-70 occurs within seconds.[171] However, optimal T-cell activation apparently requires sustained T cell–APC interactions (and hence continual TCR–MHC ligation) for up to several hours.[172] Current theories suggest that the synapse integrates and amplifies antigen signals by collecting TCRs and signal transduction molecules in a small restricted area of the membrane that synergizes molecular interactions.

Several key observations indicate that T-cell signaling is a highly dynamic process.[172] Cell-surface expression of the TCR is downregulated within minutes following synapse formation and continues for several hours, leaving only 10% to 15% of the basal TCR expression remaining.[159] Downmodulation occurs despite the fact that individual TCR–MHC interactions have half-lives of only seconds, indicating that numerous sequential TCR–MHC binding events take place—a process termed *serial triggering*.[172] In addition, TCR downmodulation following activation are the result of a kinetic equilibrium consisting of TCR reexpression, engagement by ligand, and internalization.[173] This dynamic process can be visualized by

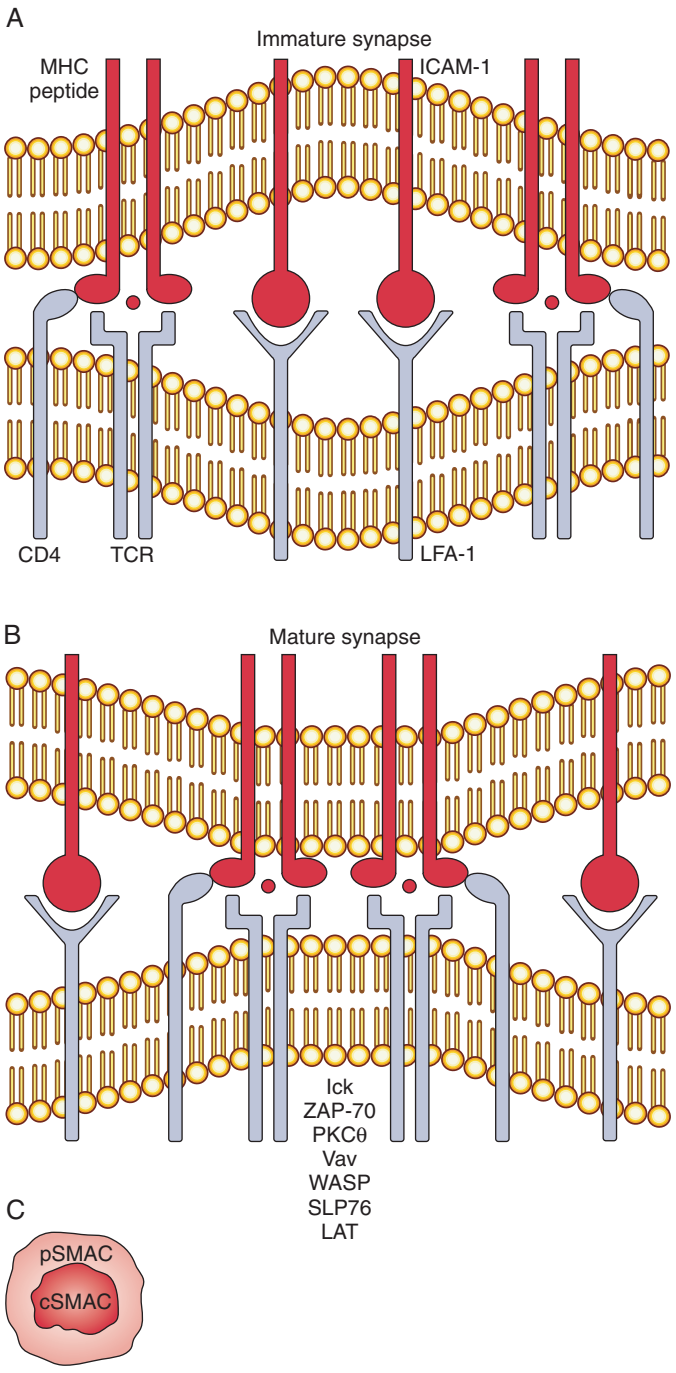

Figure 15–12 Formation of the immunologic synapse. **A**, The immature immunologic synapse consists of a central cluster of adhesion molecules (such as ICAM-1/LFA-1) surrounded by a ring of engaged TCRs. **B**, Within minutes to hours, this orientation is reversed, with a central supramolecular activation cluster (cSMAC) containing TCRs and associated signaling machinery. **C**, A bird's-eye view of the concentric topographic structure. ICAM-1, intercellular adhesion molecule-1; LAT, linker for activated T lymphocyte; LFA-1, leukocyte function-associated molecule-1; MHC, major histocompatibility complex; PKCθ, protein kinase Cθ; TCRs, T-cell receptors; WASP, Wiskott–Aldrich syndrome protein.

removal of T cells from TCR ligand after several hours of activation, which results in a rapid reexpression of surface TCR to levels that far surpass those in the unstimulated cell.[173,174] Thus, low levels of TCR following initial T-cell activation are maintained by continual TCR engagement, explaining how serial triggering is achieved despite TCR downmodulation.[172]

SECONDARY COSTIMULATORY SIGNALS FOR T-CELL ACTIVATION

Costimulation by CD28 and Related Pathways

TCR engagement alone is inefficient for inducing full activation of naive (antigen-inexperienced) T cells. Optimal cytokine production and proliferation require both TCR stimulation and a second signal. The second, or costimulatory, signal is usually delivered through the surface receptor CD28 on T cells from specific ligands on APCs (Fig. 15–13). In fact, without costimulatory signals, strong TCR stimulation of most naive T cells induces a state of long-term functional inactivation (anergy) and apoptosis.[175] CD28 costimulation lowers the antigen threshold of activation and increases the magnitude of the TCR-induced response, including an increase in cytokine gene transcription and mRNA stability.[176] Costimulation may also promote T-cell survival by inducing the antiapoptotic molecule, Bcl-X_L, which engenders more enduring immune responses.[157,177,178] Compared with naive T cells, memory T cells are much less dependent on CD28 costimulation[179] and may receive activation or survival signals through other costimulatory interactions (see below).

CD28 is a member of the immunoglobulin superfamily constitutively expressed on the T-cell surface as either a disulfide-linked homodimer or a monomer.[177] CD28 can be triggered by CD80 or CD86, often called B7-1 and B7-2, respectively, which are expressed on "professional" APC such as dendritic cells (DCs), B cells, and macrophages. CD80 and CD86 are also members of the immunoglobulin gene superfamily, but share relatively little homology with each other or CD28. The CD80 and CD86 genes are strongly induced by various immune stimuli. For example, one hallmark of DC maturation after encountering a pathogen is the upregulation of CD80, CD86 and MHC class II proteins. However, B7-1 and B7-2 are differentially expressed in that B7-2 is weakly constitutively expressed and rapidly induced, followed by slower B7-1 induction. CD80 and CD86 also avidly bind CTLA-4 (CD152), a structural analogue of CD28. However, CTLA-4 engagement downregulates T-cell responses, which is crucial for preventing severe autoimmune reactions (see later).[176]

The mechanism of CD28 costimulatory effects has not been completely elucidated but involves much more than simply causing greater adhesion between the T cell and APC. After CD28 ligation, tyrosine phosphorylation of its cytoplasmic tail promotes the association of Grb-2, Itk, and PI3K.[176] Two key pathways that are important for the substantial boost in IL-2 production involve PI3K and the c-Jun N-terminal kinase (JNK). In fact, PI3K association with CD28 may be more influential than its link to the TCR complex. These signaling mechanisms apparently mediate different functional outcomes. For example, mutation of the tyrosine in the CD28 cytoplasmic tail whose phosphorylation recruits PI3K disrupts Bcl-X_L upregulation (and cell survival) but not IL-2 production or proliferation.[180] By contrast, cytokine synthesis and proliferation require JNK activation which induces the c-Jun-containing AP-1 transcription factors that govern cytokine genes.[181,182] Cytokine gene transcription is also accelerated by cooperative effects of CD28 with the SLP76 and Vav adapters independently of TCR ligation.[183] In addition to internal signals, CD28 also garners lipid rafts and their signaling proteins into immune synapses at the cell surface.[184,185] Within the raft, CD28 invigorates one active isoform of protein kinase C, PKCθ, that stimulates antigen receptor-induced NF-κB, an event that is critical to T-cell responses.[186,187] Therefore, the T-cell reaction to antigen is a product of the convergence of synergistic signals emanating from the TCR and CD28.

T-cell activation is greatly debilitated if CD28–B7 interactions are blocked.[188,189] Mice genetically deficient in CD28 have immune responses hampered by diminished IL-2 production and T-cell proliferation.[190,191] These observations have raised hopes that the approach of B7 manipulation could be used to prevent or abort T cell-mediated immune responses in vivo.[177,188,189,192] The strong avidity of CTLA-4 for B7 ligands has been exploited in a soluble chimeric protein,

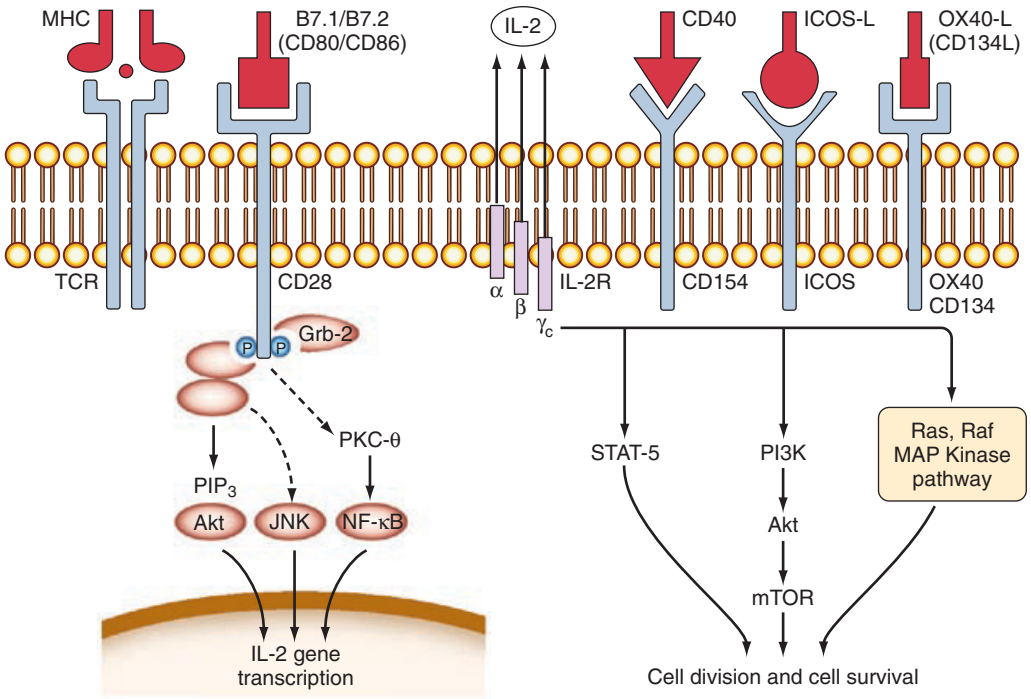

Figure 15–13 Select T-cell costimulatory and cytokine activation pathways. The CD28 receptor is the best-characterized costimulatory molecule on T cells. Ligation of CD28 activates phosphatidylinositol 3-kinase (PI3K), one of whose most important downstream mediators is Akt. Other signals associated with CD28 include activation of JNK and protein kinase Cθ (PKCθ), which in turn may activate nuclear factor-κB (NK-κB). Together these pathways support cytokine gene transcription, such as is represented by IL-2. Once IL-2 binds to its high-affinity receptor (a heterotrimer of an α, a β, and a common γc chain), it activates PI3K and STAT5 signaling pathways. Together these are necessary and probably sufficient to support cell division and promote cell survival. IL-2 signals also may activate the mitogen-activating protein (MAP) kinase pathway, but the importance of these events is unknown. Also shown in the figure are select other costimulatory interactions (CD40/CD154, ICOS ligand [ICOS-L]/ICOS, and OX40-L/OX40; see the text for details on these pathways). ICOS, inducible costimulatory molecule; IL, interleukin; MHC, major histocompatibility complex; PIP_3, phosphatidylinositol-4,5-triphosphate; STAT5, signal transducer and activator of transcription-5; TCR, T-cell receptor.

CTLA-4Ig, that contains the secretory domains of immunoglobulin and the extracellular domains of CTLA-4 (Fig. 15–14; see later).[193] Administration of soluble CTLA-4Ig can prolong allograft survival and ameliorate autoimmune disease in experimental animal models.

ICOS (*i*nducible *co*stimulator) is a distantly related member of the CD28 family.[194] Unlike CD28, which is expressed on all resting T cells, ICOS is expressed following T-cell activation and on memory T cells. The ligand for ICOS, B7-RP1 or B7-H, is expressed on B cells and monocytes.[195] Most initial studies suggested that the primary role of ICOS was to support a T_H2-type differentiation in which an antigen triggers CD4 T cells to secrete cytokines such as IL-4, 10, and 13 which assist B cells in producing antibody.[196] However, ICOS also helps T_H1 responses in which CD4 T cells produce IL-2, gamma-interferon, and lymphotoxin, thereby promoting cellular immunity.[197] The crucial role of ICOS in immunity has been revealed by the identification of mutations in ICOS in common variable immunodeficiency patients.[198] In summary, CD28 is responsible for priming T cells to initiate immune responses whereas ICOS costimulates already activated T cells to further propagate the response.

The Tumor Necrosis Factor / Tumor Necrosis Factor Receptor Superfamily

Costimulatory signals are also delivered through members of the TNF receptor (TNFR) superfamily and their ligands. There are more than 30 distinct receptor–ligand pairs in this family and the majority have either a ligand or a receptor expressed on T cells.[199] These receptors are all structurally related to TNFRs by having variable numbers of cysteine-rich pseudorepeats in their extracellular portion that mediate receptor assembly and ligand binding. Furthermore, their ligands are structurally related to TNF. Although a detailed discussion is beyond the scope of this chapter[199], it is important to highlight a few key regulators of immunity.

A powerful reciprocal interaction between T and B cells is mediated by the interaction between CD154 (CD40 ligand) and CD40.[200] CD154 is strongly induced on all activated $CD4^+$ T cells and some activated $CD8^+$ T cells. Its receptor, CD40, can be found on APCs (dendritic cells, macrophages, and B cells) as well as activated endothelial cells, platelets, and keratinocytes. T-cell engagement of CD40 induces potent pro-inflammatory responses. In the case of myeloid APCs, the responses include induction of B7 molecules that, in turn, powerfully costimulate T-cell activation together with adhesion molecules and cytokines such as IL-12 that promote T-cell immune synapses and differentiation.[201] As discussed above, CD40 stimulation delivered by T cells is required for B cell survival and antibody isotype switching (from IgM to IgE or IgG). Endothelial cells respond to CD40 stimulation by expressing integrins that promote leukocyte binding.[202] These diverse effects make CD154 and CD40 excellent targets for therapeutic intervention in T cell-mediated diseases such as graft versus host disease, transplant rejection, and autoimmunity.[203,204]

Various TNFRs and their cognate ligands have proposed roles in T-cell activation, including OX40/OX40L (CD134/CD134L), CD27/CD70, and 4-1BB/4-1BBL (CD137/CD137L), among others.[199] Others such as Fas, TNF, and LIGHT (the ligand for herpes virus entry mediator [HVEM]) have costimulatory capabilities, but the physiological significance of these effects are unknown.[205] CD134 and its ligand provide signals important for the maintenance of T-cell responses and avoidance of tolerance.[206,207] Gene knockout studies in mice suggest great redundancy in these pathways, and phenotypes are often detectable only when combined with CD28 deficiency. In summary, TNFRs have diverse roles in mediating

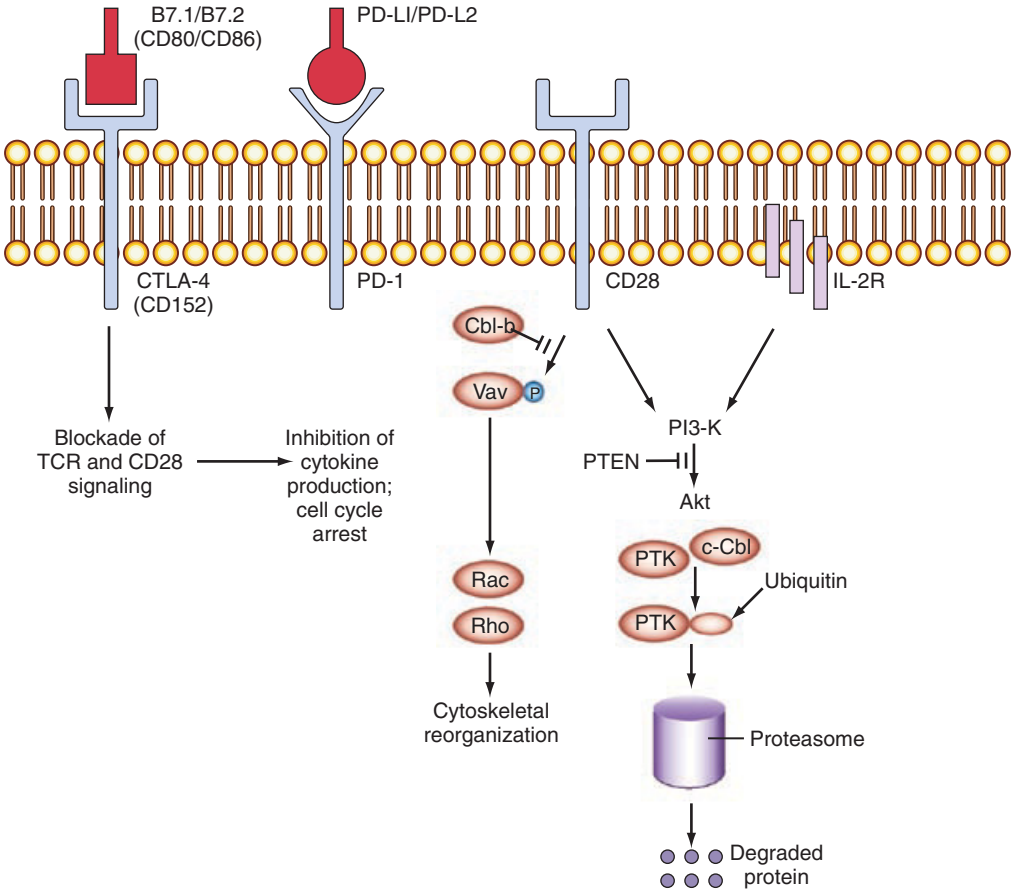

Figure 15–14 Negative signaling pathways that limit T-cell responses. CTLA-4, a homolog of CD28 sharing the same ligands (B7.1 and B7.2), transduces a negative regulatory signal that acts to block TCR- and CD28-mediated signals, leading to inhibition of cytokine production and cell cycle arrest. The inhibitory molecule PD-1 exerts similar effects. CD28 signaling also can be inhibited by Cbl-b, which represses CD28-induced phosphorylation of Vav, thus inhibiting cytoskeletal rearrangements (see text and Fig. 14–11 for further details). A related protein, c-Cbl, promotes ubiquitination of protein tyrosine kinases (PTKs), thereby facilitating proteosomal degradation of signaling molecules. PTEN acts by inactivating lipid mediators of the PI3K pathway, thus preventing activation of downstream kinases such as Akt. IL-2R, interleukin-2 receptor; PD-1, programmed death-1 protein; PI3K, phosphatidylinositol 3-kinase; TCR, T-cell receptor.

intercellular coordination that is critical for memory cell formation, T_H1 versus T_H2 differentiation, and cell survival.

Cytokine Regulation of T-Cell Activation and Function

TCR and costimulatory signals are sufficient for early T-cell activation, but subsequent proliferation and differentiation are governed by cytokines. IL-2, IFN-γ, IL-4, IL-7, and IL-15 are of prime importance.[208] The receptors for IL-2 and IL-15 contain an identical β chain. Although these cytokines are structurally distinct, their receptors share a common γ chain, γc (except IFN-γ), as well as differing, "private" α chains. This explains why human genetic deficiencies of the common γ chain cause profound defects in the production and function of lymphocytes and a near absence of immunity.[209] Genetic deficiencies of the private receptor chains cause more selective immune deficits.

The IL-2 receptor complex was the first identified and remains the most extensively studied of all cytokine receptors on activated T cells. The foundation of signaling by common γ-chain cytokines is the Janus kinase (JAK)–signal transducer and activator of transcription (STAT) proteins, and human deficiencies affecting it can incapacitate the immune system to varying degrees.[209–211] This system, in turn, drives three further signal transduction pathways, mediated by PI3K, STAT-3/5, and Ras/MAPK.[210] PI3K, a signal transducer for many growth factor receptors, typically associates directly with receptors at the cell membrane and becomes activated. However, IL-2R chains lack a PI3K docking motif and instead use adapter proteins such as Grb2 and SHC to recruit PI3K to the IL-2Rβ chain.[212] Downstream targets of activated PI3K include Akt/protein kinase-B, S6 kinase, and mammalian target of rapamycin (mTOR). Cytokine stimulation causes the phosphorylation and recruitment of the JAK kinases, such as JAK 1 and JAK 3 for the IL-2R, to the cytoplasmic domain of the receptor. The activated JAKs then phosphorylate specific STATs (STAT-3 and -5 for IL-2R) within the cytoplasm, causing homodimerization. The dimeric STAT complexes translocate from the cytoplasm to the nucleus, where they bind cognate DNA sites on target promoters, inducing selective gene expression. This enables T cells to traverse the cell cycle and induces critical survival genes such as Bcl-2 and Bcl-xL.[210,211,213] Activated JAKs also phosphorylate the receptor chain that promotes PI3K docking. Finally, the Ras/MAPK pathway also may be activated through IL-2R, although its signaling pathway and physiological role is much less well defined. Each of these pathways is under investigation for developing small-molecule inhibitors that would suppress pathological immune responses or graft rejection.

Negative Modulators of T-Cell Receptor Signal Transduction

To prevent the pathologic consequences of excessive T-cell immune responses, other cell-surface receptors and intracellular molecules

serve specifically as negative regulators of responses (see Fig. 15–14). Chief among these is CTLA-4 whose importance was demonstrated by the rapidly fatal lymphocyte infiltrative and inflammatory disease in genetically deficient mice.[214,215] In contrast to the role played by its relative, CD28, CTLA-4 directly inhibits CD28 and TCR signaling, thereby impeding activation and causing cell cycle arrest.[116,216] As with CD28, the extracellular domain of CTLA-4 contains a MYPPPY motif that mediates binding of their shared ligands, CD80 and CD86. The intracellular domain of CTLA-4 also contains an ITIM, which, as discussed above, can shut off activation and signaling events. CTLA-4 inhibits TCR signaling by an associated phosphatase, SHP-2, which dephosphorylates TCRζ, thereby undoing an essential early activation step.[116,217] This action is facilitated by the localization of CTLA-4 to the immunologic synapse following T-cell activation.[218] T cells from mice deficient in CTLA-4 are hyperresponsive to antigenic stimulation and there is uncontrolled proliferation of T cells and lethal autoimmunity in these mice almost certainly in response to self-antigens.[214,215] CTLA-4 is only expressed on activated cells but has a higher affinity for the B7 of ligands. Hence, it becomes influential at a later point in activation by competing with CD28 for its ligands.[177,216,217]

Other distantly related members of the CD28 family, including the programmed death-1 (PD-1) receptor and B- and T-lymphocyte attenuator (BTLA) (see below) have a negative role.[219–221] PD-1 is expressed on activated T, B, and myeloid lineage cells. Unlike CD28 and CTLA-4, which share ligands (CD80 and CD86), PD-1 has unique binding partners, PD-L1 (B7-H1) and PD-L2 (B7-DC), that are B7 family members and displayed on diverse normal and malignant tissues, including activated APCs, lymphocytes, keratinocytes, placenta, and pulmonary and cardiac tissue. Specifically, PD-L1 is widely distributed on various somatic and malignant tissues, including T cells, B cells, macrophages, and DCs. By contrast, PD-L2 is only expressed on macrophages and DCs. Thus, both PD-L1 and PD-L2 may regulate T cells in the lymph nodes, whereas PD-L1 may have additional roles throughout the body, including the CD28 family molecules PD-1. There is some overlap in function, however, because genetic deficiency of both molecules causes a greater elevation in interleukin (IL)-2 and interferon (IFN)-γ following T-cell activation than absence of either one alone. In an experimental mouse model of autoimmune diabetes, double deficiency (PD-L1/PD-L2$^{-/-}$) accelerated diabetes with 100% penetrance in males and females. In control mice, diabetes occurs predominantly in females. On the other hand, ligation of PD-1 inhibits TCR-mediated cytokine production and proliferation (by inducing cell cycle arrest),[222] and mice deficient in PD-1 develop a lupus-like autoimmune syndrome characterized by arthritis and glomerulonephritis.[220] Recent work reveals that PD-1 may mediate exhaustion of CD8 T cells during chronic viral infections, such as HIV, and blockade of this receptor could potentiate antiviral immune responses.[223]

BTLA is structurally similar to CD28, CTLA-4, and PD-1, but the presence of two ITIM motifs in its cytoplasmic region indicates that it is an inhibitory receptor.[205,224] It is selectively expressed in lymphocytes and is induced after T-cell activation, especially on polarized Th1, but not Th2, cells. Remarkably, the ligand for BTLA appears to be the TNFR superfamily member HVEM. A crystal structure of the BTLA–HVEM complex shows that BTLA binds the N-terminal cysteine-rich domain of HVEM using a unique binding surface unlike other CD28-like receptors. Moreover, the structure shows that BTLA recognizes the same surface on HVEM as herpes virus glycoprotein D, which is responsible for viral entry. Immature DCs express high levels of HVEM and as they mature in response to a pathogenic signal, the expression drops, implying that the negative function may correspondingly decrease.

Other B7 family ligands B7-H3 and B7-H4 (also known as B7S1 or B7x) have been shown to inhibit T-cell activation, but their receptors on T cells are not yet known.[221] The newer B7 family members, however, are widely expressed in many different tissues by both hematopoietic and nonhematopoietic cells, suggesting that these molecules may regulate effector T cells that have trafficked to somatic tissues. For instance, it has been shown that PD-L1 is expressed in the maternal part of the placenta during gestation; blockade of PD-L1 increased the spontaneous abortion rate, which indicates that PD-L1 arrests T cells in the placenta to promote fetomaternal tolerance.

Another significant negative regulator is Pten (*p*hosphatase and tensin homolog deleted on chromosome *ten*), which catalyzes the degradation of active phosphatidylinositol lipid intermediates of the PI3K pathway.[225] It can reverse the effects of PI3K and is ubiquitously expressed. Among other effects, Pten negatively regulates Akt and thereby promotes cell death in response to a number of apoptotic stimuli. Targeted deletions of *PTEN* cause an embryonic lethal phenotype, and mice with a single allele of *PTEN* missing (Pten$^{-/-}$) develop lymphoid hyperplasia, autoimmunity, and T-cell lymphomas. Mice with T cell-specific limitation of Pten display defects in thymic and peripheral deletion, and have multiple defects in T-cell apoptosis.[226] A key role of CD28 stimulation may be to overcome the negative regulatory effect of Pten.[227]

Finally, a negative regulator of T-cell and probably B-cell signaling with an interesting mode of action is the protooncogene c-*cbl*, a member of the CBL/SLI family. The c-Cbl protein is an adapter with binding domains for SH2-containing proteins. c-Cbl drives the ubiquitin modification of intracellular proteins, including many involved in T-cell signaling, such as ZAP-70 or other TCR-linked protein tyrosine kinases.[228] As with other proteins, ubiquitination leads to their degradation in the proteasome and thus dampens T-cell signaling. In B cells, Cbl targets Syk for ubiquitination and degradation. A related member of the CBL/SLI family is Cbl-b, which is also a negative regulator.[229] Cbl-b-deficient T cells exhibit hyperresponsiveness to TCR stimuli and do not require CD28 costimulation for optimal IL-2 production or proliferation, effects that has been linked with hyperphosphorylation of Vav1. c-Cbl- and Cbl-b-deficient mice have spontaneous lymphoid proliferation and autoimmune disease. Mice doubly deficient in Cbl-b and Vav1 still have autoimmunity, indicating that at least some of the effects of c-Cbl on T cells must be independent of Vav1. These could be due to the fact that Cbl-b regulates PI3K activity and lipid raft aggregation.[230] In conclusion, there are many ways in which the regulation of phosphorylation—either by inhibiting kinase activity or increasing phosphatase activity[231]—can determine the intensity of the immune activation of T cells.

SUMMARY

The portrait of lymphocyte activation that emerges from a wealth of molecular, biochemical, and cellular investigations over the past 20 years is that a dynamic balance between stimulatory and inhibitory signals is established to govern reactions to antigens. Although this chapter has focused mainly on the intermediary signaling apparatus connecting the cell surface to the nucleus, ultimately, lymphocyte activation involves the successful establishment of a gene expression program appropriate to the specific antigenic challenge. It will therefore be fundamentally important in the future to understand how the balance of positive and negative signals coordinates the nuclear chromatin and transcriptional machinery in lymphocytes for this purpose. Research continues to uncover new molecular determinants of this balance providing hope that specific immune responses can be therapeutically enhanced to generate better vaccines and fight infectious diseases or suppressed to ameliorate autoimmunity, allergies, and allograft rejection.

CHAPTER 16

CELL ADHESION

Rodger P. McEver

Cell adhesion is essential for the development and maintenance of multicellular organisms. Cell–cell and cell–matrix contacts facilitate intercellular communication and define the architecture of organs. The regulated nature of cell adhesion is particularly evident in the hematopoietic system, where cells routinely make transitions between nonadherent and adherent phenotypes during differentiation and in response to stimuli in the circulation or extravascular tissues.

In the bone marrow, proliferation and differentiation of hematopoietic stem cells are controlled not only by soluble growth factors but also by adhesion to stromal cells and matrix molecules. Weakening of these adhesive interactions is required for mature blood cells to enter the circulation. Circulating erythrocytes normally remain nonadhesive until they are finally cleared by the reticuloendothelial system. Other circulating cells often participate in regulated adhesive events during their life span. For example, prothymocytes adhere to components of the thymus, where they undergo further maturation before reentering the circulation. Lymphocytes regularly stick to the specialized high endothelial venules of lymphoid tissues, migrate into these tissues for sampling of processed antigens, and then exit via the lymphatics. During inflammation, specific classes of leukocytes roll on the endothelium, then adhere more tightly, and finally emigrate between endothelial cells into the tissues. There, neutrophils and monocytes phagocytose invading pathogens, whereas lymphocytes adhere to antigen-presenting macrophages. During hemorrhage, platelets stick to exposed subendothelial matrix components, spread, and recruit additional platelets into large aggregates that serve as an efficient surface for thrombin and fibrin generation. Leukocytes also adhere to activated platelets and to other leukocytes, and platelets roll on the endothelium. Endothelial cells express molecules that affect the adhesiveness of platelets or leukocytes. Tight contacts between adjacent endothelial cells also limit access of blood cells to the underlying tissues.

ADHESION MOLECULES

Cells adhere through noncovalent bond formation between macromolecules on cell surfaces with macromolecules on other cell surfaces or in extracellular matrix. These interactions involve either protein–protein or protein–carbohydrate recognition. Although some adhesion molecules are expressed only by blood or endothelial cells, most also are synthesized by other cells. Many adhesion molecules can be grouped into families according to related structural and functional features.

EXTRACELLULAR MATRIX PROTEINS

The principal constituents of the extracellular matrix are adhesive proteins and proteoglycans. The major proteins are von Willebrand factor (vWF), thrombospondin, collagen, fibronectin, laminin, and vitronectin. These proteins are large and often highly extended and consist of multiple domains with different binding functions. In some proteins such as fibronectin, alternative splicing can increase diversity by producing molecules with variable numbers of domains. The many binding domains allow adhesive proteins to interact with each other as well as with cell-surface receptors, resulting in multipoint contacts that stabilize matrix structure. One adhesive protein, fibrinogen, is found predominantly in plasma but also may be deposited in exposed subendothelial matrix following vascular injury. Fibronectin, vitronectin, thrombospondin, and vWF are located predominantly in the extracellular matrix but also are found in plasma. Several adhesive proteins also are stored in α-granules of platelets, where they are secreted following platelet activation at sites of vascular injury.

Proteoglycans contain protein cores to which are covalently attached many glycosaminoglycans-long linear polymers of repeating disaccharides. Most proteoglycans are in the extracellular matrix, but some are anchored on cell surfaces through a core protein that contains a membrane-spanning domain. Hyaluronan is a unique glycosaminoglycan that forms polymers with molecular masses up to several million daltons that are not covalently attached to a protein. Hyaluronan forms noncovalent interactions with globular domains on the protein core of proteoglycans and with a small molecule called *link protein*. The resultant hyaluronan–proteoglycan complexes can become very large, contributing to the structural stability of matrix. Hyaluronan can also bind to cell-surface receptors.

INTEGRINS

Integrins are a broadly distributed group of cell-surface adhesion receptors that consist of noncovalently associated α- and β-subunits (Fig. 16–1 and Table 16–1). There are at least 15 α chains and 8 β chains that pair in many, but not all, of the possible combinations. All blood cells have several different integrins. The four β_2 integrins, each paired with a unique α subunit, are expressed only by leukocytes, and the $\alpha_{IIb}\beta_3$ integrin (glycoprotein IIb–IIIa [GPIIb–IIIa]) is expressed only by megakaryocytes and platelets. Multidomain adhesive proteins of the extracellular matrix are ligands for many integrins. Some integrins bind to specific domains of several different proteins, and some adhesive proteins bind to several different integrins. These interactions generally mediate cell–matrix adhesion. Cell–cell interactions result from integrin recognition of cell-surface members of the immunoglobulin superfamily. Binding of fibrinogen to $\alpha_{IIb}\beta_3$ integrins on adjacent platelets creates a molecular bridge that promotes platelet aggregation. Furthermore, fibrinogen simultaneously binds to the $\alpha_m\beta_2$ integrin on leukocytes and to an immunoglobulin-like receptor on endothelial cells, promoting leukocyte adhesion to the endothelium.

IMMUNOGLOBULIN-LIKE RECEPTORS

Immunoglobulin superfamily members contain a variable number of disulfide-stabilized motifs like those in antibodies, which are linked to transmembrane and cytoplasmic domains (Table 16–2; see also Fig. 16–1). The immunoglobulin-like motif provides a framework on which specific recognition structures for other proteins can be added. Some of these motifs also recognize glycoconjugates. The immunoglobulin-like molecules, intercellular adhesion molecule-1 and -2 (ICAM-1 and ICAM-2) and vascular cell adhesion molecule-1 (VCAM-1), expressed on endothelial cells, as well as ICAM-3, expressed on leukocytes, mediate cell–cell contact through recogni-

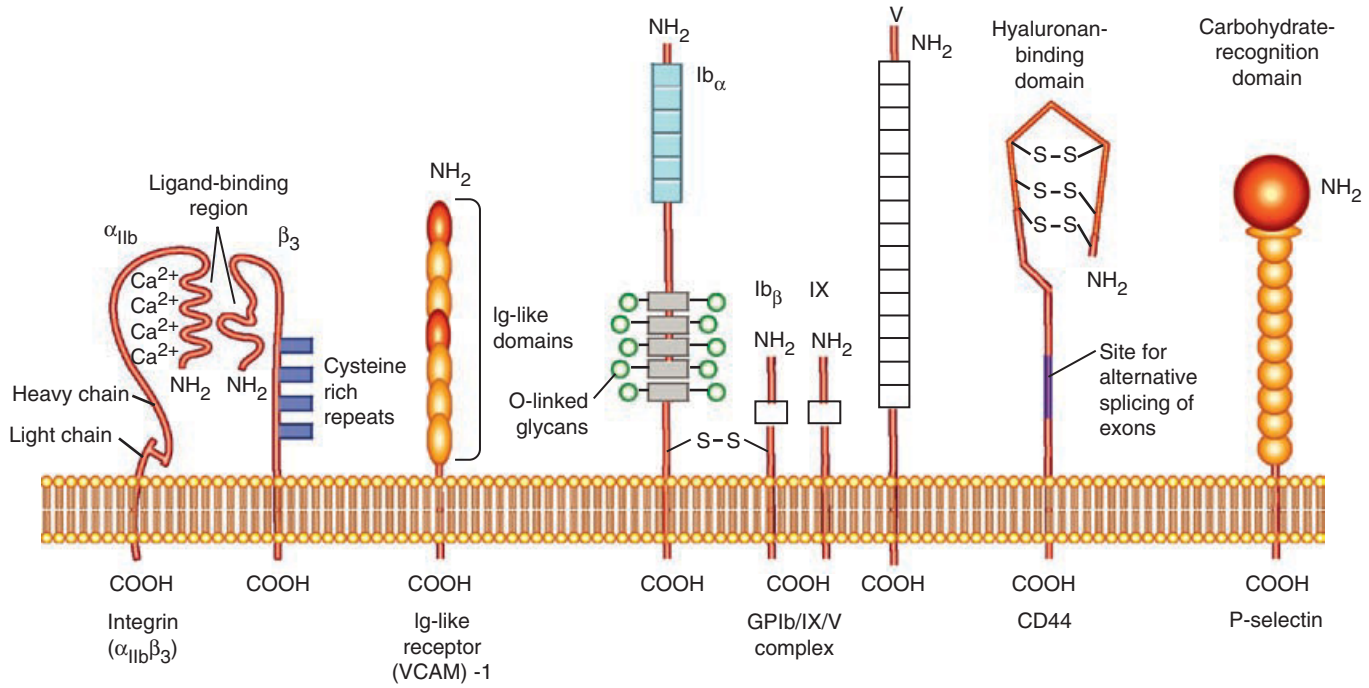

Figure 16–1 Schematic diagrams of several types of cell-surface adhesion receptors. Integrins consist of noncovalently linked α and β subunits, both of which contribute to ligand binding. The platelet $\alpha_{IIb}\beta_3$ integrin is illustrated at *far left*. Immunoglobulin-like receptors contain a variable number of immunoglobulin homology domains, of which some bind ligands and others extend the ligand-binding domains from the membrane. Shown *second from left* is vascular cell adhesion molecule-1 (VCAM-1), which contains seven immunoglobulin domains; the two domains that bind to integrins are *shaded*. The platelet glycoprotein Ib–IX–V (GPIb–IX–V) complex, depicted in the *middle diagram*, consists of several leucine-rich protein subunits. CD44, illustrated next, contains an amino-terminal (N-terminal) domain that binds to hyaluronan. Each of the selectins contains an N-terminal carbohydrate recognition domain that binds sialylated and fucosylated oligosaccharides on specific cell-surface glycoprotein ligands. Illustrated at *far right* is P-selectin, the largest of the three selectins.

tion of specific integrins on leukocytes. ICAM-4, expressed on erythroid precursors, binds to integrins on stromal cells of bone marrow, which may regulate erythropoiesis. The immunoglobulin-like GPVI on platelets promotes cell activation by binding to collagen exposed on damaged blood vessels. Interactions between immunoglobulin-like molecules help to mediate adhesion between T cells and antigen-presenting cells. Thus, the immunoglobulin-like molecules CD8 and CD4 on T cells bind to the conserved membrane-proximal domains of class I and class II major histocompatibility complex (MHC) proteins, respectively, whereas the T-cell receptor (CD3) binds to the polymorphic antigen-presenting domain. In addition, the immunoglobulin-like protein CD2 on T cells binds to the immunoglobulin-like protein leukocyte function-associated antigen-3 (LFA-3) on antigen-presenting cells. The immunoglobulin-like receptor platelet and endothelial cell adhesion molecule-1 (PECAM-1) (CD31) uses homotypical interactions to promote contacts between adjacent endothelial cells and to mediate adhesion of leukocytes to platelets and endothelium. The immunoglobulin-like junctional adhesion molecules (JAMs), expressed on endothelial cells, regulate endothelial cell junctions and leukocyte trafficking between endothelial cells by homotypical interactions or by heterotypical interactions with integrins.

OTHER ADHESION RECEPTORS THAT MEDIATE PROTEIN–PROTEIN INTERACTIONS

Cadherins are cytoskeletally linked membrane proteins that mediate cell–cell contact in many organs through homotypical binding to cadherins on adjacent cells (Table 16–3). Cadherins have not been described on blood cells but are found on endothelial cells, where, like PECAM-1 and JAMs, they help form cell junctions.

The GPIb–IX–V complex on platelets consists of leucine-rich protein subunits (see Fig. 16–1). Under conditions of high shear stress like those found in arterial circulation, this complex promotes the initial platelet adhesion to injured vessels by binding to vWF exposed in the subendothelium. It also may assist interactions with other platelets or with endothelial cells by binding to P-selectin, which normally binds to glycoconjugates, and it may assist platelet adhesion to leukocytes by binding to the integrin $\alpha_m\beta_2$.

CD36 is a receptor with at least two membrane-spanning domains that is expressed on many cell types. On platelets, it has been implicated as a receptor for collagen and perhaps for thrombospondin; both interactions could facilitate adhesion to the subendothelial matrix at sites of hemorrhage.

LECTIN ADHESION RECEPTORS

CD44 is an unusual transmembrane glycoprotein expressed to variable degrees on many subsets of leukocytes (see Fig. 16–1). It has a membrane-distal domain that is structurally related to link protein of extracellular matrix, and, like link protein, can bind to hyaluronan. CD44 also binds to the serglycin, a proteoglycan secreted by hematopoietic cells. The hyaluronan-binding function of CD44 may modulate a number of leukocyte responses. The most clearly demonstrated function is in lymphopoiesis, where maturation of lymphocyte precursors requires contacts with bone marrow stromal cells bearing surface hyaluronan. CD44–hyaluronate interactions also may promote lymphocyte entry to and transit through organized lymphoid tissues. The membrane-proximal regions of CD44 are structurally diverse because of the insertion of variable numbers of domains through alternative splicing. These insertions may regulate the ability of CD44 to bind hyaluronan and may mediate postbinding events that affect cell signaling.

Table 16–1 Integrins on Blood Cells

Integrin Designation	Other Name(s)	Expressed by	Ligand(s)	Function(s)
$\alpha_1\beta_1$	VLA-1	Leukocytes, other cells	Collagens, LM	Adhesion to ECM
$\alpha_2\beta_1$	VLA-2 GPIa/IIa	Leukocytes, platelets, other cells	Collagens, LM	Adhesion to ECM
$\alpha_3\beta_1$	VLA-3	Leukocytes, other cells	Collagens, LM, FN	Adhesion to ECM
$\alpha_4\beta_1$	VLA-4	Monocytes, lymphocytes, eosinophils	VCAM-1, FN	Adhesion to cells, ECM
$\alpha_5\beta_1$	VLA-5 GPIc/IIa	Leukocytes, platelets, other cells	FN	Adhesion to ECM
$\alpha_6\beta_1$	VLA-6 GPIc/IIa	Leukocytes, platelets, other cells	LM	Adhesion to ECM
$\alpha_9\beta_1$		Neutrophils	VCAM-1	Adhesion to ECs
$\alpha_L\beta_2$	LFA-1 CD11a/CD18	Leukocytes	ICAM-1, -2, -3	Leukocyte aggregation and adhesion
$\alpha_M\beta_2$	MAC-1 CR3 CD11b/CD18	Neutrophils, monocytes	ICAM-1, FIB	Neutrophil aggregation and adhesion to ECs
$\alpha_X\beta_2$	p150,95 CD11c/CD18	Neutrophils, monocytes	?	Adhesion to ECs
$\alpha_D\beta_2$	CD11d/CD18	Eosinophils, monocytes, lymphocytes	VCAM-1, ICAM-3	Adhesion to leukocytes and to ECs
$\alpha_{IIb}\beta_3$	GPIIb/IIIa	Platelets	FIB, FN, vWF, VN, TSP	Platelet adhesion and aggregation
$\alpha_V\beta_3$	VN receptor	Platelets, ECs	FIB, FN, vWF, VN, TSP, collagens	Platelet adhesion, angiogenesis
$\alpha_4\beta_7$	LPAM-1	Lymphocytes	VCAM-1, MAdCAM-1, FN	Lymphocyte adhesion to ECs and ECM

CR, complement receptor; ECs, endothelial cells; ECM, extracellular matrix; FIB, fibrinogen; FN, fibronectin; GP, glycoprotein; LFA-1, leukocyte function-associated antigen-1; LM, laminin; LPAM-1, lymphocyte Peyer patch adhesion molecule; MAdCAM-1, mucosal addressin cell adhesion molecule-1; TSP, thrombospondin; VCAM-1, vascular cell adhesion molecule-1; VLA, very late-appearing antigen; VN, vitronectin; vWF, von Willebrand factor.

Table 16–2 Immunoglobulin-Like Receptors

Name	Other Name	Expressed by	Ligand	Function(s)
ICAM-1		Macrophages, EC, other cells	$\alpha_M\beta_2$, $\alpha_L\beta_2$, FIB	T-cell responses, leukocyte adhesion to EC
ICAM-2		EC	$\alpha_L\beta_2$	Leukocyte adhesion to EC
ICAM-3		Leukocytes	$\alpha_L\beta_2$	T-cell responses, leukocyte aggregation
ICAM-4		Erythroid precursors	$\alpha_4\beta_1$, $\alpha_v\beta_3$, $\alpha_{IIb}\beta_3$	Regulate erythropoiesis
GP VI		Platelets	Collagen	Platelet adhesion and activation
PECAM-1	CD31	Leukocytes, platelets, EC	PECAM-1	EC junctions, leukocyte transmigration, cell signaling
VCAM-1		Activated EC, smooth muscle cells	$\alpha_4\beta_1$, $\alpha_4\beta_7$	Mononuclear cell adhesion to EC
MAdCAM-1		EC of Peyer patches	$\alpha_4\beta_7$	Lymphocyte homing
Siglecs		Leukocyte subsets	Sialylated glycans	Regulate B-cell activation, innate immunity? hematopoiesis?
JAMs		EC	JAMs, $\alpha_L\beta_2$, $\alpha_4\beta_1$	EC junctions, leukocyte transmigration
CD2		T cells	LFA-3*	T-cell responses
CD4		T cells	Class II MHC*	T-cell responses
CD8		T cells	Class I MHC*	T-cell responses
CD3	T-cell receptor	T cells	Antigen on MHC*	T-cell responses

ICAM-1, -2, -3, -4, intercellular adhesion molecules; JAMs, junctional adhesion molecules; MHC, major histocompatibility complex; PECAM-1, platelet and endothelial cell adhesion molecule-1. For other abbreviations, see Table 6–1 footnote.

*LFA-3 and classes I and II MHC molecules are also immunoglobulin-like receptors.

Table 16–3 Other Adhesion Receptors

Name	Other Name	Expressed by	Ligand	Function(s)
Cadherins		EC, many other cells	Homotypic binding	Formation of EC junctions
GPIb/IX/V		Platelets	vWF	Platelet adhesion to ECM under shear
CD36	GPIV	Platelets, many other cells	Collagens, TSP	Platelet adhesion to ECM
CD44		Leukocytes, other cells	Hyaluronan, serglycin	Lymphopoiesis, lymphocyte activation
DC-SIGN		Dendritic cells	Mannosylated glycans, other glycans	Regulate T-cell–dendritic cell interactions, recognize pathogens
Natural killer cell receptors		Natural killer cells	MHC molecules	Recognition of virus-infected or other foreign cells

DC-SIGN, dendritic cell-specific ICAM-grabbing nonintegrin; MHC, major histocompatibility complex. For other abbreviations, see Table 16–1 footnote.

Table 16–4 Selectins

Name	Other Names	Expressed by	Ligand*	Ligands Expressed by	Function(s)
P-selectin	CD62P GMP-140 PADGEM	Thrombin-activated platelets and EC, cytokine-activated EC	PSGL-1, GPIbα	Leukocytes, platelets	Leukocyte adhesion to activated EC and platelets
E-selectin	CD62E ELAM-1	Cytokine-activated EC	PSGL-1, other sialylated and fucosylated glycoproteins	Leukocytes	Leukocyte adhesion to activated EC
L-selectin	CD62L LECAM-1 LAM-1	Leukocytes	PSGL-1, also GlyCAM-1, CD34, and other mucins on EC of lymph nodes	Leukocytes, EC of lymph nodes	Leukocyte adhesion to other leukocytes; lymphocyte homing to lymph nodes

EC, endothelial cells; ELAM-1, endothelial leukocyte adhesion molecule-1; Gly-CAM-1, glycosylation-dependent cell adhesion molecule-1; GMP-140, granule membrane protein-140; LAM-1, leukocyte adhesion molecule-1; LECAM-1, leukocyte endothelial cell adhesion molecule-1; PADGEM, platelet activation-dependent granule external membrane protein; PSGL-1, P-selectin glycoprotein ligand-1.

*The selectins bind to sialylated, fucosylated, and (in some cases) sulfated oligosaccharides on specific glycoproteins, of which only some have been identified.

The selectins are a group of three receptors that terminate in a membrane-distal carbohydrate-recognition domain related to those in Ca^{2+}-dependent (C-type) animal lectins such as the hepatic asialoglycoprotein receptor (see Fig. 16–1). L-selectin is expressed on leukocytes, E-selectin on cytokine-activated endothelium, and P-selectin on macrophages, platelets, and endothelial cells exposed to secretagogues such as thrombin or histamine (Table 16–4). The selectins mediate leukocyte adhesion to platelets, endothelium, or other leukocytes through Ca^{2+}-dependent interactions of the carbohydrate-recognition domains with cell-surface carbohydrates on apposing cells. High-affinity binding appears to require specific carbohydrate structures displayed on a limited number of membrane glycoproteins. The best-characterized glycoprotein ligands for selectins are mucins that have large numbers of clustered, sialylated *O*-linked oligosaccharides. Site-specific construction of *O*-glycans with specific sialylated, fucosylated, and, in some cases, sulfated moieties is required for these mucins to bind optimally to selectins. In the case of one mucin, P-selectin glycoprotein ligand-1 (PSGL-1), sulfation of tyrosine residues near a specific *O*-glycan is required for binding to P- and L-selectin.

Dendritic cells and related macrophages express a novel group of C-type lectins, of which the best-characterized is dendritic cell-specific ICAM-grabbing nonintegrin (DC-SIGN). DC-SIGN binds to particular oligosaccharides on ICAMs, thereby regulating T-cell and dendritic cell function during antigen presentation. It also binds to glycans on a variety of pathogens, which may have critical roles in innate immunity. Natural killer cells express a different group of proteins with membrane-distal C-type lectin-like domains. Although these receptors are important for interactions of natural killer cells with target cells, they may bind to proteins rather than to glycoconjugates.

Siglecs are a subgroup of membrane proteins of the immunoglobulin superfamily that bind to carbohydrates instead of to proteins (see Table 16–2). The first two amino-terminal (N-terminal) domains appear to be necessary and sufficient for carbohydrate recognition. The N-terminal domain is a V-type structure that includes an unusual disulfide bond that is not found in the more common C-type immunoglobulin domains. Siglecs bind well to sialylated glycans on some but not all glycoproteins. Different siglecs preferentially recognize sialic acid that is linked α2,6-, α2,8-, or α2,3- to an underlying galactose residue. Siglecs can form *cis* interactions with other glycoproteins on the same cell or *trans* interactions with glycoproteins on another cell. The functions of siglecs have not been fully defined, but increasing evidence suggests that they function as important signaling molecules. The best-characterized example is CD22, which negatively regulates B-cell activation when it engages sialylated glycoproteins. Sialoadhesin, expressed on bone marrow macrophages, may regulate hematopoietic cell differentiation.

LIGAND BINDING VERSUS CELL ADHESION

As with all noncovalent macromolecular interactions, adhesion molecules bind to each other with equilibrium affinities that are defined by their association and dissociation rates. However, the efficiency of cell adhesion is not simply a function of the solution-phase equilibrium affinities of adhesion molecules for one another. Adhesion molecules in cell membranes and matrix are limited primarily to two dimensions, and even low-affinity molecular interactions may stabilize adhesion if there is time for sufficient bonds to form along the plane of cell contact. The efficiency of cell attachment, and the ensuing strength of adhesion, reflects multiple factors that dictate the probability of formation of bonds between adhesion molecules on cell or matrix surfaces. The kinetics of bond formation and dissociation are especially important for certain kinds of cell adhesion. Furthermore, interactions between cell adhesion molecules are

Table 16–5 Regulation of Adhesion Receptors

Mechanism	Example
Synthesis	Erythroid precursor synthesis of $\alpha_5\beta_1$ Lymphocyte synthesis of CD44 Cytokine-induced synthesis of E-selectin, P-selectin, ICAM-1, and VCAM-1 by endothelial cells
Surface expression	Proteolytic cleavage of L-selectin from leukocytes Redistribution of P-selectin from granule membranes to plasma membrane of platelets and endothelial cells Endocytosis of P- and E-selectin on endothelial cells
Ligand affinity	Activation-induced increased affinity of many integrins for their ligands Activation-induced increased affinity of CD44 for hyaluronan

For abbreviations, see Table 16–1 footnote.

subjected to force, which affects the lifetimes of adhesive bonds. This is particularly true in the circulation, where platelets and leukocytes must rapidly adhere to the blood vessel wall and withstand forces applied by the wall shear stresses of flowing blood. Other factors that affect bond formation include the number of adhesion molecules on a cell or matrix surface, the distance the binding domain of an adhesion receptor protrudes from the cell membrane, the lateral mobility of receptors, receptor dimerization, and the clustering of receptors on microvilli or other membrane domains. Cell adhesion can be further stabilized by events that occur after the initial interactions of adhesion molecules. For example, the cytoplasmic domains of many adhesion molecules bind to cytoskeletal components, allowing clustering of receptors into surface patches that strengthen adhesion and promote cell spreading or migration.

REGULATION OF ADHESION RECEPTORS

To prevent inappropriate interactions of cells with each other or with extracellular matrix, the expression and function of adhesion receptors must be tightly controlled. Three primary control mechanisms are used: (a) the rate of synthesis of the receptor, (b) the time during which the receptor is displayed on the cell surface, and (c) the binding affinity/avidity of the receptor for ligands (Table 16–5). All of these mechanisms are used to control interactions of blood and vascular cells.

REGULATION OF SYNTHESIS

The synthesis of many adhesion receptors is regulated. Erythroid precursors synthesize integrins that mediate their interactions with stromal cells and with extracellular matrix in the bone marrow. As the precursors mature, synthesis ceases, resulting in loss of expression of cell-surface integrins by the time a mature erythrocyte enters the circulation. Lymphocyte precursors synthesize CD44 during differentiation in the bone marrow, stop synthesis prior to release, and resume synthesis during maturation in the thymus. On exposure to antigens, immunologically naive lymphocytes synthesize increased amounts of several adhesion receptors during their conversion to the memory phenotype; this process presumably allows these cells to become more adhesive in response to a subsequent antigenic challenge. When exposed to inflammatory cytokines such as tumor necrosis factor-α and interleukin-1, endothelial cells transiently increase synthesis of E- and P-selectin, ICAM-1, and VCAM-1, resulting in an adhesive surface for leukocytes.

REGULATION OF SURFACE EXPRESSION

The surface expression of some adhesion receptors is tightly controlled. L-selectin is present on the plasma membrane of leukocytes, where it is available to bind to ligands on the endothelial cell surface. Stimulation of the leukocyte causes L-selectin to be shed into the plasma by proteolytic cleavage. P-selectin is constitutively synthesized by megakaryocytes (where it is incorporated into platelets) and by endothelial cells. Rather than being directly delivered to the plasma membrane, it is sorted into secretory storage granules: the α granules of platelets and the Weibel–Palade bodies of endothelial cells. On stimulation of these cells by agonists such as thrombin, P-selectin is rapidly transported to the cell surface during fusion of granule membranes with the plasma membrane. Once on the surface of the endothelium, both E-selectin and P-selectin are internalized and delivered to lysosomes for degradation. The cytoplasmic domain of P-selectin contains signals that direct sorting into secretory granules, internalization through coated pits of the plasma membrane, and movement from endosomes to lysosomes; the latter two signals probably also are present in the cytoplasmic domain of E-selectin. The net result of these events is to control the duration of exposure of E- and P-selectin on the endothelium, where they can mediate adhesion of leukocytes. Activation of leukocytes also mobilizes a pool of β_2 integrins from storage compartments to the plasma membrane, although some of these molecules also are constitutively expressed on the cell surface. Finally, platelet activation redistributes a portion of the GPIb–IX–V complexes from ligand-accessible positions on the plasma membrane to sequestered, invaginated membrane domains known as the *surface-connected canalicular system*. This process, which requires interactions of the cytoplasmic domain of GPIb–IX–V with the cytoskeleton, may serve to downregulate GPIb-mediated adhesion of platelets to immobilized vWF.

REGULATION OF BINDING AFFINITY

Regulation of binding affinity is an important control mechanism for other adhesion receptors. Many integrins are constitutively present on the cell surface but interact poorly with their ligands. Cell activation by a number of agonists induces conformational changes in integrins so that they effectively recognize their ligands. An example is the $\alpha_{IIb}\beta_3$ integrin, which requires platelet stimulation to bind fibrinogen; if this binding affinity were not regulated, circulating platelets would indiscriminately aggregate in the fibrinogen-rich plasma milieu. The cytoplasmic domains of integrins can exert both positive and negative influences on binding affinity. Binding of specific cytoplasmic proteins to these domains may propagate structural changes to the extracellular ligand-binding regions of the integrins. Three-dimensional structures of integrins suggest that the integrin "headpiece" faces down toward the membrane in the inactive conformation and rapidly extends upward in a "switchblade"-like opening motion on activation. Low-affinity ligand binding may stabilize some active conformations of integrins, perhaps explaining why integrins on unactivated cells will sometimes bind to immobilized, multivalent adhesive proteins but not to the same proteins in solution. Cellular activation also may regulate the binding avidities of CD44, L-selectin, P-selectin, and some integrins through changes in membrane distribution engineered by interactions of their cytoplasmic domains with the cytoskeleton or with clathrin-coated pits.

CELL SIGNALING THROUGH ADHESION MOLECULES

In addition to their roles in cell–cell and cell–matrix contacts, adhesion molecules may cause cell signaling through indirect or direct mechanisms. Proteoglycans in the extracellular matrix can sequester growth factors that can be released to bind to surface receptors on nearby cells. Some chemoattractants bind to proteoglycans on the surface of endothelial cells, where they can activate adherent leukocytes. Binding of adhesive ligands to cell-surface integrins, GPIb–IX–

V, CD44, cadherins, CD36, PECAM-1, selectins, and perhaps other receptors can directly trigger intracellular events. The consequences of such signaling include changes in affinity/avidity of other adhesion receptors for their ligands, shape change, secretion, proliferation, synthesis of cytokines and other molecules, and migration. In some cases, binding of a monovalent adhesive ligand to a receptor may induce a signal. More commonly, signaling requires cross-linking of several receptors through interactions with multivalent ligands in matrix or on apposing cells.

Many studies of adhesion receptor signaling have focused on integrins. Binding of the same ligand to different integrins can mediate different responses in the same cell. Furthermore, ligand binding to the same integrin expressed in different cells can result in different signals. These data suggest that very specific interactions occur between ligand-occupied integrins and intracellular components. The cytoplasmic domains of integrins are essential for initiating signaling. Tyrosine kinases have been localized at the interaction zones between integrins and the cytoskeleton, and tyrosine phosphorylation of a number of proteins accompanies integrin-mediated cell signaling. Tyrosine phosphorylation initiates a cascade of signaling events, including the activation of serine/threonine kinases, which cause a variety of cellular responses. Ligand binding to integrins also results in generation of lipid second messengers, alkalization of the cytoplasm, and influxes of Ca^{2+}.

COOPERATIVE INTERACTIONS BETWEEN SIGNALING AND ADHESION MOLECULES

Signaling and adhesion molecules frequently function cooperatively in sequential cascades to enhance the specificity of cell adhesion. Three examples of how these cooperative interactions facilitate blood cell responses are described next.

Platelet Adhesion and Aggregation

At sites of blood vessel injury in the arterial circuit, platelets rapidly tether to and then translocate or roll along the damaged vessel through reversible interactions of GPIb–IX–V receptors with immobilized vWF exposed in the subendothelial matrix (Fig. 16–2). These interactions are facilitated by arterial flow, perhaps because of complex effects of high wall shear stresses on the lifetimes of bonds between GPIb and vWF. An important feature of this initial reversible adhesive event is that prior activation of the platelets is not required. After adhesion, however, the interaction of immobilized vWF with GPIb receptors triggers intracellular signals that lead to platelet activation. These signals synergize with those produced by engagement of the collagen receptor GPVI. Platelet activation, in turn, increases the affinity of platelet integrins for collagen and fibronectin, which stabilizes adhesion. Binding of these ligands transduces signals that propagate further activation responses such as spreading, secretion of granule contents, and recruitment of additional platelets through cell–cell contact mediated by binding of fibrinogen to activated $\alpha_{IIb}\beta_3$ integrins. This adhesion cascade allows unstimulated platelets to home to the site of vascular injury and then be activated by locally generated mediators.

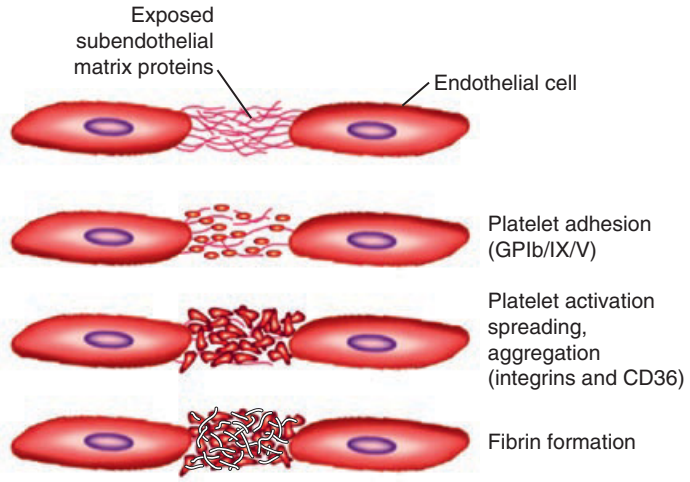

Figure 16–2 Platelet adhesion and aggregation. In response to arterial injury under high shear forces, platelets rapidly adhere to the subendothelial matrix. The initial contacts are made between glycoprotein Ib–IX–V (GPIb–IX–V) on platelets and von Willebrand factor (vWF) in the matrix. These molecular interactions help activate platelets, thereby increasing the affinity of several platelet integrins for other adhesive matrix proteins such as fibronectin, laminin, and collagen. GPVI further activates platelets by binding to collagen. CD36 also interacts with both collagen and thrombospondin. Fibrinogen cross-links activated platelets into aggregates by binding to $\alpha_{IIb}\beta_3$ integrins. The platelet plug then serves as an efficient surface for generation of thrombin and fibrin.

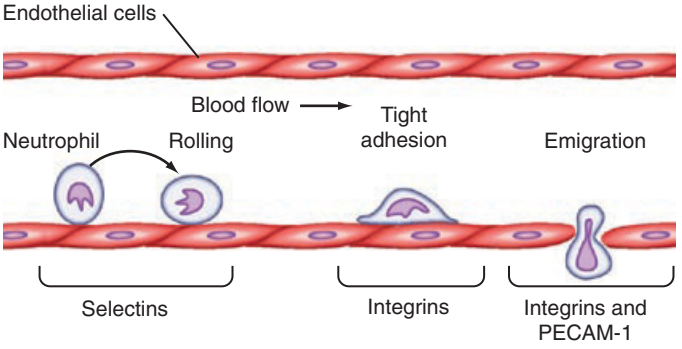

Figure 16–3 Neutrophil rolling, spreading, and emigration. At sites of tissue injury or infection, neutrophils first roll on the endothelial cells in postcapillary venules. These transient adhesive interactions are mediated by activation-induced expression of E- or P-selectin on the endothelial cell surface. E- and P-selectin bind to carbohydrate ligands on the neutrophil. These molecular bonds can form under the shear forces in the venular circulation. The rolling neutrophils are then activated by locally generated inflammatory mediators that increase the affinity of β_2 integrins for immunoglobulin-like receptors such as intercellular adhesion molecule-1 (ICAM-1) on the endothelium. These bonds slow rolling and then promote firm adhesion to the endothelium. Neutrophil migration between endothelial cells into tissues at the site of infection requires disengagement of old adhesive bonds and formation of new bonds between integrins, platelet and endothelial cell adhesion molecule-1 (PECAM-1), and their respective ligands.

Neutrophil Rolling, Spreading, and Migration

Near sites of extravascular bacterial infections, neutrophils first tether to and roll on the endothelial surface of venules through the interactions of selectins with cell-surface carbohydrate ligands (Fig. 16–3). Neutrophil rolling on the endothelium occurs under shear forces, just as platelets adhere to subendothelial matrix under shear forces, although the shear flow in postcapillary venules is lower than that in arteries. Rolling requires a balance between the formation of selectin–ligand bonds at the leading edge of the cell and the dissociation of bonds at the trailing edge of the cell. Shear forces affect the lifetimes of selectin–ligand bonds; lower forces prolong lifetimes (catch bonds), whereas higher forces shorten lifetimes (slip bonds). Catch bonds help explain why a minimum shear force is required to support leukocyte rolling, particularly through L-selectin. Just as the initial adhesion to vWF does not require prior activation of platelets, selectin-mediated rolling does not require prior activation of neutrophils. Instead, locally generated inflammatory mediators induce

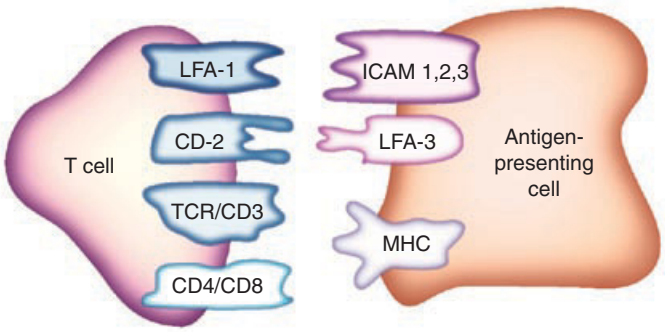

Figure 16–4 Adhesion between T lymphocytes and antigen-presenting cells. The initial contact is mediated by the T-cell receptor (TCR), or CD3, which binds with low affinity but high specificity to a specific antigen presented by a major histocompatibility complex (MHC) molecule. Additional contacts, also of low affinity, are between CD4 (on helper cells) or CD8 (on cytotoxic cells) and MHC, and between CD2 and leukocyte function-associated antigen-3 (LFA-3). These interactions signal the T cell to increase transiently the affinity of the β_2 integrin LFA-1 for the immunoglobulin-like molecules intercellular adhesion molecules ICAM-1, -2, and -3 on the antigen-presenting cell. These bonds strengthen adhesion and transduce further signals to the T cell that cause proliferation and cytokine secretion. Not shown is the redistribution of these adhesion molecules into different regions of the contact zone as adhesion strengthens. Additional signals result from binding of β_1 integrins on the T cell to adhesive proteins in the extracellular matrix.

expression of E- or P-selectin on the endothelial cell surface. The requirement for activation of endothelial cells rather than leukocytes allows the latter to adhere to vessels only at the site of vessel inflammation. Once situated on the vessel wall through selectin-mediated contacts, however, the neutrophils become exposed to activators such as platelet-activating factor, a phospholipid signaling molecule, and interleukin-8, a potent chemoattractant, both of which are presented on the surface of activated endothelial cells. These signals cooperate with others directed by engagement of selectin ligands. Neutrophil activation increases the affinity of β_2 integrins for immunoglobulin counterreceptors on the endothelial cell surface such as ICAM-1. Although flowing cells cannot form these bonds, neutrophils rolling on selectins can do so because of their slower velocities. The integrin-ICAM interactions further slow rolling and then arrest the cells on the endothelium. The leukocytes then migrate, presumably because of disengagement of integrin-ICAM bonds and redistribution of integrins to the leading edge of the cell, where new bonds form. Interactions of leukocytes with JAMs and PECAM-1 in interendothelial cell junctions facilitate transendothelial migration of the neutrophils into the underlying tissues. Adhesion of leukocytes to the endothelium disrupts cytoskeletal tethers to the endothelial cadherins; this disruption leads to dissociation of homotypical cadherin interactions that normally prevent passage of leukocytes. Both the integrin- and the PECAM-1-mediated adhesive events may signal cytoskeletal redistributions in leukocytes that enhance migration toward chemotactic molecules released in the vicinity of the infection. Once leukocytes enter in the tissues, integrin recognition of extracellular matrix protein ligands may trigger secretion of proteolytic enzymes and production of superoxide anions, both required for optimal bactericidal function.

Adhesion of T Lymphocytes to Antigen-Presenting Cells

The initial engagement of T lymphocytes with antigen-presenting cells requires that the T-cell receptor (CD3) recognize antigen presented by the polymorphic domain of MHC molecules (Fig. 16–4). Subsequent interactions include the binding of CD8 or CD4 to MHC class I or II molecules, respectively, plus the binding of CD2 to LFA-3. These molecular contacts are all of low affinity but are highly specific, because they first require specific antigen presentation to the appropriate T cell. The combination of these binding events triggers signals that increase the affinity of LFA-1 ($\alpha_L\beta_2$), a β_2 integrin on T cells, for its ligand, ICAM-1 on antigen-presenting cells, strengthening adhesion. After ICAM-1 binds to LFA-1, the T cell is further activated, resulting in cytokine secretion and proliferation. Additional signaling is mediated through binding of other integrins on T cells to protein ligands in the extracellular matrix.

The first principle of these three responses is that the initial adhesive event, although relatively limited, is highly specific. Thus, platelets bind to exposed subendothelial matrix, neutrophils bind to endothelium near the site of infection, and T cells bind to cells presenting specific antigen. The second principle is that subsequent activation events strengthen cell adhesion and lead to further responses such as secretion, fibrin formation, cellular migration and protein proliferation, or release of cytotoxic mediators. Activation often results from cooperative signaling by soluble agonists and by binding of ligands to adhesion receptors. Costimulation by multiple signals can amplify, and provide specificity to, cellular responses by mechanisms not always feasible for individual mediators. Thus, adhesion and cell signaling are highly interrelated processes.

The process of reversing cell adhesion, although less well understood, is equally important for the control of cell behavior. Some molecules such as the selectins can be proteolytically cleaved or internalized. The activation-induced increases in affinity of integrins and CD44 for their ligands are generally transient, but the mechanisms for return to the inactive conformation are obscure.

ALTERED EXPRESSION OF ADHESION MOLECULES

The highly regulated nature of adhesive events by hematopoietic cells suggests that defects in, or excessive expression of, adhesion molecules may contribute to the pathogenesis of disease. A variety of clinical observations support this hypothesis.

Genetic Deficiencies in Adhesion Molecules

Genetic deficiencies in platelet adhesion receptors such as the GPIb complex (as in Bernard–Soulier syndrome) and the $\alpha_{IIb}\beta_3$ integrin (as in Glanzmann thrombasthenia) result in hemorrhagic symptoms similar to those in patients with thrombocytopenia. Genetic deficiencies in the leukocyte β_2 integrins (as in leukocyte adhesion deficiency-1) are associated with frequent severe bacterial infections and a failure of neutrophils to enter the infected tissues. Similar symptoms are seen in patients with a congenital defect in fucose metabolism that prevents synthesis of the carbohydrate ligands for selectins (leukocyte adhesion deficiency-2) (Table 16–6).

Dysregulated Expression of Adhesion Molecules

Inappropriate expression of adhesion molecules has been implicated in thrombotic and inflammatory disorders and in tumor metastasis. For example, erythrocytes from patients with sickle cell anemia adhere to each other, to leukocytes, and to the endothelium, contributing to vaso-occlusive crises. These adhesive events may reflect, in part, the expression of integrins and selectin ligands not normally found on mature erythrocytes. Inappropriate adhesion and activation of platelets on exposed atherosclerotic plaques may contribute to thrombosis. Dysregulated expression of selectins on the endothelium of ischemic blood vessels during myocardial infarction or shock may contribute to neutrophil-mediated tissue necrosis following reperfusion of the vessel. Mediators released while the neutrophils are adherent in the reperfused vessels may activate integrin function, strengthening adhesion and generating further signals that release destructive oxygen radicals and proteases within the vasculature.

Table 16–6 Genetic Deficiencies in Adhesion Molecules

Molecule	Disease	Laboratory Finding(s)	Clinical Finding
$\alpha_{IIb}\beta_3$	Glanzmann thrombasthenia	Impaired platelet aggregation	Mucocutaneous bleeding
GPIb/IX/V	Bernard–Soulier syndrome	Impaired platelet adhesion to vWF	Mucocutaneous bleeding
β2 integrins	Leukocyte adhesion deficiency-1	Impaired adhesion of activated leukocytes to EC	Frequent infections
Selectin ligands	Leukocyte adhesion deficiency-2	Impaired fucose metabolism resulting in defective carbohydrate ligands for selectins, impaired rolling of leukocytes on venules	Frequent infections

For abbreviations, see Table 16–1 footnote.

Finally, malignant cells appear to utilize molecules normally used for adhesion of blood cells to promote metastatic spread through interactions with platelets, endothelial cells, and extravascular matrix.

These examples underscore the importance of proper regulation of adhesion molecule expression in the physiology of blood cells.

CHAPTER 17

CELL TRAFFICKING AND CHEMOKINES

Steffen Massberg, Ulrich H. von Andrian, and Leslie E. Silberstein

The mammalian immune system is designed to prevent infection while preserving self-tolerance and restraining immune-mediated pathology. To accomplish these tasks it involves billions of motile cells that continually travel throughout the body. The migration profiles vary substantially among individual types of leukocytes. Indeed, the distinct traffic patterns of different leukocyte subsets are not random but a precisely organized process that is essential for proper immune surveillance and serves to maximize the likelihood that leukocytes will encounter and eliminate or contain foreign pathogens. During differentiation in the bone marrow (innate immune cells and B cells) or thymus (naïve T cells) leukocytes are equipped with characteristic repertoires of traffic molecules that enable and restrict their migration to certain microenvironments and tissues. In general, naïve lymphocytes are poorly responsive to inflammatory signals but migrate efficiently to lymphoid organs, whereas innate immune cells and antigen-experienced lymphocytes can respond to inflammation-induced traffic cues, although at least some subsets also travel to noninflamed target tissues.[1,2] Notably, not only mature leukocytes migrate to tissues and enter the circulation or lymphatic systems; hematopoietic stem and progenitor cells also travel continuously throughout the body.[3–6]

The characteristic trafficking of each leukocyte subset is coordinated by adhesion molecules, expressed on leukocytes and endothelial cells (see Chapter 15) and through chemokines and chemokine receptors. This chapter first discusses chemokines as master navigators of leukocyte trafficking and then focuses on the specific trafficking pathways on the basis of the type of migration involved.

CHEMOKINES IN CONTROL OF LEUKOCYTE TRAFFICKING

Chemokines are the critical messengers in the complex cellular communication network used by the immune system. At least 47 chemokines have been identified to date (Table 17–1).[7–11] The two major subclasses of chemokines are distinguished as CC- or CXC-chemokines, depending on the arrangement of two canonical cystein residues within the conserved chemokine motif, which are either adjacent (CC) or separated by a single amino acid (CXC). The XC (XCL1 and XCL2) and CX3C chemokines (CX3CL1) constitute two additional structural subfamilies of chemokines. Most chemokines are secreted proteins of 67 to 127 amino acids, only CXCL16 and CX3CL1 possess a transmembrane domain, but also exist in a cleaved soluble form. Traditionally, chemokines were grouped into functional subfamilies termed *inflammatory* chemokines, which are induced by inflammatory signals and control the recruitment of effector leukocytes in infection, inflammation, tissue injury and malignancies; and *homeostatic* chemokines, which navigate leukocytes during hematopoiesis in the bone marrow and thymus, during initiation of adaptive immune responses in secondary lymphoid organs and in immune surveillance of healthy peripheral tissues (eg, CCL19, CCL21, or CXCL12). However, many chemokines cannot be assigned unambiguously to one of these two categories and are, therefore, referred to as dual-function chemokines (eg, CXCL16, CXCL9).

Chemokine messages are decoded through specific cell-surface G protein-coupled receptors (GPCRs) with seven transmembrane domains.[12] The human chemokine receptor repertoire identified at present consists of 20 different GPCRs (Table 17–2).[13] The tremendous specificity and plasticity observed in leukocyte migration and anatomic distribution is largely owed to this system, because each leukocyte subset expresses a distinct repertoire of chemokine receptors, and each chemokine receptor can bind different sets of chemokines with various binding affinities.[14,15] Chemokine receptors function as allosteric molecular relays, where chemokine binding to the extracellular portion modifies the tertiary structure of the receptor. This allows the intracellular domain of the engaged receptor to bind to and activate heterotrimeric G proteins. In response, the activated G proteins exchange guanosine diphosphate (GDP) for guanosine triphosphate (GTP) and in the process, dissociate into Gα and Gβγ subunits. The dissociated Gβγ subunits mediate most chemokine-induced signals by activating different phosphoinositide-3-kinase (PI3K) isoforms, which in turn lead to the formation of phosphatidyl-3,4,5-triphosphate (PIP_3). PI3K and its product PIP_3 then translocate to the pseudopod at the leading edge of migrating leukocytes, where they colocalize with the small GTPase Rac.[16,17] PIP_3 activates Rac through specific guanine nucleotide exchange factors (GEFs).[18,19] Rac in turn acts through the downstream effectors p21-activated kinase (PAK) and the Wiskott–Aldrich Syndrome protein (WASP) homologue WAVE, that stimulate actin-related protein (Arp) 2/3. Together, this process induces focal polymerization, required for the development and forward extension of the pseudopod, a critical step in leukocyte chemotaxis.[20] The importance of PI3K-dependent signaling for leukocyte chemotaxis is evidenced by the lack of migration of myeloid leukocytes to chemokines in mice lacking PI3Kγ.[21] Notably though, distinct signaling pathways or at least other PI3K isoforms appear to be involved in the trafficking of lymphocytes, because lymphocyte chemotaxis is not affected in PI3Kγ-deficient mice,[21,22] but depends on the Rac guanine exchange factor DOCK2.[23]

Different pathways have been identified that can terminate chemokine signaling through GPCRs. The Gα subunit possesses an intrinsic GTPase activity to hydrolyze GTP. In a negative feedback loop this GTPase activity allows the Gα subunits to reassociate with the Gβγ subunits, thereby restoring the heterotrimeric G protein to its inactive state. In addition, another class of molecules, known as regulators of G protein signaling (RGS), also modulates signaling through chemokine GPCRs. RGS are a large and diverse protein family initially identified as GTPase-activating proteins (GAPs) of heterotrimeric G-protein Gα subunits.[24] At least some RGS can also influence Gα activity through either effector antagonism by competing with effector molecules for GTP-bound Gα subunits or by acting as guanine nucleotide dissociation inhibitors (GDIs). To date, over three dozen genes have been identified within the human genome that encode proteins containing an RGS or RGS-like domain. Additional fine-tuning of chemokine communication is achieved by cleavage and inactivation of chemokines and/or chemokine receptors, further adding to the plasticity of the chemokine system.

Proteases, in particular CD26, a surface glycoprotein with intrinsic dipeptidyl peptidase IV enzyme activity, as well as matrix metalloproteases (MMPs), have recently been implicated in the control of chemokine-mediated navigation of leukocyte trafficking.[25] MMPs are a family of more than 20 enzymes with important functions in matrix degradation. They also act on chemokines to regulate varied aspects

Table 17–1 Chemokines and Chemokine Receptors[8,11,36]

Chemokine	Chemokine Receptor*

of inflammation and immunity. In particular, MCPs and CXCL12 [stromal cell-derived factor-1 (SDF-1)] are cleaved and inactivated by several MMPs, including MMP-2. Apart from MMPs, proteases stored in neutrophil granules, in particular cathepsin G and elastase, inactivate chemokines, such as SDF-1 and its receptor CXCR4, that regulate not only the migration of mature leukocytes but also the mobilization and homing of immature hematopoietic stem cells.[26,27] Hence, proteases by means of their chemokine-modifying properties must be regarded as integral components in the control of trafficking of mature leukocytes and their precursors.

In general, leukocyte trafficking can be classified into three distinct patterns of migration: (a) entry into tissues from the circulation; (b) migration within tissues; and (c) exit from tissues. Each of these classes of leukocyte trafficking will be discussed in the following sections.

LEUKOCYTE ENTRY INTO TISSUES

Leukocytes must engage several sequential adhesion steps to be able to leave the circulation and enter target tissues.[2,28–30] Initially, tethers are formed between leukocytes and endothelial cells by adhesion receptors that are characterized by the ability to rapidly bind their ligands with high tensile strength. The most important initiators of leukocyte tethering are selectins, expressed on leukocytes (L-selectin), endothelial cells (E- and P-selectin), and platelets (P-selectin). The bonds formed between selectins and their major ligands, sialomucins decorated with oligosaccharides related to sialyl-Lewis^x, including P-selectin glycoprotein ligand (PSGL)-1 and peripheral-node addressin (PNAd), are transient and do not allow permanent arrest of leukocytes. Selectin-mediated adhesive bonds continuously dissociate at the cell's upstream end whereas new bonds form downstream, resulting in the characteristic rolling motion of tethered leukocytes. To undergo firm adhesion the rolling cell must engage additional adhesion receptors that belong to the integrin family, including CD11a/CD18a (LFA-1) and the α4 integrins, α4β1 and α4β7.

Whereas selectins are constitutively active, integrins need to be activated to promote permanent adhesion. Integrin activation is induced on leukocytes by chemoattractant signals that trigger a reversible change in integrin conformation (leading to enhanced ligand-binding affinity) or in integrin clustering (enhancing avidity), or both. Some (but not all) chemokines presented on the luminal surface of microvascular endothelial cells can trigger rapid integrin activation and efficiently induce leukocyte arrest. Chemokines signal primarily through the $G\alpha_i$ subfamily of G proteins, which can be inhibited by pertussis toxin (PTX). Consequently, intravital microscopy studies have shown that lymphocytes treated with PTX initiate normal tethering and rolling interactions in high endothelial venules in lymph nodes (LN) and Peyer patches (PP), but PTX-treated cells are unable to undergo integrin-dependent firm arrest. Thus, activation of integrins is a mandatory step required to occur before integrins can bind to their ligands. Once arrested, the adherent leukocytes can migrate across the vascular wall and enter their target tissue. Two routes of leukocyte diapedesis have been described so far: a paracellular route that dominates most extravasation processes and a transcellular route, reported for neutrophils and some T cells.[31] Both routes involve the action of apical and junctional endothelial intercellular adhesion molecule-1 (ICAM-1) and, at least in some settings, also vascular cell adhesion molecule-1 (VCAM-1). In inflammatory conditions, additional junctional endothelial ligands such as PECAM-1, CD99, and junctional adhesion molecule (JAMs) can contribute to leukocyte diapedesis.[32,33]

All consecutive steps, (a) leukocyte tethering and rolling, (b) exposure to a chemotactic stimulus, (c) firm arrest, and (d) diapedesis are essential for leukocytes to enter lymphoid tissues and to migrate to sites of inflammation. Correspondingly, in patients suffering from leukocyte adhesion deficiency syndrome, a genetic defect either in β2 integrins (type 1) or in fucosylated selectin ligands (type 2), neutrophils cannot stop or roll, respectively; this syndrome is characterized by marked leukocytosis and frequent and severe soft-tissue infections.[34,35]

Chemokine Control of Lymphocyte Homing to Secondary Lymphoid Organs

Migration of blood-borne lymphocytes to secondary lymphoid organs is the best-characterized example of leukocyte trafficking from the circulation into distinct target tissues.[2,36,37] Lymphocytes constantly survey secondary lymphoid organs, which include the spleen, tonsils,

Table 17–2 Chemokines and Chemokine Receptors[8,11,37]

Receptor	Chemokine Ligands	Cell Types	Disease Association
CC Family			
CCR1	CCL3, CCL3L1, CCL5, CCL7, CCL8, CCL13, CCL14, CCL15, CCL16, CCL23	T cells, monocytes, eosinophils, basophils	Rheumatoid arthritis, multiple sclerosis, kidney disease, cancer
CCR2	CCL2, CCL7, CCL8, CCL11, CCL13, CCL16, CCL26	Monocytes, dendritic cells (immature), memory T cells	Atherosclerosis, rheumatoid arthritis, multiple sclerosis, diabetes mellitus type 2, obesity, asthma
CCR3	CCL3L1, CCL5, CCL7, CCL8, CCL11, CCL13, CCL15, CCL18, CCL24, CCL26, CCL28, CXCL9, CXCL10, CXCL11	Eosinophils, basophils, mast cells, Th2, platelets	Allergic asthma and rhinitis
CCR4	CCL17, CCL22	T cells (Th2), dendritic cells (mature), basophils, macrophages, platelets	Parasitic infection, graft rejection, asthma, skin disease
CCR5	CCL3, CCL3L1, CCL4, CCL4L1, CCL5, CCL7, CCL8, CCL11, CCL14, CCL16	T cells, monocytes	HIV-1 coreceptor, transplant rejection
CCR6	CCL20	T cells (T regulatory and memory), B cells, dendritic cells	Allergic asthma
CCR7	CCL19, CCL21	T cells, dendritic cells (mature), antigen-experienced B cells	Cancer
CCR8	CCL1	T cells (Th2), dendritic cells	Granuloma formation
CCR9	CCL25	T cells, IgA^+ plasma cells	Inflammatory bowel disease
CCR10	CCL27, CCL28	T cells	Skin manifestation of lymphoma
CXC Family			
CXCR1	CXCL6, CXCL8	Neutrophils, monocytes	Chronic obstructive pulmonary disease, inflammatory lung disease, sepsis
CXCR2	CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8	Neutrophils, monocytes, microvascular endothelial cells	Chronic obstructive pulmonary disease, inflammatory lung disease, tumor growth/angiogenesis
CXCR3-A	CXCL9, CXCL10, CXCL11	Th1 helper cells, mast cells, mesangial cells	Inflammatory skin disease, multiple sclerosis, transplant rejection
CXCR3-B	CXCL4, CXCL9, CXCL10, CXCL11	Microvascular endothelial cells, neoplastic cells	Angiostatic for tumor growth
CXCR4	CXCL12	Widely expressed	HIV-1 coreceptor, tumor metastasis
CXCR5	CXCL13	B cells, follicular helper T cells (T_{FH})	Cancer?
CXCR6	CXCL16	$CD8^+$ T cells, natural killer cells, memory $CD4^+$ T cells	Inflammatory liver disease, atherosclerosis
CXCR7	CXCL11, CXCL12	tumor cell lines, activated endothelial cells, murine fetal liver cells	Cancer?
CX_3C Familiy			
CX_3CR1	CX3CL1	Macrophages, endothelial cells, smooth-muscle cells	Atherosclerosis
XC Family			
XCR1	XCL1, XCL2	T cells, natural killer cells	Rheumatoid arthritis, IgA nephropathy
Atypical Chemokine Receptors			
CCX-CKR	CCL19, CCL21, CCL25, CXCL13	Widely expressed in tissues, immature dendritic cells	Sarcoidosis?
D6	CCL2, CCL3, CCL3L1, CCL4, CCL4L1, CCL5, CCL7, CCL8, CCL11, CCL12, CCL13, CCL14, CCL17, CCL22	Lymphatic endothelial cells in afferent lymphatics from skin, gut, lung	Experimental autoimmune encephalomyelitis, opposing effects on allergic inflammation and airway reactivity
DARC/Duffy	CCL2, CCL5, CCL11, CCL13, CCL14, CCL17, CXCL1, CXCL2, CXCL3, CXCL7, CXCL8	Vascular endothelial cells, high endothelial venules, erythrocytes	Cancer?

GCP, granulocyte chemotactic protein; GRO, growth-regulated oncogene; ENA, epithelial-cell-derived neutrophil-activating peptide; MIG, monokine induced by interferon-γ; IP-10, interferon-inducible protein 10; I-TAC, interferon-inducible T cell alpha chemoattractant; SDF-1, stromal cell-derived factor-1; BCA-1, B cell chemoattractant 1; SR-PSOX, scavenger receptor for phosphatidylserine-containing oxidized lipids; MIP, macrophage inflammatory protein; MCP, monocyte chemoattractant protein; HCC, hemofiltrate chemokine; TARC thymus and activation-regulated chemokine; MDC, macrophage-derived chemokine; LARC, liver and activation-regulated chemokine; ELC, Epstein–Barr virus-induced molecule 1 ligand chemokine; SLC, secondary lymphoid-tissue chemokine; TECK, thymus-expressed chemokine; CTACK, cutaneous T cell-attracting chemokine; MEC, mammary-enriched chemokine.

appendix, Peyer patches (PPs), and lymph nodes (LNs), to determine whether an antigen is present that poses a threat to the body. This information is provided to T cells by dendritic cells, which collect and trap antigen and then present it to T cells together with costimulatory molecules and cytokines. Mature dendritic cells that have captured antigen in peripheral tissues[38] and some memory cells[39] reach the LNs through afferent lymph vessels. In contrast, circulating T and B lymphocytes gain access to LN and PP through specialized postcapillary microvessels lined with cuboid endothelial cells that are known as *high endothelial venules* (HEV).[40–45] HEV in different secondary lymphoid organs express distinct patterns of trafficking molecules to serve as tethering platforms for defined subsets of lymphocytes. For example, HEV in LN express peripheral node addressin (PNAd), whereas HEV in PP express mucosal addressin-cell adhesion molecule (MAdCAM-1). Other mucosa-associated lymphoid organs, such as mesenteric LNs, express both MAdCAM-1 and PNAd. Although T and B lymphocytes are recruited by similar multistep cascades to home to secondary lymphoid organs, the role of individual traffic molecules is not necessarily identical, even when both subsets interact with the same microvessel.[2,36]

The first step in the homing cascade in LNs is mediated by L-selectin/CD62L expressed on all lymphocytes, except effector/memory cells. PNAd, an O-linked sulfated core 1 carbohydrate moiety that is exclusively found in HEV, is the major endothelial L-selectin ligand.[46,47] Binding of L-selectin to PNAd initiates lymphocyte rolling in HEV and slows down and marginates the free-flowing lymphocytes.[2,28–30] Although the L-selectin–PNAd interaction is required, it is not by itself sufficient to promote firm leukocyte adhesion. The subsequent firm arrest of rolling T and B lymphocytes is mediated by the integrin CD11a/CD18 (LFA-1), which binds intercellular adhesion molecules (ICAM), in particular ICAM-1 and ICAM-2, on high endothelial cells.[44] Like most integrins, LFA-1 needs to be activated before it can promote firm arrest of lymphocytes. Structural studies of LFA-1 indicate that the heterodimeric molecule is folded like a switchblade when it is in a low-affinity state, but opens to an extended, high-affinity configuration upon activation.[48,49]

Chemokines that are present in the lumen of HEV function as triggers of integrin activation.[50,51] On naïve T cells integrin activation is primarily mediated by CCL21 (also called SLC, TCA4, exodus 2 or 6-C-kine), which is constitutively expressed and secreted by HEV. The secreted chemokine is noncovalently bound to glycosaminoglycans on the surface of HEV. Here, it activates rolling lymphocytes through binding to CCR7, which is expressed on naive B and T cells. Another CCR7 ligand, CCL19 (also termed ELC or MIP3β), also supports T cell homing to LNs. CCL19 is not expressed by high endothelial cells themselves. However, CCL19 and other chemokines may be released by extravascular cells in LNs or in tissues that discharge lymph to a local LN. Lymph-borne chemokines can be transported to the luminal aspect of HEV. Correspondingly, chemokines, including CCL2, CCL19, and CCL21, injected under the skin of mice accumulate on the luminal surface of the HEV in draining LNs, where they promote integrin activation on rolling leukocytes bearing the cognate receptors.[52–54]

B cells use largely the same traffic molecules as naïve T cells to home to LN. However, B cell–HEV interactions are only moderately affected by the absence of CCR7 or its ligands. Correspondingly, LNs of mice lacking CCR7 contain few T cells, whereas the B cell compartment (and the memory T cell compartment) is less affected.[55,56] Similar observations were made in *plt/plt* mice, which have a spontaneous genetic defect resulting in deletion of CCL19 and the HEV-expressed form of CCL21 (mice, unlike humans, have a second *ccl21* gene that is only expressed in lymph vessels), demonstrating that B cells are not absolutely dependent on CCR7 to adhere to HEV.[45] In fact, rolling B cells can be induced to arrest in HEVs by either CCR7 agonists or by CXCL12 (also called stromal cell-derived factor [SDF-1]α), the ligand for CXCR4.[57] An additional chemokine pathway involving CXCL13 (also called BLC) and its receptor CXCR5 has also been implicated in B cell homing to secondary lymphoid tissues.[58] Of note, although B cells encounter several distinct integrin-activation signals in HEV, B cell homing to LNs is nonetheless less efficient than that of T cells. A likely reason is that the B cells express only approximately half the number of L-selectin molecules expressed on T cells, which greatly affects their ability to initiate the adhesion cascade in HEV.[59,60]

The requirement for a sequence of at least three distinct molecular steps that each leukocyte must undergo to arrest within microvessels explains why only certain leukocyte subsets gain access to lymphoid tissues, whereas others are excluded. Granulocytes, for example, express LFA-1 and L-selectin but not CCR7. Consequently, although granulocytes can roll in HEV (via L-selectin), these leukocytes do not perceive an integrin-activating stimulus and, therefore, fail to accumulate in LNs or PPs. Likewise, mature dendritic cells express CCR7 and CD11a/CD18, but not L-selectin. Because these cells are thus incapable of rolling in HEV, they fail to home to noninflamed LNs from the blood (although mature dendritic cells readily access LNs via afferent lymph). Hence, the GPCR-mediated integration activation step is critical, for imparting specificity to the process of lymphocyte homing to LNs.

In HEVs of PPs, similar homing mechanisms are encountered as described above for LNs. However, the levels of L-selectin ligands (which are immunologically distinct from PNAd) expressed by HEV in PPs are considerably lower when compared with that in LNs.[61,62] As a result, L-selectin itself is not sufficient to initiate a successful homing cascade for most lymphocytes in PPs.[61] Indeed, HEV in PPs (and also in mucosa-associated LNs) additionally express MAdCAM-1, a ligand for the α4β7 integrin.[62–64] The α4β7 heterodimer, which comprises an α4 integrin chain (CD49d) linked to the β7 integrin chain, is expressed at low levels by naïve T and B cells and is required for the successful homing of these cells in PP HEV.[61,64] Following formation of an initial L-selectin-dependent tether, the α4β7-MAdCAM-1 pathway stabilizes and slows the rolling lymphocytes without requiring chemokine activation. Once a chemokine signal has been transmitted, both α4β7 and LFA-1 become activated and jointly mediate firm arrest.[61]

Of note, α4β7 is strongly upregulated on gut-homing effector or memory lymphocytes but completely absent on skin-homing memory T and B cells; these differential levels of α4β7 integrin expression allow certain antigen-experienced lymphocyte subsets to acquire tissue selectivity.[65] The mechanisms underlying this specificity and plasticity of lymphocyte homing will be addressed in the next section. Like in LNs, chemokines are essentially involved in promoting integrin activation and allowing firm lymphocyte arrest in HEV of PP. Thus, CXCR4, CXCR5, and CCR7 have been implicated in B cell homing, whereas CCR7 seems exclusively responsible for T cell homing. Interestingly, although T and B cells are recruited across the same HEV in LNs, there is segmental segregation of T and B cell recruitment in PPs. HEV supporting B cell accumulation in PPs are concentrated in or near B follicles and present CXCL13, but not CCL21, whereas T cells preferentially accumulate in interfollicular HEV (ie, within the T cell area), which express high levels of CCL21 but not CXCL13.

Trafficking of Leukocytes From Blood Into Nonlymphoid Tissues

As outlined in the above section, naïve lymphocytes migrate most efficiently to secondary lymphoid organs from which innate immune cells are excluded. However, both innate immune cells and subsets of lymphocytes can respond to inflammatory and/or activation signals by modulating the expression and/or activity of traffic molecules in a way that allows them to migrate to nonlymphoid tissues.[1] For example, in response to an inflammatory stimulus, granulocytes, including neutrophils, eosinophils, and basophils, are rapidly recruited to the affected site and provide the first line of defense. Thereafter, additional immune cells, including monocytes, dendritic cells, and effector as well as memory lymphocytes may be recruited. Essentially all of these different recruitment events depend on distinct multistep adhesion cascades.

Many of the inflammation-seeking traffic molecules required for access to nonlymphoid tissues are shared by the different leukocyte subsets. The key receptors that initiate capture of neutrophils, monocytes, natural killer cells, eosinophils, and effector T and B cells at peripheral sites of injury and inflammation are the three selectins, the leukocyte-expressed L-selectin as well as P- and E-selectin, which are induced on both acutely (and in some settings) chronically stimulated endothelial cells.[66,67] In inflamed gastrointestinal venules, the integrin α4β7 and its ligand MAdCAM-1 contribute to leukocyte recruitment. In addition, leukocyte–leukocyte interactions, mediated through PSGL-1 and L-selectin, can also support accumulation of immune cells in inflamed tissues.[68] Subsequent firm arrest of leukocytes in nonlymphoid tissues involves integrins, including CD11a/CD18 (and its ligand ICAM-1 and possibly also ICAM-2), VLA-4 (and its ligand VCAM-1), as well as Mac-1 (and its ligand ICAM-1). As discussed above for lymphoid tissues, chemoattractants, including chemokines and other GPCR agonists, such as formyl peptides, activated complement fragments (particularly C5a), and lipid mediators (eg, PAF and LTB4), contribute essential integrin-activation signals for leukocytes at sites of inflammation. The molecular diversity and selective action of these different chemoattractants on distinct leukocyte subsets as well as their restricted temporal and spatial expression patterns provide a crucial mechanism for the fine-tuning of cellular immune responses.[29,69]

In most innate immune cells the changes that are induced by activation signals are relatively uniform. In contrast, the migratory properties acquired by T and B lymphocytes in response to activation are diverse, depending on the strength, the quality, and the context of the antigenic stimulus.[65] Specifically, antigen stimulation of naïve lymphocytes results in the generation of effector and memory cells that express specific repertoires of trafficking molecules that guide them back to tissues containing the stimulatory antigen.[70–72] Thus, a cutaneous challenge generates preferentially a skin-tropic memory response, whereas oral stimulation induces preferentially gut-homing effector and memory cells. Recent studies have broadened our understanding of the molecular events that induce the generation of tissue-specific memory cells.

In addition to presenting antigen, dendritic cells in different lymphoid organs are endowed with information indicating the tissue from which the antigen was obtained. Dendritic cells in mucosa-associated lymphoid tissues (unlike those in other lymphoid organs) possess the enzymatic machinery to synthesize retinoic acid (RA) from vitamin A.[73] Exposure of activated T cells to RA induces the expression of gut-homing receptors (ie, α4β7 and CCR9) and suppresses skin-homing molecules.[71,74] In the absence of RA, T cell stimulation induces few or no gut-homing molecules, but instead promotes the expression of P- and E-selectin ligands as well as CCR4, which are needed for homing to the skin. Additionally, when activated T cells are exposed to IL-12 and high levels of vitamin D3, which is physiologically induced by sunlight in the skin, they upregulate CCR10, the receptor for the epidermal chemokine CCL27.[75] This organ-specific information can reprogram and "imprint" the tissue-tropic memory cells as they differentiate from naïve lymphocytes.[72]

Like T cells, B-cell subsets also express homing receptors that permit their selective trafficking to specific tissues. For example, distinct B cell subsets produce the immunoglobulin isotype IgA that is present in secreted body fluids, including tears, breast milk, and mucus. IgA^+ B cells are characterized by their expression of CCR10.[76,77] The ligand for CCR10, MEC/CCL28, is expressed predominantly in mucosal tissues that secrete IgA.[78] Hence, CCR10 may function as a homing receptor that allows IgA-secreting B cells to migrate to tissues where IgA is required. A large subset among the IgA-secreting B cells are those in the small intestine, which in addition to CCR10 express the gut-homing receptors α4β7 and CCR9. When naive B cells are activated in the presence of intestinal dendritic cells, they upregulate not only these two traffic receptors but also undergo class-switching to IgA. This imprinting effect is dependent upon RA, which is sufficient to induce gut-homing receptors, but must be combined with dendritic cell-derived IL-5 or IL-6 to promote IgA class-switching.[74] At least 50 additional subtypes of lymphocytes have been characterized in human blood and it is likely that multiple similar associations between homing receptors, immunological effector function, and tissue specificity will be revealed in future.

Migration of Hematopoietic Stem Cells to the Bone Marrow

The bone marrow (BM) is the principal site of hematopoiesis in the adult body. Correspondingly, most hematopoietic stem cells (HSCs) are lodged in the BM cavity. Within the BM, maintenance of HSCs and regulation of their self-renewal and differentiation is thought to depend on the specific microenvironment, which has historically been termed *stem cell niche*.[79] The central role of stem cell niches for HSC function has been recognized with the discovery that *Sl/Sl*^{d} (steel-Dickie) mice bearing a mutation in the gene encoding membrane-bound stem-cell factor (SCF, also known as KIT ligand) show failure of bone marrow HSC maintenance.[80] However, the exact localization as well as the composition of BM HSC niches and the molecular crosstalk that controls the retention of HSC within the niches are subjects of intense ongoing research.[81–84]

Notably though, not all HSCs reside within the BM. In fact, it has been known for almost four decades that a small amount of hematopoietic precursors are also present in peripheral blood.[3–6] Blood-borne HSCs continuously migrate back to the BM cavity, presumably to fill any vacant stem cell niches.[6] Although the exact physiological relevance of blood-borne HSCs remains to be determined, the intrinsic capacity of HSCs to home to the BM compartment is the prerequisite for successful clinical bone marrow and stem cell transplantation.

Homing of HSCs to BM is a rapid process, because intravenously injected murine and human progenitors are quickly cleared from the recipient circulation.[6,85,86] Like mature lymphocytes, HSCs and hematopoietic progenitor cells (HPCs) interact through a multistep adhesion cascade with BM microvessels.[86–92] Initially, HPCs tether and roll along BM microvessels. This process involves α4β1 integrin on HSC/HPC, which binds vascular cell adhesion molecule-1 (VCAM-1), as well as E- and P-selectin on BM sinusoidal endothelial cells, which bind α(1–3)-fucosylated ligands including CD44 and PSGL-1 on the surface of HPCs.[86] The subsequent firm arrest is mediated by activated α4β1 and VCAM-1, which is constitutively expressed in BM sinusoids. In addition to α4β1 integrin, the integrins α4β7, α5β1, and α6β1, as well as CD44, have recently been implicated in HSC homing to the BM.[93–95]

The chemokine CXCL12, the ligand for CXCR4 expressed by most hematopoietic cells including HSCs, is thought to play a pivotal role in BM homing of HSC. BM endothelial cells (in addition to immature osteoblasts and other stromal cells) constitutively express and secrete CXCL12.[89,96,97] However, alternate pathways appear to exist because fetal liver-derived mouse HSCs home to the BM of adult recipients independent of CXCR4,[98] and adult HSCs treated with a CXCR4 antagonist are still able to home sufficiently to the BM.[99] This indicates that HSCs may use different receptors and/or respond to distinct integrin-activation signals. In this context, the recent description of CXCR7, an alternate receptor for CXCL12, may explain some of the seemingly contradictory findings.[100]

Of note, the CXCL12/CXCR4 axis is not only involved in the homing process of HSCs to the BM, but (among others) has also been linked to the retention of HSCs within stem cell niches and to the regulation of the maturation of more committed HPCs (in particular B cell progenitor cells).[27,101,102] Correspondingly, disruption of the CXCL12/CXCR4 pathway leads to premature release of HPCs into the peripheral blood.[103,104] HPCs lacking CXCR4 accumulate in the circulation and fail to undergo normal lymphopoiesis and myelopoiesis, most likely because the cells do not receive the required maturation signals. Interestingly, upregulation of metalloproteinases (see above), which cleave and inactivate CXCR4 and CXCL12, has recently been implicated in HSC mobilization.[105] Mechanisms that

modulate the CXCR4/CXCL12 axis are also thought to play a role in the coordinated mobilization of HPCs in response to cytokines that are used for this purpose in clinical practice.[26]

LEUKOCYTE MIGRATION WITHIN TISSUES

Trafficking Patterns of Lymphocytes

After a leukocyte has accessed a tissue, it must migrate to specific interstitial positions. As discussed above, homing typically requires that the blood-borne leukocyte completes a complex tissue- and subset-specific multistep adhesion cascade. One exception to this rule is the spleen, where most blood-borne lymphocytes can leave the circulation even when multiple traffic molecules are inhibited. However, chemokines are essential in all lymphoid organs, including the spleen, to guide the newly arrived lymphocytes to their proper position within the organ.

Multiphoton intravital microscopy was recently used as a tool to decipher the mechanisms that control the extravascular traffic patterns of homed lymphocytes within lymphoid and nonlymphoid tissues.[36,106–110] For example, imaging experiments have shown that T cells that have entered an LN move incessantly within the paracortex (T cell area). Here, they query the resident dendritic cells for the presence of antigens that activate their T cell receptor (TCR). B cells that home to LNs migrate to the more superficial B cell-rich follicles, where they may detect antigens presented by follicular dendritic cells. Activated B cells that encounter antigens then move to the margins of the B- and T-cell zones.[108] Here, they can receive help from antigen-specific CD4 T cells. Analogous specific microenvironments for T and B cells exist in the other lymphoid tissues also.

Migration of T Cells to T Zones Within Secondary Lymphoid Organs

After homing to secondary lymphoid organs, T cells migrate within the T zones. They engage in highly motile ameboid movement (average speed ~12 μm/min) guided by a network of fibroblastic reticular cells (FRCs) and undergo multiple brief encounters with resident dendritic cells.[111–114] As a consequence of this high motility, it has been estimated that every dendritic cell in an LN touches as many as 5000 naïve T cells within 1 hour. When T cells encounter a specific antigen, they progressively decrease their motility, become activated, and form long-lasting stable conjugates with DCs. Finally, antigen-experienced T cells start to proliferate and resume their rapid migration while contacting DC only briefly.[113,115]

The positioning and high motility of T cells in the T-cell area is dependent on CCR7 and its ligands CCL19 and CCL21.[55,56,116,117] Both ligands are abundantly expressed in T zones by radiation-resistant stromal cells. Notably, ectopic expression of CCL21 induces the formation of LN-like structures in the pancreas of mice.[118] The expression of CCL19 and CCL21, but also of CXCL13, which attracts B cells to B cell follicles (see below), by lymphoid stromal cells is strongly dependent on the cytokine lymphotoxin (LT)-$\alpha 1\beta 2$ heterotrimers signaling via lymphotoxin β receptor.[119,120] Correspondingly, mice deficient in lymphotoxin have no morphologically detectable LN or PP.[121]

Positioning of B Cells Within Secondary Lymphoid Organs

Similar to T cells, B cells enter secondary lymphoid organs from the blood to search for their specific antigens. As previously outlined, the homing and entry of B cells into secondary lymphoid organs such as the LN and PP depends on chemokine–receptor interactions that finally result in firm adhesion of integrins on the surface of HEV. This adherence is followed by movement into lymphoid tissue.[57] After entering secondary lymphoid organs the naïve B cells travel to B cell-rich areas, the B cell follicles. This migration depends on the presence of CXCR5 on the surfaces of B cells and the localized expression of CXCL13 by follicular stromal cells.[37] Follicular B cells are also highly motile, migrating in a network of follicular dendritic cells (FDC), a process that is thought to be necessary to ensure optimal surveillance of the FDC for surface-displayed antigen. After a period of random migration within follicules, B cells that have not encountered a cognate antigen return to the circulation via the lymph or, in case of the spleen, via the blood. In contrast, B cells that become stimulated by antigen relocate to the B–T boundary area to solicit help from T cells, which is necessary for further differentiation. To achieve this repositioning, activated B cells rapidly upregulate CCR7. This permits their chemotaxis toward CCR7 ligands expressed in the T cell-rich zones of the secondary lymphoid organs.[108] Real-time imaging has been performed to further characterize the timing of this relocalization process. Antigen-engaged follicular B cells initially reduce their migration velocity upon antigen exposure. Approximately 6 hours later the activated B cells move toward the follicle border with the T cell-rich zone and undergo highly dynamic interactions with helper T cells during the following several days.[108]

In the spleen, a subpopulation of B cells is lodged in the marginal zone (MZ) immediately adjacent to the marginal sinus that surrounds the white pulp cords. The exact extent to which chemokine-induced attraction and adhesion affect the positioning of MZ B cells is still unclear. However, recent studies indicate that the lodgment of B cells in the MZ is dependent upon interactions of $\alpha L\beta 2$ and $\alpha 4\beta 1$ on MZ B cells with their ligands (ICAM-1 and VCAM-1, respectively).[122] As with follicular B cells in LNs, antigen encounter of MZ B cells causes their rapid repositioning to the B–T boundary area. The retention of naïve B cells in the MZ and their relocalization to the B–T boundary area upon antigen encounter is thought to involve signaling through the phospholipid sphingosine-1 phosphate (S1P) and its receptor $S1P_1$.[123]

LEUKOCYTE EXIT FROM TISSUES

Although the coordinated role of adhesion molecules and chemokines governing lymphocyte entry into tissues has been examined in great detail, less is known about the exit of these cells from tissues. The final sections of this chapter discuss examples of emerging research on the diverse mechanisms that regulate exit of distinct leukocyte subsets from tissues.

REPROGRAMMING DENDRITIC CELLS TO EXIT TISSUES TOWARD SECONDARY LYMPHOID ORGANS

Lymphocyte homing remains without consequence unless lymphocytes encounter dendritic cells that present their cognate antigen. Dendritic cells capture and present antigen to T cells more efficiently than any other antigen-presenting cell. In general, two routes of antigen delivery to LNs have been described to date: (a) antigenic material becomes lymph-borne and is taken up by dendritic cells that reside in the LN a priori; (b) antigen is acquired by dendritic cells that reside in peripheral tissues and then transport the material to the draining LN. Dendritic cells constitutively patrol all tissues and engulf microorganisms, dead cells, and cellular debris. In the absence of inflammatory stimuli, the cells remain in an immature state that is only weakly immunogenic and often stimulates T cell tolerance, rather than activation. However, multiple signals associated with infection or tissue damage can induce dendritic cell maturation. Immature dendritic cells express a variety of chemokine receptors, including as CCR1, CCR5, and CCR6, which are believed to result in the constitutive homing of immature dendritic cells into tissues, particularly sites of inflammation where ligands for these receptors are abundant.[1,124,125] After exposure to a maturation stimulus, such as Toll-like receptor agonists (eg, LPS, bacterial lipoproteins, peptido-

glycans or CpG dinucleotides), which often originate from infectious pathogens,[126,127] dendritic cells lose CCR1, CCR5, and CCR6, whereas expression of GPCRs for lymphoid chemokines, in particular CCR7 and CXCR4, are upregulated.[128] Lymphatic endothelial cells in peripheral tissues express CCL21, the ligand for CCR7.[129] The loss of chemokine receptors that keep the dendritic cells within the tissue together with the increased expression of CCR7 results in the exit of the mature dendritic cells via the lymphatic drainage system.[55] DC migration into the draining lymphatics probably also requires β2 integrin binding to ICAM-1 expressed by lymphatic endothelial cells. While traveling to the draining LN, dendritic cells upregulate the expression of molecules for efficient antigen presentation and T-cell stimulation, and begin to generate chemokines and other cytokines that allow them to attract and stimulate T cells.

EGRESS OF LYMPHOCYTES FROM SECONDARY LYMPHOID ORGANS

When naive lymphocytes do not encounter antigen on antigen-presenting dendritic cells after a period of random walk, they exit secondary lymphoid organs through efferent lymph vessels or, in case of the spleen, by directly returning to the blood. Several adhesion receptors have been implicated in the egress of lymphocytes into lymphoid sinusoids, including PECAM-1 (CD31), the mannose receptor, which interacts with L-selectin, and common lymphatic endothelial and vascular endothelial receptor 1 (CLEVER-1).[130]

We still have very limited information about the signals that determine the dwell time of lymphocytes in secondary lymphoid organs (approximately 12–24 hours for T cells). However, the recent observation that the egress of both T and B cells from LN can be prevented by the immunosuppressant molecule FTY720 has revealed some of the principal mechanisms underlying lymphocyte egress. FTY720 is a synthetic derivative of myriocin, a metabolite of the fungus *Isaria sinclairii*, which has been used in Chinese traditional medicine. FTY720 induces lymphocyte sequestration in LN and causes profound lymphopenia. In animal models of transplantation and autoimmunity FTY720 causes immunosuppression and it has recently been shown to exert significant therapeutic effects in a placebo-controlled clinical trial of relapsing multiple sclerosis.[131,132] Although lymphocyte sequestration in LN and lymphopenia in response to FTY720 have been reported some time ago, the underlying molecular mechanisms were uncovered only recently.[133] Upon in vivo administration, FTY720 becomes rapidly phosphorylated and then binds to four of the five known sphingosine 1-phosphate (S1P) receptors ($S1P_1$and $S1P_{3–5}$).[37,134,135] Naïve B and T cells express substantial levels of $S1P_1$, and it appears to be this receptor that plays a predominant role in lymphocytes' egress from lymphoid tissues into the efferent lymph vessels. Studies using gene-targeted mice have shown that T lymphocytes deficient in $S1P_1$ cannot exit secondary lymphoid organs (and in case of T cells also the thymus).[136] Reports using FTY720 and $S1P_1$-selective agonists also supported a role for S1P–$S1P_1$ signaling in the regulation of lymphocyte egress from secondary lymphoid organs. Notably, $S1P_1$ receptors not only regulate lymphocyte exit from tissues but also modulate lymphocyte homing capacity.[137]

The sphingolipid S1P is abundant in blood and lymph, whereas low levels of S1P are maintained within lymphoid tissues. This S1P gradient is established by the action of the S1P degrading enzyme S1P lyase.[138] On the basis of these findings, it has been proposed that S1P gradients between blood, lymphoid tissue, and lymph fluid together with cyclical ligand-induced modulation of $S1P_1$ on recirculating lymphocytes regulates lymphocyte egress and determines the lymphoid organ transit time of lymphocytes. Indeed, recent observations support that concept by showing that $S1P_1$ on lymphocytes is downregulated in the blood, upregulated in lymphoid organs, and downregulated again in the lymph.[139] Notably, CD69, which is rapidly induced when T cells become activated, negatively regulates $S1P_1$ and thus promotes lymphocyte retention in lymphoid organs.[140]

SUMMARY

In this chapter we have outlined three distinct modes of leukocyte trafficking: (a) leukocyte entry into tissues from the circulation; (b) migration within tissues; and (c) exit from tissues. The constitutive and inducible migration of leukocytes throughout the body is essential for lymphocyte development and warrants proper immune surveillance. The processes involved in leukocyte migration are tightly regulated by chemoattractants and adhesion molecules. Leukocyte migration is characterized by a tremendous level of plasticity and specificity, because different leukocyte subsets express unique patterns of traffic molecules that enable their navigation to target tissues. Our expanding knowledge of the mechanisms that control leukocyte trafficking will likely influence the development of multiple therapeutic strategies, including stem cell mobilization, immunotherapy of cancer, and the treatment of tissue-specific autoimmune, inflammatory, and infectious diseases.

CHAPTER 18

TOLERANCE AND AUTOIMMUNITY

Mark J. Shlomchik

INTRODUCTION

The immune system must balance the capacity to respond to foreign antigens and the need not to respond to self-antigens. A complex and multilayered approach has evolved to successfully handle this problem. However, autoimmune diseases, in which this balance is upset, are remarkably common in the population. The diversity and variable severity of such diseases most likely reflects the various approaches the immune system takes to regulate antiself responses, and thereby, the various points at which this multilayered system can break down. The normal functions that may prevent autoimmune disease are collectively known as "self-tolerance mechanisms."

Autoimmune diseases are relevant to hematology at several levels. Autoimmune hemolytic anemia (AIHA) and idiopathic thrombocytopenic purpura are syndromes in which spontaneous autoimmunity to formed blood components may require transfusion support that is rendered difficult due to the presence of autoantibodies. Some cases of aplastic anemia may also fall into this category. Autoantibodies to red blood cells, whether pathogenic or not, are often problematic in terms of typing and screening. Another class of diseases are those induced by transfusion, but which are nonetheless autoimmune in nature: these include posttransfusion purpura (PTP)[1–3] and possibly AIHA associated with transfused thallasemia.[4–6] Finally, graft-versus-host disease, a common complication of allogeneic stem cell transplantation, although not a classical autoimmune disease, shares many features of autoimmune syndromes.[7,8]

An important principle in understanding the etiology of autoimmune diseases is that no special mechanisms, cells, antibody types, or reactions are specific to autoimmune diseases. Rather, the pathogenesis involves the inappropriate or dysregulated triggering of the normal mechanisms of immunity. Therefore, an understanding of autoimmune disease induction and pathogenesis requires a grounding in the basic immune cell functions and interactions, which can be found in the preceding chapters.

SELF-REACTIVE LYMPHOCYTES: ORIGIN AND CONTROL

Origins

Inevitably, autoreactive lymphocytes are generated as a consequence of the fact that B-cell receptor (BCR) and T-cell receptor (TCR) genes are encoded in pieces that rearrange in the DNA of precursor lymphocytes to ultimately form a complete gene. This process allows for many possible gene segment combinations (eg, 4000 different ones for the human Ig heavy chain alone), and in addition, small deletions and random additions at the sites where the pieces are joined together create additional diversity. There are two implications of this process for self-tolerance. First, it is impossible to prevent the assembly of a self-reactive receptor by filtering these out of the germline gene repertoire. Second, a developing lymphocyte cannot be considered autoreactive until the assembly process is complete and the BCR or TCR is expressed. Thus, autoreactive lymphocytes are produced every day, and it is at this key developmental stage—when the BCR or TCR is first expressed by the cell—that the immune system can first eliminate these potentially harmful cells. For B cells, this occurs in the bone marrow, the primary central lymphoid organ (Fig. 18–1), while for T cells it occurs in the thymus. The process is thus termed "central tolerance."

Regulation: Central Tolerance

Clonal Deletion

The classical experiments of Pike and Nossal were the first to demonstrate that developing autoreactive B cells can be eliminated in the bone marrow.[9–11] The details of this process remained murky until the Goodnow and Nemazee groups each developed a BCR transgenic mouse system for the study of self-tolerance.[12–14] These mice have been genetically altered to carry the preformed Ig variable (V) genes that encode a specific autoantibody. Mice that have undergone this genetic transfer are termed *transgenic* and the gene that is transferred is termed the *transgene* (Fig. 18–2). The presence of this preformed transgene short-circuits and prevents the normal rearrangement process at the natural immunoglobulin (Ig) gene loci. Thus each B cell in the animal expresses only the transgene and has the same specificity. By choosing a target antigen that is carried by only some strains of mice (such as the polymorphic major histocompatibility complex class I genes used by Nemazee), it is possible to render the transgenic B cells autoreactive when crossed onto one strain (Fig. 18–3) but not autoreactive in a different strain. The results of such systems were dramatic. A complete loss or deletion of the B cells was demonstrated in the strain of mice that had the autoantigen, but perfectly good expression of the B cells was observed when the autoantigen was absent. This provided clear proof of B-cell clonal deletion. Furthermore, it was shown that this deletion occurred at the immature B-cell stage, just when the cells first express their BCR.[15–17] It has been since discovered that deletion is just the final step in controlling autoreactive B cells.[15,17–19] B cells which have completed H- and L-chain rearrangement and then recognize self-antigen while still immature in the bone marrow may actually undergo a second round of V gene rearrangement. This most likely occurs at the L-chain loci, which are particularly suited to secondary V to J rearrangements. This process has been termed receptor editing. Evidently, a cell has a certain period of time in which to produce a second L-chain rearrangement that will inactivate the cell's self-reactivity. If this does not occur, the cell fails to mature and is eventually eliminated. The physiologic role of the editing process is still unclear, but it could represent a way to maximize the efficiency of B-cell generation while still maintaining an effective filter against strongly self-reactive B cells.

Clonal Anergy

Another type of self-tolerance mechanism was also revealed by similar experiments. This form, clonal anergy, involves inactivation of the self-reactive cell, but not its elimination.[10,14] Such B cells seem to remain in the peripheral lymphoid circulation, albeit with a shorter life span than normal B cells. In addition, these cells have a lower amount of surface Ig and, moreover, seem much less capable of sensing the presence of antigen when the sIg receptor is triggered. This second form of B-cell tolerance, demonstrated dramatically

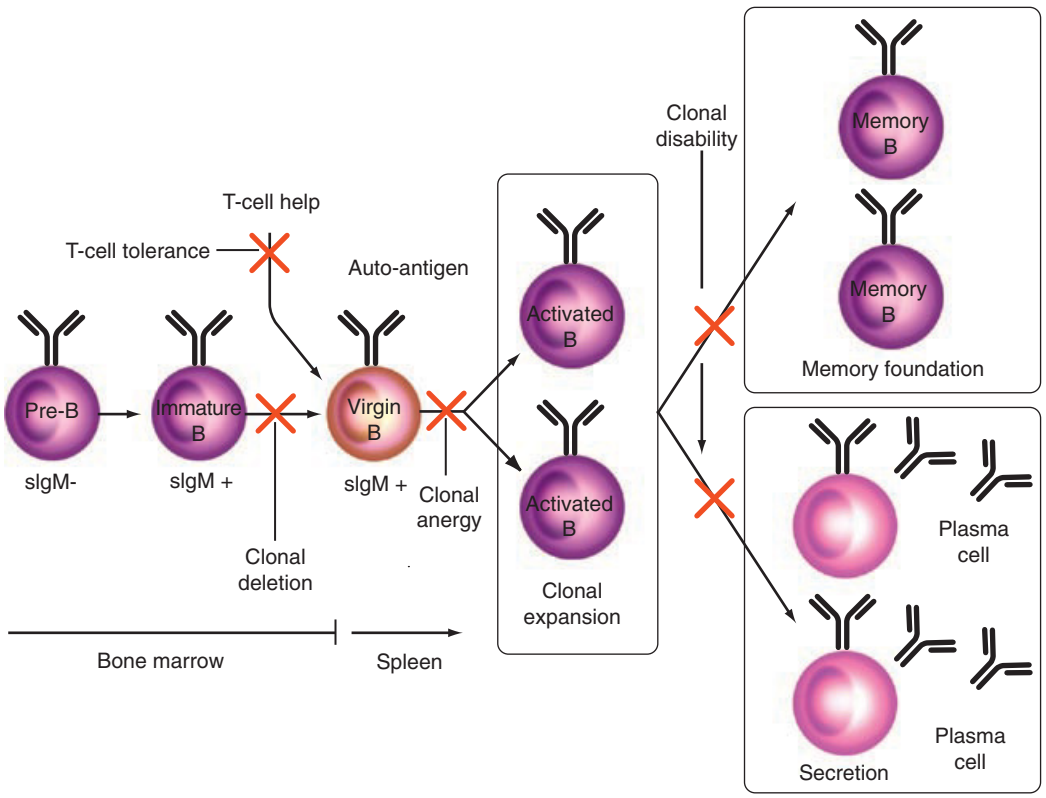

Figure 18–1 Stages at which self-tolerance can block B-cell development. Arrows indicate the normal pathway of development. X indicates where these differentiation steps can be interrupted for self-reactive B cells as a consequence of encountering self-antigen. Each X is labeled with the type of self-tolerance it represents. The clonal disability steps are somewhat more hypothetical than the earlier steps. See text for details.

through the use of Ig transgenic mice, was also anticipated in the experiments of Pike and Nossal.[10] The physiologic advantage of maintaining these anergic cells is unclear. They can be activated by strong stimulation under certain conditions; thus it has been suggested that they are maintained as a secondary repertoire to maintain greater B-cell diversity and thus better protect against a broader spectrum of pathogens. However, the presence of these cells also raises a danger that they may be activated by self-antigens as well, which could represent a source of autoantibodies. Indeed, it has been suggested that autoantibody-secreting B cells can arise by the activation of anergic B cells.

Clonal deletion, receptor editing, and clonal anergy are often referred to as "central" self-tolerance because they can occur in the central lymphopoietic organs and act on immature lymphocytes that have just expressed their antigen receptors. Central tolerance is probably most important in purging or controlling very high-affinity antiself lymphocytes.

Tolerance of Memory B Cells

Figure 18–1 indicates that there are yet other stages of B-cell development at which one could imagine that self-tolerance should occur. The most important of these is development of memory B cells, the long-lasting cells that harbor the ability of the immune system to respond better and faster to antigens that have already been encountered once. An important and unique process occurs during memory cell development—the genes that encode the antibody receptor molecule undergo a process of random mutation.[20–22] This process is thought to provide mutants with an increased affinity for the immunizing antigen, and in fact, the secondary immune response is known to be of higher affinity. However, a side effect of any random process, just as in the receptor rearrangement itself, is the potential to create novel antiself specificities.[23,24] Thus, many have postulated that there should be a screening of cells for self-reactivity during memory B-cell development.[25–27] In fact, some evidence suggests this process exists, but it is much more elusive than clonal deletion or clonal anergy.

T Cells

In many respects, self-tolerance for T cells is similar to that for B cells; both deletion and anergy exist.[28–32] The principle differences reflect the basic differences in B and T development. Deletion for T cells occurs in the thymus (where TCR gene rearrangement occurs), not in the bone marrow. In addition, the self-antigens for T cells consist of self-peptides, just as the foreign antigens for T cells are foreign peptides.

Limitations of Central Tolerance

Although these mechanisms to eliminate or inactivate self-reactive B cells as they first emerge are clearly critical for the viability of an animal, they only account for part of the overall system that protects against autoimmunity. There are many reasons to believe that central tolerance cannot and should not be perfectly efficient. One is that the ability to tolerate self must be balanced against the ability to efficiently respond to a wide variety of foreign antigens. Each cell that is eliminated in the interests of self-tolerance is one that cannot respond to a potential foreign antigen. This concept is illustrated metaphorically in Fig. 18–4. Thus one must suppose that it might be advantageous to allow some (weakly) antiself cells to escape these purging mechanisms. This is indeed the case. A second way to view this same problem is that even if it were desirable to have complete elimination of antiself lymphocytes, it would be impossible. It is unlikely that during development each cell will be exposed to a sufficient quantity of each and every self-antigen in the body to be functionally tested for self-reactivity. Furthermore, some antigens are tissue specific, such as thyroglobulin, and are unlikely to be found in the circulation at appreciable quantities.

Persistence of Self-Reactive Lymphocytes

Despite central tolerance, self-reactive cells nonetheless exist in peripheral lymphoid organs of normal animals. It has been observed

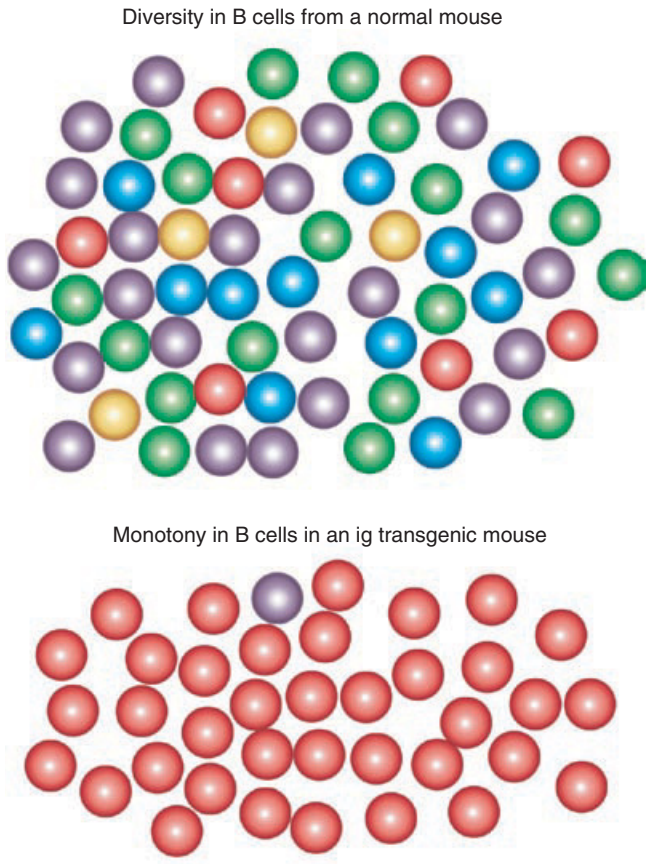

Figure 18–2 Clonal diversity in a normal versus transgenic mouse. The great diversity of B-cell specificities found in a normal mouse is indicated by the different patterns in each type of B cell. In contrast, in a transgenic mouse, each B cell expresses the same specificity because each carries the genes for a preformed heavy- and light-chain Ig gene (the transgenes). This is indicated by the same pattern in each B cell. The one B cell with a different pattern signifies that occasional cells will express a unique specificity even in a transgenic because the system is imperfect.

for some time that many immune responses are accompanied by transient antiself antibody responses.[34–38] For example, rheumatoid factors with specificity for self-IgG often accompany strong secondary immune responses to foreign proteins or viruses.[34–36] The simplest explanation for such phenomena is that the B cells that make these autoantibodies already exist in the peripheral lymphoid compartment, but are quiescent until they receive the proper stimulus. (How such cells get activated and why in normal animals this does not pose a threat are discussed following.)

Transgenic mouse models similar to those described above have provided the most convincing evidence of the existence of such B

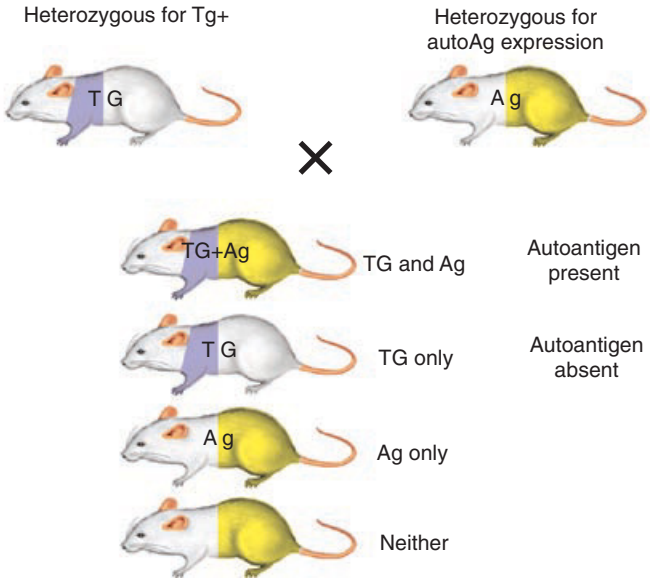

Figure 18–3 Mating strategy to generate transgenic mice with and without a polymorphic autoantigen. Two mice are crossed, each of which is heterozygous: one for the transgene and the other for a polymorphic autoantigen (much as people can be heterozygous for blood group antigens). Shown are the possible resulting progeny of such a cross, each of which would occur at 1/4 frequency. "TG" indicates transgenic and "Ag" indicates presence of the autoantigen. The first two types of mice, one with TG and Ag and the other control with TG and not the Ag are compared in experiments to determine how autoantigen affects the development of the autoreactive B cells.

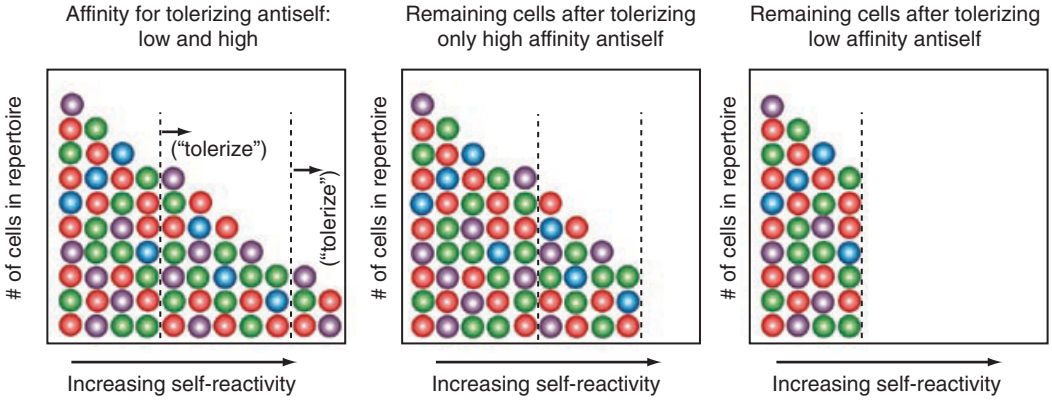

Figure 18–4 How elimination of autoreactive cells affects the repertoire of lymphocytes capable of responding to foreign antigens. A hypothetical population of diverse B cells representing the entire repertoire available to respond to foreign antigen is depicted. The population is arrayed according to increasing self-reactivity (*left panel*). Tolerizing only the high-affinity antiself B cells (*right panel*) leaves most of the potential repertoire intact. However, as the affinity cutoff for self-reactivity increases, fewer B cells will be included. It can be readily seen (*bottom panel*) that a low threshold for inactivation or deletion of self-reactive cells will lead to a small number of competent residual cells available for responses to foreign antigens. Thus, a stringent tolerization of low affinity antiself cells will compromise the ability to respond to nonself.

cells. One of particular relevance to hematology was generated by Honjo and colleagues.[39] These workers isolated the V genes that came from an actual anti-red blood cell autoantibody originally obtained from an NZB mouse with AIHA. Much like Goodnow and Nemazee, they used the transgenic approach to express the anti-red blood cell antibody in a normal nonautoimmune mouse. Although central deletion was seen in most of the transgenic mice studied, many also had some residual autoreactive B cells in spleen and lymph nodes, and some otherwise normal mice even developed frank AIHA. These results were interpreted as follows: central tolerance is not completely efficient even in a nonautoimmune mouse and some autoreactive B cells can be stimulated to cause disease. Shlomchik and colleagues, also using a transgenic approach, demonstrated that a rheumatoid factor autoantibody that was isolated from a diseased mouse was not subject to self-tolerance when expressed in a normal BALB/c mouse.[40] These B cells generally remained quiescent in a normal animal, suggesting that those B cells that are not usually regulated by self-tolerance (perhaps because they recognize the self-antigen only weakly) may be the precursors of pathogenic autoantibodies in disease.

Control of Self-Reactive Lymphocytes: Preventing Activation

The recognition that potentially self-reactive lymphocytes exist in the peripheral lymphoid repertoire of normal individuals,[41] despite central tolerance, raises the question of why they do not usually cause disease. One reason is the second layer of immune tolerance that prevents activation of self-reactive lymphocytes that exist in the periphery. This layer consists of several facets, which are described in the following sections.

Absence of Self-Antigen

The simplest explanation for why a self-specific lymphocyte is not spontaneously activated in the peripheral lymphoid compartment is the absence of self-antigen. This may be the reason why it was not eliminated in the first place. This situation has been termed *clonal ignorance*. It is related to the scenario described for rheumatoid factor B cells above in that the cell does not seem to care about the concentration of its autoantigen. In the case of rheumatoid factor, though, this is because the cell has relatively low affinity for self-IgG; in the case of thyroglobulin, for example, this is because the antigen concentration is vanishingly small. However, a change in antigen concentration, such as after thyroid damage from a viral infection, might then precipitate activation of these heretofore ignorant cells, leading to autoimmunity.

This antigen sequestration concept only applies to a limited set of autoantigens. A more general reason that self-specific lymphocytes remain quiescent, despite the ubiquity of self-antigens, is that T and B cells are dependent on each other for activation (Chapter 10).[42–45] It is evident that for this to occur, B and T cells specific for the same self-antigen must be in the same place at the same time. If such cells are rare, then the requisite coexistence of two such cells will happen very infrequently, minimizing the chance of starting an autoimmune reaction. A second consequence of T–B interdependence is that specific inefficiencies of central tolerance in one limb can be compensated for in the other. For example, T cells are probably very efficiently purged of cells that react with thymus-specific antigens, whereas B cells are probably not. However, antithymus B-cell responses are unlikely even though many thymus-specific B cells probably circulate; the cognate T cell with specificity for the same self-antigen simply does not exist.

Costimulation

Even when a B cell and a T cell that do recognize the same self-antigen encounter each other, the result may still not be activation.

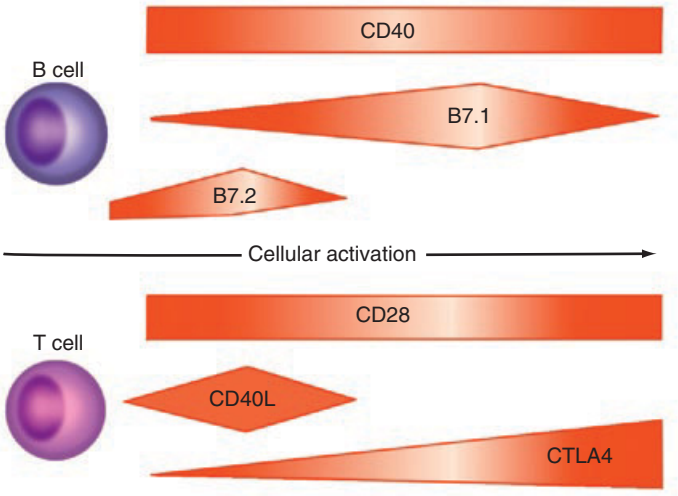

Figure 18–5 Timing of expression of costimulatory molecules. The schematic shows the regulated expression of the CD40–CD40L family (*light red*) and the B7-CD28–CTLA4 family (*dark red*) of molecules. From left to right is depicted increasing cellular activation as time elapses after initial encounter with antigen. The expression level of each molecule over time is indicated by a polygonal shape. The vertical width of the shape at any time reflects the degree of expression at that time. For example, CTLA4 is expressed little at the start and the expression increases continuously over time. The shapes depicting expression of molecules that are thought to deliver signals are outlined in bold, whereas those of molecules thought to receive signals are in fine line. The top three molecules are chiefly expressed on B cells and the lower three on T cells.

This is because a positive response by a lymphocyte to antigen encounter also requires a second signal, aside from the stimulus of antigen recognition itself. These signals are transmitted through a series of ligand–receptor molecular pairs known as costimulatory molecules (Chapter 10). The most important of these are: CD80 andCD86[46–51] (expressed on B cells, macrophages, and dendritic cells) and CD28[50,51] (expressed on T cells). Another important pair is CD40[52,53] (expressed on B cells, macrophages, and dendritic cells) and CD40 ligand[54–59] (CD40L, expressed on T cells and missing in patients with X-linked immunodeficiency/hyper-IgM syndrome[60–63]). CD40 stimulation is especially important for B cells, as it is for other antigen-presenting cells as well. Other important costimulatory molecules in T–B interactions include ICOS and ICOS-L (not shown in the figure), which are critical for germinal center responses and isotype switching.[64] Also in this category are lymphokine signals. For B cells, interleukin-4 (IL-4) signaling is important, but other cytokines such as interleukins-5, -6, and -2 (IL-5, IL-6, IL-2) also play roles in growth and differentiation. As shown in Fig. 18–5, some of these molecules are constitutively expressed, whereas others are induced in activated cells. This pattern of expression and induction leads to a cascade of events that occur during immune activation.

In general, for proper transmission of this second signal, one or the other of the lymphocytes must have been previously activated. This concept generates a paradox in that if one lymphocyte must already be activated, how is it possible to start an immune response at all? This is resolved in several ways. First, it is indeed difficult to start immune responses, and this is one of the mechanisms by which nonresponsiveness to self is maintained. However, a strong first signal to a T or B cell may be sufficient for it to induce its costimulatory molecules.[46,65] Second, inflammation of any type is a powerful nonspecific inducer of these same costimulatory molecules.[66–68] Thus, in the presence of ongoing inflammation, such as would occur with infection or trauma, immune responses are much easier to start. Indeed, recent evidence suggests an important role in systemic autoimmunity for Toll-like receptors (TLRs), which recognize molecules specific to pathogens and induce costimulatory molecules and immune system activation. Ligands for TLRs include lipopolysac-

charide, bacterial DNA enriched for CpG dinucleotides, and dsRNA. TLRs can be activated by infection and may provide a mechanism by which some infections can trigger autoimmunity. However, in the right context some self (as opposed to pathogen) molecules, like DNA found in chromatin, a target for systemic lupus erythematosus (SLE) autoantibodies, can also activate TLRs (TLR9 in the case of DNA).[69] Third, certain "professional" antigen-presenting cells, such as dendritic cells, may constitutively express these costimulatory molecules at moderate levels and can start the cascade, for example, by activating T cells, which is then amplified by T–B interactions.[68] In summary, there are two main functions of costimulatory requirements: they focus the interactions between two antigen-specific T and B cells and limit nonspecific interactions; and they restrict immune responses in the absence of inflammation. Both of these features of costimulation tend to prevent the activation of self-reactive lymphocytes that exist in peripheral lymphoid organs. For B cells this means that tolerance in the T-cell compartment alone will prevent many self-reactive B cells from being activated.

Even with antigen sequestration and costimulatory regulation, mechanisms that prevent the activation of self-reactive lymphocytes are incomplete at best. For example, it seems likely during infection or trauma that antiself responses could initiate because costimulatory molecules will be nonspecifically induced. Indeed, this is the case. Furthermore, during infection and tissue damage, self-proteins that ordinarily are sequestered can be released. This leads to activation of the ignorant cells circulating in the body.[70–75] In fact (usually) self-limited autoimmune responses after infection are well known, such as poststreptococcal glomerulonephritis or postmycoplasmal cold agglutinins. Although these syndromes can cause serious clinical problems, they are self-limited, unlike autoimmune diseases such as SLE.

Control of Self-Reactive Lymphocytes: Downregulation

The difference between transient autoimmune responses and chronic severe autoimmunity may lie in the third layer of protection against autoimmunity: downregulation of ongoing responses. Again, this layer is a normal part of the immune system, functioning to regulate both normal and autoimmune responses. Initially, in a normal response to a viral pathogen, there is great proliferation of lymphocytes specific for viral antigens. This process leads ultimately to the elimination of the pathogen, which was traditionally thought of as the signal to stop an immune response. However, when the pathogen is eliminated, in the absence of any other regulatory mechanism, there would be many residual cells that had been responding to the pathogen. Although a few such cells could be retained to provide immunologic memory, most of these are no longer useful in the short term. In addition to unnecessarily filling the lymphoid compartment, these cells may be a risk for causing autoimmunity. This is because of the possibility of the generation of newly autoreactive B cells by virtue of random somatic mutation.[24] B cells responding to foreign antigens begin to mutate their antibody V region genes. Mutation is a random process, and thus a mutation could occur that converts a nonautoimmune B cell into a self-reactive B cell.[24] No clear mechanism exists by which the body can discriminate and specifically eliminate these newly self-reactive mutant B cells. However, at a minimum, elimination of most of the reactive B cells regardless of specificity would mitigate this problem.

Over the last several years, several pathways for the elimination of such postexpansion cells have been elucidated. One seems to be an inborn program that causes cells to apoptose after undergoing a certain amount of proliferation.[76–78] Particularly important in this program in lymphocytes are the Bcl2-inhibitable pathways that are activated in large part by Bim.[79,80] In B cells, CD40 signaling in concert with BCR and IL-4 signaling may rescue some cells from this self-destructive fate, and it is believed that these cells become long-lived memory cells.[81–84] There are also active mechanisms that signal cells to apoptose. One receptor–ligand pair called Fas and FasL is central in this process. Generally, when Fas is ligated by FasL, the cell expressing Fas is triggered to die by apoptosis.[85–88] Fas and FasL are not expressed at high levels on unstimulated resting lymphocytes. On activation, T cells express both Fas and FasL, whereas B cells express Fas.[88,89] Sensitivity to the Fas signal may be regulated in the Fas-expressing cell as well. Thus, after a certain degree of activation and proliferation, a T cell (expressing FasL) encountering an activated B cell (expressing Fas) may actually kill that B cell. There are likely other ligand pairs, particularly those in the tumor necrosis factor family, that may serve similar functions, both for B and T cells.

A particularly interesting and instructive receptor ligand pair that downregulates ongoing responses has been elucidated. The receptor, CTLA4, is expressed on activated T cells, and when ligated, causes inactivation or death of the receptive T cell; it is said to therefore transduce a "negative" signal.[90–93] The other ligands in this pair are CD80 and to a lesser extent CD86, the same ligands that gives a positive signal to naive T cells by ligating CD28. Thus, the same molecule can promote activation early on in the immune response while, through a change in the receptive T cell, it can inhibit activation at a later time. An analogous receptor pair of the B7 family are PD-1, an inhibitory receptor similar to CTLA-4, and its ligands PD-L1 and PD-L2. PD-1 is expressed on a number of activated lymphocytes and its ligands are constitutively and inducibly expressed on a variety of parenchymal cells (PD-L1) and dendritic cells (PD-L2).[94] Absence of these molecules leads to exaggerated immune responses and autoimmunity.[95–97] These examples underscore the careful means by which the immune system regulates and dampens activation presumably to prevent autoimmunity.

Recently, attention has turned again to suppressor T cells as potent regulators of autoimmunity. These cells were extensively studied two decades ago but when some of the work could not be reproduced or explained, interest waned and this mechanism was largely ignored by immunologists. These cells have been rediscovered in a sense, and modern tools of immunology have elucidated how they suppress autoimmunity and have left little doubt of their importance. The best-studied regulatory cell expresses CD25, the receptor for IL-2,[98,99] and its development and function is dependent on the expression of a key transcription factor, FoxP3.[100–102] These cells can prevent autoimmune syndromes such as inflammatory bowel disease, diabetes, and autoimmune encephalomyelitis in murine models and can even be used to treat active disease.[103,104] They are also active in preventing transplantation rejection and graft-versus-host disease. These cells may function by secreting suppressive cytokines, like IL-10 and TGF-β, and also by cell–cell contact. Their importance in humans is underscored by a rare and fatal inherited autoimmune disorder, IPEX, that results from a lack of FoxP3, which is needed for the development of $CD25^+$ regulatory cells.[105,106]

How does regulation of ongoing immune responses prevent autoimmunity? In the first place, these normal forms of downregulation undoubtedly prevent common transient autoimmune responses from becoming chronic. More subtly, elimination or control of cells after immune responses will prevent the accumulation of a large number of self-specific memory cells. As long as such cells are rare, it is unlikely for autoreactive T cells and B cells, each specific for the same self-antigen, to wind up in the same place at the same time. Thus, downregulation and elimination of responding cells prevents a critical mass of self-reactive cells from ever forming.

Control of Self-Reactive Lymphocytes: Channeling the Type of Effector Response

A final layer of protection against self-inflicted immune damage involves channeling of responses so they are not harmful. Depending on the context, only certain effector functions will effectively eliminate certain pathogens. For example, antibodies will not be effective against intracellular pathogens. By analogy, only certain effector functions may cause autoimmune disease, depending on the circumstances. It is clear that there are two major types of T-helper cell responses, Th1 and Th2, that in turn lead to very different effector functions.[107–109] The propensity to make these various types of

responses depends on a number of ill-understood factors, but these include genetics, route of antigen exposure, and dose of antigen.[110,111] Intriguingly, in certain murine models of autoimmunity such as the NOD diabetes model, experimental manipulations that shift responses away from Th1 and toward Th2 are highly protective against disease.[112–114] This is also relevant to B-cell autoimmunity per se because, through the use of different isotypes of Ig, different effector functions can occur. The cytokines secreted by Th1 and Th2 cells have profound effects on the isotypes of Ig's that are produced during a response. Thus, not only is the T-cell component of the response channeled in this way, but the humoral response is also influenced. Recently, a new subset of T cells that secrete IL-17, thus dubbed Th17, has been recognized as important pathogenic cells in several autoimmune diseases, including experimental autoimmune encephalitis as well as collagen-induced arthritis.[115] At least some of these Th17 cells secrete a related cytokine, IL-22, which in turn may be responsible for their pathogensis in diseases such as psoriasis.[116] Th17 cells depend on IL-6 and TGF-β for their development and IL-23 for their maintenance.[115] The transcription factor ROR-γt is required for these cells to differentiate, which they do to the exclusion of Th1 cells.[117] It is not clear in which diseases Th17 versus Th1 cells will prove to be more important, or how their reciprocal development is controlled. Emerging evidence indicates that Th17 cells are important for resistance to extracellular bacteria as well.[115]

BREAKDOWN OF SELF-TOLERANCE IN AUTOIMMUNE DISEASES

Presumably, for autoimmune diseases and autoantibody production to occur, one or more of the multilayered mechanisms to prevent autoimmunity must fail. Surprisingly, the precise nature of these failures is not well understood. The mechanism of failure will differ for the various autoimmune diseases and perhaps even for different patients with similar syndromes. Moreover, it seems likely both from phenomenologic and genetic studies that failures at several levels are required to generate clinically significant autoimmunity. In the following section, examples of the current state of knowledge are given.

This chapter is not meant to review the nature of autoimmune diseases; however, before considering the likely points at which self-tolerance mechanisms break down it is useful to review some basic concepts about these diseases. Grossly, autoimmune diseases have often been divided into organ-specific and systemic autoimmune syndromes. This classification is useful, but as these diseases are becoming better understood, the dividing lines are blurring; pathogeneses of all these diseases are likely to have much in common. In particular, systemic autoimmune diseases are actually much more specific in their antigenic targets than is commonly realized. Table 18–1 shows the types of autoantibodies commonly found in several systemic autoimmune diseases. Certain autoantibodies are diagnostic for specific autoimmune diseases, such as anti-Sm in SLE. Thus, Sm is a specific target in SLE, but other autoimmune patients, such as those with rheumatoid arthritis, do not respond to this autoantigen. In fact, only 30% of all patients with SLE make anti-Sm, meaning that the other 70% are tolerant of their own Sm, despite having a systemic autoimmune disease.[118] Another salient feature of most human autoimmune diseases is adult onset. Both the selective nature of disease and its late onset argue against gross defects in the basic central tolerance mechanisms as being the cause.

Instead, these considerations suggest that most clinical autoimmune diseases are likely to arise from defects in the later stages of self-tolerance, such as preventing the activation of autoreactive cells or downregulating them once they are activated. Because in no case is the primary cause of a polygenic autoimmune disease known, it cannot be excluded that subtle defects in the earlier stages, including central tolerance, may also play a role. However, it does seem clear that a gross defect in central tolerance would lead to a severe syndrome of congenital autoimmunity.

Table 18–1 Patterns of Autoantibody Expression in Systemic Autoimmune Diseases

Autoantigen	Autoimmune Diseases (% of patients *with* autoantibody)			
	Systemic Lupus Erythematosus	Rheumatoid Arthritis	Scleroderma	Sjögren Syndrome
dsDNA	40			
ssDNA	70			
Histones	70			
Sm	30			
nRNP	30			
Ro (SS-A)	35			60
La (SS-B)	15			40
IgG (RF)	5	90		10–20
Scl-70 (Topo I)			70	
Centromere			70	

dsDNA, double-stranded DNA; ssDNA, single-stranded DNA; Sm, Smith ribonucleoprotein; nRNP, native ribonucleoprotein; Scl-70, scleroderma 70-kd antigen (topoisomerase I). Blank space indicates rarely or never detected.

Information derived from Tan EM: Antinuclear antibodies: Diagnostic markers for autoimmune diseases and probes for cell biology. Adv Immunol 44:93, 1989.

Genetic and Environmental Factors

Genetic Factors

Both genetic and environmental factors help to explain why autoimmunity occurs in some individuals and not others.[119] The most well-known genetic factor is the major histocompatibility complex, known as HLA in the human. Many different autoimmune diseases are more or less associated with specific genotypes at this polymorphic locus. Among these are ankylosing spondylitis (HLA–B27), insulin-dependent diabetes mellitus (HLA–DR3/4), rheumatoid arthritis (HLA–DR4), and to some degree SLE (HLA–DR2/3).[120] It should be emphasized that although individuals with these genotypes are relatively more prone, most will not develop the autoimmune disease. How certain HLA genes predispose to autoimmunity is not very clear. These genes could be involved in the efficiency or specificity of central tolerance in the thymus, but could also be involved in the activation of autoreactive T cells in the periphery.

Inheritance patterns of all systemic autoimmune diseases suggest that multiple genes, in addition to the HLA locus, contribute to susceptibility. Such genes are beginning to be identified in human and in animal models. Some genes associated with a variety of human autoimmune diseases include CTLA-4, PTPN-22, and IRF-5, all of which are known to regulate inflammation.[121,122] Recent work in murine SLE has used genomic scanning with polymerase chain reaction-based polymorphic short simple repeat sequences to identify and map genes that are associated with autoimmune phenotypes. In this type of analysis, an autoimmune strain is crossed with a nonautoimmune strain and then the progeny are back-crossed to the autoimmune strain. Genetic loci segregate in this cross, and for each individual mouse, with the help of the murine genome map, the origin of 100 to 200 genetic locations all along the chromosomes are identified as either from the autoimmune parent or the nonautoimmune parent. Simultaneously, the autoimmune phenotype of each mouse is determined in a variety of assays, most commonly including autoantibody production and glomerulonephritis. By typing a few hundred mice in this way, correlations can be made that link certain genetic loci with certain phenotypic traits. Several genes have been mapped with this approach, and their phenotypes investigated in greater detail.[123–127] Interestingly, most of them seem to have direct

Table 18–2 Genes Involved in Regulation of Autoimmune Responses

Category	Types of Genes[a]	Known Examples[b]
Central and peripheral deletion and anergy	Receptor signaling, MHC genes, receptor V genes	CD45,[128] PTP-1C,[129–131] HLA (certain types),[120] CD3,[132] CD4, CD8, CD28/B7[32]
Initiation of response	Receptor signaling, costimulatory molecules, adhesion molecules	CD45, PTP-1C, FcγRII[130]
Downregulation of response	Apoptosis genes, interleukins, negative costimulatory molecules	Fas,[142,143] TNF,[133,134] CTLA4,[91] CD40, CD3,[135] CD28/B7[50,136]
Channeling of response	Interleukins, interleukin receptors	IL-4, IL-10, IL-12, IFN-γ[113,114]
Autoantigen metabolism and apoptosis	Complement components, apoptosis signaling	C1q, C2, C4, DNAse I, MER[137,138]

PTP-1C, phosphotyrosine phosphatase; IL, interleukin; FcγRII, receptor for IgG-type II; Fas, see text; TNF, tumor necrosis factor, CTLA4, see text; IFN-γ, interferon gamma; MHC, major histocompatibility complex.

[a]Indicates some of the categories of genes that may be involved in regulating autoimmunity at the indicated step.

[b]Some genes in the "Types of Genes" category which have been shown to play a role in the process indicated in the left column. Some have also been directly shown to play a role in autoimmunity.

effects on B-cell function or activity. In the next several years, some of these genes may be identified and cloned and the exact nature of the defects defined. This will in turn permit screening for defects in the homologous genes in human autoimmune disease patients.

Although animal models suggest multigenic inheritance, there are certain instructive cases in which single gene defects play a major role. Table 18–2 lists categories of genes that are likely involved in genetic predisposition to autoimmune disease. Note that these include genes involved in the processes of antigen sequestration, T–B collaboration, and immune response downregulation that were discussed above as key features of the self-tolerance mechanisms that normally prevent autoimmune disease.

The best studied example of mutations in these genes is the *lpr/lpr* mouse, a natural variant originally discovered at the Jackson Laboratories, which carries an inactivated murine Fas.[85,139,140] The *gld* mutation (another natural variant discovered at Jackson), which inactivates murine Fas ligand (FasL),[88] has a very similar phenotype to the *lpr*. Both of these mutations lead to an age-dependent autoimmune syndrome with autoantibody profiles that remarkably resemble human SLE.[140] These mice die prematurely of renal failure. They also have an accumulation of lymphocytes that leads to marked lymphadenopathy.[141] Presumably, this is the result of failure to eliminate post-activation T and B cells by the Fas-based mechanism.[142–144] Exactly how defects in the apoptotic Fas pathway lead to autoimmunity has yet to be elucidated. Interestingly, a rare syndrome in humans with incomplete penetrance, called autoimmune lymphoproliferation syndrome, has recently been traced to mutations in human Fas.[145] Often these patients are misdiagnosed with leukemia or lymphoma and some have even been treated for (and survived) these neoplasms. Clonality and chromosomal studies in autoimmune lymphoproliferation syndrome reveal polyclonal B- and T-cell proliferations with normal karyotypes, in distinction with true lymphoma or leukemia.

The phenotypes of these mutants in the Fas pathway, though more fulminant than most human autoimmune syndromes, illustrate two important points. They demonstrate the critical nature of the late downregulatory controls in preventing autoimmune disease. They also point out pathways in which less severe mutations might be discovered that account for human disease.

A final category of genes regulate the clearance of self-antigens and dead cells, which is particularly important in systemic autoimmune diseases like SLE. These include complement components C4, C3, and C2, C1q, and less-known genes like MER, which plays a role in signaling for the uptake of apoptotic fragments by macrophages.[137,138] Evidently, when self-antigens are not cleared promptly following cell death, they can become targets of the immune system, leading to autoimmunity to intracellular components like chromatin.

As noted, TLRs can recognize some of these molecules when they are present in high concentrations, thus providing proinflammatory signals. In murine models of lupus, it was recently demonstrated in vivo that TLR9 is required to generate antichromatin autoantibodies[146] and that TLR7, which recognizes RNA, is required for the generation of autoantibodies to RNA-related antigens.[147] Indeed, a mutant mouse with a double dose of TLR7 develops spontaneous lupus with high levels of RNA antibodies.[148,149] Stimulation of these TLRs on specialized plasmacytoid dendritic cells leads to release of abundant type I interferon, which itself may be causally linked to lupus in mice and humans.[150] These findings highlight a genetic basis for recognizing self-molecules in autoimmune diseases and suggest new therapeutic targets that are currently being explored. Whether this theme extends to other autoimmune diseases beyond lupus remains to be determined.

Environmental Factors

Environment plays a role that is at least as important as genetics. This is illustrated by the fact that concordance rates among identical twins, even raised in the same household, are surprisingly low. Only 20% of twins of patients with rheumatoid arthritis also get rheumatoid arthritis.[120] There are many examples of environmental factors causing either chronic or transient autoimmune diseases. There are postinfectious syndromes such as postmycoplasmal cold agglutinin disease. The pattern of incidence of multiple sclerosis suggests a viral etiology, although no causative virus has ever been convincingly demonstrated. Another category of infectious associations includes postviral myocarditis, which follows certain coxsackievirus infections.[74] It is sometimes conceptually difficult to draw a line between viral damage and consequent immune system damage; however, if sensitization to self-antigens occurs as a consequence of viral infection, and these later are pathogenic targets independent of viral antigens, it seems reasonable to consider the syndrome as autoimmune.

Infections are not the only source of environmental stimuli for autoimmunity. Toxins, such as mercury, cause autoimmunity in animal models.[151,152] Another form more familiar to those in hematology is drug-induced autoimmunity, as in AIHA. Drugs that cause lupus-like syndromes, such as procainamide, are particularly prominent examples.[153,154] Despite these specific examples, the environmental factors that play a role in promoting common autoimmune diseases such as rheumatoid arthritis or SLE are unknown.

Examples in Hematology: Epitope Spreading in PTP

One potential way to break self-tolerance may be particularly relevant to syndromes found in hematology and is worthy of elaboration. This is a form of environmental stimulation, albeit iatrogenic. In PTP,

transfusion with allogeneic platelets that contain a platelet-specific antigen (such as HPA-1^a) lacking in the recipient (HPA-1^b) leads to rapid destruction of the transfused platelets and antibody formation to the foreign platelet antigen.[3,155] However, several days later, the recipient becomes severely thrombocytopenic owing to increased destruction of the recipient's own platelets. Although how such destruction of self-platelets occurs secondary to destruction of allogeneic platelets may still be controversial;[3,155,156] the best explanation is an autoimmune response.[1–3] How does this response get stimulated? The probable pathway bears significant parallels to one demonstrated in mice several years ago by Janeway and colleagues.[157,158] These workers immunized normal mice with human cytochrome c, which differed slightly from endogenous murine cytochrome c. The mice made both an antibody response and a T-cell response to the human cytochrome c; however, since the human and mouse cytochromes are so similar, the antibody response (but not the T-cell response) cross-reacted with murine cytochrome c. Presumably, this reflected activation of ignorant B cells with specificity for self-cytochrome c (and also human). However, several weeks later, if the mice were given a dose of self-cytochrome c, now both a vigorous B-cell and T-cell antiself response ensued. These authors suggested that priming with the cross-reactive antigen first induced self-reactive B cells, which in turn could then break tolerance in anergic or ignorant self-reactive T cells.

How does this relate to PTP? Figure 18–6 illustrates the author's hypothetical adaptation of this mechanism to the platelet transfusion situation. The foreign platelets actually share many common antigens with the host, as well as differ at the HPA-1^a locus. The foreign antigenic difference allows ignorant self-specific B cells (as well as HPA-1^a-specific B cells) to interact with helper T cells that are specific for the foreign HPA-1^a antigen and become activated. Moreover, these activated B cells can then present self-platelet antigens along with costimulatory signals to self-reactive T cells. When this happens, the immune response can perpetuate even in the absence of the foreign platelets. This is exactly what is seen in PTP, where a delayed response continues to eliminate self-platelets for many days after the disappearance of the transfused platelets. Thus, a foreign platelet is analogous to foreign cytochrome c in having a few different antigens along with many shared antigens. In the same way as shown experimentally with cytochrome c, it is hypothesized that the few foreign antigens existing on the same particle (in the case of cytochrome c it is the same molecule) allow spreading of autoimmunity from a foreign antigen to self-antigens. The key events are the activation of ignorant B cells that cross-react with both self and foreign molecules, and then the activation by these B cells or T cells that are specific for self.

It is reasonable to question how such antiself responses are ever stopped once started. PTP, for example, is a self-limited syndrome. In fact, the answer is not known; however, both downregulation of antigen as the platelet count falls to near zero and the natural mechanisms that cause apoptosis of responding lymphocytes probably play a role. In the absence of an autoimmune-prone host who has mutations affecting the downregulation of immune responses, these autoimmune reactions will remain transient. It is speculated that when similar events occur in people who do have genetically based problems in downregulating such responses, a chronic autoimmune syndrome can be induced.

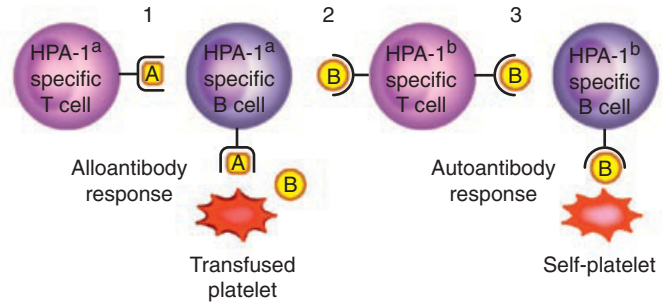

Figure 18–6 Epitope spreading as a possible autoimmune mechanism for PTP. Events are depicted as progressing from left to right. An HPA-1^b person is transfused with an HPA-1$^{a/b}$ platelet product. An alloantibody response ensues as an HPA-1^a-specific B cell recognizes the platelet, becomes activated to secrete antibody, and presents the HPA-1^a antigen to an anti-HPA-1^a T cell (step 1). In addition, the activated B cell may now activate a previously ignorant anti-HPA-1^b-specific T cell to initiate an autoimmune response (step 2). The activated B cell acquired the self-HPA-1^b antigen as a passenger on the HPA-1$^{a/b}$ allogeneic platelet. This autoreactive T cell can then activate an ignorant anti-HPA-1^b B cell to make an autoantibody response (step 3) in response to autologous platelets. Note that the sensitization involved in steps 1 and 2 may take place in a primary response during the first transfusion or exposure and that step 3 may take place in a clinically noticeable way only after a secondary exposure to homologous platelets.

IMPLICATIONS AND THERAPY

The significance of this issue to hematology ranges from syndromes such as AIHA and idiopathic thrombocytopenic purpura to iatrogenically induced autoimmunity as in PTP. In the latter case, a phenomenon known as epitope spreading, which is documented in murine models, but little discussed in terms of PTP, is speculated to be a relevant pathogenetic mechanism. A basic understanding of the mechanisms of self-tolerance and their breakdown in autoimmune disease raises the possibility of many types of specific therapeutic interventions. One of the clearest would be to identify initiating factors, such as infections, and to prevent or treat them. A second approach would be to reset tolerance. Some of the previous examples, such as in PTP, illustrate how an initiating event can be amplified, leading to broken tolerance. If the system can be set back to the state before that event, the disease could be cured. At present, it is unclear how to do this; however, an autologous or even allogeneic hematopoietic stem cell transplant may have the desired effect. In fact, this sort of radical therapy has been tried in selected cases of severe SLE and seems to have some efficacy. Another promising area is in channeling the immune response, particularly as the steering mechanisms are becoming better understood at the molecular level. Work in this area is currently active. A third area is to design more specific modulators of inflammation, including interfering with costimulatory signals. These latter approaches have seemed promising in various animal models though issues with unexpected effects on clotting have arisen in clinical trials of CD40L inhibition.

Current therapy is much more crude, and typically involves general nonspecific immunosuppression either with steroids or cytotoxic drugs. Although these therapies can be effective, they have numerous undesirable side effects, not the least of which is increased susceptibility to infection due to immunosuppression. More promising are drugs that inhibit the effects of TNF-α, which have proven successful in modifying progression of rheumatoid arthritis and also in inflammatory bowel disease, psoriasis, and graft-versus-host disease.[159–161] This approach, though a result of modern biotechnology and our understanding of immunopathogenesis, still targets effector function of the immune system and does not modify the root cause of disease. Therapies should ultimately be directed toward either prevention or else specific downregulation of ongoing responses. Recently, rituximab, an antibody to CD20 that depletes B cells and is effective in treating non-Hodgkin lymphoma, has been used to treat a variety of autoimmune syndromes. It is showing great promise[162,163] and it has been approved to treat some rheumatoid arthritis patients.[164] It will be interesting to determine how B-cell depletion leads to long-term remissions, perhaps by interrupting positive feedback loops such as illustrated in Fig. 18–6. Future work will include continuing to define how self-tolerance is imposed and how it is broken in disease, what the critical triggers and autoantigens are, and how to use immunomodulation to treat autoimmune diseases on the basis of a better understanding of the pathogenesis.

CHAPTER 19

OVERVIEW OF STEM CELL BIOLOGY

Mervin C. Yoder

INTRODUCTION

Stem cell biology continues to be an area of great interest and debate among scientists, politicians, and the public. In the face of such popularity, stem cell researchers must address new challenges in addition to opportunities. For example, many fundamental principles that define stem cells have not been well described or discussed in a truly detailed fashion in the lay literature and, thus, use of the term *stem cells* in general conversation evokes widely varying responses from engaged parties (some informed, others uninformed, many confused, and occasionally some outrageous). The widespread use of the Internet to gather information (not via physicians or scientists interpreting information from peer-reviewed scientific journals), now educates patients and their families as to the nature and biologic potential of stem cells and the hope for therapeutic application of these cells and their derivatives, and this information influences how physicians and scientist now must communicate with their patients and the public in general. The goal of this chapter is to review some general concepts that apply to all stem cells, to define vertebrate stem cells into two fundamental classes (embryonic and adult stem cells), to compare and contrast stem cells in several different organ systems, and to discuss recent information on the development of stem cell niches in these organ systems.

Defining A Stem Cell

A stem cell may be best defined by the functional properties it displays.[1] For example, many tissues of the fully developed vertebrate require that a mechanism be present for the replacement of aged, injured, or diseased cells. The turnover of blood cells forces such a requirement because 10^8 to 10^9 white blood cells are estimated to be produced every hour in the human bone marrow to replace cells that migrate into tissues and are lost during engagement with invading microbes, become engaged in tissue remodeling and repair, or are programmed to undergo senescence. Likewise, epithelial cells residing in the human small intestine are routinely sloughed into the bowel lumen every 3 to 5 days and are replaced by new epithelium. Although cutaneous epithelial skin cells turn over at different rates depending on the portion of the body being covered, the human skin is renewed on average every 4 weeks. All tissues of the body that have normal cycles of cell replacement and repair are dependent upon resident cells for ongoing cell production, and these "special" cells are termed *stem cells*. The stem cells generally reside in specific locations (niches), are not fully differentiated (may not display the appearance or all of the functions of the mature cells of the tissue), possess controlled but robust proliferative potential (for the lifetime of the host tissue), and have the capacity to divide into daughter cells in which one of the daughter cells retains all the properties of the parental cell (self-renewal) whereas the other daughter cell adopts a differentiated fate specific for the needs of that tissue. Importantly, each stem cell possesses the individual potential to regenerate the stem cells and differentiated cell progeny required to reconstitute the tissue lineage of origin; that is, hematopoietic stem cells should give rise to hematopoietic stem cells and all the progenitors and mature lineage progeny that comprise a functional hematopoietic system upon transplantation. In addition, stem cells can be defined by whether they give rise to multiple types of differentiated cells (multipotent) or a defined number of types of differentiated cells in the host tissue (two distinct cell types within a lineage would arise from a bipotent stem cell, for example). Thus, most tissue stem cells residing in vivo are defined as clonal, self-renewing, multipotent cells sustaining the homeostatic cellular requirements of a tissue or organ for the lifetime of the host.

The current concepts of clonal stem cell properties have been recognized only in the last 40 years. Prior to the 1960s, all proliferating cells in the renewing tissues of the body were thought to possess similar proliferative potential and probabilities for undergoing self-renewal divisions; one daughter cell was always preserved to maintain the proliferative pool while one daughter proceeded to form differentiated progeny. Thus, all dividing cells were thought to contribute to tissue growth and maintenance and were regarded as resident stem cells, and no specific methods were available to determine which daughter cell was specifically retained as a stem cell.

A landmark paper published in 1961 described a method for identifying repopulating cells for the hematopoietic system and established a paradigm for all studies to define stem cells. Till and McCulloch reported that rare bone marrow cells from one mouse could be infused into a lethally irradiated mouse and some of the cells that migrated to the spleen could be demonstrated to give rise to macroscopically visible hematopoietic cell nodules protruding from the spleen within 10 to 14 days posttransplant.[2] These nodules were proven to be derived from a single cell (clone) that had been transplanted from the donor mouse, and the colonies forming the nodules contained further clonogenic, as well as differentiated, hematopoietic cells. The cell clones giving rise to the spleen colonies were called colony-forming units–spleen. Although more recent studies have determined that colony-forming units–spleen are in fact short-term and not long-term repopulating hematopoietic stem cells, the pioneering studies of Till and McCulloch provided the theoretical basis for subsequent bone marrow transplantation studies with proof that the bone marrow contains undifferentiated self-renewing cells with the proliferative potential to generate cells able to differentiate into a variety of lineages with specific properties.[3]

Clonal regeneration methods have subsequently been developed for many other tissues, including epidermis, intestine, kidney, and testis, and have been used to define the resident stem cell populations of a variety of tissues.[4] Many of these approaches require that some form of tissue injury (usually irradiation) be applied to the tissue in order to permit the regenerating clones to emerge. Although there is some concern that this approach may alter the normal cellular interactions that function at homeostasis, these methods have been useful to identify a hierarchal organization of cells within the proliferative pool in these tissues. As noted earlier, stem cells are those cells within the proliferating compartment that remain relatively undifferentiated, maintain their population size when they divide (some of the progeny becoming quiescent stem cells), and produce progeny that go on to further proliferate and differentiate into mature cells comprising the tissue.

TWO CLASSES OF VERTEBRATE STEM CELLS

Vertebrate stem cells can be classified as embryonic stem (ES) cells or adult stem cells (also called somatic or postnatal stem cells). ES cells are derived in vitro from cells removed from preimplantation

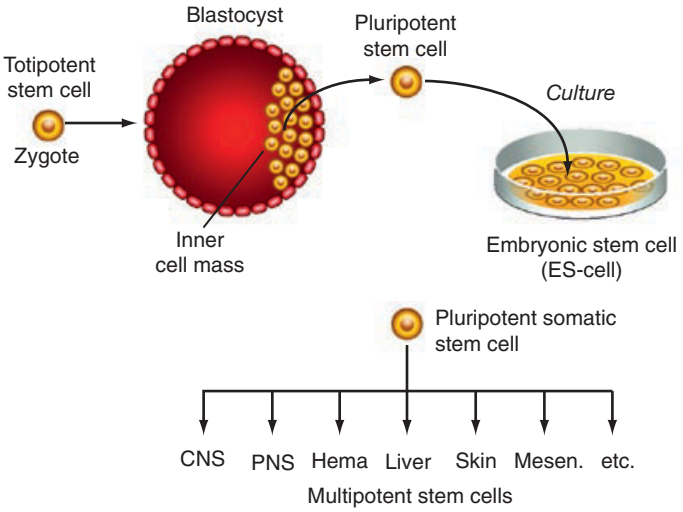

Figure 19–1 The totipotent zygote is formed from the sperm and egg. After several rounds of division, totipotent zygote-derived cells form blastocysts composed of trophoblasts that become the placenta, and the inner cell mass that forms the embryo. The inner cell mass can be collected and expanded in vitro under appropriate conditions to serve as the pluripotent embryonic stem (ES) cells. Proof of pluripotentiality is provided by injecting some of the cultured ES cells into recipient blastocysts and determining the extent of donor ES cell contribution to the cellular composition of tissues and organs throughout the chimeric embryos. The cultured ES cells can also be differentiated into cells of every somatic lineage in vitro. The intermediate stem cells that are formed from the ES cells that are restricted to the lineage of a particular organ are called multipotent stem cells. *(From Anderson DJ, Gage FH, et al: Can stem cells cross lineage boundaries? Nature Med 7:393, 2001 [modified from Fig. 1, p. 394].)*

embryos. Adult stem cells represent the self-renewing populations residing in many tissues and organs including bone marrow, brain, retina, skin, intestine, and perhaps liver, lung, and kidney. The following section will provide a comparative overview of ES cell and adult stem cell biology.

EMBRYONIC STEM CELLS

Introduction

The fertilized oocyte (zygote) is the "mother" of all stem cells (Fig. 19–1). This cell has the potential for forming all the cells and tissues of the body plan, including the placenta and extraembryonic membranes.[5] Thus, the zygote is a totipotent cell. The 3- to 5-day-old embryo is called the blastocyst. The blastocyst is composed of the following structures: the blastocoel, which is the hollow cavity inside the blastocyst; the inner cell mass, which is composed of 30 to 40 cells located at one end of the blastocoel; and the trophoblast, which is the layer of cells that surrounds the blastocyst. The first few cleavage stage divisions also produce blastomere cells, retaining totipotency. The formation of the blastocyst heralds several important changes. One portion of the blastocyst, called the inner cell mass, contains cells that will go on to form the embryo proper (epiblast). The columnar cells of the epiblast are adjacent to the trophoblast, whereas the cuboidal cells of the hypoblast are closer to the blastocoel. Trophectoderm cells comprise the cells forming the outer layer of the blastocoel; these cells will differentiate to form the placenta and some cells of the extraembryonic membranes. The inner cell mass of the blastocyst contains cells that are pluripotent; that is, each cell possesses the potential to give rise to types of cells that develop into each of the three embryonic germ cell layers (mesoderm, endoderm, and ectoderm) and if adoptively transferred into a recipient blastocyst, the donor inner cell mass cells can contribute to formation of all the tissues belonging to the resulting chimeric embryo.[6,7] The inner cell mass cells are no longer totipotent because they have lost the capacity to generate extra embryonic tissues such as a placenta and therefore cannot develop into a fetal or adult animal.

Embryonic Stem Cell Derivation

ES cells were first isolated from cultured murine blastocysts and the murine system continues to be the most amenable among mammalian species for ES cell isolation,[8,9] although precedents may have been established in earlier studies using rabbit blastocysts[10] or murine teratocarcinoma cells.[11] Plating of the pluripotent inner cell mass cells onto a preformed monolayer of mouse feeder cells with or without conditioned medium from teratocarcinoma cells were the tissue culture conditions that ultimately proved successful in promoting emergence of ES cells. In the murine system, cultured ES cells injected into a recipient blastocyst display the potential to repopulate (to some extent) all tissues of the resulting embryo, including germ cells.[12] Because adult stem cell populations are potentially present within these formed tissues and organs, adult stem cells by definition can be derived from ES cells following injection of ES cells into a host blastocyst and transfer of the embryo to a recipient foster female. Although inner cell mass cells develop into ES cells upon plating, the ES cells that emerge are now different from the parental inner cell mass cells. Whereas inner cell mass cells quickly disappear (having a finite lifetime) from the developing embryo as the epiblast develops into the complex array of cells and tissues that comprise the embryo, ES cells in vitro proliferate indefinitely, unless withdrawn from the growth conditions and induced to differentiate. No evidence has yet been presented that inner cell mass cells or ES cells reside within adult tissues, although some stem cells derived in vitro from adult murine tissues display features strikingly similar to ES cells.

Several features distinguish ES cells from resident tissue adult stem cells. Although most adult stem cells reside in specific niches within tissues, ES cells are a derivative of the inner cell mass cells. ES cells can be maintained in vitro as an essentially pure population of stem cells (free from differentiated progeny) for a prolonged period, if not indefinitely.[13] Surprisingly, despite this prolonged period within in vitro culture conditions, ES cells generally retain a normal karyotype and their pluripotentiality. In contrast to most adult stem cells that possess multipotency, ES cells are pluripotent cells and this aspect of murine embryonic stem (mES) cell biology can be demonstrated by injecting these cells into a recipient blastocyst, implantation of the blastocyst into a psuedopregnant dam, and analyzing the resulting reconstituted embryos for the degree of ES cell contribution to tissue chimerism. Thus, the pluripotent mES cells can not only be differentiated in vitro to form multiple cell lineages derived from the mesoderm, endoderm, and ectoderm, but chimeric embryos resulting from the blastocyst injections demonstrate the contribution of the mES cells to tissues derived from each of these germ layers (see Fig. 19–1).[6]

Human ES (hES) cells have also been derived from the inner cell mass of human blastocysts that had been donated for basic research by individuals who had frozen surplus embryos (generated to overcome infertility obstacles to pregnancy). The human inner cell mass cells are cocultured on a feeder monolayer of mouse embryonic fibroblasts under specific growth medium conditions. The hES cells that emerge have been shown to be pluripotent (formed teratomas upon transplantation into immunodeficient mice) with nearly indefinite proliferative capacity and to possess normal karyotypes.[14,15] The hES cells also displayed the ability to form mature cell progeny from all three embryonic germ layers in vitro.[16]

Embryonic Stem Cell Propagation

The capacity to expand ES cells in vitro while maintaining undifferentiated stem cell potential may be the most remarkable attribute of this culture system. As noted above, the earliest successful methods

Recent Advances in Development of ES-Like Cells

Vertebrate stem cells are generally classified into embryonic or adult stem cells. ES cells are derived in vitro from cells removed from preimplantation embryos whereas adult stem cells represent the self-renewing populations residing in many tissues and organs of the fully formed individual. However, there are several recent reports of isolation of cells from newborn or adult tissues that possess ES cell-like proliferative and pluripotent properties and suggest that the general classification of stem cells into embryonic or adult classes may be too simplistic.

Primordial germ cells (PGCs) derived from murine embryos between embryonic day (E) 8.5 and E12.5 display the ability to develop into pluripotent cells upon culture under specific conditions.[82,83] These embryonic germ (EG) cells can be cultured similar to ES cells with near unlimited proliferative potential, contribute to embryonic tissue reconstitution upon injection into recipient blastocysts, and contribution to endoderm, mesoderm, and ectoderm specified cell lineages in vitro. Although these studies have demonstrated that the germline lineage retains the ability to give rise to pluripotent cells, this property has been thought to be lost during gonadal development (beyond E13.5).[84] However, two recent reports suggest that ES-like cells may be derived from newborn or adult testis.

Culture of newborn murine testis cells under specific conditions that included addition of leukemia inhibitory factor (LIF), glial cell line-derived neurotrophic factor, epidermal growth factor, and basic fibroblast growth factor, led to the emergence of germline stem cells (GS) that displayed high proliferative potential, reconstituted the seminiferous tubules of infertile mice to generate normal sperm and produce offspring, and lacked the ability to generate other cell lineages.[85] However, with reproducible frequency, another population of stem cells also emerged in these GS cultures. These ES-like cells displayed higher proliferative potential than the GS cells, differentiated into multiple cell lineages in vitro and formed teratomas following transplantation in vivo.[86] In addition, these ES-like cells contributed to multiple embryonic tissues in embryos upon transplantation into recipient blastocysts including formation of germline chimeras from the living chimeric mice. Thus, ES-like cells could be developed from newborn testis, though this activity was not displayed when adult testis cells were examined.

Recently, derivation of pluripotent cells from adult testis spermatogonial stem cells (SSCs) has been reported.[87] SSCs were enriched using a transgenic mouse expressing a *Stra8* promoter driven–enhanced green fluorescent protein (Stra8-EGFP). The Stra8-EGFP-expressing cells displayed SSC activity, including the ability to reconstitute spermatogenesis in infertile germ cell-depleted mice. Further culture of the Stra8-EGFP-expressing cells in typical ES cell culture conditions (coculture with murine embryonic fibroblasts and LIF) led to emergence of a highly proliferative population of ES-like cells. These cells named multipotent adult germline stem cells (maGSCs) were able to generate differentiated progeny from mesoderm, endoderm, and ectoderm lineages in vitro and produce teratomas upon injection into recipient immunodeficient mice.[87] In addition, maGSCs contributed to multiple tissues of chimeric embryos generated upon transplantation of the maGSCs into recipient blastocysts and transfer into pseudopregnant female mice. Finally, male chimeric mice derived from the chimeric blastocysts were capable of germline transmission when mated. Thus, maGSCs display ES-like activity and suggest that if proven feasible, generation of similar human maGSCs would prove an exciting and noncontroversial source of stem cells, though restricted to male subjects.

A recent series of landmark papers may provide a method to generate induced pluripotent stem cells (iPSCs) from somatic cells of male or female subjects. Mouse embryonic or adult fibroblast cells were reprogrammed to express ES-like properties by retroviral introduction and expression of Oct3/4, Sox2, c-Myc, and Klf4 transcription factors and then selection for cells expressing Fbx15.[88] These cells could commit to differentiate into progeny from multiple germ layers, generate chimeric embryos after blastocyst injection, and form teratomas upon injection into immunodeficient mice. However, the DNA methylation and gene expression patterns were not similar to ES cells and the iPSCs did not form viable chimeric mice. An advance in the procedure with forced expression of the same four fundamental transcription factors but with selection for Nanog expression has led to the isolation of reprogrammed murine fibroblasts that now are ES-like in appearance, proliferation, differentiation potential, and germline competency.[89] A precautionary note from these studies was that nearly 20% of the offspring produced by the chimeric mice developed tumors that appeared to be related to reactivation of c-Myc expression. Finally, a second group of investigators has confirmed that expression of the four transcription factors Oct3/4, Sox2, c-Myc, and Klf4 in mouse fibroblasts resulted in DNA methylation, gene expression, and chromatin states that were similar to those of ES cells.[90] Notably, the cells derived from mouse fibroblasts could generate live chimeric mice when injected into tetraploid blastocysts. Although similar studies have not been conducted in human cells, these data are encouraging that methods are developing that reconstitute an ES-like state from somatic cells. If shown to be feasible, such studies could permit generation of patient-specific iPSCs for cell-based therapies for genetic or acquired disorders. One challenge will be to develop methods of gene insertion without use of retroviral vectors and to ensure that the introduced genes are under strict inducible control to avoid the emergence of tumors that has been observed in some of the above murine studies.[89]

for ES cell derivation required the use of murine feeder cells, suggesting that some feeder cell molecules were required for ES cell survival and/or proliferation. In short time, murine embryonic fibroblasts combined with selected batches of fetal calf serum proved to be a reliable feeder cell system to provide the correct niche for mES cell maintenance. In less than 10 years, culture-derived molecules were identified that have now permitted feeder-free and serum-free culture conditions for routine maintenance of mES cells.[13] Leukemia inhibitory factor (LIF) was reported to be an essential factor for mES cell self-renewal via gp130 activation of the signal transactivator of transcription 3 (STAT 3) signaling pathway.[17,18] Bone morphogenetic protein 4 (BMP4) is a second molecule found to be the critical serum-derived factor important in maintaining mES cell proliferation and its undifferentiated state.[19] Addition of these two molecules is sufficient to replace the original feeder cell niche and fetal calf serum requirements for mES cell maintenance. Thus, it is apparent that the principal factors required for maintaining mES cells are cell-autonomous because few input molecules are required from the feeder cells or as recombinant culture medium supplements. The ability to define the in vitro culture requirements for mES cell maintenance will undoubtedly improve methods for determining specific molecular pathways that define the autonomous self-renewal state of mES cells.

The culture conditions required to maintain hES cell self-renewal and maintenance of pluripotency have been difficult to define because it is now well known that hES and mES cells have different requirements. Whereas mES cells require LIF signaling to maintain pluripotency, hES cells do not.[20] Furthermore, whereas BMP4 is sufficient to maintain mES pluripotent cells by blocking differentiation along the neuroectodermal lineage, hES cells differentiate into trophectoderm cells when exposed to BMP4.[21] Wnt signaling appears to play an important role in maintaining mES and hES cell pluripotency, although activation of this pathway is insufficient for maintaining pluripotent hES cells in vitro.[22] Recent data implicate activin/nodal and fibroblast growth factor (FGF) pathways as the critical molecules for the maintenance of hES cell pluripotency.[23] Further studies to

define the culture medium and matrix attachment factor requirements to maintain hES cells in a serum-free media will greatly advance a more widespread study of the biologic potential of these cells.

One recent advance in the field of stem cell biology is the recognition that pluripotent epiblast stem cells (EpiSCs) can be isolated from mice.[24,25] When murine embryonic day (E)5.5–5.75 late epiblast cell layers were dissected from early postimplantation embryos, EpiSCs emerged as flat compact colonies of cells that were morphologically distinct from mES cells. Of interest, EpiSCs only emerged when plated in the presence of irradiated mouse embryonic fibroblast feeder layers or in chemically defined culture medium with added activin A and FGF2. Addition of LIF and/or BMP4, the factors required for mES cell isolation and propagation, failed to support the survival of the EpiSCs. The EpiSCs displayed a pattern of transcription factor expression that is typical of pluripotent cells, maintained normal karyotypes, and gave rise to differentiated progeny of all three embryonic germ layers. Surprisingly, the EpiSCs and hES cells were found to display similar gene expression profiles and signaling responses that correspond to the patterns observed in the epiblast. These novel insights and future study may help to better understand the similarities and differences between mES, hES, and EpiSCs and lead to more focused approaches to maintain hES cells in vitro and differentiate the cells.

Embryonic Stem Cell Differentiation

Removing LIF from the culture medium will induce mES cells to differentiate into progeny belonging to all three embryonic germ layers. Currently, mES cell differentiation is conducted using one of three approaches.[13] If the mES cells are allowed to aggregate, the cells will form three-dimensional spheres called embryoid bodies (EBs). If the mES cells are plated on a feeder cell layer, differentiation will take place as the mES cells and adherent feeder cells interact. Finally, mES cells can be plated on culture dishes coated with a variety of extracellular matrix proteins with or without fetal calf serum and other additives. Obviously, use of these methods differs greatly in the specific mechanisms existent in that system leading to lineage specification and cellular differentiation, and yet each of these approaches strives to address similar principles.[13] First, the differentiation protocol should be reproducible with a robust yield of an enriched cell population. The differentiation protocol should also recapitulate the developmental program that is normally required to establish that particular lineage in the embryo. Finally, the differentiated cells that are derived from the mES cells should display the specific and expected functional properties both in vitro and in vivo known to be representative of the in vivo functions of that particular lineage under investigation. Although great progress has been made in achieving the first two principles, considerable work remains in proving that mES cell-derived cells mimic in entirety the functional properties of their in vivo counterparts. Specific details on the differentiation potential of mES cells and human ES cells can be found in several recent review articles.[13,26–29]

ADULT STEM CELLS

Introduction

Adult stem cells represent the clonal, self-renewing, multipotent cells residing in many tissues and organs that maintain the homeostatic cellular requirements of that tissue or organ for the lifetime of the host. These cells are specified during embryogenesis from one of the primary germ layers. For example, murine hematopoietic cells first emerge from the mesoderm that emigrates from the posterior primitive streak, intestinal stem cells are derived from definitive endoderm, and skin stem cells emerge from an ectoderm origin. We will briefly review some general principles of hematopoietic, intestinal, and skin stem cell functions to highlight some of the similarities and differences among these adult stem cells.

Hematopoietic Stem Cells

Hematopoietic stem cells (HSCs) are characterized by the ability to self-renew and differentiate into all mature blood lineages.[30,31] HSCs are capable of rescuing lethally irradiated hosts by reconstituting the entire repertoire of hematopoietic cells in the host. HSCs are rare cells, occurring at a frequency of 1 in 10,000 to 100,000 murine bone marrow cells with a total pool size estimated at 10,000 to 20,000 cells per mouse.[32] At steady state, the vast majority of HSCs are quiescent with only a fraction of these cells entering into a cycling state to proliferate and give rise to daughter cells that commit to further proliferation and differentiation as progenitors for the mature blood cell lineages. It has been estimated that billions of blood cells are produced each hour in the healthy human adult subject throughout its lifespan and under most circumstances this enormous production is balanced by programmed cell losses so that the circulating number of cells remains unchanged. However, when perturbed by a systemic stress such as an infection, acute bleeding, or chemotherapy, HSCs are called upon and are responsive to proliferate extensively in order to make sufficient progeny to meet the supply of blood cells required.

The stem cell hierarchy theory predicts that the first daughter progeny derived from HSCs are short-term repopulating HSCs with the potential to give rise to both lymphoid and myeloid progeny (Fig. 19–2).[30] Subsequently, daughter cells commit to either the lymphoid lineage via a common lymphoid progenitor or the myeloid lineage via a common myeloid progenitor cell. Common lymphoid progenitors further divide and differentiate into lymphocytes of the T, B, and NK lineages. Common myeloid progenitors give rise to granulocyte–monocyte precursors and megakaryocyte–erythrocyte precursors that subsequently differentiate into granulocytes and monocytes or red blood cells and platelets, respectively.

Evidence that a cell possesses long-term repopulating HSC activity requires transplantation of that cell into a recipient subject. In the murine and human system, HSC transplantation results in complete reconstitution of all blood cell lineages if donor HSCs are injected into hosts following some form of myeloablation (to eliminate the immune system and the endogenous HSC/progenitor cells). Murine HSCs will also engraft in nonablated hosts if very large numbers of HSCs are transplanted or in situations where the vasculature of syngeneic (genetically identical) mice is joined and cells are freely able to circulate from the marrow compartment of one animal through the blood and into the marrow of the parabiotic partner.[33] If the murine donor cells engraft and reconstitute all the blood cell lineages for more than 4 months, the donor cells are confirmed to possess long-term repopulating HSC activity.[34] If the donor cells reconstitute the blood cells for the lymphoid and myeloid lineages, the cells are called long-term multilineage repopulating HSCs. Confirmation of HSC self-renewal activity can be demonstrated by transplanting the reconstituted marrow of the primary recipient animal and determining that secondary myeloablated animals are also fully reconstituted.[3] Despite the fact that HSCs express telomerase activity, replication of HSCs is finite, and donor murine HSCs can be serially transplanted only a certain number of times (four to seven), with eventual stem cell exhaustion.

The HSC repopulating ability can be enumerated by a competitive repopulation assay in the murine system. In this assay, hematopoietic cells from a test mouse are mixed in various proportions with those from a competitor mouse before injection into a lethally irradiated recipient mouse.[35] Using a limiting dilution assay, the frequency of the long-term repopulating HSCs is measured by the ability of these cells to outcompete the competitor cells for engraftment and contributions to all the blood cell lineages in the recipient mouse.[36] In the human system, one cannot perform such a competitive assay. Instead, transplantation of putative human HSCs into sublethally myeloablated immunocompromised mice permits quantitation of human pan-leukocyte antigen CD45-expressing cells residing in the bone marrow of the recipient mice. The combined use of this in vivo assay with several in vitro assays lends experimental support for a stem cell hierarchical organization of human hematopoiesis similar to the mouse model system.

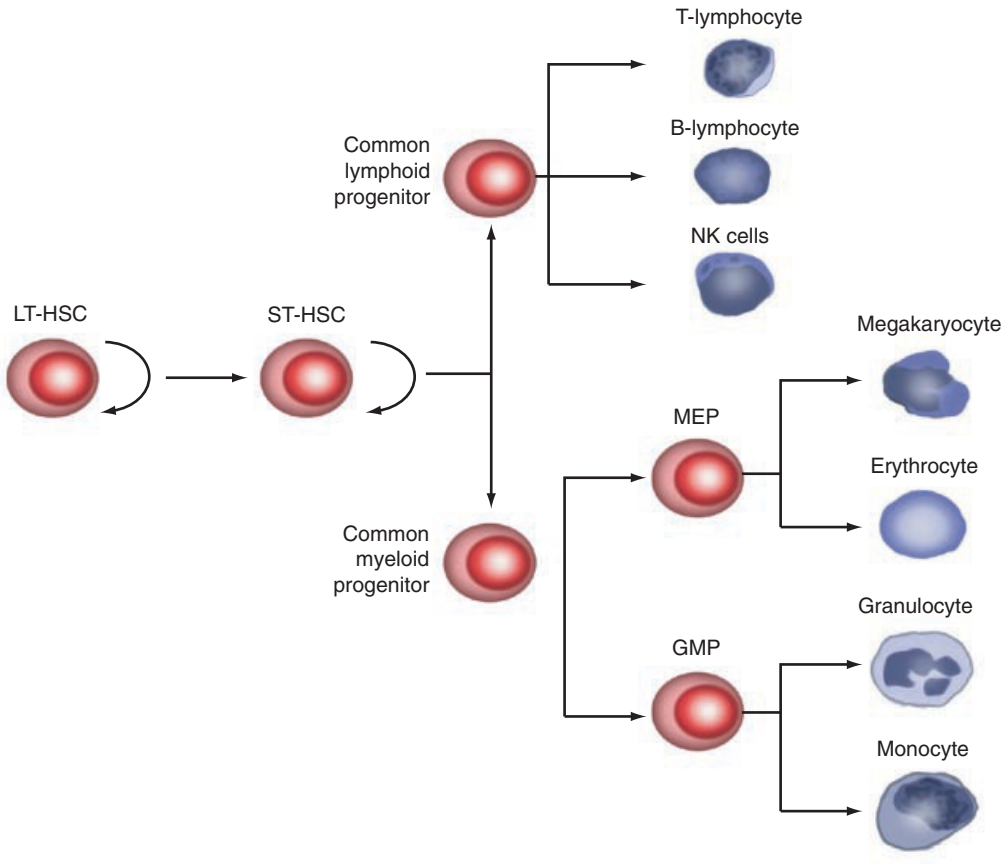

Figure 19–2 The hematopoietic hierarchy. As hematopoietic stem cells divide, they give rise to common lymphoid and common myeloid precursor cells that eventually generate all mature blood lineages of the body. GMP, granulocyte–monocyte precursors; LT-HSC, long-term hematopoietic stem cells; MEP, megakaryocyte–erythrocyte precursors; NK, natural killer; ST-HSC, short-term hematopoietic stem cells. *(From Leung AYH, Verfaillie CM: Stem cell model of hematopoiesis. In 4th Edition of Hematology: Basic Principles and Practice, p. 201, Fig. 17–1 Elsevier, Philadelphia.)*

Intestinal Stem Cells

The intestinal epithelium displays typical epithelial evidence of polarization and organization into discrete units of proliferating and differentiated cells.[37] The small intestine is characterized by complete coverage with finger-like villi protruding into the lumen. The predominant cells covering the villi are columnar epithelium that participate in the uptake of digested food elements, become senescent, and are sloughed from the tip of the villi. Surprisingly, there is no proliferation of cells at the villous tip to replace the lost epithelium, but there is a striking balance between the loss of villous epithelium and proliferation of intestinal epithelial stem cells (ISC) and transient amplifying (TA) epithelial progenitor cells near the base of the villi in regions called crypts.[38] It is estimated that the epithelium covering each villus arises from six adjacent crypts and each crypt can produce cells that migrate onto more than a single villus. More than 50% of the crypt epithelial cells are proliferating with a cell cycle of 12 hours and 200 to 300 epithelial cells are replaced daily. All of the proliferating cells can be traced back to the ISC, which resides four cell diameters from the base of the crypt in the small intestine, near the midcrypt in the ascending colon and in the base of the crypt in the descending colon.[39] Small-intestine ISC display a 24-hour cell cycle and give rise to daughter cells that become TA progenitor cells before giving rise to mature epithelial cells of several different mature cell lineages, including Paneth, goblet, absorptive enterocytes, and enteroendocrine cells (Fig. 19–3).

The highly organized spatial localization of the ISC and TA cells of the small intestine have permitted extensive analysis of villus epithelial regeneration despite the lack of cell surface markers (though some progress in marker identification has been recently reported). In the absence of a transplant assay for ISC identification, several approaches have been used to support the hypothesis of the clonal regeneration of intestinal epithelium from ISC. The crypt microcolony assay utilizes a cytotoxic injury (typically irradiation) to eliminate the villus epithelial cells to induce radioresistant crypt cells to regenerate the entire villus.[40] This assay has provided evidence that a single surviving stem cell can regenerate all of the cell types of a villus.[38] A developmental approach using mouse aggregation chimeras demonstrated that the villus crypts of chimeras were not formed through mixing of readily distinguishable strains but, in fact, were either derived from one strain or the other; that is, each crypt was composed of a clonal population.[41] Similar conclusions have been reached when examining mice carrying somatic mutations at specific loci that permitted tracking clonal succession in the intestinal crypt ISC to replace the villus epithelium.[42] Some human populations carry genetic mutations that also permit analysis of enzymatic activity in the colon, and these studies have provided evidence to support the clonal regeneration of the intestinal epithelium from ISC.[43] In sum, intestinal epithelial cells are regenerated via ISC replication and generation of TA progenitor cells that give rise to the multiple lineages of epithelial cells residing in a villus. This hierarchical organization is quite similar to that of the HSC.

Epidermal Stem Cells

As the outermost protective covering of the body, the epidermis is subjected to a host of challenges. Skin serves as the first line of defense against microbial invasion and prevents the body from dehydrating. Many physical and chemical forces are capable of abrading, cutting, burning, or breaking down the epidermis and, thus, this organ must respond with reepithelialization. Proliferation of cells in the most basal layer of the skin provides the source of cells that migrate outward, differentiate, and mature into the epithelium that produces the keratinized stratum corneum.[44] Cells are routinely sloughed from the interfollicular epidermis; thus, at homeostasis, basal cell proliferation must be balanced to produce sufficient cells to maintain the protective function of the skin but avoid overproduction, as seen in some human disorders such as psoriasis and cancer.[45] The epidermis is replaced in distinct epidermal proliferative units that emerge as

Mouse Models of Human Hematopoietic Stem Cell Engraftment

Human HSC Engraftment Models

In mice, the defining characteristic of a hematopoietic stem cell (HSC) is a cell with the capacity to engraft and reconstitute all hematopoietic lineages for more than 4 months upon injection into a myeloablated recipient mouse.[34] In man, one cannot perform such an experimental intervention, although years of successful experience in human bone marrow (BM) transplantation provides compelling evidence that human HSCs expressing CD34 (derived from BM or mobilized peripheral blood) possess long-term reconstitution efficacy.[91] Alternatively, human putative HSCs can be transplanted into xenogeneic hosts that are subsequently sacrificed and analyzed at varying times following transplant for evidence of human hematopoietic cell engraftment and differentiation into myeloid and lymphoid lineages.[92] Multiple immunodeficient murine models have been developed for this purpose. The nonobese diabetic (NOD)/severe combined immunodeficient (SCID) mouse has been tested extensively as a model to study human cell engraftment. Other genetic knockout mutants including NOD/SCID/β2-microglobulin, recombination activating gene 1 and 2 (*RAG1* and *RAG2*), NOD/*RAG1*, *RAG2*/common cytokine receptor γ chain null (γc^{null}), and the triple knockout NOD/SCID/γc^{null} mice have all been utilized in human HSC transplantation experiments.[92,93]

The murine SCID mutation was described in 1983 and is related to a nonsense mutation of a protein kinase DNA-activating catalytic polypeptide ($Prkdc^{scid}$).[94] Homozygous null mice are deficient in humoral (B cell) and cell-mediated (T cell) immunity (adaptive immunity) owing to a defect in activation of a DNA recombinase that requires a functional *Prkdc* gene. A number of experimental models have been developed on the basis of these mutant mice, including the SCID-hu mice that contain human fetal liver or BM explants of tissue inserted under the host renal capsule to provide "human" sites for human HSC engraftment, triple chimeric mice (normal mice that are lethally irradiated, transplanted with SCID marrow cells, and then transplanted with human BM cells), and the most commonly used model in which sublethally irradiated SCID mice are injected intravenously with human test cells. However, human HSC engraftment in these models remains relatively low because compensatory increases in natural killer (NK) cell, granulocyte, and macrophage cell numbers, and hemolytic complement elevations leads to human graft rejection.[95]

The NOD mouse displays spontaneous autoimmune T cell-mediated, insulin-dependent diabetes mellitus. Defects in innate immunity, including NK and macrophage functions, and diminished complement component C5 activity are also present. Cross-breeding of the NOD and SCID strains generates progeny (NOD/SCID) that are defective in both innate and adaptive immunity but do not develop diabetes. When human HSCs are injected into these animals, significantly greater engraftment is observed compared to human HSC transplantation into the SCID mice.[95] Differentiated cells predominantly of the myeloid and B lymphocyte lineages are observed in the BM of the NOD/SCID mice following transplantation and human T lymphocyte development is lacking. A caveat about the NOD/SCID model, however, is that some animals retain residual NK activity and express disparate major histocompatibility (MHC) loci, limiting the human cell engraftment. To circumvent this limitation, mice deficient in β2-microglobulin ($\beta 2m^{null}$), a protein required for MHC I expression, have been backcrossed into the NOD/SCID mice. The resulting NOD/SCID/$\beta 2m^{null}$ mice support fivefold to tenfold higher levels of human cell engraftment. Unfortunately, these immunodeficient mice are highly vulnerable to thymic lymphoma and more radiosensitive than NOD/SCID mice and have a shorter lifespan.[96]

NOD/SCID/γc^{null} mice are viable and fertile but lack any lymphocyte (B, T, or NK) development in addition to displaying innate immune defects of the NOD/SCID mouse.[95,97] Of interest, during the backcrossing of the NOD/SCID strain with the γc^{null} mice, the animals became resistant to thymic lymphoma and the NOD/SCID/γc^{null} animals exhibit a normal murine lifespan (it became evident that the T lymphoma cells of the NOD/SCID thymus require signaling through the common γ chain and, thus, genetic ablation of this pathway in the NOD/SCID/γc^{null} mice results in thymic lymphoma resistance). As one might predict, these triple knockout mice accept human hematopoietic grafts with significantly higher levels of engraftment than NOD/SCID mice. Of interest, transplantation of these animals during the neonatal period with donor human cord blood cells results in not only bone marrow reconstitution with myeloid and lymphoid cells but thymic and lymph node colonization and circulating T and B cells.[98] The innate and adaptive function of the transplanted human cells can be demonstrated by challenging the engrafted mice with an immunogen and measuring circulating antibody and cytotoxic T-cell responses.

Human Epithelial Stem Cell Engraftment Model

Although transplantation of murine epidermal bulge stem cells (BSCs) into the skin of young mice results in reconstitution of complete hair follicle structures,[99] similar studies have not been conducted with human epidermal stem cells. Likewise, neither murine nor human intestinal stem cells (ISCs) have been demonstrated to reconstitute the intestinal villi in the small or large intestine of a xenogenic model. Development of a small animal transplantation model that permits isolation of BSCs and ISCs that display long-term epithelial reconstitution (including all cell lineages that normally constitute these tissues) upon transplantation would be a great advance in permitting a clearer definition of the key cell types that may be required for therapeutic use in human subjects suffering from epidermal or intestinal epithelial dysfunction. Demonstration of clonal human epithelial reconstitution from a single transplanted epithelial stem cell would also provide an unambiguous assay to permit isolation of the human epithelial stem cells.

hexagonally packed cells.[46] Lineage-marking studies have determined that each epidermal proliferative unit arises from a single basal cell.[47] Clonal regenerative assays developed in mice have revealed that approximately 10% of basal cells function as epidermal stem cells. In the interfollicular epidermis, the self-renewing basal stem cells give rise to a small population of amplifying basal cells that migrate into the spinosum and granular layers of the dermis, differentiate, and give rise to the mature cells and eventually the cornified layer. This cycle of epidermal replenishment is estimated to occur every 4 weeks in human subjects.[44,48]

More recent studies have determined that the hair follicles in the epidermis are also in constant turnover, with specific cycles of degeneration and regeneration, and specific stem cells have been demonstrated to participate in this process (Fig. 19–4).[49] Hair follicles emerge during embryogenesis and undergo a process of follicular cycling after birth. The hair cycle is composed of three phases; anagen, catagen, and telogen (Fig. 19–5). In the murine system, the hair follicles grow synchronously until 2 weeks of postnatal age, when proliferation of cells at the base of the hair shaft ceases, and the follicle enters the destructive catagen phase. This phase is a brief 3 to 4 days in mice but most cells of the follicle undergo apoptosis. During the telogen phase, the follicle lies dormant and the hair becomes a mere remnant; this period can range from 1 to 14 days. To resume the anagen phase, proliferative cells in the follicle must regenerate a new round of hair growth, and this process recurs throughout the life of the animal.[44,49] The lowermost region of the hair follicle during the telogen phase is the site where the stem cells begin proliferating and forming a "bulge" to herald the anagen-phase onset (Fig. 19–4). These follicle stem cells (FSCs) display proliferative kinetics that differ a great deal from other proliferating cells in the basal layer. In

fact, microarray-profiling studies have identified nearly 150 genes that FSCs preferentially express compared to the proliferating basal epidermal cells.[50] Many of the genes that are enriched in FSCs are associated with inducing and maintaining cellular quiescence.[51] Nonetheless, FSCs can be activated and can regenerate the hair follicle and contribute to replace basal cells that may be depleted in response to significant reepithelialization following major cutaneous injury.[52]

Stem cell maintenance of epithelial turnover in another hair follicle appendage, the sebaceous gland, has also recently been demonstrated. Sebaceous glands are located just beneath the orifice of the hair shaft at the surface of the skin and release lipids and sebum that protect the hair canal from microbial overgrowth and invasion. Release of the lipids and sebum occurs with the death of the mature sebocyte, and thus, sebaceous epithelial progenitor cells are constantly producing mature sebocytes to replace the dying cells. Fate-mapping studies using retroviral labeling of epithelial cells in vivo strongly implicated the presence of a sebaceous stem cell population.[53] However, the recognition that cells expressing BLIMP1 can yield sebocyte colonies in vitro and undergo self-renewal provided evidence for the presence of a specific population of stem cells.[54] Surprisingly, during injury to the skin, sebaceous gland homeostasis is altered and BLIMP1-expressing cells are bolstered by an influx of FSCs. Thus, FSCs contribute to regeneration of all the major specialized cells of the epidermis and may serve as a readily accessible source of cells for potential human therapy. Again the hierarchical organization of the FSC, various basal, bulge, and sebaceous stem and progenitor cells, and the mature epidermal lineages derived from each suggest a paradigm very similar to that of the HSC and ISC.

STEM CELL NICHES

Introduction

Stem cells generally reside in specific locations (niches), are not fully differentiated (may not display the appearance or all of the functions of the mature cells of the tissue), possess controlled but robust proliferative potential (at least for the lifetime of the host tissue), and have the capacity to divide into daughter cells in which one of the daughter cells retains all the properties of the parental cell (self-renewal) whereas the other daughter adopts a differentiated fate specific for the needs of that tissue. Although some of the molecular regulation of these stem cell functions may be intrinsic to the stem cells,[55,56] recent evidence highlights the critical role of niche supportive cells that surround the stem cells to form a protective and regulatory microenvironment.[57] Cells that comprise the niche form a highly dynamic interactive system that functions as a physical anchor for the stem cells to regulate their location, generates extrinsic factors that control stem cell fate and number, and protects the stem cells from injurious external stimuli that otherwise might induce stem cell apoptosis. Defining the niche for a variety of tissue-specific stem cells has become a very active area of research. An obvious complication in attempting to dissect the molecular regulation of stem cell activity via the niche is the multicellular nature of many of the tissue resident niches. However, great advances in understanding the molecular mechanisms regulating stem cell development within specific niches in invertebrate species have opened new pathways for discovery in mammalian systems. Several key pathways including Wnt–β-catenin, TGF-β–BMP, and Notch appear to play important roles in the interactions between niche cells and hematopoietic, intestinal, and epidermal stem cells.

Hematopoietic Stem Cell Niche

The concept that hematopoietic progenitors interact with specific cellular elements within a tissue to form a specialized interactive unit (niche) is largely attributed to Schofield nearly 30 years ago.[58] But, as Scadden has recently pointed out, the niche is more of an ecologi-

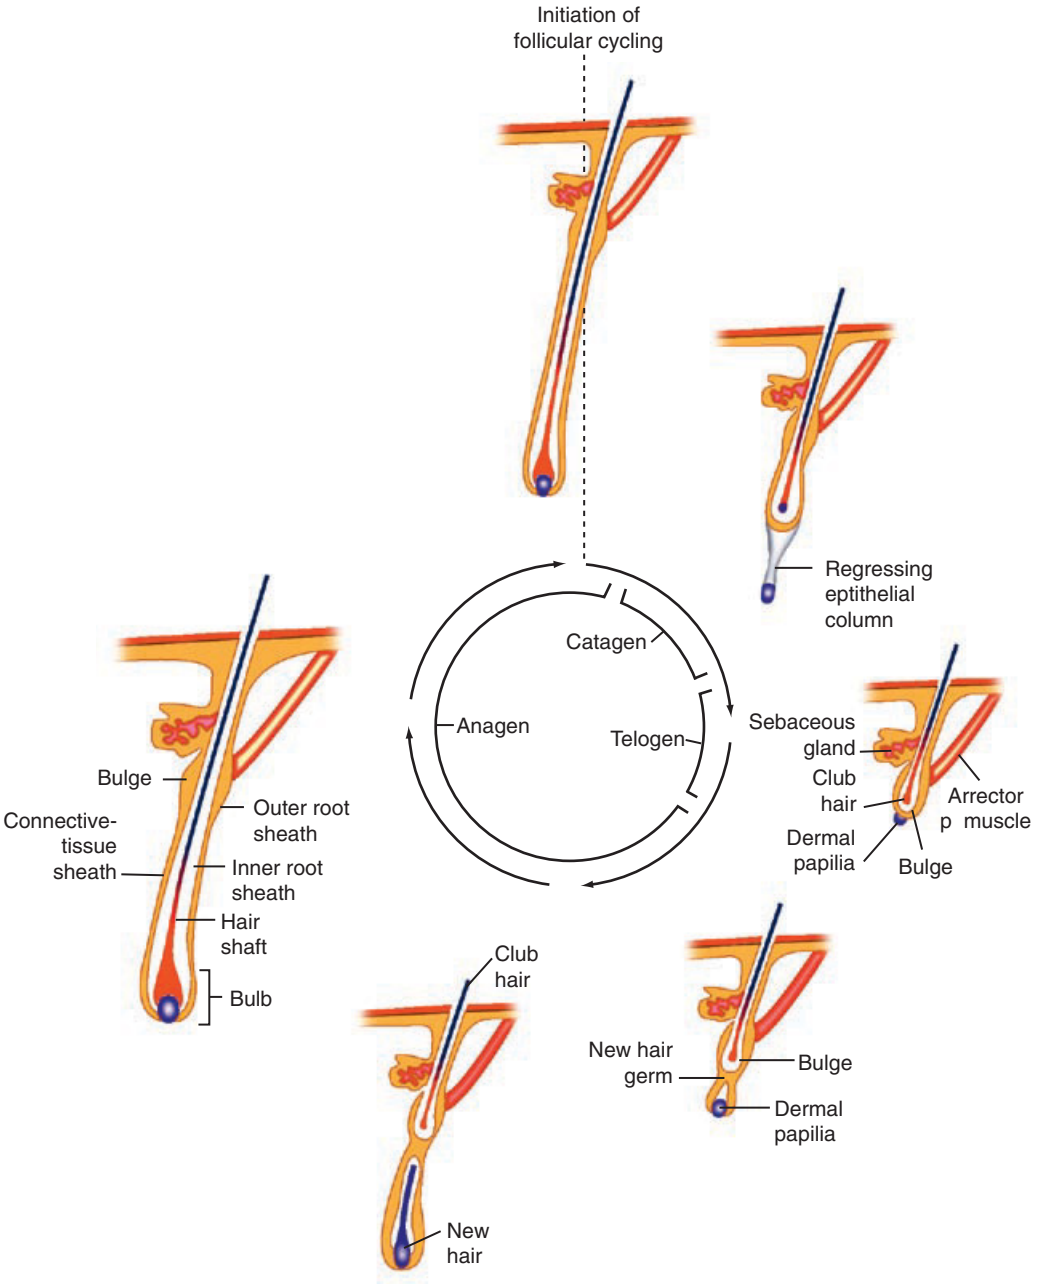

Figure 19–5 The stages of the hair cycle are depicted. Follicles progress synchronously to the destructive (catagen) phase, during which the lower two-thirds of the follicle undergoes apoptosis and regresses. The dermal papilla is brought to rest below the bulge stem cell compartment, and after the resting (telogen) phase, a critical threshold of activating factors is reached and the stem cells become activated to regrow hair. *(From Fuchs E: Scratching the surface of skin development. Nature 445:834, 2007 [modified from Fig. 3, p. 837].)*

cal habitat that requires a sustained interaction between nonhematopoietic cells and the HSCs, rather than an architectural anatomical recess where HSCs merely repose.[59] HSCs are not restricted to the marrow niches but are dynamically entering and traversing the systemic circulation with brief transit times (seconds).[33] The mechanisms for this migration are unknown but, in fact, recapitulate the ontogenic delivery of HSCs from one hematopoietic site to another as gestation progresses. In the adult mouse and man, the bone medullary cavity is the primary residence of the majority of quiescent HSC. In vivo tracking and homing studies have demonstrated a periosteal localization for intravenously injected HSC in mice.[60] The specific interacting cells that comprise the niche have only recently been identified.

Several pieces of evidence suggest that spindle-shaped osteoblasts lining trabecular bone in the marrow cavity play a seminal role in the HSC niche (Fig. 19–6). In vitro culture of osteoblastic cells with HSC promotes progenitor cell expansion, but the documentation of a direct effect of the osteoblast on HSC required in vivo approaches. Using a bone morphogenetic protein (BMP) receptor 1A conditional knockout transgenic mouse model, Zhang et al reported that down-regulation of BMP signaling resulted in ectopic trabecular bone formation throughout the medullary cavity.[61] This overall increase in the amount of trabecular bone was associated with an increase in osteoblast cells with a proportionate increase in the numbers of HSC. Of interest, the HSC were in close proximity to spindle-shaped osteoblasts and appeared to be interacting directly with these cells via formation of an N-cadherin–β-catenin adherens complex. Calvi et al generated a transgenic mouse in which the parathyroid hormone receptor was constitutively active in osteoblasts using an osteoblast-specific 2.3-kilobase fragment of the promoter of the gene encoding type 1α1 procollagen.[62] The constitutively active parathyroid receptor signaling led to an increase in osteoblasts, trabecular bone, and a concomitant increase in HSC. Of interest, the osteoblasts demonstrated an increase in Jagged 1 expression and increased Notch 1 activation in the HSC that could be blocked with γ-secretase inhibition. Whether this is an effect only active in HSC expansion in this transgenic system or plays a role in homeostatic regulation of HSC remains controversial, as Jagged 1-deficient mice have normal hematopoiesis. Support for the specific role of osteoblasts in the regulation of HSC number and function was demonstrated by Visnjic et al, who

Germline Stem Cells: Big Lessons from Small Flies

Introduction

Regulating stem cell divisions to provide for sufficient cells to maintain tissue homeostasis but avoiding overproduction of undifferentiated stem cells (a potential pool of cells susceptible to secondary mutation emergence and tumorigenesis) is a fine balance. Asymmetric stem cell divisions whereby one daughter cell commits to a differentiation pathway whereas the other daughter maintains a stem cell fate, is an obvious strategy to keep stem cell numbers adequate for tissue needs, but a restricted stem cell pool number. *Drosophila* germline stem cells (GSCs) have become well-studied models for understanding the importance of the cellular microenvironment (stem cell niche) in regulating the crucial decision between stem cell maintenance or expansion (self-renewal divisions) and production of differentiated progeny.[100,101]

Male Germ Cells

The adult *Drosophila* testis is a long coiled structure filled with a hierarchically organized arrangement of cells at all stages of spermatogenesis (Fig. 19–7).[102,103] In the apical tip of the testis, 6 to 12 GSCs are arranged in a ring that directly contacts a cluster of postmitotic somatic cells called the hub. The hub cells represent an important microenvironment (niche) that supports the regulation of GSC survival, self-renewal, and differentiation. The GSCs interact with hub cells via adherens junctions and through local signals that are so restricted that stem cells one diameter away are not responsive to the hub cell signals. Division of a male GSC results in the formation of one cell that remains in the niche in contact with the hub cells to retain stem cell activity and a second cell, called the gonialblast, which is moved away from contact with the hub cells and initiates differentiation (Fig. 19–7). The GSC self-renewal decision is mediated via activation of the Janus kinase–signal transducers and activators of transcription (JAK–STAT) pathway in the GSC via a cytokine-like ligand Unpaired (UPD) expressed by the hub cells.[104,105] During GSC division, the daughter cell that is displaced from the hub cell (gonialblast) senses a diminished UPD signal and commences differentiation, whereas the daughter cell remaining in contact with the hub cells retains a strong JAK–STAT signal and a GSC identity. The gonialblast subsequently undergoes four rounds of transient amplifying divisions marked by incomplete cytokinesis to generate a cluster of 16 interconnected spermatogonia. The importance of microenvironmental signals is so crucial to the survival and differentiation of the gonialblast cells that somatic stem cells that lie interposed between the GSCs and in contact with the hub cells divide to form cyst progenitor cells (CPCs) that encircle the gonialblast cells during their proliferation and maturation (Fig. 19–7).[103] Activation of the epidermal growth factor receptor in the CPCs appears essential in limiting the proliferation of the GSCs and promoting gonialblast differentiation.[100]

Female Germ Cells

The *Drosophila* ovarian niche is composed of cap cells (CCs) and escort stem cells (ESCs), a subset of inner germarial sheath cells, which interact with cells comprising the terminal filament of the germarium (Fig. 19–8).[100,101,106] Ovarian GSCs (two to three) directly interact with the cap cells via adherens junctions. Following each GSC division, the posterior daughter cell moves away from the niche and commits to differentiate into a cystoblast cell. The cystoblast cell undergoes four synchronous divisions that are marked by incomplete cytokinesis to form a 16-cell germline cyst. Regulation of female GSC self-renewal requires bone morphogenetic protein (BMP) signaling from the niche cap cells via the ligands decapentaplegic and glass-bottomed boat.[107] The ligand-mediated activation of BMP signaling directly represses transcription of the *bag of marbles (bam)* gene in the GSCs within the niche.[108] Forced expression of the BAM protein in GSCs causes GSCs to differentiate into cystoblast cells. It has been postulated that GSC division in which one daughter loses contact with the niche results in differentiation of that cell via E3 ubiquitin ligase degradation of residual BMP signaling molecules.[100] A subset of the inner sheath cells, called escort cells, encase the newly formed cystoblast cells and remain tightly associated with these cells as they grow into the 16-cell cysts and enter meiosis. At this stage of cyst development, the escort cells undergo apoptosis and a second niche of follicle stem cells produces follicle cells that subsequently encapsulate the passing cysts and participate in the maturation and survival of the cysts.

Stem Cell Polarity in the Niche

In both male and female *Drosophila* GSC niches, there is an apparent elaborate mechanism to constrain the division of the GSCs to ensure that one of the daughter cells is retained in the niche whereas the other daughter is displaced and becomes specified to a differentiated fate. Male and female GSCs divide with mitotic spindles oriented orthogonally to the niche (hub or cap cells).[100,107] This is accomplished in the female GSCs by anchoring the spindle pole to the apical side of the GSC by a subcellular organelle called the spectrosome. In male GSCs, the anaphase-promoting complex 2 protein colocalizes with E-cadherin at the interface between the GSCs and the hub cells. This protein appears to interact with the centrosome to orient the mother centrosome to remain in the GSC near the hub whereas the daughter centrosome is allocated to the displaced daughter cell.[109] Thus, GSC and niche cells directly interact in multiple ways that affect GSC survival, self-renewal, and production of differentiated progeny.

generated a transgenic mouse in which osteoblasts could be specifically ablated.[63] The ablation was achieved using an inducible system in which ganciclovir was administered to activate thymidine kinase specifically expressed in the osteoblast lineage. Loss of osteoblasts in the ganciclovir-treated animals was associated with depressed lymphoid and myelo-erythroid progenitors, HSC number, and an overall lower bone marrow cellularity. If ganciclovir was withdrawn, the animals demonstrated recovery of osteoblast numbers and reappearance of active hematopoiesis. Interactions between angiopoietin-1-expressing osteoblast cells and Tie2-expressing HSCs appears to be required in maintaining HSCs in a quiescent state.[64] Other extrinsic signaling pathways within the niche that may regulate HSC homeostasis include the Wnt–β-catenin pathway, which has been reported to enhance HSC self-renewal.[65] Notch signaling may also play a role in inhibiting cell differentiation in the context of Wnt protein-induced proliferation.[66] However, both of these pathways have been shown to be dispensable for HSC homeostasis in genetic ablation models.[67,68] Nonetheless, these data in aggregate demonstrate an important role for osteoblasts in regulating HSC number and function within the medullary cavity.

As noted above, HSCs display the ability to circulate throughout the systemic circulation without losing potency. Indeed, during murine development, HSCs emerge and maintain a close relationship with the vascular endothelium. Endothelial cells isolated from the yolk sac and embryo proper of the mouse can stimulate adult bone marrow HSC expansion in vitro, and certain adult tissue endothelial cells appear capable of maintaining HSC repopulating ability ex vivo for some time.[69,70] Recent studies have identified HSCs in close association with bone marrow and spleen sinusoidal endothelial cells and have suggested that HSCs may lodge in a vascular niche that provides signals for HSC homeostasis.[71] One concept proposed is that the osteoblastic niche maintains quiescent HSCs and that HSC proliferation and differentiation occur in the vascular niche. Further studies will be required to examine HSC homeostasis using direct

Systems Dependent upon Changing Niches during Development

The hematopoietic system is quite unique in that the primary sites of hematopoiesis change during in utero development. The first blood cell progenitors emerge in the murine embryo on embryonic day (E) 7.0 in the visceral yolk sac.[110,111] These progenitor cells are principally specified to give rise to primitive erythroid cells, named for their expression of embryonic hemoglobin molecules, their large size, and the fact that these red blood cells retain their nucleus for many days (even while circulating) following their emergence.[112] Macrophages and megakaryocyte progenitor cells also emerge during this time and display unique identifying features.[113,114] For the next 24 hours, all three populations increase in number and then differentiate into mature forms within the yolk sac. On E8.25, a second wave of progenitor cells emerge in clusters of cells associated with the yolk sac blood vessel endothelium. These progenitor cells display characteristics of both the myeloid and erythroid lineages and are called definitive progenitors because the erythroid cells that are produced in this site synthesize adult hemoglobin molecules similar to erythrocytes in adult bone marrow.[114] Of interest, although the definitive progenitors emerge in the yolk sac, they do not appear to differentiate into mature cells in the yolk sac. Instead, the yolk sac-derived progenitor cells are hypothesized to migrate via the circulation to engraft the fetal liver, wherein they further expand and differentiate into mature blood cells. At the same time, the emergence of similar progenitor cells can be detected within the embryo proper in the region of the para-aortic splanchnopleure (P-Sp), although the number of progenitor cells emerging from this site is limited.[115] On E10.5 the P-Sp region has differentiated into the aorta–gonad–mesonephros (AGM) region and for the first time, one can isolate HSCs from this region (specifically from mesenchymal cells just beneath or associated with the overlying endothelium of the ventral aorta wall) and these cells will engraft in myeloablated adult recipient mice.[116] The fetal liver is colonized by cells from the systemic circulation at the 28-somite-pair stage of development and by E12.5 becomes the predominant site of hematopoiesis. As noted above, the initial wave of progenitor cell engraftment in the liver has been thought to occur primarily via yolk sac-derived cells. Although the vast majority of progenitor cell differentiation into mature blood cell lineages is occurring in the fetal liver, recent evidence suggests that HSC expansion (and perhaps emergence) is concomitantly occurring in multiples sites, including the yolk sac, placenta, and the AGM in addition to the liver between day E11.0 and E13.5.[117] However, by E13.5, essentially all of the HSC activity becomes restricted to the fetal liver. The next sites of hematopoiesis emerge after E13.5 and include the spleen and finally the bone marrow. Surprisingly, the bone marrow compartment does not become the predominant hematopoietic site until approximately 3 to 4 weeks postnatally. The spleen retains the ability to support some HSC maintenance though not expansion, but serves as an active hematopoietic site throughout the life of the mouse. Thus, the site of emergence and diversity of blood types produced changes dramatically during normal murine development.

It is assumed that multiple hematopoietic niches are established and lost throughout murine ontogeny as the sites of hematopoiesis change; however, very little is known about the specific developmental niches that support blood cell emergence during embryogenesis. Two well-known examples of the importance of HSC interactions with niche cells during fetal development include stromal cell expression of stem cell factor (SCF) and stromal cell-derived factor-1 alpha (SDF-1α, also called CXCL12 for CXC chemokine ligand 12). Homozygous deficiency of SCF in murine fetal liver or bone marrow stromal cells results in profound anemia and dysregulated hematopoiesis, although HSCs are formed and expand in vivo.[118] The hematopoietic defects are generally lethal in utero in the absence of any SCF production. Fetal mice deficient in SDF-1α production in the bone marrow niche fail to establish marrow hematopoiesis, although fetal liver hematopoiesis appears unaffected.[119] Of interest, fetal liver HSCs respond with far greater migration responses to the combined exposure of SCF and SDF-1α than do adult marrow HSCs, suggesting that these stromal cell-derived factors may play a role in HSC-niche establishment in the transition from fetal liver to the marrow compartment. Future studies to identify specific niche-produced factors that are important in the seeding of fetal hematopoietic organs throughout ontogeny will be of great interest, as these sites are generally involved in HSC expansion (fetal HSCs are largely cycling) rather than maintaining the HSCs in quiescence, as is the primary role of the adult bone marrow niche.

The primary sites of hematopoiesis also change throughout human development in utero.[120] Similar to that in the mouse, primitive erythroid cells emerge on day 18 of gestation along with some macrophages in the yolk sac. CD34-expressing progenitor cells are present on day 19. Expansion of the progenitor cells with multipotent and committed progenitor cells for myeloerythroid lineages occurs until day 60 when essentially all hematopoietic progenitor emergence from the human yolk sac ceases. Clusters of hematopoietic cells can be detected in the P-Sp region of the human embryo in contact with the endothelium overlying the ventral wall of the aorta on day 27.[121] The clusters of CD34-expressing cells greatly expand through day 35 and then are abruptly lost by day 40 of human development. Although circulating myeloerythroid cells can be observed in the developing hepatic sinusoids as early as day 23 of development, the first CD34-expressing hematopoietic progenitor cells do not appear before day 30. Subsequently the liver becomes the predominant human hematopoietic site through the 20th week of human gestation. The bone marrow medullary cavity is the final site for establishment of hematopoiesis.[122] Active blood cell production of myeloid and erythroid cells commences around week 11 of gestation, surprisingly without a large preceding pool of CD34-expressing progenitor cells appearing in the organ. These data suggest that committed progenitor cells produced at other sites, most likely the liver, seed the nascent marrow cavity via hematogenous dissemination.[123] Exactly when the long-term repopulating HSCs seed the human marrow cavity is unclear but, certainly, must be established before the fetal liver ceases to function as a hematopoietic site.

imaging approaches to learn more of niche physiology and how the HSCs are recruited for hematopoietic demands. In addition, future studies must address the lineage relationship between the HSCs and endothelial progenitor cells; vasculogenic cells that play an important role in vascular repair and regeneration.

Intestinal Stem Cell Niche

Whereas the location, organization, and function of the ISCs and the TA pool of epithelial progenitor cells are well recognized, the mesenchymal cells that surround the crypt cells are less well characterized. A composite of mesenchymal, endothelial, and myofibroblast cells may comprise the ISC niche.[38] Within this niche, a variety of signaling pathways, similar to those in the HSC niche, are reported to play important roles in regulating ISC proliferation. For example, excessive Wnt–β-catenin signaling can lead to overproduction of ISCs, with associated tumor development.[72] By examining nuclear versus cytoplasmic β-catenin localization, van de Wetering et al[73] have proposed that a gradient of Wnt signaling exists in the epithelium of the villus, and more recent data predict a role for Wnt–β-catenin signaling gradient in both ISCs and surrounding mesenchymal cells of the niche.[74] Evidence for the localized expression of endogenous Wnt inhibitors also contributes to the growing understanding of the complex spatial

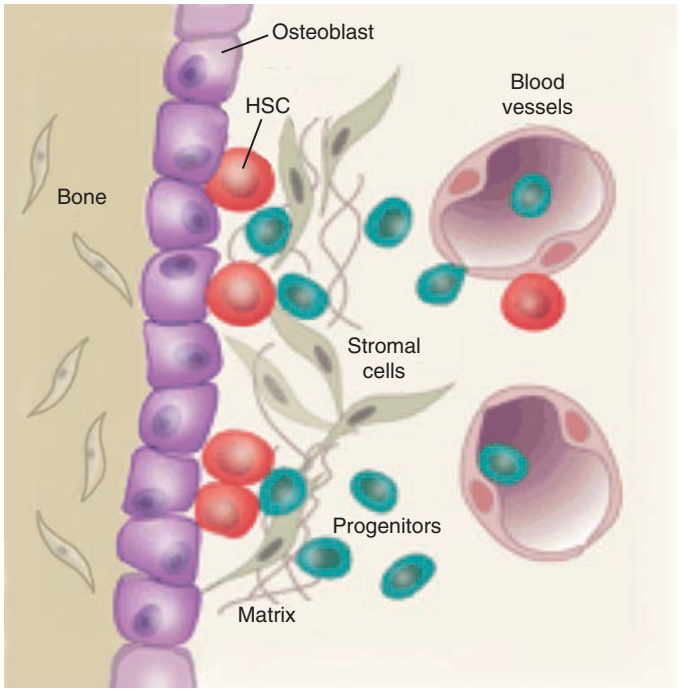

Figure 19–6 Stem cells within their niche in the bone marrow. Schematic diagram of hematopoietic and niche cellular components in the bone marrow. The exact spatial relationships are not well defined. *(From Moore KA, Lemischka IR: Stem cells and their niches. Science 311:1880, 2006 [modified from Fig. 3A, p. 1883].)*

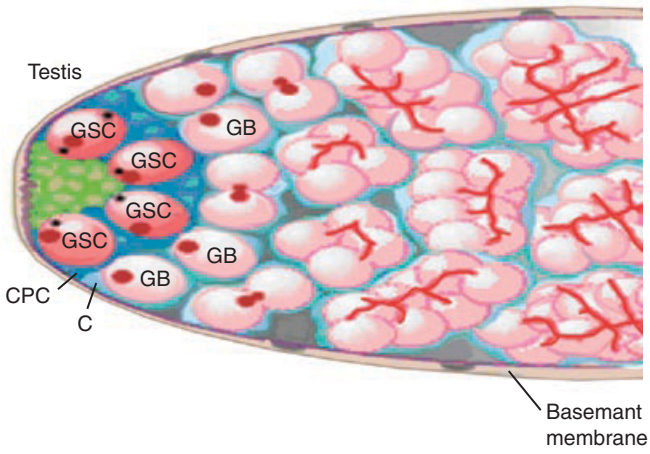

Figure 19–7 Male stem cells in their gonadal niche. Germline stem cells (GSCs) directly interact with hub cells that serve as the stem cell niche within the testis. Differentiated GSC progeny form gonialblast (GB) cells that undergo synchronous incomplete divisions to form germline cysts. Somatic cyst progenitor cells (CPC) associate with GB cells and give rise to daughter squamous cyst (C) cells that surround the differentiating GB cells during the 16-cell germline cyst formation. *(From Fuller MT, Spradling AC: Male and female* Drosophila *germline stem cells: Two versions of immortality. Science 316:402, 2007 [modified from Fig. 1B, p. 403].)*

organization of molecular gradients within the ISC niche.[75] Mesenchymal secreted BMP-4 may play a role in suppressing Wnt signals and thereby participate in balancing Wnt-induced ISC self-renewal.[76] Conditional ablation of the BMP receptor 1A in crypt epithelium results in excessive ISC proliferation. Further evidence to support a role for the BMP pathway in regulating villus epithelial fate comes in the knowledge that mutations in certain BMP receptors and downstream

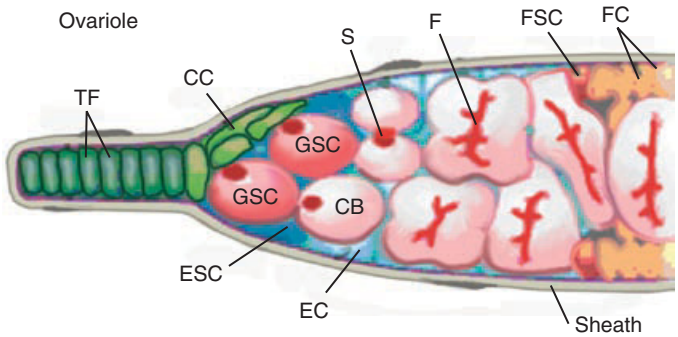

Figure 19–8 Female germline and somatic stem cells in their gonadal niches. Germline stem cells (GSCs) directly interact with cap cells (CC) forming the stem cell niche adjacent to the terminal filament (TF) of the ovariole. Somatic escort stem cells (ESC) associate with the GSC progeny that become cytoblast (CB) cells and the somatic progeny called escort cells (EC) surround the CB that synchronously but incompletely divide to form the 16-cell germline cysts. Follicle stem cells (FSC) differentiate into follicle cells (FC) that further support the differentiation and maturation of the germline cysts. The spectrosome (S) is a protein complex that may play a role in centrosome behavior and asymmetric cell fate decisions. *(From Fuller MT, Spradling AC: Male and female* Drosophila *germline stem cells: Two versions of immortality. Science 316:402, 2007 [modified from Fig. 1A, p. 403].)*

intracellular signaling molecules have been identified in human subjects with juvenile polyposis syndrome.[77] Noggin, an inhibitor of BMP signaling, is expressed by ISCs and may play a role in downregulating BMP signaling during period activation of crypt epithelial regeneration.[76] Further studies to better define the mesenchymal components of the ISC niche may permit tools to develop in vitro models to assist in the study of ISC and the TA progenitor cells of the intestine.

Epidermal Stem Cell Niche

The specific cells comprising the niche for FSCs are not characterized but are likely resident in the bulge area of the hair follicle. FSC maintenance in the niche appears to involve balancing the level of c-Myc expression.[44] Forced c-Myc expression in transgenic mice results in excessive FSC proliferation whereas conditional ablation results in failure of FSC to be maintained and alopecia ensues in the mutant animals. In contrast, LHX2 deficiency results in enhanced FSC proliferation and greater commitment to generation of epithelial progenitor cells than stem cell maintenance. Fuchs has suggested that LHX2 may function as a molecular brake to regulate the balance between FSC maintenance and activation whereas c-Myc functions to accelerate FSC proliferation.[44] Other molecules influencing FSC maintenance include the cell-division cycle 42 (cdc42) and Rac 1 proteins.[78,79] These molecules may impact on FSC maintenance via β-catenin stabilization and negative regulation of c-Myc, respectively.

Like ISCs and perhaps HSCs, FSCs are greatly influenced by the Wnt–β-catenin and BMP pathways. Constitutive expression of an activated form of β-catenin results in skin tumors in transgenic mice.[80] However, transient β-catenin activation is required to activate bulge cells to enter the anagen phase of the hair cycle. Because bulge cells express many proteins typically associated with inhibition of Wnt signaling, Fuchs has proposed that these molecules may facilitate maintaining bulge cells in an undifferentiated state.[44] Only when β-catenin is stabilized and BMP inhibition is achieved in the bulge do the FSCs and participating cells initiate hair follicle regeneration. As expected, mice deficient in expression of the BMP inhibitor Noggin display defects in the functioning of the Wnt pathway and highlight the complex regulation of FSC maintenance in the bulge.

Moore and Lemischka[81] have identified a series of challenges to the comparative study of stem cell niches, including (a) development

Are Human Endothelial Progenitor Cells Derived from Hematopoietic Stem Cells?

Endothelial progenitor cells (EPCs) have been proposed as a potential therapy to improve neovascularization in human subjects with ischemic heart disease.[124,125] At present, the mechanisms for improving myocardial recovery following infarction remain unclear, but improved neovascularization and/or diminished cardiomyocyte apoptosis appear plausible.[126–128] One potential limitation in realizing the potential of EPCs in human clinical trials has been the lack of a clear definition of what an EPC is and, thus, deciding which population of cells to infuse into the clinical subjects.[129,130] The origin of EPCs is further complicated by some evidence that suggest that human EPCs may be derived from human HSCs.

In general, EPCs are thought to represent bone marrow-derived circulating cells that demonstrate the potential to participate in new blood vessel formation (postnatal vasculogenesis).[131,132] New blood vessel formation in adult subjects has long been postulated to occur via sprouting of endothelial cells from preexisting vessels (angiogenesis) or via collateral arterial development (arteriogenesis). In the embryo, blood vessels are first formed from angioblast precursor cells (vasculogenesis) prior to angiogenesis. In 1997, Asahara et al[133] identified circulating $CD34^+$ EPCs from human cord blood that participated in new vessel formation and suggested that these angioblast-like precursor cells form new vessels via postnatal vasculogenesis (because they appeared to be marrow-derived progenitor cells without endothelial commitment at the time of isolation). Subsequently, EPCs have been identified either by cell surface antigen expression profile or through several in vitro colony-forming assays.

Although no single unique cell surface molecule serves to define an EPC, in human subjects, CD34 expression serves as a fundamental marker.[134,135] CD34 is a sialomucin that is expressed by a host of cells throughout the body including hematopoietic stem and progenitor cells, and approximately 1% of human bone marrow mononuclear cells express this cell surface molecule.[31,136] Other antigens such as CD133 and vascular endothelial growth factor 2 receptor (KDR), which are expressed on a rare subset of the $CD34^+$ cells (1%), appear to contain EPC activity.[134] In fact, some investigators propose that the $CD133^+CD34^+KDR^+$ cells serve as a precursor to the more frequent $CD133^-CD34^+KDR^+$ circulating EPC.[137] Some evidence has also been presented that EPCs may be derived from the $CD34^+$ hematopoietic stem cell, although analysis of additional informative human patients would be important to support or refute the published work as only a limited number of in vivo studies have been published.[138,139] Numerous papers have correlated the concentration of $CD133^+CD34^+KDR^+$, $CD34^+KDR^+$, or $CD34^+$ cells with the risk for development of adverse cardiovascular outcomes and in general an inverse correlation with each of these EPC subsets and highest risk category exists.[140,141]

EPCs have also been defined using in vitro colony-forming assays, and a comparative analysis of the cells identified in these assays will be the focus of this portion of the present review.[133,141,142] In one assay, peripheral blood mononuclear cells are plated on fibronectin coated tissue culture wells. After a 2-day culture, the nonadherent colony-forming unit–Hill (CFU-Hill) are removed and replated into fresh wells coated with fibronectin. The adherent cells (thought to represent blood monocyte and macrophages or mature endothelial cells) are discarded. Within 5 to 9 days, one can identify colonies emerging from the plated cells. The number of CFU-Hill-derived colonies that are present in the peripheral blood of patients inversely correlates with the severity of cardiovascular dysfunction and with the risk of developing worsening cardiovascular disease.[141]

A second assay identifies another type of endothelial colony-forming cell (ECFC).[143,144] In this assay, peripheral blood mononuclear cells are plated on collagen I coated tissue culture wells in an endothelial growth media that contains several growth factors, including vascular endothelial growth factor, epidermal growth factor, insulin like growth factor 1, and fibroblast growth factor 2.[143,145] Media is changed frequently and the nonadherent cells are discarded. In this case, late outgrowth colonies emerge from the adherent cells at 14 to 21 days.[145] These ECFCs display varying levels of proliferative potential, and some cells possess high telomerase activity and robust vessel-forming ability in vitro and in vivo.[143]

Although there are some obvious differences in the early (CFU-Hill) and late outgrowth (ECFC) colony-forming cells, little is known of the origin and relatedness of the CFU-Hill and ECFC. Both populations of EPCs function upon transplantation, to restore blood flow to the limbs of immunodeficient mice in which hindlimb ischemia was induced; in fact, CFU-Hill and ECFCs synergize in some way to provide superior blood flow restoration in comparison to either population alone in this in vivo murine model.[146]

We have recently devised an approach to examine the clonal relationship between CFU-Hill and ECFC.[147] Because some evidence exists for the emergence of CFU-Hill from the hematopoietic stem cell, we reasoned that analysis of CFU-Hill and ECFC derived from the peripheral blood of human subjects suffering from a disease caused by a hematopoietic stem cell clone should allow for determination of the clonal relationship between the EPCs and the hematopoietic stem cell (and identify any clonal relatedness of the CFU-Hill and the ECFC). Polycythemia vera (PV) is a clonal hematopoietic stem cell disorder and the clinical consequences of the increased sensitivity of hematopoietic progenitors, particularly erythroid progeny, to hematopoietic growth factors has been widely reported.[148] The fundamental etiology for PV remains unclear though uniparental disomy of chromosome 9p is a frequent defect in hematopoietic stem cells in PV patients.[149] Most recently, mutations in the *JAK2* gene (located on chromosome 9p) have been identified in PV patients and some patients with other myelodysplastic syndromes.[150–154] The *JAK2 1849 G > T* mutation leads to a gain of function and erythroid progenitor cells become hypersensitive to erythropoietin. We postulated that isolation of blood from PV patients known to carry this mutation (heterozygote or homozygote) should permit us to molecularly identify the CFU-Hill and ECFCs that are derived from plating their peripheral blood mononuclear cells and determine evidence for or against any clonal relatedness of the EPCs.

By definition, EPCs are described as cells that possess the ability to form vessels de novo in vivo.[155,156] A variety of animal models of vascular injury have been developed and the ability of EPCs to home, engraft, and function as vascular endothelial cells has been reported.[157–160] In these injury models, EPCs clearly play a role in restoring blood flow to the injured and ischemic area.[137,161,162] However, the models used do not demonstrate high levels of de novo vessel formation from the infused EPCs. Several years ago, Schechner et al[163] developed an assay to examine the role of human umbilical vein endothelial cells to form blood vessels in collagen/fibronectin gels in immunodeficient mice. This model system was used to examine the role of human endothelial cells to participate in interactions with immune cells in vivo.[164] We speculated that human EPCs implanted in vivo in the same gel constructs may possess de novo vessel-forming ability. When both CFU-Hill and ECFC were plated in collagen/fibronectin gels and implanted subcutaneously in NOD/SCID mice, ECFC gave rise to numerous human blood vessels that had gained access to murine vessels and were perfused with murine red blood cells. Although CFU-Hill survived in the gels upon implantation, they did not contribute to human–murine chimeric vessel formation. These results suggested that CFU-Hill and ECFC vary widely in their functional capacities.

This comparative analysis set the stage for testing whether there is a clonal relationship between CFU-Hill and ECFC.[147] Peripheral blood mononuclear cells from PV patients were plated in both CFU-Hill and ECFC assays. Clones of each type were isolated and DNA extracted. The *JAK2* genotyping was performed and results compared with the known genotype of the PV patient carrying the mutation (heterozygous or homozygous). All of the CFU-Hill displayed the mutant genotype of the hematopoietic stem cell clone. In contrast,

Are Human Endothelial Progenitor Cells Derived from Hematopoietic Stem Cells?—cont'd

nearly all ECFC displayed the wild-type genotype. Thus, CFU-Hill are hematopoietic progeny that do not display vessel-forming ability, whereas ECFC are not clonally related to the hematopoietic stem cell or CFU-Hill.[147]

These are not the first studies to indicate that CFU-Hill are derived from, or in fact represent, hematopoietic cells. Rehman et al[165] previously reported that the adherent acetylated–low density lipoprotein ingesting and *Ulex Europeus* lectin binding cells derived from human peripheral blood are myeloid cells not EPCs. Rohde et al[166] provided compelling evidence that peripheral blood monocytes cultured under the conditions used to generate EPCs take on the physical appearance and gene expression patterns of classically described EPCs. They interpreted their results as evidence that monocytes and their progeny can phenotypically mimic EPCs including the ability to generate CFU-Hill in vitro. Zhange et al[167] reported that culture of peripheral blood cells from normal human adult volunteer's results in formation of cells with features described as EPCs; however, close examination revealed that the cells maintained typical monocytic function and displayed little proliferative potential.

Summation of these recent data, including the clonal analysis and in vivo vessel-forming capacity, simply illustrates the complexity in defining an EPC. Several recent studies indeed implicate an important role for myeloid cells in initiating the early events to promote changes in the endothelial intima to stimulate endothelial sprouting and neoangiogenesis.[168–175] Further studies will be required to specifically determine the role that the hematopoietic derived angiogenic cells and the ECFC play in neoangiogenesis.

of equivalent definitions and assay systems for stem and progenitor cells, (b) a more comprehensive analysis of niche signaling pathways, (c) creation of in vitro systems that reconstitute the in vivo niches, (d) development and use of real-time imaging to analyze stem cell functions within a niche, (e) description of macromolecular assemblies at cellular interfaces within the niche, (f) elucidation of how niche signals couple to stem cell cell-cycle regulation and/or distinct transcriptional programs that modify cell fate, and (g) elucidation of how niches are altered during stress or pathology. Although some advances have been made in some of these areas, most remain targets to achieve for interested stem cell researchers.

SUMMARY

Stem cells reside in specific locations (niches), are not fully differentiated (may not display the appearance or all of the functions of the mature cells of the tissue), possess controlled but robust proliferative potential (at least for the lifetime of the host tissue), and have the capacity to divide into daughter cells, in which one of the daughter cells retains all the properties of the parental cell (self-renewal) and the other daughter adopts a differentiated fate specific for the needs of that tissue. Although much of the control of the stem cell state may be cell-autonomous, the stem cell niche clearly affects the four major HSC states: quiescence, self-renewal, apoptosis, and differentiation. The recent ability to reprogram somatic cells to exhibit ES cell-like activity is an exciting though preliminary step in development of the methods required to manipulate these stem cell states and raises exciting possibilities for expanding a similar paradigm of research on other stem cell types. One may even hope to contemplate development of tools (small molecules, nanotechnology, etc) to reactivate certain stem cell behaviors in situ in affected patients to repair or regenerate dysfunctional tissues and organs. Thus, the ultimate future for stem cell therapy is to manipulate the stem cells within the host rather than utilize adoptive transplant regimes.

CHAPTER 20

CELLULAR BIOLOGY OF HEMATOPOIESIS

Hélène Schoemans and Catherine Verfaillie

INTRODUCTION

Hematopoiesis refers to the process of formation, development, and differentiation of the formed elements of blood. This process originates from hematopoietic stem cells (HSCs). These cells are characterized by the ability to self-renew and differentiate into all mature blood cell lineages. They are also capable of rescuing lethally irradiated hosts by reconstituting the entire repertoire of hematopoietic cells in the recipients.[1]

HSCs are rare, occurring at a frequency of 1 stem cell per 10,000 to 100,000 bone marrow (BM) cells. Under steady state, HSCs are quiescent (ie, noncycling), and only a fraction of the HSCs enter into the cell cycle to proliferate and give rise to differentiated progenitors. However, in response to hematopoietic stress (eg, infections, acute bleeding, or chemotherapy), HSCs proliferate extensively. Self-renewal and differentiation are tightly regulated processes which ensure homeostasis. Deregulation of these processes will inevitably manifest as myeloproliferative diseases (such as acute myeloid leukemia) or as bone marrow failure syndromes (such as aplastic anemia). Understanding the cellular biology of HSCs is therefore essential.

HSC studies began in the mid-1950s, when BM transplants were found to rescue lethally irradiated mice by reconstituting ablated hematopoiesis. In the 1960s, similar transplantation experiments identified primitive hematopoietic progenitor cells as BM clonogenic cells which could give rise to discrete colonies in the spleen of irradiated recipient animals. These cells were also capable of forming more spleen colonies in secondary recipients and were therefore referred to as *colony-forming unit-spleen (CFU-S)*. Later, development of in vitro colony assays of hematopoietic myeloid and lymphoid progenitor cells enabled their enumeration. With the advent of monoclonal antibodies and flow cytometry, HSCs and their progenitors have been further characterized by the presence or absence of specific surface markers and by the ability to efflux fluorescent dyes.[2]

In this chapter, we focus on the contemporary concepts regarding the cellular biology of HSCs and its impact on our understanding of early hematopoiesis, and highlight areas relevant to clinicians and transplant physicians. However, as information on HSC behavior is derived from data generated from different species (zebrafish, mice, human and nonhuman primates) and cell sources (BM, umbilical cord blood [UCB], and peripheral blood [PB]), all conclusions should be interpreted with caution because qualitative and quantitative differences in HSCs are bound to exist.

DEFINING HEMATOPOIETIC STEM CELLS

Embryology and Hematopoiesis

Hematopoietic development is highly conserved among frogs (*Xenopus laevis*), zebrafish (*Danio rerio*), and mammals and originates from mesodermal tissue. During gastrulation, mesoderm is induced by the prospective endoderm and is patterned along the dorsal-ventral axis. Two families of proteins seem to play a pivotal role in this process: bone morphogenetic proteins (BMPs) and hedgehog (Hh) proteins.

Cells from the ventral mesoderm then migrate to the extraembryonic yolk sac (in mammals), the tail (intermediate cell mass in zebrafish), and near the liver (ventral blood island in *Xenopus*), where they generate the first wave of hematopoiesis, called primitive hematopoiesis. *Primitive hematopoiesis* is transient and consists primarily of large nucleated erythroid cells that express embryonic hemoglobin and mature macrophages.[3] In mouse and chick embryos, this occurs around embryonic day 7.5 (E7.5). Morphologic analysis of these tissues showed that the site of primitive hematopoiesis comprises erythroid and vascular endothelial cells. Their proximity suggests that they may be derived from a common precursor, known as *hemangioblasts*. The existence of such a precursor in humans, however, remains difficult to establish as the earliest stages of human development are inaccessible for experimentation. However, human embryonic cell (hES) lines provide an interesting alternative to study this, and several groups have recently shown that culture of hES cells with a cytokine cocktail containing either BMP-4 or serum can give rise to a population of cells displaying both endothelial and hematopoietic characteristics, thus providing compelling evidence for the existence of an early human hemangioblastic founder population.[3,4] This finding may be of importance as ES derived hemangioblasts could serve as an unlimited source of both HSCs and endothelial progenitors for human tissue engineering.[4]

Shortly afterward (E8-8.5 in mice), the second wave of hematopoiesis, called *definitive hematopoiesis*, takes place in the aortic-gonad-mesonephros (AGM) region of the embryo (mammals), dorsal aorta (zebrafish), and dorsal lateral plate (*Xenopus*), where HSCs expand and then migrate to the fetal liver and spleen (in mammals) or the kidneys (in zebrafish) to generate hematopoietic cells of all lineages.[5] The origin of HSCs that gives rise to definitive hematopoiesis remains unclear, although evidence suggests that they may be derived from specialized endothelial cells in the dorsal aorta that differentiates to generate hematopoiesis (the *hemogenic endothelium*).[6] During the late fetal stage, HSCs migrate further to BM and thymus in mammals. These definitive hematopoietic progenitors have the unique ability to generate long-term engrafting HSCs and lymphoid populations, thus sustaining lifelong hematopoiesis.[4] Whether the early HSCs that give rise to primitive and definitive hematopoiesis come from one anatomic site and then migrate to the other or the two forms of hematopoiesis are derived from two entirely different HSC pools remains, however, unclear.[7]

From a clinical point of view, understanding the processes by which hematopoiesis shifts during embryonic development may provide insights into the mechanism of HSC mobilization, which is routinely performed to procure HSCs for transplantation. Previous studies have shown that factors, including interaction between stromal cell-derived factor-1 (SDF-1, also called CXC-ligand-12 or CXCL12) and chemokine receptor 4 (CXCR4)[8] or β_1-integrins,[9] are important for HSC migration during embryonic development.[10] In the setting of clinical transplantation, $CD34^+$ cells mobilized by granulocyte colony-stimulating factor (G-CSF) and chemotherapy (eg, cyclophosphamide) express lower levels of CXCR4 with decreased levels or affinity to $\alpha_4\beta_1$-integrin (an adhesion molecule of the very late antigen-4 [VLA-4] adhesion pathway). In fact, G-CSF mediated murine and human HSC mobilization occurs by accumulation of neutrophil serine protease in BM, leading to proteolytic cleavage and inactivation of CXCR4 and SDF-1.[11] Similarly, AMD3100 is a mobilizing agent which reversibly blocks interaction between CXCR4 and SDF-1, in a more direct manner, resulting in very rapid and efficient mobilization of PB HSCs and is currently under clinical investigation.[12] Murine data also suggests that a large subset of HSCs do not only display CXCR4 but also carry CD26 (cluster of differ-

entiation), a cell surface marker with protease activity, which can cleave the N-terminal portion of SDF-1, thereby eradicating its chemotactic potential, without impacting on SDF-1-CXCR4 interactions.[10] Combinations of G-CSF and CD26-agonists could thus be exploited to improve HSC mobilization in vivo. However, use of these alternative mechanisms in the clinic requires further investigation. The process of homing and the hematopoietic microenvironment are discussed further in Chapter 23.

Finally, the migratory nature of HSCs during embryonic development may also explain their existence in adult nonhematopoietic tissues, and the observation that when they migrate to the BM, they can resume hematopoietic properties. This may be one explanation for the phenomenon of stem cell plasticity reported in recent years.[13] The notion is supported by murine studies showing that the ability of adult skeletal muscle to reconstitute hematopoiesis in lethally irradiated recipients could be attributed to $CD45^+$ $Sca1^+$ stem cells residing in muscles.[13] Likewise, it is possible that adult BM may contain, in addition to HSCs, stem cells capable of reconstituting nonhematopoietic tissues (for more details, please refer to Chapter 22).

Definition of Hematopoietic Stem Cells

The two essential attributes of true HSC populations are their "immortality," as characterized by their *self-renewal* potential and their "undifferentiated" state, whilst being able to give rise to multilineage *differentiation*. At the single cell level, this translates into 4 possible fates: self-renewal, differentiation, migration or apoptosis (Fig. 20–1).[1] This means that the HSC compartment will necessarily contain a population of various cell types with specific potentials.

Self-Renewal

The substantial self-renewal capacity of HSCs is essential to provide a continuous lifelong supply of functional hematopoietic cells.

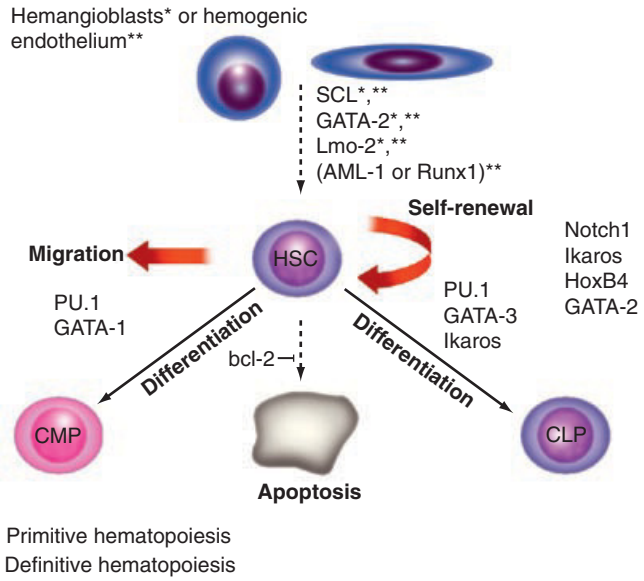

Figure 20–1 DERIVATION AND FATES OF HEMATOPOIETIC STEM CELLS (HSCS). During embryonic development, HSCs may be derived from hemangioblasts (ie, precursors of HSCs and endothelial cells) or hemogenic endothelium (ie, endothelial cells that acquire the potential to generate hematopoiesis). HSCs have one of four fates: self-renewal, differentiation (eventually becoming common lymphoid progenitors or common myeloid progenitors), migration or apoptosis. The cell-fate decision is highly regulated, involving specific transcription factors. *(Adapted from Zhu J, Emerson SG: Hematopoietic cytokines, transcription factors and lineage commitment. Oncogene 21:3295, 2002.)*

From an experimental point of view, this characteristic of HSCs can currently only formally be assessed by evaluating their long-term ability to reconstitute the hematopoietic system of a lethally irradiated host, either in an autologous, allogeneic or xenogeneic setting. In mice, cells capable of unlimited self-renewal are referred to as *long-term repopulating hematopoietic stem cells (LTR-HSC)*. As their self renewal potential decreases, cells are referred to as *short-term-repopulating HSC (STR-HSC)* and *multipotent progenitors (MPP)* respectively (Fig. 20–2).[14] These cells, together with more differentiated progenitor cells, will therefore essentially provide transient hematopoiesis to bridge the aplastic period following lethal irradiation, but will not give rise to long term sustained hematopoiesis.

The earliest description of HSCs was based on studies showing that murine BM transplanted into lethally irradiated mice was able to rescue the recipient by reconstituting donor hematopoiesis. Likewise, human HSCs are characterized by their ability to home to BM and to reconstitute hematopoiesis in xenogeneic transplantation models using sub-lethally irradiated immunodeficient mice or nonirradiated preimmune fetal sheep (Xenogeneic Models of Human Stem Cell Engraftment).

Self-renewing divisions of HSCs can be *symmetric*, in which one HSC gives rise to two identical HSC daughter cells, or *asymmetric*, in which one daughter cell remains as an HSC and the other differentiates or undergoes apoptosis (see Fig. 20–1). The ability of HSCs to self-renew and to maintain hematopoietic homeostasis indicates that, on average, most HSC divisions yield at least one daughter cell which remains as an undifferentiated HSC. However, HSCs must be able to respond to hematopoietic stress by population expansion. Under those circumstances, HSCs probably divide symmetrically into two identical HSCs to replenish the depleted HSC pool. HSCs can also undergo *apoptosis*, because overexpression of *Bcl2* (an anti-apoptotic gene) in transgenic mice increases the number of HSCs and enhances competitive repopulation cell frequency, suggesting that apoptosis is an important mechanism for controlling HSC turnover during steady state conditions.[15]

Finally, the self-renewal potential of HSCs is thought to be partially associated with the activity of telomerase, a reverse transcriptase which makes new telomeric DNA. Telomeric shortening during cell division is secondary to incomplete replication of the lagging strand by the conventional DNA polymerase during chromosomal replication and is associated with replicative senescence.[16] However, despite the fact that HSCs express some telomerase activity, replication of HSCs is finite, as they can be serially transplanted only five to seven times in mice.[17] In humans, HSCs also undergo telomeric shortening after repetitive cell division, particularly when occurring under stress, such as during transplantation,[18] though this does not seem to have clinical relevance to date. These observations suggest that the telomerase activity in HSCs, although endowing them with substantial self-renewing potential, may not be sufficient to prevent telomeric shortening during the stress of replication. Further evidence for this comes from disease states such as dyskeratosis congenita where inherited defective telomerase activity is associated with bone marrow failure. In aplastic anemia and paroxysmal nocturnal hemoglobinuria a correlation between telomere shortening and the degree of pancytopenia has also been found; however, whether this is a consequence of increased HSC turnover or caused by a telomere-mediated replicative exhaustion of the HSC pool remains to be answered.[16]

Multilineage Differentiation

HSCs are capable of differentiating into all mature hematopoietic cell lineages. As HSCs divide, they generate differentiated progenies, which gradually display an increasingly limited capacity to self-renew and much more restricted differentiation options.[19] The first cells committed to lymphoid and myeloid lineages are called *common lymphoid progenitors (CLP)* and *common myeloid progenitors (CMP)* (see Fig. 20–2).

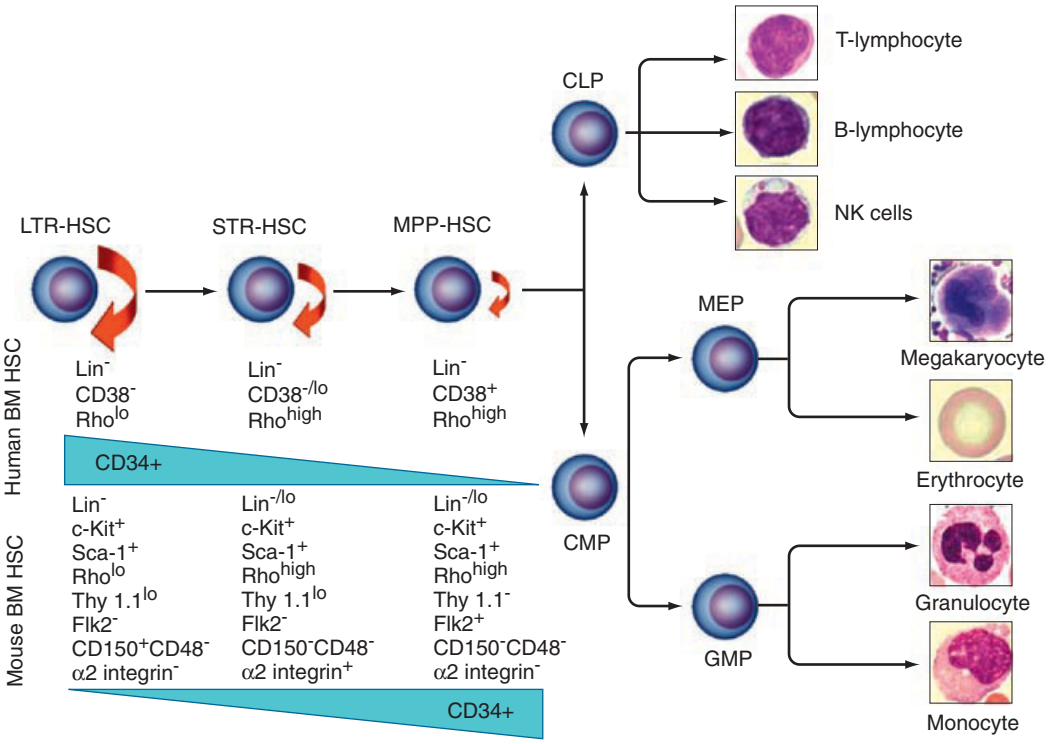

Figure 20–2 THE HEMATOPOIETIC HIERARCHY. As hematopoietic stem cells progressively differentiate, they acquire different phenotypes and are successively referred to as LT-HSC (long term HSC), ST-HSC (short term HSC) and MPP-HSC (multipotent progenitor HSC). The MPP-HSCs then give rise to common lymphoid and common myeloid precursor cells (CLP and CMP respectively) that eventually generate all mature blood lineages of the body (GMP, granulocyte-monocyte precursors; MEP, megakaryocyte-erythrocyte precursors; NK, natural killer). *(Adapted from JA, Negrin RS, Weissman IL: Hematopoietic stem and progenitor cells: clinical and preclinical regeneration of the hematolymphoid system. Annu Rev Med 56:509, 2005.)*

Xenogeneic Models of Human Stem Cell Engraftment

The ability to engraft myeloablated recipients and reconstitute long-term, multilineage hematopoiesis remains of the only definition of HSCs. To study human HSCs, different doses of HSCs from different sources or different culture conditions can be transplanted into xenogeneic hosts, which are sacrificed and analyzed at defined times after transplantation. The key feature of these animals is their immune-incompetence, which allows for xenogeneic engraftment of human HSCs.

Mouse Transplantation Models

Earlier studies, using heavily irradiated mice and mice homozygous for the *nude* gene *(Hfh1l^{nu})*, were hampered by low levels of human HSC engraftment. Newer models have been developed, including mice that are null for the *b*eige, *n*u, and *X*-linked immunodeficiency loci (ie, *Bnx mice*); mice deficient in *recombination activating genes (Rag1 and Rag2)*, and mice that are homozygous for the *Prkdc^{scid}* (ie, *SCID mice*). The *severe combined immunodeficiency (SCID)* mutation was described in mice in 1983 and is related to a nonsense mutation of a *protein kinase DNA-activated catalytic polypeptide (Prkdc^{scid})*. Homozygous mutation of this gene results in defective activation of a DNA recombinase (which requires a functional *Prkdc* gene) and consequently gives rise to defects in humoral (B-cell) and cell-mediated (T-cell) immunity (ie, adaptive immunity). The latter model has been extensively studied and forms the platform for the development of the *NOD/SCID* model.[165] A number of experimental models have been developed based on these animals, including the *SCID-hu* mice (ie, human fetal liver or bone marrow transplanted under the renal capsule of SCID mice), the *triple chimeric* mice (ie, lethally irradiated normal mice transplanted with BM from SCID mice, followed by a large dose of human BM cells), and a model in which human HSCs are injected intravenously into *irradiated SCID* mice. However, human HSC engraftment in these models remains low because the animals have enhanced innate immunity in compensation for the defective adaptive immunity. Natural killer (NK) cell, granulocyte, and macrophage function and hemolytic complement are increased, accounting for graft rejection and the low rate of engraftment in these animals.

The *nonobese diabetes (NOD)* mouse is an animal model of spontaneous autoimmune T-cell-mediated, insulin-dependent diabetes mellitus (IDDM). They are defective in innate immunity, including NK and macrophage activity, and they lack C5 and are therefore deficient in hemolytic complement activation. *NOD/SCID* mice are generated by crossing SCID mice with NOD mice. Therefore, they are defective in adaptive and innate immunity and they do not develop insulinitis or insulin-dependent diabetes mellitus. When human HSCs are injected intravenously into irradiated NOD/SCID mice, the combined immunodeficiency in these animals facilitates a more robust engraftment compared with the SCID model. Differentiated cells (predominantly of myeloid and B-cell lineages) can be detected in the BM of recipients, but human T-cell development is lacking. A caveat about the NOD/SCID model, however, is that these animals retain some residual NK activity and express disparate *major histocompatibility (MHC) loci*, limiting engraftment of human HSCs. To circumvent this limitation, mice deficient in *β_2-microglobulin (β_2m^{null})*, which is required for MHC I expression, have been backcrossed onto NOD/SCID mice. The resulting *NOD/SCID/β_2m^{null}* mice support five-fold to tenfold higher levels of human cell engraftment. However, because these animals are even more vulnerable to thymic lymphoma and are more radiosensitive than NOD/SCID mice, their lifespan is

Xenogeneic Models of Human Stem Cell Engraftment—cont'd

often shorter. The use of *NOD/SCID/common cytokine receptor γ chain (γc)* triple mutant mice[153] or infusion of antibodies against a sialoprotein or Il-2Rβ can also improve transplantation results by hindering NK response.

Sheep Transplantation Models

In the fetal sheep model, human HSCs are injected in utero into preimmune fetal lambs, and the permissive fetal environment enables long-term HSC engraftment into postnatal life and multilineage differentiation, including myeloid, T, and B cells.[166] Similar to the murine models, only recipients transplanted with $CD34^+CD38^-$ cells (but not those with $CD34^+CD38^+$) exhibit long-term engraftment during serial transplantations. The model does not involve recipient myeloablation or irradiation, and human HSC engraftment can be further enhanced by stimulating the recipients in vivo with human growth factors. The expense of this model, however, has hampered its widespread application.

Nonhuman Primate Transplantation Models

An autologous transplantation model using nonhuman primates, including rhesus macaques (*Macaca mulatta*) and baboons, has begun to shed light on HSC behavior during transplantation. This model is used to provide information on how an individual HSC is related to total hematopoiesis after transplantation.[167] One way to track individual HSCs is by retroviral marking. Because retroviruses integrate randomly into the host genome, the DNA sequence flanking the viral integrant is unique to each host cell, enabling tracking of progeny (clone) from individual cells in vitro or in vivo. There are advantages in using nonhuman primates for this purpose. First, compared with murine models,[40,168] the high genetic and biological similarity within the primate family provides more reliable data regarding human HSCs. Second, the longevity of nonhuman primates (up to 30 years) allows long-term tracking of HSCs after transplantation, which is not possible with small animal models. Third, cross-reactivity of cytokines and antibodies enables the use of human cytokines for peripheral blood mobilization and anti-human antibodies for HSC phenotypic characterization. Autologous transplantation circumvents the problems of homing inherent to the xenogeneic transplantation models when using mice and fetal sheep. Using rhesus macaques and baboons, it has been demonstrated that a single HSC clone is capable of generating mature and functional cells of lymphoid and myeloid lineages, reiterating the multipotency of transplanted HSCs.[169] Moreover, mature progeny from a single HSC clone persists for at least years, demonstrating for each individual HSC the capacity for sustained long-term hematopoiesis after transplantation. More importantly, multiple integration sites can be identified in mature progenies, suggesting that the HSC population that gives rise to hematopoietic reconstitution is highly polyclonal.[169,170] Because of the close resemblance to humans and the advantages described, these primate models may also become a powerful tool to investigate the effect of clinically relevant manipulations such as cytokine stimulation, chemotherapy, and irradiation on hematopoiesis.

$CD34^+$ or $CD34^-$: The Changing Paradigm

CD34 is a sialomucin-like adhesion molecule expressed on 1% to 5% of mononuclear cells, including hematopoietic stem and progenitor cells, vascular endothelial cells, and some fibroblasts. One of the earliest studies supporting the notion that CD34 was a marker of HSCs was reported 15 years ago by Berenson and colleagues.[154] Autologous $CD34^+$-enriched bone marrow (BM) cells were used to engraft lethally irradiated baboons. Two other animals received CD34-depleted marrow; one animal died of nonengraftment on day 29, and the second animal suffered from prolonged pancytopenia. In mice, however, it has become clear that HSCs are $CD34^{-/lo}$ and single $CD34^{-/lo}Kit^+Sca^+Lin^-$ cells transplanted into recipients can reconstitute long-term myelolymphoid hematopoiesis.[155] Murine BM side-population (SP) cells, which are highly enriched in HSCs, are also $CD34^-$.

A model has evolved in which expression of CD34 on murine HSCs varies with HSC activation.[156] Murine HSCs from resting BM of adult mice are $CD34^-$. On activation by 5-fluorouracil (which recruits quiescent HSCs into the cell cycle by depleting marrow of committed progenitors), administration of stem cell factor, or during in vitro culture, some of the $CD34^{-/lo}$ HSCs convert to a $CD34^+$ phenotype. After transplantation, HSCs lose CD34 expression as they become quiescent again in the recipient bone marrow. Interestingly enough, CD34 expression has also been shown to be present in stem cells from neonatal to five-week-old mice, and then to progressively disappear.[157] The same reciprocal relationship is true for CD38 expression, which is typically negative in primitive human HSC and present on steady state murine HSC. Upon activation however, murine HSC can transiently lose CD38 expression.[157]

In humans, $CD34^+$ cells derived from BM, mobilized peripheral blood, and umbilical cord blood (UCB) are able to engraft and repopulate NOD/SCID mice and fetal sheep. It is also clear from clinical observations that such a population of cells contains cells with long-term engraftment ability. A comparison between $CD34^+$ and $CD34^-$ cells showed that the latter made only minor contributions to human cell engraftment in NOD/SCID mice.[158] This has lead to the dogma that human HSCs are $CD34^+$. Consequently, CD34 expression is used clinically to enumerate transplantable cells, since the dose of $CD34^+$ cells can predict the outcome after transplantation.[159] However, there is evidence that human BM $CD34^-Lin^-$ and UCB $CD34^-Lin^-CD38^-$ cells can engraft long term and give rise to multi-lineage differentiation in NOD/SCID mice and fetal sheep.[160,161] $CD34^-Lin^-$ cells are much less clonogenic in vitro but can generate $CD34^+$ cells in vitro and in vivo. The clonogenicity and the ability to engraft in NOD/SCID mice and generate $CD34^+$ cells in liquid culture of $CD34^-Lin^-CD38^-$ cells appears to be confined to a small population that are $CD133^+CD7^-$, suggesting that $CD34^-Lin^-CD38^-CD133^+CD7^-$ may define a very primitive, but also very rare (0.02%), cell population.[41,162] Similar to murine HSCs, the expression of CD34 on human HSCs may be reversible, because $CD34^-CD38^-$ cells transplanted into Bnx mice could give rise to $CD34^-$ progeny, which revert to a $CD34^+$ phenotype upon transplantation into secondary recipients.[163]

The question of whether the most primitive HSCs are $CD34^+$ or $CD34^-$ remains unanswered.[164] The laboratory findings supporting the notion that $CD34^-$ cells are more primitive than $CD34^+$ cells appear at odds with the clinical experience that patients receiving positively selected $CD34^+$ transplants have stable, long-term engraftment. If the most primitive HSC are $CD34^-$, recipients of highly purified $CD34^+$ positively selected transplants may develop late graft failure when these $CD34^+$ progenitors become exhausted, although no evidence has suggested this to be the case.

Common lymphoid progenitors further divide and differentiate into lymphocyte progenitors capable of generating the *T*, *B* and *natural killer (NK)* cells. Common myeloid progenitors give rise to *granulocyte-monocyte progenitor cells* and *megakaryocyte-erythrocyte progenitor cells*. The former develops into granulocytes and monocytes, and the latter develops into platelets and erythrocytes. It was once firmly believed that after a cell was committed to a given lineage, it could no longer change its fate. More recent studies, however, showed that lineage-committed cells (mostly from lymphomatous and transformed cells but also normal murine hematopoietic cells) under specific cytokine stimulation can switch between myeloid and lymphoid fates. This change may even be possible for more differentiated progenitors.[20] Whether and how this reported phenomenon of transdifferentiation between blood lineages contributes to normal hematopoiesis is unknown.

CHARACTERIZING HEMATOPOIETIC STEM CELLS

The study of HSCs is often hampered by their scarcity in hematopoietic tissues and the lack of specific markers and tests for identifying HSCs that fulfill all the defining features of stem cells, including their ability to sustain a long-lasting multi-lineage clone in vivo. Generally speaking, HSC characteristics can be assessed using assays in the in vivo setting, long-term in vitro cultures or based on cell surface and molecular markers. In most circumstances, a combination of tests will need to be used to identify and isolate HSCs, resulting in populations displaying various degrees of purity. The following section describes methods used for HSC characterization.

In Vivo Characteristics

The only true definitive assay for HSCs is based on their ability to reconstitute the entire hematopoietic system of a myeloablated recipient, the two major endpoints being longevity and multi-potentiality. *STR-HSC* have limited self-renewal capacity (they appear after approximately 2 weeks and disappear 4 to 6 weeks later) but can rescue animals from otherwise lethal radiation-induced pancytopenia. These cells can be further divided into day 8 or 12 *colony forming unit spleen (CFU-S),* according to the time elapsed before they form colonies in a recipient spleen. *Pre-CFU-S* are slightly more primitive cells which are identified in the bone marrow of recipients after 15 days and are defined by their ability to produce *CFU-S* in secondary recipients.[21] *LTR-HSC* have also been identified: they protect against irradiation and give rise to long-term hematopoiesis following serial transplantations.[22] The latter can be enumerated by a *competitive repopulating unit (CRU) assay*. In this assay, hematopoietic cells from a test mouse are mixed with various proportions of those from a competitor mouse before injection into a lethally irradiated recipient mouse. Using a limiting dilution assay, the frequency of LTR-HSCs in the test mouse is measured by their ability to compete for engraftment in the recipient mouse. Typically, Poisson statistics predict that mice are reconstituted by a single LTR-HSC when 33% of transplanted hosts are reconstituted (defined as at least 1% of donor derived cells from both the myeloid and lymphoid lineage identified 3 to 4 months after transplantation).[21]

In humans, HSC enumeration is more difficult because a competitive repopulation assay can clearly not be performed. Instead, *xenogeneic transplantation* models (Red Box 1) have been developed in which human hematopoietic cells are injected into sublethally irradiated, immunodeficient mice or nonirradiated, preimmune fetal sheep. The presence of human hematopoietic cells in BM of recipient animals, characterized by the expression by more than 1% of the cells of the human pan-leukocyte antigen CD45 or the presence of 0.1% to 1% human specific DNA in the bone marrow of mice (in contrast to murine studies where engraftment can be assessed by analysis of the peripheral blood), has been used to determine successful engraftment and the presence of HSCs in the injected cell population. These cells are referred to as human *SCID-repopulating cells (SRC)*. Ideally, identification of not only CD45+ cells but also myeloid as well as lymphoid cells should be used to further demonstrate the presence of SCID-repopulating cells. In all of these models, however, enumeration of transplanted human HSCs is complicated by their xenogeneic nature (leading to homing problems and risk of immunological rejection), and true information on competitive engraftment is not available.

In Vitro Characteristics

There is as yet no in vitro assay that specifically detects HSCs. However, a number of different methods can assess two crucial characteristics of these cells, namely: proliferation and differentiation potential. Experimental conditions should therefore meet the specific requirements of each type of progenitor, while excluding the growth of others. Most of the time, this will require using different methods to avoid underestimating the proliferation and differentiation potential of a given cell. These methods are available for murine and human HSCs and can be categorized according to two different parameters: *short-term* (evaluating approximately 5–10 cell divisions over a maximum of 3 weeks) versus *long-term* assays (evaluating more than 15 cell divisions over a period exceeding 5 weeks) and *clonal* versus *polyclonal* expansions. Clonal assays are single cell cultures, in which each progenitor remains separated and the size of the colony reflects the proliferative potential of the progenitor. The major caveat of these studies is of course that the purified cells are also physically isolated from their normal neighboring cells. Another option is to study cells in their cellular context, inferring the number of progenitor cells with the desired function from statistical methods (law of Poisson, discussed above) based on the maximum likelihood of occurrence of an unlikely event, ie differentiation.[21]

Short-Term Assays

These tests evaluate and quantify lineage restricted progenitors in well-standardized conditions. They are not suitable for identifying very immature progenitors because the lifespan of the viscous medium used typically does not extend beyond three weeks and cannot be renewed. Liquid cultures can also be used, but require clonal cultures and subsequent flow cytometry analysis to identify progeny. Generally speaking, progenitors with different levels of maturity can be recognized from their sensitivity to cytokines, the time required to generated differentiated cells and the size of colonies. These progenitors are then referred to as *CFC (colony forming cells)*, and lead to *CFU (colony forming units),* referring to their more differentiated progeny, followed by a hyphen and the first letter of the lineage produced (eg, CFU-E for erythroid, etc.).[21]

Long-Term Assays

Extending culture time beyond three to five weeks (typically 5–8 weeks), will allow for differentiation of more immature progenitors, while ruling out any contribution of surviving CFC. All of these assays are performed on feeder layers of supportive cells, mesenchymal bone marrow cells or immortalized murine bone-marrow derived stromal cell lines. Two different cells types can then be identified: *LTC-IC (long-term culture initiating cells),* whose progeny will be identifiable in the supernatant or feeder and whose myeloid differentiation potential is assessed in subsequent short term assays; and *CAFC (cobblestone area forming cells)*, referring to the appearance of colonies as they integrated into the feeder layer. The interpretation of LTC-IC and CAFC assays is further hindered by the heterogeneous nature of the LTC-IC/CAFC compartment whose progeny can vary widely under identical conditions. When the original culture time on feeder layers is extended to 10 to 12 weeks, these cells are referred to as *ELTC-IC (extended LTC-IC)*. The CAFCs can be

counted directly on the initial feeder layer, but this analysis must be performed at limiting dilutions to prevent overlap of cobblestone areas and stromal cells must be prescreened as only some will integrate CAFC. In mice, CAFCs correlate well with numbers of long-term repopulating cells but in humans, these cultures enumerate lineage-committed progenitors, and none of them on their own can predict HSC number.

Secondly, it is essential to realize that these culture conditions in general only give rise to myeloid progenitors. Studying evolution to B, T of NK cell differentiation requires other specific culture systems. While B cells can be generated in liquid media and analyzed by flow cytometry, T-cells ideally require reconstitution of a thymic three-dimensional architecture in *fetal thymus organ culture (FTOC)* (which is possible in mice by using embryonic day 14 thymic lobes depleted from their endogenous T cell populations, but obviously not feasible in humans) to perform quantification of T-cell progenitors using limiting dilutions.[23] Other options include the use of murine stromal lines expressing the Notch ligand Delta-1, however, this simultaneously impairs B cell differentiation and thus precludes simultaneous detection of B and T cells from single progenitors.[24] Specific long term cultures using murine fetal liver cell lines on BM stromal cells, human serum and recombinant interleukin-2 (IL-2) have also been useful in identifying precursors of the natural killer (NK) cell lineage.[25]

Switch Culture Systems

In addition to lineage-specific cultures, *switch culture systems* have been developed in which multipotent human hematopoietic cells can be enumerated. In principle, a switch culture system involves sorting single hematopoietic cells of a primitive cell phenotype into a primary culture system to enable clonal proliferation followed by subculturing its progeny in conditions that facilitate myeloid or lymphoid differentiation. The ability of single-cell–derived progeny to differentiate into myeloid and lymphoid lineages is considered evidence that the initial cell is multipotent. For instance, when single human $CD34^+CD38^-$ cells are grown on the murine stromal line S17 for 1 week and progeny that are $CD33^-CD19^-$ are then transferred into myeloid-specific conditions, they become $CD33^+$ and give rise to CFCs, but when transferred into B-lymphoid-specific conditions, they become $CD19^+$.[26] When single human BM $CD34^+Lin^-DR^{dim}$ cells or UCB $CD34^+CD38^-Lin^-$ cells are cocultured with the murine liver AFT024 cell line for 2 to 4 weeks, followed by re-plating progeny into myeloid and lymphoid systems, they generate primitive myeloid and lymphoid progenitors that are capable of reinitiating long-term myeloid and lymphoid hematopoiesis in vitro and known as *myeloid-lymphoid initiating cells (ML-ICs)*.[27,28] Other studies demonstrated that ML-ICs, in addition to their multi-lineage differentiation capacity, can also self-renew. The ML-IC assay therefore may measure cells that closely resemble true HSCs. A common caveat of all these systems, however, is their inability to measure homing and engraftment of putative HSCs into BM, which can be accomplished only by using transplantation models.

MOLECULAR MARKERS

There is unfortunately no unique unambiguous surface marker that identifies HSCs. However, some combinations of markers are currently being used to define stem cell populations, with various degrees of purity. These markers however differ between species (cf. Fig. 20–2).

Surface Markers

In the mouse, phenotypic analysis of BM and fetal liver cells has identified a population of hematopoietic cells highly enriched for HSCs. This population in BM is *c-Kit$^+$ (receptor for stem cell factor)*, *Thy1^{low} (thymus cell antigen 1), Sca1$^+$ (stem cell antigen)*, and *Lin$^-$ (lineage negative, ie negative for granulocytic, erythroid, and lymphoid antigens)*. This phenotype is often referred to as the *'KTLS' phenotype* and corresponds to about 0.1% of all BM nucleated cells. Since Thy1 is not expressed by all mouse species, cells are sometimes referred to as having a *'KLS'* phenotype, but its use can also be replaced by the absence of *fetal liver kinase 2 (Flk2* also referred to as *Flt3 receptor or fms-related tyrosine kinase 3*[29]*)* on BM cells to identify LTR-HSC.[30] Murine fetal liver HSCs, by contrast, have a slightly different phenotype, expressing other markers such as *AA4.1* and *Mac1$^+$*, while $FLK2^+$ cells will also display some long term repopulating activity.[30,31]

One murine KTLS cell can reconstitute stable long-term multilineage hematopoiesis after transplantation in about 10% of transplanted mice. This suggests either that this population is not totally pure, that some cells transiently lose their engrafting potential, or that only a random proportion of cells properly homes to the bone marrow. Most of these cells will also be $CD34^{-/lo}$ especially in adult mouse BM (this is only the case in 50% of the BM of juvenile mice, and could also be dependent on the activation status of the cell).[32] Combining both phenotypic features, KLS and $CD34^{-/lo}$ identifies a near to homogenous HSC population. The frequency of the latter cells within BM has been estimated to be approximately 0.004%.

It is however possible to further refine this population by using other surface markers such as *signaling lymphocytic activation molecules (SLAM),* for example, CD150, CD41, and CD48. $CD150^+CD48^-$ cells will lead to long term reconstitution of 21% of mice transplanted at the single cell level, whereas combination of these markers with the "KLS $CD34^{-/lo}$" phenotype will yield a 47% reconstitution under similar conditions. However, the $CD150^+CD48^-$ KLS $CD34^{-/lo}$ cell population represents only 0.00125% of murine BM.[33,34] These markers are conserved across mice strains and give consistent results in old, reconstituted and cyclophosphamide/GCSF mobilized mice.[34,35] Alternatively, KLS cells have also been sorted according to expression of Tie2, which identifies a subpopulation of quiescent HSCs with long term repopulation ability, shown to be equivalent to side population BM HSCs (see next section on dye exclusion).[36] Finally, the 5% to 15% of KTLS cells expressing low levels of *α2 integrins* also show robust multilineage long term engraftment in contrast to their $\alpha2^+$ counterparts, which are enriched for STR-HSC.[37] This is relatively surprising considering that α2 integrin expression is subsequently lost again by the more differentiated progenitors.[37] Several new positive markers of stem cell populations include *CD201* or *EPCR (endothelial protein C receptor), CD 105* or *endoglin (a component of the TGF-β receptor)* and the *FGFR (FGF receptor)*, which are currently under investigation.[32] Interestingly enough however, it has also been shown that the antigens used to potentially characterize HSCs can vary depending on their cellular activation status, without affecting their regenerative potential, making the marking of "stemness" even more elusive.[38]

In humans, however, the phenotypic features of HSC are less well defined. In contrast to mice, CD34 is expressed on about 1% to 4% of BM cells and contains the majority of cells with in vivo repopulating potential. However, selection of cells based on CD34 expression alone yields a very heterogeneous population of cells of which 20% have CFC activity, 1% LTC-IC and <0.1% SCID-repopulation activity. Based on xenogeneic transplantation into non-obese diabetes/severe combined immunodeficiency (NOD/SCID) mice and on results of in vitro assays, human HSCs can be further characterized by isolating the $CD38^{-/lo}$ fraction of $CD34^+$ cells.[39,40] Alternatively, the subset of $CD34^+$ cells that coexpressed CD133 (also referred to as human homolog of *prominin 5 transmembrane glycoprotein or PROML1*) corresponds to a very primitive population of HSC, as they seem highly enriched for long-term repopulation potential in NOD/SCID mice.[41] Some studies have suggested that $CD34^-CD38^-Lin^-$ cells are also capable of engraftment and multilineage differentiation in NOD/SCID mice and that CD34 expression can be acquired from $CD34^-$ cells after in vitro culture, challenging the dogma that human HSCs are $CD34^+$ (cf. Red Box 2). However, the true importance of the CD34- fraction in hematopoietic reconstitution from

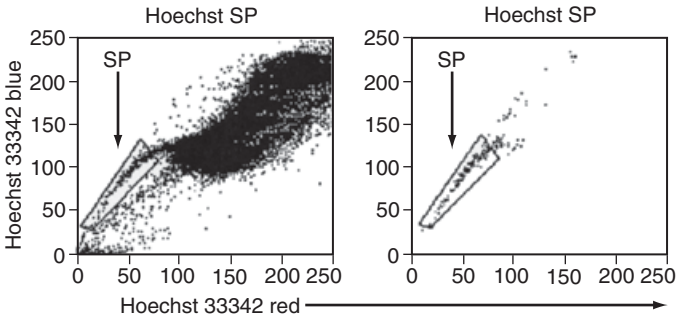

Figure 20–3 Hoechst-33342 side-population (SP) analysis identifies primitive hematopoietic stem cells (HSCs). In the mouse, there is significant overlap between the SP and KTLS phenotype (ie, murine HSC phenotype). SP cells have been identified in hematopoietic and nonhematopoietic tissues from multiple species and are generally considered primitive stem cells. *(Adapted from Bunting KD: ABC transporters as phenotypic markers and functional regulators of stem cells. Stem Cells 20:11, 2002.)*

human BM remains unknown. Other markers used to further define human stem cells are *CDCP1 (Cubdomain containing protein)*, *c-Kit* (which is expressed on about 2/3 of CD34+ cells) and *VEGF receptor 1 and 2* (also called *KDR*) which are expressed on about 5% and 0.1 to 0.5% of $CD34^+$ cells respectively and seem to include the majority of NOD/SCID activity.[32]

Dynamic Methods of HSC Isolation

Another potential strategy to isolate HSC is to make use of detection of enzymatic activity to select for cells which express high levels of specific enzymes. Murine and human HSCs are able to efflux DNA dyes, including *Rhodamine-123 (Rho)* and *Hoechst-33342 (Ho)* dyes, via at least two ATP-binding cassette (ABC) transporters: the *multidrug-resistance P-glycoprotein (MDR1)* and the *breast cancer-resistance protein (BCRP),* with a certain level of redundancy between these two transporters.[42] These complexes transport Rhodamine-123 and Hoechst-33342 dyes out of the cells through an ATPase-dependent process resulting in a small but distinct subset of cells referred to as *side population cells (SP)*, further characterized as Hoechst or Rhodamine low when a low amount of the fluorescence is displayed simultaneously in two emission wavelengths (Fig. 20–3).[43,44] The physiological function of these transporters in HSCs is unclear, but their ability to efflux dye can be exploited to distinguish HSCs ($Rho^{-/lo}$, $Hoechst^{-/lo}$) from committed progenitors (Rho^{hi}, $Hoechst^{hi}$), as cells exhibiting the highest efflux activity are the most primitive or least restricted in terms of differentiation potential. In mice, SP cells account for about 0.05% of all bone marrow cells, and are enriched 1000 to 3000-fold for stem cell activity.[42] It is however possible to further purify these cells. Selecting only the SP cells with *very low dye efflux* identifies a population referred to as SP^{low} which only comprises 0.005% of all BM cells and overlaps with other phenotypic markers known to identify HSCs (KTLS, $CD34^{-/lo}$, $Tie2^+$ and $Flk2^-$), whilst showing long term repopulating efficiencies of about 35% in lethally irradiated mice.[36,45] It must be noted however, that similarly to antigenic phenotyping, dye efflux has been shown to vary with developmental stage (it is almost absent in fetal liver and bone marrow from young mice, whereas it is present in adult mouse bone marrow) and activation status of HSCs (ie, lost upon activation and differentiation).[38] It is therefore enticing to speculate that both surface markers and dye transporters are mediated by a common pathway involving perhaps cell cycle check points.[38]

In human cord blood, highly purified $CD34^+CD38^-Lin^-$ cells capable of initiating myeloid and lymphoid hematopoiesis are almost exclusively Rho^-.[28] These cells have a high SCID repopulating efficiency (1:30 instead of 1:600 for the total population of $CD34^+CD38^-Lin^-$), thus they can be expected to contain most long-term repopulating cells.[46]

Aldehyde Dehydrogenase (ALDH), an enzyme responsible for oxidizing a variety of aldehydes including vitamin A, is also highly expressed in primitive hematopoietic cells in a number of species and its activity can be detected by supplying cells with polar fluorescent products which will accumulate in cells displaying a high enzymatic activity. This makes it possible to detect potential HSCs which will appear brighter on flow cytometry analysis *($SSC^{lo}ALDH^{br}$ cells)*. *$SSC^{lo}ALDH^{br}$ cells* represent about 1% of UCB cells.[47] Combining this method with conventional CD34 staining, makes it possible to identify two cell populations: the *$ALDH^{br}CD34^+$ cells*, enriched for short term and long term SRC as well as myeloid progenitors, and the *$ALDH^{neg}CD34^+$ cells*, displaying low repopulation activity and possibly enrichment for lymphoid progenitors determined using short term cultures.[48] Hess and colleagues showed that although *$ALDH^{br}CD133^+Lin^-$ UCB cells* contain both the $CD34^+CD38^-$ and the $CD34^-CD38^-$ subsets, they are enriched for HSC as there is a tenfold enhancement of hematopoietic repopulating capacity compared to $CD133^+Lin^-$ cells in a *NOD/SCID/β_2m^{null}* mouse transplantation model.[49] A major advantage of this type of technique is its potential clinical application as the use of toxic DNA intercalating dyes discussed above cannot be used for clinical procedures. In fact, preliminary data already suggests that ALDH activity could be a better predictor of graft quality than $CD34^+$cell content.[50] The actual function of ALDH in HSC metabolism remains unknown, but it was recently demonstrated that addition of ALDH inhibitors to standard cytokine-based human HSC expansion cocktails could potentially lead to preservation of long term repopulating potential of BM and UCB HSCs in a NOD/SCID transplantation model.[51]

A frequent problem with use of dye exclusion and enzymatic activity to identify stem cells, however, is that both are dynamic processes. This implies that slight variations in protocols (eg. tissue dissociation, cell counting, dye concentration, staining time, temperature, FACS gating) can dramatically influence viability, homogeneity and yield of SP cells.[42] Consequently, results from different studies are often difficult to compare and can sometimes considerably differ.

HSC FATE AND REGULATION OF HEMATOPOIESIS

The mechanisms regulating HSC self-renewal, differentiation or apoptosis are intensively studied as it is clear that these cell-fate decisions are responsible for homeostasis. Furthermore, from a clinical point of view, understanding these mechanisms is crucial in many hematopoietic malignant diseases and could be used in developing optimal HSC expansion systems suitable for clinical transplantation.

The first model that attempted to describe cell-fate decisions in hematopoiesis was proposed by Till and McCulloch in 1961.[52] In this model, HSCs would *randomly* commit to self-renew or differentiate: this is called the *stochastic* model. In fact, several studies, where single murine or human HSC clones were followed by viral marking, recently stressed the unpredictability of clonal behavior.[53,54] Results derived from other studies, however, support the *deterministic* model, where the central concept is that the *microenvironment* in which HSCs reside determines whether they self-renew or differentiate.[55] It is possible that the very early decision of HSCs to self-renew or differentiate may be stochastic but that subsequent lineage differentiation and maturation of progenitor cells is instructed by external cues from the microenvironment.[40] However, one could also argue that chance is often the most satisfactory answer for unexplained phenomenon and that stochastic cell decisions simply remain to be understood.

Gene expression in hematopoiesis involves both intrinsic and extrinsic regulation pathways. This has been approached from different angles. Some genes, such as transcription factors and genes involved in epigenetic regulation (including subsets known to be aberrantly expressed in leukemia), have been studied using various

loss-of-function (knock-out) and gene overexpression studies (for discussion of transcriptional regulation of hematopoiesis, see Chapter 21). Another approach is to compare the transcriptomes of stem cell populations with variable self-renewal potential, to get a broader picture of the intrinsic regulation at work in determining HSC fate. Finally, cell cycle modifications and signals emanating from the microenvironment are also being investigated to single out important components responsible for preserving stem cell function.

HSC INTRINSIC REGULATION

Transcription Factors

In vertebrates, the stem cell leukemia gene (*SCL*, also known as *TAL1*), Lim-only protein 2 (*LMO2*), *GATA2*, *AML1* (also called *RUNX1*) and *MYB* are all indispensable for hematopoietic specification during embryonic development. Their gene activation profile during hematological ontogeny has been described in vertebrate systems (see Fig. 20–1).[6,7,19] *SCL, LMO2* and *GATA2* are expressed at the hemangioblast and HSC level and are indispensable for primitive and definitive hematopoiesis.[56–58,59] whereas *AML1* and *MYB* are exclusively involved in definitive hematopoiesis in mice and zebrafish.[60–62] Very little is known, however, about the role of these genes and their products during postnatal and adult hematopoiesis or how they may regulate self-renewal or the differentiation decision by postnatal HSCs.

Homeobox genes (HOX) are an evolutionary preserved family characterized by a 60 aminoacid DNA-binding motif called the homeodomain and play a role in normal and malignant hematopoiesis. Additional DNA binding specificity is obtained by interaction between clustered HOX proteins and the non clustered Para-HOX proteins, primarily the *three amino acid loop extension (TALE)* family of transcription factors including *pre-B-cell leukemia homeobox 1 (PBX1)* and *myeloid ecotropic viral integration site 1 (MEIS1)*.[63] The class I HOX family comprises four clusters (A to D) on different chromosomes, and individual genes are numbered in a 3′ to 5′ order in 13 paralog groups, based on sequence homology. HOX genes are expressed in $CD34^+$ cells, and those of the 3′ region, such as *HOXB3* and *HOXB4*, are preferentially expressed in the more primitive $CD34^+CD38^+$ cells.[64] The significance of individual genes has been investigated in loss-of-function and in overexpression studies. Mice homozygous null for *HOXA9* are viable and fertile and have only mild skeletal abnormalities. However, adult mice show significant abnormalities in granulopoiesis and T- and B-cell lymphopoiesis.[65] More importantly, the BM of $HOXA9^{-/-}$ mice shows delayed autologous hematopoietic recovery after sublethal irradiation, and their HSCs engraft poorly when transplanted to wild-type animals.[66] In contrast to *HOXA9*, studies on other *HOX* gene knockouts have been less revealing, because perhaps of redundancy within the multiple HOX dependent pathways. Knocking down both HOXB3 and HOXB4, for example, only resulted in a moderate decrease in cellularity in hematopoietic organs, probably secondary to a limited reduction of primitive fetal liver progenitors.[67] In the transplantation setting, the slightly lower repopulation potential. It seemed to be associated with slower cell cycle kinetics, as demonstrated by the better tolerance of HOXB3/B4 BM cells to pretransplant 5-fluorouracil (5-FU) treatment, which selectively depletes the activated HSC from the BM.[67] The phenotype of $HOXB4^{-/-}$ was in fact strikingly similar to the double knockdown model, but slightly less pronounced, suggesting a potential cooperation between different HOX genes or a dosage effect.[68]

Overexpression of HOX genes however, has repeatedly been shown to impact on HSC turnover. BM cells that overexpress *HOXA9* for instance are leukemogenic,[69] consistent with the clinical observation that *HOXA9* is a fusion partner with *nucleoporin 98kDa (NUP98)* in chromosomal translocation t(7;11), which occurs in about 1% cases of acute myelogenous leukemia (AML). Overexpression of HOXB4, however, appears to increase HSC self-renewal without altering the cell's ability to commit to different lineages.[70–73] Human $CD34^+Lin^-$ cells when overexpressing HOXB4 were transplanted in NOD/SCID mice a threefold to fourfold increase in SRC occurred. Likewise, when murine BM cells overexpressing HOXB4 were cultured in vitro for 10 to 14 days and transplanted into mice, HSC frequency was increased by more than 1000-fold compared with mock-transduced BM cells, without skewing their lymphomyeloid repopulating potential. A possible mechanism for this is suggested by studies with murine yolk sac cells and embryonic stem cells showing that HOXB4 confers definitive hematopoietic potential and facilitates engraftment of hematopoietic cells, possibly by upregulating expression of the chemokine receptor CXCR4 and the transcription factor TEL, both of which are important homing factors for HSCs.[74] Of note, an extra competitive advantage was conferred by concomitantly knocking down the expression of PBX1 cofactors, thereby suggesting that PBX1 acts as a negative regulator of HOXB4-induced HSC proliferation.[75] Leukemic transformation has not occurred in recipients, suggesting that regulated HOXB4 overexpression may be used for ex-vivo HSC expansion suitable for clinical transplantation. In contrast, overexpression of other homeobox genes, such as clustered genes (eg, *HOXB8*, *HOXB3*, and *HOXA10)* or nonclustered genes (eg. *homeobox-like 1 Xenopus laevis (MIXL1) or caudal type homeobox transcription factor 2 (CDX2)*) using retroviral transduction alters lineage-commitment at the progenitor cell level, and can sometimes lead to the development of acute leukemia in recipient animals.[76–78]

Interestingly, several upstream mechanisms regulating expression of HOX genes have been found to be associated with pathological hematological disorders. For instance, *retinoic acid response elements (RARE)* have been identified at the 3′ end of *HOXA* and *HOXB* gene clusters and retinoic acid has been implicated in regulating HOX gene expression during embryonic development.[79] *All-trans-retinoic acid (ATRA)* is used as first-line treatment for *acute promyelocytic leukemia (aPML)*, because it facilitates differentiation of leukemia blasts by degrading the pathological PML-RAR-α fusion protein complex. *HOXC4* expression is in fact typically absent at diagnosis, but appears simultaneously with differentiation markers both in vivo and in vitro after starting ATRA treatment.[80] Another example is the upstream regulation of HOX genes by other highly conserved genes: *mixed-lineage leukemia (MLL)*, a common target of chromosomal translocations in human acute leukemias, which is responsible for positive gene expression during development and its antagonist, the *polycomb gene (PCG)* family. Both of these are believed to regulate gene expression by complex epigenetic mechanisms (see below). Interestingly, while disruption of MLL function generally inhibits growth and differentiation of HSCs, the presence of oncogenic MLL fusion proteins increases their proliferative capacity. Overexpression of HOXA9 and HOXA10 have indeed been observed in patient leukemia cells involving MLL translocations, suggesting an early arrest in hematopoietic differentiation leading to the immature phenotype associated with MLL leukemia.[81] By contrast, expression of some PCG genes, for example *B lymphoma Mo-MLV insertion region 1 (BMI1),*[82] and in a lesser extent *polyhomeotic-like 1 (PHC1)*[83] and *polycomb group ring finger 2 (PCGRF2)*[84] seem to be necessary for the maintenance and self-renewal of HSC.

Epigenetic Regulation

In addition to gene-specific regulation, the cell-fate decision of HSCs may be regulated by modification of chromatin components, known as *epigenetic regulation*.[85] The basic chromatin unit of a cell, the *nucleosome*, is composed of histone proteins and double-stranded DNA arranged in a beads-on-a-string configuration. Older dogma indicates that such a configuration serves to package the genome within the confines of the cell nucleus. Subsequent data suggest that covalent modification of histone proteins, including phosphorylation, acetylation, methylation, ADP ribosylation and ubiquitination, can affect nucleosomal structure and encode information for gene regulation. Histone modification can be induced locally in a

gene-specific manner, in which specific DNA binding proteins activate histone-modifying enzymes to their cognate sites, or induced globally, in which case chromatin is compartmentalized in nuclear subdomains that are enriched with specific modifiers. Such modifications at sites of key lineage-specific genes may be interpreted by HSCs as *restrictive* or *permissive* signals for differentiation. Subsequent protein interaction involving these codes further modulates the activity of the associated genes, thereby restricting differentiation along a chosen lineage.

An example of a candidate gene involved in the epigenetic regulation of HSC cell-fate decision is *Ikaros,* a zinc finger protein that is expressed during primitive and definitive hematopoiesis. Ikaros acts by a bivalent chromatin regulation mechanism, paradoxically either silencing or promoting transcription via specific remodeling.[86] Mice carrying the Ikaros^{null} allele have reduced HSC activity, suggesting that Ikaros may maintain survival and proliferation of HSCs during steady-state hematopoiesis. Furthermore, fetal development of B, T, and NK cells is totally abolished along with a relative increase in myeloid activity, suggesting that Ikaros may be involved in HSC commitment to the lymphoid lineage.[87]

Transcriptome, MRNA Stability Control, and Proteome Analysis

Because the blueprint of the human genome and techniques such as DNA microarray technologies are widely available, it is now possible to study the transcriptional regulation of HSCs on a genome-wide scale. Several studies based on *subtraction hybridization* and *array analyses* have identified classes of genes that are highly expressed in HSCs and other stem cell populations.[88–91] What can be gleaned from these initial studies is that the presence of multiple transcripts, rather than one or a few genes, probably endows stem cells with their unique properties. These observations are in keeping with the multilineage priming model proposed earlier for HSCs.

Several comparisons of LTR-HSC versus STR-HSC and MPP in mice and humans have recently shown the importance of genes associated with quiescence, cell adhesion (with the surrounding environment but also intercellular), and cytoprotection in the long term repopulating cells,[90,92] whereas genes involved in differentiation, proliferation, and chemotaxis seemed to be associated to more differentiated stages.[14] These data also suggest that self-renewal might be more associated with an inhibition of differentiation than an active promotion of self-renewal, but this remains to be proven. Interestingly, HSCs seemed to express several ligand-receptor pairs, suggesting that part of the regulation might be autocrine.[92] Similar pathways could also be detected by comparing stem cells of different origins (fetal versus adult, or neuronal versus hematopoietic) and species subsets, supporting the idea of key stem cell properties needed for stem cell renewal.[90,92] By focusing on differences between human stem cell sources (namely the transcriptomes of Rho^{lo} and Rho^{hi} CD34^{+}Lin^{-} CD38^{-} cells from umbilical cord blood (UCB) and bone marrow (BM)) known to have variable bone marrow transplantation outcomes, it was also possible to single out the importance of cell cycle regulators and certain transcription factors, known to play a role in hematopoiesis or leukemogenesis (such as HLF, EVI1), but as for the previous screens, about 40% of genes identified still had an unknown function, suggesting that these may all represent uncharacterized regulators of HSC fate decisions.[90,93]

Apart from the limitations inherent to the choice of genes used for the microarray, the major hurdle of this type of analysis is obviously the technical difficulties of purifying the stem cell population. Selecting them according to their response to transplantation might actually select cells capable of redirecting themselves to the appropriate niche responsible for long-term self renewal (and thus expressing higher amounts of cell-cell and cell-matrix interaction genes) rather than those responsible for the process of self renewal itself.[14]

Furthermore, the amount of protein produced from an mRNA transcript will not necessarily correlate with the amount of mRNA produced, but also will depend on the *stability* of this transcript. Examples of these mechanisms in hematology are still scarce, but cytokine control of GM-CSF and Interleukin 3 (Il-3) signaling for instance are now known to be regulated at least partially by the turnover of *AU-rich elements (ARE)* in physiological circumstances, where the adenosine/uracil (AU) content of the mRNA defines its stability. This also seems to be the case in certain hematological malignancies, where cyclin D1 or BCL2 mRNA stabilization seem to be associated with mantle cell lymphoma and chronic lymphocytic leukemia.[94]

Aside from gene transcription, it has become clear in recent years that mRNA levels are not only determined by transcriptional control alone, but that posttranscriptional events affect mRNA stability. The posttranscriptional regulation is mediated by *micro RNA (miRNA) and small interfering RNA (siRNA)*. These small (20–28 base pair) noncoding RNAs, once activated, associate to *miRNA-induced silencing complex (miRISC)* and result in cleavage of their matching target mRNA and/or in more subtle translational repression of target genes when the target contains multiple incomplete matches in the 3′UTR region.[95] Alternatively, they can also mediate gene silencing through chromatin remodeling. Interestingly, the impact of the same miRNA can sometimes differ widely between species.[96] Specific miRNAs are associated with specific hematological cell types and play important regulatory roles in all stages of differentiation: miRNA155 for instance has been shown to negatively regulate normal myelopoiesis and erythropoiesis.[97] They can also function both as oncogenes (eg, miRNA142 translocated in B cell pro-lymphocytic leukemia) and tumor suppressors (eg, miRNA15A deletion in 13q^{-} chronic lymphocytic leukemia leads to an activation of BCL2), but the fine tuning of their regulation remains largely unknown.[96]

Finally, a gene that is transcribed will not necessarily be translated into an active protein, as some mRNAs will be translated into nonfunctional proteins, which then require posttranslational modifications to become active. Tao and colleagues, for instance, compared the *proteomes* of CD34^{+} UCB cells versus CD15^{+} mature granulocytes. This showed that the CD34^{+} stem/progenitor cells had a much larger proteome than the more terminally differentiated cells, suggesting that lineage choice might occur by shutting down the expression of a specific "stem-cell associated" set of proteins and activating a limited number of lineage-related proteins. Several of the proteins identified to be different between the two populations were also implicated in protein folding and posttranslational quality control systems, further emphasizing the possible impact of this posttranslational remodeling in the self-renewal/differentiation process. Finally, these results also confirmed the hypothesis from the genomic studies that these cells possess attributes of cells under stress.[98]

Cell Cycle Regulation in HSC

Cell cycle regulation (thoroughly discussed in Chapter 7) is crucial in HSC biology, as it regulates the cellular turnover and choice between quiescence and division, leading to self-renewal or differentiation. The critical step for progression to cell division is the transition from *Gap phase 1 (G_1)* to the *Synthesis phase (S)*, where DNA is synthesized, as this subsequently commits the cell to cycle progression.[99] The role of several proteins in these fate decisions has recently been elucidated. The *D-type cyclins* (D1, D2, and D3) are the first components to become induced in response to mitogenic stimulation, and are indispensable for hematopoiesis as simultaneous deletion of all D-type cyclins completely suppresses expansion and differentiation of HSC.[100] The roles of these proteins is, however, redundant as Ciemerych and colleagues have shown that the presence of at least one D-type cyclin was sufficient to allow normal development.[101] Interestingly, single knockouts of individuals D-type cyclins resulted in defects in lymphoid development of B and T lymphocytes for cyclin D2 and D3 respectively.[99]

Expectedly, knocking down the preferred catalytic subunits of cyclin D *(cyclin-dependent kinase 4 and 6 (CDK4 and 6)* results in a similar, but milder hematological phenotype as mice lacking D-type

cyclins altogether. However, absence of CDK2 (which is normally activated by E-type and A-type cyclins, driving cell proliferation by an alternative pathway) did not seem to impact hematopoiesis.[99]

Cyclin-dependent kinase inhibitors (CDKI) are divided in the *CIP/Kip* (encompassing proteins such as $p21^{cip1}$ and $p27^{kip1}$) and *INK4* families which also participate in cell cycle by sequential activation and inactivation of CDKs. For instance, p21 knock-out mice exhibit an increase in HSC cycling and exhaustion upon transplantation,[102] and ex-vivo targeting in UCB also showed relative expansion of HSC, defined by a higher number of CFU colonies, LTC-IC and a higher engraftment in NOD-SCID mice.[103] p27 Knock-out mice, however, have hyperplasia of most organs (hematopoietic organs included), the progenitor cell population is expanded, without impact on the true primitive stem cell function.[104] By contrast, most of the INK4 family proteins do not appear to play essential role in hematopoiesis, except for $p15^{INK4b}$ and $p18^{INK4c}$ which, when knocked down, cause a widespread hyperplasia of the hematopoietic system, demonstrating once more the importance of redundancy of function in these regulatory systems.[99]

HSC EXTRINSIC REGULATION

The cellular proximity in the BM milieu suggests that HSC cell-fate decisions may be subject to the influence of adjacent HSCs and stromal cells in specialized three dimensional niches. Such niches may provide proliferation and differentiation signals to HSCs through direct *cell-cell* or *cell-extracellular matrix (ECM)* interactions or through secretion of cytokines, chemokines, or other extracellular signaling molecules.[105] This concept is supported by observations that HSCs and stromal cells express reciprocal genes encoding for secreted proteins and cytokines that are important for HSC proliferation and differentiation, suggesting that early hematopoiesis is under paracrine or autocrine regulation, or both. Moreover, several cell lines that are capable of maintaining human and murine HSCs in vitro have been generated from the AGM region, yolk sac fetal liver, or BM. The following section describes the roles of early-acting cytokines and embryonic signaling molecules that are implicated in postnatal hematopoiesis and their potential clinical applications. Detailed information on "cell-cell/cell-ECM interactions" and cytokines in the hematopoietic microenvironment can be found in Chapter 23 and 24.

The Stem Cell Niche

Two HSC niches have been identified to date: the endosteal niche and the vascular niche. The *endosteal niche* is situated close to the trabecular bone, where osteoblasts, stromal fibroblasts and CXCL12-abundant reticular cells (CAR cells) appear to play a major role in controlling stem cell number through a number of pathways, such as bone morphogenic pathway (BMP) signaling, Tie2-Angiopoietin 1 signaling, N-cadherin and parathormone (PTH) receptor Notch activation.[33,36,106,107] The concept of a *vascular niche* for HSC arose from the observation of extra-medullary hematopoiesis and the ability of cytokines to mobilize HSCs into the circulation very rapidly. This was further defined by colocalization of HSC expressing a SLAM family signature ($CD150^{+}CD48^{-}CD41^{-}$) with CAR cells and sinusoidal endothelium both in spleen and bone marrow.[33,34]

The concept of a stem cell niche relies on the effect of this microenvironment on HSC: the factors secreted in the niche ensuring stem cell quiescence or renewal, whereas migration of HSCs out of the niche would result in differentiation.[108] The five major highly conserved pathways thought to play a role in these interactions (*Wnt, Notch, FGF, sHH,* and *BMP* pathways) are briefly reviewed here.

Wnt

The canonical Wnt signaling cascade, thought to play a role in hematopoiesis, is activated by the binding of the Wnt protein to a cell-surface receptor made up of *frizzled* and *low-density lipoprotein receptor related protein (LRP)* 5 and 6. In the absence of Wnt signaling, β-*catenin* is phosphorylated by interacting with an *Axin/GSK3*β (glycogen synthase kinase 3β) complex and thereby targeted for degradation. Wnt signaling blocks this interaction, resulting in accumulation of β-catenin and its translocation to the nucleus, where it binds to *LEF/TCF* transcription factors to activate target genes.[109] Gain of function experiments involving β-catenin overexpression promotes the preservation of a primitive HSC phenotype in vitro despite prolonged culture, and leads to functional expansion of HSC measured in competitive repopulation assays in mice, whereas use of inhibitors of the Wnt pathway (eg, ectopic expression of axin) inhibit HSC growth in vitro and repopulation capacity in vivo.[110] Moreover, gain of function experiments also suggest that activation of this signaling pathway in STR-HSCs or even more committed MPPs may endow these cells, that usually have limited or no self-renewal ability, with the ability to self-replicate.

Notch

The family of Notch receptors encompasses four cell-surface receptors (Notch 1–4) capable of binding two types of ligands: *Delta* (Delta-like 1,3 or 4) and *Jagged* (Jagged 1 or 2). This binding results in proteolytic cleavage of Notch, thus releasing its cytoplasmic intracellular domain and allowing it to translocate to the nucleus where it binds to *CBF-1* and *RBP-J*κ. Binding converts these transcriptional repressors into activators. Activation of this pathway has repeatedly been associated with cell-fate determination such as self-renewal (both in vitro and in vivo), as they act as a gate-keeper against differentiation signals.[109,111] It must be noted however, that a certain degree of redundancy must exist within this signaling system since selective loss of function experiments, such as blocking of Jagged-1 dependent notch signaling for instance, had no effect on hematopoiesis.[112] Interestingly, Notch signaling is also associated with T-cell cell fate specification, as aberrant expression is seen in several types of T-cell acute lymphoblastic leukemias.[24] This pathway could also be associated with later stages of B cell development, as core binding factor inactivation led to loss of splenic marginal zone B cells, with a moderate increase of follicular B cells, whereas deficiency in *MINT* (a negative regulator of Notch signaling) resulted in the reciprocal phenotype.[24] Expression of Notch receptors and ligands has also been reported in Hodgkin lymphoma, T-cell derived anaplastic large cell lymphoma and B-cell chronic lymphocytic leukemia, but the actual role of this pathway in the pathogenesis of these disorders still needs to be elucidated.[24]

Fibroblast Growth Factors (FGF)

More than 20 different *FGFs* have been identified in mammals, with variable affinity to four different FGF receptor tyrosine kinases (1–4), further modulated by additional binding to *heparin* or *heparin sulfate proteoglycans (HSPG).* Activation of the pathway takes place by dimerization and phosphorylation of the receptors, leading to transduction of the signal through the *Ras/mitogen activated protein kinase* pathway.[109] There is also growing evidence for the role of this pathway in hematopoiesis. For example, Fgf21 is essential for myeloerythroid progenitor cell fates in zebrafish.[113] Furthermore, murine HSC can be kept in culture in serum free conditions for up to 5 weeks when FGF 1 and/or 2 are added to the medium, while retaining long term repopulating activity.[114]

Bone Morphogenic Proteins (BMPs)

BMPs are members of the *transforming growth factor-β (TGF-β)* superfamily, which play a pivotal role in directing cells toward a ventral mesoderm fate and embryonic hematopoiesis.[115] Binding of BMP ligands to their surface receptor activates the receptor kinase

activity, resulting in translocation of complexes of *Smad* proteins to the nucleus to regulate gene transcription.[109] The BMP pathway also involves complex feedback mechanisms via members of the Smad family[115] and zinc finger proteins such as *OAZ*[116] and *Early Hematopoietic Zinc Finger protein (EHZF)* in Xenopus and mice. Precise upstream signals that activate BMP expression are not known, although hedgehog proteins[117] and retinoids[7,118] seem to be involved.

Zebrafish embryos carrying null mutations of genes encoding *BMP2b* and *BMP7* are characterized by with reduced ventral structures, including hematopoietic tissue.[119] Mice that are deficient in *BMP4* die early in utero with defective ventral mesoderm specification and absence of primitive hematopoiesis in the yolk sac.[120] Furthermore, several teams[3,121] have now demonstrated that a combination of *BMP4* and other cytokines promotes hematopoietic differentiation of human ES cells. Components of the BMP pathway, including BMP receptors and intracellular signaling molecules, have also been identified in postnatal human hematopoietic tissues, including BM, UCB, and PB. When exogenous BMP4 is added to in vitro cultures of primitive $CD34^-CD38^-Lin^-$ cells, SRCs are better preserved as compared with control cultures.[122] The downstream effectors of BMP4 have not been fully elucidated. In rhesus monkey embryonic stem cells, exogenous BMP4 regulates expression of VEGFR, CD34, GATA2, SCL, c-Kit, IL-6R, and EpoR and facilitates differentiation toward hematopoietic cells.[123] An essential question remains whether the effect of BMPs is mediated by pure ventral mesoderm specification (ie, more ventral tissues giving rise to more hematopoietic cells) or whether they induce specific proliferation of HSCs and progenitors, which would have potential implications in the development of ex-vivo culture systems for HSCs to improve clinical transplantation results.

Hedgehog Proteins (HH)

Hedgehog proteins are secreted glycoproteins, which impact on both on tissue specification during embryogenesis and proliferation of adult HSC via cell cycle regulation. Under basal circumstances, the HH transmembrane receptor *Patched (Ptc)* suppresses another transmembrane protein called *Smoothened (Smo)*. However, when HH binds to Ptc, Smo becomes active, and triggers HH target gene transcription via the *Gli* transcription factor family.[124] Three homologs of hedgehog proteins are involved in mammal embryonic and postnatal hematopoiesis through distinct mechanisms: *Sonic (SHH)*, *Indian (IHH)*, and *Desert (DHH)*. IHH seems to be involved in bone formation and in the development of the bone marrow microenvironment. It upregulates BMP-4 expression and leads to induction of primitive hematopoiesis and vasculogenesis in mouse embryos.[125] It has also recently been shown to reversibly increase human cord blood *colony forming units (CFU)* in vitro and lead to greater short term engraftment and higher frequency of NOD-SCID reconstitution by human cord blood cells, when cells were co-cultured with stromal cells overexpressing IHH.[126] On the other hand, SHH, a key signaling component of the notochord, has been shown to be expressed with Ptc, Smo, and Gli in human cord blood $CD34^-CD38^-Lin^-$ cells and BM stromal cells.[117] When added to in vitro cultures, SHH also enhances proliferation of $CD34^-CD38^-Lin^-$ cells and supports expansion of SRCs.[117] Although this appeared to improve short term repopulation, the presence of SHH negatively affected long term repopulation results of NOD-SCID mice, possibly due to exhaustion of the HSC compartment.[124]

Cytokines Acting at the Hematopoietic Stem Cell Level

Several cytokines affect the process of self-renewal and differentiation of HSCs. Mice carrying a null mutation for *steel factor* or *stem cell factor (SCF)*, have defects in the HSC microenvironment such that transplantation of HSCs from wild-type mice to $SCF^{-/-}$ animals leads to poor hematopoietic reconstitution. Likewise, bone marrow from mice with a null mutation in the SCF receptor c-Kit (*W* mutants) has reduced long-term repopulating capacity when transplanted to wild-type recipient animals.[127] Murine HSCs deficient in *Flt3 receptor* (also known as *Flk2*, a tyrosine kinase receptor) are defective in lymphoid and myeloid reconstitution when transplanted into wide-type recipient animals.[128] Mice carrying a null mutation for the *Flt3 ligand (FL)* have reduced common lymphoid progenitors, and when wild-type HSCs are transplanted into lethally irradiated $FL^{-/-}$ recipients, reconstitution of common lymphoid progenitors is defective, suggesting that FL is important for cell-fate decisions of HSCs.[129] When $Flt3^{-/-}$ mice are crossed to $SCL^{-/-}$ mice, the double knock-outs have a more severe defect in HSCs, resulting in early postnatal lethality.[128] These results suggest that the *SCF/c-Kit* and *Flt3/FL* pathways interact synergistically in the self-renewal of HSCs.

Another cytokine that acts at the HSC level is *thrombopoietin (Tpo)*, which is also known to enhance megakaryocyte proliferation and differentiation. Mice deficient in genes encoding Tpo, or its receptor, *c-Mpl*, have reduced numbers of megakaryocytes and multilineage progenitors, and $Tpo^{-/-}$ mice poorly support proliferation of transplanted wild-type HSCs.[130,131] The defects in HSC proliferation in these mice are correctible by exogenous Tpo.[130] Moreover, HSCs from mice carrying a null mutation for *c-Mpl* have significantly reduced competitive repopulating cell activity, suggesting that *Tpo* and *c-Mpl* are important in the maintenance of stem and early progenitor cells.[132]

Other important interleukins, growth factors and early-acting cytokines, including *vascular endothelial growth factor (VEGF)* and *angiopoietins*, which act concomitantly on HSCs and endothelial cells, are discussed in Chapter 24. The mechanisms of action of these cytokines are probably multifactorial, involving effects on HSC proliferation, expression of adhesion molecules, and endothelial cell function. Analogous to the use of *granulocyte stimulating factor (G-CSF)* to hasten neutrophil recovery after transplantation, it is possible that early-acting cytokines given to patients may enhance proliferation of HSCs in vivo, thereby facilitating short-term and long-term engraftment, especially in adult patients receiving small UCB grafts.[130] Exogenous *Tpo*, when given to $Tpo^{-/-}$ mice receiving wild-type HSC grafts, was able to enhance HSC engraftment and proliferation in vivo.[133] Whether SCF or FL have a similar effect and, more importantly, whether transplant recipients (who already have increased levels of these cytokines) would benefit from such interventions will require further investigation. Another application of these early-acting cytokines is based on their ability to maintain or stimulate the proliferation of HSCs. They constitute an integral part of most laboratory culture systems that aim at expanding HSC ex-vivo. Although many of these factors will stimulate the proliferation of HSC, they induce differentiation at the expense HSC expansion or even maintenance. The challenge today is to develop culture conditions which retain pluripotentiality of HSC while increasing stem cell number.

SOURCES OF HEMATOPOIETIC STEM CELLS

HSCs for clinical transplantation can be derived from BM, peripheral blood after mobilization by chemotherapy and or cytokines (mPB), and UCB. BM grafts have been the classic source of HSCs since the first successful transplantation reported by Thomas in 1959.[32] During the past 2 decades, mPB has become more popular because its collection obviates the need for donors to undergo general anesthesia and because recipients of mPB transplants often have faster neutrophil and platelet recovery. The first UCB transplantation was conducted in 1988, and thereafter, UCB became an alternative source of HSCs for patients without a matched adult donor. Success of UCB transplantation, however, is limited by the cell dose available to patients.[134]

From a biological point of view, these grafts differ quantitatively and qualitatively in stem cell content, as reflected in the kinetics of hematological recovery. In general, patients receiving mPB transplants have a more rapid neutrophil and platelet recovery, BM trans-

plants result in slower recovery, and UCB transplants demonstrate the most delayed recovery. Phenotypically, the percentage of primitive $CD34^+CD38^-$ cells in all three tissues is similar.[135] When the same number of CD34+ cells from mPB or BM are transplanted in fetal sheep, those from mPB engraft faster, but they are more quickly exhausted during serial transplantation.[136] When mononuclear cells from BM, mPB, and UCB were transplanted into NOD/SCID mice at limiting dilutions, the frequency of SRCs in UCB was 1 in 9.3×10^5 and was significantly higher than that in BM (1 in 3.0×10^6) or mPB (1 in 6.0×10^6).[137] The superiority of UCB was also confirmed by more recent ML-IC studies.[138] Although these laboratory results may suggest that mPB $CD34^+$ cells are less potent than BM $CD34^+$ cells, these studies must be interpreted with caution, because there is no clinical evidence to suggest that patients receiving mPB transplants are more susceptible to delayed graft failure. Whether the inferior proliferative and long-term engraftment of HSCs from mPB observed in the laboratory is compensated for by a larger cell dose transplanted into patients is unknown.

EX-VIVO EXPANSION MODELS

The rationale for ex-vivo expansion of hematopoietic cells are either to generate expanded populations of committed cells (to decrease the time to neutrophil and platelet recovery) to generate sufficient HSCs from small grafts such as UCB to be transplanted into adult patients, to enhance proliferation of HSCs as targets for gene therapy to purge autologous transplants of contaminating tumor cells. Several protocols have been developed that expand progenitor cells on a clinical scale, and initial clinical studies suggest that such expanded cell products may shorten the time to neutrophil and platelet recovery after myeloablation.[139] Clinical-scale expansion of HSCs however has not been achieved. Several culture systems have been evaluated.

A number of laboratories have attempted to expand HSCs using early-acting cytokines in the presence of serum without stromal support. These culture systems lead to a massive expansion of committed progenitors but no increase or even loss of HSCs.[140] In a case study, two patients were myeloablated with chemoirradiation, followed by transplantation with autologous mPB grafts alone. The latter were expanded for 8 days in the presence of autologous serum and a cytokine mixture comprising SCF, IL-3, IL-6, IL-1β, and erythropoietin. Both failed to show sustained neutrophil and platelet engraftment after transplantation, suggesting that these culture systems did not maintain HSCs.[141] Similar results were seen in serum-free culture conditions in the presence of a more than tenfold higher concentration of these cytokines. In particular, human UCB $CD34^+$, when cultured in serum-free medium for 14 days in the presence of SCF, TPO, and G-CSF and transplanted into fetal sheep, provide more rapid but only transient engraftment in primary recipients in contrast to uncultured cells that are capable of slower but durable engraftment.[139] In most subsequent clinical trials, expanded UCB HSC grafts were cotransplanted with unmanipulated grafts such that the contribution by expanded grafts alone could not be assessed.[142,143]

Other investigators have evaluated cultures in which hematopoiesis is supported by stromal feeders. The earliest stromal feeders were established from autologous BM mononucleated cells in the presence of horse and bovine serum-containing medium (ie, Dexter cultures). Later, a number of stromal cell lines were developed from murine or human AGM region, yolk sac, fetal liver, or BM. The murine fetal liver AFT024, murine BM MS5, human BM HS27, and human and porcine BM-derived endothelial cells appear to support a twofold to fivefold expansion of HSCs.[144] These stromal cells express specific proteoglycans and ligands for Notch receptors (ie, JAG1 and DLK), which may promote HSC survival and proliferation in vitro.[31,145,146] Because direct contact between HSC and xenogeneic or allogeneic stromal feeders is not suitable for clinical transplantation, investigators have also tested whether HSC can be maintained in *transwells* held above the feeders (ie, noncontact system). Another method to circumvent the problem of direct cell contact is to supplement cultures with media that are *conditioned* by certain stromal feeders. In noncontact and conditioned medium systems, HSCs can be maintained to an extent similar to that achieved with stromal contact systems.[144] Most of these approaches, however, are still at the experimental stage and have not been able to expand HSCs extensively enough to be applicable at a clinical scale.

Why is it so difficult to expand HSCs? To accomplish HSC expansion, the cells must be stimulated to divide repeatedly in a symmetric fashion such that the two daughter cells retain the same stem cell properties as the mother cells. Several factors can cause failure of HSC expansion:

1. Proliferation of HSCs in vitro is limited. In vivo under steady state conditions, HSCs are *quiescent* but they can be recruited into cell cycle (hence, proliferate) upon cytokine stimulation. Thus, it is unlikely that lack of HSC expansion is caused by the inability of HSCs to proliferate.
2. Daughter cells are driven into *differentiation*. One of the biggest problems encountered in the development of ex-vivo HSC expansion culture is that most or all conditions cause lineage commitment. Several advances have pointed to ways to circumvent this problem. A promising method under investigation is the overexpression or in vitro activation of endogenous HOXB4.[73] A second method is the activation of the Notch pathway. Constitutive expression of activated Notch receptors in murine HSCs can redirect them from differentiation to self-renewal.[147] Likewise, culture of UCB $CD34^+CD38^-$ cells with immobilized Delta-1, one of the ligands for Notch, increases the number of multipotent HSCs, as shown by enhanced myeloid and lymphoid engraftment in immunodeficient mice.[148] Finally, modulation of ALDH activity and retinoid signaling might also be a new effective strategy to amplify human HSCs.[51]
3. HSCs or their immediate progenies undergo *apoptosis*. Because apoptosis is involved in the regulation of the HSC pool during steady-state hematopoiesis, ex-vivo expansion of HSCs may be limited by increased apoptosis. Culturing BM $CD34^+$ cells induces expression of *FAS* (CD95, a surface receptor that induces apoptosis when bound to its ligand) and downregulates expression of anti-apoptotic protein BCL2.[46] Although the signals that induce apoptosis are unknown, it is possible that blockade of cell apoptosis may enhance HSC expansion, but carries the risk of leading to uncontrolled cell expansion. This has been shown for murine cells where BCL2 overexpressing cells can be expanded with the simple addition of SCF.
4. HSCs or their progenies fail to *home* to BM. Even though HSCs may persist in the expansion system, the ability to home to BM may be reduced during culture. There is evidence that expression of $\beta_1$integrin and CXCR4 on cultured HSCs may be downregulated, reducing the capacity of HSCs to home and reconstitute hematopoiesis after transplantation.[149] At least in nonhuman primates, there is evidence to suggest that this might be overcome by incubating cells 12 to 24 hours prior to transplantation with SCF alone, which allows cells to reenter G_0/G_1 and enhance homing.[150–152] Whether other methods to reinduce cell cycle quiescence might be developed remains to be determined.

CONCLUSION

The HSC is at the base of the hematopoietic tree. It is defined by its ability to self-renew, to differentiate into all blood lineages, and to reconstitute hematopoiesis in lethally irradiated hosts. HSCs are rare in hematopoietic tissues, and enumeration and characterization of these cells require combinations of laboratory tests, including surface phenotype, dye efflux, in vitro culture, and animal transplantation. Because of the relative ease of procuring HSCs and defining experimental conditions and the availability of knock-out mouse models, murine studies and, to some extent, *Xenopus* and zebrafish studies have provided important information about HSCs that may be extrapolated to their human counterparts. The HSC cell-fate decision

is regulated at cell intrinsic (transcriptional and epigenetic) and extrinsic (autocrine or paracrine) levels, and determining how these processes operate in vivo has begun to provide important information that may improve clinical HSC mobilization and transplantation and advance ex-vivo HSC expansion.[153]

CHAPTER 21

TRANSCRIPTION FACTORS IN NORMAL AND MALIGNANT HEMATOPOIESIS

Richard Dahl and Robert Hromas

INTRODUCTION

The phenotype and function of any given cell is the sum of genes expressed in that cell. Thus, as blood cells mature during hematopoiesis, their gene expression markedly changes. The regulation of gene expression is therefore critical to hematopoiesis. Much of hematopoietic disease, either aplasia or malignancy, occurs when this gene expression is permanently altered. Thus the control of gene expression during hematopoiesis is of utmost importance for survival. Most of gene expression is regulated by transcription factors, whose structural integrity and appropriate function is crucial to proper hematopoiesis. Transcription factors are DNA binding proteins that interact with the regulatory regions in their target genes to activate or repress gene transcription. These regulatory regions may be either immediately adjacent to the transcription start site (promoters) or many kilobases upstream or downstream of the transcribed gene (enhancers or silencers). Cloning of leukemic translocations and gene targeting in mice has identified many transcription factors that are important in the hematopoietic lineage specification and maturation.

Because transcriptional cascades regulate the sum of gene expression in developing hematopoietic cells, and malignancy represents a fundamental change in gene expression, it is not surprising that these factors are often dysregulated in hematologic malignancy. Chromosomal translocations and point mutations involving transcription factors are common in leukemia and lymphoma. In most cases chromosomal translocations result in the creation of an oncogene, which actively promotes hematological malignancy, often by inhibiting differentiation of progenitors. Conversely, point mutations in a transcription factor appear to inactivate tumor suppressor activity, often resulting in uncontrolled proliferation. Perturbing the ability of a transcription factor to direct maturation of a hematopoietic cell leads to a pool of cells that are susceptible to subsequent oncogenic mutations, producing an undifferentiated progenitor with uncontrolled proliferation typical of acute leukemia. Additionally point mutations in transcription factors have been associated with other hematological diseases besides acute leukemia such as thrombocytopenia and neutropenia. These mutations usually lead to an inability of a progenitor in these lineages to turn on critical gene products for mature cell function.

In this chapter we discuss transcription factors that are important in specifying hematopoietic lineages, concentrating on factors that are involved in hematological diseases. Models of how early acting transcription factor interact to direct specific lineage commitment will be discussed.

ORIGINS OF HEMATOPOIESIS

Hematopoietic stem cells (HSCs) give rise to all mature cells of the hematopoietic system for the life of an animal. They have the ability to expand, self renew, and differentiate into multipotential precursors, which have a more restricted developmental potential, and can not proliferate indefinitely. These precursors then give rise to lineage committed progenitors that develop into the mature functional hematopoietic cell.

The first site of hematopoiesis in the developing murine embryo is seen at 7.0 days postcoitus (dpc) in the yolk sac.[1–6] Blood islands appear in the yolk sac, which are made up of proliferating endothelial cells and nucleated erythrocytes. These nucleated erythrocytes contain the embryonic globins. Because these nucleated erythrocytes do not survive long after embryogenesis, and are only produced in the yolk sac, this process is termed primitive hematopoiesis.[1–6] Besides the nucleated erythrocytes, embryonic yolk sac hematopoiesis also generates macrophages.

In contrast to primitive hematopoiesis, definitive hematopoiesis is not restricted in location to the extra-embryonic yolk sac, in lineage to erythrocyte/macrophage lineages, or in time to embryonic blood development, but contains the potential to form all adult hematopoietic lineages.[1–6] Definitive hematopoiesis can be found in several intraembryonic tissues, and survives for the life of the organism. Definitive erythrocytes are not nucleated, and contain fetal and adult globins. Definitive hematopoiesis begins in the yolk sac at 8.75 dpc.[4] Definitive hematopoiesis also initiates in intraembryonic sites such as the Paraaortic Splanchnopleura (PSp) at days 8 to 9.5 pc and the adjacent aorta-gonads-mesonephros (AGM) region at day 10 pc.[7,8]

PSp/AGM hematopoiesis is likely independent of yolk sac hematopoiesis. A definitive hematopoietic stem cell (HSC) that can repopulate ablated adults with long-term hematopoiesis can be found in the PSp as early as 10 dpc.[7,8] In contrast, primitive yolk sac HSC isolated at day 8 to 10 pc can only transiently engraft erythrocytes and some myeloid lineages in ablated adults.[9] However, a day 9 pc yolk sac $CD34^+$/c-kit^+ HSC can engraft all hematopoietic lineages when injected into the liver of busulfan-ablated newborn mice.[4,10] Thus, a specific microenvironment is required for long-term complete repopulation by this yolk sac HSC as compared to the PSp HSC. By day 12 pc, the definitive HSC migrates from the PSp/AGM region to the liver, and hematopoiesis shifts to the liver for most of the remainder of embryogenesis. The liver HSC then later seeds the spleen and marrow with HSC by day 16 pc, which are the sites of hematopoiesis for the duration of the life of the mouse.[4,8] The regulation of the complex spatial and temporal shifts in embryonic hematopoiesis is unknown.

DIFFERENTIATION OF HSCS INTO HEMATOPOIETIC PROGENITORS

Weissman and colleagues defined multipotential progenitors downstream of the HSC in mice by the expression of specific proteins on the cell surface (Fig. 21–1).[11–13] Hematopoietic stem cells are negative for cell surface proteins (such as B220, Gr-1, CD3, glycophorin) associated with mature lineage restricted cells (termed Lin^-) and are positive for the primitive progenitor markers Sca1 and c-kit. These mouse HSCs can be referred to LSK cells. In the mouse bone marrow HSCs give rise to two distinct multipotential progenitors: the common lymphoid progenitor (termed CLP) and the common myeloid progenitor (termed CMP). The CLP gives rise to B, T, and NK cells, but is unable to generate erythrocytes, megakaryocytes, monocytes, or granulocytes. The CMP in contrast cannot give rise to lymphoid cells but instead generates two more lineage restricted multipotential progenitors, the granulocyte-macrophage progenitor (GMP) and the megakaryocyte-erythroid

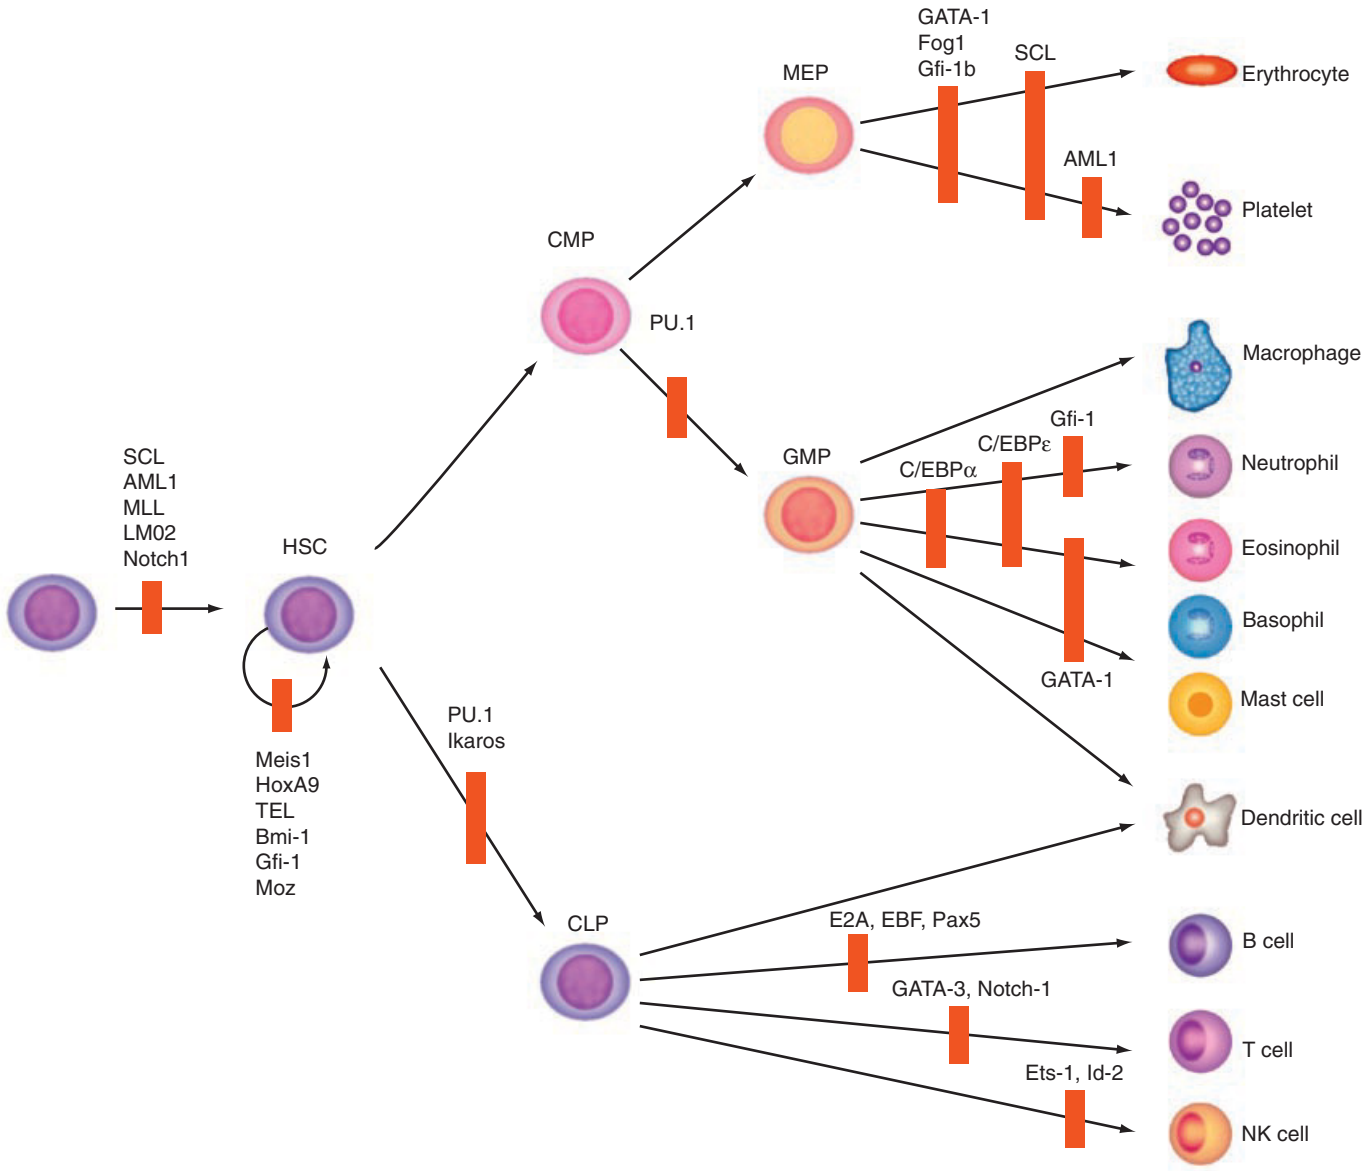

Figure 21–1 THE WEISSMAN-AKASHI MODEL OF HEMATOPOIETIC DIFFERENTIATION. *Red bars* indicate where lack of specific transcription factors discussed in the text affect hematopoietic differentiation. HSC: hematopoietic stem cell, CLP: common lymphoid progenitor, CMP: common myeloid progenitor, GMP: granulocyte-macrophage progenitor, and MEP: megakaryocyte-erythrocyte progenitor.

progenitor (MEP). The GMP gives rise to monocytes and granulocytes only and the MEP is restricted to megakaryocyte and erythroid differentiation.

Dendritic cells are derived from the HSC and are critical antigen presenting cells (APCs) for the immune system. There are probably four different types of dendritic cells, including those derived from myeloid and lymphoid precursors, and Langerhans and plasmacytoid dendritic cells.[14] Interestingly, dendritic cells can be derived from either a CMP or CLP.[15–17] They also can be derived from more mature precursors including the GMP, and pro-T cells but not pro-B cells. The plasticity of the origin of dendritic cells suggests a closer relationship between myeloid and lymphoid cells than one would assume from the model in which monocytes and granulocytes are derived from a precursor with no lymphoid potential.

Although this general differentiation scheme developed in mice is helpful in our understanding of where transcription factor activity is critical in determining lineages decisions, there are important caveats. For example, one must be careful in interpreting results in this model because the progenitors are defined by expression of cell surface proteins which themselves may be 7 targets of a transcription factor of interest. Additionally, there is data to suggest that the barrier between lymphoid and myeloid differentiation is not as stringent in humans as in mice. In humans a subset of bone marrow pro-B cells ($CD34^+/CD19^+$), which lacked expression of the chemokine receptor CXCR4 were shown to differentiate into B, cells, monocytes, and granulocytes in vitro.[18] In mice an LSK subset which expressed the tyrosine kinase receptor $Flt3^+$ was shown to have lost the ability to make erythrocytes and megakaryocytes but could produce all other hematopoietic cell types, including lymphoid lineages.[19] These reports suggest that there exists a bone marrow monocyte/granulocyte/lymphoid progenitor. In addition, a fetal liver CLP was shown though to have the ability to differentiate into macrophages, but not erythroid or megakaryocytic cells.[20] Other groups have also described murine fetal liver progenitors that have monocyte/lymphoid potential but not the ability to make erythroid/megakaryocyte potential.[21] Although there is evidence to support the existence of progenitors outside of the Weissman model of hematopoiesis, especially in humans, we use this model to describe the action of transcription factors because this model has been extensively used to characterize the phenotypes of mice lacking various transcription factors.

TRANSCRIPTION FACTOR FAMILIES INVOLVED IN HEMATOPOIESIS

Transcription factors have two requisite domains, a DNA binding domain that confers specificity of target genes regulated, and a transcriptional regulatory domain, that either represses or activates transcription of the target gene. There is a third possible domain that some transcription factors have, and that is a histone modification domain. This domain can mediate methylation or acetylation of the histones packaging DNA, and regulate how accessible the DNA regulatory regions are to other transcription factors. Acetylation of histones usually improves access to DNA, thereby increasing transcription. Methylation of histones can either open or close access to DNA, depending on where on the histone the methylation occurs. Transcription factors fall into families based on shared amino acid sequences, usually in the DNA binding domain. These shared amino acids create the tertiary structure framework necessary to bind the DNA regulatory regions. Not all amino acids within the DNA binding domain of a given family are the same, and differences in the DNA binding domain between transcription factors define which DNA sequences are bound, and transcription of which genes are activated. DNA binding domains often have a high basic amino acid content in order to facilitate DNA interaction, and regulatory domains can have a high acidic amino acid content, which often mediates interaction with other proteins in the transcriptional apparatus. There are five transcription factor families that we describe briefly, and most of the transcription factors discussed in this chapter fall into these families.

Basic Helix-Loop Helix Family

Basic helix loop helix (bHLH) family members have two conserved yet functionally distinct domains, both together make up the approximately 60 amino acid bHLH domain.[22] At the amino-terminal end of this region is the basic domain, which binds the transcription factor to DNA at a consensus hexanucleotide sequence known as the E box: G(or A)CAXXTGG(or A).[23] Different families of bHLH proteins recognize different E-box consensus sequences. At the carboxy-terminal end of the region is the HLH domain, which facilitates interactions with other protein subunits to form homodimeric and heterodimeric complexes. Many different combinations of dimeric structures are possible, each with different binding affinities between monomers. The heterogeneity in the E-box sequence that is recognized and the dimers formed by different bHLH proteins determines how they control diverse developmental functions through transcriptional regulation.

The bHLH motif was first observed by Murre and colleagues in two murine transcription factors known as E12 and E47. With the subsequent identification of many other bHLH proteins, a classification was formulated on the basis of their tissue distributions, DNA-binding specificities and dimerization potential.[24] This classification, which divides the superfamily into six classes, was initially based on a small number of HLH proteins but has since been applied to larger sets of eukaryotic proteins. Examples of bHLH family transcription factors mentioned here include E2A, Id2, and SCL (Tal1).

Leucine Zipper Family

Cytoskeletal proteins, such as myosins and intermediate filaments were noted to dimerize in a coiled-coil motif. This coiled-coil consisted of a 7 amino acid repeats that were termed a heptad. Later, as transcription factors were first being isolated, one group of such factors were also found to use a coiled-coil to dimerize, and these were termed leucine zippers, because of regular repeating leucines.[25] This coiled-coil domain was termed a leucine zipper because of the presence of leucines every heptad (every 7 amino acids). Usually, a minimum of four heptads are required to form a leucine zipper. In leucine zipper transcription factors the amino-terminal portion contains basic amino acids that bind to the major groove of specific DNA sequences. The carboxy-terminal portion makes up the leucine zipper, which mediates the dimerization responsible for DNA binding. There are 53 leucine zipper proteins in the human genome, and homodimerization and heterodimerization can potentially form 1,405 different dimers, generating a huge amount of potential specificity in the number of genes regulated by this family of transcription factors.[26] Examples of leucine zipper proteins mentioned in this chapter include c-Jun C/EBP α and ε.

Ets Family

Ets family transcription factors belong to the winged helix-turn-helix (wHTH) superfamily of DNA-binding proteins.[27] This family also includes other transcription factors such as hepatocyte nuclear factor, heat shock factor, and catabolite activator protein. The family is characterized by the Ets domain, which is composed of 85 amino acids that make up three α-helices and four β-strands.[28] This domain recognizes DNA sequences that have a GGAA/T core.[29] However, the flanking sequences from this core vary widely, and these flanking sequences mediate the DNA binding of the different members of the family. The activation domain of Ets family members is often near the carboxy terminal end, and has a high content of acidic residues. Ets family members also share nuclear localization signatures, and an amino terminal calcium sensitive phosphorylation site. There is occasionally a carboxy terminal auto-inhibitory region as well in this family. Ets family transcription factors discussed in this chapter include PU.1 and Ets-1.

Hox Family

Hox genes were first characterized through the study of mutations that give rise to body segment disruption in Drosophila.[30] These proteins constitute a family characterized by a highly conserved 183-nucleotide sequence encoding a 61 amino acid domain, the homeodomain. These homeodomains are structurally related to the helix-turn-helix motif of prokaryotic DNA-binding proteins and have sequence-specific DNA binding activity. In concert with additional sequences flanking the homeodomain, Hox proteins can serve as transcriptional activators or repressors on their target genes.

During human and murine embryogenesis, *HOX* gene transcription occurs 3′ to 5′ through each paralog group.[31] This is similar to the pattern of *HOX* gene transcription during fly development. The 3′ genes impact development of cephalad structures and the 5′ genes impact caudal structures in the developing human, mouse and fly. Orderly *HOX* gene activation is also essential for normal blood cell development.[32] *HOX* gene activation is also 3′ to 5′ during definitive hematopoiesis. Studies of human and murine hematopoietic stem cells (HSCs) demonstrate the importance of *HOX* genes of the A and B paralog groups for HSC maintenance and expansion.[33] Genes 3′ in the *HOX* clusters are maximally expressed in HSC and Hox7-11 (the Abd B *HOX* genes) are maximally expressed in committed progenitors.[32] Homeobox containing proteins discussed here include Meis1 and HoxA9.

Zinc Finger Family

The zinc finger transcription factor family is by far the largest family of transcriptional regulatory proteins in the genome. The family name comes from the fact that each family member has one to up to thirty multiples of cysteines and histidines that chelate a zinc ion. The first zinc finger protein characterized is the basal transcription factor TFIIIA,[34] and many members of this family are also basal transcription factors, like the well-studied SP1.[35] There are many sub-classes of zinc finger genes, based on the spacing and number of the zinc finger genes.[36] Zinc finger proteins can be also be grouped according to additional shared regulatory domains that mediate inter-

action with other members of the transcriptional apparatus, such as KRAB, SCAN or BTB domains.[37]

The most common class of zinc finger proteins when grouped according to cysteine-histidine spacing is the C2H2 class (or Kruppel family), where each finger chelates one zinc ion and binds the major groove of DNA, interacting with a specific 3 bp sequence.[38] Thus, the more zinc finger domains, the more specific the sequence bound. The exact amino acids needed to bind specific 3 bp DNA sequences has been worked out, and this is now being exploited to create designer DNA binding transcription factors.[39] These designer transcription factors can be used to block or activate gene expression. In the mouse genome there are 1537 genes that have C2H2 zinc finger motifs, making up approximately 1.5% of all expressed genes.[40] This makes it one of the largest gene families in the genome. Examples of this family of transcription factors mentioned below include Ikaros, Gfi-1 and Gfi-1b, GATA-1 and 3, EGR1 and 2, Bmi1, MOZ, and LMO2.

Another large class of zinc finger transcription factors is the steroid nuclear receptor class. These transcription factors function have two Cys2-Cys2 zinc finger domains that chelate zinc and fold together to mediate DNA binding after interaction with the appropriate steroid ligand.[41] Steroid receptor zinc finger proteins discussed include the RAR α.

MOUSE GENE TARGETING

Much of what we know about the role of transcription factors in hematopoiesis has come from gene targeting in mice.[42] Using homologous recombination in murine embryonic stem (ES) cells, investigators are able to specifically delete genes of interest (Fig. 21–2A).[43] Heterozygous ES cells, which harbor one mutated gene and one normal gene, are then used to generate mice that are heterozygous for the engineered mutation. These mice are then bred to make homozygous mutants, which are examined for the loss of function phenotype.

Gene targeting has been a powerful technique for elucidating the in vivo role of gene products. However, with germline mutations one often only observes defects associated with the earliest developmental requirement for a gene product. If a gene is essential for early developmental processes then one does not know whether the gene may also play a role in later developmental or adult processes. One technique used to examine requirements for a gene product throughout development is to examine chimeric mice.[43] ES cells engineered to have both alleles of a mutated gene are injected into a wild-type blastocyst, and this mixed blastocyst implanted into a foster mother. The resulting mouse will be made up of cells from both the host blastocyst and the injected homozygous ES cells. Investigators then examine what tissues the mutant ES cells are able to contribute to. A modification of this technique has been useful for studying gene contributions to B cell and T cells. For example, chimeric mice can be made with blastocysts derived from RAG2-deficient mice.[44] Immunoglobulin and T-cell receptor gene rearrangements cannot occur without RAG2. Because such rearrangements are critical for the formation of mature B- and T-cells, RAG2 deleted mice do not have any B cells or T cells. Any resulting B or T cells in the mouse derived from the mixed blastocyst must have come from the contributions of the donor ES cells. Contribution of donor ES cells can be assayed by flow cytometry or PCR.

Such chimeric mice will allow one to observe defects in multiple tissues which otherwise would not be observed because of a potential embryonic lethality in germline mice caused by a defect in a single tissue type. However, it will not allow one to see multiple defects in a single lineage. For example, if a gene product is important in HSC survival, and also is involved in the function of monocytes, one would not be able to observe any monocyte defects because monocytes would not be produced. Thus, in chimeric mice one will see that the engineered ES cells do not contribute at all to the hematopoietic system because of the HSC defect, and will never observe the defect in monocytes. A relatively new technique to observe such later defects, below the HSC, is to make conditional knockouts (Figure 21–2B).[45] In this procedure the gene of interest is modified so that it is flanked by 35 bp sequences from a bacteriophage that are called LoxP sites. These LoxP sites are recognized by the enzyme CRE recombinase, which will delete the DNA between the two sites, and then rejoin the gene without the deleted segment. The LoxP sites are placed in introns flanking the exons to be deleted, and therefore do not interfere with normal expression of the gene. Mice homozygous for the LoxP flanked allele will be normal. They can then be bred to several available mouse strains that either have tissue specific expression of CRE, or mice that have an inducible version of CRE. The most popular inducible strain of CRE recombinase for hematopoietic studies is MX-CRE mice.[45] CRE is under control of the interferon-inducible promoter from the MX gene. Injecting mice with interferon or polyIpolyC, which elicits an interferon response in vivo, results in a global deletion of the LoxP flanked allele. This technique has been particular useful for looking at the role of transcription factors that are needed for early progenitor cells but also required in later lineages, as CRE can be induced in cells past the HSC.

TRANSCRIPTION FACTORS SPECIFYING EMBRYONIC HEMATOPOIETIC STEM CELLS

HSCs are specified from the developing mesoderm of the embryo. Gene targeting in mice has defined four pathways that can be disrupted which affect HSCs.[46] In this section we will discuss transcription factors that are critical for specifying HSCs from mesoderm. Interestingly, all the factors to be discussed were initially shown to be essential for initial HSC specification when deleted from the mouse germline, but some are not indispensable for continued HSC activity when deleted in adult mice. CRE-Lox conditional gene targeting in mice was critical for showing the difference in requirements for initial specification and later maintenance of the HSC.[47,48] Transcription factors important in the initial specification of the HSC from mesoderm include SCL, AML1, MLL, LMO2, and Notch1, all of which are genes that appear at sites of translocations in human leukemias.

SCL (TAL1)

Stem cell leukemia factor (SCL) was one of the first transcription factors documented to be required for initial HSC development from mesoderm. SCL was originally identified as a gene frequently translocated in T-cell leukemias.[49,50] It is a basic helix-loop-helix (bHLH) transcription factor. Mice lacking SCL die in utero at approximately 9.5 dpc[51,52] because of a complete absence of yolk sac hematopoiesis. Using *SCL*$^{-/-}$ES cells it was shown both by in vitro differentiation and the generation of mutant ES-derived chimeric mice that SCL was also required for definitive hematopoiesis.[50] Interestingly, SCL is only required for specification of the HSC, but not the maintenance of the HSC. This was shown using a conditional knockout. Using the MX-CRE recombinase system SCL was deleted in adult mice.[48] After CRE deletion of SCL, these mice retained the ability to make both lymphoid and myeloid cells. Additionally SCL deficient HSCs were able to repopulate transplanted mice, indicating stem cell activity was intact. However, adult mice deleted of SCL had defects in maintaining erythropoiesis and megakaryopoiesis. This experiment indicated that SCL functions to specify but not maintain the HSC, and then functions downstream in hematopoiesis to maintain erythroid and megakaryocyte progenitors.

AML1 (RUNX1 or CBF α) and CBF β

Perhaps the most frequently translocated gene in acute leukemia is the transcription factor AML1 (RUNX1 or CBF α), and it is also involved in the initial specification of the HSC. It is highly homolo-

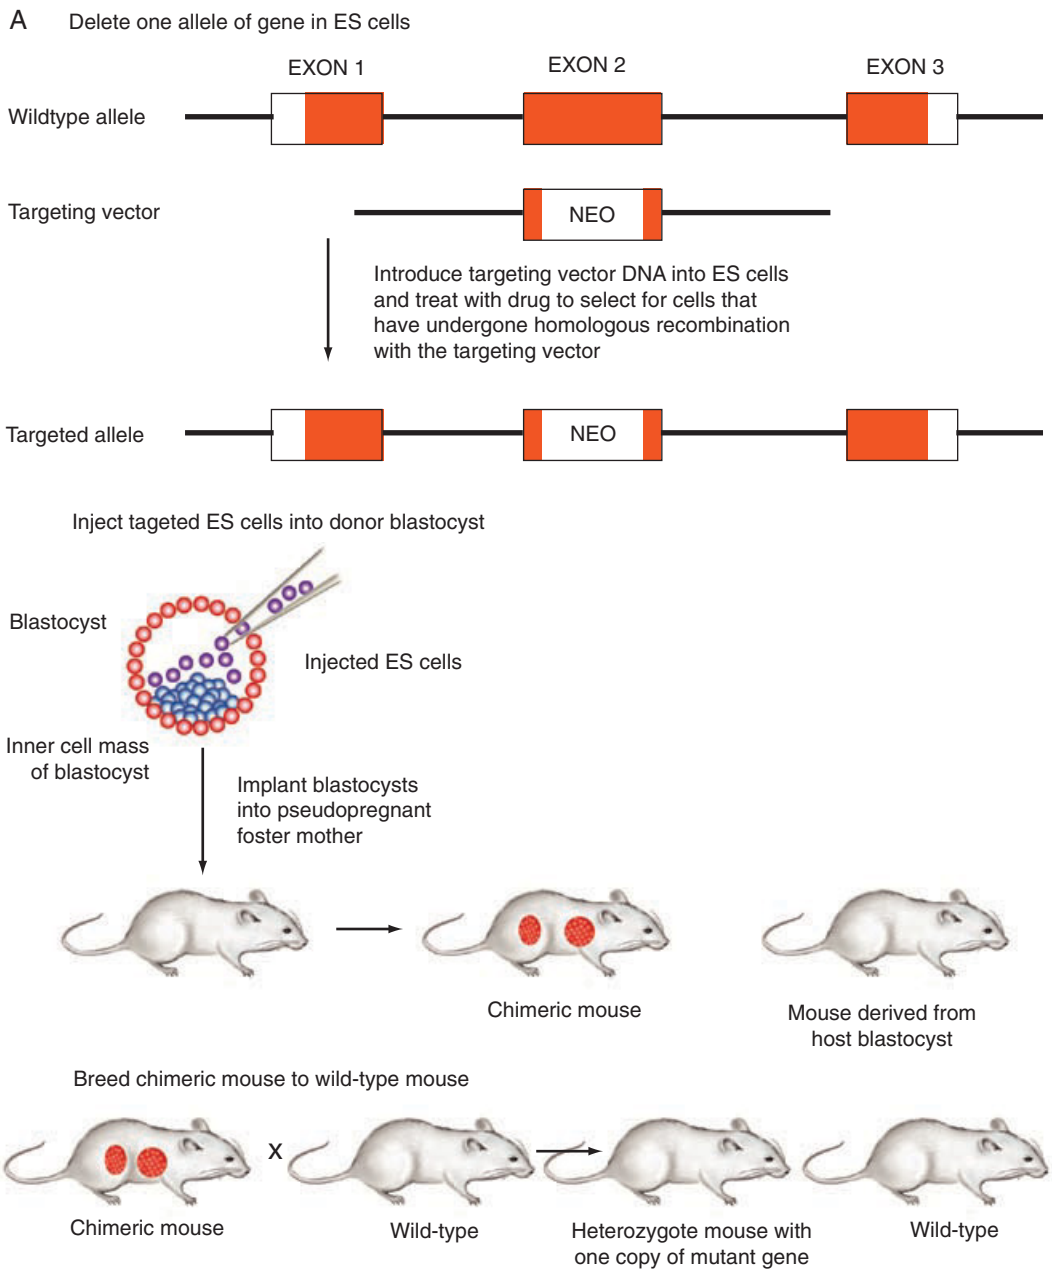

Figure 21–2 GENE TARGETING IN MICE. **(A)** Embryonic stem cells (ES) have one gene allele modified using homologous recombination to disrupt a gene of interest. Heterozygous mutant ES cells are injected into a donor blastocyst. These modified blastocysts are implanted into a recipient mother and allowed to develop. Chimeric mice should result which are made up of cells from the donor blastocyst and the injected ES cells. Chimeric mice are mated to wild-type mice in order to generate mice carrying the mutant allele. Heterozygous mutant mice are mated in order to generate mice that have two mutant alleles.

Continued on page 218

gous to the Drosophila transcription factor runt, and defines its own family of transcription factors.[53] AML1 functions as a heterodimer, complexing with CBF β through its DNA binding domain (which is homologous to the Drosophila Runt DNA binding domain). CBF β does not contact DNA but instead increases the affinity of the heterodimer for DNA.[53,54] AML1 expression is predominantly in the hematopoietic system, whereas CBF β is expressed in most adult tissues. CBF β is also an obligate partner for all other RUNX family members, RUNX2 and RUNX3.

Mice deficient for AML1 die at 12.5 dpc[55,56] Unlike SCL deficient mice, *AML1*$^{-/-}$ mice do undergo yolk sac hematopoiesis. However, they do not have definitive fetal liver hematopoiesis. Like the *SCL*$^{-/-}$ HSC defect, *AML1* deficiency leads to a defect in specifying the definitive HSC but not its maintenance in adults. Inducible gene targeting has demonstrated that deletion of AML1 in the adult animal no longer affects stem cell activity.[47] Similar to SCL, AML1 has essential functions downstream of the HSC as megakaryocyte and lymphoid maturation are perturbed in adult mice deleted of AML1. Mice deficient for CBF β have a very similar phenotype to mice with AML1 deleted, demonstrating its importance for forming a heterodimer with AML1.[56,57]

MLL

Another transcription factor commonly translocated in acute leukemias is the mixed-lineage leukemia gene (MLL). The *MLL* gene is frequently disrupted in both infant acute lymphoblastic leukemia and therapy-induced acute myeloid leukemias. Acute leukemias harboring a MLL translocation are characterized by coexpression of early

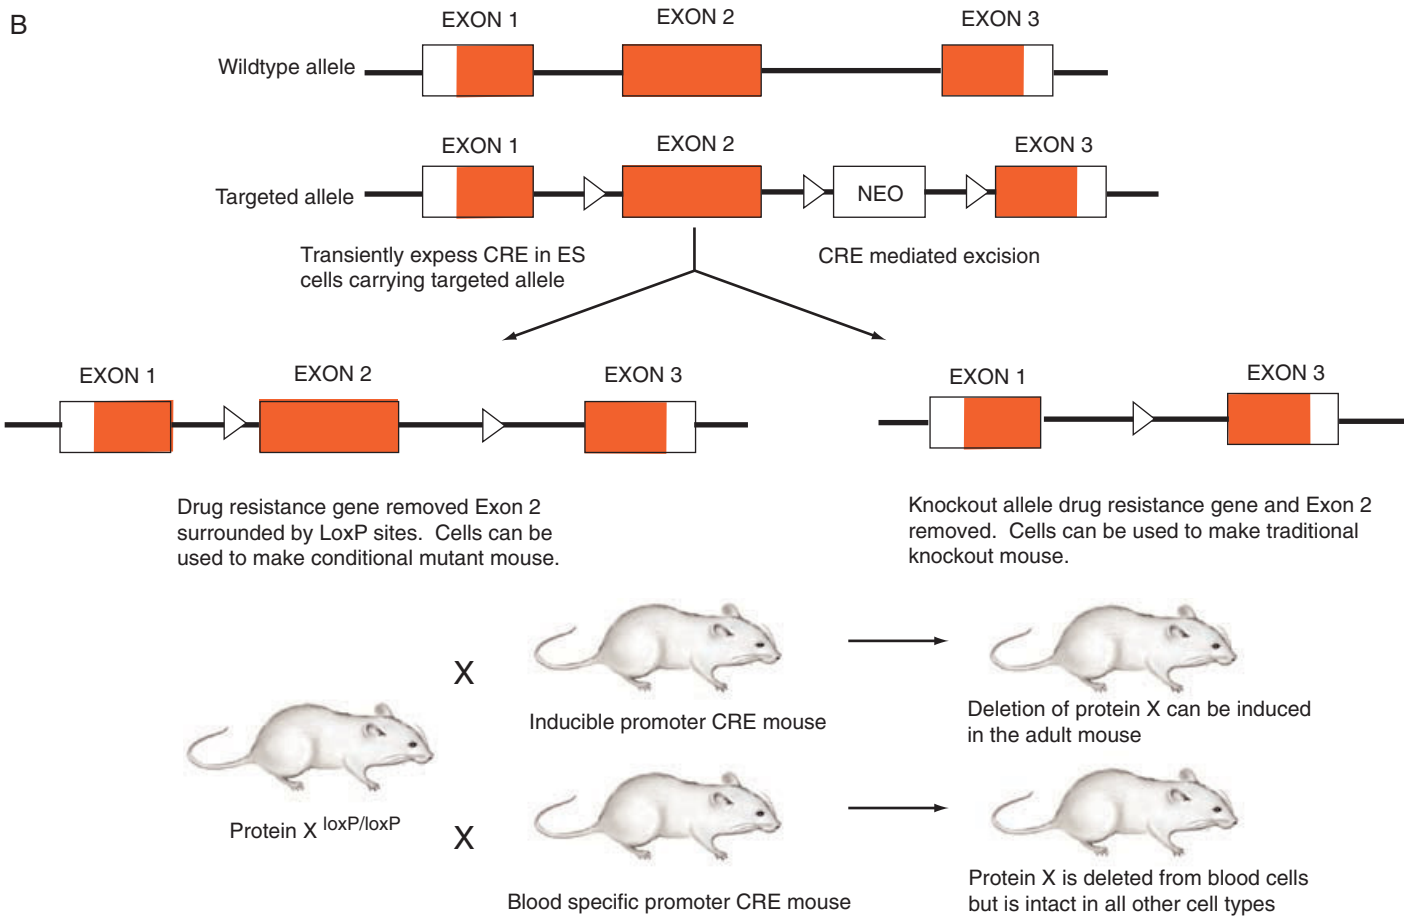

Figure 21–2, cont'd (B) Instead of deleting a gene allele homologous recombination in ES cells can be used to generate an allele in which a critical exon of a gene is flanked by a specific DNA sequence called LoxP sites. Introduction of these sequences in introns flanking the exon should not affect gene expression. As described above mice carrying the LoxP allele can be generated. These mice then can be mated to mice that were engineered to express the enzyme CRE recombinase in specific tissues. CRE recombinase excises the DNA in between LoxP sites. This results in a gene being deleted in a specific tissue instead of throughout the mouse.

lymphoid and myeloid associated genes. During normal hematopoiesis MLL is expressed in all lineages, including early progenitor cells (Kawagee 1999, Phillips 2000). The MLL protein has zinc finger domains and a histone methylase domain, and is involved in chromatin remodeling. *MLL*$^{-/-}$ mice die embryonically of multiple defects. Decreased hematopoietic colony formation of both yolk sac and fetal liver cells was observed, indicating that MLL is important for both primitive and definitive hematopoiesis. However, because of other defects it was not clear if problems in hematopoiesis were caused by an intrinsic cell defect or by other nonhematopoietic defects that might affect the microenvironment.

LMO2 (RBTN2)

LMO2 is a zinc finger LIM domain transcription factor that is indispensable for the initial specification of the HSC from mesoderm.[58,59] It is also frequently a target of chromosomal translocations that lead to human T-cell acute lymphoblastic leukemia.[60,61]

LMO2 knockout mice die around 10.5 dpc because of a lack of yolk sac erythropoiesis.[59] Examination of chimeric mice demonstrated that LMO2 knockout cells could not contribute to any definitive hematopoietic lineages indicating that LMO2 has a role in the HSC. No conditional knockout of LMO2 has been derived, so it is not known if it is required for maintenance of adult HSCs or whether it has a role in more mature cells. Interestingly, LMO2 does not function as a DNA binding protein but instead assembles DNA binding complexes by associating with other transcription factors that bind DNA.[62,63] LMO2 binds to SCL and the essential erythroid transcription factor GATA1.

Notch1 (TAN1)

Notch1 is another nonprototypic transcription regulator involved in definitive HSC specification from mesoderm. It is one of four mammalian homologs of the drosophila Notch protein.[64,65] Notch1 is an unusual transcription factor in that it is initially found at the cell surface. Upon binding to one of its ligands, usually expressed on the surface of a juxtaposed cell, a series of enzymatic cleavages occur, which release the intracellular portion of Notch1, termed ICN1. ICN1 then translocates to the nucleus where it associates with the DNA binding factor RBJ κ to regulate transcription.[66–68] Retroviral expression of ICN1 in HSCs or coculture of HSCs with stromal cells expressing Notch ligands was shown to increase the self-renewal of HSCs.[69–73] Mice that have Notch1 deleted demonstrate an arrest in development at around 9.5 dpc and die within a day afterward as a result of multiple defects, including failure of angiogenesis.[74,75] Hematopoietic colony formation from *Notch1*$^{-/-}$ yolk sacs was observed to be normal. However, when colony formation was examined from the P-Sp region of the early 9.5 dpc embryo there was a severe reduction in colony formation indicating a defect in definitive hematopoiesis. Transplanting P-Sp cells from 9.5 dpc into newborn

mice demonstrated that *Notch1*$^{+/-}$ cells could contribute to the hematopoietic system of the recipient mouse, but not *Notch1*$^{-/-}$ cells.[76] However, similar to what is seen with SCL and AML1, conditional disruption of Notch1 in adult mice demonstrated that Notch1-deficient adult HSC could be transplanted without defect.[77] These Notch1 mutant HSCs could differentiate into all mature hematopoietic lineages except for T cells.

TRANSCRIPTION FACTORS MAINTAINING ADULT HEMATOPOIETIC STEM CELL FUNCTION

In contrast to the factors discussed above, there are several transcription factors that do not appear to be involved in initial HSC specification from mesoderm, but are instead required for maintaining the HSC once it arises developmentally. For survival of itself and the organism, an HSC must be able to both self-renew and to differentiate into mature blood cells of all lineages. The transcription factors involved in HSC maintenance after its specification from mesoderm include Meis1, TEL, Gfi-1, Bmi1, and MOZ. These transcription factors can be involved in either self-renewal or lineage differentiation.

Meis1

Meis1 is a transcription factor in the homeobox family, which was originally characterized in Drosophila through the study of mutations that give rise to body segment disruptions.[30,78,79] Homeobox (Hox for mouse and HOX for humans) proteins can serve as transcriptional activators or repressors on their target genes. Although Hox genes were originally identified as master control genes during embryonic development, they also affect various steps in hematopoiesis.[80–82] Meis1 is most related to the Pbx subfamily of homeobox proteins. Pbx1 is a translocation partner for the E2A transcription factor, and the fusion gene E2A-Pbx is observed in human pre-B cell leukemias. Meis1 is expressed in fetal liver stem cells.

Meis1$^{-/-}$ mice die at approximately 13.5 dpc because of extensive hemorrhage.[83] These Meis1-deleted mice also have multiple hematopoietic defects. Hematopoietic progenitors are present but reduced in number in day 13.5 fetal livers in these mutant mice. These mutant fetal liver cells fail to radio-protect lethally irradiated mice, and perform poorly in HSC competitive repopulation assays, indicating a defect in definitive HSC function. Meis1 can partner with Pbx1 to regulate transcription.[84] Pbx1$^{-/-}$ mice share many of the same hematopoietic defects with Meis1$^{-/-}$ mice.[85] Pbx1$^{-/-}$ fetal liver cells form reduced numbers of hematopoietic progenitors. In addition, these fetal liver HSCs perform poorly in competitive repopulation assays. Interestingly, proliferation assays have demonstrated a reduced proliferation capacity of the fetal liver CMP. This suggests that the Meis1- and Pbx1-deficient mice may have defects in HSC proliferation.

HoxA9

The homeobox protein HoxA9 heterodimerizes with Meis1 to activate gene expression, and therefore it is not surprising that it also plays a critical role in maintaining the adult HSC phenotype. Forced overexpression of HoxA9 markedly expands the adult HSC pool.[86] Indeed, continued overexpression of HoxA9 in murine marrow results in a primitive leukemia. This leukemia may require the coexpression of Meis1 to be fully penetrant.[87] Homozygously deleting HoxA9 in mice results in mild defects in both myeloid and lymphoid maturation, indicating that HSC function is partially disrupted.[80] However, these mice are viable and can survive the minor HoxA9 disruption of hematopoiesis, perhaps indicating that another of the many closely related HoxA cluster genes can compensate for the missing HoxA9.

TEL (Etv6)

The TEL (Etv6) gene codes for an Ets family transcriptional repressor. The TEL gene is translocated in several myeloid and lymphoid leukemias. Expression of TEL is not limited to hematopoietic tissue but occurs widely in both embryonic and adult tissues.[88] *TEL*$^{-/-}$ mice die at 10.5 dpc[88] The mice die of defective yolk sac angiogenesis and increased mesenchymal and neural tissue apoptosis. Generation of chimeric mice demonstrated that *TEL*$^{-/-}$ ES cells could contribute to both yolk sac and fetal liver hematopoiesis, indicating that TEL is not required for initial HSC specification from mesoderm.[89] However, TEL$^{-/-}$ ES cells could not contribute to bone marrow hematopoiesis. This indicated that without TEL, the definitive HSC could either not home to the bone marrow or could not be maintained in the bone marrow microenvironment. Conditional disruption of TEL in adult animals leads to a rapid depletion of HSC in the bone marrow.[90] When deleted in more mature hematopoietic progenitors, loss of TEL does not have observable effects on cell differentiation.

Bmi-1

Bmi-1 is a Polycomb family zinc finger protein.[91,92] This group of proteins are involved in epigenetic regulation of gene expression by controlling the accessibility of DNA to transcription factors by regulating chromatin opening.[93] Bmi-1 was originally isolated as a gene which cooperated with the myc oncogene in the induction of murine lymphoid leukemia.[94,95] Bmi-1 is expressed in early hematopoietic progenitors.[96–98] Mice deficient for Bmi-1 are born with severe aplastic anemia caused by a depletion of HSCs.[99,100] Progenitors of all blood lineages are dramatically reduced and mice die within a week from multiple infections. However, the HSC is specified from mesoderm in these mice, rather the proliferative capacity of the HSC and downstream progenitors is greatly reduced. The proliferative defect is observed in the fetal liver HSC but is much worse in the adult bone marrow HSC, indicating that the defect worsens with age. Re-expression of Bmi-1 in HSC by retroviral transduction rescues the cells from this proliferative defect.[98]

Gfi-1

The zinc finger transcriptional repressor Gfi-1 appears to play an opposite role to Bmi-1. Gfi-1 is expressed in the HSC, CLP, GMP, and more mature lineage progenitors such as pro-B cells and pro-T cells.[101] It is also expressed in mature neutrophils.[101] It was originally isolated because of its ability to confer growth factor independence to a rodent T-cell line.[102,103] Additionally, Gfi-1 cooperates with c-myc in the generation of murine T-cell leukemias.[102–104] The major defect seen in *Gfi-1*$^{-/-}$ mice is severe neutropenia.[105,106] Subsequently it was shown that Gfi-1 is essential for proper HSC function.[101,107] Competitive repopulation assays in irradiated mice showed that the mutant HSC failed to compete with normal HSC. Additionally, HSCs that had Gfi-1 deleted were unable to rescue long-term hematopoiesis in a transplant model. When HSCs were isolated from Gfi-1 mutant mice it was shown that these cells had a higher proliferative rate than wild type HSCs. This suggested that the reason Gfi-1 marrow could not rescue irradiated mice was that the mutant HSCs over proliferated and exhausted the stem cell pool. This overproliferation may occur through the lack of Gfi-1 to induce the cell cycle inhibitor p21.[101,107,108] Gfi-1 associates with the p21 locus and the related protein Gfi-1b, which shares an identical DNA binding domain has been shown to increase p21 expression in a myeloid cell line.[108] P21 levels were decreased in Gfi-1 mutant mice.[101,107]

Normally Gfi-1 represses gene expression so it is unclear how Gfi-1 would up-regulate p21 expression.

MOZ

MOZ (monocytic leukemia zinc finger protein) was first isolated through its involvement with the t(8;16) in acute monocytic leukemia. MOZ functions as a transcriptional coactivator interacting with other DNA binding transcription factors. It has histone acetyl transferase activity, which is involved with activating transcription by opening chromatin and making DNA more accessible to the transcriptional apparatus.

MOZ is widely expressed in embryonic and adult tissues.[109] Its expression is not limited to the hematopoietic system. MOZ, however, does interact with the hematopoietic transcription factors PU.1 and AML1 to augment their transcriptional activity.[110,111]

Two MOZ mutant mouse strains have been generated which have similar defects in the hematopoietic system.[109,111] One strain is considered to be a null mutation of MOZ with homozygotes dying after 14.5 dpc[111] At 14.5 dpc, normal Mendelian frequencies of genotypes were seen, but *MOZ*$^{-/-}$embryos were pale and the fetal livers were noticeably smaller. The second mouse strain is not characterized by a complete loss of MOZ function.[109] The targeting of the MOZ allele was designed to truncate the MOZ gene in the carboxy terminal portion of the protein, which would be equivalent to the breakpoints involved in t(8;16) translocations. Mice homozygous for the truncation mutation (*MOZ*$^{\Delta/\Delta}$) died at birth. These mice were not anemic but instead failed to oxygenate the blood because of an aortic arch defect. The mice had deformities including craniofacial defects. It was also observed that the spleen and thymus of these animals developed poorly.

In the *MOZ*$^{\Delta/\Delta}$ mouse all lineages could mature properly. However, in the *MOZ*$^{-/-}$ mouse there was an accumulation of erythroblasts caused by a defect in erythroid maturation. Progenitors for all lineages in both mutant models are reduced in number as compared to wild type animals. Cells characteristic of HSCs as determined by flow cytometry could be detected in the fetal livers of both models of mutant MOZ mice. However, these putative HSC could not reconstitute the hematopoietic system of irradiated mice in a transplantation model.[109,111] These results suggested a defect in HSC activity; the exact nature of this defect is not known.

TRANSCRIPTION FACTORS SPECIFYING THE ERYTHROID/MEGAKARYOCYTIC LINEAGES

GATA1

GATA1 is considered the master regulator of erythropoiesis. It was originally identified as a factor that binds to the conserved GATA sequences in the β-globin enhancer.[112–114] It contains two zinc fingers; with the carboxy proximal finger required for high-affinity DNA binding, and the amino terminal proximal finger stabilizing the interaction with DNA.[115–117] It is expressed in erythrocytes, megakaryocytes, mast cells, and eosinophils.[118] It is also detected in early hematopoietic precursors. Outside of the hematopoietic system, GATA1 expression is only detected in the testes. Using ES cells in which GATA1 is deleted, it was shown that GATA1 is essential for the development of erythrocytes.[119] GATA1-deficient mice die at day 10.5 dpc of severe anemia. Erythroid maturation is blocked at the proerythroblast stage. There is also a block in megakaryocyte development. Mice with GATA1 specifically deleted in megakaryocytes had failure of endoreduplication, proliferation, and platelet production.[120] Interestingly, a novel mutation that deleted a GATA binding site in the GATA1 promoter demonstrated that this site was required for GATA1 expression in eosinophils.[121] Without this site, mice were unable to produce eosinophils, demonstrating an essential role for GATA in eosinophil maturation.

FOG1

GATA1 works in cooperation with another transcription factor, Friend of GATA, or FOG1. This factor was identified in a screen for GATA1 interacting partners.[122] GATA1 binds to FOG1 to activate or repress transcription, depending in the target gene. FOG1 does not bind to DNA by itself, but only associates with DNA through its interaction with GATA1. FOG1 contains nine zinc fingers, none of which have been shown to mediate DNA binding but instead mediate protein-protein interactions. FOG1 acts predominantly as a transcriptional repressor, although on certain promoters it has been shown to enhance transcriptional activation with GATA1.[123,124] It is predominantly expressed in erythroid and megakaryocyte precursors.[122] It is also expressed in T cells where it may interact with another GATA family member, GATA3. Homozygous gene disruption of FOG1 results in lethality of mice between 10.5 and 11.5 dpc[125] Similar to GATA1 deleted mice, FOG1 deficient mice die of severe anemia caused by a block at the proerythroblast stage. Distinct from GATA1, FOG1 mice do not make megakaryocytes at all.

Gfi-1b

Another transcription factor involved in the early development of erythrocytes and megakaryocytes is Gfi-1b. Gfi-1b was identified by homology to Gfi-1,[108] and shares nearly identical c-terminal zinc fingers and a repressor domain with Gfi-1. The two proteins are divergent in the sequence between the repressor domain and the carboxyl terminal six zinc fingers. Deletion of Gfi-1 results in embryonic lethality from severe anemia.[126] The embryos do progress further than GATA1 or FOG1 knockouts, with −/− embryos dying at 15 dpc. *Gfi-1b*$^{-/-}$ animals specify megakaryocytes but they fail to mature, never becoming functional.

TRANSCRIPTION FACTORS PROMOTING MYELOID LINEAGE SPECIFICATION

There are two major transcription factors are important for specifying monocytes and granulocyte formation from the HSC. These are PU.1 and C/EBP α, both of which may play a role in acute leukemias.

PU.1

PU.1 is an Ets family transcription factor that is also an oncogene upregulated in murine erythroleukemia cells (MEL) infected with Friend virus.[127,128] Forced expression of PU.1 is essential for blocking the differentiation of the infected erythroblasts, and maintaining the erythroleukemia.[129,130] PU.1 is expressed at low levels in early hematopoietic progenitors. As cells mature PU.1 expression is extinguished in erythrocytes, megakaryocytes and T cells, but rises in monocytes, granulocytes and B cells.[131,132] A role for PU.1 in directing myeloid lineage commitment was first established by experiments using the multipotential avian cell line E26-MEPs.[131–133] PU.1 over-expression in these cells redirected the normal megakaryocyte differentiation into monocytes. Gene targeting in mice also confirmed a critical role for PU.1 in myeloid differentiation. Mice lacking PU.1 do not make macrophages, granulocytes or lymphoid cells.[134,135] Examination of bone marrow cells in PU.1 conditional knockout mice showed that *PU.1*$^{-/-}$ HSCs do not make detectable CLPs or CMPs.[136,137] Deletion of PU.1 in adult GMP cells demonstrated that PU.1 was not required for granulocyte lineage specification, but was still required for proper granulocyte maturation.[136]

PU.1 also has an important role in B-cell development.[134–138] It is essential for specification of the B-cell lineage, but once pro-B cells are specified, PU.1 no longer is critical for further B-cell maturation. Two models of conditional knockout mice were shown to have

reduced HSC function as *PU.1*$^{-/-}$ HSCs could not engraft in competitive repopulation transplantation assays.[136,137] Target genes of PU.1 include several crucial cytokine receptor genes, including the receptors for M-CSF, G-CSF and GM-CSF.[139] However, re-expression of G-CSF receptor or M-CSF receptor in *PU.1*$^{-/-}$ hematopoietic cells however does not rescue granulocyte or macrophage differentiation, although it does restore survival and proliferation when precursors are cultured in G-CSF or M-CSF.[140,141]

C/EBP α

C/EBP α is a basic leucine zipper transcription factor that functions as a dimer. It can homodimerize with itself or heterodimerize the related family members C/EBP β, γ, and ε through its carboxy terminal leucine zipper. Within the hematopoietic system C/EBP α is predominantly expressed in monocytes, granulocytes and the progenitors of these cells.[142,143] Ectopically expressing C/EBP α in cells capable of both monocyte and granulocyte differentiation promotes granulocyte differentiation.[142] One of the functions of C/EBP α in granulocyte differentiation is to slow proliferation by inhibiting the transcription of E2F and c-myc, which promote cell cycle progression.[144–146] Mice lacking C/EBP α do not make any mature granulocytes and are also impaired in producing monocytes.[147]

Conditional deletion of C/EBP α in adult mice has demonstrated that it is indispensable for GMP progenitors but not CMP progenitors.[148] This suggests that C/EBP α acts at a later stage than PU.1, which is required to form the CMP.[136,137] However, C/EBP α can regulate PU.1, and if its expression is forced in early B cells, it induces PU.1 transcription, which leads to trans-differentiation of these B cells into monocytes.[149,150]

TRANSCRIPTION FACTORS REQUIRED FOR MYELOID MATURATION

Other transcription factors are needed for the proper maturation of granulocytes and monocytes but not for myeloid lineage specification. These factors include Egr1 and 2 in monocytes; C/EBP ε, Gfi-1, and RAR α in granulocytes.

C/EBP ε

C/EBP ε is a basic leucine zipper transcription factor that is highly related to C/EBP α. It is most highly expressed in granulocytic cells and their precursors, but it is not detected in monocytes.[151,152] Targeted deletions of C/EBP ε demonstrated an essential role in granulocyte differentiation.[153] Although they are viable and fertile, *CEBPE*$^{-/-}$ mice do not produce normal neutrophils or eosinophils. Because of this granulocytopenia, the mice die of opportunistic infection within a few months of birth. C/EBP ε deficient granulocytes do not produce cytoplasmic secondary or tertiary granules. The secondary granule protein lactoferrin has been shown to be a direct C/EBP ε target.[154]

Gfi-1

Gfi-1 is not only important for proper maintenance of adult HSC, but it is also required for granulocyte differentiation. Mice with Gfi-1 deleted suffer from neutropenia.[105,106] The mice make granulocyte progenitors normally, but these progenitors fail to mature. In addition, these granulocytes have aberrant expression of the monocyte genes M-CSFR and Mac3. These granulocytes are functionally compromised, leading to the death of the mice within a few months as a result of systemic infections. One of the critical functions of Gfi-1 in granulocytes may be to downregulate monocyte-specific genes in the GMP as they commit to the granulocyte lineage.[155] Initially myeloid precursors are primed to express genes specific for both lineages, but as cell commit they must turn off the genes corresponding to the other lineage, or they fail to mature properly.

Egr-1 and 2

The zinc finger transcription factors Egr1, and 2 can act as both transcriptional activators and repressors. They are widely expressed outside the hematopoietic system.[156–158] They function opposite of Gfi-1, by turning off granulocyte genes in GMP cells committing to the monocyte lineage.[155] Forcing their expression increases monocytic differentiation at the expense of granulocyte differentiation.[159–161]

Retinoic Acid Receptor α (RAR α)

RAR α is a member of the large nuclear hormone receptor family. These are heterodimeric transcription factors that are regulated by binding to retinoids. RAR α heterodimerizes with the RXR proteins, and binds DNA through its zinc finger DNA binding domains only when retinoic acid (RA) is present.[162] In the absence of RA, this heterodimer binds corepressor complexes and represses transcription. In the presence of RA corepressor complexes are exchanged for coactivator complexes and transcription is induced. RAR α is predominantly expressed in myeloid cells.[163,164] A dominant negative RAR α arrests granulocyte differentiation of a myeloid cell line at a promyelocyte.[165] There are no defects seen in myeloid development of mice lacking RAR α.[164] However, mice lacking both RAR α and γ have neutrophils that are blocked in development at a similar stage as C/EBP ε knockouts.[164]

TRANSCRIPTION FACTORS REGULATING LYMPHOID MATURATION

There are a number of transcription factors that regulate lymphoid maturation. Some act alone, and others act in concert with each other. In some situations ratios of one factor to another may be critical in determining lineage or stage decisions, as will be discussed in a later section (Antagonistic Interactions between Transcription Factors). These transcription factors include PU.1, Ikaros, E2A, EBF, PAX5, Notch1, and GATA3.

PU.1

As discussed, PU.1 is essential for specifying CLP formation. Conditional knockout of PU.1 in the adult marrow leads to a loss of CLPs.[137,166] Germline deleted PU.1 mice have decreased B-cell and T-cell formation.[134,135,138] T-cell development appears to be delayed in PU.1 knockout animals.[135,167] PU.1 is normally expressed in the early stages of T-cell development before expression of the T-cell receptors CD4 and CD8.[168,169] The delayed T lymphopoiesis may be caused by loss of an early proliferative function of PU.1, which is also seen in early erythroblasts that express PU.1.[170,171] Alternatively, the delay may be caused by having to produce T cells through a developmental pathway that does not involve the CLP.

PU.1 is also critical for B-cell maturation, beyond the CLP. Many B-cell specific target genes have been identified for PU.1 including IL7 receptor, the surrogate light chain Mb1, CD45, and immunoglobulin light chains κ and λ.[172,173] Interestingly, in pro-B cells specifically deleted for PU.1 these genes continue to be expressed.[137,166] Similar to the case of SCL and AML1 in HSCs, PU.1 no longer is absolutely required for the B cell lineage once the B-cell precursor is specified from the CLP. There are slight functional defects in *PU.1*$^{-/-}$ B-cells. Additionally, an Ets family member closely related to PU.1, called Spi-B, is also not required to maintain expression of

the putative PU.1 target genes in B cells.[166] A potential early target gene of PU.1 that may be involved in committing the CLP to the B-cell lineage may be EBF. PU.1 was shown to regulate EBF and retroviral expression of EBF could overcome the block to B cell development in the absence of PU.1.[174] EBF is discussed more fully below (E2A, EBF, and Pax5).

Ikaros

Along with PU.1, the transcription factor Ikaros is involved in early lymphoid development.[175] Similar to PU.1, it is expressed broadly throughout the hematopoietic system.[176–179] It is a zinc finger DNA binding protein. Its carboxyl terminal zinc fingers are involved in DNA binding and the amino terminal zinc finger mediate partner binding.[177,178,180] Ikaros can function as both a transcriptional repressor and an activator. It also interacts with chromatin remodeling proteins and transcriptional repressor complexes.[181–185] An initial mouse model of Ikaros deletion was found to produce a dominant negative form of Ikaros, which could interfere with the function of Ikaros and the related family members Helios and Aiolos.[186] These mice did not develop T cells, B cells or NK cells. Interestingly, mice with one allele of Ikaros mutated developed T cell leukemia and lymphoma.[187] Null mutations of Ikaros were later engineered, and these mice lack both fetal B cells and T cells.[188,189] In the adult, though, the B cells remain absent but T cells are produced.

E2A, EBF, and PAX5

Other genes involved in B-cell development are E2A, EBF, and PAX5 (also termed BSAP). These transcription factors often work in concert with each other to regulate B-lymphopoiesis. The E2A gene gives rise to two proteins, E12 and E47, by differential splicing of E12- and E47-specific bHLH-encoding exons.[190–192] E12 and E47 are bHLH proteins that dimerize with other bHLH proteins to regulate many genes involved in B-cell antigen receptor arrangement and B cell receptor signaling, often in cooperation with EBF.[193] Deletion of either E2A or EBF results in a block of B cell development at the pro–B-cell stage, before B-cell receptor rearrangement.[194–196] PAX5 acts downstream of E2A and EBF. EBF has been shown to activate the PAX5 promoter.[193,197,198] PAX5-deficient B cells are blocked in development following the rearrangement of the B-cell receptor, yet they express both EBF and E2A.[199] *PAX5*$^{-/-}$ pro-B cells express several myeloid genes, including the cytokine receptors M-CSFR, G-CSFR and GM-CSFR α.[200] These cells have been also shown to be multipotent, with the ability to differentiate into macrophages, erythrocytes and T cells. Similar to Gfi-1 in granulocytes, a critical role of PAX5 may be to turn off inappropriate myeloid gene expression in B cells.[201,202]

Notch1

T-cell development absolutely requires Notch1.[77] In the section on HSC specification we previously discussed Notch1, which not only assists in specifying HSC during embryonic development, but also is crucial for T-cell differentiation. Expressing the transcriptionally active form of Notch1, ICN1, in murine bone marrow induces T-cell development.[203] Similarly, a bone marrow stromal cell line expressing the Notch ligand Delta-like 1 (DL1) induces T-cell differentiation, and blocks B-cell differentiation of fetal liver hematopoietic progenitor cells.[204] Interestingly, low expression of Notch can inhibit B-cell differentiation, but higher levels of expression are required to block NK cell development.[205] Additionally, *Notch1*$^{-/-}$ hematopoietic cells injected into donor mice produce B cells in the thymus, indicating that without Notch1 the CLP is driven towards B lymphopoiesis.[77,206] These experiments suggest that Notch1 is critical in both specifying T-cell development and also promoting T-cell maturation.

As mentioned, Notch1 deficient mice die during embryonic stages of development. *Notch1*$^{-/-}$ bone marrow failed to generate T cells when transferred to irradiated recipients.[77] Closer examination of the blockade of T-cell development indicated that *Notch1*$^{-/-}$ cells had difficulty transitioning the TCR β checkpoint. *Notch1*$^{-/-}$ thymocytes had impaired V-DJ rearrangement and a decreased number of TCR β-expressing cells.[207] This study also showed that although *Notch1*$^{-/-}$ cells could not make α/β T cells, they could generate γ /δ T cells. Notch1 is also thought to be involved in directing CD4 versus CD8 T cell fate cell decisions.[208,209] However, deletion of Notch1 in T cells that had already undergone thymic selection resulted in no defects in the generation of CD4 or CD8 cells.[210] This could be caused by activity from other Notch family members. Thus, Notch1 plays diverse roles at multiple stages of hematopoiesis.

GATA3

GATA3 is a member of the GATA family of zinc finger transcription factors, which includes GATA1 described above.[211] These two proteins are very homologous, and GATA3 can rescue the development of GATA1-deficient erythroblasts.[212,213] GATA3 was originally isolated as a regulator of the TCR α gene enhancer.[214] It is also implicated in the regulation of several other T-cell genes including TCR β, δ and CD8.[215–219] Its expression in the hematopoietic system is limited to T cells and NK cells.[214,220] Mice deficient for GATA3 die between 11.5 and 13.5 dpc of multiple defects, including growth retardation, severe hemorrhage, and neuronal defects.[221] Chimeric mice generated with *GATA3*$^{-/-}$ ES cell demonstrated that GATA3 deficient cells could contribute to all hematopoietic lineages except T cells.[222] *GATA3*$^{-/-}$ *RAG2*$^{-/-}$ chimeric mice had a complete absence of double positive and single positive T cells in the thymus, and no T cells were detected in the periphery.[223] Using a conditional allele of GATA3, it was shown that GATA3 is required at the β-selection point of T-cell development.[224] At this point in T-cell development, CD4/8 double positive thymocytes must rearrange their TCR β chain, and express it on the cell surface in order to proceed to single positive CD4 or CD8 T cells. Surprisingly, TCR-β chain RNA is detected at normal levels in GATA3-deficient CD4/8 double positive T cells.[224] However, they express reduced TCR β protein suggesting that GATA3 is regulating TCR-β through a posttranscriptional mechanism. Later in T-cell development, GATA3 is required for T-cell differentiation into the TH2 helper T-cell subset and is necessary for expression of the cytokine IL4 that partially defines the TH2 subset.

Transcription Factors in NK Cell Development

PU.1 and Ikaros are both required for proper NK development. Transplantation experiments into *RAG2*$^{-/-}$ mice with *PU.1*$^{-/-}$ bone marrow have shown that the *PU.1*$^{-/-}$ cells contributed poorly to the NK progenitor pool, and very few of these progenitors mature and make it to the periphery.[225] The NK cells that did develop had reduced expression of the IL2 receptor, c-kit, and LY49 family receptors. Significantly, *PU.1*$^{-/-}$ NK cells that did make it to the periphery did not seem to be impaired in their cytolytic activity. Therefore, PU.1 may be required for early NK development but may be dispensable in the mature cells, similar to what is observed with B cells.[137,166,225] In addition, *Ikaros*$^{-/-}$ mice also do not make NK cells, and this may be caused by the decreased expression of Flt3 and CD122 in these cells.[226]

Other transcriptions factors required for NK development includes the Ets family member Ets-1 and the inhibitory basic helix loop helix protein Id-2. Deletion of Ets-1 in mice result in functional defects with B cells and T cells, and an absence of functional NK cells.[227] Ets-1 deleted mice have almost a complete absence of NK cells in the bone marrow, spleen and periphery. In vivo, Ets-1-deficient NK cells lacked cytolytic activity. In vivo Ets-1-deficient mice were also susceptible to tumors that are usually cleared by NK cells.[227]

Id-2 is an inhibitory member of the basic-helix-loop-helix family of transcription factors.[228] It lacks the basic domain commonly

conserved in this family, but can heterodimerize with other transcription factors, including E2A described above. Because the basic domain interacts with DNA, Id2-containing heterodimers are unable to bind to DNA. Thus, Id-2 appears to function by binding to and inhibiting other helix-loop-helix transcription factors. Mice deficient in Id-2 lack any mature NK cells, and NK cell progenitors are substantially reduced.[229] The ratio of Id-2 to E2A proteins may be critical for determining lymphoid cell fates, where high E2A drives B-cell production, and high Id-2 drives NK cell production. Overexpression of Id-3 in hematopoietic progenitors blocks T cell development, but stimulates NK cell production.[230] The increased production of NK cells by Id-3 may be a result of its mimicking Id-2 activity, because no NK defect has so far been reported for Id-3 deficient mice.[231,232]

Transcription Factors in Dendritic Cell Development

As discussed, dendritic cells (DC) can be derived from cells that come from either the CMP or CLP.[15–17] Because of this many of the same transcription factors involved in myeloid and lymphoid development are required for proper dendritic cell development. There are three major groups of dendritic cells: Langerhans cells, plasmacytoid dendritic cells and conventional dendritic cells, which can be derived from either monocytic or lymphocytic precursors.[233] Requirements for individual transcription factors differ with each subset. The conventional DCs can be further subdivided by expression of cell surface markers. All conventional DCs express both CD11b and CD11c.[233] However, they can be further divided into three subsets: $CD4^+$ or $CD8^+$ DCs (both lymphoid), and CD4/8 double negative (myeloid derived). The lack of either PU.1 or Ikaros produces profound defects in DC development.[234,235] PU.1 is expressed at high levels in conventional DCs, and at lower levels in plasmacytoid DCs.[132] *PU.1*$^{-/-}$ embryos or neonates do not make $CD11b^+/CD11c^+/CD8^-$ (myeloid) or $CD11b^+CD11c^+CD8^+$ (lymphoid) dendritic cells.[234,235] However, using fetal thymus organ culture it was shown that lymphoid DCs could be produced from *PU.1*$^{-/-}$ precursors, and that these DCs were functional.[235] This indicates that the lack of *PU.1*$^{-/-}$ DCs is at least in part caused by a microenvironmental defect. Langerhans and plasmacytoid DCs have not been closely examined in PU.1 null animals. However, PU.1 is upregulated in human myeloid cells differentiated toward Langerhans DCs with TGF β.[236] Additionally, PU.1 retroviral transduction of human $CD34^+$ progenitors promoted Langerhans DC development.[237] The related transcription factor Spi-B has also been implicated in the development of human plasmacytoid cells.[238,239]

PU.1 has been proposed to have an instructive role in DC cell development. Forced expression of PU.1 in monocytes can drive them to differentiate to DCs.[240] The decision between monocyte and dendritic cell fates could be controlled by a balance between the PU.1 and another transcription factor MafB.[240] Exogenous PU.1 expression in monocytes downregulates the expression of MafB. Additionally, PU.1 binds to MafB and inhibits its ability to positively regulate transcription and drive monocyte differentiation of a hematopoietic progenitor cell line.

Ikaros is also critical for DC development. Mice homozygously carrying the dominant negative allele of Ikaros do not generate any of the conventional dendritic cell subsets.[179] However, mice deficient for any expression of Ikaros lack myeloid but not lymphoid DCs.[241] Additionally, expression of a dominant negative form of Ikaros in human CD34+ progenitors blocked their ability to make myeloid but not lymphoid DCs.[242] A role for Ikaros in Langerhans DCs has not been described. Mice expressing a hypomorphic allele of Ikaros lack plasmacytoid DCs.[243] These mice are hindered in their ability to make the antiviral cytokine Interferon γ, and are highly susceptible to viral infection. Ikaros mutant HSC lack the expression of the tyrosine kinase receptor Flt3,[244] which has been shown to be important in dendritic cell development. Thus, the poor DC development in Ikaros mutant mice may be caused by lack of expression of this receptor by DC progenitors.[245,246]

Other factors involved in generating DC subsets that were previously discussed for other lineages are Gfi-1 and Id-2. Gfi-1-deficient mice have a dramatic reduction in myeloid and lymphoid-derived DCs in vivo.[247] Conversely, Langerhans DCs were significantly increased in vivo. In vitro, DCs could not be generated from *Gfi-1*$^{-/-}$ hematopoietic progenitors. Instead, the progenitors had a much greater tendency to differentiate into macrophages.

Id-2 is also required for Langerhans and lymphoid DCs.[248,249] No Langerhans DCs are generated in *Id2*$^{-/-}$ mice, and the $CD11b^+/CD11c^+/CD8^+$ lymphoid DC population is greatly reduced. Id-2, like PU.1, is induced by TGF-β in human hematopoietic progenitors.[236] Forced Id-2 expression alone, or in combination with PU.1, cannot induce Langerhans DC differentiation in the absence of added DC cytokines. However, Id-2 expression does downregulate expression of monocyte genes, and when TGF-β is added, induces Langerhans DC formation.[236]

TRANSCRIPTION FACTOR CONCENTRATIONS IN HEMATOPOIETIC DEVELOPMENT

Several hematopoietic transcription factors have been shown to have concentration dependent effects on lineage specification or stage progression. This concept first arose from work with Oct-4 in ES cells, where different concentrations resulted in distinct cell fates. High expression of Oct-4 in differentiating ES cells promotes mesodermal commitment, whereas low expression of Oct-4 promotes trophoblast commitment.[250] In hematopoiesis, c-myb and PU.1 are the best examples of the principle that different cellular concentrations of transcription factors affect lineage specification.

The presence of PU.1 is needed for the development of monocytes, granulocytes, and B cells.[134,135] In addition, PU.1 is required for proliferation of erythroid precursors.[170,171] However, for erythrocytes to fully mature, PU.1 expression must be extinguished. Similarly, PU.1 is expressed early in T-cell development and may be important for early thymocyte proliferation, but that expression must be extinguished for full T-cell maturation.[169] Because monocytes express higher levels of PU.1 than B cells, it was hypothesized that high levels of PU.1 specified monocyte commitment over B-cell commitment.[131,251] By retrovirally expressing PU.1 in *PU.1*$^{-/-}$ hematopoietic progenitors, it was shown that high concentrations of PU.1 directed the development of $CD11b^+$ macrophages, and low concentrations of PU.1 directed the development of $CD19^+$ B cells.[251] In a later study, it was demonstrated that high levels of PU.1 pushed the GMP towards monocytes rather than granulocytes.[252] *PU.1*$^{+/-}$ ES cells produced more granulocyte precursors and fewer monocytic precursors than normal ES cells compared to wild-type cells. In addition, PU.1 heterozygosity could partially correct the neutropenia of a G-CSF deficient mouse.[252] This observation has implications for leukemogenesis, as both *PU.1*$^{+/-}$ mice and mice with a hypomorphic PU.1 allele have an increased susceptibility to develop AML.[253,254]

The c-Myb gene is abundantly expressed in immature cells of the hematopoietic system. It was originally identified as the transforming gene of the avian retroviruses AMV and E26.[255–257] Mice without c-Myb do not generate definitive hematopoietic cells.[258] In embryos homozygous for deletion of c-Myb, hematopoietic progenitor cells are produced in the AGM. These cells initially migrate to the fetal liver, but do not expand normally there, and the mice ultimately succumb anemia.[259,260] Based on this, it is thought that the major function of c-Myb in early hematopoiesis was to regulate proliferation of hematopoietic progenitor cells, and that loss of c-Myb results in a loss of fetal liver progenitors because of a relative decrease in proliferation versus commitment to terminal differentiation. C-Myb concentrations also play a role in directing distinct lineage fates.[260] Embryos homozygous for hypomorphic c-Myb alleles, resulting in decreased c-Myb expression, had increased numbers of immature cells in the fetal liver. In these embryos, macrophage and megakaryocyte development was increased but erythroid and lymphoid development was compromised.

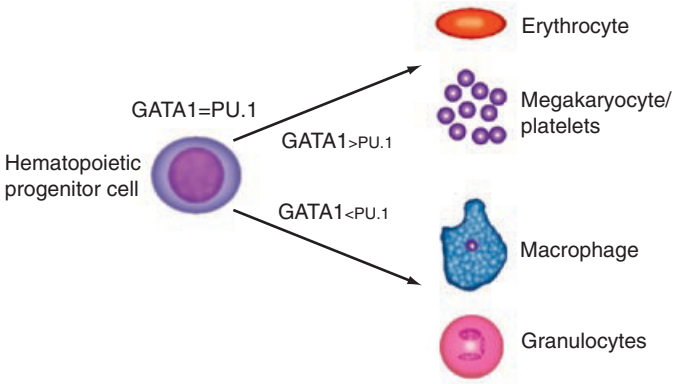

Figure 21–3 Model of how GATA-1 and PU.1 direct hematopoietic differentiation. In an uncommitted progenitor cell the concentrations of PU.1 and GATA-1 are equivalent. PU.1 is able to bind to GATA-1 bound to erythroid target genes and repress transcription and GATA-1 can bind to PU.1 bound to the regulatory elements of myeloid genes, and displace the factor c-Jun which is needed for activation of transcription. By random chance or through environmental signals such as cytokines the levels of GATA-1 could increase allowing it to continue to repress PU.1 targets but also be able to titrate away PU.1 From erythroid genes and allow the activation of the erythroid differentiation program. Similarly levels of PU.1 could increase and drive myeloid development while continuing to repress the erythroid differentiation program.

ANTAGONISTIC INTERACTIONS BETWEEN TRANSCRIPTION FACTORS

Concentrations of transcription factors may play an important role on another level, as a result of antagonistic interactions with other transcription factors. Thus, high levels of one transcription factor may be required to overcome the antagonistic effect of another factor. The interaction between GATA1 and PU.1 demonstrates this principle (Fig. 21–3). Both of these factors are expressed at low levels in the uncommitted CMP.[11,132] In this uncommitted cell, the activities of these factors are thought to be in balance. GATA1 binds to the DNA binding domain of PU.1 through its carboxy proximal zinc finger and inhibits its transcription.[261,262] Likewise, PU.1 also interacts with the GATA1 protein.[261–263] GATA1 interacts with PU.1 and displaces the critical coactivator protein, c-Jun, decreasing the ability of PU.1 to promote transcription.[261,262] Conversely, PU.1 recruits the protein Rb to GATA1, and this in turn recruits a transcriptional repression complex.[264] Several differentiation systems have demonstrated that this cross-antagonism is important in lineage fate choices. The more highly expressed factor turns on its target genes and represses the alternative factor's target genes, which results in distinct lineage commitments—erythroid for GATA1 and granulocyte/monocyte for PU.1. This was demonstrated in murine erythroleukemia cells transduced with a PU.1 retrovirus. Overexpression of PU.1 resulted in the downregulation of endogenous GATA1 expression and switched these cells to a myeloid cell fate, as demonstrated by cell surface markers and the acquisition of phagocytic activity.[265,266] Similarly, manipulating the relative concentrations of PU.1 and GATA1 in *Xenopus* or Zebrafish affected the ratio of macrophage to erythroid differentiation.[267,268]

Another important example of this principle is the ratio of PU.1 to C/EBP α in the GMP, which determines whether the myeloid precursor commits to the granulocyte or monocyte lineage.[252] Both PU.1 and C/EBP α are necessary for proper monocyte and granulocyte differentiation. When PU.1 activity exceeds that of C/EBP α, the expression of PU.1-responsive downstream target genes will direct monocytic differentiation. However, if C/EBP α activity is higher, the GMP will commit to the granulocyte lineage. C/EBP α inhibits PU.1-induced transcription from reporter genes regulated by a multimerized PU.1 binding site.[237] This repression is a result of binding between the leucine zipper domain of C/EBP α and the Ets domain of PU.1. Like GATA1 binding to PU.1, C/EBP α binding results in the dissociation of c-Jun, which blocks PU.1 transactivation.[237] Additionally C/EBP α overexpression had an effect on cell fate decisions. In myeloid progenitors the ratio of PU.1 and C/EBP α to one another may determine whether myeloid progenitors become monocytes or granulocytes.

TRANSCRIPTION FACTORS IN LEUKEMIA

Transcription factors important in hematopoiesis are commonly involved in chromosomal translocations in human leukemias. These translocations alter the function of these transcription factors, often producing blocks in differentiation of hematopoietic progenitors. Indeed, many of these transcription factors were first isolated by cloning of the translocation break point. Thus, defining what has gone wrong in leukemia has greatly assisted in defining what is required for normal hematopoiesis. There are a large number of transcription factors involved in leukemic translocations, but we will focus on Notch1, MLL, SCL, AML1, CBF β, LMO2, E2A, TEL, and MOZ because they have each shed light on crucial characteristics of normal versus malignant hematopoiesis (Table 21–1). Transcription factors can also be altered in acute leukemia by point mutations, and this can lead to inactivation of the function of those transcription factors as well. Examples of this include C/EBP α, GATA1, and PU.1. Alterations in expression of key transcription factors can also promote the development of acute leukemia, and an example of this is Bmi1.

The study of these transcription factors has lead to major advances in understanding leukemogenesis. The fusion oncoproteins resulting from the AML1-ETO and PML-RAR α translocations do not result in the generation of acute leukemia in mice when transduced into bone marrow progenitors.[269,270] An additional genetic lesion was needed in these models to produce acute myeloid leukemia. This additional genetic lesion was often the constitutive activation of a protein that stimulated proliferation, such as the Flt3 internal tandem duplication. This led to the paradigm that two genetic lesions are required for the generation of acute leukemias, one lesion that enhances proliferation and one lesion that blocks differentiation.[271] Translocations involving transcription factors in leukemia most often result in repression of differentiation, by inhibiting the expression of genes normally required for proper maturation. This often occurs because the translocation oncoprotein turns the transcriptional activator into a repressor. Thus, many of the transcriptional activators that are required for proper myeloid or lymphoid differentiation are targets of leukemic translocations. This paradigm has implications for therapy, as both genetic lesions must be targeted for appropriate destruction of the malignancy.

Translocations Involving Transcription Factors Associated with Leukemia

Notch1

In rare cases of T-cell acute lymphoblastic leukemia the t(7;9)(q34;q34.3) translocation occurs. Cloning of this translocation showed that Notch1 (also termed TAN1) located on chromosome 9 was translocated relatively intact to the TCR β locus on chromosome 7, resulting in its constitutive expression.[272] Because Notch1 expression is required for production of early hematopoietic progenitors, it is thought that constitutive aberrantly high expression of Notch1 in a T-cell progenitor maintains the progenitor phenotype and blocks appropriate maturation. Interestingly, although translocations involving Notch1 are very rare, point mutations may be quite common in T-cell ALL. It has been reported that more than 50% of all human T-ALL cases have activating mutations that involve the extracellular heterodimerization domain or the C-terminal PEST domain of

Table 21–1 Transcription Factor Genes Translocated in Leukemia

Transcription Factor	Normal Function	Translocation	Fusion Partner	Disease
Notch1 (TAN1)	HSC specification Lymphoid cell fate decisions T-cell development	t(7;9)(q34;q34.3)	TCR β locus	T-ALL
MLL	HSC specification	t(4;11) t(6;11) t(9;11) t(10;11) t(11;19) t(11;19)	AF4 AF6 AF9 AF10 ELL ENL	ALL AML AML AML AML AML/ALL
SCL (TAL1)	HSC specification Erythropoiesis Megakaryopoiesis	t(1;14)	TCR α/δ locus	T-ALL
AML1 (RUNX1)	HSC specification Megakaryopoiesis	t(8;21)	ETO (MTG8)	AML
CBFb	HSC specification	Inv(16) t(16;16)	MYH11	AML, M4Eo
LMO2	HSC specification	t(7; 11) t(11;14)	TCR δ locus TCR β locus	T-ALL T-ALL
E2A	Lymphopoiesis	t(1;19) t(17; 19)	Pbx HLF	Pre B-ALL Pre B-ALL
TEL	HSC maintenance	t(12;21) t(5;12)	AML1 PDGFR	B-ALL CMML
MOZ	HSC maintenance	t(8;16) t(8;22)	CBP TIF2	AMoL M5 AML

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; B-ALL, B-cell acute lymphoblastic leukemia; CMML, chronic myelomonocytic leukemia; HSC, hematopoietic stem cells; T-ALL, T-cell acute lymphoblastic leukemia; TCR, T-cell antigen receptor.

NOTCH1.[273] This implies that inappropriate activation of the Notch signaling pathway is a key step in the origin of most T-cell leukemias. Thus, targeting this pathway may be an important new addition to therapy of T-ALL.

MLL (ALL1, HRX)

Recurring translocations involving chromosome 11q23 have been observed that occurred in a wide variety of both ALL and AML. After a prolonged search, several groups cloned the gene at 11q23 disrupted in the t(4;11), t(9;11), and the t(11;19) translocation and termed it variously MLL, ALL1, or HRX.[274,275] MLL gene translocations and subsequent fusion oncoproteins are seen in about 70% of AML and ALL in infants, and are also frequent in treatment-related leukemias, especially in patients treated with drugs inhibiting topoisomerase II.[276,277] There are more than 36 distinct translocation partners of MLL, making it the most promiscuous of the transcription factors disrupted in leukemia.[278] This implies that the critical common element in these leukemias might not be the partner, but rather the loss of the C-terminal regions of MLL. MLL can even be self-rearranged, resulting in a partial tandem duplication of the gene in some cases of AML.[279,280]

The protein has homology to Drosophila trithorax, which regulates homeotic segment formation in development. MLL has amino terminal AT hooks, six zinc finger domains, and a histone methyltransferase domain. MLL normally regulates homeobox gene expression through many mechanisms, including interaction with CBP, histone deacetylases, and TFIID at promoter sequences, and methylating histone H3 lysine 4, which opens chromatin and promotes transcription.[278] In most of the MLL translocations the histone methyltransferase activity is lost, but often the translocation partner provides such methyltransferase activity. The mechanism by which the MLL fusion oncoproteins generate leukemia is complex, and not completely understood.[278] It is thought that MLL transforms hematopoietic progenitors by inappropriately reactivating homeobox gene expression, which prevents differentiation of these progenitors. Constitutive expression of one target of MLL, HoxA9, produces acute leukemia in mice, suggesting a transcriptional mechanism by which MLL generates acute leukemia in humans.[86] In addition, MLL-ENL-transduced mice get leukemia only if HoxA9 and HoxA7 are present, indicating that activation of these homeobox genes is a crucial for MLL leukemogenesis.[281]

SCL (Tal1, TCL5)

Hematopoietic progenitor cell lines were identified from T-cell ALL cases that had a t(1;14) chromosomal translocation. Two groups isolated a gene termed SCL (or TCL5) translocated relatively intact from chromosomes 1 to the TCR δ region on chromosome 14.[282,283] The translocation remaining on chromosome 14 occurred at the TCR δ diversity (D-δ-2) segment, and the reciprocal translocation occurred at the TCR δ diversity segment D-δ-1. The finding that the TCR δ diversity segments were involved in the translocation junctions suggested that the translocation occurred during an attempt at δ-1/δ-2 joining in an early T-cell progenitor as it underwent TCR rearrangement. This implies that aberrant function of the immunoglobulin recombinase proteins may play important roles in the creation of leukemic translocations. Interestingly, rearrangement of the TCL5 locus was also seen in a human melanoma cell line carrying a deletion at 1p32.[282] In this translocation, SCL is not fused to another gene partner, indicating that its abnormal constitutive expression was leukemogenic.

The occurrence of biphenotypic leukemias with both lymphoid and myeloid characteristics, occurring especially frequently in infants,

and following chemotherapy administration, is evidence of the stem cell origin of such leukemias. One of the groups isolated SCL from a t(1;14) translocation found it in a leukemic cell line that was capable of differentiating into either myeloid or lymphoid cells, implying that the SCL translocation might occur in the HSC, even though the primary human ALL leukemia had a T-cell phenotype. These data provided evidence for the existence of leukemic stem cells, which are rare, but capable of unlimited proliferation, and giving rise to multiple differentiated progeny. These more differentiated progeny, which make up the bulk of the disease, are capable of only limited proliferation. The finding of SCL in a cell capable of both myeloid and lymphoid differentiation also led to the studies on the essential role of SCL in normal HSC. About a quarter of all T-ALL patients have another abnormality of SCL, a 90-kb deletion of upstream sequences of the first allele of the SCL locus. This fuses the Sil gene promoter to the downstream SCL gene, producing abnormally high expression of SCL.[284] Transgenically overexpressing the Sil-SCL fusion in mice can produce an aggressive form of T-ALL in conjunction with over-expressed LMO1.[285] This study also found that inappropriately expressed SCL interfered with the development of other tissues derived from mesoderm.

AML1

AML1 and CBF β are heterodimeric partners that are critical for the differentiation of myeloid progenitors; translocation of either results in AML. Miyoshi and colleagues isolated and sequenced cDNA clones for a gene they named AML1 on chromosome 21, which was rearranged by the t(8;21) translocation.[286] AML1 is fused to the ETO gene (also termed MTG8) in this translocation. AML1-ETO inhibits transcription of genes important for proper myeloid differentiation, promoting a block of the maturation of a primitive progenitor by several mechanisms. First, AML1-ETO interacts with and inhibits transcriptional activation by E proteins, which precludes recruitment of p300 CREB-binding protein (CBP) coactivators.[287] These interactions occur through the conserved ETO TAF4 domain. Second, AML1-ETO interacts with the nuclear corepressor N-CoR) and histone deacetylase (HDACs) complex, which also inhibits transcription at myeloid differentiation genes. This interaction was found to be required to block hematopoietic differentiation.

Interestingly, AML1-ETO transcripts have been found in patients' hematopoietic cells belonging to many lineages long after they are thought to be cured, indicating that this genetic lesion occurs in a stem cell.[288] It also is evidence that another genetic lesion is required for induction of AML. AML1-ETO was knocked into the mouse AML1 locus to generate a model of the t(8;21) translocation. These mice died before birth from CNS hemorrhage and failure of fetal liver hematopoiesis, identical to the AML1 knock-out discussed above.[289] This indicates that the main function of AML1-ETO fusion protein is to block normal AML1 transcriptional activation. This hypothesis was underscored by the cloning of several translocations in which AML1 was fused out of frame to its partners, demonstrating that it may be disruption of AML1 more than fusion to ETO that is critical for leukemogenesis.[290,291] In addition, a truncated splice variant of AML1-ETO was isolated that had only a small portion of ETO, without the repressor interacting domains, and this truncated version was more leukemogenic that the full length AML1-ETO in mouse models.[292]

There are several other translocation partners of AML1, and they appear to substantiate the hypothesis that disruption of AML1 and perhaps disruption of the partner gene are critical for leukemogenesis.[293,294] Thus, AML1 and its partners may function more as tumor suppressor genes promoting differentiation, compared to the traditional model of fusion products functioning as dominant oncogenes. Although the t(8;21) AML has a good prognosis, all other AML1 translocations occur often in secondary leukemias and have a poor prognosis.

CBF β

Lui and colleagues cloned the breakpoint in the inv[16](p13q22) seen in acute monocytic leukemia with eosinophils.[295] They found that this inversion created a fusion gene between the 5′ portion of CBF β on 16p13 and the myosin heavy chain gene MYH11 on 16p13. A similar fusion occurs in the less common t(16;16)(p13;q22). The result of this is abnormal localization of CBF β, preventing it from forming heterodimers with CBF α, and activating monocyte differentiation.

Like AML1-ETO, transgenic overexpression of this fusion gene in murine marrow progenitors did not produce monocytic leukemia.[296] However, myeloid maturation was impaired, as there were increased numbers of immature myeloid cells in the marrow, and there was less neutrophil differentiation in progenitor colony formation assays. Coexpression of both the fusion gene and activated N-RAS produced a more severe phenotype characterized by myeloid precursor cell dysplasia, somewhat similar to myelodysplastic syndrome. However, acute leukemias were still rare. When the CBF β-MYH11 fusion is expressed during embryonic development leukemia can occur, but with a long latency of approximately five months.[297] These findings led to the search for cooperating genes which might be important in the generation of human acute monocytic leukemia with eosinophils. This search was more successful than in AML1-ETO, and several candidates have been identified.[298]

LMO2

LMO2 is translocated relatively intact to the TCR β region on chromosome 14 in a t(11;14), and to the TCR δ region in a t(7;11) in T-cell acute lymphoblastic leukemia.[299,300] Because it is not fused to a partner gene in these translocations, it is probable that the its constitutive overexpression is leukemogenic. Further evidence of the leukemogenicity of LMO2 in T cells came from a gene therapy study where the IL-2 receptor γ was retrovirally transduced into CD34+ hematopoietic cells in children with X-linked SCID. Three patients ultimately developed T-cell leukemia when the retroviral integration site was in proximity to the LMO2 promoter.[301,302] This led to abnormal constitutive expression of LMO2 in a situation analogous to that of the T-cell ALL cases in which LMO2 was first isolated. By searching the retroviral integration site database (containing more than 3000 sites) cloned from mice with retrovirally-induced leukemias, one leukemia was found to have integration in both the LMO2 and the IL-2 receptor γ sites, similar to the human cases.[303] These integrations were clonal in this leukemia, indicating that they represent an early step in the transformation of a single hematopoietic progenitor that became malignant. Thus, abnormal constitutive expression of LMO2 in T-cell progenitors can be an important step in the transformation of these progenitors to ALL, once again demonstrating the crucial importance of tight transcriptional regulation of the regulators themselves.

E2A

The t(1;19) in the common pre-B ALL was found to translocate the bHLH gene E2A on chromosome 19 to a homeobox gene on chromosome 1 termed Pbx1 (or Prl).[304] This fusion oncogene encodes an 85-kD protein consisting of the N-terminal two-thirds of E2A fused to the carboxy terminal portion of Pbx1. The fusion protein is a chimeric transcription factor with the DNA-binding domain of E2A replaced by the DNA-binding domain of Pbx1. Thus, genes important for B-cell maturation normally activated by E2A no longer are activated, but rather the genes regulated by Pbx1 are now activated.

Rarely B-cell ALL has a t(17;19) translocation involving E2A. Here E2A is fused to the DNA binding portion of a gene on chromosome 17 that encodes a hepatic leukemia factor (HLF). This chimeric

transcription factor has the amino-terminal transactivation domain of E2A linked to the carboxyl-terminal DNA binding basic region-leucine zipper domain of HLF.[305]

Transgenically overexpressing E2A-HLF produces acute lymphoid malignancies in mice and disrupts B-cell and T-cell maturation.[306] Overexpressing different structural deletions of the E2A-Pbx1 fusion oncogene in mice resulted in lymphomas after a latency.[307] Interestingly, when the Pbx1 homeodomain of the fusion oncogene was deleted, the remaining fusion oncogene continued to transform.

TEL

In B-cell ALL, there is commonly a t(12;21) translocation associated with a good patient prognosis. Golub and Gilliland cloned this translocation breakpoint, and found that the Ets family gene, TEL, on chromosome 12 was fused to AML1 on chromosome 21.[308] This results in the fusion of the helix-loop-helix dimerization domain of TEL to both the DNA-binding and transactivation domains of the transcription factor AML1. TEL loses its Ets family DNA binding domain, and alters the transcriptional regulatory properties of AML1. This is conspicuously different from AML1 translocations in myeloid leukemia, in which the transactivation domains of AML1 are lost. TEL was first described based on its fusion to PDGF receptor in the t(5;12) translocation seen in CMML.[309] More than 20 other translocation partners of TEL have been described in both lymphoid and myeloid malignancies.[310] These partners appear to fall into two classes. They may be signaling proteins like PDGF receptor, ABL, or ARG, where the HLH domain of TEL enhances inappropriate dimerization and subsequent constitutive activation of the signaling molecule; or they may be transcription factors like AML1, whose activity is altered by fusion to TEL. Interestingly, TEL probably also functions as a tumor suppressor, as its other untranslocated allele is lost in approximately 15% of all B-cell ALL.[311]

Transducing the TEL-AML1 fusion into mouse marrow with a retroviral vector produced ALL in a small fraction of mice.[312] Deletion of the tumor suppressor p16 enhanced the rate of formation of leukemia. Another group transplanted TEL-AML1 transduced progenitors, and this resulted in an accumulation of primitive progenitors, a disruption of B-cell maturation, but normal myeloid development.[313] The low level of leukemogenesis indicates that there are likely other genetic lesions that are required. This hypothesis is supported by the finding that TEL-AML1 transcripts can persist long after ALL patients have obtained a continuous complete remission.[314]

MOZ

MOZ (monocytic leukemia zinc finger protein) was originally isolated as part of fusion protein created by the t(8;16) chromosomal translocation associated with AML with monocytic arrest.[315] This translocation fuses MOZ to another transcription factor CBP (CREB binding protein). MOZ is also involved in another leukemic translocation, t(8;22), which fuses MOZ to the transcription factor TIF2.[316,317] TIF2 is known to interact with CBP, thus providing a common link between leukemogenesis in both translocations.[318] MOZ is the founding member of a group of highly conserved proteins characterized by a single C2HC3 zinc finger next to an acetyltransferase domain. MOZ also contains two C4HC3 zinc finger domains, protein-interaction motifs associated with chromatin-bound proteins. These motifs suggested that MOZ is a histone acetyltransferase and may promote transcription by opening chromatin to allow access by transcription factors to DNA regulatory regions. MOZ was found to be fused to CREB-binding protein (CBP), a transcriptional coactivator in the t(8;16) translocation. Mutation of CBP is responsible for Rubinstein-Taybi syndrome. This inherited disorder is characterized by mental retardation, dysmorphic facial structure, and broad thumbs. Interestingly, these patients have an increased risk for developing benign and malignant tumors including certain kinds of brain tumors.

Overexpressing MOZ-TIF2 in murine marrow produced an acute leukemia with some latency.[318] Induction of this leukemia required the CBP interacting domains of TIF2, further evidence that the two translocations have the same molecular mechanism.

POINT MUTATIONS ASSCOCIATED WITH LEUKEMIA

C/EBP α Mutations in Acute Myeloid Leukemia

C/EBP α is a transcription factor critical for the generation of granulocytes. Because of its essential role in differentiating myeloid cells, it was hypothesized that C/EBP α activity may be perturbed in AML. An initial study of 137 AML patients identified 10 individuals with mutations in the C/EBP α gene (CEBPA).[319] Seven of those 10 samples had no karyotypic abnormalities, and all but one of them contained one normal allele of CEBPA. Five of these mutations were in the region coding for the amino terminus of C/EBP α. Because of the use of an alternative initiating methionine CEBPA normally codes for a 42kD protein and a 30kD form. The 30KD form can acts as a dominant negative and represses transcription. The 42kD C/EBP α isoform but not the 30kD form induces terminal differentiation through cell cycle arrest.[320,321] All five amino terminal mutants had increased production of the 30kD protein compared to the 42kD protein. In addition 4 of the amino terminal mutants produced a shorter 159 amino acid 20kD protein. All mutants demonstrated a reduction in DNA binding with several of carboxy terminal mutants having lost DNA binding ability all together. All of the mutants could inhibit DNA binding of wild-type C/EBP α.

Subsequently, more than a thousand hematologic malignancy patients have been screened for CEBPA mutations.[322] These patients include those with AML, myelodysplastic syndrome, acute lymphoblastic leukemia, and non- lymphoma. CEBPA mutations have been detected only in myeloid malignancies. Approximately 9% of the AML samples examined have CEBPA mutations. Almost 20% of AML samples of the M2 subtype have CEBPA mutations. Along with mutations in the amino terminus that changed the ratio of the p42 to p30 ratio, isolated mutations in the basic leucine zipper region of CEBPA occur.[323–325] These mutations are thought to maintain the ability to dimerize with wild-type C/EBP α protein but with the loss of the ability to efficiently bind DNA.

Altering of C/EBP α activity in AML is not isolated to point mutations. Expression of C/EBP α is downregulated by the AML1-ETO fusion protein (Pabst 2001). AML1-ETO decreased the mRNA and protein expression of C/EBP α in a myeloid cell line. Additionally, exogenous expression of C/EBP α into the AML1-ETO-transformed Kasumi cell line induces granulocytic differentiation. Downregulation of C/EBP α expression by translational silencing has been proposed to occur in chronic myelogenous leukemia.[326] Blasts from p210 BCR-Abl induced CML express CEBPA mRNA but very little C/EBP α protein. Introduction of C/EBP α into CML blasts can induce differentiation.

GATA1 in Down Syndrome Associated with Megakaryocytic Leukemia

Children with Down syndrome (trisomy 21) are prone to develop leukemia, and approximately half of those leukemias are AML. Most of the AMLs in Down syndrome patients are acute megakaryoblastic leukemias (AMKL). In addition, about 10% of children with Down syndrome develop a transient myeloproliferative disorder (TMD). In most patients, TMD spontaneously remits, but in a few cases this develops into a severe myeloproliferative disease, with blasts infiltrating the heart and liver. TMD is considered a preleukemic disorder because more than 20% of children diagnosed with TMD later develop AMKL.

In a study looking for GATA1 mutations associated with AML, it was found that GATA1 was mutated in six of six Down syndrome-associated AMKL.[327] No mutations were discovered in all the other AML subtype samples examined. Subsequent studies have shown that GATA1 is mutated in almost all cases of AMKL in Down syndrome and in the TMD of Down syndrome.[328–332] The mutations that have been identified include missense, nonsense, and splice site mutations, along with insertions and deletions. All of the mutations are in exon 2 or the immediate downstream intron 2. The mutations abrogate expression of the full-length 50 kD protein, and lead to the generation of a truncated 40kD protein (GATA1s), which lacks the domain responsible for activating transcription, but retains both zinc fingers. The importance of the amino terminal transactivation domain is unclear, because in several in vitro assays it is not necessary for the promotion of erythroid development. In vivo a shortened GATA1 still rescues murine GATA1 deficiency.[333–335] Thus, it is unknown how GATA1s promotes leukemia. However, it is assumed that it cooperates with other genetic defects associated with trisomy 21.

PU.1 Mutations and Myeloid Leukemia

PU.1 was originally described as the oncogene in murine erythroleukemia. The SFFV virus integrates into the PU.1 locus and causes PU.1 to be overexpressed in erythroid progenitors,[336] blocking their differentiation. In mice it has been shown that reduction of PU.1 levels can lead to the development of myeloid leukemias.[136,137] Hypomorphic alleles of murine PU.1 also lead to development of leukemia. Deletion of a −14kb enhancer element in the PU.1 locus results in expression of approximately 20% of the normal levels of PU.1 in HSCs and myeloid progenitors.[253] These mice first accumulate of abnormal myeloid progenitors, and then progresses to a fatal AML. Differentiation of these AML blast can be restored by exogenous expression of PU.1 through retroviral transduction.

Further evidence supporting a role for reduced PU.1 concentration in myeloid leukemia comes from murine myeloid leukemias induced by γ irradiation.[254,337] Myeloid leukemias induced by γ irradiation frequently undergo a deletion of a portion of chromosome 2 which harbors the *PU.1* gene. Analysis of the other allele of PU.1 demonstrated that it had undergone point mutations in the DNA binding domain. These mutations reduced but did not completely abrogate the ability of PU.1 to associate with DNA. No malignant cells were ever identified that harbored a null mutation in the remaining *PU.1* allele, suggesting that some PU.1 function is required for maintenance of the leukemic state. To date, PU.1 mutations have not been identified in patients with radiation therapy induced AML.[254]

Loss of one allele of *PU.1* has not been shown to have adverse effects in mice although protein levels are reduced by 50% in hematopoietic tissues examined.[134,138,338] However $PU.1^{+/-}$ mice are more susceptible to leukemia development after transduction of PML-RAR α than wild type mice,[339] indicating that reduced PU.1 levels might contribute to the development of acute promyelocytic leukemia.

AML patient samples have been screened for PU.1 mutations. One study observed 10 mutant alleles of *PU.1* in 9 of 126 AML samples examined.[340] These findings are controversial because a subsequent study did not identify any mutations in PU.1's coding region of 77 AML samples.[341] In another study, mutations in PU.1 were discovered in 2 of 60 AML patient samples and 1 of 21 myeloid leukemia cell lines analyzed.[342] The importance of these mutations is unclear because the 2 AML mutations were point mutations in intronic sequence and the one mutation from a myeloid cell line is a silent G-to-A transition at *PU.1*'s codon 65.

Although it is unclear to what extent *PU.1* mutations contribute to leukemia there are additional studies that have demonstrated that PU.1 expression and/or activity is targeted by leukemic oncogenes. The t(8;21) translocation results in the formation of the chimeric oncogene AML1-ETO.[343] Normal AML1 protein has been shown to cooperate with PU.1 in the regulation of myeloid target genes. In contrast, the fusion protein AML1-ETO has been shown to bind to PU.1 and repress the ability of PU.1 to activate transcription.[139] Binding of AML1-ETO displaces c-Jun as a PU.1 coactivator. Additionally, it has been shown the ETO portion of the fusion protein can bind corepressor proteins, and this could also lead to the antagonism of PU.1 transactivation activity.[344] Thus, although mutations within PU.1 itself are unlikely to play much of a role in AML, altering its level of expression may be an important step in leukemogenesis.

Ikaros and Hematological Malignancy

A dominant negative form of Ikaros has severe effects on hematopoietic development. This dominant negative mutant lacks the DNA binding domain of Ikaros, but retains protein-protein interaction domains. The mutant Ikaros forms inactivate dimers with wild-type Ikaros and the related factors Aiolos and Helios. Mice heterozygous for the mutant Ikaros allele do not have any obvious hematopoietic defect in the first month after birth. Soon after the mice develop a lymphoproliferative disorder, which then leads to the development of T-cell leukemias.[187] During the development of this disease the wild-type allele of Ikaros is lost, in a classic tumor suppressor manner.

The Ikaros gene is alternatively spliced in both mice and humans. There are at least 6 different isoforms of Ikaros expressed in hematopoietic cells.[180,345] One of these isoforms, IK6 (lacks the DNA binding domain), is predicted to produce a protein similar to the mouse dominant negative allele. Ectopic expression of IK6 in human $CD34^+$ progenitors impairs B cell differentiation.[346] IK6 expression has been detected in several B and T cell malignancies.[346–351] Additionally, the oncogene BCR-Abl has been shown to induce aberrant splicing of Ikaros, increasing the expression of IK6.[352] This implies that aberrant alternative splicing can play a role in leukemogenicity.

Maintenance of Leukemic Stem Cells: Bmi1

It has been proposed that leukemia is a stem cell disease,[353,354] where only a fraction of cells are able to initiate and maintain the leukemia when transplanted. Similar to its role in the HSC, Bmi-1 is dispensable for the initial development of HoxA9-Meis1 induced leukemia.[98] However, Bmi-1-deficient leukemias are not transplantable into secondary hosts. After transplantation, donor cells underwent a cell cycle arrest, differentiation and/or apoptosis. It is possible that leukemic stem cells require Bmi-1 for maintenance in a like manner as normal HSC.

TRANSCRIPTION FACTORS IN OTHER HEMATOLOGICAL DISEASES

GATA1 in Anemia and Thrombocytopenia

Several human hematopoietic diseases have been associated with point mutations in GATA1. Several families have been identified that has missense mutations in GATA1 which damage normal GATA1 function but do not completely ablate it. The first identification of GATA1 mutations was identified in two half brothers that were anemic and thrombocytopenic.[355] The peripheral blood of these siblings contained very few platelets, and their erythrocytes had abnormal size and shape. Their bone marrow was hypercellular, with large multinucleated erythroblasts and dysplastic megakaryocytes. Interestingly the brothers had three unaffected sisters, suggesting that the disorder was X-linked. Because GATA1 is on the X chromosome, it was sequenced for identification of possible mutations. Both boys had a G to A transition mutation in the coding region of GATA1, which leads to amino acid 205 being mutated from valine to methionine. The valine residue is in the highly conserved amino terminal zinc finger of GATA1 which mediates DNA binding and binding to the cofactor FOG1.[122] Interestingly, this mutation is similar to a V205G

mutation, which was identified through an in vitro screen to identify mutants of GATA1 that could no longer bind FOG1.[356] It was shown biochemically that the human GATA1 V205G mutant bound DNA as well as the wild-type protein, but was impaired in its ability to bind FOG1. Additionally, the V205G mutant could not promote differentiation of a mouse *GATA1*$^{-/-}$ erythroblast cell line.

Other families have been subsequently identified that carry mutations in the amino terminal finger of GATA1. These mutations include G208S, D218G, and D218Y.[357–359] All of these mutations effect GATA1 binding to FOG1, and severity of their disease appears to correlate with the strength of the interaction with FOG1. An R216Q mutation in the amino terminal finger was also identified in patients with macrothrombocytopenia and β-thalassemia.[360] This mutation interfered with DNA binding but left FOG1 binding intact.

AML1 and Familial Platelet Disorder

Deletion of AML1 in murine adult hematopoietic cells leads to defects in megakaryocytopoiesis. Defects in AML1 can also lead to dysfunctional megakaryopoiesis in humans. Familial platelet disorder (FPD) is an autosomal dominant disorder characterized by a decrease in platelet number and function. Inherited syndromes of leukemia are rare, but when investigated, have led to important insight into leukemogenesis. Two FPD family pedigrees were identified that included members with high propensity to develop AML.[361] The disease-associated region was linked to chromosome 22q22.1-22.2. Subsequent identification of 4 more FPC/AML families delineated the responsible region down to 880 kb on chromosome 21.[362] Based on examining candidate genes in the region, one allele of AML1 was consistently found to be mutated in affected members. Families had either nonsense mutations or intragenic deletions in the AML1 gene, which resulted in loss of function in one allele of AML1. Analysis of bone marrow or peripheral blood demonstrated that affected individuals had defects in megakaryocyte colony formation. The study showed that haploinsufficiency for AML1 can result in defects in megakaryopoiesis and predispose to leukemia. Like PU.1, AML1 concentration appears to have effects on hematopoiesis.

GFI-1 Mutations in Human Neutropenia

Because Gfi-1 mice are neutropenic, a study was performed to determine if mutations in human Gfi-1 are associated with neutropenia.[363] There are two congenital forms of neutropenia: cyclic neutropenia and severe congenital neutropenia (SCN). Mutations in the neutrophil elastase gene ELA2 cause cyclic neutropenia, and are also associated with the majority of SCN cases. More than 200 patient samples from neutropenia patients without known ELA2 mutations were screened for mutations in the Gfi-1 coding region.[363] Two distinct heterozygous missense mutations were discovered. A four-month-old boy with SCN had an A to G transition mutation, which resulted in a change of asparagine to serine at amino acid position 382 of Gfi-1. This mutation is in the fifth zinc finger of Gfi-1. Zinc fingers 3 through 5 are required for DNA binding. Subsequent analysis showed that the patient's brother and father had the same Gfi-1 mutation. The patient lacked neutrophils and monocytes, and there was a reduction in CD4+ T cells and B lymphocytes. In vitro assays detected no defect in production of erythroid progenitors, but did reveal a reduction in the number of myeloid progenitor colonies. Another A to G transition mutation was discovered in a 66-year-old female patient with nonimmune chronic idiopathic neutropenia. This mutation resulted in a change of lysine to arginine at amino acid position 403 in the sixth zinc finger of Gfi-1. The patient had persistent low levels of neutrophils, but elevated numbers of monocytes.

In vitro experiments showed that these mutations interfere with the activity of Gfi-1. Both mutations could inhibit the ability of wild-type Gfi-1 to repress transcription, potentially explaining how the two mutations exert an effect even though heterozygous. DNA binding assays showed that the N382S mutant could not bind DNA, and could inhibit wild-type Gfi-1 binding to DNA. The K403R mutation however does not appear to affect DNA binding of Gfi-1.

C/EBP ε in Severe Granule Deficiency

Neutrophil-specific granule deficiency (SGD) is a rare inherited disorder.[364] Neutrophils from these patients have abnormal nuclei and do not express secondary and tertiary granule proteins.[365] The primary granule proteins myeloperoxidase and lysozyme are expressed but the defensin proteins are not,[366,367] and these neutrophils are functionally defective.[368,369] They have no bactericidal activity potentially caused by the lack of granules, respiratory burst activity and a defect in chemotaxis. Because the secondary granule gene lactoferrin is expressed normally in other cells of the body, it was hypothesized that the defect is caused by a transcriptional regulatory defect in granulocytic cells.[368]

Several transcription factor proteins have been identified as being critical for proper granulocyte differentiation to occur in knockout mice including PU.1, C/EBP α and C/EBP ε. However, the phenotype of CEBPE$^{-/-}$ mice most resembled the phenotype of patients with SGD. Because of this, a study was initiated to determine if SGD patients had mutation in the CEBPE gene.[370,371] Cells from two of the five known patients at the time were examined. One patient was homozygous for a 5-nucleotide deletion in the second exon of CEBPE.[370] This produces a frame shifted protein which lacked the dimerization and DNA binding domains of C/EBP ε. This mutated protein also lost its ability to activate transcription. The second patient had a homozygous A nucleotide insertion into exon 2, which also resulted in a frameshift.[371] The predicted protein from this patient would lack the DNA binding, dimerization, and nuclear localization domains. When the patient's neutrophils were examined, it was determined that mutant C/EBP ε protein accumulated in the cytoplasm and was thus unable to regulate transcription. These two patients and the C/EBP ε mutant mice strongly suggest that CEBPE mutations are causative for SGD. However, other subsequent SGD patients have been shown not to have CEBPE gene mutations.[372] It has not been ruled out that C/EBP ε in these patients may be dysregulated in other ways besides coding sequence mutations.

CHAPTER 22

NONHEMATOPOIETIC STEM CELLS ORIGINATING WITHIN THE BONE MARROW

Magdalena Kucia, Janina Ratajczak, and Mariusz Z. Ratajczak

INTRODUCTION

Bone marrow (BM) was for many years primarily envisioned as the "home organ" of hematopoietic stem cells (HSC). In this chapter we discuss current views of the BM stem cell compartment and present data showing that BM also contains a heterogeneous population of nonhematopoietic stem cells. These cells have been variously described in the literature as (a) endothelial progenitor cells (EPC),[1,2] (b) mesenchymal stem cells (MSC),[3,4] (c) multipotent adult progenitor cells (MAPC),[5] (d) marrow-isolated adult multilineage inducible (MIAMI) cells,[6] (e) unrestricted somatic stem cells (USSC),[7] and (f) very small embryonic-like (VSEL) stem cells.[8] It is likely that in many cases similar or overlapping populations of primitive stem cells in the BM were detected using different experimental strategies and hence were assigned different names. Unexpectedly, it was found that the BM could also be a potential source of precursors of germ cells (oocytes and spermatogonial cells).[9,10] It is still unclear whether BM contains a pluripotent stem cell (PSC). Several attempts have been made to identify such a cell in the BM that at the single cell level in vitro could give rise to cells from all three germ layers (mesoderm, ectoderm, and endoderm). However, the most valuable evidence for pluripotentiality of the stem cell is its contribution to the development of multiple organs and tissues in vivo after injection into the developing blastocyst.

It is hypothesized that the presence of these various populations of stem cells in the BM is a result of the "developmental migration" of stem cells during ontogenesis and the presence of the permissive environment that attracts these cells to the BM tissue. HSC and nonhematopoietic stem cells are actively chemoattracted by factors secreted by BM stroma cells and osteoblasts (eg, stromal derived factor-1, SDF-1, hepatocyte growth factor, HGF); they colonize marrow by the end of the second and the beginning of the third trimester of gestation.[11–14] Accumulating evidence suggests that these nonhematopoietic stem cells residing in the BM play some role in the homeostasis/turnover of peripheral tissues and, if needed, could be released/mobilized from the BM into circulation during tissue injury and stress, facilitating the regeneration of damaged organs.[15–23]

Below is a brief summary of the developmental hierarchy of the stem cell compartment (Fig. 22–1 and Table 22–1). This serves to clarify terms and presents the currently recommended nomenclature for these cells. Next, the mechanisms that lead to the developmental deposition of versatile populations of stem cells in adult BM are discussed, as are the biological consequences of this phenomenon for physiological tissue turnover and regeneration.

Developmental Hierarchy of the Stem Cell Compartment from the Totipotent Zygote to Bone Marrow-Residing Stem Cells

Stem cells are endowed with the property of self-renewal and the ability to differentiate into cells that are committed to particular developmental pathways. The compartment of stem cells is organized in a hierarchical way from the most primitive (totipotent) to already differentiated tissue-committed (monopotent) stem cells. In this context HSC are an example of monopotent stem cells already committed to lympho/hematopoiesis.

In Fig. 22–1 and Table 22–1, the developmental hierarchy of the stem cell compartment is outlined. It begins with the most primitive totipotent stem cell, the zygote, which is the result of the fusion of two germ cells (oocyte and sperm) during the process of fertilization. As a totipotent stem cell, the zygote is able to give rise to both the embryo and the placenta. The "artificial" counterpart of the totipotent zygote is referred to as a *clonote* and can be created in the laboratory with an experimental approach known as somatic nuclear transfer, involving removal of the nucleus from a somatic cell and its insertion/transfer into an enucleated oocyte.[24,25] The first blastomeres are totipotent stem cells that are derived from the first division of the zygote or clonote. In support of this is the well-known fact that the first blastomeres, if separated from each other, can give rise to two independent embryos,[26] as seen in the case of monozygotic siblings.

When the blastomeres have divided into the 32-cell stage the embryo is known as a morula. Cells which form the morula have already lost their totipotentcy and are now pluripotent. The pluripotent stem cell (PSC) is defined as being able to contribute to the development of the embryo but has lost the capacity to form the trophoblast (which gives rise to the placenta). Thus the term PSC refers to the stem cells that contribute to all three germ layers, mesoderm, ectoderm and endoderm, but not to the trophoblast.

During early embryogenesis, the growing morula develops a central cavity and becomes the blastocyst.[27] A fully developed blastocyst contains cells that are precursors for extraembryonic tissues and a distinct group of cells called the inner cell mass (ICM).[28,29] The cells of the ICM are also pluripotent and can give rise to all three germ layers of the developing embryo.[30,31]

Another potential source of PSC are embryonic germ cells (EG), which are derived ex-vivo from primordial germ cells (PGC).[32–35] Precursors of PGC are the first population of stem cells that can be identified in a mouse model at the beginning of gastrulation in the proximal primitive ectoderm (epiblast), a region adjacent to the extraembryonic ectoderm.[36–38] These founder cells subsequently move through the primitive streak and give rise to several extraembryonic mesodermal lineages and to germ cells. From a developmental point of view, PGC are the most important population of stem cells because as precursors of germ cells (sperm and oocytes) they are responsible for passing genetic information to the next generation.[39,40] However, if isolated from the developing embryo and cultured ex-vivo, these cells are mortal and undergo terminal differentiation.[41]

One explanation for this is the fact that PGC are protected from uncontrolled expansion by epigenetic modification/erasure of the somatic imprint on so-called somatic imprinted genes (eg, H19 and Igf2).[42–47] This process occurs very early during development, at a time when the PGC begin to migrate to the genital ridges[48] and it is one of the basic mechanisms that prevents (a) their uncontrolled proliferation, (b) initiation of potential parthenogenesis, and (c) teratoma formation.[49,50] PGC, however, if plated over murine fetal fibroblasts in the presence of selected growth factors (leukemia inhibitory factor[LIF]; basic fibroblast growth factor [bFGF]; and kit ligand),[51,52] may undergo epigenetic changes when maintained within in vitro culture conditions and regain the somatic imprint (and thus become an immortalized population of PSC, the embryonic germ cells [EG]).[32] EG in many aspects are equivalent to ES cells.[53] Both ES

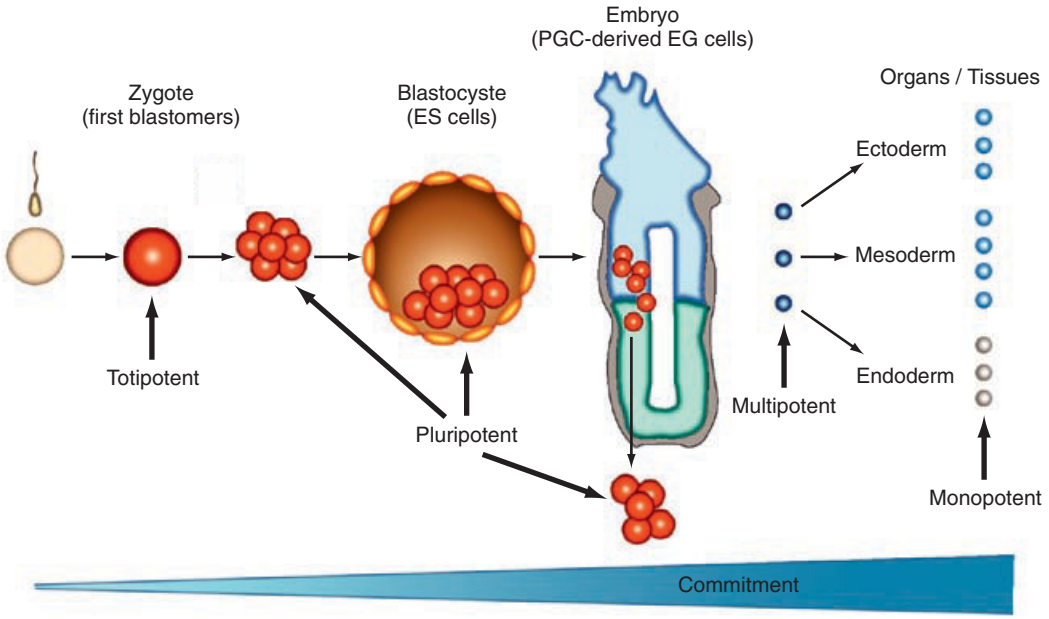

Figure 22–1 Developmental hierarchy of the stem cell compartment. The most primitive stem cell is a totipotent zygote or first blastomere that derives from the first division of the zygote. A totipotent stem cell divides to form both embryo and placenta. Pluripotent stem cells are cells isolated from the inner cell mass (ICM) of a blastocyst or embryonic germ cells (EG) that are in vitro derivatives of primordial germ cells (PGC). These cells contribute to all three germ layers in the developing embryo (ectoderm, mesoderm, and endoderm). Multipotent stem cells give rise to monopotent stem cells that are committed to particular organs/tissues.

Table 22–1 Developmental Hierarchy in Stem Cell (SC) Compartment

Totipotent SC	Give rise to both embryo and placenta. The physiological totipotent stem cell is a fertilized oocyte (zygote) or first blastomere. The artificial counterpart is a clonote obtained by nuclear transfer to an enucleated oocyte.
Pluripotent SC	Give rise to all three germ layers of the embryo after injection to the developing blastocyst. Pluripotent stem cells are cells from the inner cell mass of the blastocyst (ICM), embryonic stem cells (ES), embryonic germ cells (EG) and epiblast-derived stem cells (ESC).
Multipotent SC	Give rise to one of the germ cell layers only, ecto-, meso-, or endoderm.
Monopotent SC	Are tissue-committed stem cells that give rise to cells of one lineage, eg, hematopoietic stem cells, epidermal stem cells, intestinal epithelium stem cells, neural stem cells, liver stem cells, or skeletal muscle stem cells.

Table 22–2 Tissue Contribution of Three Germ Layers

Ectoderm	Brain, sympathetic ganglions, peripheral nerves, eye, epidermis, skin appendices, pigment cells
Mesoderm	Hemato/lymphopoietic cells, endothelium, skeletal muscles, heart, adipocytes, connective tissues (bone, tendon, cartilage), smooth muscles, tubule cells of the kidney
Endoderm	liver, pancreas, lung, gut, thyroid gland

and EG contribute to all three germ layers including the germ cell lineage after injection into a blastocyst. This assay known as blastocyst complementation is a crucial one for confirming in vivo functional pluripotentiality of stem cells.

Next, because during gastrulation three distinct germ layers of cells are established, it is believed that the embryo must possess three stem cell types specific for mesoderm, ectoderm and endoderm. These cells are multipotent stem cells which subsequently give rise to monopotent stem cells specific for tissues/organs that develop from a given germ layer (Table 22–2). For example, multipotent mesodermal stem cells give rise to monopotent hematopoietic, skeletal muscle, heart, endothelial, and mesenchymal tissue-committed stem cells; multipotent endodermal stem cells give rise to monopotent liver, pancreas, and gut epithelium; and ectodermal multipotent stem cells give rise to monopotent brain, peripheral ganglia and nerves, eye, epidermis, and skin tissues.

Looking at this schema of the stem cell developmental hierarchy (Fig. 22–1, summarized in Table 22–1), three questions emerge. First, if the differentiation process is reversible, can monopotent stem cells committed to the given tissue trans-dedifferentiate into other monopotent stem cells? Second, do adult tissues contain, in addition to monopotent tissue-committed stem cells, more primitive populations than pluripotent or multipotent stem cells? Third, if so, are these primitive stem cells, functional not only during ontogenesis but also later on during adult life? These questions are discussed in terms of the BM-derived stem cells.

Bone Marrow Nonhematopoietic Stem Cells—Lessons Learned from the Concept of "Plasticity" of Hematopoietic Stem Cells

Several investigators in the past few years have demonstrated that BM-derived cells can contribute to the regeneration of various organs and tissues.[22,54–62] These observations were mainly explained by the hypothesis that HSC are "plastic" and thus could trans-dedifferentiate into stem cells committed to various nonhematopoietic organs and tissues.[63,64] Occurrence of this phenomenon requires (a) a parallel switch of commitment for HSC in the compartment of monopotent stem cells or (b), as postulated, a step back in the differentiation process of HSC with their dedifferentation into multipotent (one

Table 22–3 Alternative Explanations of the Phenomenon of Trans-Dedifferentiation or Plasticity of HSC

Epigenetic changes	Factors present in the environment of damaged organs induce epigenetic changes in genes that regulate pluripotency of HSC (involvement of changes in DNA methylation, acetylation of histones). More evidence needed that it is a robust and reproducible phenomenon.
Cell fusion	The relatively rare phenomenon by which infused HSC may fuse with cells in damaged tissues and form heterokaryons. Heterokaryons created this way express markers of both donor and recipient cells (pseudochimerism).
Paracrine stimulation	HSC are a source of different trophic and angiopoietic factors that may promote tissue/organ repair.
Microvesicles-dependent transfer of molecules	Some of the plasticity data could be explained by a transient modification of cell phenotype by the transfer of receptors, proteins and mRNA between HSC and damaged cells by membrane-derived microvesicles.
Heterologous population of stem cells in BM	In addition to HSC, BM contains other stem cell populations. Regeneration could be explained by the presence of endothelial progenitors that promote neovasculogenesis and also by the presence of other stem cells including PSC. This could also explain the loss of contribution of BM cells to organ regeneration with use of highly purified populations of HSC.

BM, bone marrow; HSC, hematopoietic stem cells; PSC, pluripotent stem cell.

germ layer-committed) or even pluripotent (three germ layer-committed) stem cells.

This hypothetical possibility that HSC are plastic and able to trans-dedifferentiate raised much hope that HSC isolated from BM, mobilized peripheral blood (mPB) or cord blood (CB) could become a universal source of stem cells for tissue/organ repair. This excitement was bolstered at that time by several reports that demonstrated the remarkable regenerative potential of "HSC" in animal models, for example, after myocardial infarct,[58] stroke,[65] spinal cord injury,[66] and liver damage.[67]

However since these first exciting and promising reports, the role of BM stem cells in the repair of damaged organs has become controversial.[68–70] Further experiments with highly purified populations of HSC showed them not to be effective in regenerating damaged heart[71] or brain.[72] In response to these unexpected results the scientific community became polarized in its view of the concept of stem cell plasticity.

These obvious discrepancies in published results could be explained by differences in the tissue injury models employed and/or problems in detection of tissue chimerism. However, several other possibilities have been proposed to explain these discrepancies (Table 22–3). First, it is possible that, for trans-dedifferentiation of HSC to occur, the appropriate tissue damage models are required which are able to create the permissive "pro-plastic" environment enriched in factors needed to promote this process. Hypothetically such a "permissive" environment could induce epigenetic changes in HSC and thus force them to change lineage commitment.[73,74] Second, it has been postulated that some plasticity data could be explained simply by the phenomenon of cell fusion.[75–79] Accordingly, the donor-derived cells observed in damaged tissues which express nonhematopoietic markers could be in fact heterokaryons, the result of the fusion of BM-derived stem cells with somatic host cells in the damaged organs. Both cell fusion and epigenetic changes, however, are extremely rare and randomly occurring events that certainly could not fully account for all of the positive trans-dedifferentiation data published. Furthermore, fusion as a major contributor to the observed donor-derived chimerism has been excluded in several recently published studies.[80–82]

Another possible explanation of some of the benefits observed in organ/tissue regeneration after infusion of BM-cells is the result of paracrine effects. It is well known that HSC are a source of several trophic cytokines and growth factors and that these factors if released from these cells could promote tissue repair and vascularization.[83] Furthermore, it has been recently shown that cells may transiently modify the phenotype of neighboring cells by transferring surface receptors, intracellular proteins and mRNA by mechanisms that involve exchange of cell-membrane-derived microvesicles.[84,85] Shedding of membrane-derived microvesicles is a physiological phenomenon that accompanies cell growth and cell activation eg, hypoxia or oxidative injury.[86–89] Thus, microvesicle-mediated exchange of receptors, proteins and mRNA between infused BM cells and cells in damaged organs could temporarily modify the phenotype of cells in the damaged organ. An open question is whether microvesicles can also exchange some of the reporter-gene markers employed to detect tissue chimerism (eg, GFP or β-galactosidase).

Surprisingly, during all of these deliberations concerning stem cell plasticity (Table 22–3) and the potential contribution of BM-derived cells to organ regeneration, the concept that BM may contain heterogeneous populations of stem cells was not taken into careful consideration.[69,90] We postulate that regeneration studies demonstrating a contribution of donor-derived BM, mPB or CB cells to nonhematopoietic tissues without addressing this possibility (by including the appropriate controls) has led to misleading interpretations. It is reasonable to assume that the presence of heterogeneous populations of stem cells in BM, mPB, or CB would be considered before experimental evidence is interpreted as examples of plasticity or trans-differentiation of HSC.[91]

Hence the presence of nonhematopoietic stem cells in BM rather than trans-dedifferentiation of HSC, could explain some of the positive results of tissue/organ regeneration as witnessed by several investigators using BM-derived cells.[55,56,67,92] On the other hand, when highly purified HSC were employed for regeneration experiments nonhematopoietic stem cells were likely excluded from these cell preparations. In the current state of knowledge, the phenomenon of trans-dedifferentiation of HSC and their contribution to regeneration of damaged tissues remains questionable.

In summary, the "positive" data supporting stem cell plasticity can be reinterpreted by the assumption that BM-derived stem cells are heterogeneous and that BM tissue contains different types of stem cells including perhaps a rare population of pluripotent stem cells (PSC) (Fig. 22–2). The question remains, however, whether these cells can continuously contribute in adult life to the renewal of other stem cells, including the most numerous population of stem cells in BM, HSC. The mechanisms proposed as responsible for the developmental accumulation of stem cells in BM are discussed below.

Bone Marrow—the Promised Land for Migrating Stem Cells

Early human embryogenesis is the most active period for the developmental migration/trafficking of stem cells. With the beginning of gastrulation and organogenesis, stem cells migrate to places where they establish rudiments for new tissues and organs. Thus at certain points of development, stem cells colonize tissue-specific niches, where they reside as a population of self-renewing cells. These cells supply new cells that effectively replace senescent ones or those undergoing apoptosis. Therefore the role of monopotent tissue residing stem cells during adult life is restricted mainly to cell turnover proper in a given organ or tissue.

The first population of stem cells that are identifiable in the early embryo in the proximal ectoderm (epiblast) are precursors of the PGC already mentioned.[93,94] These cells are endowed from the beginning with robust migratory properties.[95,96] Microscopic analysis of the

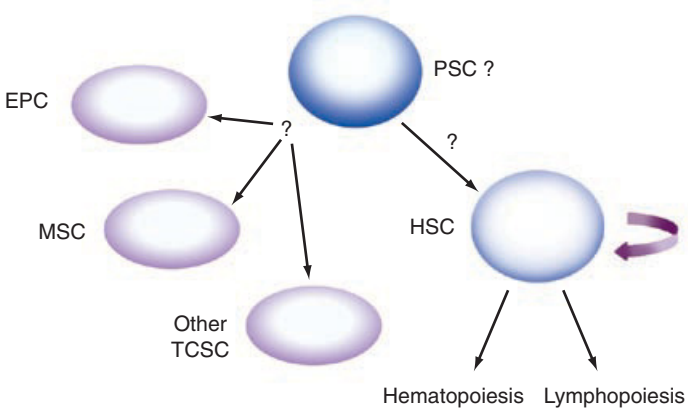

Figure 22–2 Versatile populations of stem cells in bone marrow (BM). BM is traditionally the home of self-renewing hematopoietic stem cells (HSC). BM also contains a small admixture of several nonhematopoietic stem cells such as endothelial progenitor cells (EPC), mesenchymal stem cells (MSC), and perhaps other tissue-committed stem cells (TCSC). The open question is whether BM contains pluripotent stem cells (PSC) and these cells are functional and able to supply all other types of stem cell in BM.

early murine embryo has revealed that by 7.25 days postconception, a distinct cluster of approximately 50 PGC is present at the base of the allantois in the extraembryonic mesoderm close to an area known as the primitive streak.[36] From this place, PGC begin to migrate through the embryo proper towards the gonadal anlagen or genital ridges.[97] Because PGC express the seven-transmembrane span G-protein coupled CXCR4, and because its specific ligand α-chemokine SDF-1 is already expressed in the developing genital ridges, the SDF-1-CXCR4 axis plays a pivotal role in PGC migration and colonization of the developing gonads.[98–101]

It has been proposed that around the same time as PGC are present in the area close to the primitive streak a population of hemangioblasts becomes specified in the same region of the developing embryo.[102,103] Shortly after this in mammals the first primitive HSC are found in the yolk sac and the first definitive HSC can be identified a few days later in the paraaortic splanchnopleura, the aorta-gonad-mesonephros (AGM) region.[104–108] Interestingly, the AGM region is a crossroads through which a population of CXCR4$^+$ PGC migrates to the genital ridges chemoattracted by SDF-1.[96] This association of PGC specification and the appearance of hemangioblasts in the primitive streak and primitive HSC in the yolk sac followed by definitive HSC in the AGM region during the migration of PGC to the genital ridges through the embryo proper gave rise to the hypothesis that PGC could differentiate into HSC and thus could be potential precursors of HSC in the developing embryo.[109,110] This interesting idea, however, requires further study.

Subsequently, HSC from the yolk sac and/or AGM region migrate to the fetal liver which during the second trimester of gestation becomes the major mammalian hematopoietic organ.[111] By the end of the second trimester HSC leave this organ and colonize BM tissue.[106] Signals for the translocation of HSC from the fetal liver to BM are again provided again by SDF-1, which are now being highly secreted by osteoblasts lining the developing marrow cavities, marrow fibroblasts and endothelial cells.[11,12,112] In response to an SDF-1 gradient, CXCR4$^+$ HSC leave the fetal liver and began to home into BM where they finally establish adult hematopoiesis.

It is likely that during these early stages of development the fetal liver and BM are also colonized by other stem cell types that may circulate during organogenesis and rapid body growth/expansion. First, it is possible that during early development epiblast-derived CXCR4$^+$ cells closely related to a population of PGC are deposited in the tissues or even CXCR4$^+$ PGC themselves go astray while migrating through the AGM region to the genital ridges and, together with definitive HSC, follow the same SDF-1 gradient and seed to the fetal liver, subsequently colonizing the BM and perhaps other tissues as well (Fig. 22–3). In support of this hypothesis studies in turtles[113] and more importantly in small and large mammals[114,115] have revealed that during migration to the genital ridges some PGC may stray from the main migration stream and become deposited in various tissues. It is also likely that Oct-4$^+$ cells that were recently identified in several adult organs and tissues could be related to this population of stem cells.[9,10,116–124] Based on this it is possible that the population of Oct-4$^+$ SSEA-1$^+$ CXCR4$^+$ VSEL stem cells recently isolated from adult hematopoietic organs including BM, spleen and thymus are closely related to epiblast-derived cells or migrating PGC that went astray.[8]

Furthermore, it is possible that during later phases of embryogenesis other migrating/circulating stem cells similar to epiblast-derived cells may colonize BM. Supporting this is the fact that all monopotent tissue-committed stem cells (eg, endothelial, neural, skeletal muscle, liver oval, renal tubular endothelium, retina pigment epithelium stem cells) express CXCR4 on their surface and follow an SDF-1 gradient[125–134] thus potentially being able to "home" to the BM. The SDF-1-CXCR4 axis alone or in combination with other chemoattractants could play a crucial role in accumulation of nonhematopoietic stem cells in BM. These cells find a permissive environment in the BM that allows them to survive into adulthood.

It is possible that these BM-residing nonhematopoietic stem cells could play a role as a reserve pool of circulating stem cells for organ/tissue regeneration during postnatal life. Fig. 22–4 shows a schema of stem cell circulation in postnatal life that is supported by several observations.[2,15,16,18,135,136] CXCR4$^+$ HSC, EPC, MSC, skeletal muscle satellite, liver oval, neural, and other monopotent stem cells circulate at low levels in the PB to maintain stem cell pools in distant parts of the body and compete for SDF-1-positive niches in various organs.[15,16,18,21,133] It is also likely that, in addition to these cells, even more primitive PSC (VSEL?) could be released from BM and other tissue niches to circulate in the PB. The number of these cells in the PB increases during tissue damage or pharmacological mobilization.

Further study is required to identify the chemoattractants, besides SDF-1, released from damaged tissues and able to mobilize and chemoattract these cells to these tissues.[17,20,133,137,138] It is postulated that BM, as a source of many stem-cell chemoattractants and survival factors, provides an environment that encourages circulating CXCR4$^+$ tissue-committed stem/progenitor cells to home there.

In this context BM tissue becomes a "home" not only of HSC but also of already differentiated circulating CXCR4$^+$ tissue-committed stem/progenitor cells and more primitive CXCR4$^+$ PSC (VSEL). These cells reside in BM and could play an important role in tissue/organ repair as a mobile reserve pool of tissue-committed stem/progenitor cells. This concept will be discussed in more detail later in this chapter.

Evidence of the Heterogeneity of Bone Marrow Stem Cells

The concept that BM may contain some nonhematopoietic stem cells has been postulated by several investigators and, as previously mentioned, the best evidence that BM stem cells are in fact heterogeneous was provided by experiments showing that BM-derived cells could support the regeneration of various tissues/organs.[69,90,139]

Table 22–4 lists different types of nonhematopoietic stem cells that have been postulated to reside in BM tissue. These cells will be discussed below, and the similarities between these versatile populations of stem cells indicated. It is very likely that several investigators using different isolation strategies described the same populations of stem cells but gave them different names according to circumstance.

Endothelial Progenitor Cell (EPC)

The identification in the BM and PB of cells with endothelial progenitor activities has generated considerable interest in the role of

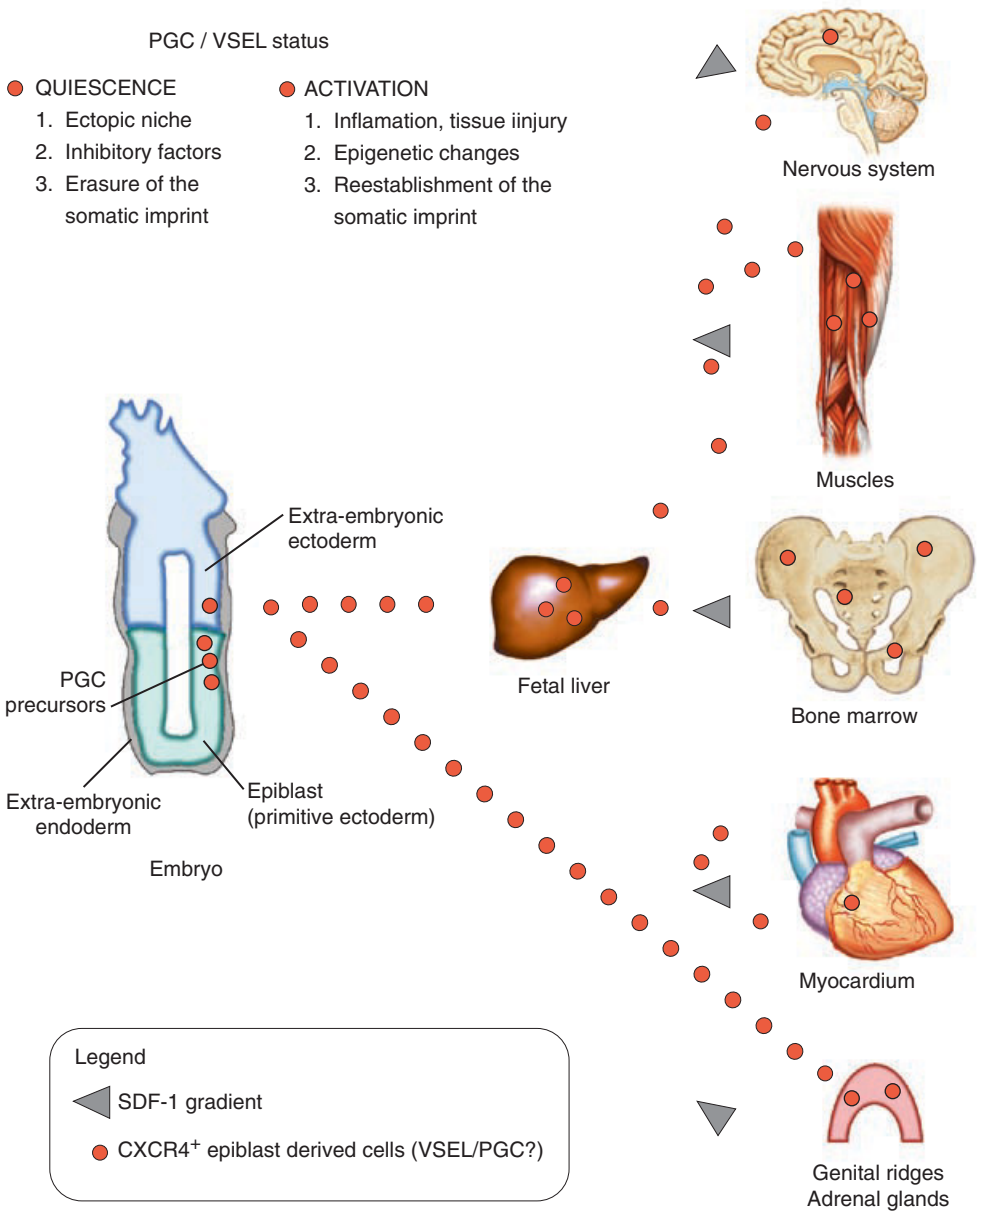

Figure 22–3 Hypothesis of developmental deposition of Oct-4$^+$ epiblast-derived embryonic stem cells (VSELs?) in adult tissues.The presence of Oct-4$^+$ stem cells in the fetal liver, BM and other tissues could be explained by the developmental deposition in different organs (mainly BM) of CXCR4$^+$ epiblast derived stem cells (eg, VSELs) that follow an SDF-1 gradient. The potential relationship of these cells to early epiblast/primordial germ cells (PGC) requires further investigation.

these cells during the maintenance and repair of blood vessels.[140,141] From a historical point of view the close relationship between hematopoiesis and vasculogenesis was postulated almost 2000 years ago by Aristotle. This ancient Greek philosopher came to the conclusion based on his empirical work on development that the heart along with blood vessels were the first structures to appear during embryogenesis in eggs from different species. This notion now appears especially significant because it implies that the heart and the blood have a common origin. Translated into today's language, this means that both descend from a common endothelial and hematopoietic progenitor, the putative hemangioblast in the embryonic mesoderm.[102,103,105] Hemangioblast activity was demonstrated to exist in embryoid bodies formed by embryonic stem cells in in vitro cultures.[142] However, whether hemangioblasts persist in adult life and reside in the adult BM, is not yet clear.[143–145]

Nevertheless, adult BM-derived cells have been shown to contain endothelial precursors in both mice and humans.[1,141] The possible role of these cells in the hierarchy of BM-derived stem/progenitor cells and their potential relationship to PSC and hemangioblasts is shown in Fig. 22–5, panel A. Accumulating evidence suggests that the BM may contain a population of EPCs residing in BM tissues that could be released/mobilized into PB as a source of cells able to play a role in the vascularization of damaged organs.[2,146–148] The phenotype of these cells is shown in Table 22–4. Recently it has been suggested that these cells also express CXCR4 and can be mobilized from the BM.[149–151] While circulating in peripheral blood, they are following an SDF-1 gradient that is deployed at sites of tissue/organ injury, and the ultimate result may be tissue regeneration.

To confirm that BM is a source of endothelial cells, murine HSC (Kit$^+$Scal$^+$lin$^-$ were transplanted into lethally irradiated mice, with the result that these animals were subsequently found to have donor-derived endothelial cells in many tissues, including liver, lung, muscle, gut and heart.[152] Furthermore, a phenotypic and functional evaluation of human HSC subsets revealed that CD34,$^+$ KDR$^+$ (VEGF-R2) HSC can generate both hematopoietic and endothelial cells in vitro and human BM-derived CD34$^+$ cells transplanted into immunodeficient mice can give rise to neovascularization in a retinal ischemia model.[153] Studies in allogeneic sex-mismatched hematopoietic transplants in humans revealed the presence of 2% of donor-derived endothelial cells in the skin and gut.[154] However, although in some experimental models a robust contribution of BM-derived cells in neovascularization was demonstrated, using sophisticated cell-marking strategies other studies indicated that marrow-derived EPC may play minimal or no role in neovascularia-

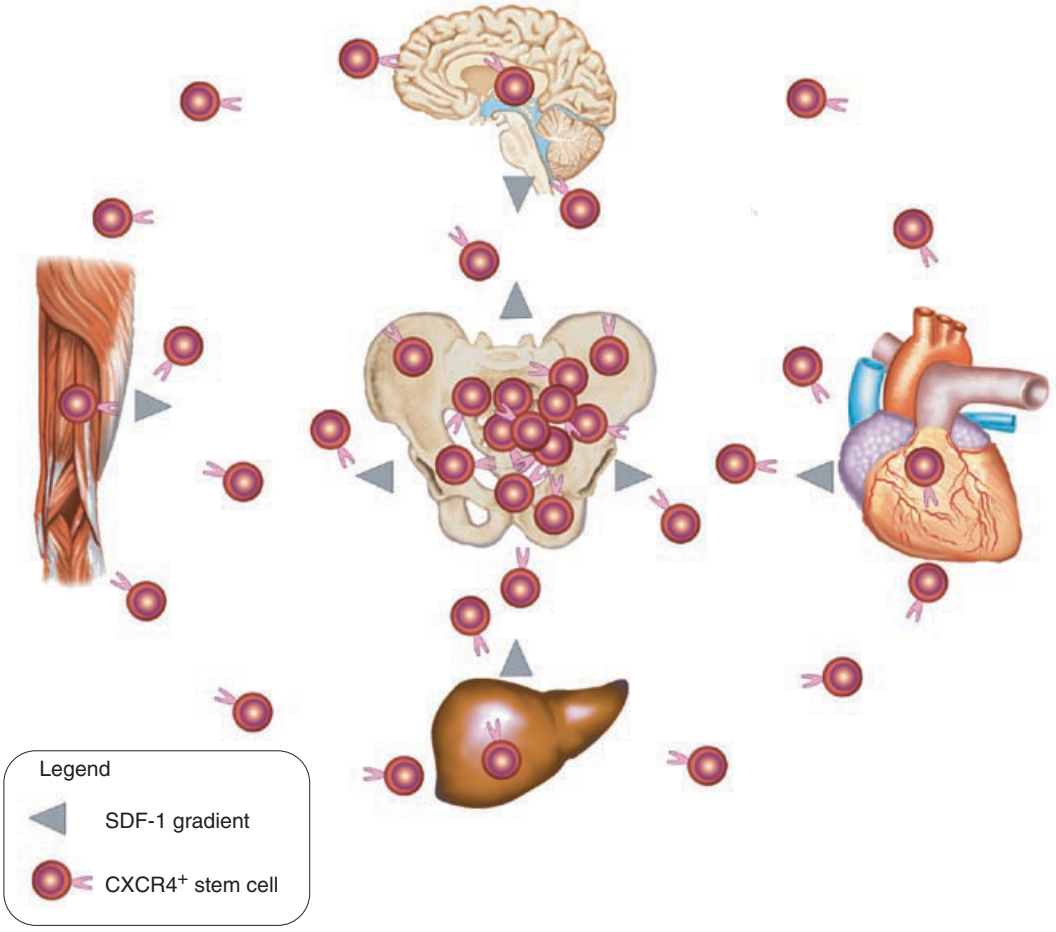

Figure 22–4 Hypothesis postulating circulation of CXCR4$^+$ BM-derived nonhematopoietic stem cells. The concept is presented based on the assumption that CXCR4$^+$ nonhematopoietic stem cells circulate in the PB. Although the percentage of these cells circulating in PB is much lower than that of early hematopoietic stem/progenitor cells, these mobilized nonhematopoietic stem cells may play an important role in tissue repair following injury. The mobilization of these cells occurs during tissue damage/injury (eg, heart infarct, stroke, toxic liver damage). It is postulated that after mobilization into PB CXCR4$^+$ nonhematopoietic stem cells may subsequently be chemoattracted by an SDF-1 gradient to the damaged tissues. In this context BM tissue becomes a "hideout" not only of HSC but also of circulating CXCR4$^+$ nonhematopoietic stem cells (eg EPC, MSC, or VSELs). These cells are deposited early in development and consequently reside in the BM, and we hypothesize that they could play an important role in tissue/organ repair as a mobile reserve pool of pluripotent stem cells. The trafficking of these cells involves, besides the SDF-1-CXCR4 axis, several other motomorphogens such as HGF, VEGF, and LIF. BM, bone marrow; EPC, endothelial progenitor cells; HGF, hematopoietic stem cells; LIF; MSC, mesenchymal stem cells; PB, peripheral blood; VSELs, very small embryonic-like stem cells.

tion of tumors, vessel repair, or normal vessel growth and development.[155,156]

Nevertheless, it was postulated that EPC, which is a rare and very primitive founder population of endothelial cells, may be released during stressed situations and circulate in PB.[1,83,157] Furthermore, BM was also identified as a source of more differentiated circulating endothelial cells (CEC).[2,158] It is not clear whether these cells (Fig. 22–5, panel A) are direct progeny of EPC or can arise from a well-defined population of myeloid lineage-restricted BM progenitors.[159,160] In support of this latter possibility, a recent report has shown that in fact CEC differentiate both from common myeloid progenitors (CMP) and the more mature granulocyte/macrophage progenitors (GMP).[160] In addition, endothelial cells derived from transplanted BM-derived myeloid progenitors expressed CD31, von Willebrand factor and Tie-2 and were CD45$^-$.[152,160] Thus BM-derived CEC probably reside outside the stem cell population consistent with the hypothesis that CEC arise from differentiated progeny of HSC (Fig. 22–5, panel A).

To summarize, it is postulated that the BM is endowed with neoangiogenetic activity and BM in steady state is a source of EPC and CEC that subsequently circulate in PB at very low levels (0.0001% and 0.01%, respectively) and may play a role in the repair of damaged endothelium and contribute to postnatal neoangiogenesis.[161] Although EPC are probably progeny of PSC or perhaps direct descendants of hemangioblasts, the more differentiated CEC originate in the myeloid compartment from a common myeloid progenitor (CMP). The level of contribution of BM-derived cells to organ/tissue vascularization, however, still requires further study.

Mesenchymal Stem Cells (Multipotent Mesenchymal Stromal Cells)

Mesenchymal stem cells (MSC) were identified 40 years ago by Fridenstein as a population of BM-derived adherent bone/cartilage-forming progenitor cells.[162] It was known at the time that BM-adherent cells generate in vitro colonies of fibroblastic-like cells which have a high replating potential.[163] At the same time, it was postulated that among these colonies are some progenitor cells that can generate new fibroblastic colonies and such cells were assigned a functional name, colony-forming units of fibroblasts (CFU-F).[164] If plated at a low density CFU-F grow distinct colonies of spindle-forming cells whereas, by contrast, if they are plated at high a concentration they rapidly establish confluent cell cultures. Of particular interest, if CFU-F-derived cells are implanted in the subrenal capsule or are

Table 22–4 Nonhematopoietic Stem Cells Described in Bone Marrow

Stem Cells	Phenotype
Endothelial Progenitor cells (EPC)	Human: CD133+, CD34+, c-kit (CD117)+, VE-cadherin+, VEGFR2+, CD146+, vWF+, CD31+ Mice: Sca-1+, c-Kit (CD117)+, Lin−, VEGFR2+, VE-cadherin+, Tie2+, CD146+, vWF+, CD31+
Mesenchymal Stem Cells (MSC)*	International Society for Cellular Therapy criteria: CD105+, CD73+, CD90+, CD45−, CD34−, CD14−, CD11b−, CD79a−, CD19−, HLA-DR− Additional markers: Stro-1+, SB-10+ (CD166), SH-2+ (epitope on CD105), SH-3+ (epitope on CD73), SH-4+ (epitope on CD73), CD44+, CD29+, CD31−, vWF− Markers of most primitive MSC: CXCR4, CD133, CD34 (?), p75LNGFR
Multipotent Adult Progenitor Cells (MAPC)*	SSEA-1+, CD13+, Flk-1low, Thy-1low, CD34−, CD44−, CD45−, CD117(c-kit)−, MHC I−, MHC II−
Marrow-isolated Adult Multilineage Inducible Cells (MIAMI)*	CD29+, CD63+, CD81+, CD122+, CD164+, c-met+, BMPR1B+, NTRK3+, CD34−, CD36−, CD45−, CD117 (c-kit)−, HLA-DR−
Unrestricted Somatic Stem Cells (USSC) found in cord blood*	CD13+, CD29+, CD44+, CD49e+, CD90+, CD105+, vimentin+, cytokeratin (CK8/18)+, CD10low, Flk-1low, HLA-Ilow, CD14−, CD33−, CD34−, CD45−, CD49 (b, c, d, f)−, CD50−, CD62 (E, L, P)−, CD106−, c-kit (CD117)−, glycophorin−, DLA-DR−
Very Small Embryonic-Like (VSEL) Stem Cells	CXCR4+, CD133+, CD34+, SSEA-1+ (mouse), SSEA-4+ (human), AP+, c-met+, LIF-R+, CD45−, Lin−, HLA-DR−, MHC I−, CD90−, CD29−, CD105−

*phenotype of expanded/cultured adherent cells.
AP, fetal alkaline phosphatase; BMPR1B, bone morphogenetic protein receptor 1B; c-met, receptor for hepatocyte growth factor; LIF-R, receptor for leukemia inhibitory factor; NTRK3, neurotropic tyrosine kinase receptor 3; vWF, von Willebrand factor.

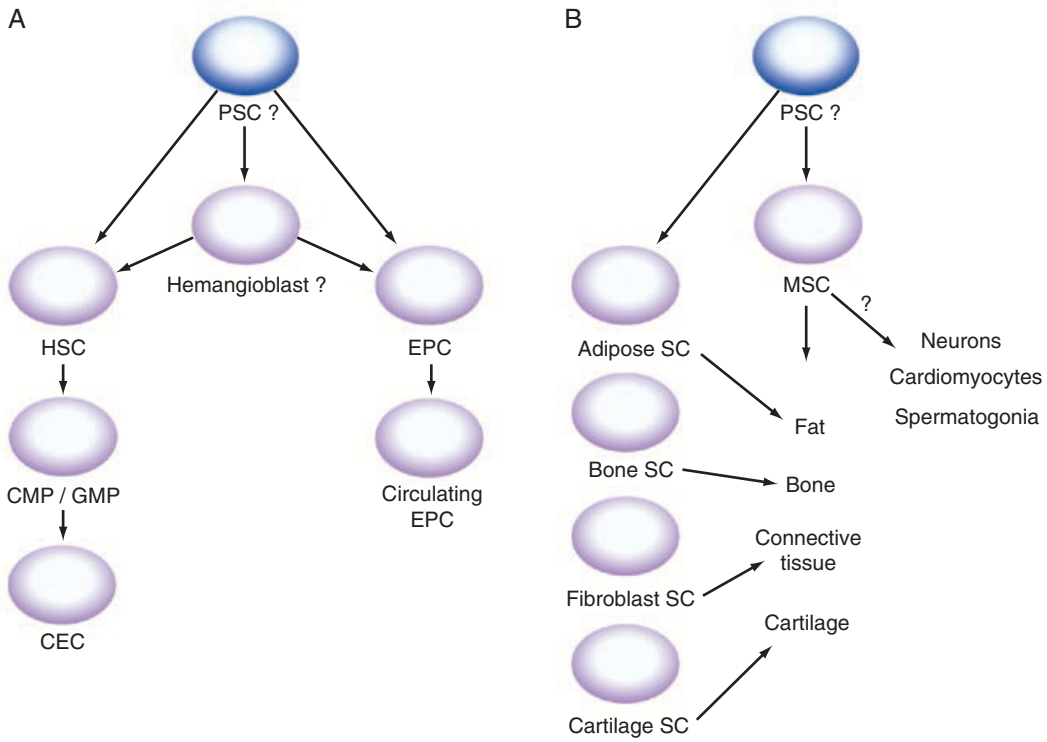

Figure 22–5 Origin of BM-derived EPC and MSC. **(A)** Endothelial progenitor cells (EPC) originate in the BM from the hemangioblast or the even more primitive pluripotent stem cells (PSC). These rare cells may be released from the BM and circulate in the PB (circulating EPC). Another fraction of circulating endothelial cells (CEC) derives directly from descendants of HSC which are common myeloid progenitors (CMP) or granulocyto-monocytic progenitors (GMP). **(B)** MSC are precursors for fat, bone, connective tissues and cartilage. However, it is very likely that separate monopotent stem cells exist for these tissues. The possibility of trans-differentiation of MSC into neurons, cardiomyocytes, and spermatogonia is not clear at this point and requires further studies. BM, bone marrow; MSC, mesenchymal stem cells; PB, peripheral blood.

cultured in differentiating media they are able to accumulate fat and calcium phosphate and grow ectopic bone fragments. Similarly, if they are cultured as a bulk mass in the presence of transforming growth factor (TGF)-β they are able to differentiate into chondrocytes.[165]

It is now widely accepted that MSC cells (Fig. 22–5, panel B) contribute to the regeneration of mesenchymal tissues (eg, bone, cartilage, muscle, ligament, tendon, adipose, and stroma).[166,167] At this point, however, we cannot exclude the possibility that monopotent stem cells specific for all of these tissues exist (Fig. 22–5, panel B). MSC are essential in forming the hematopoietic microenvironment in which HSC grow and differentiate.[166,168,169] In fact it is well known that fresh passages of unpurified MSC always contain a hidden population of HSC.[170] Thus in LTCIC assays, BM-derived stroma cells have to be irradiated before the HSC are plated, not only to inhibit the growth of MSC, but also to eliminate contaminating HSC, which could change conditions for the exogenous HSC to be assayed. However, it is likely that MSC, as well as HSC, may be contaminated by other populations of primitive nonhematopoietic stem cells. This possibility should be considered whenever a transdedifferentiation of MSC into cells from other germ layers is demonstrated. Interestingly, MSC engraft very poorly in the BM of recipients of hematopoietic transplants. However, recently a significant degree of chimerism for BM stroma was demonstrated following hematopoietic transplants in pediatric patients.[171]

MSC express several surface markers that could be used for their isolation (Table 22–4), including most importantly Stro-1, SB-10, SH-2, SH-3, SH-4, CD44, CD29, and CD90.[172] They do not express classical hematopoietic (CD34, CD45, CD14) and endothelial markers (CD34, CD31, vWF).[3,173,174] Interestingly some of the MSC were found to express CXCR4 and c-Met receptors and thus may respond to SDF-1 and HGF/SF gradients.[175–177]

The major problem with the exact phenotyping of MSC is the fact that fluorescence activated cell sorter (FACS) analysis is always performed on MSC expanded ex-vivo and not on cells that initiate growth of fibroblastic colonies (CFU-F). Thus it is not clear at this point if the rare MSC precursor cells that initiate these cultures express, for example, CD34 and CD133. Supporting this was the finding of populations of $CD34^+$ cells isolated from human BM and murine fetal liver that included CFU-F cells.[178] It has also been reported that $CD34^+$ cells are able to establish colonies containing BM fibroblasts and recently it was even postulated that HSC could be the precursors of MSC.[179]

As mentioned, cultures containing MSC are heterogenous, and not all the cells present in these cultures are able to regrow CFU-F colonies after replating (Fig. 22–6 panel A). In early passages of low-density plated MSC, two morphologically distinct populations of cells have been described, a population of more mature, large, flat and slowly replicating cells and one of rapidly self-renewing cells (RS cells) which are small and spindle-shaped.[180] Furthermore, serum deprivation of human MSC cultures selects for expansion of so-called serum-deprived (SD) MSC.[181] These SD-MSC are small like RS cells, express mRNA for embryonic markers such as Oct-4, ODC antizyme, and hTERT, and proliferate more slowly than RS cells.[181] It was postulated that these SD-MSC cells are the most primitive fraction of MSC from which RS and more mature MSC are derived. Unfortunately, SD-MSC cells or their precursors have not yet been directly purified from BM MNC and thus it is difficult to judge whether they are derivatives of marrow-derived PSC or a population of MSC that undergoes epigenetic changes caused by the serum-deprived in vitro culture conditions. Nevertheless, these data indicate that cultures containing growing MSC are heterogeneous and contain fibroblastic-like cells at different levels of commitment and maturation.

An unexpected discovery made in recent studies has been that MSC are able to differentiate across germ-layers and give rise to neuronal cells or cardiomyocytes (Fig. 22–5, panel B).[182–186] These phenomena were recently called into question in particular for neural differentiation of MSC,[187] caused by the possibility of some in vitro artifacts.[188,189] Morphological changes of MSC may be induced during their culture by the addition of some components that are included in neural-differentiating media eg, β-mercaptoethanol, dimethylsulfoxide, and butylated hydroxyanisole. Fibroblasts cultured in these conditions could mimic neurons, but in fact it proved to be only an in vitro morphological artifact.[188] These observations raise the question of how much culture conditions may influence the phenotype of MSC, during, for example, osteogenic or adipose differentiation of MSC. Accordingly, MSC cultured in vitro may accumulate special media supplements, for example, calcium phosphate and lipids, according to their osteoblastic or adipocytic differentiation, respectively.

Further work is also needed to explain the actual contribution of MSC to the regeneration of skeleton.[190–193] Relevant to this is evidence suggesting that BM may contain a separate type of monopotent stem cell committed to the skeleton that is distinct from BM-derived MSC.[194] In a recently published paper reporting on the transplantation of BM-derived cells in children suffering from osteogenesis imperfecta, it was suggested that these osteoblastic monopotent stem cells and not marrow fibroblasts were in fact responsible for some of the beneficial therapeutic effects seen.[195] In this context it is not clear whether the process of calcium phosphate accumulation in MSC cultured in high concentrations of ascorbic acid, β-glycerophosphate and dexamethasone is related to the real differentiation process initiated in the stem cell compartment, or is merely an effect of phenotypical changes of fibroblastic cells induced by the in vitro culture conditions.[172] The reported evidence for the presence of an osteoblastic stem cell that resides in BM and differs from the MSC mentioned above, supports this latter concept.

Likewise it is not clear whether accumulation of fat in MSC growing in media containing a cocktail of dexamethasone, isobutyl methyl xanthine, and indomethacin could result from lipoid degeneration of fibroblasts cultured in vitro.[172] The accumulation of lipids in fibroblasts cultured ex-vivo could be explained by fat accumulation induced by culture conditions and not by a process initiated at the level of stem cell differentiation for adipose tissue. In these types of cultures usually all MSC begin to display small lipid droplets that are spread through their cytoplasm. Thus, an important question emerges: is fat accumulation in cultured marrow fibroblasts merely an effect of the pathological steatosis of cells exposed in vitro to high concentrations of medium supplements such as hydrocortisone, or is this an in vitro epigenetic phenomenon? Or is it a process that is initiated at the stem cell level? If the latter is true, then is there a separate monopotent stem cell for adipose tissue?

Supporting the hypothesis of a distinct monopotent stem cell, Fig. 22–6, panel B, shows a colony of adipocyte-like cells that were generated in MSC cultures in which the cells contain large lipid droplets, and the colony itself is clearly visible among BM-derived fibroblasts as a distinct cluster of lipid-containing cells. This suggests that this particular rare colony could have been generated by a stem cell dedicated to the adipocyte lineage. This implies that a primitive stem cell for adipocytes may hide among MSC cells and that such cells can generate a distinct type of adipocyte colony.

Because various inconsistencies have come to light in the field of MSC biology, the International Society for Cellular Therapy recently recommended avoiding the name of MSC stem cells and changing it to multipotent mesenchymal stromal cells.[196] This change in nomenclature is a result of the fact that MSC cultures contain heterogeneous populations of cells and the majority of fibroblastic cells growing in vitro do not meet the criteria to be identified as stem cells (Fig. 22–6 panel A). This name should be reserved for a small population of cells, closely related to CFU-F, RS, or SD cells. More importantly, the abbreviation for mesenchymal stromal cells, MSC remains the same as for mesenchymal stem cells, allowing literature searches using both names.

In addition, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy proposed minimal criteria to define human MSC.[197] First, MSC must be plastic-adherent when maintained in standard culture conditions. Second, MSC must express CD105, CD73, and CD90 and lack expression of CD45, CD34, CD14 or CD11b, CD79α or CD19, and HLA-DR

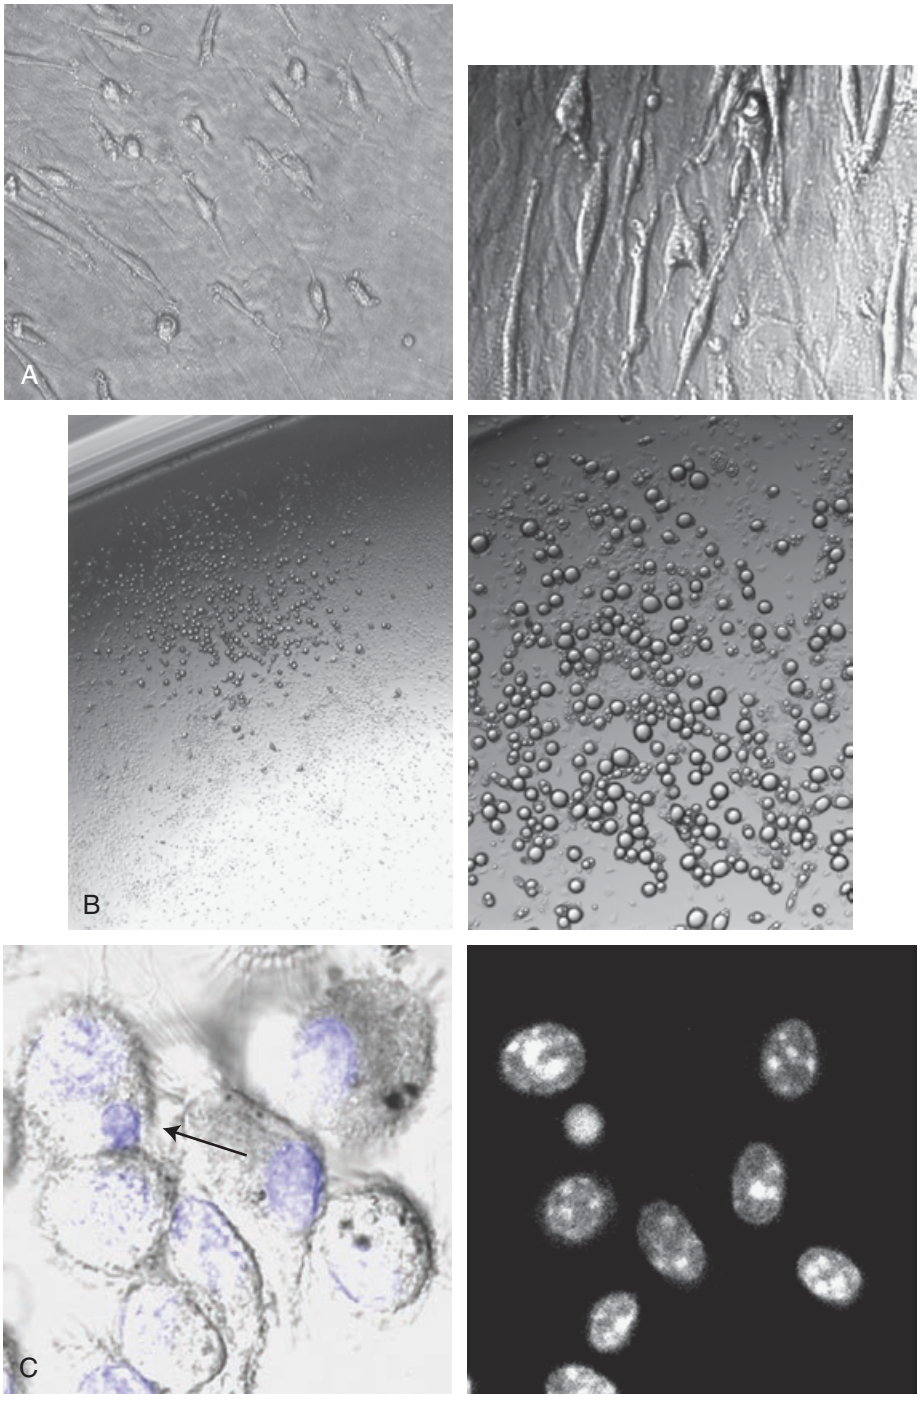

Figure 22–6 Controversies about MSC. **(A)** Low-power and high-power pictures of MSC growing in vitro. These cells look heterogeneous and possess a fibroblast-like morphology. **(B)** A distinct colony containing adipocytes, formed probably by monopotent adipocytic stem cells. Low power (*left*) and high power (*right*). **(C)** *Left:* Confocal analysis of MSC cultures reveals the presence of a very small cell hiding between fibroblastic cells. *Right:* DNA staining of nuclei of cells in these cultures confirms the presence of a small cell hiding among MSC. MSC, mesenchymal stem cells. (VSEL?)

surface molecules. Third, MSC must differentiate into osteoblasts, adipocytes, and chondroblasts in vitro (Fig. 22–5 panel B). This minimal set of standard criteria should foster a more uniform characterization of MSC and facilitate the exchange of data among investigators.[197]

Finally, there are recent reports that a subpopulation of undifferentiated MSC expanded from BM adherent cells could express embryonic stem cell and PSC markers such as Oct-4 and Rex1 or Oct-4 and Nanog.[198] The relationship of these undifferentiated MSC with other populations of putative PSC described in BM requires further study. It is very likely that similar/overlapping populations of stem cells were isolated by employing different strategies and hence assigned different names. Of note, MSC so far have not been shown to be able to complete blastocyst development, and thus they do not fulfill the complete criteria for a pluripotent stem cell.

Furthermore, the reported robust contribution of MSC in regeneration of damaged organs in vivo could be explained by the paracrine effects of these cells affecting angiogenesis in damaged tissues rather than a direct contribution of MSC to supplying tissue-specific functional cells for organ regeneration. Also to be considered is the notion that MSC could serve as scaffolds during regeneration of damaged tissues. Finally, this controversial yet interesting cell type can be successfully employed to modulate Graft-versus host-disease (GvHD) and enhance engraftment in patients after hematopoietic transplants.[171,199]

Multipotent Adult Progenitor Cells (MAPC)

MAPC have been isolated from BM MNC as a population of $CD45^-$ $GPA\text{-}A^-$ adherent cells and display a similar fibroblastic morphology

as MSC.[5] Thus it has been postulated that an MAPC could be a more primitive cell than MSC; however, the potential relationship between MSC, in particular RS-MSC and SD-MSC cells and MAPC has yet to be established.

The colonies of cells enriched in murine MAPC express low levels of FLK-1, Sca-1, and CD90, and higher levels of CD13 and SSEA-1.[5] They are also negative for the expression of CD34, CD44, CD45, CD117, and MHC class I and class II.[5,200] The growth of these rare cells depends on selected serum batches and is tightly regulated by oxygen tension. This could explain why several laboratories have had difficulty in establishing cultures of MAPC.

Interestingly MAPC are the only population of BM-derived stem cells that, so far as is known, contribute to all three germ layers after injection into a developing blastocyst, indicating their pluripotency.[5] The contribution of MAPC to blastocyst development, however, requires confirmation by other, independent laboratories.

Marrow-Isolated Adult Multilineage Inducible (MIAMI) Cells

This population of cells was isolated from human adult BM by culturing BM MNC in low oxygen tension conditions on fibronectin.[6] Colonies of small adherent cells were subsequently isolated and further expanded on fibronectin, at low oxygen tension. Cells derived from these cultures expressed CD29, CD63, CD81, CD122, CD164, c-Met, bone morphogenetic protein receptor 1B (BMPR1B), and neurotrophic tyrosine kinase receptor 3 (NTKR3), and were negative for CD34, CD36, CD45, CD117, and HLA-DR. Interestingly, these cells also expressed the embryonic stem cell markers Oct-4 and Rex-1.[201] MIAMI cells were isolated from the BM of people ranging from 3 years to 72 years of age. Colonies derived from MIAMI cells expressed several markers for cells from all three germ layers, suggesting that, at least as determined by in vitro assays, they are endowed with pluripotency. However, these cells have not been tested so far for their ability to complete blastocyst development.

The potential relationship of these cells to MSC and MAPC described above is not clear, although it is possible that these are overlapping populations of cells identified by slightly different isolation/expansion strategies. Lending credence to this is the fact that MIAMI cells are derived from a population of BM-adherent cells like MSC or MAPC and can also differentiate into cells that express markers unique to osteoblasts, chondrocytes and adipocytes.

Unrestricted Somatic Stem Cells (USSC)

Neonatal cord blood (CB) is an important source of nonhematopoietic stem cells. It is well known that CB-derived cells contribute to skeletal muscle,[202,203] liver,[204–206] neural tissue,[61,207] and myocardium regeneration;[208,209] and more importantly, recent multiorgan engraftment and differentiation has been achieved in goats after transplantation of human CB $CD34^+$ in^- cells.[210] Generally, we can envision CB as neonatal PB mobilized by the stress related to delivery. Release of several cytokines and growth factors, as well as hypoxic conditions during labor, may mobilize neonatal marrow cells into circulation. For this reason it is very likely that the population of USSC cells identified in CB originates in neonatal BM.[7]

USSC are very rare cells that are detectable in ~40% of CB units at a frequency 1 to 11 cells/CB unit.[7] These cells were identified in CB as a putative founder cell population that is able to grow adherent colonies with fibroblastic morphology and is present among CB-derived $CD45^-$ adherent cells. USSC can be expanded to 10^{15} cells without losing their potential to differentiate into a variety of cells. In vitro cultures USSC showed homogenous differentiation into osteoblasts, chondroblasts, adipocytes, hematopoietic, and neural cells.

The exact phenotype of cells isolated from USSC-derived colonies is shown in Table 22–4. Unfortunately, the markers which are expressed on the founder cells for these colonies are not described. Further studies are needed to purify USSC and compare these cells with other potentially pluripotent stem cells that could be present in CB (eg, MAPC or, as described next, VSELs).

Very Small Embryonic-Like (VSEL) Stem Cells

Recently a homogenous population of rare (~0.01% of BM MNC) $Sca\text{-}1^+$ lin^- $CD45^-$ cells was identified in murine BM. They express (as determined by RQ-PCR and immunhistochemistry) markers of pluripotent stem cells such as SSEA-1, Oct-4, Nanog and Rex-1 and Rif-1 telomerase protein.[8] Direct electron microscopical analysis revealed that these cells display several features typical of embryonic stem cells such as (a) a small size (2–4 μm in diameter), (b) a large nucleus surrounded by a narrow rim of cytoplasm, and (c) open-type chromatin (euchromatin) (Fig. 22–7). Interestingly, these cells despite their small size posses diploid DNA and contain numerous mitochondria. They do not express MHC-1 and HLA-DR antigens and are $CD90^-$ $CD105^-$ $CD29^-$ For the first time a sorting procedure

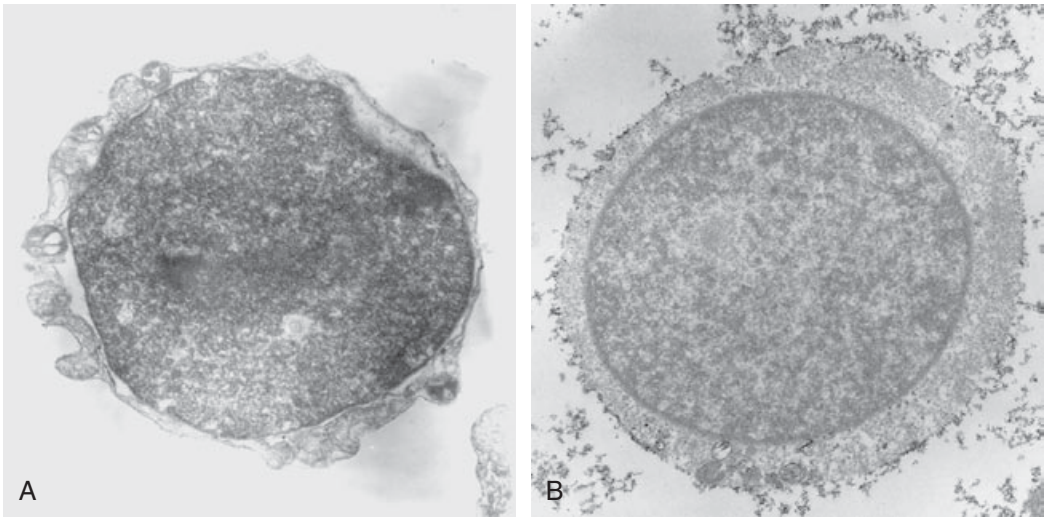

Figure 22–7 TEM of $Sca\text{-}1^+Lin^-CD45^-$ VSEL stem cells. **(A)** Murine BM-derived VSEL stem cells are small, measuring 2–4 μm in diameter. They possess a relatively large nucleus surrounded by a narrow rim of cytoplasm. At the ultrastructural level the narrow rim of cytoplasm can be seen to possess a few mitochondria, scattered ribosomes, small profiles of endoplasmatic reticulum and a few vesicles. The nucleus is contained within a nuclear envelope with nuclear pores. Chromatin is loosely packed and consists of euchromatin. **(B)** CB-VSELs are also small and measure 3–5 μm in diameter. Similarly, they possess a relatively large nucleus surrounded by a narrow rim of cytoplasm. Chromatin is loosely packed and consists of euchromatin.

that indicates how to purify from adult BM a distinct population of very primitive embryonic-like stem cells and, more importantly, the morphology (Fig. 22–7) and the surface markers of these rare cells at the single cell level, have been described.

It is possible that these VSELs may be released from BM and circulate in PB during tissue/organ injury (eg, heart infarct and stroke). Interestingly ~5% to 10% of purified VSELs if plated over a C2C12 murine sarcoma cell feeder layer are able to form spheres that resemble embryoid bodies. Cells from these VSEL-derived spheres (VSEL-DS) are composed of immature cells with large nuclei containing euchromatin, and like purified VSELs are CXCR-4$^+$SSEA-1$^+$Oct-4.$^+$

Furthermore, VSEL-DS, after re-plating over C2C12 cells, may again (up to 5–7 passages) grow new spheres or, if plated into cultures promoting tissue differentiation, expand into cells from all three germ-cell layers. Because VSELs isolated from GFP$^+$ mice grew GFP$^+$ VSEL-DS showing a diploid content of DNA, this confirms that VSEL-DS are derived from VSELs and not from the supportive C2C12 cell line; it also excludes the possibility of cell fusion. Similar spheres were also formed by VSELs isolated from murine fetal liver, spleen, and thymus. Interestingly, formation of VSEL-DS was associated with a young age in mice, and no VSEL-DS were observed in cells isolated from old mice (>2 years).[8,91] This age-dependent content of VSELs in BM may explain why the regeneration processes is more efficient in younger individuals. There are also differences in the content of these cells among BM MNC between long- and short-lived mouse strains. The concentration of these cells is much higher in BM of long-lived (eg, C57Bl6) as compared to short-lived (DBA/2J) mice.[91] It would be interesting to identify genes that are responsible for tissue distribution/expansion of these cells as they could be involved in controlling the life span of mammals.

Because VSELs express several markers of primordial germ cells (fetal-type alkaline phosphatase, Oct-4, SSEA-1, CXCR4, Mvh, Stella, Fragilis, Nobox, Hdac6), they might be closely related to a population of epiblast-derived PGC. VSELs are also highly mobile and respond robustly to an SDF-1 gradient, adhere to fibronectin and fibrinogen, and may interact with BM-derived stromal fibroblasts. Confocal microscopy (Fig. 22–6, panel C) and time "time-lapse studies"[91] revealed that these cells attach rapidly to, migrate beneath and undergo emperipolesis in marrow-derived fibroblasts.[91] Because fibroblasts secrete SDF-1 and other chemottractants they may create a homing environment for small CXCR4$^+$ VSELs. This robust interaction of VSELs with BM-derived fibroblasts has important implications, namely that isolated BM stromal cells may be contaminated by these tiny cells from the beginning. This observation may explain the unexpected "plasticity" of marrow-derived fibroblastic cells (eg, MSC or MAPC).

Recently, a very similar population of cells that show similar morphology and markers to murine BM-derived VSELs has been purified from human CB.[211] Evidence has also mounted that similar cells are also present in the human BM, particularly in young patients. It is anticipated that VSELs could become an important source of pluripotent stem cells for regeneration. At this point, however, it is not clear whether VSELs contribute to blactocyst development.

Bone Marrow-Derived Oocytes and Spermatogonia?

Recently somewhat unexpectedly BM was also identified as a source of oocyte-like and spermatogonia-like cells.[9,10] This observation supports to some extent the concept that during embryonic development some of the primordial germ cells (Fig. 22–3) may go astray on their way to the genital ridges and colonize fetal liver, and subsequently by the end of the second trimester of gestation, together with fetal liver-derived HSC, move to the BM tissue.

Accordingly, oocyte-generating germ line stem cells were found in murine BM in a set of elegant experiments in which BM transplantation restored oocyte production in normal animals sterilized by chemotherapy as well as in ataxia telangiectasia-mutated gene-deficient mice, which are otherwise incapable of making oocytes.[9] Direct sorting analysis revealed in BM the presence of c-kit$^+$Sca-1$^-$lin$^-$ cells that expressed primordial germ cell markers such as Mvh, Dazl, Stella, and Fragilis. Expression of all of these markers correlated with an adherent fraction of BM cells. Based on these observations the authors concluded that BM could be a potential source of germ cells that could sustain oocyte production in adulthood. So far, however, evidence is lacking that these BM-derived oocytes are fully functional, capable of fertilization, and can give rise to embryos.

Another independent group also recently reported that BM cells may also be a source of male germ cells.[10] These cells expressed primordial germ cell markers such as Fragilis, Stella, Rnf17, Mvh, and Oct-4, as well as molecular markers of spermatogonial stem cells and spermatogonia including Rbm, c-Kit, Tex18, Stra8, Piwil2, Dazl, and Hsp90α. Thus BM unexpectedly is emerging as a potential source of cells for reproductive medicine.

This concept, however, recently became somewhat controversial after recent parabiotic experiments excluded BM as a source of oocytes during normal steady state conditions.[212] Nevertheless, the role of BM in supplying oocytes and spermatogonia in stress situations requires further confirmation by other, independent laboratories.

All Roads Lead to the Pluripotent Stem Cell—Does It Really Exist in Bone Marrow?

Above we discussed several types of nonhematopoietic stem cells that have been identified so far in the BM. An important question remains, however: whether a PSC, a founder cell for cells forming all three germ layers, resides in the adult BM. According to definition, these cells ultimately should also give rise to a population of mesoderm-derived HSC. Thus it is likely that such a cell could be related to the so-called long-term repopulating HSC that begins to supply hematopoietic cells a few months after hematopoietic transplantation.[213,214]

Several lines of evidence support the presence of PSC in BM tissue. First, expression of typical PSC markers such as SSEA-1, Oct-4, and Nanog was reported in BM-derived stem cells isolated using various strategies. These early embryonic transcription factors that are characteristic for ES and epiblast-derived cells were demonstrated at the protein and/or mRNA levels in VSEL, MAPC, MSC (in particular the SD fraction), and MIAMI cells.[5,6,8,121,181,198] Second, the contribution of BM-derived cells to regeneration of multiple nonhematopoietic organs and tissues indirectly suggests the existence of pluripotent or multipotent stem cells in BM. Illustrating this are experiments performed at the single cell level with BM-derived stem cells (Fr25 Sca-1(+)Kit$^+$in$^-$ or Fr25SKL cell) that contributed to multiorgan, multilineage engraftment in lethally irradiated mice.[215] These cells were first fractionated by elutriation at a flow rate of 25 mL/min (Fr25), then lineage depleted (lin(–)) and labeled with cell membrane-marking fluorochrome (PKH26) and injected intravenously into lethally irradiated animals. Two days posttransplant, PKH26$^+$ cells were recovered by cell sorting from recipient BM. These single adult BM-derived Fr25SKL cells have a robust capacity to differentiate into epithelial cells of the liver, lung, gastrointestinal tract (endoderm), and skin (ectoderm).[215]

Nevertheless, several questions relating to the presence of a putative PSC in BM remain. First, it is important to elucidate whether this cell is merely a remnant from developmental embryogenesis that resides in a dormant state in the BM tissue, or if it is a rare but mitotically active cell that contributes to the renewal of the pool of other BM-residing stem cells including HSC, EPC, and MSC. Second, what is the relationship of this cell to the cells recently described and purified from BM: (a) SSEA-1$^+$ Oct-4$^+$ Nanog$^+$ VSELs, (b) small Oct-4$^+$ MAPC, (c) Oct-4$^+$ SD-fraction of MSC, and (d) Oct-4$^+$ MIAMI cells? As mentioned, it is likely that each of these versatile BM-derived Oct-4$^+$ on-hematopoietic stem cells, which have been given different operational names, are in fact very closely related to the same type of BM-residing PSC.

As shown in Fig. 22–3, it is possible that these BM-residing PSC, as remnants of embryonic development (eg, derivatives from the epiblast), reside in a dormant state in ectotopic BM niches. The dormant status of these cells could be the result of the fact that these cells are (a) located in a nonphysiologic niche, (b) exposed to inhibitors, (c) deprived of some appropriate stimulatory signals, and finally (d) limited in pluripotency because of the erasure of the somatic imprint on some of the crucial somatically-imprinted genes (eg, H19 and IGF2). These cells, however, could be activated if they are exposed to some appropriate activation signals (eg, upregulated during organ/tissue injury, oncogenesis) or undergo epigenetic changes that change the methylation status of their DNA and acetylation of histones. Finally they may be reactivated if a proper somatic imprint is reestablished (Fig. 22–3).

In summary, there is mounting evidence that BM in fact contains PSC. For example, BM contains a population of VSEL stem cells that express SSEA-1 Oct-4 Nanog and are Lin^- $CD45^-$.[8] These cells display a very primitive morphology and as shown at the single cell level are able in in vitro cultures to differentiate into cells from all three germ layers. Furthermore, Oct-4 and Nanog are also expressed in small MAPC, SD-MSC, and MIAMI cells.[6,121,181]

The most convincing evidence for the pluripotency of BM-derived stem cells would be the demonstration that these cells can complement blastocyst development after injection into a developing blastocyst. Unfortunately, such evidence for pluripotency has so far not been achieved in a reproducible way with any of the BM-derived stem cells.

Bone Marrow as a Source of Circulating Nonhematopoietic Stem Cells

A small number of BM-derived HSC circulates in PB even in steady state conditions as a result of self-renewal of stem cells in BM niches but serves as a way to keep in balance the stem cell pool in stem cell niches in different anatomical locations of the same BM. Stem cells circulating in the PB can also compete for organ/tissue-specific niches (Fig. 22–4). This may explain, for example, why heterogeneous populations of stem cells can also be detected in various organs (eg, HSC in muscle tissue). The number of HSC released/mobilized into PB increases after injection of mobilizing cytokines (eg, G-CSF)[216] or agents (eg, AMD3100)[217] as well as in several stress-related situations (eg, tissue/organ injury, strenuous exercise).[18,133,146]

A similar phenomenon has been described for BM-residing nonhematopoietic stem cells, which are also able to egress from BM tissue and circulate in PB during (a) pharmacological mobilization or (b) stress related to tissue/organ injury (Fig. 22–4). It has been further reported that the number of circulating nonhematopoietic stem cells in PB can be increased after administration of G-CSF alone or in combination with compounds that block the CXCR4 receptor (eg, T140 or AMD3100).[90,218] Hence the process of stem cell mobilization from BM into PB should be envisioned not only as mobilizing HSC but also other BM-residing nonhematopoietic stem cells. Thus pharmacological mobilization could become a means to obtain nonhematopoietic stem cells as well as HSC from the BM.

Table 22–5 shows several clinically relevant situations that lead to an increase of circulating stem cells in PB. Increases in the number of circulating BM-derived cells have been reported in skeletal muscle damage,[16,219,220] heart infarct,[18,19] stroke,[20] multiple bone fractures,[136] liver injury, kidney injury,[133] lung transplantation,[15] cardiac surgery,[221] liver transplant,[222] and limb ischemia.[223] These circulating BM-derived stem cells were identified as endothelial progenitors (EPC and EC), skeletal muscle satellite stem cells,[219] myocardiac,[18] neural and bone tissue-committed stem cells[20,136] and circulating MSC, as well as so-called fibrocytes,[224,225] which are probably a functionally altered subset of MSC.

In summary, mounting evidence suggests that during organ/tissue damage nonhematopoietic stem cells are mobilized from the BM and perhaps other tissue-specific niches into PB where they circulate prior to "homing" to damaged tissues and participating in organ repair. It is well documented that damaged tissues upregulate expression of several potential chemoattractants for these circulating stem cells such as SDF-1, VEGF, HGF/SF, LIF, or FGF-2.[137,226–229] Furthermore, the hypoxia regulated/induced transcription factor (HIF-1) plays an important role in the expression of several of these factors.[230,231] In support of this notion promoters of SDF-1, VEGF, and HGF/SF contain several functional HIF-1 binding sites.[138,230,232,233] Thus hypoxic conditions created by increasing expression of these factors may orchestrate mobilization from BM and subsequently the homing of circulating stem cells to damaged organs/tissues (Fig. 22–4).

Table 22–5 Data Supporting Circulation of Bone Marrow-Derived Nonhematopoietic Stem Cells in Various Clinical Situations

Skeletal muscle damage	Mice: murine BM-derived stem cells were reported to contribute after transplantation to irradiated muscles to skeletal muscle satellite stem cells. These cells subsequently contributed in skeletal muscle regeneration after exercise induced damage
Heart infarct	Human: Increase in circulating $CD34^+$, $CXCR4^+$, c-Met^+ cells in peripheral blood after acute myocardial infarction (MI). Increase in mRNA for GATA4, Mef-2C and Nkx.25/Csx in circulating MNC. Mice: Increase in mRNA for GATA-4, Mef-2C and Nkx.25/Csx in peripheral blood MNC in mice after experimental acute MI.
Stroke	Mice: Increase in mRNA for GFAP, Nestin, and βIII-tubulin in peripheral blood MNC in mice after experimental induced stroke.
Multiple bone fractures	Human: Increase in mRNA for bone-related genes (osteocalcin, bone alkaline phosphatase, collagen type I) in peripheral blood MNC in patients with multiple bone fractures.
Liver injury	Human: Increase in homing of human $CD34^+CXCR4^+$ in NOD/SCID mice livers damaged by exposure to CCl_4.
Kidney injury	Mice: Increase in circulating $CD34^+CXCR4^+$ and $Lin^-Sca\text{-}1^+$ cells in peripheral blood (PB) during acute renal failure.
Lung transplants	Human: Increase in circulating $CXCR4^+$ cytokeratin-5^+ cells in PB.
Cardiac surgery	Human: Increase in circulating $CD34^+CXCR4^+$ cells in PB.
Liver transplant	Human: Increase in circulating CD34+ cells and increase in mRNA for GATA4, cytokeratin 19, and α-fetoprotein in PB MNC.
Limb ischemia	Mice: BM-derived $Sca\text{-}1^+$ $FLK\text{-}1^+$ $Tie\text{-}2^+$ $CD34^+$ cells circulate and play a role in neovascularization.

THE ROLE OF BONE MARROW-DERIVED STEM/PROGENITOR CELLS IN HUMAN DISEASE

In parallel, evidence has also accumulated that BM-derived stem cells may play an undesirable role in the development of some pathological disorders.[234] It is likely that if these cells are mobilized at the wrong time and home to the wrong place (eg, into areas of chronic inflam-

Table 22–6 Pitfalls Related to Clinical Application of BM-Derived Nonhematopoietic Stem Cells

— Isolation of a sufficient number of these cells from BM
— Proper "repertoire" of homing signals in damaged organs
— Adequate homing to damaged organs
— Optimal delivery by systemic or local infusion
— Effective contribution to organ/tissue regeneration
— Lack of efficient ex-vivo expansion of stem cells

mation) they may exert unwanted effects.[235,236] For example, BM-derived stem/progenitor cells have been implicated in the pathogenesis of lung fibrosis, ocular pterygia, and diabetic neuropathy.[237–239]

Somewhat unexpectedly, it has been found that BM-derived stem cells may also contribute to the development of some nonhematopoietic tumors. This possibility was recently demonstrated in a model of murine stomach cancer caused by a chronic *Helicobacter pylori* infection.[240] In this model BM-derived cells were identified as a source of developing gastric mucosa adenocarcinomas, and the SDF-1-CXCR4 axis was implicated in the initiation of this tumor.[240] Accordingly, SDF-1 was found to be upregulated in the gastric mucosa affected by chronic inflammation caused by *H. pylori* infection and postulated to be the chemoattractant responsible for attracting $CXCR4^+$ stem cells from the BM. Exposed to the chronic inflammatory environment in the gastric mucosa, these cells transformed into adenocarcinoma initiating cells.[241] A similar phenomenon has recently been postulated in the pathogenesis of colon adenocarcinomas. Mounting evidence also suggests that BM may be a source of EPC and MSC for developing cancer tissue.[242,243] Thus, BM stem cells may in different ways contribute to both initiation and expansion of the growing tumor.

Lending further support to the concept that BM-derived cells may initiate the growth of nonhematopoietic malignancies, was the recent report that BM cells, exposed in vitro to the carcinogen 3-methycholanthrene, could transform into many tumor types, including epithelial, neural, muscular, fibroblastic, blood vessel, endothelial, and poorly differentiated tumors.[244] Moreover, a single transformed BM cell has the ability to self-renew, differentiate spontaneously into various types of tumor cells in vitro, express markers associated with multipotency, and form a teratoma in vivo. These data support the notion that multipotent cancer stem cells originated from transformed BM cells.[244] This provides further evidence that BM stem cells may be the origin of several nonhematopoietic cancers, and that BM is the most likely home of nonhematopoietic stem cells that are susceptible to transformation by carcinogens.

Do Bone Marrow-Derived Nonhematopoietic Stem Cells Hold Promise for Regenerative Medicine?

One can ask the question whether, if BM really contains pluripotent nonhematopoietic stem cells, then why is there so much controversy about the role of BM-derived cells in tissue/organ regeneration? There are several answers to this provocative, but timely, question (Table 22–6), especially in view of the current numerous clinical trials recently performed with BM-derived stem cells in patients with cardiac and neurological disorders.

First, there is the obvious problem of isolating a sufficient number of these cells from the BM. The number of these cells within BM MNC is very low (eg, VSELs represent 1 cell in 10^4–10^5 of BM MNC). Furthermore, there are some indications that these cells are enriched in the BM of young mammals and that their number decreases with age. It is likely that these nonhematopoietic stem cells released from the BM, even if they are able to home to the areas of tissue/organ injury, play a role only in regeneration of minor tissue injuries. Myocardial infarct or stroke, on the other hand, would be considered to involve severe tissue damage beyond the capacity of these rare cells to effectively repair. Second, the allocation of these cells to the damaged areas depends on homing signals that may be inefficient in the presence of other cytokines or proteolytic enzymes released from leukocytes and macrophages associated with damaged tissue. For example, matrix metalloproteinases released from inflammatory cells degrade SDF-1 locally and thus perturb homing of $CXCR4^+$ stem cells.[216,245,246] Third, it is not clear whether the optimal delivery system of these cells is intravenous infusion or direct injection into damaged tissues. Fourth, in order to reveal the full potential of these cells they have to be fully functional. We cannot exclude the possibility that these cells, while residing/being "trapped" in the BM, are not fully functional but remain "locked" in a dormant state and need the appropriate activation signals by unidentified factors (Fig. 22–3). Finally, a major limitation is the lack of effective ex-vivo expansion strategies for the most primitive stem cells. However, when such expansion protocols do become available, they should help resolve the crucial problem of the low numbers of these cells available in the BM.

Humanity continually searches for the holy grail of an end to the suffering caused by illness and a better quality of life in advancing years. There is no doubt that medical science is now looking to stem cells to provide some of milestones in this important quest. However, there is a crucial need for a reliable and noncontroversial source of stem cells. Adult BM stem cells could potentially provide a real therapeutic alternative to the controversial use of human ES cells and therapeutic cloning. Hence, while the ethical debate on the application of ES cells in therapy continues, the potential of BM-derived nonhematopoietic stem cells is ripe for exploration. Researchers must determine whether these cells can be efficiently employed in the clinic or whether they are merely developmental remnants found in the BM that cannot be harnessed for regeneration. The coming years will bring important answers to these questions.

CHAPTER 23

INTERACTIONS BETWEEN HEMATOPOIETIC STEM/PROGENITOR CELLS AND THE BONE MARROW: THE BIOLOGY OF STEM CELL HOMING AND MOBILIZATION

Ayelet Dar, Orit Kollet, and Tsvee Lapidot

INTRODUCTION

During the final stages of embryo development, hematopoietic stem cells (HSC) migrate from the fetal liver via the circulation, across the physical blood-bone-marrow barrier of endothelial cells and extracellular matrix and home to the bone marrow (BM).[1,2] These progenitor cells repopulate the bone marrow by extensive proliferation and differentiation while maintaining their self-renewal potential and motility, which enables them to egress back to the circulation.[3] Hematopoietic progenitor cells (HPC) in the bone marrow continuously replenish the blood with new maturing myeloid and lymphoid cells with a finite life span throughout life. In parallel, a rare and small subset of stem cells is retained in the bone marrow.[4] Blood forming progenitor cells are retained along the border between the bone and the bone marrow, the endosteum region and are also located in periarterial sites.[5,6] Recent results in mice reveal that certain endosteal osteoblasts are niche-supporting cells.[7] In addition, specific murine bone marrow endothelial regions were also found to support stem cell anchorage and retention.

Bones are dynamic organs, which are continuously remodeled throughout life. Bone remodeling is regulated by interactions between (hematopoietic stem cell derived) bone resorbing osteoclasts and (stromal derived) bone forming osteoblasts.[8] Osteoclasts are multinucleated giant cells, which are formed as a result of fusion of activated myeloid monocytes. Osteoclast precursors are recruited from the circulation to the bone marrow and are activated by osteoblasts via the membrane expressed or secreted cytokines, receptor activator of NF-κB ligand (RANKL), and macrophage colony-stimulating factor (M-CSF).[9] Osteoclast/osteoblast bone remodeling, also takes place in the endosteum region, the site which contains hematopoietic stem cell niches. Stem cell interactions with niche supporting cells maintain their anchorage via adhesion and membrane bound cytokines, which induce retention of quiescent, primitive cells in the bone marrow microenvironment. The bone marrow harbors a reservoir of stem cell derived, immature and maturing lymphoid and myeloid cells with a finite life span, which continuously egress to the circulation as part of homeostasis. Thus, via proliferation, differentiation, and migration, stem cells continuously replenish the blood with new cells throughout life while maintaining a small pool of undifferentiated stem cells in the bone marrow. Some of the circulating leukocytes home back to the bone marrow across the physical blood-bone-marrow-barrier of endothelial and extra cellular matrix. For example, circulating monocyte-derived osteoclast precursors, home back to the bone marrow, fuse in this tissue and transform into bone resorbing osteoclasts in response to signals provided by osteoblasts.[9] Old neutrophils also home back to the bone marrow for their apoptotic cell death.[10] In both cases the chemokine stromal derived factor-1 (SDF-1, also termed CXCL12) and its receptor CXCR4 are involved in this homing process. In addition, very low levels of progenitor cells also egress to the circulation. In mice, intravenously infused progenitors are rapidly cleared from the circulation within a few minutes, yet the low levels of circulating progenitor cells are continuously present in the blood as part of homeostasis.[11] Steady state stem cell proliferation, differentiation and egress to the circulation are dramatically amplified during alarm situations in response to secreted stress signals. These events occur during inflammation induced by viral or bacterial infections, injury, bleeding, ischemia, and DNA damage caused by radiation or chemotherapy. Hence, the transitions between steady state homeostasis egress to massive proliferation and mobilization require the existence of a versatile dynamic mechanism for regulation of the crosstalk between the bone marrow reservoir of leukocytes, peripheral blood and other organs, regulating the need for new blood cells on demand as part of host defense and repair mechanism.

HEMATOPOIETIC STEM AND PROGENITOR CELL HOMING

Homing is a multistep process, which requires directional migration of hematopoietic stem and progenitor cells through the circulation and extravasation across the physical barrier of the blood vessel into the bone marrow or other organs.[12] The bone marrow endothelium is the first anchoring site for homing cells, presenting adhesion molecules and producing stimulating chemokines. The small blood vessels in both human and murine bone marrow, the sinusoids, in which transendothelial migration is thought to take place, are composed of specialized cell structures, which regulate cell trafficking.[10,13] Rolling and firm adhesion of progenitors to endothelial cells in small marrow sinusoids under blood flow is coordinated by signaling via chemokines and cytokines (eg, SDF-1, SCF), resulting in cytoskeleton rearrangement and activation of integrins (eg, VLA-4) and metalloproteinases (eg, MMP2/9, MT1-MMP), followed by trans-migration across the physical endothelium/ECM barrier. Conditioning of the host with ionizing irradiation in the form of total body irradiation (TBI) and chemotherapy (cyclophosphamide) have been shown to disrupt the physical bone marrow endothelium barrier allowing erythrocyte passage from the circulation to the extravascular hematopoietic space of treated, but not control mice[14–16] and irradiated bone marrow endothelium of conditioned patients appears necrotic and disrupted with small gaps.[17] Stem cells finalize their homing uniquely, by selective access and anchorage to their specialized niches in the extravascular space of the endosteum region and in periarterial sites.[5,18,19] The ability of primitive hematopoietic stem and progenitor cells to migrate to specific organs has been identified during early developmental stages. HSC originate in the yolk sac and the aorta-gonadal-mesonephros (AGM) region, migrate to the fetal liver and finally to the BM shortly before birth.[1,2] Autologous or allogeneic transplantation protocols utilize GCSF mobilized cells, umbilical cord blood or adult bone marrow. These cells differ in their BM homing and repopulation properties as demonstrated in the preclinical and functional immunodeficient NOD/SCID mouse model.[17] The biology of human progenitor cell homing has been studied using two main preclinical animal models. The preimmune sheep model, developed by Zanjani and his colleagues, uses preimmune sheep fetuses implanted with immature human $CD34^+$ and $CD34^-$ cells without preconditioning. This model allows one to monitor both short-term and long-term stem cell engraftment in both primary and serially transplanted secondary sheep recipients. In this model, immature human bone marrow $CD34^+$ enriched cells transplanted to sheep fetuses can be detected 24 and 48 hours later in the recipient bone

marrow.[20] The second model is based on the use of immune deficient mice preconditioned with sublethal TBI. Transplantation of SCID mice with normal and leukemic human progenitor cells developed by the group of Dick and his colleagues facilitates high levels of multilineage (both myeloid and lymphoid) human hematopoiesis in the murine BM, which is initiated by primitive SCID repopulating cells (SRC), and SCID leukemia initiating cells (SLIC).[21,22] Subsequently, NOD/SCID mice with greater degrees of reduced immunity have been created by Shultz et al and have been used to identify primitive $CD34^+CD38^-$ and $CD34^-CD38^-$ SRC.[23,24] B2 microglobulin null NOD/SCID (B2mnull NOD/SCID) mice have further reduced innate immunity because of the lack of natural killer cell activity. Definitive stem repopulating cell function of high level multilineage engraftment in primary NOD/SCID mice and serially transplanted B2mnull NOD/SCID mice is dependent on human CXCR4 signaling by murine SDF-1 which is cross-reactive[25] with human SDF-1. Maturing, $CD34^+CD38^+$ short term repopulating cells (STRC), which are enriched in mobilized peripheral blood were identified by the group of Eaves et al using B2mnull NOD/SCID mice[26] or by inactivation of natural killer cell activity in NOD/SCID mice by other groups.[27,28] Mechanisms of human stem cell homing have been largely characterized in immune deficient NOD/SCID and B2mnull NOD/SCID mice.[17,29]

A small subset of immature cord blood $CD34^+$ cells, $CD34^+CD38^-$ cells, consist of more primitive hematopoietic progenitor cells, which home successfully to the murine bone marrow and spleen while sorted CB $CD34^+CD38^+$ maturing progenitor cells, which lack long term repopulation capacity have poor homing capabilities, unless they are prestimulated with cytokines such as SCF in vitro or GCSF introduced for mobilization of adult progenitors in vivo[17] or cotransplanted with mature mononuclear cells.[28,29] Selectins also play a role in regulating HPC trafficking.[30,31] The selectin family of adhesion molecules contains three family members: P- and E-selectin, which are expressed on endothelial cells (and their expression is induced in response to inflammatory signals), and L-selectin, which is constitutively expressed on mature leukocytes and HPC. Previous studies revealed that homing of HPC to the bone marrow of P- and E-selectin deficient mice is defective.[32]

Most clinical protocols use the intravenous administration route for transplantation of hematopoietic cells aimed at reconstituting the bone marrow of patients who have received TBI or chemotherapy. In an attempt to improve the efficiencies of bone marrow homing, seeding and repopulation, transplanted cells have been injected directly into the bone marrow cavity of immune deficient NOD/SCID and normal mice (intraosseous [IO], intra bone marrow [IBM], or intrafemur [IF] transplantation). Studies with enriched human progenitors demonstrate superior seeding efficiencies when the endothelial and extracellular matrix (ECM) barriers are bypassed. IBM injections yielded a 15-fold higher frequency of SRC in sorted cord blood $CD34^+CD38^-$ cells in comparison to conventional intravenous (IV) injection. Increased engraftment and improved ability of bone marrow cells obtained from primary recipients to repopulate secondary transplanted recipients have also been documented. Interestingly, neutralization of CXCR4 by antibody treatment similarly abolishes engraftment by human $CD34^+$ enriched cells administrated in both protocols, demonstrating an essential role for this receptor not only in SRC homing to the bone marrow, but also in bone marrow seeding and colonization.[33] Cord blood derived Lin^-D34^- primitive cells display limited repopulation potential when transplanted via the tail vein,[24,34] as opposed to high SRC activity when transplanted IO,[35] despite low expression levels of CXCR4 and reduced migration to SDF-1,[35–37] indicating for the crucial role of CXCR4 function in stem cell endothelial transmigration during the course of homing to the BM. Applying intrafemural injection of cord blood $CD34^+D38$(-/low)$CD36^-$ purified cells, Dick and colleagues were able to identify a new short-term SRC subset which is capable of migrating to other bones, and colonizing them with myeloid and erythroid cells.[38] Of interest, when total cord blood mononuclear cells or murine bone marrow cells were transplanted IBM, increased engraftment including a dramatic increase in immature human $CD34^+$ cells was documented transiently about one month post-IF transplantation as compared to IV transplantation, but not two and three months post transplantation.[39] In addition, IF transplanted murine cell levels in the peripheral blood were lower than with IV injected cells, three months posttransplantation.[39]

Despite reduced IF homing in irradiated recipients, donor cell proliferation and repopulation rates are increased as compared to nonirradiated mice. However, retention of undifferentiated donor stem cells in the bone marrow of nonconditioned recipients is evident by transplantation into lethally irradiated secondary recipients,[40] implying that TBI is further needed to reduce competition by host stem cells, and to provide signals which enhance bone marrow reconstitution.[41] Finally, to prevent stress and severe damage to the bone marrow structure associated with IF injection, and to ensure introduction of cells to the blood vessels of the femur rather than to the bone marrow cavity, Scadden and colleagues have examined homing properties of murine bone marrow Lin^- cells injected to the artery of the femur. While homing to the bone marrow and spleen was significantly increased by femoral artery versus tail vein injection in lethally irradiated mice, no differences were found in long-term donor cell repopulation,[42] suggesting that bone marrow repopulation is not enhanced by this approach and that stress and damage caused by the implantation procedure also contributes to the repopulation levels. Preliminary results of clinical, human IBM transplantation of adult BM cells did not lead to improved engraftment,[17] yet iliac crest transplantation of cord blood cells is promising.[43]

Retention of Hematopoietic Stem and Progenitor Cell in the Bone Marrow

The final step for successful homing requires directed migration of homing cells into specialized niches within the bone marrow, which are capable of retaining and promoting the controlled proliferation of the homing primitive hematopoietic stem cells. Of interest, studies conducted with sorted Lin^- murine progenitor and stem cells have revealed that progenitor cells transplanted intravenously specifically home to the endosteum region whereas maturing leukocytes do not.[18] The bone marrow-bone lining cells of the endosteum are known to anchor and support HSCs. However, bone marrow endothelium and extramedullary hematopoiesis, as in the liver and spleen, indicate that the endosteum/osteoblast microenvironment is not the sole supportive niche for HSCs. Murine HSCs, characterized by $CD150^+D244^-D48^-$ expression were shown to be associated with sinusoidal endothelium in murine spleen and bone marrow. Implying that sinusoidal endothelial cells have the ability to function as specific portals for murine hematopoietic stem cell entry into the marrow space, defining the localization of progenitor cells and serving as stem cell niches throughout hematopoietic tissues.[5,44] In addition, endothelial cells regulate HSC function and are capable of maintaining HSCs in culture.[45–47] Furthermore, ablation of endothelial cells in vivo by administration of anti-VE-cadherin leads to hematopoietic failure.[48] In agreement with these reports, using intravital microscopy studies have shown that murine hematopoietic stem/progenitor cells as well as lymphocytes, that were transplanted IV to recipient mice homed to the bone marrow, adhered to unique bone marrow vascular microdomains, which express SDF-1 after two hours and are retained there as long as two months, documenting the role of these domains as specific portals for the entry of cells into the marrow space.[6]

Intracellular signaling downstream from the chemokine receptor CXCR4, the tyrosine kinase receptor c-kit and ?β1-integrins within HSC and HPC have been shown to be crucial for the migration, homing, and retention of hematopoietic stem cells and progenitors. Each of these receptors signal through Rac-type Rho guanosine triphosphatases (GTPases). Rac GTPases play a major role in the organization of the actin cytoskeleton and also in the control of gene expression and the activation of proliferation and survival pathways. Rac2 regulates the retention of HSC and HPC in the bone marrow microenvironment, and a deficiency of Rac2 is associated with enhanced numbers of circulating hematopoietic stem and progenitor

cells. The final localization in the endosteal area of HSC is impaired by the absence of Rac1.[49] Another crucial component in HSC and progenitor cell retention in the endosteal region is the glycosaminoglycan hyaluronic acid (HA), which is synthesized and expressed by endosteal stromal cells.[50] Furthermore, the presence of HA appears to be critical for homing of immature human $CD34^+$ cells via CD44 interactions, and although murine stem cell homing is not dependent on CD44, their spatial distribution in the bone marrow of transplanted mice and their ability to reconstitute hemopoiesis in vivo is correlated with HA expression levels.[51] Together, these results reveal that stem cell directed motility, which includes navigation to target hematopoietic organs and into their specialized niches within these tissues, is essential for their in vivo function, which includes homing to the bone marrow, retention, proliferation, differentiation, and release back to the circulation.

Hematopoietic Stem and Progenitor Cell Mobilization

While most of the stem cell compartment is located within the bone marrow endosteal and endothelial specialized niches, a small and rare population is found in the blood circulation because of steady state homeostatic processes of constitutive release from the bone marrow as part of host defense and repair. Physiological stress, such as injury, and inflammation, or artificial clinical treatments with mobilizing agents (GCSF, chemotherapy), induce massive proliferation of hematopoietic stem and progenitor cells in the bone marrow, which is accompanied with significant increase in progenitor cell egress to the circulation, a process termed *mobilization*. Mobilization is characterized by imbalance of steady state homeostasis, induction of stem and progenitor cell proliferation, differentiation, and massive egress to the circulation. The SDF-1/CXCR4 axis is a pivotal player in this process and is discussed in detail in the following paragraph. Additional major features and dynamic processes involved in HSC mobilization consist of various ligand/integrin or cytokine receptor interactions including VLA-4/VCAM-1, CD62L/PSGL, CD44/HA, and Kit/Kit ligand. Very late antigen-4 (VLA-4 or 41 integrin) is expressed by the majority of HPC in a low-affinity state; however, in response to cytokines such as GM-CSF, interleukin-3, and stem cell factor its function can be rapidly and transiently activated to promote adhesion to fibronectin. The importance of the interactions between VLA-4 with vascular cell adhesion molecule-1 (VCAM-1), which is constitutively expressed by endothelial cells and stromal cells in the bone marrow, to HSC trafficking in the bone marrow has been confirmed by studies using antibodies directed against VCAM-1 or VLA-4 which leads to HPC mobilization.[52,53] Moreover, the inducible deletion of 4 integrins in adult mice results in constitutive HSC mobilization.[54] Anti-VLA-4 induced HSC mobilization is significantly enhanced in CD18 (2-integrin) deficient mice or in wild-type mice treated with anti-2-integrin antibodies, suggesting that both VLA-4 and 2-integrins contribute to the anchoring of HSC in the bone marrow.[55] Mice lacking the receptor for the glycosaminoglycan hyaluronan (HA), CD44, have an impaired mobilization response to GCSF,[56] and treatment of mice with an anti-CD44 antibody results in a modest mobilization of HPC to the blood.[57] Numerous cytokines and growth factors elevation in the plasma induce hematopoietic stem cell mobilization, such as VEGF and angiopoietin-1,[58] SCF, and SDF-1 itself.[8,59] Other factors have been reported to synergize with GCSF to increase mobilization such as, placental growth factor-1 (PlGF-1) in both primate and murine models[60] and the SDF-1 antagonist compound AMD3100, which also induces rapid and massive mobilization when administered solely.[61] Moreover, a combined loss of Rac1 and Rac2 leads to massive egress of HSC/P, in spite of the inability of these cells to actively migrate in response to in vitro gradients of SDF-1.[49] Of notice, preliminary results demonstrate an essential role for the CD45 phosphatase, which negatively regulates adhesion interactions and secretion of the metalloproteinase MMP-9 in homing and repopulation by human $CD34^+$ cells. Neutralization of this receptor impaired migration to SDF-1, bone marrow homing, and repopulation of NOD/SCID mice.[62]

Proteases and metalloproteinases (extracellular matrix degrading enzymes) also regulate cell migration, facilitating movement across the physical barrier of the ECM and inactivating bone marrow derived growth factors and chemokines, which are responsible for hematopoietic cell adhesion and retention. N-terminal cleavage of SDF-1 associated with its chemotactic inactivation, was demonstrated by several degrading enzymes including CD26/dipeptidylpeptidase IV[63–65] neutrophil elastase, cathepsin G,[66–68] cathepsin K,[8] and matrix metallopeptidase (MMP)-2/9.[69] In addition, membrane-bound SCF (c-kit ligand) is also cleaved by MMP-9[70] and cathepsin K. It was previously shown that this ligand is essential for endosteal lodgment by murine stem cells[71] and that the release of membrane bound SCF from the bone marrow to the peripheral blood caused by proteolytic activity of MMP-9 induces stem cell mobilization.[70] MMP-9 (also termed gelatinase B) accumulates in the plasma and/or bone marrow following mobilization with interleukin-8, GCSF, or cyclophosphamide.[72,73] In line with these observations, human bone marrow $CD34^+$ progenitors in steady state conditions do not secrete the metalloproteinases MMP-2 and MMP-9, which are implicated in cell motility, while circulating $CD34^+$ cells secrete these enzymes, as do GCSF-mobilized progenitors.[74] GCSF treatment in vitro and in vivo in patients or mice preengrafted with human $CD34^+$ cells, increase also the expression of MT1-MMP by hematopoietic human progenitors, which mediates their mobilization.[50,75]

Of interest, by using parabiotic mice with a joint circulation, Abkowitz et al showed a dramatic elevation in the levels of GCSF-mobilized stem cells which efficiently home back to the partner bone marrow as compared to only low homing levels of steady state circulating stem cells.[76] This report demonstrates that during stress-induced mobilization, homing rates are also augmented, confirming that mobilization and homing are sequential, physiological processes.

A recent report suggests that the sympathetic nervous system is involved in a newly recognized pathway by which signals initiated in peripheral organs may reach the bone marrow. Signals from the sympathetic nervous system triggered GCSF or fucoidan-induced mobilization of progenitors. This study demonstrates that while norepinephrine signaling induced a decrease in GCSF induced stem cell mobilization, β2 adrenergic agonists increased mobilization.[77]

Another major component, which plays a role in specifically regulating HSC and progenitor cell mobilization are bone-resorbing osteoclasts.[8,9] Differentiation and activation of osteoclasts are tightly regulated by endosteal bone forming osteoblasts which are derived from mesenchymal stem cells. It is anticipated that conditions, which turn the balance towards osteoblast proliferation and differentiation, would result in the expansion of the size of the stem cell pool and niches within the bone marrow. Indeed, postoperative parathyroid hormone (PTH) administration increased the numbers of endosteal osteoblasts and the number of anchored stem cells in the niche, opposing the situation in PTH-deficient mice.[78] Recent report demonstrates that bone-resorbing osteoclasts are directly involved in mobilization of progenitor cells from the bone marrow to the circulation, both in homeostatic and stress-induced conditions.[8] Physiologic stress, ie, mild bleeding and lipopolysaccharide (LPS) administration mimicking bacterial inflammation or administration of the cytokines SDF-1 or hepatocyte growth factor (HGF), caused robust appearance of bone resorbing $TRAP^+$ active osteoclasts along the endosteum region. This process is associated with mobilization of hematopoietic progenitors to the circulation. Likewise, administration of RANKL, the osteoclast differentiation cytokine, which is presented by osteoblasts to activate osteoclasts, induced in addition to bone resorption also preferential mobilization of immature murine progenitors. In contrast, the hormone calcitonin, which prevents formation of ruffled border and TRAP production by osteoclasts and therefore is used as an anti osteoporotic drug in aging patients, reduced mobilization of progenitors in mice treated with GCSF or LPS; and also lowered the levels of circulating progenitors during homeostasis.[8] A genetic disorder involving osteoclasts caused by protein tyrosine phosphatase ε (PTPε) deficiency in young female mice[79] is accompanied by reduced levels of primitive hematopoietic stem ($Lin(-)/Sca\text{-}1^+c\text{-}kit^+$ cells in

the blood in comparison with wild-type phenotype during steady state conditions and also in response to GCSF stimulation. The mechanisms by which bone resorbing osteoclasts induce mobilization includes secretion of the cytokine IL-8 by active human osteoclasts,[80] secretion of MMP-9, cathepsin G and cathepsin K,[81] which cleaves SDF-1 and SCF expressed by endosteal osteoblasts. Another major regulator of the stem cell niche is osteopontin, which is expressed by bone lining osteoblasts during homeostasis. Osteopontin is remarkably reduced in the endosteum of mice treated with RANKL.[8] Taken together these results reveal that the endosteal stem cell niche is dynamic, producing hematopoietic cells on demand. Low level cell production occurs during steady state homeostasis, which is dramatically accelerated in response to alarm signals caused by injury, bleeding and inflammation, which are mimicked by clinical mobilization protocols. Stem cell anchorage and quiescent retention at a nonmotile mode by the stromal niche supporting cells is interrupted in order to induce HSC proliferation, differentiation and recruitment to the circulation as part of host defense and repair. Our view is that the stem cell niche is a negative regulator aimed at preventing stem cell migration and development, maintaining undifferentiated cells in a quiescent nonmotile state. Once these interactions are overcome, stem cells follow signals that determine their tissue localization phenotype and function, involving cytoskeletal rearrangement required for cell motility, proliferation and differentiation, regulation of adhesion interactions within their microenvironment vicinities, and expression of enzymes involved in their active migration, crossing the vasculature endothelium to the bone marrow and other peripheral organs as part of their development.

Chemokine SDF-1 and Its Receptor CXCR4 in Stem Cell Homing and Mobilization

The constitutive egress and induced release of immature and maturing leukocytes as well as rare primitive stem cells to the circulation suggests a regulated active process that has to overcome homing/retention interactions. A major role in regulation of homing and mobilization is attributed to the modulations in the interactions between the G-protein coupled chemokine receptor CXCR4 and its ligand SDF-1. Chemokines are small signaling molecules, which are part of the cytokine super family. These ligands are best known for their ability to attract leukocytes to sites of inflammation by chemotactic signaling via receptors expressed on the migrating leukocytes, as part of host defense. Chemokines are also involved in organ development and angiogenesis, and some chemokines serve as survival factors for immature progenitor cells. The chemokine SDF-1 was first discovered as a pre-B cell growth factor, secreted by the mouse bone marrow stromal cell line, MS5. The major receptor for this chemokine, CXCR4, is expressed by many cell types, including neuronal, endothelial, epithelial, muscle, liver and hematopoietic, and immature and mature lymphoid and myeloid cells. CXCR4 is also used by the HIV virus as a coreceptor to infect human CD4 T lymphocytes. SDF-1 and its receptor are essential for murine embryonic heart and brain development. Of interest, recent data reveal the existence of another receptor on some human leukocytes, named RDC1 (also termed CXCR7), which can bind SDF-1 and respond to adhesion and survival/proliferation mediated by this chemokine,[82,83] revealing a more complex network of interactions between SDF-1 and its receptors. However signaling mediated by this receptor does not induce calcium release and at present it is not clear if or how RDC1 is involved in SDF-1 induced proliferation, migration and/or adhesion. Human and murine SDF-1 are cross-reactive and differ in one amino acid. This ligand is a survival factor for murine myeloid progenitor cells[84] and also for primitive human hematopoietic $CD34^+CD38(-/low)$ cells and mesenchymal $Stro1^+$ cells.[85] Human and murine bone marrow stromal cells, including bone marrow endothelial and endosteal osteoblasts, express high levels of SDF-1 in vivo and also functionally express its receptor CXCR4. Expression of the receptor RDC1 was documented also on activated endothelial cells.[82] Murine embryos that lack SDF-1, or its receptor CXCR4 have multiple lethal developmental defects, including lack of bone marrow seeding by hematopoietic progenitor cells, migrating from the fetal liver. These results reveal the essential roles that this chemokine and its receptor play in bone marrow seeding during development. However, fetal liver cells isolated from CXCR4 KO embryos can home and engraft the bone marrow of irradiated, adult wild-type mice. These cells have reduced bone marrow homing, preferentially at the more differentiated progenitor stage, and reduced retention of stem cells in the bone marrow. These reduced retention levels can be over come by increasing the transplantation cell dose, leading to normal levels of donor type CXCR4 KO primitive progenitor cells in the bone marrow of primary recipients, but not in the bone marrow of serially, secondarily transplanted wild-type mice. Murine fetal liver cells also express RDC1, which can partially compensate for the lack of CXCR4.[82,86] Currently, SDF-1 is the only known powerful chemotactic factor for human $CD34^+CD38^-$ and murine $Sca1^+ckit^+Lin^-$ (SKL) hematopoietic stem cells. The observation that this ligand is also a survival factor for both human and murine hematopoietic progenitor cells,[84] suggests that it is also involved in cell cycle regulation. In agreement with this concept, SDF-1 was shown to inhibit cycling of long term repopulating human bone marrow hematopoietic progenitors but not of myeloid leukemic CFC cells.[87] In addition, the expression levels of SDF-1 were significantly elevated in the $S/G_2/M$ phase proliferating murine stem cells compared with its levels in G_0/G_1 phase. Of interest, blocking SDF-1 in mice transplanted with cycling progenitors restored their engraftment ability implying that cell cycle progression is SDF-1 dependent and is associated with their potential to successfully reconstitute the bone marrow.[88] Alterations of SDF-1 concentrations also contribute to the delicate balance between the regulation of hematopoiesis and directed motility: low levels of SDF-1 induce directional migration and proliferation, while high levels induce desensitization of the receptor CXCR4, quiescence and inhibition of cell motility.

Cell motility requires shape changes, dramatic cytoskeletal rearrangements and focal adhesion with the ECM components. Activation of HSC bySDF-1 induces signaling pathways that have been shown to be essential for efficient homing of transplanted human and murine HSC in preclinical murine models. SDF-1 activation induces actin polymerization[89] and phosphorylation of focal adhesion molecules such as FAK, RAFTK/Pyk2, p130Cas, Crk, and paxillin. Rho GTPase family members such as RhoA, Rap, and cdc42 and its binding protein WASP are also required for SDF-1 induced morphological changes.[90,91] Functional elevation of CXCR4 expression by immature human $CD34^+$ cells is mediated by the atypical PKCζ upon cAMP stimulation and results in enhanced homing to the bone marrow.[92,93] In the course of mobilization PKC-ζ,[92,93] Rac, RohA, and CDC42 play major roles in CXCR4 mediated migration and proliferation. SDF-1 induces secretion of a number of different proteolytic enzymes, which in turn cleave and inactivate it. For example, CD26 (dipeptidyl peptidase IV), a membrane-bound extracellular serine-protease expressed on a subset of HPC, inactivates SDF-1 through proteolytic cleavage.[94] GCSF induced HPC mobilization is defective in CD26 deficient mice or in wild-type mice treated with a specific CD26 inhibitor[94,95] and CD26-deficient HPC display enhanced homing to the bone marrow and long-term engraftment potential.[94] In addition, SDF-1 signaling induces secretion of MMP-9 by immature human CD34 cells and murine stem cells, which in turn cleaves and inactivates this ligand. Migrating human CD34 cells in the circulation secrete MMP-2 and MMP-9 both during homeostasis and GCSF induced mobilization, while stationary CD34 cells in the bone marrow do not,[74] implicating these enzymes in the regulation of human CD34 progenitors cell motility. Another enzyme, the cell surface protease MT1-MMP, which is expressed by human CD34 cells, is also activated by SDF-1, can cleave this ligand, and is involved in homing and mobilization.[50,75] SDF-1 mediates activation of adhesion molecules such as LFA-1, VLA-4/5, and CD44, which are all part of the motility machinery. Immobilized SDF-1 activates LFA-1 and VLA-4 integrins on immature human CD34 cells under physiological shear flow to bind their respective ligands ICAM-1 and VCAM-1 in vitro. Furthermore, immobilized SDF-1 is also required

for development of firm integrin-mediated adhesion and spreading.[96,97] Moreover, the cytoskeleton rearrangement and protrusion formation, as part of immature human CD34$^+$ cell migration, are inhibited by CD44 neutralizing antibodies, revealing a cross-talk between this chemokine and the adhesion machinery, which can veto its chemotactic effect.[50,51,98] These results suggest that immature CD34 progenitors anchored to the bone marrow endosteum, which is rich in hyaluronic acid (the major CD44 ligand) can inhibit MMP-2/9 secretion, proliferation, and migration of progenitor cells, in the presence of SDF-1.

Interestingly, increased SDF-1 expression in injured peripheral organs emerges as a common mechanism that recruits stem cells from the bone marrow reservoir and targets them to the site of injury. SDF-1 expression in ischemic tissues as the skin, which is regulated by the transcription factor hypoxia-inducible factor-1 (HIF-1), increased the adhesion, migration, and homing of recruited CXCR4$^+$ progenitor cells to these ischemic tissues.[99] Myocardial infarction documented in human and animal models is another good example of the importance of SDF-1/CXCR4 interactions in stem cell behavior. Acute myocardial infarction by itself induces progenitor cell mobilization in patients[100] and SDF-1 increased expression in rats.[101] A combination of GCSF administration to increase HSC mobilization, with local upregulation of SDF-1 in peri-infract zone, resulted in enhanced homing of c-kit$^+$ murine progenitors to the injured tissue and improved cardiac function.[101] However, in humans with chronic ischemia of the heart, signals transferred from the damaged organ to the bone marrow, severely affect the function of bone marrow hematopoietic progenitors. Thus, despite a similar frequency of CD34 progenitors in the bone marrow of patients with chronic ischemic cardiomyopathy, these cells demonstrate lower colony formation capacity, which reflects their inferior developmental potential, together with reduced migration to SDF-1 or VEGF.[101] The CXCR4 receptor, expressed by the stationary bone marrow endothelial and other stromal cells but not motile hematopoietic cells, also serves to bind functional SDF-1 present in the blood, which is internalized and transcytosed via special clathrin-coated pits vesicles. SDF-1 is then translocated to the abluminal side of the endothelial cells and secreted into the bone marrow space. The released SDF-1 is able to functionally support and increase the homing of human CD34$^+$ progenitors to the bone marrow of B2mnullNOD/SCID mice.[102,103] Similar mechanisms may explain the extended SDF-1 expression by the endothelium of the injured livers of mice treated with CCL4, or by the bile duct liver epithelium of human individuals infected with hepatitis C virus. Moreover, this increased expression of SDF-1 in the periphery may explain the associated stem cell recruitment and increased liver engraftment by hematopoietic cells.[104] In this case as well, inhibition of CXCR4 or MMP-9, abrogates stem cell recruitment and homing to the injured liver. Additional evidence for the importance of SDF-1/CXCR4 interactions in determining stem cell behavior emerges from studies with the CXCR4 antagonist, AMD3100. A single injection of AMD3100 rapidly induces stem and progenitor cell mobilization to the peripheral blood in mice, humans,[61,100] and primates.[105] AMD3100 mobilized cells exhibit higher expression of CXCR4, which correlates with increased migration to its ligand SDF-1.[61,106] This efficient process may be mediated by binding of AMD3100 to CXCR4 expressed on hematopoietic stem and progenitor cells, to CXCR4 expressed by endothelial cells and other stromal cells, or both. Since AMD3100 synergistically increases G-SCF induced mobilization, additional mechanisms are apparently activated. Preliminary data reveal that AMD3100 induced mobilization is accompanied by increased SDF-1 release from the bone marrow.[107] This finding is consistent with several previous reports demonstrating a correlation between leukocytes and immature hematopoietic cells and an increase in SDF-1 concentrations in the circulation after injection of either fucoidan,[108] SDF-1 overexpressing adenovirus[59] or direct administration of the SDF-1 ligand itself.[8] In addition, inhibition of CXCR4-dependent release of SDF-1 during homeostasis or upon treatment with AMD3100, is correlated with a selective reduction in recruitment of hematopoietic progenitor cells but not mature leukocytes to the circulation. SDF-1 release was mediated by the β-adrenergic receptors of the sympathetic nervous system.[107] Altogether these results imply that homing and recruitment of progenitor cell egress is orchestrated by mutual and reciprocal SDF-1/CXCR4 interactions occurring within the bone marrow stromal and hematopoietic cells as well as between the bone marrow, peripheral blood and distant organs, navigating cell destiny and function in response to stress signals and organ repair and defense requirements.

Leukemic Stem Cells: Migratory Behavior and Immune Regulation

The concept of cancer stem cells was first documented for human leukemia.[21,109] In agreement with this concept, several brain and breast tumor initiating stem cells have been identified recently,[110,111] which can be related to mutations that occur in the normal stem and progenitor cells and lead to malignant transformation and tumor initiation.[112,113] Since leukemic stem cells ultimately are derived from normal hematopoietic stem and progenitor cells, they also express the CXCR4 receptor, which directs the homing of cancer stem cells[113,114] and tumor metastasis (eg, breast, prostate, ovarian) to organs that highly express its ligand SDF-1 (eg, bones, lymph nodes, liver). For example, a positive correlation between SDF-1 expression in a mouse model and human prostate cancer metastatic bone lesions was documented, whereas CXCR4 inhibition reduced the metastatic load.[115] Similarly, CXCR4 expressing human breast cancer cells metastasize to the bone marrow in response to SDF-1 signals from this tissue.[116] In agreement with this concept, prostate cancer cells were found to migrate across bone marrow endothelial cell monolayers in response to SDF-1 in a CXCR4 dependent manner and pretreatment of the prostate cancer cells with SDF-1 significantly increased their adhesion to osteosarcomas and endothelial cell lines.[117] The NOD/SCID mouse model serves also as a preclinical model to study the phenotype of human leukemic stem cells. The SCID leukemia-initiating cells (SLIC), are characterized by primitive nondifferentiated CD34$^+$CD38$^-$ expression profile. These cells extensively repopulate the bone marrow of irradiated mice and initiate a disorders, which is similar to the disease in humans.[22,118] Interruptions of CXCR4/SDF-1 interactions prevent homing of pre-B ALL cells[119] and blocking anti-CXCR4 antibodies when administered to chimeric mice previously engrafted with acute myeloids leukemia stem cells, lead to a dramatic reduction in the levels of human AML cells in the BM, blood, and spleen in a dose- and time-dependent manner, revealing that the malignant cells are more dependent on these interactions than are normal human SRC.[113] Similarly, murine leukemic stem cells expressing bcr/abl were found to express higher levels of cell surface CD44 as compared to their normal hematopoietic counterparts and were dependent to a greater extent on CD44 for homing and engraftment than normal HSCs, providing a potential use in autologous transplantation of patients with CML.[120] High levels of cell expression of CXCR4 levels are poor prognostic factors in both human AML and childhood pre-B ALL.[114,119] Recent reports have revealed novel players in CXCR4 mediated spreading and metastasis of tumor cells. Submicron CXCR4 positive vesicles which are shed from the plasma membrane of CD45 positive leukocytes are capable of transferring the CXCR4 molecule to AML cells, enhancing their migration in response to SDF-1 in vitro and increasing their homing to the bone marrow of NOD/SCID mice. These findings indicate for the involvement of CXCR4$^+$ microparticles in cancer progression and reveal their potential as diagnostic tool.[121]

Fibroblast derived SDF-1 has been shown to attract CXCR4-expressing malignant human cells to pre-metastatic niches and to promote invasive breast carcinoma growth.[122] Disruption of CXCR4/SDF-1 interactions inhibits the homing of human Pre-B acute lymphoblastic leukemia cells to the bone marrow. Interestingly, the same bone marrow endothelial domains also define the homing and retention microenvironment for transplanted murine HSC. This vasculature expresses E-selectin and SDF-1 in discrete, discontinuous areas that direct early metastatic cells to those locations.[6] Similarly, human CD34 leukemia cells, transplanted IV into the immunodeficient

murine model, were observed using immunohistopathology, and exhibit a similar spatial distribution to cord blood derived CD34+ cells: initially localizing on the surface of osteoblasts and than expanding to the inner vascular and diaphysial regions.[123] In accordance, during the course of preangiogenic niche formation, the retention of recruited bone marrow CXCR4+ myeloid cells, which position and maintain VEGF induced angiogenesis, is mediated by perivascular SDF-1 in the murine liver.[124] Recently, an additional mechanism promoting the establishment of premetastatic sites of human cancer stem cell models in mice has been suggested. Bone-derived hematopoietic progenitor cells expressing vascular endothelial growth factor receptor 1 (VEGFR1, also known as Flt1) home to tumour-specific premetastatic sites and form cellular clusters prior to the arrival of tumour cells. Taken together, these data indicate that SDF-1/CXCR4 interactions anticipate in the migration, repopulation, and development of malignant stem cells in the BM and other organs by regulating the establishment of premetastatic and preangiogenic sites as well as anchorage of malignant cells to the stromal microenvironment and cell survival. Based on differences in reduced sensitivity to blockage of key homing components such as CXCR4 and CD44, neutralization of these molecules may serve as a foundation for potential therapeutic approaches, which may inhibit leukemic stem cell proliferation and migration while only minimally affecting normal stem cells.

SUMMARY

This chapter discusses mechanisms and pathways involved in the regulation of hematopoietic stem and progenitor homing (Fig. 23–1), retention as well as hematopoietic stem cell egress, recruitment and mobilization (Fig. 23–2), emphasizing the major role that the

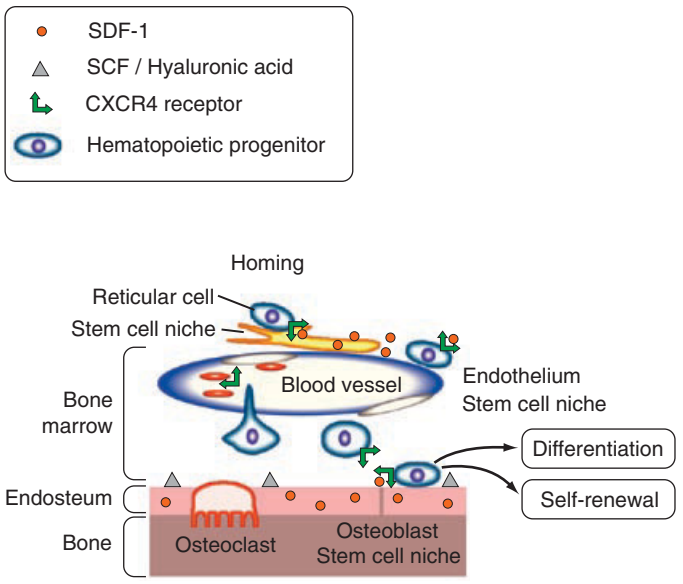

Figure 23–1 Stem and progenitor cell homing into the bone marrow. CXCR4 expressing stem and progenitor cells (*blue cells*) are activated by SDF-1, which is secreted from bone marrow endothelial cells and triggers integrin interactions. The arrested CXCR4+ progenitors, in response to SDF-1, extravasate and migrate through the vessel-marrow barrier. Migrating stem cells eventually reach the "stem cell niches," which consist of stromal cells (reticular cells, endothelial cells, and osteoblasts) that present the proper set of adhesion molecules (eg VCAM-1, hyaluronic acid), SDF-1, and growth stimulatory factors (eg, stem cell factor). SDF, stromal derived factor; VCAM, vascular cell adhesion molecule.

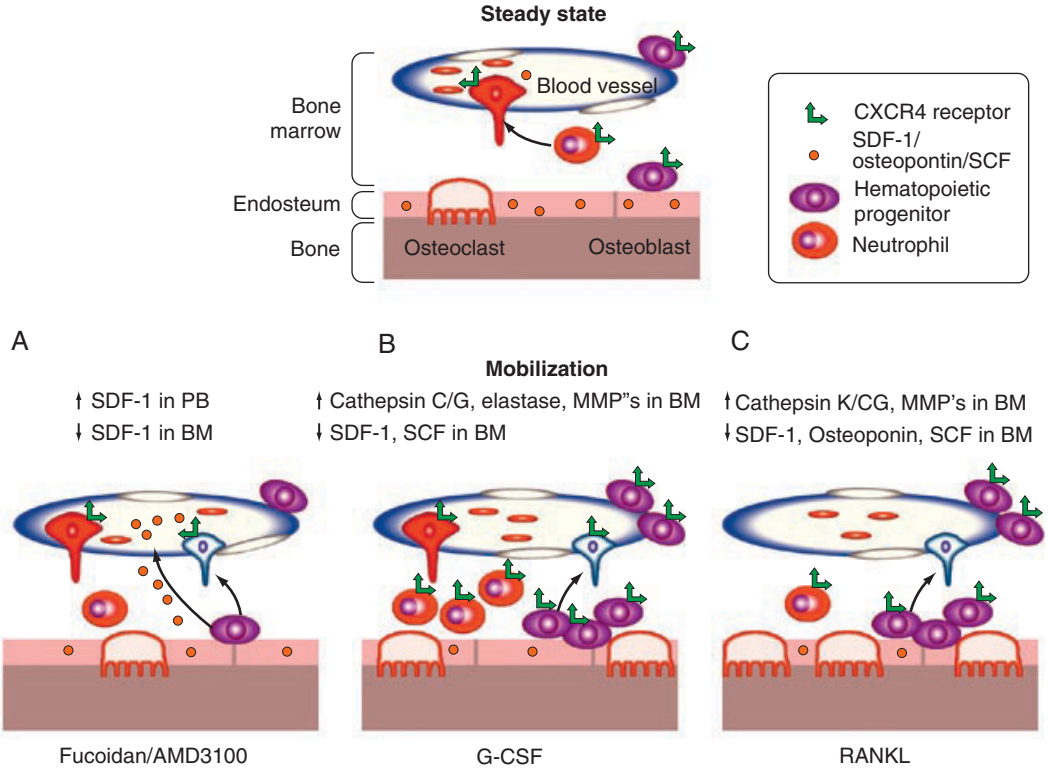

Figure 23–2 Alternative mechanisms of progenitor mobilization. Increased recruitment of hematopoietic progenitors to the circulation upon administration of fucoidan or AMD3100, which induce rapid mobilization (within 1 hour). (**A**) is mediated by massive release of SDF-1 from the bone marrow into the peripheral blood, which in turn chemoattract bone marrow progenitors. The other two mechanisms of mobilization induced by either repetitive administrations of GCSF (**B**) or RANKL (**C**) mediate bone and bone marrow remodeling including: progenitor proliferation and release (**B, C**), bone-resorbing osteoclasts proliferation and activation in the endosteal stem cell niche, and modulation of bone marrow levels of cytokines, growth factors and proteases as indicated (**B, C**). While proliferating mature neutrophils have a fundamental role in GCSF induced mobilization, secreting various proteases (**B**), activated osteoclasts mediate RANKL-induced mobilization preferentially of immature progenitor cells by retraction of bone lining osteoblasts and degradation of components that maintain stem cell retention in the bone marrow endosteal region (**C**). GCSF, granulocyte colony-stimulating factor; RANKL, receptor activator of NF-κB ligand; SDF, stromal derived factor.

Relevance to Clinical Hematology

Most hematopoietic stem and progenitor cells reside in the bone marrow (BM), anchored to specialized niches in the endosteal region and in periarterial sites. However, very low levels of circulating progenitors are continuously present in the blood as part of homeostasis. These low levels are dramatically increased together with maturing leukocytes, which are both recruited from the BM reservoir during situations of stress as part of host defense and repair mechanism. Similarly, clinical protocols, such as repeated GCSF administration, result in stem and progenitor cell proliferation in the BM, differentiation (mostly to myeloid neutrophils), and egress of stem and progenitor cells to the circulation at elevated levels. This process is termed *mobilization* and is used clinically to harvest hematopoietic progenitor and stem cells for transplantation. Successful BM reconstitution requires directed stem cell movement from the circulation, across the blood-marrow barrier into their specialized niches in the BM, a process termed *homing*, wherein stem cells proliferate and differentiate to give rise to multilineage hematopoietic cells while maintaining a small pool of primitive stem cells.

Several cell sources are currently used for BM transplantation: allogeneic umbilical cord blood (CB) from leftover placentas of new born babies, adult BM or mobilized peripheral blood (MPB) cells, which in some cases are enriched for immature CD34 derived cells. While GCSF induced mobilization yields relatively large numbers of immature CD34 cells in the circulation, the numbers of CB MNC and immature CD34 cells is relatively limited. For this reason, the major disadvantage of CB transplantation in adult patients is delayed engraftment. Although children who receive transplants of BM with a cell dose 13 times greater than CB grafts achieve much faster neutrophil and platelet recovery, the levels of progenitors in the BM of such children one year after transplantation with CB were significantly higher, implying that CB has a higher number of long-term repopulating cells. Approaches aimed at overcoming the delayed engraftment with CB transplantation include double CB transplants or together with MPB/BM derived CD34 cell infusion from a matched donor in order to achieve transient engraftment until the CB cells reconstitute the BM. Recently, a pilot study points out the potential of direct intrabone injection of CB cells. This protocol eliminates the step of blood vessel wall transmigration in intravenous infusion to overcome the delayed engraftment. These preliminary results suggest that intrabone transplantation of human CB shortens the time frame for neutrophil and platelet recovery post transplantation and also reduces graft versus host disease initiated by the cord blood cells.

In addition, the CXCR4 chemokine receptor and its ligand SDF-1, the only known powerful chemoattractant for hematopoietic stem and progenitor cells, are major regulators of both stem cell homing, retention, and mobilization processes. Recent studies reveal that the bicyclam AMD3100, a CXCR4 antagonist, induce rapid mobilization of human CD34 cells and synergizes with GCSF, improving clinical progenitor cell mobilization. Since some patients (and also a minority of healthy donors) are poor mobilizers, because of the impact of factors such as aging, heavy prior treatment with chemotherapy, and a diagnosis of AML or ALL in these patients, manipulations of CXCR4/SDF-1 interactions and expansion of primitive hematopoietic stem and progenitor cells ex-vivo prior to autologous transplantation could lead to new perspectives on the development of improved clinical protocols for stem cell mobilization (as well as correcting the release of maturing cells in neutropenic patients and improved homing and repopulation in clinical transplantation protocols).

CXCR4/SDF-1 axis plays in the regulation of these complex interactive processes. The stromal stem cell niche appears to be a dynamic site, which regulates stem and progenitor cell retention proliferation and development by mutual multiple interactions between both cell types and communication with other organs/compartments. The stromal stem cell niche is a negative regulator, which maintains undifferentiated stem cells as quiescent nonmotile cells, which are anchored to the niche supporting stromal cells via adhesion interactions. However, the niche is dynamic and the anchoring interactions can be broken and degraded, allowing the progenitor cells to proliferate, differentiate, and migrate before the niches are reestablished. The findings that are described in this chapter demonstrate fundamental differences between the mechanisms of AMD3100/fucoidan-mediated and GCSF-mediated or RANKL-mediated mobilization (Fig. 23–2). While rapid mobilization induced by AMD3100 or fucoidan within a few hours involves increased release of SDF-1 from the bone marrow into the circulation, which is accompanied by increased release of mature leukocytes and immature progenitors, multiple, daily doses of GCSF and RANKL is mediated by substantial bone and bone marrow remodeling prior to cell egress. Importantly, RANKL administration is unique by inducing massive proliferation and activation of bone-resorbing osteoclasts, which in turn preferentially induce progenitor cell proliferation and mobilization with minor effects on the release of more mature leukocytes. Based on these findings, RANKL should be considered together with other mobilizing agents aimed at selective mobilization of primitive stem and progenitor cells for a broad range of clinical transplantation protocols, in particular for donors who are poor mobilizers: the elderly or heavily chemotherapy-treated patients. Various signals provided during homeostasis versus stress-inducing conditions, provided by the bone marrow tissue and by peripheral organs, determine the fate and localization of the niche residents, the hematopoietic stem cells.

CHAPTER 24

THE HUMORAL REGULATION OF HEMATOPOIESIS

Montaser Shaheen and Hal E. Broxmeyer

INTRODUCTION TO HEMATOPOIESIS

Hematopoiesis, a delicately regulated process, results in the production of a variety of cell lineages with diverse functions that range from delivering oxygen to all tissues to immunity, and hemostasis. This highly orchestrated process requires the division of hematopoietic stem cells that give rise to committed progenitors which proliferate and differentiate into functional blood cells. The passage of hematopoietic cells through different stages of stem and progenitor compartments requires the presence of multiple soluble factors known as cytokines.

A major milestone in our understanding of the cellular basis of hematopoiesis was the discovery that intravenously injected marrow cells could save the life and generate hematopoietic colonies in the spleens of lethally irradiated mice.[1] Further analysis revealed that these clusters of cells were clonal progenitors of single hematopoietic cells termed colony forming units-spleen (CFU-S), and that the colonies could mature into hematopoietic populations of multiple lineages.[2] In addition, these colonies contained CFU-S that could generate more splenic colonies in secondary irradiated animals indicating the capacity of these cells for self-generation. Later, CFU-S were found to be distinct from other more primitive bone marrow (BM) cells termed *hematopoietic stem cells* (HSCs) that are able to undergo self-renewal and generate cells of all hematopoietic lineages.[2,3] It has been realized that CFU-S are unable to repopulate irradiated mice on a long-term basis.[4,5] One primitive subset of cells was recognized as repopulating cells that are able to produce all hematopoietic lineages for a long time. These long-term repopulating cells contrast with short-term repopulating cells, which cannot sustain hematopoiesis for the whole animal lifetime, but which are likely responsible for supporting blood formation for the first eight weeks after HSC transplantation in mice.

Identifying the soluble factors regulating hematopoietic functions was hindered by the lack of advanced molecular biology techniques prior to the 1970s and 1980s and was mainly phenomenological and based on detection of biological activities. The interest of immunologists in the 1960s in studying factors mediating various immune reactions was shortly followed by parallel interest to isolate the factors that drive hematopoietic progenitor cells to survive and differentiate into colonies in semi-solid culture systems. The development of such semisolid agar[6,7] or methylcellulose-based[8] systems led to the conclusion that "inducers" required for the formation of these hematopoietic colonies were secreted by the feeder layer cells and could diffuse through the medium. The beginning of 1980s ushered in the molecular cytokine era with the first successful cloning of a cytokine (interferon β1).[9] This type of cloning introduced a unique opportunity to directly and specifically study the cellular and molecular properties of cytokines after producing pure quantities of these factors in a large scale. In this chapter we review the current understanding of hematopoiesis by focusing on cytokines that display hematological activities and that have or are likely in the future to have clinical utility for treatment of malignant and nonmalignant hematopoietic disorders.

CYTOKINES/SOLUBLE FACTORS AND HEMATOPOIESIS

Cytokines may have stimulatory, costimulatory/augmenting, inhibitory, or multiple different activities on hematopoietic progenitor/stem cells. A listing of hematopoietically active cytokines can be found in Table 24–1. Interleukin-4 (IL-4) represents a classic cytokine with a dual activity on hematopoiesis.[10] This activity can be direct, as seen with most cytokines, or indirect and mediated by the induction of other cytokines. IL-17 represents a classic cytokine whose hematopoietic activity is largely indirect.[11] It is oversimplistic to place cytokines into distinct groups, given the overlap and redundancy seen among them (Table 24–2).[12,13]

One group can stimulate colony formation even when added alone to semisolid culture systems. This includes GM-CSF, G-CSF, M-CSF, IL-3, Epo, Tpo, and IL-5. SCF and FL are two important costimulatory factors that have important functions in the hematopoietic system and display significant synergy with other cytokines. IL-6 family members have been demonstrated to be important hematopoietic regulators with overlapping activities that are mediated through the common receptor signal transducer glycoprotein 130 (gp130). Wnt family, Notch ligands, bone morphogenic protein-4 (BMP-4), sonic hedgehog, and the angiogenic factors have been implicated in the regulation of HSC self renewal and differentiation. Other cytokines play an inhibitory role on hematopoiesis. These factors crucially regulate hematopoiesis by influencing different aspects of this process such as self-renewal, cell survival, differentiation, proliferation, mobilization, and homing. These secreted, soluble, membrane or extracellular matrix-bound molecules affect their target cells through high affinity binding of specific receptors that triggers intracellular signaling, leading to the final phenotype or phenotype change.

This chapter starts by briefly discussing current knowledge about the nature of hematopoietic stem and progenitor cells and the different processes that characterize their lifespan. We then discuss the structure and signaling pathway of cytokine receptors and the influence of each cytokine on hematopoiesis.

HEMATOPOIETIC PROGENITOR AND STEM CELLS

The report by Till and McCulloch[1] on CFU-S and subsequent reports by Bradley and Metcalf,[7] and Pluznik and Sachs[6] on in vitro colony forming cells heralded the four-decade search to purify and characterize hematopoietic stem cells as defined by the features of self-renewal and the ability to give rise to all hematopoietic lineages. Direct evidence of these features comes from the observation that single BM cells can repopulate lethally irradiated primary and secondary recipient mice with all hematopoietic lineages.[14,15] Studies of retroviral marketing of HSCs provides data in support of this concept.[16]

The possibility of existence of a precursor cell common to all hematopoietic lineages dates back to 1951 when Dameshek[17] observed that in patients with myeloproliferative disorders affecting one blood cell lineage, other blood lineages were often affected. Subsequently, it was realized that bone marrow of genetically identical mice could rescue recipients exposed to lethal doses of irradiation.[18] CFU-S form splenic colonies 8 to 16 days post transplant. Cells that give rise to colonies in eight days are termed CFU-S_8, which are largely unipotential and form colonies compound erythroid lineage cells. These colonies do not contain cells able to form colonies in secondary recipients. In contrast, CFU-S_{12} colonies contain cells belonging to several hematopoietic lineages including erythrocytes, megakaryocytes, macrophages, and granulocytes. CFU-S_{12} cells represent a more

Table 24–2 Redundancy in Cytokine Activities

Hematopoietic Process	Cytokines with Important Enhancing Activity
Erythropoiesis	Epo, SCF, IGF-1, IL-9, IL-3, Tpo, IL-20, SDF-1
Megakaryopoiesis	Tpo, IL-3, IL-6, IL-11, LIF, SCF, Epo, SCF, FL
Mast cell formation	IL-3, SCF, IL-10?
Eosinophil formation	IL-5, IL-3, GM-CSF, SCF
Granulopoiesis	G-CSF, GM-CSF, IL-3, SCF, IL-6, FL, SDF-1
Macrophage formation	M-CSF, GM-CSF, IL-3, FL, SDF-1
Lymphocyte production	IL-7, FL, SCF, SDF-1, IL-2, IL-4, IL-5, IL-10, IL-13, IL-15, notch ligands

Demonstration of the clear redundancy in cytokine activities on every blood lineage maturation process. However, certain cytokines exert more prominent influence on one lineage than the others. For example, Epo is the essential cytokine for erythroid maturation, whereas Tpo deficiency leads to severe thrombocytopenia. IL-5 is the main cytokine driving eosinophil formation. G-CSF is the only cytokine whose deficiency results in neutropenia. IL-7 is essential for both T-cell and B-cell development. Absence of M-CSF results in failure of monocyte maturation into other effector cells such as osteoclasts.

quiescent and primitive population of multipotential cells,[19] and cells taken from these splenic colonies are able to produce colonies in secondary recipients, which attests to their capacity for self-renewal. Subsequent experiments have shown that CFU-S are unable to repopulate recipients on a long-term basis and in essence do not represent true stem cells.[4,5] This led to a conclusion that a smaller subset of repopulating cells exists. Because of lack of a parallel in vivo transplantation system in humans, different in vitro assays have been developed in an attempt to characterize surrogate cells that may be close to true stem cells. A variety of suspension cultures assays indicated that the stromal cells were important for the maintenance and possible expansion of CFU-S and the repopulating cells.[20,21] Later, a cell termed a long-term culture initiating cell (LTC-IC) was characterized.[22–24] This cell is identified in an assay in which BM derived stromal cells or an appropriate mixture of cytokines support the proliferation of hematopoietic cells for at least five weeks. At this time the remaining cells are plated in semisolid culture systems and the colonies are enumerated. These colonies reflect the number of primitive cells that can maintain their colony forming potential for five weeks. These cells are considered more primitive than the colony-forming cells (CFC) that are assayed directly without prior incubation in stromal cell based suspension cultures. The LTC-IC does not necessary represent the most primitive stem cell in vivo. The cobblestone area-forming cell (CAFC) assay[25,26] is another in vitro system in which BM cells are plated on top of a specialized stromal layer. Some cells form colonies of at least five small, nonrefractive cells underneath the stromal layer. These cells can generate progenitors for up to 12 weeks and are considered primitive cells as well. The colony-forming cell with high proliferative potential (HPP-CFC)[27] is a cell that produces a large size colony (>0.5 mm and usually contains >50,000 cells) after a long period of in vitro incubation. It responds to stimulation by a multicytokine cocktail and shows resistance to 5-fluorouracil (5-FU) treatment.

Methods to evaluate the in vivo repopulating potential of human hematopoietic stem cells have been developed. These methods utilize the Non obese diabetic/severe combined immunodeficiency (NOD/SCID) mice that can be repopulated after lethal irradiation with human cells.[28,29] This system provides a quantitative method for what is called the SCID repopulating cell (SRC) through limiting dilution of the injected cells. The NOD/SCID mouse model has been instrumental in the study of the in vivo proliferation of human hematopoietic stem cells and their differentiation into all blood lineages including lymphoid cells.[30] This system has proved the self-renewal capacity of SRC through serial transplantation into secondary and tertiary recipient mice.[31] However, due to the short lifetime of SCID-NOD mice (most of them develop thymoma by age 6 months) the SRC may not represent the true human stem cell that sustains hematopoiesis for longer periods than this. Other SCID mouse models with longer life spans are being evaluated. Another in vivo model of human hematopoiesis utilizes in utero transplantation of stem cells into sheep fetus before the development of the ovine immune system.[32,33] Human HSCs from fetal liver, cord blood, mobilized PB, and BM are able to engraft the ovine BM and undergo multilineage differentiation. In this system, short-term repopulating cells, which give rise temporarily to mature blood cells, can be distinguished from long-term repopulating cells that sustain hematopoiesis in primary and secondary recipients for a long time.[34]

Along with functional characterization of hematopoietic stem/progenitor cells in vitro and in vivo, phenotypical characterization of these cells has been pursued. Extensive screening of murine antibodies against cell-surface molecules elucidated antibodies that could be used to enrich murine BM cells 1000 to 2000-fold for their ability to radioprotect lethally irradiated mice. This subset of BM cells are low for the Thy-1 antigen, negative for mature cell lineage markers (Lin^-), and positive for a stem cell marker called Sca-1; they are termed $Thy\text{-}1^{lo}$ Lin– $Sca\text{-}1^+$.[35] This subset contains all of the repopulating potential of murine BM cells. Twenty to 40 cells belonging to this subset can radioprotect 50% of lethally irradiated mice. Eight percent of $Thy\text{-}1^{lo}$ Lin^- $Sca\text{-}1^+$ cells express the stem cell factor receptor c-Kit. These Kit+ $Thy\text{-}1^{lo}$ $Lin^-Sca\text{-}1+$ (KTLS) cells are highly

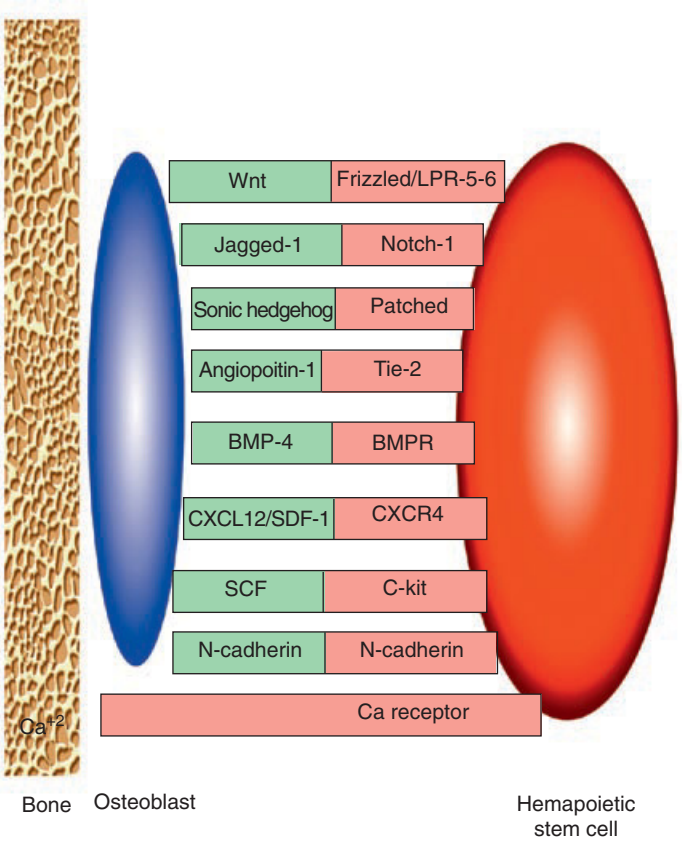

Figure 24–1 The current understanding of HSC in its niche. This figure depicts the currently known regulators through which HSC interacts with the osteoblast. This interaction is thought to determine the stemmness; self-renewal, quiescence, and differentiation of HSC. BMP, bone morphogenetic protein; HSC, hematopoietic stem cells; SCF, stem cell factor.

enriched for self-renewing and repopulating cells.[36,37] One report suggested that the c-Kit$^-$ subset might represent a population of very primitive quiescent cells that do not contribute to hematopoiesis until 40 weeks after transplantation.[38] These cells are heterogeneous for the expression of murine CD34,[15] whereas most human progenitor/stem cells express the sialomucin antigen CD34 on their surface.[39] However only a minority of CD34$^+$ cells have NOD/SCID repopulating potential. The human CD34$^+$ CD38$^-$ fraction is enriched for more primitive cells.[40] It has been found that the CD34$^-$ Lin$^-$ fraction also has SCID- repopulating capacity. These CD34$^-$ Lin$^-$ cells engraft in fetal sheep and form human hematopoietic cell chimeras.[41] However, the exact relationship of CD34$^+$ to CD34$^-$ stem cells remains to be adequately defined, and the presence of CD34 may only define cell activation status.

Another frequently utilized approach to isolate HSCs has been through their ability to efflux fluorescent dyes and to appear as a "side population" on flow cytometric analysis.[42] More recently, novel cell surface markers have been used to isolate a relatively homogenous HSC population. Such markers include endoglin (an ancillary TGF-β receptor),[43] the endothelial protein C receptor (CD201),[44] and SLAM family receptors (see Chapter 20).[45]

Fig. 24–1 represents the current understanding of the hematopoietic hierarchy with emphasis on the principle cytokines that affect each maturation step.

The Interaction of Hematopoietic Stem Cell with Growth Factors Within Its Niche

The concept Of HSC niche was first proposed in 1978.[46] Recent interest in HSC niche was triggered by studies in gonadal tissue of *Drosophila* that identified specific cell-cell interaction between germ stem cells and the niche "cap cells."[47] This interaction determines which of the resulting two cells after germ stem cell division will remain as a stem cell and which will become a differentiating daughter cell. HSC has been proposed to interact closely with the stromal cells within the bone marrow niche.[48] Multiple lines of evidence point to the localization of this niche close to the trabecular bone within BM. Osteoblasts have emerged as principal stromal cells that regulate HSC maintenance and proliferation. Endothelial cells represent an alternative niche.[45,49] Genetically modified mice that overproduce osteoblasts are characterized by an increase in the HSC pool within BM without an increase in the numbers of progenitors.[50,51] Osteoblasts express key cytokines and other surface molecules that are known to play key roles in HSC homing in the BM such as SDF-1/CXCL12, Jagged-1 (notch ligand), SCF, wnt members, angiopoietin-1, and N-cadhern. The angiogenic factor angiopoietin-1 has emerged as a key regulator of HSC quiescence within the niche.[52] Ionic calcium plays an important role in the niche organization since HSCs that lack the Ca^{+2} receptor fail to engraft in the BM.[53] A schematic view of this niche concept with the up-to-date interaction between HSC and the mesenchymal cell is shown in Fig. 24–2.

CYTOKINE REGULATION OF COLONY FORMATION

The first observed biological activity of hematopoietic growth factors was the ability to promote hematopoietic cell colony formation.[6–8] Colony formation is optimal in the presence of multiple cytokines that synergize with each other to increase the number and size of colonies formed by the same seeding dose of progenitor cells. It is important to realize that even though a certain colony-stimulating factor may have a major influence on one blood lineage, it often affects other blood lineages, particularly in the presence of other factors.[54] For instance, G-CSF stimulates the proliferation of granulocyte progenitors but it also augments megakaryocyte colony formation by IL-3.[55] An important theme that has been controversial is the permissive versus instructive role of cytokines in hematopoietic lineage commitment.[56,57] Once the commitment decision has been made, cytokines exert signals for proliferation, survival, and to some extent differentiation that lead to the production of functional hematopoietic cells. We discuss each of the processes that contribute to the observed outcome of cytokines on colony formation.

Instructive Versus Permissive Activity of Hematopoietic Cytokines

The instructive model of cytokine action resembles that of several developmental systems in which secreted factors determine cell fate. The most direct evidence for the operation of such a system in hematopoiesis is the committment decision by bipotential granulocyte-macrophage colony-forming cells (GM-CFC = CFU-GM).[58] In this situation, the daughter cells of GM-CFC are examined for their fate decisions. The addition of M-CSF to cultures results in the formation of macrophage-committed progenitor cells, whereas the addition of GM-CSF results in a higher frequency of granulocyte-committed progenitors. When stem cell factor is used to stimulate early progenitor cells to form blast colonies composed of progenitor cells, the addition of thrombopoietin (Tpo) increases frequency of colonies containing megakaryocyte progenitors, while the addition of IL-5 induces colonies containing eosinophil-committed progenitor cells.[59] Another line of evidence supporting the instructive role of cytokines was generated by a study[60] in which the common lymphoid progenitor cell could change commitment into the myeloid lineage when transduced with IL-2 and GM-CSF receptor genes and transduced cells were cultured in the presence of the corresponding cytokines. This study documented that GM-CSF and M-CSF receptors were expressed at low to moderate levels by primitive hematopoietic cells and were absent on common lymphoid progenitors. These receptors were upregulated with the myeloid lineage induction by IL-2. In

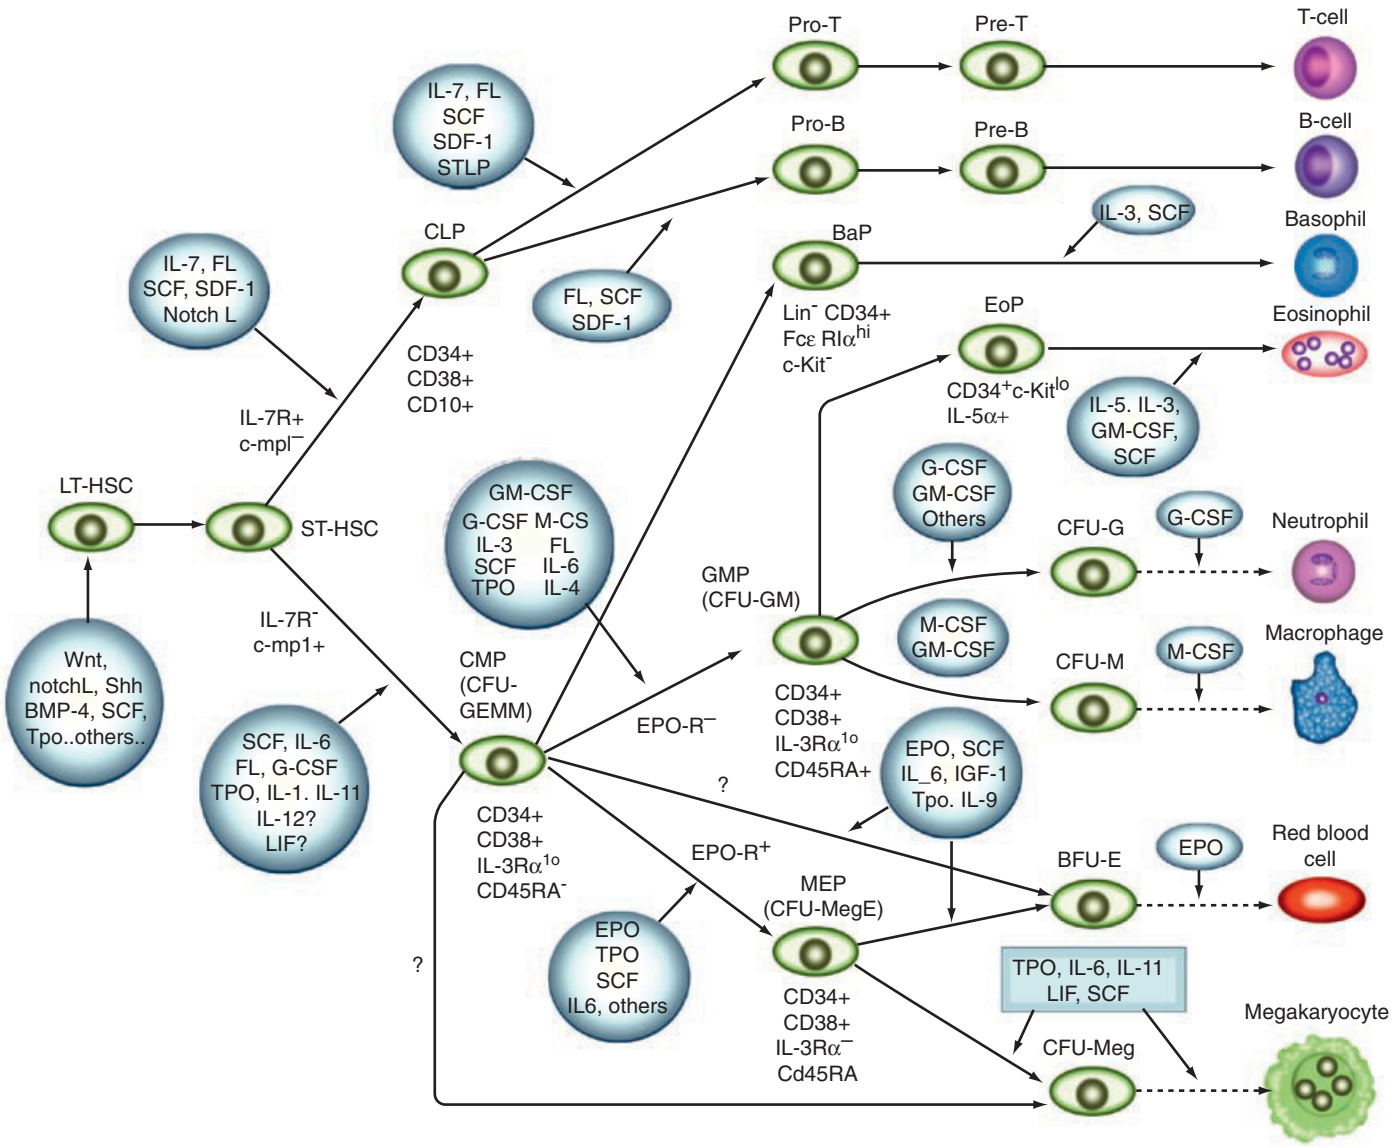

Figure 24–2 Cytokine Activities in Hematopoiesis. The current understanding of hematopoietic hierarchy with the influence of cytokines is indicated. The long-term hematopoietic stem cell (LT-HSC) gives rise to short-term hematpoietic stem cell (ST-HSC). The latter diverges into either common lymphoid progenitor (CLP)[483] or common myeloid progenitor (CMP).[486] CLP harbors transcriptional activity consistent with the lymphoid lineage and gives rise to all lymphoid elements while CMP displays myeloid related gene expression and diverges into granulocyte-macrophage progenitors (GMP) or megakaryocyte-erythroid progenitors (MEP). This progression of maturation associates with suppression of lineage-genes that are not needed. BFU, burst-forming unit; BFU-E, burst-forming unit-erythroid; CFU-MK, colony forming unit megakaryocyte; BMP, bone morphogenetic protein; CSF, colony-stimulating factor; EPO, erythropoietin; IL, interleukin; LIF, leukemia inhibitory factor; SCF, stem cell factor; Tpo, thrombopoietin.

another type of experiment, exogenous erythropoietin receptor (EpoR) expression by the pre-B cell line induced proteins specific to the erythroid progeny in the presence of Epo.[61,62] Ectopic EpoR expression by daughter cells of cord blood CD34+ cells skews the outcome of forming colonies containing more erythroid progeny.[63] Finally the ectopic expression of M-CSFR in an Abelson virus transformed pre-B cell line resulted in a lymphoid to monocytic lineage switch in the presence of M-CSF.[64]

On the other hand, several lines of evidence point to a permissive role of cytokines in the hematopoietic commitment process. In this model the commitment decision is stochastic (random) and independent of cytokine action whose function is to drive proliferation and survival of committed cells that respond to cytokines based on expression of corresponding receptors. The term stochastic was initially utilized by Till et al[65] to explain the mechanism by which a stem cell decides to self-renew or differentiate. Using micromanipulation techniques, Ogawa's group provided evidence in support of a stochastic model of hematopoiesis by analyzing the commitment of cells in the blast colonies.[66,67] The cells of these colonies are characterized by the ability to form secondary multipotential colonies. Analysis of different lineage colonies derived from a single blast cell origin revealed random combinations of lineages.[66] Two daughter cells originating from a single cell origin also gave dissimilar combinations of lineages under identical growth factor conditions.[67] Simulated mathematical models in conjunction with in vivo verification also support a stochastic model of hematopoietic commitment.[68] The most compelling evidence in favor of this model has been obtained from a series of experiments utilizing chimeric cytokine receptors. In one study a chimeric receptor of the extracellular domain of the thrombopoietin receptor (c-mpl) and the cytoplasmic domain of G-CSFR replaced c-mpl in a knock-in model.[69] The homozygous mice had normal platelet levels suggesting that the cytoplasmic domain of the G-CSFR can replace c-mpl to support megakaryocytopoiesis. The cytoplasmic domain of the G-CSFR was replaced with that of the EpoR in a similar approach, without affecting the lineage commitment to neutrophils.[70] The commitment of progenitor cells into a certain lineage

seems to be irreversible without converting into cells belonging to other lineages under the influence of cytokines. For example, introducing the EpoR into macrophage precursors results in Epo-stimulated macrophage colonies without development of erythroid cells.[71] Conversely, insertion of the M-CSFR into erythroid precursors results in formation of erythroid colonies under the influence of M-CSF.[72] In other experiments,[73] overexpression of anti-apoptotic gene Bcl-2 in mice deficient in IL-7 receptor reverses the immune dysfunction seen in these mice, which means that a survival signal can compensate for the defect in a cytokine signal, indicating that the specificity in cytokine action may be related to cognate receptor expression on particular cells. Similarly, expression of Bcl-2 restores osteoclast and monocyte deficiencies in M-CSF deficient *op/op* mice.[74] Knock-out models of cytokines and their receptors also support a permissive role of cytokine action. For example, disruption of either Epo or EpoR by gene targeting results in severe anemia.[75] However, the resultant anemia is not due to defective commitment since erythroid progenitors are preserved in these mice.

Cytokines may work though either the instructive or permissive mechanism or both according to the developmental stage of the stem/progenitor cell. It has been clearly demonstrated that multiple lineage genes are transcriptionally active in early progenitors/stem cells and these cells suppress the transcription of irrelevant genes as they progress along the hematopoietic differentiation pathway.[76,77] Certain transcriptional factors are keys in the molecular mechanisms controlling progenitor cell differentiation. The transcriptional factor PU.1 which is an ets family member plays a vital role in myelopoiesis and lymphopoiesis.[78] PU.1 deficient mice lack both myelocytes and lymphocytes. Reintroducing this protein to PU.1 deficient HPCs initially induces mixed myelocyte/macrophage gene expression, but increasing levels of PU.1 promote macrophage differentiation and suppress granulocyte formation.[79] PU.1 (like other transcriptional factors) appears to induce progenitor differentiation at least partly through induction of growth factor receptor expression.[80] The zinc-finger protein GATA1 induces progenitor differentiation into erythroid, eosinophilic and megakaryocyte lineages.[81] There appears to be opposing effects between PU.1 and GATA1 based on their concentrations which direct whether HPC will become myeloid or erythoid cell respectively.[82] In addition, low levels of c-mb favor macrophage and megakaryocyte differentiation, while high levels promote erythropoiesis and lymphopoiesis.[83]

Some of these factors exert negative effects on the development of other lineages. This suppressive activity is released in the absence of such factors. When Pax-5 (a B-cell lymphocyte lineage regulator) is deleted, the knock-out HPCs fail to restrict their lineage choice and differentiate into a variety of cells including macrophages, neutrophils and osteoclasts based on the cytokines added.[84]

Cytokine Regulation of Hematopoietic Progenitor/Stem Cell Proliferation

Progenitor cell proliferation is required for colony formation to occur in vitro and to sustain hematopoiesis in vivo. Lineage-committed progenitors can be triggered to proliferate with the addition of single late acting cytokines such as M-CSF, IL-5, G-CSF, and Epo. On the other hand, triggering proliferation of early progenitors requires stimulation by more than one cytokine. Ogawa divided early-acting cytokines into three groups. One group includes IL-3, GM-CSF, and IL-4, which induce proliferation of multipotential progenitors only after they exit from G_0 and enter cell cycle.[85] A second group includes IL-6, IL-11, IL-12, G-CSF, and LIF and triggers the cycling of dormant early progenitors. A third group includes SCF and FL; this group interacts and synergizes with the factors belonging to the first two groups. Other cytokines have been identified and shown to have activity on HSC/HPC. Cytokine regulation of cell cycle machinery has been studied in detail.[86,87] Cyclin-dependent kinase inhibitors (CDKIs) have stood out as key regulators of HSC/HPC maintenance/proliferation. In knock-out mice of the CDKI $p21^{cip1/waf1}$ the absolute number and proliferation of HSC are increased. HSC self-renewal, as tested by serial transplantation and cyotoxic resistance, was impaired in these mice.[88] It was concluded that $p21^{cip1/waf1}$ controls cell cycle entry of HSCs, and in its absence increased cycling occurs which leads to exhaustion of these cells. Paradoxically $p21^{cip1/waf1}$ plays a role in cytokine-induced proliferation of HPCs and it is upregulated following exposure to synergistic cytokine combinations.[89] In $p21^{cip1/waf1}$ deficient mice, the number and cycling of HPCs apprear decreased as compared to wild-type cells.[89,90] This could be due to the association between CDK4 and D-cyclins mediated by $p21^{cip1/waf1}$ and other CDKIs.[91] $p27^{kip1}$ CDKI plays an important role in determining the progenitor pool size and cycling status,[92] where HPC number and cycling is markedly increased in P27 deficient mice. These mice display organomegaly and hyperplasia of different tissues, with tendency to form tumors.[93] HSC cycling and number are not altered in these mice, whereas p27 deficient HPCs dominates hematopoiesis in competitive repopulation experiments.[94] Deletion of the early G_1 phase inhibitor p18 leads to improved long-term engraftment due to improved self-renewal divisions in vivo.[95] Recently, p16 another CDKI was shown to be involved in stem cell aging including HSCs. In its absence, some of the aging qualities such as repopulating defect and apoptosis are reversed.[96] Bim-1 is a polycomb family suppressor gene whose deletion leads to depletion of HSCs and decrease in their self-renewal.[97] This negative effect of Bim-1 loss appears to be largely mediated by derepressing p16 and p19 which are encoded by the same locus.[98] Within the same context another transcriptional repressor; Growth factor independent (Gfi-1) restricts the proliferation of HSCs and enhances their self-renewal and repopulating capacity.[99]

Cytokine Regulation of Hematopoietic Progenitor/Stem Cell Survival

One of the essential functions of cytokines and in general growth factors is to prevent programmed cell death or apoptosis of the target cells.[100] There are few exceptions to this role as seen with some of the suppressive cytokines such as interferons (IFNs) and tumor necrosis factor-α (TNF-α). For example, IFNs increase the expression of pro-apoptotic receptor Fas by hematopoietic progenitors.[101] It is well established that hematopoietic progenitor/stem cells undergo apoptosis upon cytokine withdrawal from culture. This survival enhancing effect of cytokines appears to be independent from the proliferation enhancing action. For example, genistin, a tyrosine kinase inhibitor, blocks IL-3/GM-CSF mediated DNA synthesis but does not affect the action on apoptosis reversal.[102] The GM-CSFR mediates proliferation signals through a cytoplasmic region which is different from that mediating the survival signal.[102] Certain cytokines, such as SCF, can promote hematopoietic progenitor/stem cell survival in the absence of cell division.[103] However, it is too simplistic to consider the processes of proliferation and survival to be mutually exclusive. Quiescent hematopoietic cells are less susceptible to apoptosis inducing stimuli than cycling cells. Variable expression of apoptosis genes occurs during cell cycle progression.[104] Multiple cytokines such as SCF, FL, IL-3 and Tpo suppress apoptosis of $CD34^+$ $CD38^-$ cells in single-cell assays, indicative of a direct effect of these cytokines on progenitor/stem cell survival.[105] Tpo has more potent activity than the other cytokines in this regard. Tpo alone can support the survival of Sca-1^+ Lin^- c-kit^+ cells without stimulating active cell proliferation.[106] Activation of a chimeric receptor that contains the TpoR (mpl) domain results in expansion of BM multipotential progenitors. This effect is not observed with G-CSF or Flt3 fusion receptors, which suggests an essential role for Tpo/mpl in sustaining primitive progenitor survival.[107] Hematopoietic cytokines are selective in their survival enhancing effect. For example, IL-3 enhances $CD34^+$ HLA-DR^+ cell survival more than SCF, while the opposite is true for $CD34^+$ HLA-DR^- cells.[108] Other nonclassic survival promoting factors have the ability to promote hematopoietic progenitor

survival as seen with the chemokine stromal cell-derived factor-1 (SDF-1/CXCL12).[109]

Hematopoietic cytokines and their receptors appear to be essential for the survival of a variety of leukemic cells and may cooperate with oncogenes and tumor suppressor genes to promote leukemogenesis.[110] It is beyond the scope of this chapter to discuss the complex signaling pathways involved in this survival enhancing activity, but there is evidence that more than one survival signal is required. For instance, BCL-2 overexpression can cooperate with c-Kit signaling to prevent primitive progenitor/stem cell apoptosis but neither signal is effective alone.[111]

Synergy among Hematopoietic Cytokines

Another important feature of cytokine activity on hematopoietic progenitors is the synergy seen among cytokines in enhancing colony formation.[112] For example, a combination of Epo, IL-3, GM-CSF, and SCF stimulates the appearance of large colonies of CFU-GEMM, BFU-E, and CFU-GM. Adding Epo alone to BM cells results in the formation of BFU-E derived colonies. CFU-GM derived colonies can form in the presence of GM-CSF as a single cytokine. The size of these single-cytokine induced colonies is smaller and their number is less than those formed in the presence of two or more cytokines. This greater-than-additive effect has been demonstrated with a wide range of cytokine combination. This synergistic activity is explained by several mechanisms including the presence of multiple cytokine receptors on the single progenitor cell,[113] and the induction of the level of some cytokine receptors in the presence of other cytokines.[114] Cytokines may exert their synergy through amplifying the intracellular signals directed towards enhancing survival, and/or proliferation or suppressing differentiation.[115]

Hematopoietic Stem/Progenitor Cell Expansion by the Use of Cytokines

HSCs have the ability to self-renew and divide in vivo to give rise to daughter cells capable of differentiation into all hematopoietic lineages. It is of major clinical interest to expand the pool of HSCs ex-vivo in order to utilize the expanded cells for multiple applications, such as increasing HSCs number in cord blood grafts so that adult recipients can more efficiently undergo cord blood transplantations with single collections. Expanding HSCs and progenitors collected from BM or peripheral blood could potentially shorten or prevent the period of pancytopenia observed after BM ablation. Generating fully functional HSCs from embryonic stem cells is a future goal. Immune-active cells against different tumors might also be produced in adequate quantities from ex-vivo manipulated progenitor/stem cells.

The initial attempts to use cytokines to expand progenitor/stem cells were initiated in the 1980s using crude conditioned media as a source of cytokines.[116] Later, recombinant forms of early-acting cytokines such as SCF, FL, Tpo, Il-6, G-CSF, and IL-3 were used in different combinations in attempts to expand HSCs.[117] Ex-vivo systems that expand committed progenitors have been developed and used with very limited success in clinical settings to shorten the time of pancytopenia following stem cell transplantation.[118,119] Cytokine cocktails have been added to stromal cell-based or stroma-free cultures, in the presence or absence of serum. Many of these systems have resulted in hundreds of fold expansion of the numbers of committed progenitors.[120] However, the major goal is the expansion of primitive stem cells that are capable of engrafting humans. This area of research overlaps with that aimed at understanding the mechanisms of stem cell self-renewal. Several attempts to expand HSCs in cytokine-supplemented conditions have resulted in a modest increase in the numbers of SCID-repopulating cells (SRCs) when culture time is limited to a period of seven days.[121,122] Only a single study has reported a very large expansion of SRC after 9 to 10 weeks of culturing cord blood in vitro.[123] This same group of investigators expanded human adult SRCs sixfold after three weeks of ex-vivo culture.[124] Most other reports have revealed that culturing cord blood HSCs or HSCs from other sources for more than 7 to 14 days results in a loss of long-term engrafting potential as manifested by loss of the capability to engraft secondary or tertiary murine recipients.[125] With the identification of more essential regulators of the HSC self-renewal such as HoxB4, wnt, or notch ligands, it is likely that future efforts may result in more effective expansion of HSCs that could be evaluated in clinical trials.

Cytokine-Mediated Hematopoietic Stem/Progenitor Cell Mobilization and Homing

In mid-1980s it was recognized that hematopoietic cytokines, when administered in vivo, induce elevations of progenitor/stem cell numbers in the peripheral blood.[126] A small percentage of these cells circulates in peripheral circulation during the steady state.[127] Multiple cytokines including certain chemokines exhibit HSC mobilizing activity with variable potency. GROβ, which is a CXCL2 chemokine mobilizes HCS within 15 to 30 minutes of administration in mice and within one hour in rhesus monkeys,[128] whereas cytokine mobilization with factors such as G-CSF occurs days after its administration. G-CSF administration results in degranulation of neutrophils in the BM which release proteases such as neutrophil elastase, cathapsin G, and matrix metalloproteinase-9 (MMP-9). These enzymes cleave essential molecules such as vascular cell adhesion molecule-1/CD106 which is expressed by BM stromal cells and interacts with integrin a4β1 (VLA-4) on HSCs resulting in their release into the circulation.[129] It is of interest that most of the mobilized cells are not cycling and reside in the G_0/G_1 phase of the cell cycle.[130] G-CSF is also an essential regulator of neutrophil trafficking from the BM to peripheral blood.[131] G-CSF administration causes a decrease in the levels of the BM chemokine SDF-1/CXCL12 which has been suggested to play an important role in the mobilization process.[132] SDF-1/CXCL12 is strongly implicated in progenitor/stem cell homing to the BM.[133] SDF-1/CXCL12 is a potent chemoattractant of the progenitor/stem cells.[134,135] Conversely, the hematopoietic stem cell compartment is heterogeneous for CXCR4 (SDF-1 receptor) expression,[136] and CXCR4 null cells from fetal liver engraft normally into BM of wild-type mice. It appears that the SDF-1/CXCL12 pathway is one essential actor, but that other cell surface proteins are also important for homing/mobilization. One strategy that is being pursued is to enhance HSC mobilization is the blockade of the CXCR4-SDF-1/CXCL12 axis, a goal that is achievable with the availability of several CXCR4 antagonists presently being evaluated in clinical trials.[137] Certain cell surface molecules such as the dipeptidylpeptidase CD26 which cleaves SDF-1/CXCL12 play important roles in the homing/mobilization process.[138] Other cytokines may also play a role in HSC homing, such as the membrane form of stem cell factor through interaction with its receptor. A recent report implicates osteoclasts in HSC mobilization in physiologic situations such as bleeding.[139]

Fig. 24–3 illustrates the current understanding of HSC/HPC mobilization.

CYTOKINE RECEPTORS

Cytokine receptors bind their ligands in a specific manner and at low cytokine concentration in order to transduce signals leading to biological responses.[140] These receptors display significant conservation in their structure and activity which allows them to be placed within the cytokine receptor superfamily.[141] There are examples of newly cloned proteins that were determined to be cytokine receptors based on the presence of conserved domains in their structures. For instance, c-mpl was initially cloned as a retroviral oncogene and was promptly designated as an orphan cytokine receptor gene based on its predicted amino acid sequence.[142] This eventually led to the cloning of its ligand, Tpo. Cytokine receptors function as dimeric or oligomeric complexes consisting of two to four chains. Ligand binding results

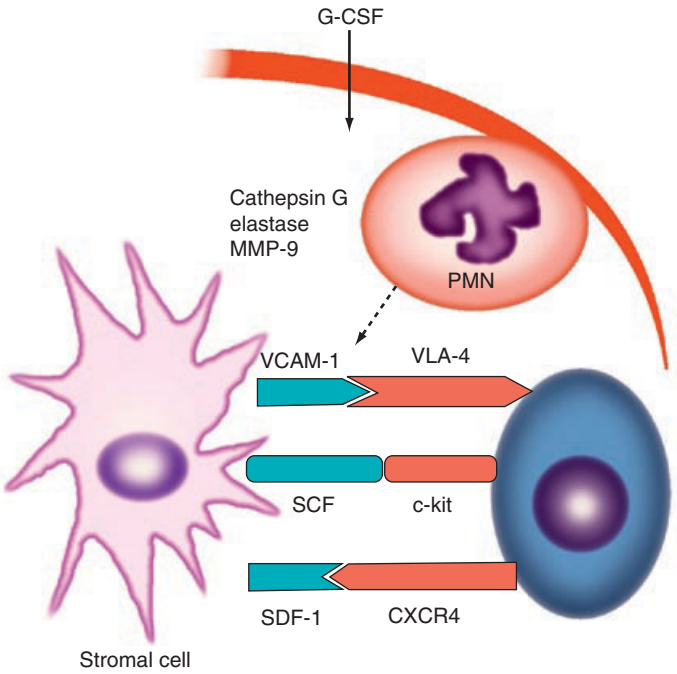

Figure 24–3 Hematopoietic Progenitor/Stem Cell Mobilization. The current understanding of hematopoietic progenitor/stem cell mobilization by growth factor administration is shown. In the model, G-CSF induces proliferation of the progenitor/stem cells and activation of the mature neutrophils. The latter release proteases such as MMP-9, cathepsin G, and Elastase. These disrupt the retention bonds between stromal cells and progenitors/stem cells such as vascular cell adhesion molecule-1 (VCAM-1) on stromal cells and its ligand the integrin VLA-4 on progenitor/stem cell.[129] Other retention signals may include SDF-1/CXCR4,[132,133,135] and SCF/c-kit.These proteases may also contribute by disrupting the extracellular matrix and opening the endothelial gaps. One membrane-bound dipeptidylpeptidase (CD26) is present on progenitor/stem cells, and other cells, and cuts the N-terminal dipeptide of SDF-1 which contributes to producing an inactive SDF-1 which competers with full length SDF-1 for binding to CXCR4.[138]

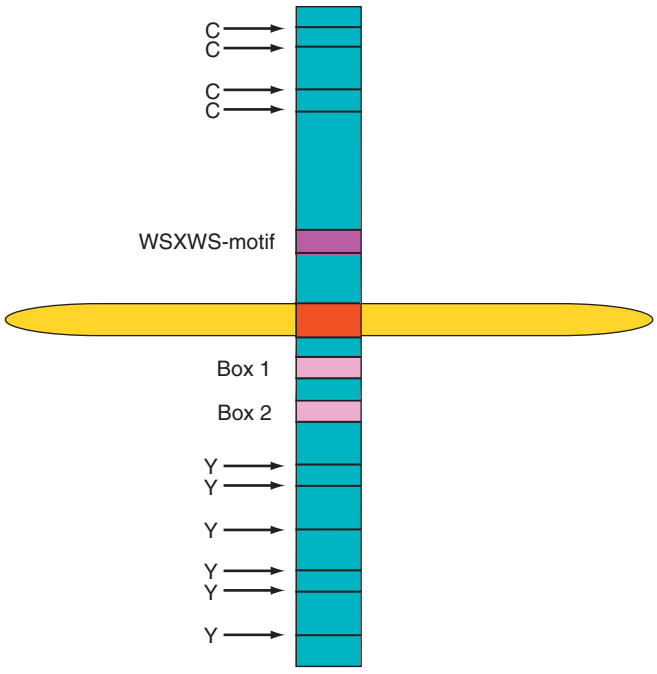

Figure 24–4 Cytokine Receptor Superfamily. The general structure of cytokine receptor superfamily.[141–143] In the extracellular cytokine receptor module (CRM) 4 conserved cysteine residues involved in disulfide bonds. A WSXWS (tre, ser, any, tre, ser) motif that is essential for receptor processing, ligand binding and activation of the receptor. In the intracellular portion, two short domains termed box 1 and box 2 are important for Janus kinases (Jaks) binding. Tyrosine residues are present on the intracellular part to be phosphorylated upon receptor activation.

in dimerization or oligomerization of the receptor chains which causes receptor activation and signal transduction.[143] This mechanism of receptor chain clustering appears to be universal among hematopoietic cytokine receptor and receptor tyrosine kinase families. Other hematopoietic active molecules such as chemokines activate receptors of a different nature.

Cytokine receptor subunit chains can be identical as seen with SCF, Epo, G-CSF, and GH receptors, or different as with IL-6 and IL-3. The cytokine receptor superfamily is generally divided into a few groups based on similarities among members of each group as follows:

Type I Cytokine Receptor Family

The type I cytokine receptor family is also called the hematopoietin receptor family. It contains receptors for most hematopoietic cytokines. The ligands of these receptors have a common four α-helical structure.[144] These receptors exhibit a conserved region of about 200 amino acid residues denoted the cytokine receptor module (CRM) that consists of two β-barrel structural domains. The first domain contains four conserved cyteine residues involved in disulfide bonds and the second domain contains a well-conserved WSXWS motif in its c-terminus.[144] Elucidating the structure of growth hormone receptor (GHR) in complex with GH has provided some explanation of the roles of these conserved residues.[145] Each structural domain within the CRM is related to fibronectin type III domains. These features are present in the extracellular portion of the receptor. Intracellularly, these receptors are more divergent but they have a conserved membrane-proximal domain of two boxes including a hydrophobic α helical segment that serves to bind Janus kinases (Jaks).[146] A general model of type I cytokine-receptor binding comes from a comprehensive evaluation of GH-GHR interaction.[145] In this model, GH binds to one monomer of GHR (which is a homodimer) via a high affinity "site1." After that, the second monomer makes contact with the GH via "site 2." This complex is further stabilized by a receptor-receptor interaction site denoted "site 3." Fig. 24–4 illustrates the general structure of type I cytokine receptors. Fig. 24–5 demonstrates the important signaling molecules that bind to the cytokine receptor and mediate or negatively-regulate its signaling. In the type 1 cytokine receptor family, clusters of receptors share similar components and can be grouped into subfamilies. Fig. 24–6 depicts the cytokine receptor type 1 subfamilies that contain common receptor chains.

IL-3, IL-5, and GM-CSF share a common cytokine receptor β chain (βc) while each receptor has a distinctive α chain.[147] In mice, there is another IL-3 receptor specific chain denoted βIL-3. Targeted disruption of βc results in defective responses to IL-5 and GM-CSF (but not IL-3 due to the presence of βIL-3) with no significant hematological impairment with the exception of reduced numbers of eosinophils due to defective IL-5 signaling.[148] These mice develop alveolar proteinosis.

The IL-6 cytokine subfamily includes IL-6, IL-11, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), novel neurotrophic-1/B cell-stimulatory factor-3/cardiotrophin-like cytokine (NNT-1/BSF-3/CLC), and cardiotrophin-1 (CT-1). These cytokines exert multiple actions in the hematopoietic, immune, cardiovascular, and central nervous system. They share the gp130 signal transducing molecule as a component of their receptors, whereas the other chains in each receptor contribute to ligand binding.[149] Disrupting gp130 in mice results in embryonic lethality which reflects the importance of gp130 signaling in multiple tissues.[150]

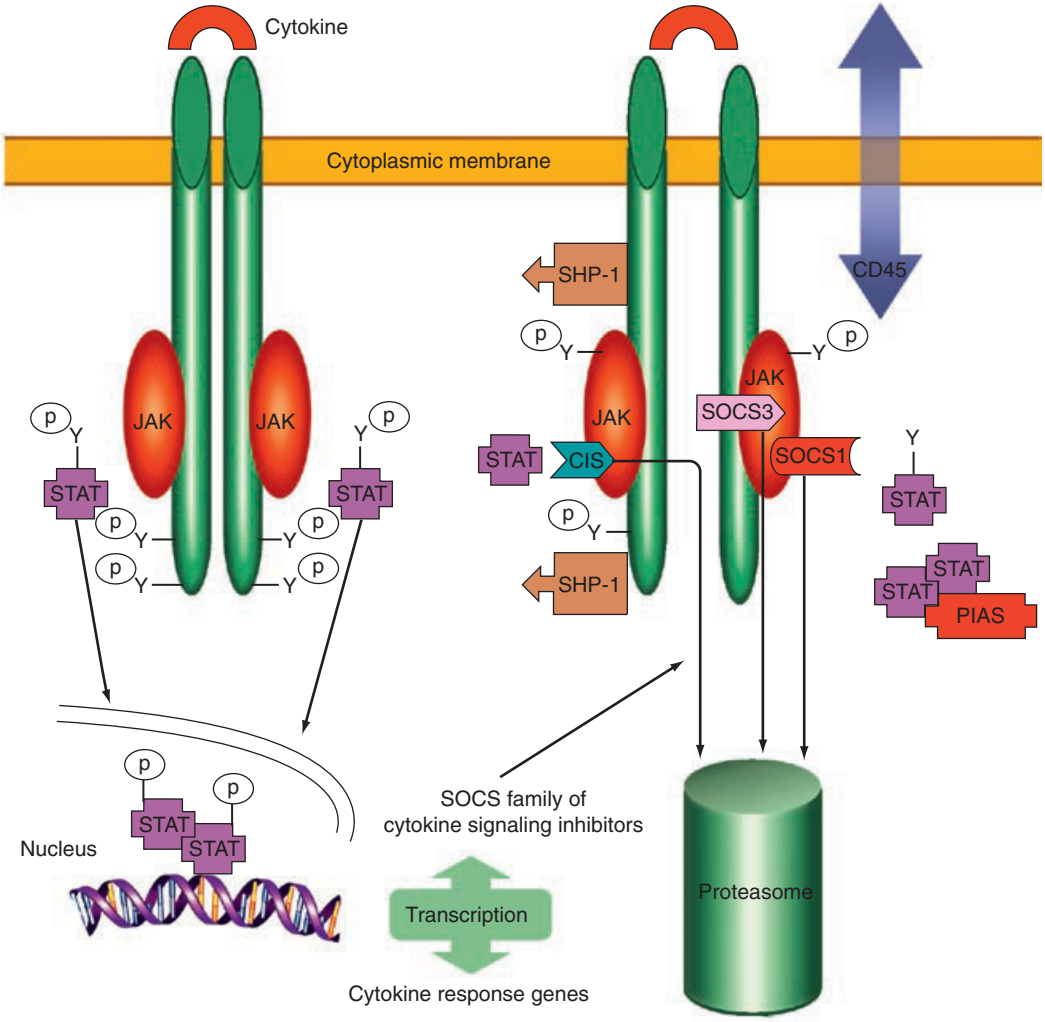

Figure 24–5 Cytokine Activated Signal Transduction. A general depiction of signal transduction by cytokine receptor superfamily. Ligand binding leads to dimerization[143] or oligomerization of the receptor which brings into proximity the associated Janus kinases (Jaks) that phosphorylate tyrosine residues on the receptor and Jaks. This phosphorylation creates docking sites for proteins containing Src-homology 2 (SH2) domains such as signal transducers and activators of transcription (STATs).[156] The latter hetero-or homodimerize and translocate to the nucleus where they affect transcription of target genes by interacting with enhancers/promoters. Several mechanisms exist to reverse this cytokine-activated state. STATs trigger a negative feedback loop by inducing transcription of suppressors of cytokine signaling (SOCSs). There are 8 SOCS members identified. SOCS1 interact directly with Jak and inhibits its catalytic activity. CIS (another SOCS) binds the receptor and blocks binding and phosphorylating STATs. SOCS3 binds the receptor before inhibiting Jak. SOCS proteins contain SOCS box that probably leads to proteosomal degradation of the SOCS associated molecules. SHP-1 is a tyrosine phosphatase that negatively regulates the cytokine transduction process by dephosphorylating Jaks and the cytokine receptors. CD45 is a transmembrane phosphatase that inactivates Jaks as well. PIAS (protein inhibitor of activated STAT) family members bind to STAT dimers and prevent their access to DNA.

The receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 share the common cytokine receptor γ chain (γc). This common chain was originally cloned as a third component of the IL-2 receptor and was denoted IL-2Rγ.[151] Mutations in IL-2Rγ result in X-linked severe combined immunodeficiency (X-SCID) in humans.[152] It appears that the severe deficiency in T cells in this disease results from lack of IL-7 signaling, since deletion of IL-7 and IL-7R genes in mice[153] and mutated IL-7R gene in humans[154] results in T-cell deficiency. Defective NK cell function in either IL-15 or IL-15R knock-out mice indicates that NK cell deficiency seen in X-SCID patients is related to defective IL-15 signaling.

Type II Cytokine Receptors

The members of this family are structurally related to typeI receptors and they follow similar patterns of activation and intracellular signaling. This family includes the receptors for IFNs, IL-10 family members, IL-28, IL-29, and the tissue factor (TF or FVIIa) receptor. The extracellular portion contains tandem fibronectin type III domains with other conserved features in analogy with type I receptors.[140] Receptor dimerization or oligomerization results in conformational change in the receptor chains, and the receptor associated Jaks[155] come into opposition with each other. This results in transphosphorylation and catalytic activation of the kinase domain. The activated Jaks in turn phosphorylate the receptor intracellular domain and both phosphorylated receptor and Jaks provide docking sites for a variety of src-homology 2 (SH2) domain containing proteins, particularly the STATs.[156] The latter are then activated by Jak-mediated tyrosine phosphorylation, form homodimers or heterodimers, dissociate from the receptors, and translocate to the nucleus to influence transcription. Table 24–3 demonstrates that cytokines in the same family generally activate the same STAT. IFNs transmit their signals through two types of receptors,[157] type I IFN receptor which binds to type I interferons (IFN-α, IFN-β, IFN-ω, etc). Type I IFNR consists of two components, the IFNAR1 (previously called α

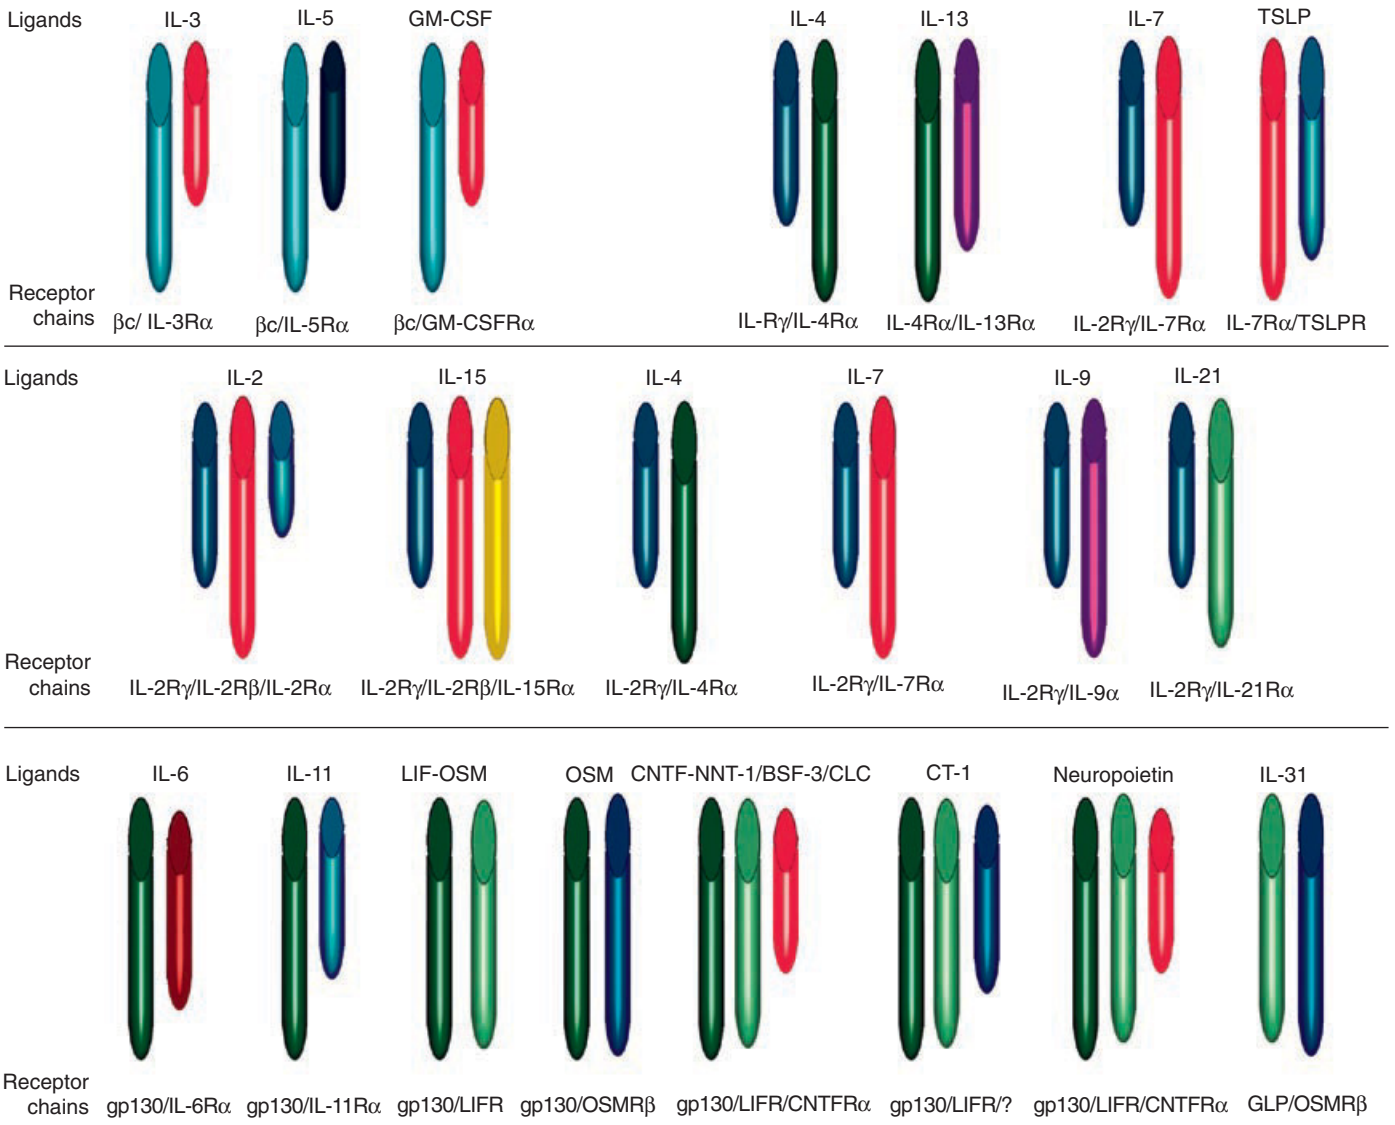

Figure 24–6 Simple depiction of type 1 cytokine receptor subfamilies. IL-3R, IL-5R, and GM-CSFR share a common bc chain that place them in one group. Multiple cytokines (IL-2, IL-4, IL-7, IL-9, IL-15, IL-21) share the IL-2Rg chain, which is mutated in a subset of patients with severe combined immunodeficiency. IL-4R shares a subunit with IL-13R. Both IL-4 and IL-13 drives Th2 response. IL-7R shares one subunit with the thymic stromal lymphopoietin (TSLP). This sharing of receptor subunit may explain why deletion of the gene encoding IL-7R affects the lymphoid system more severely than deleting the IL-7 gene. Finally the IL-6 family includes multiple cytokines that all share the common signal transducer gp130. Deleting gp130 results in embryonic lethality. Some IL-6 family members activate more than one receptor. Oncostatin M (OSM) can work through a heterodimer receptor consisting of gp130 with OSMRb or gp130 with leukemia inhibitory factor-receptor (LIF-R). Ciliary neurotrophic factor (CNTF) shares its receptor with novel neurotrophic-1/B cell-stimulating factor-3/Cardiotrophin-like cytokine (NNT/BSF-3/CLC). Cardiotrophin-1 (CT-1) uses a receptor composed of gp130, LIF-R, and another yet to be identified subunit. Neuropoietin shares the same receptor as CNTF. Il-31 receptor is composed of gp130 like receptor (GLR) and OSMRβ.

subunit) and INFAR2 (previously called β subunit). Type II IFN receptor is also composed of two distinct subunits; IFN-γR1 and IFNγR2. Type II IFN receptor binds to IFN-γ or type II interferon. The receptor chains within a given type II cytokine receptor complex can be divided into two classes denoted R1 and R2. R1 type subunit (eg, IFN-γR1, IL-10 R1) binds its ligand with high affinity, has a long intracellular domain associated with Jak1. IFN-γ and IL-10[158] are homodimers and their binding to R1 subunit leads to homodimerization.[159] However, this event is not sufficient to initiate signaling. The R2 subunit does not bind the ligand and it posses a short intracellular domain which is associated with Jak2 or Tyk2 (IL-10R2).[160] This finally leads to the activation of STATs which translocate to the nucleus. Table 24–4 lists phenotypes of the knock-out mice of the molecules that play important roles in cytokine receptor signalng.

Receptor Tyrosine Kinase Family

The receptor tyrosine kinase family includes c-kit (stem cell factor receptor), flt-3, and c-fms (M-CSF R) in the hematopoietic system. Receptor tyrosine kinases (RTK) act by phosphorylating tyrosine residues on the receptors themselves and on downstream signaling molecules.[161] RTKs consist of an extracellular portion that binds the ligand, a transmembrane helix and a cytoplasmic portion that possesses tyrosine kinase catalytic activity.[162] Most RTKs exist as a single polypeptide chain in a monomeric form in the absence of ligand binding. The extracellular part of RTKs contains a diverse array of globulin domains such as immunoglobulin (Ig)-like domains, fibronectin type III-like domains, cysteine-rich domains and EGF-like domains.[162] In contrast, the cytoplasmic portion is less complicated and consists of a juxtamembrane region followed by tyrosine kinase

Table 24–3 STATs and Associated Jaks

STAT Family Member	Primary Activating Cytokines	Associated Jak(s)
STAT1	IFN-α, β, γ. IL-6, IL-11, OSM, LIF	Jak1, Jak2
STAT2	IFN-α, β	Jak1
STAT3	IL-6, IL-11, LIF, OSM, SDF-1 G-CSF, IL-10, IL20, IL-21, IL-31	Jak1
STAT4	IL-12, IL-23	Tyk, Jak2
STAT5 a/b	Epo, Tpo, FL, GM-CSF, IL-5, IL-3 IL-2, IL-15, IL-7, IL-9, GH	Jak1, Jak2, Jak3
STAT6	IL-4, IL-13	Jak1, Jak3

Listing of signal transducers and activators of transcription (stats), with corresponding activating cytokines and associated Janus kinases (Jaks). Cytokine families tend to activate the same STAT, such as IFN family members that activate STAT1 and STAT2, and IL-6 family members that activate STAT3 and to a less degree STAT1. T-lymphocyte helper (Th)1 cytokines (IL-12, IL-23) activate STAT4, whereas Th2 cytokines (IL-4, IL-13) activate STAT6. STAT5 is activated by multiple hematopoietic-active cytokines such as IL-3, GM-CSF, IL-5 (which share a receptor subunit), Tpo, Epo, and cytokines activating the IL-2 receptor family.

catalytic domain and a carboxy-terminal region. Ligand-induced dimerization or oligomerization of the RTK leads to autophosphorylation of the cytoplasmic domain.[162] This results in enhancement of the catalytic activity and creation of binding sites to recruit downstream signaling proteins. The two well identified phosphotyrosine binding modules within signaling proteins are the SH2 and the phosphotyrosine-binding (PTB) domains.

TGF-β Receptors

TGF-β family members transduce their signals by utilizing heterotetrameric complexes of two transmembrane receptors known as type I and type II receptors.[163] These receptors contain an N-glycosylated, cysteine rich extracellular domain, and an intracellular serine/threonine kinase domain. Type II receptor kinase is constitutively active. Ligand-induced oligomerization of the complex type II receptor kinase phosphorylates typeI receptors on serine/threonine residues which activates the kinase.[163] The latter then phosphorylates specific proteins called smads which translocate into the nucleus to change transcription of their target genes. Each of TGF-β, activins and bone morphogenic proteins (which form the TGF-β family) signal via a distinct set of type I and type II receptors. In addition to binding type I and type II receptors, TGF-β can bind to receptor-associated transmembrane proteins such as betaglycan[164] (also denoted TGF-βR-III) and endoglin. These receptors do not have any intrinsic enzymatic activity but have been shown to modulate TGF-β signaling.

Table 24–4 Consequence of Deficiencies in Genes for Intracellular Signaling Molecules

Signal Transduction Molecule	Phenotype Of Deficient Mice
STAT1	Complete lack of responsiveness to either IFN-α/β or IFN-γ and high sensitivity to infections by viruses and other microbial pathogens. Normal response to other cytokines such as growth hormone (GH), IL-10, and epidermal growth factor (EGF).
STAT2	Lack of responsiveness to IFN-α/β; susceptibility to viral infections
STAT3	Early embryonic lethality prior to gastrulation STAT3 –/+ mice demonstrate decreased HSC/HPCs
STAT4	Defective Th1 response due to defective IL-12 signaling
STAT5a	Defective mammary gland development and lactogenesis; GM-CSF and FL signaling is impaired, but no gross hematopoietic abnormalities
STAT5b	Disrupted sexual dimorphism of body growth rates. Defective GH signaling.
STAT5a/b	Anemic embryos of the double knock-outs with apoptotic erythroid progenitors due to impaired Epo signaling. Adult mouse erythrocyte RBC number is normal. Loss of GH and prolactin signaling. Infertile females. Severe impairment of IL-2 induced T-cell responses
STAT6	Defective Th2 response with eliminated IL-4 signaling
Jak1	Perinatal mortality, defects in IL-6, IL-2, and cytokine receptor type II families.
Jak2	Embryonic lethality due to defective definitive hematopoiesis. Defects in Tpo, IL-2 family, IL-3, and IFN-γ signaling
Jak3	Immunodeficiency due to absent common γ chain signaling. Jak3 expression is restricted to the hematopoietic system
Tyk2	Reduced responses to IFN-α/β, IL-12, and unexpectedly IFN-γ
SHP-1	Natural mutation in *Motheaten* mice results in hair loss, immunodeficiency, autoimmune disorders, enhanced SDF-1 chemotactic activities, enhanced hematopoietic progenitor proliferation in response to cytokines such as GM-CSF.
CD45	Enhanced cytokine and interferon-receptor-mediated activation of Jaks and STATs
SOCS1	Neonatal lethality probably due to excessive IFN-γ responses, with hematopoietic infiltration of multiple organs, lymphopenia, and fatty liver degeneration.
SOCS2	Gigantism due to GH and/or IFG-1 excessive signaling
SOCS3	Embryonic lethality with placental defect. Erythrocytosis in embryos.

This table reveals the phenotypes of mice deficient in the major signaling molecules that directly interact with the cytokine receptors. The phenotype ranges from significant embryonic lethality due to hematopoietic impairment to less remarkable defects in other organ systems. Refer to Figure 24–3 for further information on the functions of these molecules.

Jaks, Janus kinases; SHP-1, Src homology 2 tyrosine phosphatase-1; SOCS, suppressor of cytokine signaling; STAT, signal transducers and activators of signaling.

CHEMOKINE RECEPTORS

Chemokine receptors belong to the superfamily of serpentine seven-transmembrane G-protein coupled receptors. There are 18 chemokine receptors identified which include six CXC, 10 CC, one CX3C, and XC receptors.[165] Each receptor can bind more than one chemokine of the same class, for example, CCR1 binds the chemokines MIP-1α, RANTES and MCP-3 with high affinity.[166] On the other hand, different chemokines can bind a number of receptors such as MIP-1α which binds CCR1, CCR3, and CCR5 with high affinity. Chemokine receptor activation results in conformational change in the trimeric G-proteins which dissociate into α and βγ subunits. These subunits, in turn, activate different targets that lead to the final biological response.[167]

CYTOKINES WITH HEMATOPOIETIC ACTIVITIES

Colony-Stimulating Factors

The colony-stimulating facotrs can induce hematopoietic colony formation in vitro even when used as single factors in the absence of serum. Most of these factors when used alone exert preferential growth-promoting activity on a single blood lineage.

Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)

GM-CSF was one of the original four colony stimulating factors identified by its ability to stimulate hematopoietic colony formation in semisolid culture medium systems.[168] The cloning of GM-CSF cDNA led to production of recombinant GM-CSF which provided the opportunity to study its function alone and in combination with other factors.[169] GM-CSF can be produced by a variety of cell types including BM stromal cells, monocytes and T lymphocytes.[170] IL-1 and TNF-α induce the expression of GM-CSF from its source cells.[171,172] GM-CSF induces proliferation and formation of granulocyte-macrophage and eosinophil colonies when added alone to hematopoietic cell cultures.[173] It works in synergy in vitro and in vivo with other cytokines to enhance the proliferation of erythroid, eosinophil, megakaryocyte, and multipotential progenitor cells.[174–176] The concentration of GM-CSF determines myeloid versus monocytic commitment by controlling c-fms (M-CSFR) expression.[177,178] At low concentrations of GM-CSF, macrophage colonies predominate because of the high expression of c-fms, whereas at high concentration mixed (GM) colony formation is favored. When GM-CSF is administered to humans, it enhances the production of neutrophils, monocytes, and eosinophils.[179] Its action on neutrophils production may be indirect and possibly mediated through G-CSF.[180] GM-CSF activates the function of most phagocytes such as neutrophils, macrophages, and eosinophils.[170,181] It can increase their adhesion, chemotaxis, phagocytosis, superoxide production, and their release of other inflammatory cytokines.[182–184] GM-CSF also directs the maturation of dentritic cells from their precursors in combination with other cytokines.[185] The inactivation of GM-CSF in mice does not lead to a significant deficiency of the hematopoietic cells.[186,187] These mice do not display any depletion of mature cells in the peripheral blood. There is also no reduction of BM or spleen cellularity and the progenitor numbers are normal which leads to the conclusion that despite its potent effects in vitro, GM-CSF does not play an essential role in regulating hematopoiesis in vivo at least in mice under basal conditions. Further support of this hypothesis is the observation that the degree of neutropenia in G-CSF knock-out mice is comparable to that of G-CSF and GM-CSF double knock-outs.[188] However, GM-CSF deficient mice are characterized by a deficiency in repopulation by fetal liver stem cells or sorted stem cell, but not by whole BM cells which suggest that GM-CSF production by stromal cells plays a role in radioprotection.[189] The GM-CSF deficient mice develop a characteristic pulmonary pathology that resembles the human disorder alveolar pulmonary proteinosis, since the alveoli contain granular eosinophilic material with peribronchovascular lymphocytic infiltrates.[186,187] These mice acquire multiple bacterial and fungal infections. It is thought that these pulmonary findings are results of hypofunction of alveolar macrophages. GM-CSF receptor is a type I cytokine receptor that is composed of an α chain and a β chain.[190] The latter is shared with IL-3 and IL-5 receptors.[147] One study revealed that the GM-CSFR was not expressed by primitive rhodamine-123 low early progenitor/stem cells but was expressed by more mature progenitor population.[191] GM-CSFR inactivation results in a similar phenotype to that of GM-CSF deficient mice, with the exception that the β-common chain deletion also prevents IL-5 action and causes reduced eosinophil numbers.[192] Conversely, GM-CSF transgenic mice accumulate macrophages and develop blindness and a fatal syndrome of tissue damage.[193]

Granulocyte Colony-Stimulating Factor (G-CSF)

G-CSF was initially purified as a factor that drives the terminal differentiation of a murine myelomonocytic leukemia cell line (WEHI-3B).[194] G-CSF induces the proliferation of granulocyte progenitors and their differentiation into granulocytes.[195] Cloning of the G-CSF gene[196] led to the testing of recombinant G-CSF effects on hematopoietic cells in vitro.[197] G-CSF exerts a proliferative effect on multipotential hematopoietic progenitors[198] that is seen clearly in synergy with other early acting cytokines such as IL-3.[199] Other cytokines that synergize with G-CSF to induce early progenitor proliferation include IL-1, IL-6, and SCF.[200]

G-CSF exerts significant influence on the biological activity of mature neutrophils. For example, it increases neutrophil chemotaxis, adhesion, phagocytic activity, superoxide production, and antibody-dependent cell-mediated cytotoxicity.[201] When a stromal cell feeder line was engineered to produce G-CSF there was an increase in the number of early BM progenitor cells when cultured in the presence of this feeder line.[202] This influence was not observed with a feeder cell line engineered to produce GM-CSF. A role for G-CSF in inducing Th2 and tolerogenic dendritic responses has been suggested.[203] A key role for G-CSF in stem cell mobilization was previously discussed. G-CSF is produced by different mesenchymal cells under the influence of multiple factors such as endotoxin, IL-1[204] and TNF-α.[205] Inactivating the G-CSF gene results in mice with a 70% reduction of circulating neutrophils and a reduced capacity to mount an adequate neutrophil response to infections.[206] In addition, a 50% reduction of progenitors of all lineages is noted, implying the important role of G-CSF in the formation and maintenance of multilineage progenitors from stem cells.[206] Dogs injected with human G-CSF become chronically neutropenic because of the development of neutralizing antibodies to G-CSF.[207] Inactivating mutations of G-CSF receptors can also cause severe congenital neutropenia.[208] The G-CSF receptor is a member of type I cytokine receptor family. It is present on precursor and mature cells of the granulocyte lineage as well as myeloid leukemic cells. It is also expressed on early progenitor/primitive cells.[209] The growth and differentiation signals are mediated by different regions of the cytoplasmic domain of the receptor.[210] Similar to G-CSF knock-out mice, G-CSFR deficient mice have decreased numbers of circulating neutrophils, which are susceptible to apoptosis.[211] In addition there is a decrease in numbers of various hematopoietic progenitors in the bone marrow.

Macrophage Colony-Stimulating Factor (M-CSF)

M-CSF, also known as CSF-1, stimulates macrophage colony growth from hematopoietic progenitors.[212] It is secreted by monocytes/macrophages and BM stromal cells.[213] M-CSF is present in both membrane-bound and soluble forms which are products of alternative splicing.[214] The receptor of M-CSF is the proto-oncogene v-fms which belongs to type III tyrosine kinase receptors.[215] In addition to being a growth factor for monocyte colony formation, M-CSF activates the

phagocytic,[216] and respiratory burst activity[217] of these cells. This cytokine is also essential for osteoclast formation[218] and it also affects placental development.[219] Op/op mice, which have a natural M-CSF deficiency, exhibit osteopetrosis and BM failure.[220] The number of hematopoietic progenitors is significantly increased in aorta-gonad-mesonephros (AGM) culture of op/op embryos.[221] The role of M-CSF as a survival factor for monocytes and their derivative cells is nicely demonstrated by the fact that overexpression of the transgenic Bcl-2 gene in these cells corrects the osteopetrosis and marrow failure seen in op/op mice.[74] Finally, certain tumor cell lines secret M-CSF. This implies a possible autocrine or paracrine role in tumor genesis.[222]

Interleukin-3 (IL-3)

Il-3 is a pleiotropic cytokine that is mainly produced by activated T cells although other cell types such as mast cells have been reported to express this cytokine.[223] There is no evidence that BM stromal cells produce IL-3.[171,224] IL-3 has been termed the multi-colony stimulating factor (multi-CSF) due to its wide influence on multiple hematopoietic lineages.[225–227] IL-3 activity is limited when used alone,[228] however, it acts in synergy with multiple cytokines to stimulate the growth of hematopoietic colonies. Such cytokines include SCF, FL, GM-CSF, M-CSF, G-CSF, IL-1, IL-4, IL-5, IL-6, and IL-11.[175,199,229–232] IL-3 stimulates the proliferation of multipotential progenitors[228] and enhances the survival of early hematopoietic progenitors.[108,233] IL-3 exerts a negative effect on lymphoid progenitors.[234] Stromal cell lines have been genetically engineered to produce IL-3.[235,236] These IL-3 producing stromal lines can support sustained hematopoiesis in a murine xenograft model.[235] IL-3 is a direct stimulator of CFU-GM.[229] This cytokine has been reported to promote erythroid burst-colony formation in the absence of detectable Epo.[236] It induces eosinophil formation in synergy with IL-5,[230] and megakaryocyte formation in synergy with IL-11 and SCF.[232] IL-3 can directly promote the differentiation of isolated single megakaryocytes.[237] It is believed that IL-3 may be the main growth and differentiation factor for basophils.[238] This cytokine promotes the differentiation of mast cells from progenitors in murine but not human BM.[239] In humans, mature basophils express IL-3R (CD123) but it is not expressed by mast cells.[240] IL-3 activates basophils and induces them to release histamine. A role for IL-3 in dentritic cell maturation and function has been utilized for generating dendritic cells production in vitro.[241] The IL-3 receptor is a type I cytokine receptor that consists of a specific α chain and a common β chain (βc) that is shared with IL-5 and GM-CSF receptors. In the mouse, a second β chain has been identified that associates exclusively with IL-3Rα and has been termed β IL-3. In mice deficient for βc, the IL-3 response is normal due to compensation by β IL-3.[192] Mice lacking β IL-3 develop normally with normal hematopoiesis.[242] Similarly, hematopoiesis is not impaired in IL-3 deficient mice.[243] This is in contrast to its wide spectrum of in vitro activities.

Erythropoietin (Epo)

Epo was the first hematopoietic cytokine to be cloned[244] and used in a clinical setting: the treatment of the anemia of renal failure. Epo is a hormone in the sense that it is produced by the kidney and to a lesser level by the liver, and it is released to the circulation.[245] VEGF blockade increases hepatic Epo production by more than 40-fold.[246] Hypoxia is the regulator of Epo production.[247] Upon hypoxia, hypoxia-induced factor-1 (HIF-1) enhances production of Epo RNA. HIF-1 participates in the formation of a large protein complex that binds the Epo enhancer.[247] HIF-1 levels are regulated by prolyl hydroxylases (PHDs) which primes HIF-1 for degradation mediated by the Von-Hippel Lindau (VHL) protein.[248] PHD activity is regulated by O_2. Epo does not appear to be required for early progenitor commitment to the erythroid lineage, since both BFU-E and CFU-E are produced in mice lacking either Epo or EpoR.[75] The expression of the EpoR is highest on CFU-E/proerythroblasts and its level decreases with erythroid differentiation.[249] The EpoR is also present on megakaryocytes,[250] endothelial cells,[251] placenta, and cells derived from neuronal tissue. There is an increasing role of Epo in neuronal regeneration and protection from stroke.[252] In the current model of erythropoiesis, Epo appears to rescue EpoR expressing cells from apoptosis[253,254] and it induces erythroid specific proteins such as heme synthesis enzymes and globin. However, there is experimental evidence to indicate that complete erythroid maturation can occur in the absence of Epo. That occurs with the combination of IL-6, SCF, and IL-3.[255] In fact c-kit, the SCF receptor, seems to interact and activate EpoR.[256] Tpo also rescues erythroid colony formation from yolk sac cells of EpoR−/− mice.[257] EpoR is a 66 Kd single chain protein that is a member of the cytokine receptor superfamily.[258] It appears to be activated by homodimerization.

Thrombopoietin (Tpo)

Although suggested to exist more than four decades ago,[259] Tpo is a recently characterized hematopoietic cytokine with a main function of regulating platelet production. Cloning of Tpo was facilitated by identifying the cellular homologue of a retroviral oncogene that causes murine myeloproliferative leukemia.[260] This cellular oncogene termed c-mpl has the amino acid sequence of a cytokine receptor. Three groups cloned the cDNA of the c-mpl ligand.[261–263] Two other groups purified a protein that was found to be identical to Tpo.[264,265] Tpo is produced in the liver, kidney, smooth muscle, and bone marrow among other tissues.[266–268] Its main sources are the liver and kidney. Tpo serum levels are reduced in patients with cirrhosis and increase after liver transplantation.[269] Tpo production is constant, so the increase in its level observed in patients with thrombocytopenia reflects the fact that it is absorbed by platelets by binding to mpl.[270] Tpo levels are relatively low in patients with idiopathic thrombocytopenia (ITP) because of megakaryocytic hyperplasia; megakaryocytes also carry mpl receptors on their surfaces.[270] Certain patients with familial essential thrombocytosis have high levels of Tpo caused by mutations in the 5′-translated region of Tpo gene that causes increased translation of Tpo mRNA.[271] The mpl receptor is expressed by cells belonging to the megakaryocyte lineage from progenitors to platelets[272,273] in addition to being expressed on other lineage committed progenitors.[274] Tpo is the main promoter of megakaryocyte proliferation and differentiation.[274–277] This effect is enhanced by synergistic action of other cytokines.[273,278] There is evidence that Tpo may not enhance the final stage of platelet production.[279]

Tpo effects on hematopoiesis go beyond platelet production into other lineages. Tpo is a well-established stimulant of the proliferation of multipotential progenitor/stem cells both in vitro and in vivo.[280–282] Tpo greatly promotes the in vivo self-renewal and expansion of HSC following BM transplantation.[283] Tpo is an essential cytokine in postnatal stem cell expansion.[284] It synergizes with Epo to expand erythroid progenitors and red cell production.[285,286] The numbers of myeloid progenitors are reduced in Tpo-and c-mpl-deficient mice.[287] C-mpl is a type I cytokine receptor family member. C-mpl deficient mice have been generated.[288] These mice have thrombocytopenia with 100% penetrance. Both megakaryocyte and platelet counts are reduced $\cong$ 90% while other BM progenitors are reduced from 70% to 90%.[289] Other peripheral blood counts are normal.[288] Tpo deficient mice show a similar phenotype.[290] This phenotype is reversible with administration of Tpo.[287] The remaining platelets are functional in these knock-out mice.[291] The residual megakaryocyte and platelet production in c-mpl deficient animals is not dependent on the action of other active thrombopoietic cytokines such as IL-6, IL-11, IL-3, or LIF.[292,293] Mutations in c-mpl have been identified in children with congenital amegakaryocytic thrombocytopenia.[294]

Interleukin-5 (IL-5)

IL-5 was cloned as an eosinophil differentiation factor.[295] It supports the terminal differentiation and proliferation of eosinophilic precursors.[296] When added alone to untreated BM, it induces the formation

of small numbers of colonies, all of which are eosinophilic.[297,298] IL-3 or GM-CSF alone produces similar colonies.[299] These cytokines synergize with each other and with others including SCF and IL-1 in promoting eosinophil colony formation.[299,300] In vivo administration of IL-5 antibodies inhibits eosinophilia in parasitized mice.[301] IL-5 transgenic mice display 65- to 265-fold increases in eosinophil blood counts.[302] Constitutive overexpression of IL-5 in vivo results in a 1.5-fold decrease in BM LTC-IC and 10-fold decrease in fibroblast colony-forming units (CFU-F), with an increase in extramedulary hematopoiesis.[303] Ossification of the spleen has been observed in another transgenic mouse line.[304] Lack of IL-5 severely reduces the eosinophilic response to parasite infection.[304]

Stem Cell Factor and Flt3 Ligand

These two factors demonstrate important costimulatory and synergistic activities with other cytokines, particularly on early hematopoiesis. Mice deficient in these factors or their receptors display significant hematopoietic abnormalities.

Stem Cell Factor (SCF)

The identification of SCF (also known as Steel factor, mast cell-growth factor, and c-kit ligand) and its receptor c-kit culminated years of search for the genetic loci of two naturally occurring mutations in mice: the white (*W*) locus and Steel (*Sl*) locus.[305] The *W* and *Sl* mice have identical phenotypes of hypopigmentation, macrocytic anemia, reproductive difficulties, and defective interstitial cells of Cajal.[305] Transplant studies have demonstrated that the defect in *W* mice is in the hematopoietic stem/progenitor cells, while the defect in *Sl* mice is in the BM microenvironment.[306,307] The *W* locus was identified as encoding the c-kit tyrosine kinase receptor,[308,309] and *Sl* locus was shown to encode the ligand for c-kit that was termed steel factor or stem cell factor.[310–313] Human SCF is present in two isoforms due to alternative splicing.[313] Both forms contain a transmembrane domain that renders them inserted in the cell membrane. The larger form contains a cleavage site that enables a soluble SCF to be released. Both forms are biologically active. However, the cell-bound form appears to be important for in vivo SCF function, since a mutation (Sl^{d}) that eliminates the membrane-bound form without affecting the soluble one results in anemic, sterile, and hypopigmented mice.[314,315] SCF is widely expressed during embryogenesis,[316,317] which suggests that the influence of SCF goes beyond HSC. Germ cells and melanocytes are affected in *W* and *Sl* mutant mice. SCF is expressed on stromal cells,[318] fibroblasts,[319] and sertoli cells.[320] No cytokines have been reported to induce SCF expression, whereas TGF-β represses this expression.[321] C-kit expression has been studied in detail at different stages of the hematopoietic hierarchy.[322] In brief, most murine long-term repopulating stem cells (LTRC) express c-kit,[323–326] although c-kit^{low} LTRC exist. The embryonic AGM progenitor/stem cells of definite hematopoiesis are also characterized by c-Kit expression.[327] Most Thy-1^{lo} Lin^{-} Sca-1^{+} cells are c-kit^{+}, however 20% of these cells are negative for c-kit expression.[324] These c-kit^{-} cells are thought to lack hematopoietic activity. However, one study has suggested that a small population of c-kit^{-} Sca-1^{+} BM cells are very primitive HSC which do not contribute to hematopoiesis until 40 weeks after transplantation.[37] With regard to human stem cells, the data are less definitive because of the absence of a comparable transplant assay. In general, CD34^{+} CD38^{-} BM cells are highly positive for c-kit.[328] Enrichment of primitive human progenitor cells in the CD34+ c-kit^{low} fraction as compared with the CD34+ c-kit^{high} or CD34+ c-Kit^{-} fraction has been reported in long-term engraftment studies in fetal sheep.[329] Similarly CD34+ c-kit^{low} cord blood cells contain more cell-cycle dormant and blast cell progenitors than c-kit^{high} or c-kit^{-} cells.[330]

C-kit is highly expressed by myeloid, erythroid, megakaryocytic, and multipotential progenitors.[331,332] C-kit is also expressed by primary mast cells as well as mast cell lines and primary neoplastic mast cells.[333] It is constitutively activated in a number of mastocytomas.[334] Such gain of function mutations of c-kit are present in human gastrointestinal stromal tumors (GIST).[335] C-kit is frequently expressed by acute myeloid leukemia (AML) blasts of all French-American-British (FAB) subtypes, and activating mutation of c-kit confers a negative prognosis in the subset harboring core binding factor mutations.[336] C-kit expression is restricted to the earliest stages of B-cell progenitors whereas the pre-B cells and subsequent stages are c-kit^{-}.[337] SCF prevents apoptosis of HSC under serum free condition in cooperation with Bcl-2 overexpression.[111] This survival promoting activity can occur in the absence of cell division.[102] SCF sustains HSCs survival in vitro most likely without affecting the self-renewal of these cells.[338,339] There is evidence that this SCF effect on HSC maintenance may be dispensable and other factors may compensate for its loss at least in vitro.[340] Absence of SCF/c-kit axis in vivo results in a partial defect in HSC maintenance and/or self-renewal.[327,341] SCF has little or no effect on colony formation alone, even though it synergizes with other cytokines to promote colony formation.[342–344] This synergy has been reported with almost every known hematopoietic cytokine. This includes, but is not necessarily limited to, IL-3, Epo, GM-CSF, G-CSF, Flt-3, Tpo, IL-9, IL-7, IL-6, IL-4.[343–349] The synergitic activity of SCF is most prominent on the development of mast cell, erythroid, and megakaryocytic lineages. SCF regulates the migration, maturation, proliferation, and activation of mast cells in vivo.[350] Promastocytes proliferate and differentiate in the presence of SCF and IL-3.[351] SCF synergizes with Epo to promote the growth of early erythroid progenitors.[344,345,352,353] Epo overexpression appears to rescue the anemia seen in *W* mice, which suggests a defect in erythroid progenitor cells rather than stem cells.[354] The combination of SCF, IL-6, and soluble IL-6 receptor can support the proliferation, differentiation, and terminal maturation of BFU-E in vitro in the apparent absence of Epo.[346,355] The interaction between c-kit and EpoR may be essential for erythroid precursor response to Epo.[356] SCF synergizes with Tpo to promote megakaryocyte precursor proliferation and maturation.[357,358] Both factors also work in synergy to support multipotential progenitor cell growth.[349,359] The combination of SCF plus other cytokines was used to demonstrate that cord blood contains a higher ratio of immature to mature progenitors than bone marrow.[359] SCF works as adhesion or homing molecule for progenitor/stem cells either directly through its membrane-bound form[360,361] or indirectly by activating the integrins VLA-4 and VLA-5.[362,363] In addition, in vivo administration of SCF causes mobilization of hematopoietic progenitors into peripheral blood.[364–366] It appears that the recruitment of stem and progenitor cells from the quiescent to the proliferative BM niche requires matrix metalloproteinase 9 mediated release of soluble SCF.[367] The molecular defects of c-kit in W mice are heterogeneous but are due to the reduction of tyrosine phosphorylation activity of the protein.[368,369] Such a mutated c-kit is responsible for the human piebald syndrome.[370] Some c-kit activity is needed for postnatal life because homozygous deletion of c-kit or SCF is lethal in mice.[371]

Flt-3 Ligand (FL)

Flt-3 stands for the c-fms (M-CSFR)-like tyrosine kinase 3.[372] Flt-3 as a tyrosine kinase was isolated from a highly purified murine fetal liver progenitor/stem cell pool.[373] Subsequently, its ligand, FL was cloned.[374–376] FL has emerged as an important regulator of hematopoietic progenitor/stem cells.[322] FL is widely expressed by cells in both the murine and human hematopoietic system with the highest level of expression in peripheral blood mononuclear cells.[374–376] Its expression was also reported in the brain and placenta.[377] Flt-3 is expressed on hematopoietic progenitors including 20% to 60% of Lin^{-} Sca-1^{+} c-kit^{+} murine BM cells.[378,379] Flt-3 is expressed by 60% to 80 % of CD34^{+} BM cells.[380] It is expressed by B- and T-cell precursors, CFU-GM, and HPP-CFC, whereas BFU-E cells appear to be negative for Flt-3.[379–381] Mature hematopoietic cells fractionated from peripheral blood do not express Flt-3.[382] In the Lin^{-} Sca-1^{+} c-kit^{+} pool, only the Flt-3^{-} fraction supports sustained multilineage hematopoiesis.[379] The Flt-3^{+} fraction rapidly reconstitutes B and T cell lymphopoiesis in

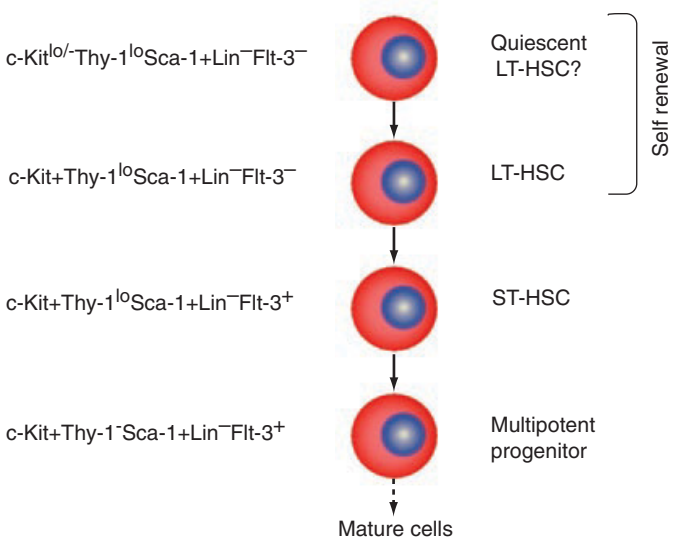

Figure 24–7 Phenotype of Mouse Hematopoietic Stem and Progenitor Cells. C-Kit (SCF receptor) and flt3 expression in early hematopoietic stages.[322] C-Kitlo/- cells used to be called the "mystery cells." Now there is evidence that they may represent quiescent stem cells which require activation before contributing to hematopoiesis.[38] C-Kit expression is seen on the long-term hematopoietic stem cells that give rise to all blood lineages for a lifetime. The latter are negative for Flt3 expression. The appearance of Flt3 corresponds with the short-term repopulating cells that produce multilineage hematopoiesis for the first period (for instance, 8 weeks in mice) after transplantation. The disappearance of Thy-1 antigen indicates maturation into a more restricted stage of multipotent progenitor.

vivo with limited and short-term myeloid reconstitution,[379,383] indicating that Lin^{-}Sca-1^{+} c-kit^{+} Flt-3^{+} cells may represent common lymphoid progenitors.[379] Further analysis of this population revealed some myeloid reconstituation with loss of megakaryocye/erythoid potential.[384] The primitive HSC express c-kit but not Flt-3, and it appears that Flt-3 expression is more limited than c-kit expression on committed progenitors by the fact that flt-3 expression is largely limited to the CD34^{+} CD38^{-} subset.[385] FL fails to support the survival of the most primitive HSC.[379] However, it promotes the survival of both myeloid and lymphoid progenitors.[386,387] Fig. 24–7 demonstrates the correlation between Flt3 and/or c-kit expression and developmental stage of hematopoietic stem/progenitor cell.

FL has little or no direct in vitro activity on hematopoietic progenitors when used alone. Rather, this cytokine works in synergy with other hematopoietic cytokines, such as SCF, GM-CSF, G-CSF, IL-3, IL-6, Tpo, M-CSF, IL-11, and IL-12 to promote the growth of early progenitor cells.[349,385,388–391] FL promotes the in vitro growth of early B-cell progenitors. Primitive murine (CD34^{+} B220^{low} CD24^{-}) B cell progenitors do not respond to either FL or IL-7 as single factors, but they do respond to a combination of these cytokines.[392] More differentiated CD34^{+} B220^{low} CD24^{+} B-cell progenitors fail to respond to FL.[393] FL synergizes with IL-7 to enhance the production of B220^{+} cells from B220^{+} and B220^{-} murine BM cells. It can promote IL-7 independent B220+ cell development.[394] FL also synergizes with IL-7 to enhance the growth of human CD34^{+} CD19^{+} pro B cells.[395] In combination with other cytokines, FL stimulates the growth of CD4^{low} thymic progenitor cells. This effect extends to T-cell production from human CD34+ cells in combination with IL-12.[396] FL enhances the production of dendritic cells (DC) from BM and mobilized CD34^{+} cells in combination with GM-CSF, TNF-α, and IL-4.[397,398] In vivo administration of FL results in significant increases in a number of both myeloid and lymphoid derived DC in different lymphohematopoietic tissues.[399] This administration results in leukocytosis with mobilization of progenitor/stem cells into peripheral blood.[399,400] Mice with targeted deletion of flt-3 are generally healthy with normal levels of peripheral blood cells.[401] However, these mice have reduced numbers of early B-cell progenitors, plus a defect in repopulating stem cells. Mice homozygous for deletion of both flt-3 and c-kit have markedly reduced hematopoietic progenitor/stem cells and die between days 20 and 50 of age.[401] Further evaluation has revealed that flt-3 deficient mice have a 10-fold reduction in the number of common lymphoid progenitors (CLP) while the numbers of HSCs and common myeloid progenitors (CMP) are normal.[402] FL knock-out mice have a similar phenotype to Flt-3 deficient mice except for decreased cellularity in the peripheral blood, spleen, and BM.[403] This difference has not been convincingly explained. The forced expression of FL in mice results in increased numbers of circulating white blood cell levels with abnormal cellular infiltrates associated with splenic fibrosis.[404]

Interleukin-6 (IL-6) Family

IL-6 family members share multiple characteristics. Most importantly they share the signal transducer gp130 as a component of their receptors. Definite hematopoietic activities have been ascribed to four members of this family: IL-6, IL-11, leukemia inhibitory factor (LIF), and oncostatin M (OSM). These cytokines exert variable effects on and beyond the hematopoietic system. They all share significant stimulating activity on early hematopoietic progenitors, and they all induce the megakaryocyte lineage.

Interleukin-6 (IL-6)

IL-6 was cloned as a novel cytokine that induced B lymphocytes to produce immunoblobulins.[405] It is now realized that IL-6 has a board range of activity on multiple cell types. The IL-6 receptor is a heterodimer consisting of IL-6Rα and gp130.[406] The latter is expressed in cells that do not express IL-6Rα. A soluble form of IL-6R can bind gp130 in the presence of IL-6 and render these cells responsive to IL-6.[407] When used alone, IL-6 has no in vitro hematopoietic activity on human cells even though it induces murine granulocyte-macrophage colony formation.[408] IL-6 synergizes with IL-3 and other early acting cytokines to support the proliferation of early hematopoietic progenitors.[409] It also synergizes with GM-CSF and M-CSF in the formation of granulocyte and macrophage colonies respectively.[410,411] IL-6 stimulates immature megakaryocytes in the presence of other megakaryocytic growth factors.[412] When administered in vivo it stimulates multilineage hematopoiesis and accelerates bone marrow recovery after 5-FU injection or radiation therapy.[413] It increases platelet count in a dose-responsive manner.[414] There is evidence that a significant portion of IL-6 hematopoietic activity is indirect and related to stimulating other cytokines.[415] IL-6 deficient mice display impaired immune and acute-phase responses.[416] In addition, these mice have a decrease in early-multilineage progenitor cell survival.[417] IL-6 is the major cytokine driving myeloma cell proliferation[418] and it is the principal hepatocyte acute phase reactant factor.

Interleukin-11 (IL-11)

IL-11 is a cytokine with a primary hematopoietic function.[419] It was originally cloned from BM stromal cell line.[420] IL-11 exerts minimal influences on hematopoiesis on its own, but it synergizes with multiple cytokines to enhance progenitor cell colony formation. This synergy has been reported with SCF, GM-CSF, IL-3,IL-4, IL-6, and Tpo.[278,421,422] The IL-11 hematopoietic influence is most prominent on the megakaryocytic lineage.[423,424] However, this activity extends to other hematopoietic progenitors such as CFU-GEMM, CFU-GM, BFU-E, CFU-G, CFU-E, and CFU-M.[424,425] When administered in vivo, IL-11 hastens bone marrow recovery after cytotoxic therapy as reflected by increased peripheral blood platelets and neutrophil counts.[424,426] IL-11 stimulates proliferation of multipotential progenitors[425,427] without promoting stem cell self-renewal.[425] IL-11 can maintain early progenitor/stem cell survival in vitro in combination with other cytokines.[428] IL-11 is one of the cytokines that facilitates

the entry of dormant hematopoietic cells into the cell cycle.[85,429] IL-11 has activities similar to that of IL-6 in that it promotes the proliferation of immunoglubulin secreting B cells and it enhances the growth of IL-6 dependent plasmacytoma cell lines.[430] It also induces the secretion of hepatic acute phase proteins, but with less potency than IL-6.[431] BM stromal cells, fibroblasts, brain, and testes have been reported to produce IL-11.[432] The receptor for IL-11 consists of two chains, IL-11 Rα[433] and gp 130[434] shared with other IL-6 receptor family members. Despite the tangible influence of IL-11 on in vitro hematopoiesis, IL-11 Rα deficient mice do not display any hematopoietic abnormality.[435]

Leukemia Inhibitory Factor (LIF)

Leukemia inhibitory factor is a pleotropic cytokine with unequivocal hematopoietic activity.[436] It was purified as a factor that induces differentiation of murine myeloid leukemic M1 line.[437] It is a cytokine known for its ability to inhibit the differentiation of mouse embryonic stem (ES) cells.[438] LIF is produced by marrow stromal cells,[439] monocytes, and blastocytes. Cloning[440] and production of pure LIF has shown that it does not stimulate hematopoietic progenitors when used alone, but it induces proliferation of multipotential (CFU-GEMM) and eosinophil (CFU-EO) progenitors when added with serum.[441] BFU-E size is also increased in the presence of LIF.[441] This cytokine is as effective as IL-6 or G-CSF in stimulating IL-3 dependent human blast colony-forming cells that are considered primitive hematopoietic cells.[442] When administered in vivo, LIF expands megakaryocyte mass in mice.[443] LIF induces acute phase proteins and raises platelet counts in primates.[444] Other activities include influencing bone and muscle metabolism, inhibition of lipoprotein lipase, and induction of cytokines production. The LIF receptor shares gp130 with other members of IL-6 family receptors, plus a specific α chain (LIF-Rα) that binds LIF with a low affinity.[445] Targeted disruption of LIF-Rα results in placental, skeletal, neuronal, and metabolic defects, leading to perinatal death.[446] Hematologic and primordial germ cell compartments appear normal in the LIF-Rα knock-out pups.[446]

Oncostatin M (OSM)

OSM was isolated as a growth inhibitor of epithelial cell carcinoma cell lines.[447] It belongs to the IL-6 cytokine family and shares activities, particularly with LIF, such as blocking differentiation of ES cells.[448] T lymphocytes, monocytes, stromal cells, and eosinophils secrete OSM. OSM has no direct effect on hematopoietic progenitors when used alone. Preincubation of BM cells with OSM inhibits cytokine-induced progenitor proliferation.[449] OSM has been implicated in Th1 stimulation of hematopoietic progenitor cell proliferation.[450] OSM, along with SCF and IL-1, is produced by an AGM derived cell line that sustains the survival of SCID-NOD repopulating cells for four weeks.[451] Fetal hepatocyte development is induced in vitro by the addition of OSM and steroids.[452] It is thought that the paracine action of OSM (secreted by hematopoietic cells) is essential for fetal liver development.[453] When fetal hepatic cells are induced to mature by OSM, they lose their hematopoietic supportive capacity.[453] This mechanism is suggested as an explanation for termination of liver hematopoiesis during fetal development. In vivo administration of OSM results in the dramatic accumulation of immature and mature T cells in the lymph nodes that is independent of the presence of the thymus.[454]

OTHER CYTOKINES WITH HEMATOPOIETIC ACTIVITIES

In this section, we discuss a group of classic cytokines that have wide-spectrum regulatory functions on different physiologic and pathologic processes such as immunity and inflammation, and show hematopoietic stimulatory or inhibitory activities as well.

Interleukin-1 (IL-1) Family

IL-1α and IL-1β are the most widely investigated of the IL-1 cytokine family.[455] Although monocytes and macrophages are considered the main source of IL-1,[204] almost every cell type produces and responds to this cytokine. Two IL-1 receptors exist: type I receptors which transmit the intracellular signal[456] and type II receptors which do not signal and may work as a decoy receptor.[457] IL-1 does not induce hematopoietic colony formation when used alone. However, it synergizes with multiple cytokines in this regard. It is thought that most of the hematopoietic activity of IL-1 is indirect and related to its stimulation of cytokine secretion[458] and to a lesser degree cytokine receptor expression. When administered in vivo, IL-1 induces neutrophilia, and a single low dose injection of IL-1 accelerates multilineage recovery after BM ablation.[459] At higher doses IL-1 suppresses myelopoeisis in vivo[460,461] probably due to induction of IFNs, TNF-α and prostaglandin E2 that inhibit progenitor cell proliferation. Chronic administration of IL-1 to mice results in anemia in association with a decrease in the numbers of CFU-E.[461] IL-1 does not appear to be important for normal hematopoiesis since IL-1β deficient mice have no hematopoietic abnormalities.[455] IL-1β and IL-1α double knock-out mice have been created with no disrupted hematopoiesis reported.[462]

Interleukin-2 (IL-2)

IL-2, or T-cell growth factor, was initially isolated from conditioned media that stimulates T-cell proliferation.[463] The main source of IL-2 is the T cells themselves. Apart from its important immunologic activities, IL-2 exerts minimal influence on hematopoiesis. Conflicting reports have described this influence. Some suggested stimulatory functions of IL-2 on in vitro hematopoietic colony formation,[464,465] although others reported inhibition of colony formation by IL-2.[466,467] Most studies indicate that the IL-2 effect on hematopoiesis requires the presence of T cells.[467] IL-2 administration to mice results in enhancement of extramedullary hematopoiesis.[468] The IL-2 receptor is expressed on some hematopoietic cell lines and this expression is induced by IL-3.[469] IL-2 knock-out mice develop autoimmune hemolytic anemia, inflammatory bowel disease, and reduced T-cell response to mitogens.[470] No hematopoietic abnormalities have been reported in these mice.

Interleukin-4 (IL-4)

IL-4 was identified as a T-cell derived B-cell growth factor.[471] The receptors for IL-4 are present on B and T lymphocytes, mast cells, macrophages, and hematopoietic progenitors.[472,473] IL-4 exerts both positive and negative activities on hematopoietic colony formation depending on its target cells and the nature of other cytokines added to the culture media.[10] IL-4 supports the formation of multipotential blast colonies and small GM colonies from BM or spleen cells of 5-FU treated mice.[474] IL-4 is considered to be an intermediate-acting cytokine that acts on early hematopoietic progenitors.[12] It also interacts with lineage specific cytokines, such as G-CSF and Epo to produce neutrophil or erythroid (both CFU-E and BFU-E) colonies, respectively.[475] IL-4 inhibits murine IL-3-dependent colony formation by granulocyte, macrophage, and multipotential progenitors.[476] Some of the IL-4 hematopoietic activity is indirect and related to its induction of other cytokines.[476] IL-4 deficient mice are characterized by reduced hematopoietic progenitor numbers and cycling[477] in addition to having a defect in immunoglobulin production.[477]

Interleukin-7 (IL-7)

IL-7 was cloned as a murine pro-B cell growth factor.[478] Shortly after, it was recognized to have prominent activity on immature and mature T cells.[479] IL-7 is produced by multiple stromal cells particularly the

in the thymic stroma. It is also produced by the bone marrow stromal cells.[480] IL-7 is a critical regulator of both T cells and B cells in mice and of T cells in humans.[480] It stimulates the proliferation[481] and prevents the apoptosis[482] of both B- and T-cell progenitors leading to significant increases in B- and T-cell numbers. IL-7R expression has been identified as the earliest phenotypical marker of HSC commitment to the common lymphoid progenitor which gives rise to all lymphoid cell types.[483] IL-7 is also a critical regulator of homeostatic proliferation and survival of naïve T cells.[484] Some reports suggested modest synergistic activity of IL-7 with other cytokines[485] on the myeloid lineage despite earlier reports of absence such activity. However, given the fact that the common myeloid progenitors are present in the IL-7 receptor negative compartment[486] (at least in mice), it is likely that IL-7 myeloid enhancing activity is indirect and mediated by inducing other cytokines. IL-7 knock-out mice have a critical deficiency in the lymphocyte compartment,[487] with 10 to 20-fold reduction in the number of T cells. IL-7Rα deficient mice display a more severe phenotype with massive reduction in thymocytes and peripheral T cells.[488] This may be secondary to a disrupted signaling of the thymic stromal-derived lymphopoietin (TSLP) which utilizes IL-7Rα as a component of its receptor.[489] B-cell development is significantly impaired in both IL-7 and IL-7Rα deficient mice. The IL-7Rα inactivation is seen in subset of patients with severe-combined immunodeficiency.[490] The presence of B cells in these patients indicates different activities of IL-7 in humans compared to mice.

Interleukin-9 (IL-9)

IL-9 was cloned as a cytokine that supports the growth of the human megakaryoblastic leukemia cells line M07E.[491] IL-9 has a positive proliferative activity on the erythroid progenitors.[492] It acts on an early progenitor population of IL-3 responsive BFU-E.[492] This colony-enhancing activity is Epo dependent, although IL-9 alone sustains the survival of erythroid progenitors in vivo as assessed by delayed addition of Epo. SCF and other cytokines enhance the erythroid colony-forming activity of IL-9.[493] IL-9 increases the number of multipotential progenitors in the presence of SCF.[493] Despite its activity on M07E cells, IL-9 has no activity on megakaryocyte colony formation.[491] Transducing $CD34^{++}$ $CD33^{-}$ cord blood cells with retroviral vectors carrying IL-9 or IL-9 receptor resulted in enhanced proliferation of erythroid progenitors.[494] IL-9 deficient mice demonstrate a role for IL-9 in pulmonary mastocytosis and goblet cell hyperplasia.[495] No hematopoietic abnormalities were reported in these mice.

Interleukin-10 (IL-10)

IL-10 was identified as a cytokine synthesis response inhibitory factor that is secreted as a part of Th2 response and that inhibits IL-2 and IFN-γ production by Th1 cells.[496] In contrast to its prominent immunomodulatory effects, IL-10 modestly affects hematopoiesis. It inhibits human BFU-E probably by suppressing other cytokines such as GM-CSF.[497] It also inhibits CFU-GM by the same mechanism.[498] Others reported stimulatory effect of IL-10 on megakaryocytes, mast cells and multilineage colonies in the mouse.[499] IL-10 deficient mice develop chronic enterocolitis if not kept in a germ-free environment.[500]

Interleukin-12 (IL-12)

IL-12 was originally identified as a cytokine that stimulates mature T lymphocytes and NK cells.[501] It promotes the development of Th1 $CD4^{+}$ T cells.[502] IL-12 is a heterodimer of a P40 unit that shows homology to IL-6 receptor, and a P35 unit that is homologous to IL-6 and G-CSF (so it is thought that IL-12 is a complex of a cytokine and a receptor).[503] One monomer of the IL-12 receptor displays high homology to gp130, which is the common signaling chain of IL-6 family receptors.[504] As is the case with costimulatory cytokines, IL-12 requires the presence of other hematopoietic factors to enhance colony formation. It potently and synergistically stimulates murine Lin^{-} $Sca\text{-}1^{+}$ cells to form various hematopoietic colonies in combination with other cytokines such as G-CSF, IL-3, M-CSF, SCF, and FL.[505] It stimulates the proliferation of CFU-GEMM when added with SCF, and supports the growth of progenitors with both myeloid and lymphoid potential indicating an activity on early progenitors.[506] Single-cell experiments suggest that this effect is direct. It is also known that hematopoietic progenitors express the IL-12 receptor. In vivo administration of IL-12 results in enhanced extramedullary hematopoiesis in the spleen and bone marrow hypoplasia with pancytopenia.[507] This in vivo inhibitory effect is secondary to its induction of IFN-γ, because this inhibitory activity is not seen when IL-12 is administered to IFN-γ R–/– mice.[508] IL-12 deficient mice display defective IFN-γ production and type-1 cytokine response.[509] Numbers and cycling of progenitors in the BM are reduced compared to wild-type.[509]

Interleukin-17 (IL-17)

IL-17 was cloned as a CD4 T-Cell secreted cytokine with homology to a herpes virus saimiri gene.[510] IL-17 stimulates epithelial, endothelial and fibroblastic cells to secrete cytokines such as IL-6, IL-8, GM-CSF, Epo, and IL-1.[511] This cytokine is devoid of direct effects on hematopoietic progenitors but works through induction of other cyokine secretion.[511] When cultured in the presence of IL-17, fibroblasts sustain the proliferation of $CD34^{+}$ cells with a preferential maturation into neutrophils.[511] SCF and G-CSF are required for IL-17 mediated granulopoiesis.[512] Overexpression of IL-17 in vivo results in significant granulopoiesis.[513] Other IL-17 family members have been cloned.[514] These display variable activity on hematopoiesis,[515] with mainly inhibitory effects on progenitors.[516]

IL-20

IL-20 stimulates the hematopoietic multipotential progenitors without affecting the more mature progenitors.[517]

IL-31

IL-31 is a recently discovered helical cytokine that is involved in promoting the development of dermatitis. IL-31 R is involved in positive regulation of cycling and numbers of immature subsets of HPCs. IL-31 does not alter in vitro proliferation of HPC, but it enhances the survival of these cells when growth factor addition is delayed.[518]

CANDIDATE STEM CELL REGULATORS

Recent investigations have implicated novel membrane-bound or soluble factors in the regulation of hematopoiesis particularly the early stages of this process. Members of these groups have wide activities outside the hematopoietic system as well.

The Notch Ligands

Four mammalian notch family members have been indentified. These are highly-conserved transmembrane glycoprotein receptors that get activated by binding their ligands such as Jagged-1, Jagged-2, and Delta1-4 which are in turn transmembrane proteins.[519] This binding leads to proteolytic cleavage of the intracellular portion of notch. The latter translocates to the nucleus to influence transcription

of target genes. Notch proteins are widely expressed in multiple cell types including the hematopoietic progenitors, T and B lymphocytes, monocytes, and neutrophils.[520] On the other hand, notch ligands are expressed on BM stromal cells, fetal liver and thymus.[520] The first human notch orthologue was discovered as a product of the gene involved in translocation in T-cell lymphoblastic leukemia.[521]

The evidence for a strong involvement in hematopoiesis was inferred when the expression of the constitutively active form of notch1 in murine hematopoietic progenitors resulted in the production of a cell line with the characteristics of primitive cells that can differentiate into lymphoid or myeloid cells in vitro in the presence of relevant cytokines.[522] This cell line can also repopulate lethally irradiated mice. The activation of notch receptors with exogenous ligands presented in soluble or immobilized forms results in an increase in murine progenitor cell numbers with a block in their differentiation. For example, Jagged1 and Jagged2 induce significant amplification of Sca-1$^+$ c-kit$^+$ Lin$^-$ and HPP-CFC cells, respectively.[523,524] A form of Delta1 bound to the Fc portion of immunoglobulin in combination with a cytokine cocktail can cause a massive increase in short-term myeloid and lymphoid repopulating cells.[525] Activated notch1 expression in murine hematopoietic cells resulted in an increase in the number of early progenitor/stem cells in vivo.[526] The effect of notch ligands on the proliferation of human hematopoietic progenitors has been less remarkable. However one report has suggested that an immobilized form of Delta1 is able to remarkably expand human CD34$^+$ cells and SRC again in combination with a cytokine cocktail.[527] There is evidence that Jagged-1 can maintain cord blood NOD/SCID Repopulating Cells (SRCs) in vitro for at least two weeks while these cells lost their repopulating activity in control media.[528] One report has implicated Notch signaling in osteoblast maintance of HSC niche through production of Jagged1.[50] Another report suggested a role of notch signaling in preventing HSC differentiaion, and through the use of Notch/Wnt double reporter mice, the authors revealed the interaction between these pathways. Wnt3a induced notch target genes, and notch signaling had to be intact for Wnt to enhance self-renewal of HSC.[529] Notch signaling has been implicated in cell-fate determination. This has been observed in the hematopoietic system since this system favors lymphoid over myeloid commitment.[525,526] Knock-out mice have been generated for most of the notch receptors and ligands.[519,520] Their embryos die early before E9.5 because of profound developmental defects. No abnormal yolk-sac primitive erythropoiesis is seen.

Wnt Family Members

The Wnt family is a conserved group of proteins with diverse functions in embryogenesis, cell fate, and formation of almost every organ.[530] Wnt proteins are essential for cellular polarity, and they stimulate mammary tumors in mice. Some of them induce axis duplication when ectopically expressed in frog embryos. Wnt proteins are secreted and usually associated with the cell surface or extracellular matrix. Media conditioned with human or murine cells overexpressing these proteins have been used to delineate their roles in the hematopoietic system. Among multiple Wnt members, Wnt-5A and Wnt-10B are expressed in murine yolk sac and fetal liver AA4$^+$ cells.[531] Wnt-10B is expressed in fetal liver AA4$^+$ Sca-1$^+$ c-Kit$^+$ (flASK) primitive cells. Wnt receptors, frizzled 3–7, are also expressed in murine fetal liver. Wnt-1, Wnt-5A, and Wnt-10B stimulate several fold expression of hematopoietic cells after seven days in combination with SCF, compared to a control of SCF alone.[531] Wnt-5A, Wnt-2B, and Wnt-10B are expressed in human fetal bone stromal cells and several hematopoietic cell lines.[532] CD34$^+$ Lin$^-$ cells do not express Wnt proteins even though Wnt-5A may be expressed in some of these cells. Six frizzled genes are expressed in human or fetal CD34+ cells. When conditioned media from stromal cells over-expressing Wnt-5A, Wnt-2B, Wnt-10B are added to CD34$^+$ Lin$^-$ cells, a 20-fold increase in multipotential progenitors is noted. There is also twofold increase in their number compared with SCF or IL-3 containing media.[532] Wnt-11 anti-sense prevents the differentiation of the quail mesoderm stem cell line QCE6 into blood cells in optimized media. Addition of Wnt-11 or Wnt-5A-conditioned media restores the multilineage hematopoietic differentiation of the parent QCE6 cells.[533] Some Wnt proteins are mitogenic for pro-B cells,[534] while Wnt-3A reduces the number of B cells and myeloid-lineage cells produced in long-term bone marrow cultures only in the presence of stromal cells.[535] A lipid modified form of Wnt-3A has been purified and shown to display characteristics of stem cell growth factor.[536] Manipulating molecules of the Wnt signaling pathway affects stem cell expansion as seen with overexpressing β-catenin.[537] Glycogen synthase kinase-3 inhibitors enhance HSC repopulating capacity in vivo.[538] Valproic acid which can work as an histone deacetylase inhibitor was shown to increase the self-renewal potential of mouse stem cells. It was reported to upregulate β-catenin expression.[539] In another experiment conditional inactivation of β-catenin in BM did not affect the self-renewal or the repopulation potential of HSC, which suggests that Wnt may work through a non-canonical pathway.[540] However recent reports utilizing conditional expression of a stable form of β-catenin resulted in blockade in HSC differentiation, loss of repopulating potential and entry into cell cycle.[541,542] This complicates further understanding the exact role of Wnt within the HSC niche and indicates the delicate impact of Wnt signalling dose on HSC response. Mice lacking different Wnt genes display a wide range of abnormalities particularly musculoskeletal, neuronal and kidney defects. Some die perinatally. No specific hematopoietic abnormalities have been reported in these mice.[530]

Sonic Hedgehog

Sonic hedgehog Shh is one of a three member family that is implicated in tissue specification during embryogenesis. Shh was shown to induce HSC proliferation via bone morphogenic protein BMP signaling.[543] Activated Shh pathway induces cycling of HSC but at the expense of self-renewal.[544]

Bone Morphogenic Proteins (BMPs)

BMPs are members of the TGF-β superfamily which also includes Activins. BMP-4 plays a key role in mesoderm induction and hematopoietic commitment.[545] BMPs promote the differentiation of human embryonic stem cells into cells belonging to the hematopoietic lineage in combination with other cytokines.[546] Treatment of human HSCs (CD34$^+$CD38$^-$Lin$^-$) with BMP2 and BMP7 inhibited proliferation while, using relatively high concentrations of BMP4 enhanced survival and increased the engraftment following ex-vivo culture.[547] Mice lacking BMP4 die between E7.5 and E9.5 and exhibit severe defects in mesoderm formation. Embryos that survive up to E9.5 show defective blood islands.[548]

Angiogenic Factors and Angiopoietin-Like Proteins

Multiple angiogenic factors have been identified in different biological systems. We focus on the vascular endothelial growth factor (VEGF) family and angiopoietins (ang-1-4). The VEGF family includes five mammalian members: VEGF-A-D and placental growth factor (PLGF).[549] 4 Receptors have been identified: VEGFR-1 (Flt-1), VEGFR-2 (Flk-1/KDR), VEGFR-3 (Flt-4), and neuropilin-1. Each of these receptors binds more than one ligand which complicates the interpretation of each ligand/receptor function. VEGF family members are essential for regulating various aspects of normal and pathologic angiogenesis. VEGF-A exerts both a stimulatory effect on mature subsets of hematopoietic progenitors and an inhibitory effect on the more immature subsets in the presence of other cytokines.[550] These effects are mediated by both direct and indirect actions on the hematopoietic progenitors.[550] Cells are induced to secrete

VEGF-A by cytokine stimulation.[551] VEGFR-2 (the main receptor for VEGF-A) expression defines a population of early embryonic hematopoietic progenitor/stem cells.[552] NOD/SCID repopulating HSCs were reported to be present in the population of $CD34^+$ $VEGFR2^+$ cells, whereas the $CD34^+$ $VEGFR2^-$ fraction contained no such cells.[553] However, murine BM-derived $VEGFR2^+$ cells could not repopulate lethally irradiated mice in another report.[554] VEGF-A may regulate hematopoietic stem cell survival by an internal autocrine loop mechanism.[555] In vivo over-expression of VEGF-A or angioproietin-1 results in mobilization of HSCs into peripheral blood and spleen.[556] This is associated with initial enhancement followed by transient suppression of BM hematopoiesis. VEGFR-1 is expressed on human $CD34^+$ and murine Sca-1^+ c-Kit^+ Lin^- repopulating cells.[557] PLGF (which signals through VEGFR-1) restores early and late phases of hematopoiesis following BM suppression.[557] VEGFR-2 deficient mice display failure of blood-island formation and vasculogenesis and die in utero.[558] Both primitive and definite hematopoiesis are disrupted in these mice.[559] Embryonic lethality with vascular and hematopoietic defects are seen in mice lacking even one allele of the VEGF-A gene.[560] Angiopoietins and their receptor Tie2 play significant role in HSC interaction with the stromal cells in the niche.[561] Ang-1/Tie2 signalling regulates HSC quiescence.[561] Tie2 expression is limited to the long-term LT-HSCs.[544] HSCs also express ang-1 which suggests an autocrine/paracrine influence.[562] Tie2 deletion impairs definitive hematopoiesis.[563] Angiopoietin-like (Angptl)2 and Angptl3 molecules were expressed in fetal liver $CD3^+$ cells, and they enhanced net ex vivo expansion of long-term repopulating murine HSC when used in combination with saturating amounts of other growth factors.[564]

CLASSIC GROWTH FACTORS WITH HEMATOPOIETIC ACTIVITIES

There are multiple examples of classic non-hematopoietic growth factors that show some hematopoietic activity both in vitro and in vivo. We elected to discuss three of these: Insulin-like growth factors, Hepatocyte growth factor, and basic fibroblast growth factor.

Insulin-Like Growth Factor (IGF) I and II

IGF-I and IGF-II are well-known growth factors affecting multiple cell types. They mediate their effects through IGF-I R and IGF-II R, which are present in different tissues including the hematopoietic system.[565] IGF-I, whose activity is better delineated, exerts a stimulatory effect on hematopoiesis. BM stromal cells synthesize and secrete IGF-I and IGF-binding proteins.[566] When added to BM cells, IGF-I mediates an Epo-like activity that promotes erythroid lineage differentiation even in the absence of added Epo.[567] Although there is consensus on the hematopoietic effect of IGF-I, there is controversy over whether or not this influence is direct or mediated by other cytokines.[568] It seems that IGF-I is more important than IGF-II for erythroid colony formation by adult hematopoietic progenitors, whereas IGF-II has more significance for colony formation by the cord blood progenitors.[569] IGF-I stimulates granulopoiesis in semisolid culture systems, and IGF-II induces granulocyte-macrophage colony formation.[570] IGF-I can also promote in vitro lymphopoiesis.[571] In vivo administration of IGF-1 stimulates BM B- lymphocyte production and enhances lymphocyte recovery after BM transplantation.[572]

Basic Fibroblast Growth Factor (bFGF)

BFGF is an angiogenic and mitogenic factor for multiple cell types, with an important function in cell differentiation. In the BM environment it is secreted by stromal cells and is a potent mitogen for these cells.[573] It is also expressed by macrophages, megakaryocytes, T lymphocytes, and granulocytes.[574] BFGF enhances the colony stimulating activity of IL-3 and GM-CSF on $CD34^+$ $CD33^-$ progenitors in vitro.[575] It increases the number of CFU-S_9, and CFU-S_{12} in synergy with GM-CSF.[576] bFGF synergizes with SCF in augmenting committed myeloid progenitor growth.[577] Megakaryocyte progenitors are also targets of bFGF activity.[578]

Hepatocyte Growth Factor (HGF)

HGF was initially purified as a liver regenerating factor from the plasma of a patient with fulminant hepatitis.[579] Shortly after, it was cloned and shown to be the most potent mitogen for mature hepatocytes.[580] HGF exerts wide mitogenic and morphogenic activity on multiple cell types. Both HGF and its tyrosine kinase receptor c-Met proto-oncogene are expressed in BM, fetal liver and yolk sac.[581] In the BM, HGF is predominantly produced by stromal cells, while c-Met is expressed on immature $CD34^+$ $CD38^-$ but not on $CD34^+$ $CD38^+$ cells.[582] It has no colony-stimulating activity when used alone,[582,583] but it synergizes with GM-CSF and IL-3[581,582] with less potency than SCF and FL. HGF promotes proliferation, survival and adhesion of human $CD34^+$ cells.[582] It plays roles in the induction and maintenance of bone marrow stromal cell production of IL-11, SDF-1 α, and stem cell factor.[584] It also increases red blood cells, white blood cells, and platelet counts in SCF/c-Kit deficient mice when given in vivo.[585]

CONSEQUENCES OF CYTOKINE AND/OR CYTOKINE RECEPTOR GENE DEFICIENCY

Table 24–5 reveals the phenotype of mice deficient in the main hematopoietic cytokines and/or their receptor-genes. It is clear that deletion of some genes causes more severe consequences than deletion of others.

Suppressor Cytokines

These cytokines share the ability to suppress hematopoietic colony formation under variable circumstances. Some of them have been implicated in pathologic hypoproliferative processes such as anemia of inflammation and aplastic anemia. We will discuss the chemokine family members, IFNs, tumor necrosis factor (TNF) α, and transforming growth factor (TGF) β family.

CHEMOKINES

Chemokines are small molecules that were originally named for their ability to attract mature leukocytes.[586] Currently, there are more than 45 known chemokines which are classified into four groups according to the position of invariant cystein (c) motifs near the N-terminal portion of the molecule.[587] Table 24–6 is an up-to-date listing of the chemokine groups. The CC and CXC (X indicates any amino acid) groups contain most of the known chemokines. These cytokines have been implicated as negative and to a lesser extent positive regulatory of hematopoiesis. The prototype of the inhibitory chemokines is macrophage inflammatory protein-1α (MIP)-1α, now designated CCL3. MIP1-α was first identified as a suppressor molecule for spleen-CFUs.[588] It was later shown to inhibit multi-cytokine induced growth of CFU-GEMM, BFU-E, and CFU-GM.[589] In vivo administration of MIP-1α results in suppression of hematopoiesis.[590,591] This effect is direct and seen on single cells growing in serum-free medium.[592] The suppressive activity of MIP-1α is initiated during S-phase of cell cycle.[593] The in vivo administration of MIP-1α results in reversible suppression of cycling status and absolute numbers of BM and spleen progenitors.[590,591] MIP-1α also works in opposite fashion by enhancing the proliferation of CFU-GM and CFU-M when stimulated by a single CSF: GM-CSF or M-CSF, respectively.[594] Twenty-three other chemokines demonstrate similar

Table 24–5 Consequences of Cytokine and/or Cytokine Receptor Gene Deficiency

Cytokine	The Hematopoietic Phenotype	Other Important Nonhematologic Defects
SCF/c-kit	Embryonic lethality in homozygous mice Macrocytic anemia in *W* and *Sl* mice which harbor heterozygous mutations of c-Kit and SCF respectively	Hypopigmentation, reproductive defect in *W* and *Sl* mice.
FL/Flt3	Reduced number of early B-cell progenitors and a defect in repopulating stem cells in flt3 knock-outs. FL deficient mice display an additional decrease in peripheral blood, spleen, and BM cellularity.	
G-CSF/G-CSF Receptor (R)	Decrease in number of circulating neutrophils plus in number of BM progenitors of various lineages.	
GM-CSF/GM-CSFR	No obvious hematopoietic defects. Eosinopenia in GM-CSF R deficient mice (caused by IL-5 signaling defect).	Alveolar pulmonary proteinosis
IL-3/IL-3R	Normal hematopoiesis. Eosinopenia in IL-3R deficient mice (caused by IL-5 signaling defect)	
M-CSF/c-fms	BM failure due to osteopetrosis in op/op mice	Osteopetrosis
Epo/Epo	Embryonic lethality due to failure of definite fetal liver erythropoiesis. Committed erythroid progenitors are present.	
TPO/c-mpl	Thrombocytopenia. A decrease in BM progenitors of various lineages	
IL-5/IL-5R	Lack of eosinophilia to allergen challenge in IL-5 deficient mice. Eosinopenia in IL-5R knock-out	
IL-6/IL-6R	Decrease in BM progenitor survival	Impaired immune and acute phase responses Embryonic lethality of gp130 deficient mice (gp130 common to all IL-6 family receptors)
IL-11/IL-11R	Normal hematopoiesis	Embryonic lethality of gp 130 deficient mice
LIF/LIF-R	Perinatal mortality. Hematopoietic system appears normal	Placental, skeletal, neuronal and metabolic defects leading to perinatal mortality
IL-1/IL-1R	Normal hematopoiesis	IL-1R1 deficiency protects against endotoxin-induced lethality
IL-4/IL-4R	Decrease in BM progenitor number and cycling	Defect in immunoglobulin production

Phenotypes observed in mice deficient in the major hematopoietic cytokines. The impact of one cytokine deficiency may be as remarkable as resulting in embryonic lethality as seen with the SCF/c-Kit axis, or as subtle as having no tangible effect on the hematopoietic system as seen with IL-11.

suppressive activities.[595] Table 24–7 lists these known suppressive chemokines. Responsiveness of hematopoietic progenitor cells to suppression by inhibitory chemokines requires the entry of cells to cycle and also the expression of major histocompatibility class II antigens.[596] Chemokines can act in synergy with each other and with other cytokines, such as macrophage stimulatory protein (MSP) and VEGF to inhibit progenitor cell proliferation in vitro.[595] Suppressive chemokines also synergize with each other to inhibit absolute numbers and cycling status of hematopoietic progenitor cells in vivo.[597] A small number of chemokines such as Eotaxin (a CC chemokine) have been shown to exert an enhancing activity on myelopoiesis.[598] Other regulatory roles of chemokines have been uncovered. For instance, MIP-1α has been used in a cocktail of cytokines to maintain myeloid and lymphoid progenitor numbers in long-term marrow culture.[599] Stromal derived factor-1 SDF-1 (or CXCL12) is a chemokine that was isolated from BM stromal cells.[600] It was also cloned as a pre-B cell growth stimulatory factor (PBSF)[601] and recently was shown to regulate the earliest stage of B-cell precursor development.[602] SDF-1 deficient mice die perinatally because of lack of BM hematopoiesis that is thought to be secondary to impaired stem cell migration from fetal liver to the BM.[603] SDF-1 exerts in vitro chemoattracting activity for multipotential (CFU-GEMM), erythroid (BFU-E), granulocyte-macrophage (CFU-GM), and megakaryocyte (CFU-MK) progenitors and for LTC-IC.[134,135] In addtion, there is a strong evidence for an essential role of SDF-1 in stem cell homing to the BM microenvironment when human $CD34^+$ are transplanted into NOD/SCID mice.[16] SDF-1 has also been implicated in hematopoietic progenitor survival.[109,115] It appears that SDF-1 also exert indirect activity on HSC/progenitors by retaining these cells within the niche where other cytokines/GFs are active.[604] SDF-1 is an essential cytokine for early stages of lymphopoiesis.[605] It plays a role in thrombopoiesis as well.[606]

Two other chemokines (CK)β-11/CCL19 and SLC/CCL21 have been shown to be selectively chemotactic for macrophage progenitors.[607] Chemokine receptors are seven transmembrane G-protein-linked receptors.[165] There is redundancy in the chemokine system in that one chemokine may bind more than one receptor and one receptor may bind more than one chemokine. Analysis of mice deficient in some of these receptors has shed light into their roles in hematopoiesis. MIP-1α binds CCR1, CCR5, and CCR9. CCR1 deficient mice display abnormalities in trafficking of myeloid progenitor from BM to spleen particularly in response to bacterial lipopolysaccharide.[608] The inhibitory response is preserved while the enhancing effect on M-CSF and GM-CSF is lost[609] in CCR1 deficient mice. CCR2 is one of the receptors for the myelosuppressive chemokine MCP-1. CCR2 deficient mice demonstrate increased cycling of myeloid progenitors. However the absolute numbers of progenitors are unchanged compared with wild-type, probably because of increased apoptosis in the CCR2−/− mice.[610] IL-8 is another myeloid-inhibitory chemokine. CXCR2 functions as a receptor for IL-8. Deleting CXCR2 results in enhanced myelopoiesis with loss of BM sensitivity to IL-8. This enhanced myelopoiesis is observed in mice bred and raised under a normal environment but not seen in mice kept under germ-free conditions.[611]

Table 24–6 Classification of Chemokines

Chemokine	Other Names	Receptor
	CXC Chemokine/Receptor Family	
CXCL1	GROα/MGSA-α	CXCR2 > CXCR1
CXCL2	GROβ/MGSA-β	CXCR2
CXCL3	GROγ/MGSA-γ	CXCR2
CXCL4	PF4	unknown
CXCL5	ENA-78	CXCR2
CXCL6	GCP-2	CXCR1, CXCR2
CXCL7	NAP-2	CXCR2
CXCL8	IL-8	CXCR1, CXCR2
CXCL9	Mig	CXCR3
CXCL10	IP-10	CXCR3
CXCL11	I-TAC	CXCR3
CXCL12	SDF-1α/β	CXCR4/CXCR7
CXCL13	BLC/BCA-1	CXCR5
CXCL14	BRAK/bolekine	unknown
(CXCL15)	No human ligand identified yet	unknown
CXCL16	No human ligand identified yet	CXCR6
	CC Chemokine/Receptor Family	
CCL1	1–309	CCR8
CCL2	MCP-1/MCAF	CCR2
CCL3	MIP-1α	CCR1, CCR5
CCL4	MIP-1β	CCR5
CCL5	RANTES	CCR1, CCR3, CCR5
(CCL6)	No human ligand identified yet	unknown
CCL7	MCP-3	CCR1, CCR2, CCR3
CCL8	MCP-2	CCR3
(CCL9/10)	No human ligand identified yet	unknown
CCL11	Eotaxin	CCR3
(CCL12)	No human ligand identified yet	CCR2
CCL13	MCP-4	CCR2, CCR3
CCL14	HCC-1	CCR1
CCL15	HCC-2/LKN-1/MIP-1δ	CCR1, CCR3
CCL16	HCC-4/LEC	CCR1
CCL17	TARC	CCR4
CCL18	DC-CK1/PARC/AMAC-1	unknown
CCL19	Mip-3β/ELC/exodus-3	CCR7
CCL20	Mip-3α/LARC/exodus-1	CCR6
CCL21	6Ckine/SLC/exodus-2	CCR7
CCL22	MDC/STCP-1	CCR4
CCL23	MPIF-1	CCR1
CCL24	MPIF-2/Eotamin-2	CCR3
CCL25	TECK	CCR9
CCL26	Eotaxin-3	CCR3
CCL27	CTACK	CCR10
CCL38	MEC	unknown

Table 24–6 Classification of Chemokines—cont'd

Chemokine	Other Names	Receptor
	C Chemokine/Receptor Family	
XCL1	Lymphotactin/SCM-1α/ATAC	XCR1
XCL2	SCM-1β	XCR2
CX3C	Chemokine/receptor family	
CX3CL1	Fractalkine	CX3CR1

Chemokines are divided into two major groups based on the positions of the N-terminal cysteine residues.

CXC family and CC family where X represent an amino acid. Two other smaller groups have been identified. The C chemokine family members contain just one cysteine and the CX3C family single member has three amino acids separating the two cysteine residues. Several chemokines were cloned at the same time by different groups and given different names. A new classification system has been widely utilized in an attempt to simplify dealing with this perplexing system. AMAC, alternative macrophage activation-associated CC chemokine; BCA, B-cell attracting chemokine; BLC, B-lymphocyte chemoattractant; BRAK, breast and kidney-expressed chemokine; CTACK, cutaneous T cell attracting chemokine; DC-CK, dendritic cell-derived CC chemokine; ELC, EBV-induced gene 1 ligand chemokine; GCP, granulocyte chemoattractant protein; Gro, growth-related oncogene; HCC, hemofiltrate CC chemokine; IP, γ-interferon inducible protein; ITAC, interferon-inducible T-cell α-chemoattractant; LARC, liver and activation-regulated chemokine; LEC, liver expressed chemokine; Lkn, leukotactin; MCAF, monocyte chemotactic and activating factor; MCP, monocyte chemoattractant protein; MDC, monocyte derived chemokine; MEC, mucosa-associated epithelial chemokine; MGSA, melanoma growth-stimulatory activity chemokine; Mig, monokine induced by γ-interferon; MIP, macrophage inflammatory protein; MPIF, myeloid progenitor inhibitory factor; NAP, neutrophil-activating peptide; PARC, pulmonary and activation-regulated chemokine; PF, platelet factor; ENA, epithelial-derived neutrophil attractant; RANTES, regulated on activation of normal T cell expressed and secreted; SDF, stromal cell-derived factor; SLC, secondary lymphoid tissue chemokine; STCP, stimulated T cell chemotactic protein; TARC, thymus and activation-regulated chemokine; TECK, thymus expressed chemokine.

Modified from Bacon K, Baggiolini M, Broxmeyer HE, et al: Chemokine/chemokine receptor nomenclature. J Immunol Methods 262, 2002.[662]

Interferons (IFNs)

The term interferon originally referred to a factor produced by virally infected chick cells that on transfer to fresh chick cells could protect against infection by the same virus.[612] IFNs have a wide spectrum of biological effects including antiviral, antiproliferative, and immunomodulatory activities.[613] They are divided into two groups; type I IFNs which include IFN-α, β, and ω, which are molecularly related and probably arose by divergence from a common ancestral gene; and type II IFN or IFN-γ. There are 14 distinct IFN-α genes and four IFN-α pseudogenes, one IFN-β, one IFN-ω, and one IFN-γ gene.[613] Type I interferons bind to the same receptor; type I IFN receptor, whereas IFN-γ binds to the type II IFN receptor. It was noted early on that IFNs inhibit erythroid colony formation.[614] IFNs are well-known inhibitors of hematopoietic progenitors, including CFU-GEMM, CFU-GM, and megakaryocytic (CFU-MK) progenitors.[615–617] IFN-α, β, and γ have equal influence on CFU-GEMM and BFU-E but have differential effect on CFU-GM.[615] IFN-γ is the most studied interferon in this regard and it appears to inhibit to growth of $CD34^+$ $CD38^-$ cells indicating a role in early progenitor/stem cell regulation.[618] In the hematopoietic system, IFNs inhibit cell cycle progression[619] and induce apoptosis.[620] This apoptosis enhancing effect is facilitated by upregulation of Fas expression on CD34+ cells and erythroid colony forming cells.[621] It has been reported that IFN-γ reduces the expression of cytokine receptors such as c-kit and EpoR on hematopoietic progenitors[622] which contributes to its apoptosis-inducing activity. This inhibition on the hematopoietic system is synergistic among IFNs.[623] IFN-γ has been implicated in the pathogenesis of aplastic anemia,[624] and a major role has been suggested for IFN-α/β in virus-induced transient bone marrow aplasia.[625] Despite the well-documented inhibitory function of IFNγ, a few studies reported stimulatory activity on certain hematopoietic cells.[626] No signs of disturbed baseline hematopoiesis have been reported in IFN-γ deficient mice.[627] However, infecting these mice with mycobacteria results in a transition to extramedullary hematopoiesis with expansion of macrophages, granulocytes, and extramedullary hematopoietic tissue.[628]

Tumor Necrosis Factor α (TNF-α)

TNF-α is a potent cytokine produced by many cell types including macrophages, monocytes, lymphocytes, keratinocytes, and fibroblasts in response to inflammation, infection, injury, and other environmental challenges. TNF-α is named for its ability to regress tumor masses when these get infected with bacterial infections. TNF-α was isolated in 1984 and was found to be a pleiotropic cytokine that is expressed as a transmembrane protein that can be cleaved into a soluble form. It belongs to a family of about 20 factors that are grouped together in the TNF superfamily.[629] TNF-α transmits its signal through two receptors: TNFR1 or p55TNFR and TNFR2 or p75TNFR.[630] The influence of TNF-α on hematopoietic progenitor/stem cells is somewhat complex.[630] TNF-α plays a bifunctional role in that it directly inhibits hematopoietic progenitors[631] at least partially by down-regulating CSF receptors.[632] TNF-α also synergizes with IFNγ to inhibit proliferation of hematopoietic progenitor cells.[631] On the other hand, it stimulates proliferation of hematopoietic progenitors probably by inducing secretion of CSFs.[630,633] This differential influence may be related to the particular CSF present in the culture media and the concentration of the added TNF.[632] Retroviral transduction of single hematopoietic progenitors with c-kit decreases the sensitivity to inhibition by TNF-α.[634] One study showed that TNF-α inhibited the development of committed progenitors while stimulating CFU-S in murine long-term BM cultures.[635] TRAIL which belongs to TNF family has a negative regulatory role on erythropoiesis[636] that could be implicated in pathologic states such as multiple myeloma and myelodysplastic syndrome. Study of hematopoiesis in TNF receptor deficient mice has further elucidated the role of the TNF system in this process. P55 TNFR deficient mice display an increase of $Sca\text{-}1^+$ Lin^- $c\text{-}kit^+$ cells. Increased BM cellularity, and an increase in numbers of myeloid and erythroid colony forming progenitors are seen in p55–/– but not p75–/– deficient mice at age older than six months.[637] This is associated with a fourfold decrease in the number of HSCs, as assayed by quantitating repopulating capacity.[638] These mice also have decreased BM pre-B CFCs and elevated peripheral blood counts compared to the wild-type. Finally Sca-1+ Lin– c-kit+ cells acquire Fas expansion and severely lose their short- and long-term repopulating capacity when cultured in the presence of TNF.[639]

Transforming Growth Factor β (TGF-β)

TGF-β was originally described as a soluble factor that transformed mouse 3T3 fibroblasts.[640] Three mammalian isoforms are recognized with a forth one recently described. TGF-β is present in biologically inactive or latent form that needs to be activated in the extracellular matrix by different mechanisms. TGF-β has no in vitro effect on hematopoietic colony formation when used alone,[641] however it exerts inhibitory[642,643] or stimulatory[644,645] functions in combination

Table 24–7 Suppressive Chemokines

New Designation	Previous Designations
CCL1	1–309
CCL2	MCP-1/MCAF
CCL3	MIP-1α/LD78α

CXCL10	IP-10
CXCL11	I-TAC
XCL1	Lymphotactin

This represents a listing of the hematopoietic suppressive chemokines. One can appreciate the large number of suppressive chemokines that may affect the progenitor/stem cells at a variety of physiologic and pathologic states. These suppress HPC colony formation in vitro. Those tested in vivo decrease the absolute number and the cycling status of HPCs. The suppressive chemokines synergize in vitro and in vivo to inhibit HPC proliferation and concentrations below those by which they inhibit HPCs individually.

ELC, EBV-induced gene 1 ligand chemokine; GCP, granulocyte chemoattractant protein; Gro, growth-related oncogene; HCC, hemofiltrate CC chemokine; IP, γ-interferon inducible protein; ITAC, interferon-inducible T-cell α-chemoattractant; LEC, liver expressed chemokine; Lkn, leukotactin; MCAF, monocyte chemotactic and activating factor; MCP, monocyte chemoattractant protein; MDC, monocyte derived chemokine; MEC, mucosa-associated epithelial chemokine; MGSA, melanoma growth-stimulatory activity chemokine; Mig, monokine induced by γ-interferon; MIP, macrophage inflammatory protein; MPIF, myeloid progenitor inhibitory factor; PF, platelet factor; ENA, epithelial-derived neutrophil attractant; STCP, stimulated T-cell chemotactic protein; TECK, thymus expressed chemokine.

with other cytokines. This effect is direct and dependent on the differentiation status of the target cells, the type of the cytokines used, and on TGF-β concentration.[645,646] TGF-β inhibits the proliferation of early progenitor/stem cells but not that of late progenitors.[646] For example, it inhibits the proliferation of CFU-GEMM,[645] and Lin^- $Thy\text{-}1^{low}$ (early progenitors) cells while it increases the frequency of Lin^- $Thy\text{-}1^-$ (late progenitor) cells.[647] TGF-β completely blocks the cytokine driven proliferation of quiescent Lin^- Hoescht/$Rhodamine132^{low}$ (Ho/Rho) early progenitor/stem cells.[648] Human $CD34^+CD38^-$ cells are highly sensitive to cell-cycle inhibition by TGF-β, whereas more mature $CD34^+CD38^+$ cells are poorly affected or even stimulated.[649] This reversible cell cycle inhibition appears to occur without detectable cell death,[650] and it is augmented by the presence of other inhibitors such as IFNs. Fifty percent of TGF-β deficient mice experience intrauterine mortality due to severe developmental retardation. Dysregulated hematopoiesis is manifested by myeloid hyperplasia, plasmacytosis, reduced number of erythroid cells, and lack of Langerhans dendritic cells.[651,652] These mice develop systemic a massive T-cell inflammatory syndrome and die by five weeks of age. Attempts at isolating the quiescent Ho/Rho^{low} c-kit+ cells from these mice have shown more than 90% reduction in these cells, which suggests a pivotal role of TGF-β in stem cell quiescence. Finally endoglin, an ancillary TGF-β receptor has been found to be a marker that defines long-term repopulating hematopoietic stem cells.[43]

Lactoferrin and H-Ferritin

Lactoferrin and H-ferritin belong to the iron binding family. Members of this family are produced and secreted by a number of different cell types.[653] Lactoferrin in particular has multiple roles in iron homeostasis, innate immunity, inflammation, and differentiation.[653] Both lactoferrin[654,655] and H-ferritin[656–658] suppress hematopoiesis in vitro and in vivo. H-ferritin has direct inhibitory activity on progenitors,[659,660] while lactoferrin has both direct and indirect effects on progenitors.[204,659,661] Major histocompatibility complex class II (MHC II) expression is necessary for these inhibitory effects,[596] as they are for the suppressive chemokines.

CONCLUSION

Hematopoietic cytokines render the suitable milieu for the growth of each hematopoietic lineage that has lead to extensive utilization of a few of these cytokines in variable clinical settings. Multiple challenges still lie ahead, such as translating the ample and overlapping activities of cytokines seen in vitro and in vivo into applications in parallel clinical situations. Another important obstacle is the identification of the environment which permits stem cell division and self-renewal that will lead to a wide range of clinical applications.

CHAPTER 25

BIOLOGY OF ERYTHROPOIESIS, ERYTHROID DIFFERENTIATION, AND MATURATION

Thalia Papayannopoulou, Anna Rita Migliaccio, Janis L. Abkowitz, and Alan D. D'Andrea

Production of erythroid cells is a dynamic and exquisitely regulated process. The mature red cell is the final phase of a complex but orderly series of genetic events that initiates when a multipotent stem cell commits to the erythroid program. Expression of the erythroid program occurs several divisions later in a greatly amplified population of erythroid cells, which have a characteristic morphology, maturation sequence, and function. These maturing cells are termed *erythroid precursor cells* and *reticulocytes*. Terminally differentiated cells have a finite lifespan, and they are constantly replenished by influx from earlier compartments of progenitor cells that are irreversibly committed to express the erythroid phenotype. During ontogeny, successive waves of erythropoiesis occur in distinct anatomic sites. Erythroid cells developing in these sites have distinguishable phenotypes and intrinsic programs that are dependent on gestational time and their microenvironment. At each site, erythroid cells are in intimate contact with other cells (e.g., stromal cells, hematopoietic accessory cells, and extracellular matrix) composing their microenvironment. Within this microenvironment, erythroid development is influenced by cytokines, which are either elaborated by microenvironmental cells or produced elsewhere and then entrapped in the extracellular matrix.

Knowledge of the properties of erythroid progenitor and precursor cells and their complex interactions with the microenvironment is essential for understanding the pathophysiology of erythropoiesis. Aberrations either in the generation and/or amplification of fully mature and functional erythroid cells or in the regulatory influences of microenvironmental cells or their cytokines/chemokines form the basis for various clinical disorders, including aplasias, dysplasias, and neoplasias of the erythroid tissue.

ERYTHROID PROGENITOR CELL COMPARTMENT

The erythroid progenitor cell compartment, situated functionally between the multipotent stem cell and the morphologically distinguishable erythroid precursor cells, contains a spectrum of cells with a parent-to-progeny relationship, all committed to erythroid differentiation. A complete understanding of how erythroid commitment is achieved at the biochemical or molecular level is lacking, although some attempts at determining the molecular basis have been made.[1–4] Evidence from in vitro cultures of single multipotent progenitor cells allowed to differentiate in competent environments as well as evidence obtained by studying the phenotype of leukemic cells suggests that commitment to a specific hematopoietic lineage is accomplished not by acquisition of new genetic information but by restriction (probably on a stochastic basis) to specific programs from a wider repertoire available to pluripotent progenitor cells.[5,6] Molecular evidence supports this view.[6–8] Although all erythroid progenitor cells share the irreversible commitment to express the erythroid phenotype, the properties of these cells progressively diverge as the cells become separated by several divisions.

Erythroid progenitor cells are sparse (Table 25–1) and difficult to isolate in sufficient purity and numbers for study. For these reasons, the existence and characteristics of these cells were inferred from their ability to generate hemoglobinized progeny in vitro in clonal erythroid cultures (Fig. 25–1). Two classes of progenitors have been identified using this approach.[9] The first, more primitive class consists of the burst-forming unit-erythroid (BFU-E), named for the ability of BFU-E to give rise to multiclustered colonies (erythroid bursts) of hemoglobin-containing cells. BFU-E represent the earliest progenitors committed exclusively to erythroid differentiation and a quiescent reserve, with only 10% to 20% in cycle at any given time. However, once stimulated to proliferate in the presence of appropriate cytokines, BFU-E demonstrate a significant proliferative capacity in vitro, giving rise to colonies of 30,000 to 40,000 cells, which become fully hemoglobinized after 2 to 4 weeks, with a peak incidence at 14 to 16 days. They have a limited self-renewal capacity; at least a subset of BFU-E is capable of generating secondary bursts upon replating. In contrast to this class of progenitor cells, a second, more differentiated class of progenitors consists of the colony-forming unit-erythroid (CFU-E). Most (60%–80%) of these progenitors already are in cycle and thus proliferate immediately after initiation of culture, forming erythroid colonies within 7 days. Because CFU-E are more differentiated than BFU-E, they require fewer divisions to generate colonies of hemoglobinized cells, and the colonies are small (8–65 cells per colony).

Although the two classes of committed erythroid progenitors (BFU-E and CFU-E) appear distinct from each other, in reality progenitor cells constitute a continuum, with graded changes in their properties. Only progenitor cells at both ends of the differentiation spectrum have distinct properties. Perhaps the earliest cell with the potential to generate hemoglobinized progeny is an oligopotent progenitor, which is capable of giving rise to mature cells of at least one other lineage (granulocytic, macrophage, or megakaryocytic) in addition to the erythroid. This progenitor, a multilineage colony-forming unit (CFU) called a *colony-forming unit-granulocyte, erythrocyte, macrophage, megakaryocyte* (CFU-GEMM) or *common myeloid progenitor*, and the most primitive BFU-E have physical and functional properties that are shared by both pluripotent stem cells and progenitor cells committed to nonerythroid lineages. These properties include high proliferative potential, low cycling rate, response to a combination of cytokines, and presence of specific surface antigens or surface receptors (Table 25–1). In contrast, the latest CFU-E have many similarities with erythroid precursor cells and little in common with primitive BFU-E. Their proliferative potential is limited, they cannot self-renew, they lack the cell surface antigens common to all early progenitors, and they are exquisitely sensitive to erythropoietin (Epo; Table 25–1).

Although clonal erythroid cultures are indispensable for the study of erythroid progenitors, they do not faithfully reproduce the in vivo kinetics of red cell differentiation/maturation, and many maturing cells have a megaloblastic appearance and lyse before they reach the end stage of red cell development. In vivo, erythropoiesis probably occurs faster than predicted from culture data. For example, studies in dogs with cyclic hematopoiesis, a genetic stem cell defect leading to pulses of hematopoiesis, provide evidence that BFU-E mature to CFU-E over 2 to 3 days in vivo, although this process may require 5 to 6 days in canine marrow cultures.[10]

Erythroid progenitors can be cultured in serum-depleted media[11,12] as well as in serum-containing media. The effects of recombinant growth factors can be studied in serum-depleted cultures without the complicating influences of multiple or unknown factors present in

Table 25–1 Changes in General Properties During Differentiation of Erythroid Progenitors

	CFU-GEMM (CMP)	BFU-E	CFU-E
General Features			
Self-renewal	++	+	0
Differentiation potential	Multipotent	Erythroid committed	Erythroid committed
Cycling status percent suicide with ^{3}H-thymidine	15–20	30–40	60–80

[a]23.6 (SFL 23.6) is a monoclonal antibody reactive with CFU-E, erythroblasts, and erythrocytes.[447]

[b]ABH and iI are blood group antigens.

[c]Presence of other cytoadhesion molecules (i.e., CD31, L-selectin, P-selectin, E-cadherin) has been described in progenitors (see text). However, the extent of their presence in BFU-E compared to other cells is not clear.

BFU-E, burst-forming unit-erythroid; CFU-E, colony-forming unit-erythroid; CFU-GEMM (CMP), colony-forming unit-granulocyte, erythrocyte, macrophage, megakaryocyte (common myeloid progenitor); EKLF, erythroid Kruppel-like factor; Epo, erythropoietin; FL, FLT-3 ligand; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HCAM, homing-associated cyto adhesion molecule; HLA, human leukocyte antigen; IL, interleukin; KL, kit ligand; SCL, stem cell leukemia; TGF, transforming growth factor; TPO, thrombopoietin.

serum. Conditions that imitate lower oxygen pressures, found in bone marrow in vivo, favorably influence erythroid development in culture and may be advantageous.[13]

BFU-E are generated from multipotent or oligopotent progenitors within the marrow, and their survival and proliferation are dependent on the presence of cytokines, elaborated by either stromal cells or accessory cells within the microenvironment. A number of cytokines influence proliferation and/or survival of early progenitors. Among the cytokines, kit ligand (KL), which is produced by stromal cells, and interleukin (IL)-3, which is produced by a subset of T cells, alone and in synergy, have a profound proliferative effect on BFU-E and its progeny. Other cytokines, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-11, and thrombopoietin (TPO), stimulate a subset of BFU-E.[14–16] Cytokines exert their effects through interaction with specific receptors present on the BFU-E surface. The presence of such receptors also has been documented in

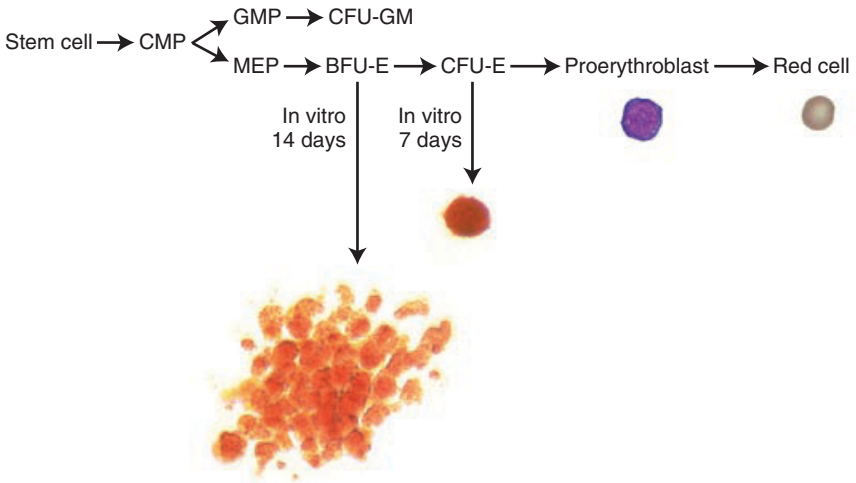

Figure 25–1 Cellular model of erythroid differentiation. Multipotent stem cells generate cellular compartments defined on the basis of their antigenic profile and restricted toward the myeloid differentiation pathway defined common myeloid progenitor (CMP).[64,65] CMP in turn give rise to granulocyte-monocyte progenitor (GMP) and megakaryocyte-erythroid progenitor (MEP), which probably correspond to the burst-forming unit-erythroid (BFU-E). Lastly, MEP generate cells capable of unilineage differentiation toward either the megakaryocytic (colony-forming unit-megakaryocyte [CFU-MK], not shown) or the erythroid pathway (colony-forming unit-erythroid [CFU-E]). These cells occur infrequently in the marrow (approximately 0.3% of mononuclear cells) and are defined on the basis of clonogenic assays. If marrow is placed in semisolid medium (e.g., methylcellulose) to decrease cell motility, with appropriate nutrients and growth factors (e.g., transferrin, insulin, erythropoietin, and interleukin-3), CFU-E (after approximately 7 days) differentiate into small clusters of hemoglobinized or red cells termed *erythroid colonies*. Most BFU-E present in the inoculum differentiate to form multiclustered colonies of hemoglobinized cells, or erythroid bursts, by days 14 to 16. Each erythroid colony or burst derives from one BFU-E or CFU-E, respectively.

the leukemic counterparts of normal BFU-E and in leukemic cell lines.[17] BFU-E in culture cannot survive for more than a few days in the absence of cytokines. If they are deprived of cytokines for more than 6 days, more than 80% of BFU-E are lost.[18] In addition to positive regulators (IL-3, GM-CSF, TPO, KL, and IL-11), substances with negative influences on BFU-E proliferation have been identified. They include tumor necrosis factor α (TNF-α), tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), transforming growth factor β, and interferon γ.[19–21] These negative regulators are responsible, at least in part, for the anemia associated with chronic inflammatory states. The effects of TNF-α and TRAIL are mediated through induction of apoptosis at specific stages of erythroid maturation. In the case of TRAIL, a complex system of signaling and decoy receptor isoforms determines the precise cell window susceptible to TRAIL-induced apoptosis.[21] TRAIL probably induces apoptosis by competing with Epo for activation of Bruton tyrosine kinase. Its effects are counteracted by stem cell factor[22,23] and protein kinase Cε[24] signaling. TRAIL also is involved in determining the anemia associated with multiple myeloma (TRAIL is overproduced by the malignant plasma cells of these patients[25]) and myelodysplastic syndrome (myelodysplastic erythroid progenitors overexpress the adaptor Fas-associated death domain [FADD] of the TRAIL receptor[26]). On the other hand, the negative effects of transforming growth factor β[27] and interferon γ[28] are mainly achieved by accelerating cell differentiation. In addition to the negative growth factors, overexpression of hepcidin, a key regulator of systemic iron homeostasis (see Pathology of iron metabolism[35]), is involved in determining the anemia associated with chronic inflammation.[29] The increased hepcidin synthesis that occurs during inflammation traps iron in macrophages, decreases plasma iron concentrations, and causes iron-restricted erythropoiesis characteristic of the anemia of inflammatory states. Hepcidin deficiency induces iron overload in transgenic mice, whereas hepcidin excess induces iron accumulation in macrophages similar to observations in patients with chronic inflammation.[30] Hepcidin might inhibit proliferation of erythroid progenitors at low Epo concentrations.[31]

BFU-E and immediate progeny (but not CFU-E) are motile cells found in significant numbers in peripheral blood. As with BFU-E, the ability of stem cells and progenitor cells to circulate is physiologically important for the redistribution of marrow cells in cases of local damage to the microenvironment and for reconstitution of hematopoiesis after transplantation. The spectrum of BFU-E in circulation probably is narrower (consisting mostly of early, quiescent BFU-E) than that of BFU-E in the bone marrow; otherwise, their properties are similar to those of marrow BFU-E. The number of circulating BFU-E (along with other progenitors and stem cells) can increase to significant levels after cytokine/chemokine treatments and after chemotherapy, a finding that has been exploited for transplantation purposes.[32] At present, mononuclear cells contained in the blood from subjects mobilized with granulocyte colony-stimulating factor (G-CSF) are routinely used as a source of stem/progenitor cells in autologous and allogeneic transplantation.[33]

In addition to forming colonies in semisolid medium, hematopoietic progenitors from different sources can generate erythroid cells in liquid culture.[34] Liquid cultures do not allow progenitor cell enumeration but may generate more differentiated cells per progenitor cell than do semisolid cultures.[35,36] The number of erythroblasts generated in liquid cultures can be further increased by adding to the media glucocorticoid steroids,[37] which exert a reversible inhibition on proerythroblast maturation.[38,39] Erythroid cells equivalent to one unit of blood can be generated from a quantity of cord blood too small to be stored for transplantation (<50 mL).[40]

Surface antigens of human BFU-E have been defined through the use of monoclonal antibodies.[41,42] The antibodies tested include two broad categories: antibodies raised against leukemic cells or cell lines with progenitor cell properties, and antibodies raised against normal, terminally differentiated red cells. Enrichment in BFU-E (or CFU-E) after labeling with these antibodies, or their loss after complement-dependent lysis, is considered indicative of the presence of test antigens on the BFU-E surface. Reactivities of BFU-E with several antibodies directed against defined surface antigens are listed in Table 25–1. Like other hematopoietic progenitors, BFU-E display human leukocyte antigen (HLA) class I (A, B, C) and class II (DP, DQ, DR) antigens on their surface. Class II antigens (especially the products of the DR locus), in contrast to class I, are variably expressed among BFU-E. This may relate to variations in their cycling status, as myeloid progenitors in S phase have relatively higher expression of class II antigens.[43] The presence of HLA class II antigens (DR and,

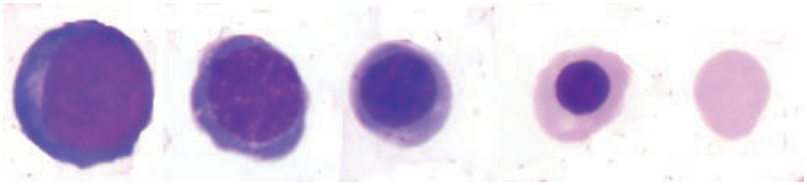

Figure 25–2 Erythroid maturation sequence. As proliferation parameters (i.e., rates of DNA and RNA synthesis) and cell size decrease, accumulation of erythroid-specific proteins (i.e., heme and globin) increases, and the cells adapt their characteristic morphology. (Adapted from Granick S, Levere R: Heme synthesis in erythroid cells. In Moore CV, Brown EB [eds.]: Progress in Hematology, Vol. 4. Orlando, FL, Grune & Stratton, 1964, p 1.[445])

to a lesser extent, DP and DQ) most likely allows BFU-E to recognize and interact with the immunoregulatory cells (e.g., T cells, monocytes), which also express class II determinants.[44] In addition to HLA antigens, several other antigenic structures are found on cells within the BFU-E compartment (Table 25–1). The best representative of these is the CD34 molecule (identified through monoclonal antibodies MY10, 12.8, or HPCA1), which has been successfully exploited for isolation of BFU-E and other progenitors. CD34 is a highly *O*-glycosylated cell surface glycoprotein. It is expressed in all hematopoietic progenitors and vascular endothelial cells.[45] The role of CD34 in hematopoiesis is not clearly defined. The numbers of all hematopoietic progenitors were reduced in CD34 "null" murine embryos and adult animals, but no other abnormalities were identified.[46] Expression of CD34 was low or absent in a population of adult long-term repopulating cells in mouse[47] and in man.[48] However, the clinical significance of this finding is not clear because of the fluctuating expression of CD34[49] and the difference in regulatory mechanisms of CD34 gene expression in mouse and human stem cells.[50] Furthermore, use of antibodies or conjugated ligands determined that BFU-E present in enriched progenitor preparations display receptors for KL, Epo, TPO, GM-CSF, IL-3, IL-6, and IL-11 receptors. However, the majority of BFU-E, in contrast to myeloid progenitors (colony-forming unit granulocyte-macrophage), do not express the restricted hematopoietic phosphatase CD45RA.[51,52] Furthermore, BFU-E appear to share with late colony-forming unit megakaryocyte progenitors the expression of the megakaryocytic receptor c-mpl[52,53] and glycoprotein IIb/IIIa (CD41), a marker of the divergence between definitive hematopoiesis and endothelial cells during development.[54]

As BFU-E mature to the CFU-E stage, they begin to express surface proteins characteristic of erythroblasts, the morphologically recognizable erythroid cells. For example, CFU-E express Rh antigens and the erythroid-specific sialoglycoprotein glycophorin A. Blood group antigens of the ABH Ii type are detectable in a subset of CFU-E. In contrast, CD34 molecules, class II antigens, and certain growth factor receptors (i.e., IL-3R, c-kit) are greatly diminished or virtually absent at the CFU-E stage (Table 25–1). The most important functional difference between BFU-E and CFU-E is the abundance of erythropoietin receptors (EpoRs) on CFU-E and their dependence on Epo for cell survival. CFU-E, in contrast to BFU-E, cannot survive in vitro even for a few hours in the absence of Epo. Although greater than 80% of CFU-E have detectable EpoRs,[55] only a small proportion of BFU-E have receptors[56,57] and can terminally differentiate in culture in the presence of Epo alone.[58] Direct binding studies show that the number of EpoRs peaks at the CFU-E/proerythroblast level and progressively declines when cells mature further (Table 25–1),[55] reflecting the declining influence of Epo. In addition to the abundance of EpoRs, erythroid progenitors are distinguished from other marrow progenitors by the presence of high levels of transferrin receptors (Tfrs).[57,59,60] Peak levels of Tfrs are seen on CFU-E and erythroid precursors, and lower levels are present on reticulocytes.[53,59] (For a detailed review on iron metabolism and heme synthesis in erythroid cells, see references 61–63).

In addition to the functional definition, the hemopoietic compartments in the marrow of a normal adult mouse have been prospectively identified on the basis of expression of specific cell surface antigens and subsequent differentiation in vitro and in vivo.[64] The $Lin^{neg}IL\text{-}7R^{neg}Thy1^{neg}c\text{-}kit^{pos}Sca1^{neg}$ fraction of the marrow of normal adult mice has been subdivided into three populations based on the expression of CD34 and CD16/CD32: $CD16/CD32^{low}$ $CD34^{high}$ representing the common myeloid progenitor, $CD16/CD32^{low}CD34^{low}$ representing the megakaryocyte-erythroid progenitor (MEP), and $CD16/CD32^{high}CD34^{high}$ representing the granulocyte-monocyte progenitor (Fig. 25–1).[64] Many laboratories are prospectively identifying the corresponding human compartments.[65] Whether the correlation between phenotype and function of cells isolated on the basis of these antigenic expression profiles is maintained under conditions of perturbed or stressed erythropoiesis or during ontogenesis remains to be seen.

ERYTHROID PRECURSOR CELL COMPARTMENT

The erythroid precursor cell compartment, also termed the *erythron*, includes cells that, in contrast to the erythroid progenitor cells (BFU-E and CFU-E), are defined by morphologic criteria. The earliest recognizable erythroid cell is the *proerythroblast*, which after four to five mitotic divisions and serial morphologic changes gives rise to mature erythroid cells. Its progeny include *basophilic erythroblasts*, which are the earliest daughter cells, followed by *polychromatophilic* and *orthochromatic erythroblasts*. Their morphologic characteristics reflect the accumulation of erythroid-specific proteins (i.e., hemoglobin) and the decline in nuclear activity (Fig. 25–2). After the last mitotic division, the inactive dense nucleus of the orthochromatic erythroblast moves to one side of the cell and is extruded, encased by a thin cytoplasmic layer. Expelled nuclei are ingested by marrow macrophages, and the resulting enucleated cell is a *reticulocyte*. Although all mammals have enucleated cells in their circulation, the evolutionary advantage of enucleation is not readily apparent. It may allow for more red cell deformability when traveling through the small vasculature, or it may minimize cardiac workload.

Maturation from proerythroblast to reticulocyte likely does not always adhere to a rigid sequence in which each division is associated with the production of two more differentiated and morphologically distinct daughter cells (i.e., basophilic erythroblast gives rise to two polychromatophilic ones). Rather, significant flexibility, both in the number and rate of divisions and in the rate of enucleation, may be allowed. Such deviations from the normal orderly maturation sequence may be dictated by the level of Epo. Thus, in cases of acute demand for red cell production (because of blood loss or hemolysis), the kinetics of formation of new reticulocytes are significantly more rapid. Resulting red cells may be larger (i.e., with increased mean corpuscular volume). This has led to the concept of "skipped" divisions.[66] The orderly unilineage differentiation pathway shown in Fig. 25–1 likely is restricted to conditions of steady-state hematopoiesis. Similar to occurrences in the lymphoid system,[67] alternative routes are taken under conditions of stress. Murine models have been developed to address phenotype–function cell relationships during recovery from acute and chronic erythroid stress. A model for acute stress is represented by the hemolytic anemia induced by phenylhydrazine treatment. Recovery from this acute anemia involves recruitment of the spleen as an additional erythropoietic site and is dependent on Epo. The amount of ^{3}H-thymidine incorporated by splenic erythroblasts produced in response to this stress has long represented the

biologic assay for Epo.[68] Genetic evidence indicates that recovery from this hemolytic anemia is controlled by a receptor complex formed between the EpoR and a truncated version of the Stk receptor encoded by $Fv2^s$, a locus that also determines strain susceptibility to Friend virus infection.[69] An additional control on the response to acute erythroid stress in mice is exerted by the glucocorticoid receptor, as mice in which this receptor is targeted recover poorly from phenylhydrazine treatment.[70] On the other hand, experimentally induced mutations in genes involved in the regulation of erythroid differentiation, such as signal transducer and activator of transcription 5 $(STAT5)^{null}$ [71] and $GATA1^{low}$,[72] induce chronic erythroid stress by increasing the rate of erythroblast apoptosis. The spleen also is recruited as a hemopoietic site in response to chronic erythroid stress.[71,72] Several studies in aggregate suggest that the erythron does not respond to stress only by amplifying the normal erythroid progenitor cell compartments (i.e., common myeloid progenitor, MEP, and CFU-E). The erythron also generates alternative routes of differentiation, possibly through cooperation between EpoR and other receptors (e.g., Stk and glucocorticoid receptor) specifically recruited as part of the stress response.[73,74] Genetic heterogeneity in the control of gene expression of these receptors may add another layer of variability in recovery from anemia in humans.

The alterations in cell morphology that occur as erythroid precursor cells mature (Fig. 25–2) are determined by complex biochemical changes, which accommodate the accumulation of erythroid-specific proteins and the progressive decline in proliferation. Compared to erythroid progenitor cells, erythroid precursor cells have been more accessible to study, and considerable information is available about their maturation-related biochemical changes.

The shape and deformability of the red cell are determined by its membrane proteins. Most membrane cytoskeletal proteins (spectrin, glycophorin, band 3, band 4.1, and ankyrin) accumulate after the CFU-E stage (i.e., within the precursor cell compartment). Specifically, expression of membrane glycoproteins such as band 3 and band 4.1 is greatly enhanced at the later stages of erythroid maturation.[75–77] Likewise, the quantity of polylactosaminoglycan, a specific carbohydrate chain that carries blood group ABH and Ii antigenic determinants, is much higher in mature erythrocytes than in erythroblasts.[78] Whereas a linear, virtually unbranched polylactosamine structure is present in fetal and newborn erythroid cells (reflected by i antigenic reactivity), a branched polylactosaminyl structure is present in adult erythroblasts (reflected by I antigenic reactivity), and branching increases further as maturation progresses.[78,79] A correctly assembled cytoskeleton is important for the deformability and dynamic plasticity of red blood cells in circulation. A new player required for actin assembly in red cells, Rac GTPase, has been identified.[80] Glycophorins, especially glycophorin A, are expressed fully at the CFU-E or proerythroblast level just before expression of globin, and few changes occur during maturation.[42] In contrast, the membrane glycoproteins p105 and p95 decline during the later stages of maturation,[78] and yet other membrane glycoproteins, such as vimentin (an intermediate filament protein), are totally lost.[75] Loss of vimentin expression at the late erythroblastic stages most likely facilitates enucleation. The process of erythroblast enucleation involves chromatin reorganization, as evidenced by separation of the nuclei surrounded by plasma and nuclei extrusion from the cell. The expelled nuclei are picked up by macrophages. Sorting of erythroblast plasma membrane components to reticulocytes is regulated by the degree of skeletal linkage,[81] whereas engulfment of nuclei by macrophages occurs only after the nuclei are disconnected from reticulocytes. Phosphatidylserine, the "eat me" flag for apoptotic cells, is also used for engulfment of nuclei expelled from erythroblasts.[82] The enucleation process is caspase independent[83] and erythroblast macrophage protein dependent.[84] Erythroblast macrophage protein is expressed by erythroblast and macrophage and must be expressed by both populations for proper enucleation to occur.[84] The fact that proper enucleation requires interaction with the macrophages explains the old observation that erythroid differentiation in the marrow occurs in discrete sites, the erythroblastic islands, which are composed of erythroblasts surrounding a central macrophage (see Hematopoietic Microenvironment).

In addition to quantitative changes that occur during maturation, gradual switches in subunit composition of some cytoskeletal proteins occur. For example, exclusively erythroid subunits of α and β spectrin are displayed only in end-stage cells.[46] Likewise, multiple transcripts of ankyrin or protein 4.1 have been identified, and the ratios of these transcripts change during maturation.[85] Initial expression of many of these membrane components likely begins at the progenitor cell level. However, in these cells, final assembly may be discouraged because of the higher turnover of these proteins, which minimizes mutual interactions, or because of asynchrony in protein synthesis. Prevention of cytoskeletal assembly at these early stages may secure more membrane fluidity and cell motility needed during this proliferative phase of differentiation. Because molecular probes for many of the red cell cytoskeletal components have been developed, detailed information about the transcription and processing of most of these proteins is beginning to emerge.[77]

Expression of the majority of genes encoding cytoskeletal components is not restricted to red cells. Dissecting hemopoietic from nonhemopoietic consequences of abnormalities in these genes has been difficult, but the development of mouse models that mimic defects found in human diseases has been helpful in this respect.[86]

Gene activity during erythroid maturation is dominated by globin expression. Globin represents less than 0.1% of protein at the proerythroblast level but constitutes 95% of all protein at the reticulocyte level.[87] Globin expression has been extensively studied, and its gene regulation is well understood in molecular terms. Major steps in globin transcription and processing are known in considerable detail and are summarized elsewhere in this text (Chapter 33). The globin type synthesized by adult precursors is hemoglobin A (HbA; $\alpha_2\beta_2$). In addition, two other minor globin components, HbA_2 ($\alpha_2\delta_2$) and HbF ($\alpha_2\gamma_2$), are present. Of significant biologic interest are the low amounts of HbF that continue to be synthesized throughout life.

The small amount of HbF, which is present in all normal individuals, has the following characteristics.[88] (a) It is confined to a small fraction of red cells, called *F cells*, which are detected by sensitive immunofluorescence assays or acid elution techniques and usually constitute 2% to 5% of all red cells. Within each F cell, HbF or γ globin constitutes 14% to 25% of total globin. (b) The number of F cells is genetically determined, and the gene(s) linked or nonlinked to the β-locus is responsible for F-cell formation. (c) F cells do not display other features of "fetalness" because their membrane components and enzymes are characteristically adult. (e) Synthesis of HbF peaks earlier than that of HbA, so the proportion of HbF is higher in immature cells compared with mature, fully hemoglobinized cells. (e) F cells and cells that contain only HbA are not derived from distinct stem cell populations but from a common adult stem cell. Whether this cell will form F or non–F (i.e., A) cells is determined at the BFU-E level and throughout the CFU-E level. In vitro the great majority of BFU-E have the potential to express HbF, whereas in vivo only a very small proportion of red cells contain HbF. This potential appears to be lost during normal cell differentiation and maturation in vivo. This concept links the potential for HbF expression to the pathway of erythroid differentiation and thus may have implications for interpreting the reactivation of HbF that occurs in adults under diverse circumstances (e.g., after chemotherapy or with acute bleeding).[88] Many of these circumstances seem to influence HbF levels by directly or indirectly modifying the kinetics of the normal differentiation/maturation process.[89,90] HbF levels in red cells can be increased by exposing the cells during maturation to chemical inhibitors of histone deacetylase. This class of enzymes nonspecifically suppresses gene transcription by catalyzing histone deacetylation and, consequently, chromatin condensation.[91] Therefore, they can directly activate transcription of γ-globin genes in vitro and in vivo[92–94] and in a number of patients with β-thalassemia.[95,96]

Synthesis of globin appears to be coordinated with synthesis of heme throughout erythroid maturation so that functional hemoglobin tetramers are formed rapidly and spontaneously after release of newly synthesized globins from polysomes. Information about the accumulation of heme and its synthetic intermediaries has been provided by crude biochemical approaches (Fig. 25–2). However, now

that the genes for several enzymes in the heme synthetic pathway (e.g., δ-aminolevulinic acid synthetase, porphobilinogen deaminase, and heme synthetase) have been cloned, information about their regulation is rapidly emerging.[61,63]

An important role in coordinating heme and globin chain assembly during hemoglobin production is exerted by alpha hemoglobin-stabilizing protein (AHSP). AHSP is a protein abundantly expressed in erythroid cells[97] whose function is to bind free α-chains, stabilizing their structure and limiting their ability to participate in chemical reactions that generate reactive oxygen species.[98,99] In addition, AHSP binding increases the affinity of α-chains for β-chains, accelerating the formation of Hb tetramers. The essential role exerted by this gene in erythroid development has been demonstrated by the fact that its deletion in normal mice impairs red cell production. AHSP^{null} red cells have a decreased half-life, contain Hb precipitates, and exhibit signs of oxidative damage.[97] The observation that double AHSP^{null} β-thalassemic mutant mice have an exacerbated phenotype[100] suggests that AHSP is a gene modifier that, like the hereditary persistence of HbF mutations, ameliorates the phenotype of thalassemic patients. However, the search for AHSP polymorphisms that might correlate with milder clinical phenotypes in thalassemia has not provided consistent results. Gene mapping, direct genomic sequencing, and extended haplotype analysis did not reveal any mutation or specific association between haplotypes of AHSP in 120 β-thalassemic patients.[101] On the other hand, a polymorphism in the putative AHSP promoter leading to a threefold higher expression of the gene in reticulocytes was observed in the normal population,[102] but any clinical consequences are unknown.

Crucial to the functional response of erythroid precursors is the expression of EpoRs and Tfrs. EpoRs decrease progressively (from approximately 1000 to <300 receptors per cell) as proerythroblasts mature, and they are undetectable at the reticulocyte level.[55,103] Through these receptors, Epo exerts its proliferative influence on proerythroblasts and basophilic erythroblasts, but maturation beyond these stages can proceed in the absence of Epo.

Tfrs are found in characteristic abundance in erythroid cells (300,000–800,000 Tfrs per cell).[104] This composition reflects not only the proliferative needs of erythroid cells but also their extreme requirements for iron uptake for hemoglobin synthesis. For this reason, Tfrs persist in maturing nondividing erythroblasts and in reticulocytes. Tfrs belong to a large group of receptors that internalize their ligand through receptor-mediated endocytosis. This cycle allows for reuse both of the ligand (transferrin) for resaturation with iron and of the receptor for entering an another route of endocytosis.[105] Tfr density decreases with maturation. After the reticulocyte stage, receptors appear to be shed as small lipid vesicles.[106] An inverse relationship exists between receptor density and iron availability. Deprivation of iron results in receptor induction, and excess iron results in receptor suppression.[105] However, the mechanisms that regulate the number of Tfrs throughout the maturation of precursors (even within progenitors) are largely unknown. Erythroid precursor cells differ from nonerythroid cells not only by requiring a higher number and higher occupancy of Tfrs. They also display immunologically distinct receptor isoforms.[60] A second gene for transferrin receptor (TfR2) has been identified,[107] and monoclonal antibodies recognizing distinct receptor isoforms are useful in isolating erythroid cells from bone marrow.[60,108] TfR1 and TfR2 are members of a family of genes encoding at least seven different homologous proteins in primates.[109] TfR1 is a type II membrane glycoprotein that, as a cell surface homodimer, binds iron-loaded transferrin as part of the process of iron transfer and uptake. TfR2 is expressed in two forms—membrane-bound (TfR2-α) and nonmembrane (TfR2-β)—both of which bind transferrin with low affinity. The specific role of TfR2 in hematopoietic cells is unclear. In cells from 67 patients with de novo acute myeloid leukemia (AML), high levels of TfR2-α expression were correlated with better prognosis, and higher levels of both TfR2-α and TfR2-β were associated with longer survival, suggesting that Tfr-independent iron uptake plays a role in in vivo proliferation of AML cells.[110] TfR2 plays its most prominent role in the liver[111] as the key regulator of iron metabolism. Maintenance of stable extracellular iron concentrations requires the coordinate regulation of iron transport into plasma from dietary sources in the duodenum, recycled senescent red cells in macrophages, and storage in hepatocytes. Diferric transferrin is detected in the liver via a complex machinery involving the product of the hereditary hemochromatosis gene HFE (a protein of the major histocompatibility complex class I), TfR2, and the product of the hemojuvelin (HJV) gene (also known as HFE2). Given that the levels of TfR2 expression are exclusively regulated by holotransferrin, TfR2 expressed by hepatocytes likely is the first element of the iron sensory pathway in the liver.[112] Hepatocytes respond to iron sensoring by modulating hepcidin expression and secretion. Hepcidin, a 25-amino-acid disulfide-rich peptide, acts as a systemic iron regulatory hormone that regulates both dietary iron adsorption by the enterocytes and iron recycling by the macrophages. Because ferroportin shuttles iron from the enterocytes to the macrophages and hepcidin is required for ferroportin internalization and degradation, decreased hepcidin expression blocks iron export in the two cell types.[113] Each gene involved in iron metabolism has a role in regulating the expression of the other genes. In particular, reduced expression of HEF, TfR2, and HJV reduces expression of hepcidin. It is not surprising, then, that mutations altering the function of all of these genes have been found associated with hereditary hemochromatosis. The most prevalent form of familial hematochromatosis (type 1; HFE1) involves mutations in HFE.[114] Most families with juvenile hemochromatosis (HFE2) have mutations in the HJV gene.[115] Homozygous nonsense[116] and single-point mutations causing methionine→lysine substitution at position 172 of the protein M172K[117] have been detected in the gene encoding TfR2 in patients with familial hemochromatosis HFE3. Autosomal dominant iron overload is associated with previously unrecognized ferroportin 1 mutations (p.R88T and p.I180T)[118] and with mutations in the divalent metal transporter 1 gene DMT1, which mediates apical iron uptake in duodenal enterocytes and iron transfer from the Tfr endosomal cycle into the cytosol in erythroid cells.[119] The observation that targeted deletions of any of these genes (including TfR2) induce a hematochromatosis-like syndrome in mice provides proof of direct involvement of the mutations in disease development.[120–123] On the other hand, the finding that hepcidin is a gene modifier of the HEF^{null} mouse model of hemochromatosis suggests that heterogeneity at the hepcidin locus mediates the low penetrance of the genetic disease.[124] In addition to its role in determining the pathobiology of hereditary hemochromatosis, hepcidin plays an important role in determining the anemia of chronic diseases. Based on the central involvement of hepcidin in iron regulation and its pathologies, a hepcidin assay has been proposed as a useful tool for diagnosing iron disorders and monitoring their treatment. On the other hand, development of hepcidin agonists and antagonists may provide useful therapeutics for treatment of iron disorders.[125]

The patterns of Tfr and glycophorin A expression during erythroid maturation have been exploited to define flow cytometric criteria that distinguish the different populations of erythroid precursors in mice and men. By coupling size and forward scatter (both progressively reduced) with CD71 (Tfr) and TER-119 (an antibody that recognizes an antigen associated with glycophorin A[126] expression), erythroid precursors were divided into the classes TER-119^{med} CD71^{high}, TER-119^{high}CD71^{high}, TER-119^{high}CD71^{med}, and TER-119^{high}CD71^{low}, which correspond to proerythroblasts and basophilic, chromatophilic, and orthochromatophilic erythroblasts, respectively.[71] However, such distinction is not conserved in all mouse strains. For example, in C57Bl/6 mice, CD71 expression levels remain constant during maturation.[127] Double CD71/glycophorin A staining has been proposed to define human erythroblast precursors by flow cytometry. However, the pattern of CD71 expression during erythroid maturation presents a high level of donor variability. Given that downmodulation of CD36 expression during erythroid maturation is relatively independent of genetic variability, an alternative flow cytometric definition of erythroblast subclasses is proposed by the phenotype CD36^{high}/glycophorin A^{medium}, CD36^{high}/glycophorin A^{high}, and CD36^{low}/glycophorin A^{high}, corresponding to basophilic, polychromatic, and orthochromatic erythroblasts, respectively.[128]

ERYTHROPOIETIN AND EPO-R

Epo, a 35-kd glycoprotein,[129] is the physiologically obligatory growth factor for erythroid development. It is produced mainly in the kidney by peritubular cells.[130] A heme-containing protein senses oxygen need and then triggers the synthesis of Epo and its release into the bloodstream.[131,132] Through the interaction of Epo with receptor-bearing cells within the bone marrow, physiologic oxygen demands are translated into increased red cell production. Thus, Epo is a true hormone, manufactured at one anatomic site and transported through the bloodstream to the site of activity.

According to the prevailing model of hematopoiesis, progenitor cells committed to erythroid differentiation (i.e., BFU-E) are generated in a stochastic fashion from pluripotent stem cells.[4,5] Neither Epo nor other lineage-restricted regulators play any role in determining lineage commitment. According to this model, Epo influences erythroid differentiation by rescuing (from apoptosis) cells that express EpoR and amplifying them further. Whether EpoRs are present on all BFU-E (detectable only in a subset of BFU-E) is not clear.[56] Thus, whether the presence of EpoR in BFU-E is synchronous with the initial commitment event or follows it is not known. In addition to the permissive role of Epo ascribed by the stochastic theory, experiments in vivo, in anemic states, or after pharmacologic doses of Epo suggest that high levels of Epo hasten the transition from BFU-E to hemoglobin-synthesizing cells by decreasing either the number of divisions required for this transition[66] or the resting periods between cell divisions.[133] Autoradiographic studies of purified BFU-E populations indicate that EpoRs increase as BFU-E mature to CFU-E, with the highest level observed at the CFU-E/proerythroblast boundary.[56] That the transition from BFU-E to CFU-E occurs under the influence of Epo suggests ligand (Epo)-induced receptor upregulation. Whether the magnitude of such upregulation is dependent on Epo dose and whether it can modulate the rate of entry of these cells into the maturing compartment is unclear.

BFU-E and CFU-E can be generated in vitro[134] and in vivo,[135] in the absence of Epo or EpoR (in Epo or $EpoR^{null}$ mice), but their survival and terminal maturation normally are dependent on Epo. For CFU-E, Epo seems to stimulate all the biochemical processes characterizing erythroid cells (i.e., heme synthesis, globin synthesis, and synthesis of cytoskeletal proteins). However, the necessity of Epo in these processes is not absolute. In vitro experiments showing complete maturation of BFU-E in the absence of Epo suggest that other factors or combinations of factors can influence red cell maturation. Activation of the gp130 signaling pathway by use of soluble IL-6 receptor and IL-6 leads to full terminal erythroid maturation (in the presence of stem cell factor and IL-3 but in the absence of Epo), suggesting some form of cross-circuiting in signaling pathways among hematopoietic growth factor receptors.[136,137] Furthermore, stimulation by TPO of erythroid colony formation from yolk sac cells in the absence of EpoR (in $EpoR^{-/-}$ embryos)[138] can be explained by the same reasoning and the finding of a very high proportion of bipotent erythroid/megakaryocytic progenitors in yolk sac carrying both Epo and TPO receptors (c-mpl) compared to adult bone marrow.[139–141]

Whatever the precise mode of Epo action, it directly affects the number of CFU-E and the maturation of their progeny. This control is achieved by influencing CFU-E survival and not their cycling status.[142] CFU-E are irrevocably lost after one cycle of DNA synthesis if Epo is not present.[143]

With the availability of radiolabeled recombinant Epo and purified or enriched populations of progenitors and precursors has come information about the characteristics of EpoRs in erythroid cells. Direct binding studies have shown that a progressive decrease in the number of EpoRs as CFU-E and proerythroblasts mature to reticulocytes.[56,57,103] Pure reticulocyte populations show no detectable binding to Epo. The maturation-associated decline in the number of EpoRs parallels the declining influence of Epo on erythroid cells during the terminal phase of maturation. The exquisite role of Epo in determining red cell numbers in the circulation has been clearly established by direct correlations between hematocrit and Epo plasma concentrations in individuals exposed to hypoxia and in patients with compromised kidney functions.[144] However, the variabilities around the mean of hematocrit and Epo plasma levels found in normal individuals under steady-state conditions are not correlated, indicating that other factors (sex and age) cooperate with Epo in determining the fluctuations in red cell mass under steady-state hematopoiesis.[145]

Cloning and expression of EpoR has allowed a better understanding of the role of Epo in the regulation of erythroid development. The EpoR polypeptide is a 66-kd membrane protein that is a member of the cytokine receptor superfamily.[146,147] Many of the structural features of the cell surface EpoR have been previously reviewed.[148] Like other members of the cytokine receptor superfamily, which includes the receptors for IL-3, GM-CSF, and IL-5, the EpoR polypeptide contains four conserved cysteine residues and a WSXWS motif in the extracellular region. Additional extracytoplasmic sequences of EpoR determine the specificity for Epo binding. The cytoplasmic region of EpoR does not contain a tyrosine kinase catalytic domain; instead it interacts with cytoplasmic tyrosine kinases. Cross-linking of radiolabeled Epo to cell surface EpoR results in formation of at least two major cross-linked protein complexes of 140 and 120 kd.[149] The molecular composition of these complexes remains unsolved but suggests that EpoR contains additional subunits or accessory proteins.[150] The extracytoplasmic region of the EpoR polypeptide contains the Epo binding activity of the receptor.[151–153] Therefore, additional EpoR subunits may provide other structural and functional elements of the receptor but are not required for high-affinity Epo binding. The extracytoplasmic region of the EpoR polypeptide has been crystalized.[154–156] The crystal structure confirms the dimeric structure of the activated receptor. Interestingly, small synthetic peptides are capable of inducing EpoR dimerization, suggesting a profitable avenue for Epo-mimetic and Epo-antagonist drug design.[157] Epo-mimetic agents are represented by polypeptides restricted to the portion of the protein that binds the receptor, by forms of the protein molecularly engineered to increase its glycosylation state and therefore its stability in vivo, or by dimeric forms of proteins obtained by genetic introduction of bridging sites or chemical cross-linking.[158] It also is possible that nonpeptide chemicals sharing the same stereo and electric properties of the receptor binding domain of the protein might be identified. As shown for carbamylated Epo, modified isoforms may have biologic activity partially different from, and possible more effective than, the native protein,[159] especially with regard to the activity of the growth factor in nonhematopoietic tissues.[160]

EpoR mRNA, originally isolated from murine erythroblast cell lines (MEL and HCD57)[129] and from a human erythroid cell line (OCIM1),[161] has been found in nonerythroid cells as well. Epo promotes the differentiation of megakaryocytes at physiologic concentrations of hormone, suggesting that megakaryocytes have functional cell surface EpoRs. Rat and mouse placenta also have cell surface EpoR, detected by radiolabeled Epo cross-linking. Epo promotes a chemotactic effect on endothelial cells,[162,163] suggesting the presence of a cell surface receptor in these cells. Other studies suggest that EpoR is expressed in neural cells[164] and smooth muscle cells.[165] Adverse effects in cancer patients treated with Epo have been attributed to the effects of Epo on tumor cells.[166] The functional importance of EpoR expression in nonerythroid cells has been revealed by rescue experiments in $EpoR^{null}$ mice.[167] As $EpoR^{null}$ mutant mice die of severe anemia between days 13 and 15 of embryonic development, the mutant embryos are rescued by transgenic expression of EpoR under the control of the hemopoietic-specific GATA1 regulatory domain. Under steady-state conditions, the rescued animals are normal, as the gene is expressed only in erythroid cells. However, in comparison with normal mice, the increase in plasma Epo concentration in response to induced anemia was delayed in the rescued animals, suggesting that one of the major functions of EpoR expression in nonerythroid cells is fine tuning the regulation of the response to stress (see Alterations in EPOR and its Signalling in Disorders of Erythropoiesis).[167]

The existence of naturally occurring splice variants of the EpoR gene encoding EpoR polypeptides of variable length and activity has

been shown.[168–171] The soluble secreted form of EpoR[172] binds Epo and thereby competes with the cell surface receptor isoform. The biologic function of alternative forms of the cell surface EpoR, including a truncated form of EpoR found in early progenitors,[173] remains unknown but may be related either to differential Epo signaling and responses (survival, proliferation, differentiation) at different stages in erythroid development or to the establishment of erythroid-specific versus myeloid-specific niches in the marrow microenvironment.

SIGNAL TRANSDUCTION BY EPO-R

Considerable progress has been made in our understanding of EpoR-mediated signal transduction. Early studies demonstrated that stimulation of EpoR on primary erythroid cells resulted in increased calcium ion flux and increased globin mRNA synthesis.[174] Since the cloning of the EpoR polypeptide and its stable expression in heterologous cell systems, such as the Ba/F3 cell system,[175] considerable molecular insight has been gained.[176] For instance, it now is clear that Epo induces homodimerization of the EpoR polypeptide.[177,178] Following receptor dimerization at the cell surface, a series of tyrosine phosphorylation events occurs, resulting in a mitogenic signal and a differentiative signal.[179,180] Initial studies of the EpoR signal transduction pathway made use of mutant forms of EpoR stably expressed in the indicator cell line Ba/F3. Ba/F3 cells are a murine IL-3–dependent pro–B-lymphocyte cell line. These cells can be readily transfected with the cDNA for EpoR, resulting in stable expression of the receptor on the cell surface. Expression of the full-length, wild-type EpoR polypeptide in these cells resulted in Epo-dependent growth and partial Epo-induced erythroid differentiation.[179,180] Expression of truncated forms of the EpoR polypeptide in these cells resulted in variable growth responses. For instance, truncation of the membrane proximal region of EpoR demonstrated a critical positive regulatory domain of EpoR required for mitogenesis.[175] Furthermore, truncation of the carboxy-terminal 40 amino acids of EpoR resulted in increased Epo-dependent growth, suggesting that the carboxy-terminal region contained a negative regulatory domain normally required for downmodulating EpoR mitogenic signals.[175]

The biochemical basis for these positive and negative regulatory domains has been elucidated. The membrane proximal positive regulatory region of EpoR binds constitutively to Janus kinase 2 (Jak2),[181] a cytoplasmic tyrosine kinase necessary for erythroid differentiation, as evidenced by mice lacking the corresponding gene dying at an early embryonic stage.[182] Upon Epo binding to the receptor, the receptor dimerizes, resulting in activation of prebound Jak2. The Jak2 next tyrosine phosphorylates multiple signaling proteins in the cell, leading to various mitogenic and differentiative responses. The negative regulatory domain of EpoR is required for recruiting the phosphatase SHP1 to EpoR.[183] SHP1 binds to an activated tyrosine phosphate on the EpoR polypeptide and rapidly downregulates Jak2 activity and dephosphorylates the EpoR polypeptide. Failure to recruit the SHP1 phosphatase can result in increased EpoR signaling and a polycythemic state (see Alterations in ERO-R and its Signalling in Disorders of Erythropoiesis).

Jak2 is required for appropriate Golgi processing and cell surface expression of EpoR.[184] Once activated by Epo/EpoR binding on the cell surface, Jak2 initiates several events in EpoR-mediated signal transduction. Jak2 initially activates tyrosine phosphorylation of several tyrosine residues of the cytoplasmic tail of EpoR. These phosphorylated tyrosine residues next serve as docking sites for binding of other cytoplasmic effector proteins containing Src homology 2 (SH2) domains, such as the p85 subunit of phosphatidylinositol 3-kinase,[185] the adaptor protein *Shc*,[186,187] and STAT5.[188,189] (Examples of signal transduction proteins expressed in primary human erythroblasts are given in Table 25–2). Once these proteins have docked on EpoR, they become tyrosine phosphorylated and engage other downstream signaling events. In addition, Jak2 activates the Ras/Raf/MAPK (mitogen-activated protein kinase) pathway, further contributing to the Epo-induced mitogenic signal.[190,191] The molecular mechanism of Ras activation by Jak2 remains unknown but may entail direct binding of the proteins and tyrosine phosphorylation.[191]

Activation of the Jak2/STAT5 signaling pathway has been studied in considerable detail. Upon EpoR tyrosine phosphorylation, STAT5 protein binds to a specific phosphorylated tyrosine residue of the EpoR.[188,192] Binding is mediated by the SH2 domain of STAT5. Following EpoR binding, STAT5 itself becomes tyrosine phosphorylated at amino acid Y694.[193] Activated STAT5 then disengages from EpoR, undergoes homodimerization, and translocates to the cell nucleus, where it activates transcription of Epo-inducible genes. Some Epo-inducible genes, such as *myc* and *fos,* are common to other hematopoietic growth factor signaling pathways. Other Epo-inducible genes are specifically expressed in erythroid cells and are not shared by other growth factor responses.[194]

Other signal transduction pathways downstream from cytokine receptors have been identified. For instance, Epo and IL-3 activate tyrosine phosphorylation of the signaling protein cbl and the subsequent binding and tyrosine phosphorylation of the signal protein CrkL.[195] The mechanism of activation of this pathway by EpoR is not known, and the relative role of this pathway in Epo-induced growth and erythroid differentiation remains largely unexplored. Inositide-specific phospholipases C (PLCs) and the protein kinase C (PKC) pathway also are involved in Epo signaling. PLCs catalyze hydrolysis of phosphatidylinositol 4,5-bisphosphate to generate diacylglycerol and inositol 3,4,5-bisphosphate, a well-known intracellular messenger for PKC activation and intracellular Ca^{2+} mobilization. PLCs are classified into four isoform families (α, β, γ, and δ), and each family has multiple isoforms.[196,197] The involvement of PLCs in erythroid differentiation was suggested by early studies demonstrating that stimulation of EpoR in primary erythroid cells results in increased calcium ion flux.[174] More recent studies demonstrated that primary erythroblasts express only some (i.e., PLC β_1, β_2, β_3, δ_1, γ_1 and γ_2) PLC isoforms. Among these, PLC β_1 most likely is involved in Epo signaling, based on findings that its expression is induced by 6 hours of stimulation with the growth factor.[22,128,198] On the other hand, PKC represents a family of nine different serine-threonine kinases genes, encoding a total of 12 different isoforms, involved in the regulation of many cellular functions.[199] These enzymes exert their biologic functions as a cytoplasmic–nuclear shuttle of the transduction machinery and become phosphorylated, and hence activated, in response to a variety of stimuli. Human multipotent $CD34^+$ progenitor cells express all of the PKC isoforms.[200,201] Commitment of these cells along the erythroid lineage requires suppression of PKCε.[200,202] PKCα exerts a positive control on erythropoiesis, as its inhibitors specifically impair the ability of erythroid cells to respond to Epo[203] and to phosphorylate EpoR, STAT5, GAB1, ERK1/2, and AKT.[204] It also is possible that different PKC isoforms are active at different ontogenic stages, as PKCα and PKCδ are differentially phosphorylated, and hence activated, during differentiation of neonatal and adult erythroblasts.[205]

A critical question in the field of EpoR signal transduction is the mechanism of Epo specificity. Most, if not all, of the signal transduction pathways activated by EpoR (i.e., Ras/Raf/MAPK and Jak/STAT) are shared by other hematopoietic cytokine receptors, such as the receptors for IL-3, GM-CSF, and IL-5. How EpoR triggers a specific growth factor response resulting in erythroid differentiation is unclear. Several models are possible. First, EpoR may activate unique but unknown signaling pathways specific to EpoR and distinct from other cytokine receptors. Alternatively, EpoR may activate identical pathways, activated by other cytokine receptors. In the latter model, the specificity of the Epo signal is derived not from EpoR itself but from interactions with other developmentally programmed events in the erythroid cell, such as expression of erythroid-specific transcription factors.

Activation of EpoR in the murine IL-3–dependent cell line Ba/F3 results in induction of both mitogenesis and β-globin accumulation.[103] In contrast, the murine IL-2–dependent cell line CTLL-2, when engineered to express the heterologous EpoR, grows in Epo but does not differentiate into globin-bearing cells. These data suggest

Table 25–2 Major Transcription Factors/Signaling Molecules Involved in Control of Erythropoiesis

Transcription Factor	Binding Motif	Role in Hematopoiesis	Knockout Phenotype	Mutations/Human Disease
GATA1	(A/T)GATA(A/G)	↑Erythroid differentiation	• No terminal erythropoiesis • Arrest in megakaryocyte development (with hyperproliferation)	• X-linked thalassemia/ thrombocytopenia • Leukemia (Down syndrome)
GATA2	(A/T)GATA(A/G)	↑Proliferation ↓Differentiation	↓Proliferative expansion of primitive and definitive erythropoiesis Absence of mast cells	
FOG1	None	GATA1 cofactor	↓Erythroid maturation Block in megakaryocytopoiesis	
EKLF	CACCC	Promotes terminal erythroid differentiation	Severe anemia β-globin deficiency	β-Thalassemia
SCL	CANNTG (E box)	Specification of hematopoiesis	Absence of prenatal hematopoiesis ↓Erythro/Mk in adults	Translocation in T-ALL
LMO2	LIM domain		Absence of hematopoiesis	T-cell ALL
Myb	(T/C)AAC(G/T)G	↓Definitive erythropoiesis	Block in definitive erythropoiesis	
Fli-1	Winged helix–turn helix	Inhibition of GATA1 expression		
BKLF	CACC		Myeloproliferative disorder	
SHP-1 (BKLF activated?)				Erythroleukemia Polycythemia vera
STAT5	GAS		Transient fetal anemia due to apoptosis of erythroid progenitors Mild anemia exacerbated by stress in adult life	
PU.1	GGAA	↓Erythropoiesis	Absence of myelomonocytic differentiation	
Id		Blocks terminal differentiation of all cell types		
IaPI-3 kinase (p85)		↓Proliferation/differentiation	↓Fetal erythropoiesis Perinatal death	
Gfi-1B	Zinc finger domain	↑Proliferation (↑GATA2)		
Sp3			↓Fetal erythropoiesis Perinatal death	
NF-E2	TGAGTCA	Promotes terminal erythroid differentiation in vitro	Thrombocytopenia Absence of erythroid abnormalities (?)	

BKLF, basic Kruppel-like factor; FOG1, friend of GATA1; LMO2, LIM domain only 2. ALL: acute lymphoblastic Leukemia; ↓ erythro/μg: Decrease in erythropoiesis/megakaryocytopoiesis

that expression of EpoR is necessary for erythroid differentiation but is not sufficient alone. Other erythroid-specific markers, such as GATA1 and NF-E2, or erythroid Kruppel-like factor (EKLF), likely are required for cells to differentiate down the erythroid pathway. Other cytokine receptors, such as IL-3R and IL-2R, do not drive β-globin synthesis in these cell lines. Taken together, these results suggest that EpoR generates a differentiation-specific signaling within the context of a proper transcriptional environment.

Regardless of the mechanism of cytokine specificity, each cytokine receptor activates a similar but not identical pattern of signaling events. For instance, EpoR shows a preferential activation of the Jak2/STAT5 pathway in cultured erythroid cells in vitro. In contrast, the IL-2 receptor shows preferential activation of the Jak1/Jak3/STAT6 pathway.[193,206,207] Interestingly, although Epo activates STAT5a and STAT5b in cultured cells, knock-out of the STAT5a or STAT5b gene by homologous recombination results in a mouse phenotype with slightly impaired stem cell activity but apparently normal erythroid development.[208,209] More extensive analysis of this phenotype has revealed that the mice experience increased apoptotic rates at erythroblast levels that are compensated by a cellular compensatory mechanism very similar to that described for GATA1^{low} mutants,[71] involving expansion of hemopoietic progenitors in the marrow and recruitment of the spleen as an additional hemopoietic site. These results suggest that, in vivo, other STAT proteins are at least partially capable of substituting for STAT5 and functioning downstream of the EpoR. These findings emphasize the importance of in vivo studies in confirming the phenotypic relevance of in vitro studies.

Studies have suggested that Epo functions synergistically with other multilineage growth factors, such as KL and IL-3. As discussed in Erythroid Precursor Cell Compartment section, Epo and KL function together, resulting in increased erythroid colony cell growth in methylcellulose culture. Studies with the EpoR polypeptide suggest a molecular mechanism for such synergy.[210] Activation of the kit

receptor by KL results in transphosphorylation of EpoR at the cell surface. A direct interaction between EpoR and the kit receptor has been demonstrated.[211] Physical interaction between EpoR and the β common chain of the IL-3 receptor in erythroid cells has been demonstrated.[212] This interaction might be involved in the neuroprotective action exerted by Epo.[213] In fact, a carbamylated derivative of Epo prevents motoneuron degeneration in vitro and in vivo[213] and ameliorates recovery from several in vivo models of brain and heart injuries, such as chronic autoimmunoencephalomyelitis in mice,[214] radiosurgery- or ischemia-induced brain injury,[215] and myocardium ischemia–reperfusion injury[216] in rats. (For a review of the nonhematopoietic activity of Epo, see reference 217.) Taken together, these results suggest that receptor cross-talk at the cell surface may account, at least in part, for the physiologic interaction of some cytokines in controlling hematopoietic versus nonhematopoietic effects of Epo.

ALTERATIONS IN EPO-R AND ITS SIGNALLING IN DISORDERS OF ERYTHROPOIESIS

As discussed earlier in the section of Erythropoietion and EPO-R, the normal role of Epo is to stimulate cell surface EpoR in developing erythroid cells. The latter cells respond to Epo via a proliferative and differentiation response. Epo-activated signal transduction of EpoR is quickly downregulated in the cell, and continuing presence of Epo is required for optimal differentiation.

In some cells, the EpoR may become constitutively activated. In these cases, erythroid progenitor cells are placed into a sustained proliferative state. Interestingly, these mechanisms underlie several murine and human examples of erythrocytosis (erythroid overproduction). Multiple mechanisms exist by which EpoR may become constitutively activated. First, the Friend spleen focus-forming virus of the Friend erythroleukemia complex encodes the glycoprotein F-gp55, which binds and activates murine EpoR.[218–220] F-gp55 appears to bind to EpoR via its transmembrane region. Epo and F-gp55 binding sites are discrete; tertiary complexes of EpoR, Epo, and F-gp55 have been detected on the surface of Friend virus–infected cells.[221] Second, EpoR can be constitutively activated by a point mutation (R129C) in the extracytoplasmic region of the polypeptide.[222] This mutation occurs in the "dimerization domain" of EpoR and results in constitutive homodimerization of the EpoR polypeptide, presumably through a disulfide bond. This mutation further underscores the importance of receptor dimerization in the initiation of a receptor signaling response. Third, EpoR can be constitutively activated in an autocrine manner. Murine erythroleukemia cell lines have been established that coexpress EpoR and Epo. A fourth mechanism of EpoR constitutive activation results from EpoR overexpression. For instance, some murine erythroleukemia cell lines have increased EpoR mRNA, resulting from spleen focus-forming virus proviral integration within the first intron of the murine EpoR gene.[223] Overexpression of the normal murine EpoR polypeptide may thereby contribute to oncogenesis.

Soon after the cDNA of mouse and human EpoR were cloned, the mouse and human genomic structures were identified. The gene for mouse EpoR was found to map to mouse chromosome 9,[224] whereas the human gene was found on human chromosome 19p.[225] Mapping of the EpoR genes led to their implication in various human disease states. For instance, studies demonstrated that a chromosomal breakpoint 3′ to the human EpoR gene results in increased EpoR expression.[226] The rearranged EpoR allele appears to encode a mutated EpoR polypeptide with increased activity, perhaps secondary to loss of the carboxy-terminal negative regulatory domain.

EpoR plays a role in the rare congenital disease familial erythrocytosis. Familial erythrocytosis is a heterogeneous group of hereditary conditions characterized by an increase in red blood cell mass in the setting of low serum Epo levels. A few families that demonstrate autosomal dominant inheritance have been identified.[227] The linkage between the EpoR gene and familial erythrocytosis was first established by the observation that a mutant EpoR allele segregates with the disease in one familial erythrocytosis kindred. This allele contains a nonsense mutation in the coding region of the gene that results in synthesis of a truncated EpoR that lacks the negative regulatory domain of its carboxy-terminal region.[228,229] Since that report, several other frameshift and deletion EpoR gene mutations, all encoding carboxy-terminal–truncated forms of the protein providing Epo hypersensitivity and resulting in familial erythrocytosis, have been reported.[230–234]

Congenital polycythemia may arise not only from gene mutations leading to abnormal Epo/R signaling but also from gene mutations altering Epo production. The T598T mutation in one of the genes controlling oxygen sensoring (von Hippel–Lindau [VHL] gene), which leads to increased Epo production by the kidney, is associated with congenital erythrocytosis, the Chuvash polycythemia.[235,236] The C598T VHL mutation is endemic in Chuvashia, Russia, Federation, and in the small island of Ischia, in southern Italy. The frequency of the mutation on this small island is higher than in Chuvashia (0.07% vs 0.02%), but the haplotype of Italian patients matches that identified in the Chuvash cluster, supporting a single-founder hypothesis.[237]

Acquired mutations in the EpoR signaling pathway have been identified in polycythemia vera (PV), essential thrombocythemia, and idiopathic myelofibrosis, a class of myeloproliferative disorders that do not present the Philadelphia chromosome abnormality (Ph) and, therefore, cannot be cured with inhibitors, such as Gleevec, which are specific for the signaling pathway altered by the Ph abnormality. These diseases originate at the level of the pluripotent hematopoietic stem cell and are characterized by proliferation of one or more of the myeloid lineages but relatively normal hematopoietic cell maturation (see Hematologic Malignancis). Several investigators have reported a mutation in the Jak2 gene resulting in a valine→phenylalanine substitution at position 617 of the protein (^{V617F}Jak2 mutation) in patients with Ph-negative chronic proliferative disorders.[238–241] Since the early reports, the presence of ^{V617F}Jak2 in patients with Ph-negative myeloproliferative disorders has been confirmed by numerous publications. Depending on the study, ^{V617F}Jak2 has been reported in 60% to 90% of patients with PV, 30% to 50% of patients with essential thrombocythemia, and 30% to 60% of patients with idiopathic myelofibrosis. The mutation is harbored at either the heterozygous or, by somatic recombination, the homozygous stage. It is detectable in all myeloid cells up to the clonal hematopoietic stem cells.[242] The mutation affects the domain of the protein that is directly involved in signal transduction but is necessary to return the protein to its resting configuration after signaling. As a consequence, after its first engagement with Epo, EpoR signaling becomes constitutively activated. Because Jak2 is the earliest element of the EpoR pathway, it is conceivable that the high red cell numbers found in patients with PV carrying the ^{V617F}Jak2 mutation is a direct consequence of constitutive Epo signaling in erythroid cells. The extent to which the downstream EpoR signaling pathway is altered as a consequence of this constitutive activation is a debatable issue. The observation that erythroblasts derived in vitro from patients with PV carrying the ^{V617F}Jak2 mutation are highly resistant to TRAIL-induced apoptosis[243] suggests that the mutation exquisitely increases erythroblast survival. However, additional abnormalities induced by the presence of ^{V617F}Jak2 are represented by hypersensitivity to insulin-like growth factor-1[244] and increased EpoR recycling from the Golgi apparatus.[184] Therefore, inhibitors directly targeting the ^{V617F}Jak2 mutation might represent the best candidates for PV therapy. More difficult to understand is why the mutation is also present in some patients with essential thrombocythemia and idiopathic myelofibrosis. Jak2, in addition to EpoR, has an important role in transducing the signal from Mpl, the TPO receptor.[245] The protein has two opposing effects on the intracellular processing of the two receptors after growth factor stimulation: it favors EpoR recycling from the Golgi apparatus,[184] but it determines retention and degradation of Mpl in the cytoplasm.[246] As such, the ^{V617F}Jak2 mutation should increase the number of EpoR on the surface of erythroid cells while reducing that of Mpl on megakaryocytes. This hypothesis explains why the mutation is found preferentially in PV. However, megakaryocytes originating from ^{V617F}Jak2 stem cells might express a reduced number but constitutively active

Mpl, so it can be argued that the mutation manifests itself prevalently in the erythroid or the megakaryocytic lineage, depending on genetic polymorphisms outside the Jak2 locus present in the population. This hypothesis is supported by the observation that mice transplanted with ^{V617F}Jak2 hematopoietic stem cells develop either a PV- or an essential thrombocythemia–like syndrome, depending on their genetic background.[247] Studies on the biology and biochemistry of the ^{V617F}Jak2 mutation are actively being pursued by many investigators. Furthermore, in ^{V617F}Jak2-negative PV or IE patients, several other gain-of-function mutations affecting Jak2 exon 12 with a distinct phenotype (idiopathic erythrocytosis) have been identified.[248] The identification of specific mutations and the availability of the crystal structures of Epo, EpoR, and Jak2 should allow use of computer modeling to design targeted protein-signaling inhibitors for treatment of Ph-negative myeloproliferative disorders.[249]

HEMATOPOIETIC MICROENVIRONMENT

In invertebrates such as worms and sessile marine creatures, erythropoiesis occurs adjacent to peritoneal and endothelial cells. In premammalian species, the spleen is the primary site of erythropoiesis. With evolutionary advancement, the function gradually shifts to the liver and the sinusoidal cavities of bones.[9] These observations suggest that sufficient oxygen, a stagnated flow of blood to avoid dispersion of factors produced locally, and extensive and redundant surfaces for cell–cell interactions are essential to support red cell production. Similar sites support erythropoiesis during human development (see Ontogeny of Erythropoiesis). During both phylogeny and ontogeny, the liver and spleen are primarily erythropoietic organs; granulocytic cells dominate in the bone marrow.[9] Within the bone marrow, hematopoiesis is restricted to the extravascular space, where compact collections of cells are interspersed among venous sinuses. These sinuses originate adjacent to the endosteal bone surface and empty into a central longitudinal vein. Studies in mice demonstrate that BFU-E follow a bimodal distribution with peaks adjacent to the periosteum and mid-cavity, whereas CFU-E and later erythroid cells have a broad distribution with highest incidence toward the axis of the femur, adjacent to the central vein,[9,250] thus suggesting that the local anatomy (specialized niches?) influences the maturation of erythroid cells.

The bone marrow microenvironment consists of three broad components: stromal cells (e.g., fibroblasts, endothelial cells, osteogenic cells), accessory cells (monocytes, macrophages, T cells), and extracellular matrix (a protein–carbohydrate scaffold). Accessory cells are progeny of hematopoietic stem cells; hence, after marrow transplantation, these cells are of donor origin, whereas stromal cells are host derived.[251,252] Extracellular matrix molecules are synthesized and secreted by microenvironmental cells and include collagens (types I, III, IV, and V), glycoproteins (fibronectin, laminins, thrombospondins, hemonectin, and tenascin), and glycosaminoglycans (hyaluronic acid, chondroitin, dermatan, and heparan sulfate).[253,254] Besides providing structure to the marrow space and a surface for cell adhesion, the microenvironment is important for hematopoietic cell homing, engraftment, migration, and the response to physiologic stress and homeostasis.

Although the functional consequences of the microenvironment ultimately must be defined by in vivo studies in mice, dissection of the cellular components of the microenvironment, definition of the cytokines that are produced by individual cells, and the nature of cell–cell interactions have been aided by in vitro models. Long-term bone marrow cultures provide an experimental approach for such studies.[255,256] Under these in vitro conditions, murine hematopoiesis can be maintained for 8 to 10 months and human hematopoiesis for 2 to 3 months.[255] An adherent layer consisting of fibroblasts, adipocytes, and macrophages is a crucial component of the culture system. Progenitor cells adherent to stroma are generally quiescent (dormant), whereas those in the nonadherent cell compartment are in active cell cycle.[256,257]

In vitro studies have demonstrated that stromal cells, including endothelial cells and fibroblasts, elaborate cytokines such as GM-CSF, G-CSF, IL-1, IL-3, IL-6, IL-11, KL, FLT-3 ligand, activin A, and basic fibroblast growth factor, which influence, alone or in combination, the growth of adjacent marrow progenitors.[255–258] In addition to positive regulators of replication and differentiation, stromal cells elaborate factors such as transforming growth factor β, interferon γ, and TNF, which exert a negative influence on proliferation and may help maintain a dormant (noncycling) state.[256,257] Because some regulators inhibit differentiation along certain lineages but not others, there is an intriguing possibility that lineage-specific regulation within the microenvironment can be achieved through negative, rather than positive, factors.[259] Several cytokines are expressed in a transmembrane form as well as a soluble (secreted) product. Others bind extracellular matrix, a mechanism that not only allows for high concentrations of a factor within the microenvironment that metabolically stabilizes these factors but also keeps them adjacent to developing progenitors.

Among the factors elaborated by stromal cells, KL has the most profound effect on erythropoiesis. Mice unable to synthesize KL die in utero because of severe anemia. Steel-Dickie (Sl^d) mice that are unable to make the membrane-restricted form of KL are viable but severely anemic, whereas other lineages in these animals are marginally affected or not affected by this defect.[260] The fact that erythropoiesis is abnormal, despite high levels of circulating Epo and the presence of soluble KL, suggests that normal erythroid differentiation and maturation require both a functional membrane-restricted KL/kit and an Epo signaling pathway. Cross-phosphorylation of EpoR by KL may provide a basis for the predominately erythroid effect.[211] Furthermore, data suggest that tyrosine cross-phosphorylation of EpoR is sustained longer when cells are cultured on steel stromal cells engineered to express the membrane-restricted form of KL than cells expressing the soluble form.[261]

Besides cell–cytokine interactions, (paracrine) cell–cell adhesion and adhesion of cells to the extracellular matrix are important functions of the microenvironment.[262,263] Perhaps most studied are the β_1 integrins VLA-4 and VLA-5, which mediate the adherence of hematopoietic cells to stromal cells, fibronectin, or other components of the extracellular matrix.[263,264] In mice lacking β_1 integrins, hematopoietic stem cells fail to colonize the fetal liver during embryonic development,[265] and cells lacking α_4 integrin fail to contribute to normal hematopoiesis postnatally.[266] Antibodies to VLA-4 or to the vascular cellular adhesion molecule 1 (VCAM-1, a VLA-4 ligand on endothelial cells) impair homing and lead to mobilization of progenitor cells and stem cells in adult mice and primates.[267–270] In in vitro studies, hematopoietic progenitors bind to specific domains of fibronectin in a differentiation-dependent manner (long-term culture-initiating cell and day 12 colony-forming unit-spleen in mice adhere mainly through the heparin-binding domain and CS-1). BFU-E and other progenitor cells adhere to both the cell-binding (RGDS) and heparin-binding domains, whereas CFU-E preferentially bind the RGDS sequence, and reticulocytes fail to adhere to fibronectin.[254,271–274] This differential binding could influence the proliferation and maturation of erythroid progenitor cells as well as the migration of these cells in and out of the bone marrow cavity. Hematopoietic cytokines present in the microenvironment also can modulate the affinity of β_1 integrins for ligand,[275,276] adding complexity to the regulation of erythropoiesis within the marrow microenvironment.

Many observations suggest that hematopoietic progenitor cells at one stage of fetal development may not be supported by a hematopoietic microenvironment of a different ontogenetic stage. For example, cells present in the murine yolk sac are not able to repopulate adult recipients,[277] although they can repopulate newborn recipients with active fetal liver hematopoiesis.[278] Targeted disruption of CXCL12/SDF1, a member of the CXC chemokine family that is constitutively expressed by bone marrow stromal cells (i.e., reticular/endothelial cells or, osteoblasts), leads to inhibition of marrow hematopoiesis, although fetal liver hematopoiesis is unaffected,[279] suggesting that this chemokine has a role in colonization of bone marrow from fetal liver. TEL (translocation-ETS [E26 transformation-specific]-leukemia) transcriptional factor was shown to be critical in

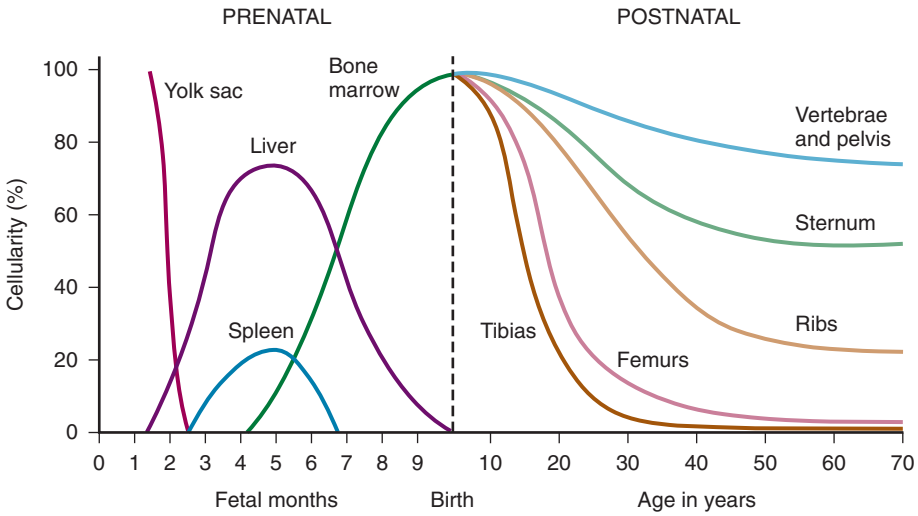

Figure 25–3 Sites of hematopoiesis during fetal development and after birth. Only erythroid cells and possibly lymphocytes are generated by the yolk sac and early embryo. Significant megakaryopoiesis and granulopoiesis develop at 4 to 5 months. After birth, hematopoiesis occurs in the sinusoidal cavities of the tibias, femurs, and axial skeleton. (Adapted from Erslev A, Gabuzda T: Pathophysiology of Blood, 2nd ed. Philadelphia, WB Saunders, 1979.[446])

establishing stable bone marrow hematopoiesis but was not required for embryonic and fetal liver hematopoiesis.[280]

Accessory cells, such as stromal cells, secrete cytokines and express adhesion molecules, and they may influence marrow hematopoiesis by their nonrandom distribution in the marrow cavity. T cells (along with mast cells) are the only source of IL-3 and, through secretion of TNF-α and interferon γ, may negatively impact erythropoiesis. In histologic sections of normal marrow, islands of maturing erythroblasts (erythroblastic islands) often surround a central macrophage, termed a *nurse cell*.[281] Adhesion may be mediated through the binding of VLA-4 (on erythroid cells) to VCAM-1 (on central macrophages).[282] Molecular interactions have been identified as being critical for erythroblastic island integrity. Erythroblast macrophage protein expressed on erythroblasts and macrophages mediates cell–cell attachment through homophilic binding, and erythroblast intercellular adhesion molecule 4 (ICAM-4) links erythroblasts to macrophages by interacting with α_v integrin expressed in macrophages.[283–285] Mice with targeted deletion of erythroblast macrophage protein are severely anemic and die at an embryonic stage,[84] and ICAM-4 kos[284] have markedly reduced erythroblastic islands. Of interest, Rb-deficient macrophages do not bind Rb^{null} erythroblasts,[286] and failure of this interaction may mediate the defect in fetal liver erythropoiesis observed in Rb kos. Rb normally stimulates macrophage differentiation by counteracting inhibition of Id2 (a helix loop-helix protein) on PU-1, a transcription factor crucial in macrophage differentiation. In addition to the aforementioned pathways, macrophage CD163 can serve as an erythroblast adhesion receptor in erythroblastic islands, promoting erythroid proliferation and/or survival.[287] More studies addressing the specific interactions between macrophages and erythroid cells that promote erythroid differentiation are needed for definite conclusions regarding specialized "erythroid niches." Of note, tissue macrophages express RNA for Epo[288] and may influence erythropoiesis through this mechanism.

The microenvironment is not only a passive surface for the adherence of progenitor cells; it exerts a crucial and interactive role in development and maturation. Some interactions are lineage (red cell) specific, whereas other interactions affect hematopoiesis more broadly. Stromal and accessory cells secrete cytokines and/or express them in a transmembrane form on their cell surface. Cytokines are retained via binding to components of the extracellular matrix. All components of the microenvironment are involved in adhesive interactions, some of which maintain quiescence (i.e., interactions of stem cells with endosteal surfaces[289,290]), whereas other cell–cell interactions or interactions of cells with matrix components induce proliferation and/or differentiation.[291–293] An individual progenitor cell, in an anatomic niche adjacent to certain stromal cells, accessory cells, and extracellular matrix molecules, likely responds to the sum of the signals that it uniquely receives. In this way, erythropoiesis, or the entire hematopoiesis, is influenced by the complexity of the interaction network.

ONTOGENY OF ERYTHROPOIESIS

During human development, distinct anatomic areas for production of erythroid cells are recruited sequentially, in a temporal succession that allows overlap (Fig. 25–3). In addition, parallel changes occur in the morphology and functional properties of the erythroid cells themselves.

During the phase of embryonic erythropoiesis in the blood islands of yolk sac, aggregates of immature erythroid cells undergo maturation synchronously as a single cohort. Before their maturation is completed, they begin to circulate, and by gestational week 5 they are found in the vascular spaces of the rudimentary liver (Fig. 25–4). At about the same time, foci of immature erythroid cells emerge within the fetal liver as the fetal (or hepatic) phase of erythropoiesis commences.[294] From week 7 onward, the liver is progressively filled with erythroid precursors and becomes the dominant site of erythroid cell production until approximately gestational week 30. Although some red cell production can be found in the thymus, the spleen, or occasionally in the lymph nodes, these other sites are never dominant. From month 6 onward, the cavities of long bones are invaded by vascular sprouts and become competent to support red cell development. Shortly after birth, all bone cavities are actively engaged in erythroid production, and the hepatic (fetal) phase of erythropoiesis comes to an end, as the final (adult) phase of erythropoiesis unfolds exclusively within the bone marrow.

In addition to the anatomic shifts in the sites of erythropoiesis are associated shifts in the phenotypic characteristics of erythroid cells. Embryonic erythroid cells (derived from the yolk sac) are large (approximately 200 mm), circulate as nucleated cells, and have a megaloblastic appearance (Fig. 25–4). The fact that primitive erythroblasts of mammals, like erythroid cells of lower vertebrates, retain their nuclei at terminal stages of maturation may serve as an example of embryonic recapitulation of the phylogenetic evolution of the erythroid system. However, a study has identified the presence of enucleated megaloblasts in the blood of the mouse embryo at late stages of development, indicating that the enucleation process is at least partially at work.[295] Other studies using genetic reporter models further suggest that embryonic (primitive) cells represent a stable cell population that persists through the end of gestation,[296] but these observations require verification by other independent approaches. Fetal erythroid cells (produced in the fetal liver and later in fetal bone marrow spaces) are smaller than embryonic cells (approximately 125 μm) but have a macrocytic appearance compared with adult normocytic red cells (approximately 80 μm). However,

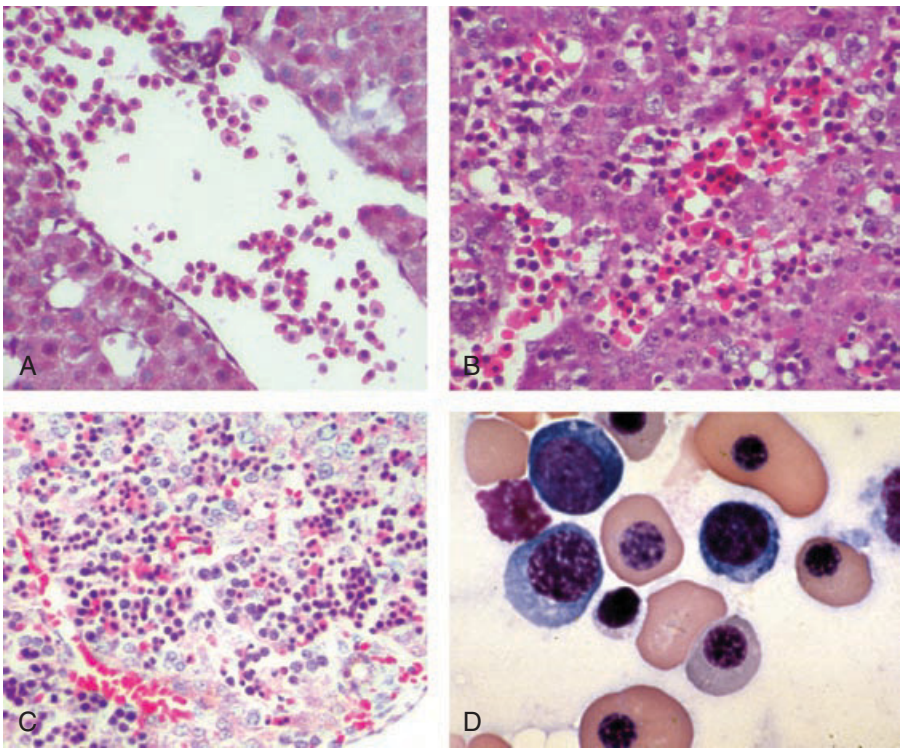

Figure 25–4 A, Section of an 8-mm embryo depicting a portion of hepatic parenchymal cells with embryonic erythroblasts present within primitive sinusoidal cavities. **B,** At 6 to 8 weeks, discrete aggregates of definitive erythroblasts appear within the liver parenchyma, whereas mature embryonic erythroblasts persist in well-developed sinusoids. **C,** Definitive erythroblasts are spread throughout the liver (100-day fetus). **D,** Cytologic spread from disaggregated fetal liver cells of a 55-day embryo. Characteristic morphology of embryonic erythroblasts and immature (basophilic) definitive erythroblasts is shown. (A, B, C, hematoxylin-eosin stain; D, Wright-Giemsa stain.)

like adult cells, fetal erythroid cells eject their nuclei during maturation.

Apart from variations in size and morphology, embryonic and fetal erythroid cells differ from each other and from their adult counterparts in several other characteristics, including hormonal or growth factor requirements, proliferative status, and transplantation potential. For example, whereas fetal erythropoiesis is under the control of Epo,[297] the extent of Epo's influence on embryonic erythropoiesis is disputed. Most convincing are the results of Epo/EpoR knock-outs[135] that showed only partial effects on embryonic erythropoiesis, in contrast to fetal erythropoiesis. Evidence suggests that precursor cells from the extraembryonic mesoderm are dependent on Epo for proliferation and erythroid differentiation.[298] Epo levels increase between weeks 9 and 32 of gestation, and fetuses respond to hypoxia or anemia with increased Epo as early as 24 weeks. Fetal erythroid progenitors when studied in vitro appear more sensitive to Epo and KL than adult progenitors. In contrast, their in vitro response to lymphokines (e.g., IL-3 or GM-CSF) is minimal compared to that of adult erythroid progenitors.[299,300] Of note, in the early stages of fetal liver erythropoiesis, mainly erythroid differentiation/maturation is promoted.[187] Progenitors committed to other lineages are abundant in the fetal liver, but few mature cells (granulocytes, megakaryocytes) from other lineages are seen. In addition to their heightened sensitivity to Epo, fetal erythroid progenitors and precursors are characterized by high proliferative potential and shorter doubling times than adult cells when cultured in vitro.[300,301] The dependency of stem/progenitor cells on KL changes during ontogeny. Although generation of repopulating stem cells (c-kit$^+$/Sca1$^+$/Thy1^{lo}/Lin$^-$) and colony-forming unit-spleen is minimally affected during fetal life in mice that cannot produce KL, adult steel-Dickie (Sl/Sl^d) mutant mice (which produce only some soluble KL) display greatly impaired erythropoiesis and hematopoiesis, suggesting that the KL/c-kit pathway plays a role in the recruitment and self-renewal behavior of adult stem cells in vivo.[302,303] The long-term transplantation potential is impaired in cells with mutations of c-kit kinase activity.[303] Transplantable stem cells from the yolk sac, in contrast to fetal liver cells, cannot engraft adult recipients, because of altered homing behavior or inability of bone marrow to support their development,[278] as suggested by their engraftment in neonatal liver.[304] The homing properties of fetal stem cells transplanted into adult irradiated recipients were found to be inferior to those of their adult counterparts.[305] Whether this finding is related to their increased cycling or other reasons is unclear. However, fetal liver stem cells, despite their reduced homing potential,[305] have higher engraftment levels, likely because of their proliferative prowess compared to adult stem cells.[306]

The surface antigenic profiles of erythroid progenitors and precursors are distinct at each ontogenic stage. For example, HLA class I and class II antigens are not detected in embryonic erythroid progenitor cells but reach adult levels at approximately gestational week 9.[307] CD34$^+$ hematopoietic progenitors present in yolk sac express Mac-1 but are negative for stem cell antigen 1 (Sca-1), which is expressed in fetal and adult CD34$^+$ murine progenitor cells.[308] On the other hand, adult CD34$^+$ progenitors lack Mac-1 and AA4.1, which are expressed in fetal CD34$^+$ progenitor cells. Fetal BFU-E and CFU-E express similar levels of HLA class II antigens, whereas adult CFU-E are largely devoid of these antigens.[307,309] β_1 integrins, especially $\alpha_4\beta_1$ and α_5, are expressed widely in all hemopoietic cells, including nucleated erythroid cells. However, in the latter, they display a differentiation-dependent, developmentally segregated pattern of expression, as they are absent in embryonic murine erythroblasts,[310] and among adult cells, stem/progenitor cells express them in a constitutively active form in contrast to more mature cells.[311–313] Fetal red cells display a straight, unbranched polylactosaminyl chain (i antigen) on their surface, whereas in adult cells, this structure, which bears ABH blood group determinants, is highly branched (I antigen).[77] The enzymatic activity of several enzymes in the glycolytic pathway is greater in fetal than in adult red cells.[314] In contrast, carbonic anhydrase levels are very low during intrauterine and early neonatal life.[315] Distinct isozyme patterns for several enzymes (i.e., phosphoglycerate kinase, acetylcholinesterase) also distinguish fetal from adult red cells.[316,317]

The most widely studied changes during red cell ontogeny are the shifts or "switches" in globin types. Embryonic erythroblasts are characterized by their avid accumulation of iron, which is stored as ferritin[318] (0.3–1% of total protein) and by the synthesis of the unique hemoglobins Gower I ($\zeta_2\varepsilon_2$), Gower II ($\alpha_2\varepsilon_2$), and Hb Portland ($\zeta_2\varepsilon_2$). The ζ- and ε-globin chains are embryonic α-like and β-like chains, respectively.[88] These three embryonic types of hemoglobin are most likely synthesized in succession, as the concentration of Gower I is highest in smaller embryos. Thus, a switch from ζ- to α-

and ε- to γ-globin gene production begins during the embryonic phase of erythropoiesis but is not complete until fetal erythropoiesis is well established. During the transition from yolk sac to fetal liver erythropoiesis (6–9 weeks), erythroid precursors within the fetal liver coexpress embryonic (ζ- or ε-) and fetal (α- or γ-) globin both in vivo and in vitro.[319,320] The predominant type of hemoglobin synthesized during fetal liver erythropoiesis is HbF ($\alpha_2\gamma_2$), with a high proportion of γ^G:γ^A (7:3). Adult HbA ($\alpha_2\beta_2$), which is detectable at the earliest stages of fetal liver erythropoiesis, is synthesized as a minor component throughout this period. However, HbA_2 ($\alpha_2\delta_2$), which is a minor hemoglobin in the adult, is undetectable in these early stages. From about gestational week 30 onward, β-globin synthesis steadily increases so that, by term, 50% to 55% of hemoglobin synthesized is HbA. By 4 to 5 weeks of postnatal age, 75% of the hemoglobin is HbA. This percentage increases to 95% by 4 months as the fetal-to-adult hemoglobin switch is completed. HbF levels in circulating red cells are in a plateau for the first 2 to 3 weeks (as a result of the decline in total erythropoiesis that follows birth), but the HbF level gradually declines so that normal levels (<1%) are achieved by 200 days after birth.[321]

Several in vitro and in vivo approaches have been used to study the basis of globin switching through development. Beyond its biologic interest, rigorous research in this area was propelled by the possibility of manipulating globin switching to increase HbF production in adults and ameliorate the clinical symptoms of disorders of the β-globin locus (e.g., sickle cell anemia, thalassemia). Transplantation experiments and ablative endocrine maneuvers in the sheep model have failed to provide convincing support for the effects of environmental or humoral factors on the switching process, although some modulation of the rate of switching was seen in these models.[322,323] The most important determinant of fetal-to-adult hemoglobin switching seems to be postconceptual age, with the sharpest period for transition between 30 and 52 weeks. The fetal-to-adult switch appears to be unaffected by the time at which birth occurs or by changes in the kinetics of erythropoiesis induced by perinatal hemolysis.[324] A delay in switching usually is observed in cases of general developmental retardation, in patients with certain chromosomal abnormalities (e.g., trisomy 13), and in diabetic infants because of increased circulating levels of α-aminobutyric acid, which directly affects HbF synthesis.[325] Integration of data from studies using in vitro and in vivo approaches indicates that developmental control of globin switching is intrinsic to erythroid cells. Stage-specific transcriptional forces with negative or positive influences (or both) on specific globin genes may provide the molecular basis for differential transcriptional activity during development. This view is favored by experiments in transgenic mice[326] and in heterokaryons (produced by fusion of human with mouse cells),[327] as well as by isolation of stage-specific transcriptional factors in other erythroid systems (e.g., avian).[328] Furthermore, because β-like and α-like globin genes are activated sequentially in the order of their location in chromosome 11 or 16, respectively, it is possible that polarity of the transcriptional activity and globin promoter competition for the locus control region and developmental stage-specific transcriptional factors contribute to this regulation.[329] Alternatively, specifically for ε globin, direct silencing by factors such as the SOX6 repressor, which operates in definitive erythroid cells, has been shown.[330]

In summary, throughout human development, waves of hematopoiesis are initiated sequentially in newly recruited sites. The first wave of erythropoiesis is seen in yolk sac between days 15 and 18 (7.5 days after conception in mice). In addition to erythroid cells, uncommitted progenitors and progenitors for nonerythroid cells are present in the yolk sac and are thought to be the source of cells colonizing the fetal liver.[141,331–333] However, in addition to yolk sac, foci of hematopoietic activity have been detected within the embryo around the developing aorta (in paraaortic-splanchnopleura [P-Sp] and aorta/gonad/mesonephros [AGM] area).[334–336] In fact, the P-Sp/AGM site in mice was shown to harbor progenitor cells before circulation begins and 1 day before these cells are found in the yolk sac. Long-term repopulating cells after their transplantation in adult recipients were detected only in the AGM area, leading to speculation that this intraembryonic site is the main or only source of fetal liver colonization,[336] in contrast to earlier experiments implicating the yolk sac in that role.[331–333] Presence of mesodermally derived hematopoietic cells in two distinct anatomic sites (extraembryonic and within the embryo proper), one intraembryonic and the other extraembryonic, has been seen in explant studies of *Xenopus* and after analysis of chick-quail chimeras.[337] More recent experiments with human cells have led to similar conclusions.[338] Although the presence of progenitors for definitive hematopoiesis in two independent sites (extraembryonic and within the embryo proper) is indisputable, the extent to which these two sites contribute to fetal liver colonization has been a matter of dispute. The conclusion that only the AGM area contributes to fetal liver colonization was based on transplantation experiments in adult recipients and has been challenged.[278] Transplantation experiments using newborn mice with active fetal liver hematopoiesis as recipients showed that adult long-term repopulating cells are detectable in the yolk sac at day 9 postconception and are 37-fold higher than repopulating cells present in the P-Sp/AGM area at the same time. Therefore, failure of yolk sac cells (or AGM cells before day 10 postconception) to engraft adult recipients may be caused by either compromised homing or impaired survival and proliferation within the adult bone marrow environment (because of positive regulators or inhibition by negative regulators). In light of this information, the 30-year-old theory that yolk sac colonizes the fetal liver has been revived.[331] A question that remains unanswered is whether stem cell activity 9 days postconception in yolk sac and P-Sp/AGM is generated autonomously and independently or is derived from a common precursor cell with migratory properties. Murine studies comparing newborn transplant outcomes before the onset of systemic circulation between the yolk sac site and the intraembryonic AGM site are emerging and promise to resolve this issue.[304]

A common precursor cell giving rise to erythroid cells with either yolk sac or fetal liver characteristics has been identified by culture of murine or human embryonic stem cells in vitro.[339,340] Environmental regulation of specification to the primitive or definitive lineage has been shown in *Xenopus*.[341] However, because BFU-E present in yolk sac, fetal liver, and fetal bone marrow have a definitive-like progeny and these progenitors were not present after ablation of core-binding factor (CBF)β[342] despite the presence of normal embryonic erythropoiesis, the derivation of embryonic erythroblasts from a distinct progenitor, not present in subsequent life, remains a viable hypothesis. Of further interest is the observation that deletion of Mdm2 and Mdm4, two critical negative regulators of p53, exerted distinct outcomes for primitive and definitive hematopoiesis. Whereas Mdm2 is required for primitive erythropoiesis, Mdm4 is required for massive expansion of definitive erythropoiesis in fetal liver and is dispensable for adult erythropoiesis. These data also suggest distinct molecular control between fetal and adult cells.[343]

TRANSCRIPTIONAL FACTORS IN ERYTHROPOIESIS

Lineage-specific transcriptional factors are widely believed to be responsible for regulating the expression of erythroid genes during both ontogeny and the course of erythroid differentiation. The majority of erythroid-specific transcription factors has been identified from cloning of breakpoints or translocations associated with human leukemias or from expression libraries obtained from erythroid cell lines. The precise role exerted by each of these factors in erythropoiesis was later clarified by painstaking experiments with somatic cell fusions and in transgenic mice.[327,344,345] Some of the major transcription factors implicated in the control of erythropoiesis are listed in Table 25–2.

Studies of mice with targeted gene disruption have provided key insights into the complex molecular pathways that regulate hematopoiesis in general and erythropoiesis in particular.[1,2] These studies, complemented by in vitro differentiation of mutated embryonic stem cells into different lineages, have provided clear evidence about distinct regulatory requirements of primitive (yolk sac) versus definitive (fetal liver and bone marrow) erythropoiesis, or of early versus late

stages of erythroid differentiation. Because erythropoiesis is the first differentiated lineage in embryonic yolk sac hematopoiesis and the predominant lineage in fetal liver hematopoiesis, factors that affect hematopoiesis in general will disturb erythropoiesis during early stages of development and lead to lethality at different gestational days, depending on the defect. The time in development at which disruption of each specific gene manifests its phenotype is used to establish a hierarchical control among the different transcription factors. The earliest disruption of erythroid differentiation is observed in mice lacking the bHLH factor Tal-1/SCL, which is encoded by a gene initially identified on the basis of its localization in a chromosomal breakpoint region frequently associated with T-cell acute leukemia.[346] SCL^{null} embryos are bloodless and die very early, with abrogation of both yolk sac and fetal liver erythropoiesis.[347] Because of the requirement for SCL in the formation of the transcription complex with the nuclear protein Rbtn2/LMO2 (rhombotin 2/LIM domain only 2) and GATA1 (detailed below), it is not surprising that targeted disruption of Rbtn2 and LMO2 also produces a bloodless phenotype.[348]

Mice lacking expression of GATA2, a member of the GATA family of transcriptional factors, exhibit an early and severe quantitative defect in hematopoiesis that influences all lineages.[349] Other regulatory factors seem to totally spare embryonic (yolk sac) hematopoiesis and have a specific effect only on fetal liver hematopoiesis, with death occurring at later days (12.5 days postconception). In this category are the protooncogene c-myb and the core-binding factors $CBF\alpha_2$/AML-1 and $CBF\beta$.[350–352] Embryonic erythropoiesis is spared in mice with targeted ablation of these genes. Both c-myb, the cellular homologue of v-myb protooncogene, and the heterodimeric transcription factor CBF are abundantly expressed early in normal myelolymphoid cells, with decreasing expression as differentiation proceeds. Their expression pattern and their functional influence on growth factor receptor genes (i.e., IL-3, GM-CSF, CSF-1, T-cell antigen receptor [TCR]α,β) may underlie their importance in the development of all definitive hematopoietic lineages.[1]

Of paramount importance for adult erythropoiesis is the transcription factor GATA1, the founder of the GATA family of factors.[1] The GATA1 protein controls erythroid differentiation at several levels by controlling (in cooperation with GATA2) the proliferative capacity of erythroid progenitor/precursor cells, the apoptotic rate of erythroblasts, and the expression of lineage-specific genes. These effects are mediated through activation of expression of target genes by binding to specific sequences (WGATAR) present in the regulatory domains of virtually any erythroid gene, including EpoR and GATA1 itself. However, WGATAR binding sites also are present in genes specific for megakaryocytic, eosinophilic, and mast cell lineages as well as in genes expressed in testicular Sertoli cells. Insights into the specificity of GATA1 in erythroid differentiation have been provided by studies on the organization of WGATAR sites in erythroid-specific regulatory sequences. A minimal erythroid transcription–activation sequence that consists of a core-binding motif flanked by two canonical GATA1 binding sites has been identified. The core-binding motif is composed of one SCL binding site and one GATA binding site separated by 10 bp.[2] Different domains of the GATA1 protein are responsible for binding to the core and the flanking sequences. At least three functional domains in the GATA1 protein have been identified: two zinc finger domains [amino-terminal finger (NF) and carboxyl-terminal finger (CF)] and an active amino-terminal domain. The NF domain is required for association with friend of GATA1 (FOG1), a protein encoded by a gene identified using GATA1 as bite in the two hybrid yeast assay.[353] FOG1 contains 10 zinc finger domains, only the first of which is required for GATA1 binding. The function of its other nine zinc finger domains is not clear because they appear to be dispensable in structure–function studies but they are well conserved in evolution. The GATA1–FOG1 heterodimeric complex binds to the two flanking sites of the minimal erythroid transcription activation domain. Experimentally induced genetic mutations impairing GATA1–FOG1 interaction in mice lead to impaired megakaryocytopoiesis and absence of definitive erythropoiesis while primitive erythropoiesis is normal.[354] These results indicate that DNA binding of the GATA1–FOG1 complex is necessary for activation of the target genes in definitive erythroid cells but is dispensable for their activation in primitive erythroblasts. It should be emphasized that GATA1–FOG1 interaction, while activating the expression of erythroid genes, inhibits target gene activation in testicular Sertoli cells.[355] This result provides insight into how one factor regulates more than one differentiation program by suggesting that its function, but not its expression, is different depending on the cellular context. Whether GATA1–FOG1 interaction inhibits erythroid gene expression in myelomonocytic cells has not been investigated.

The CF domain, on the other hand, recognizes and binds to the GATA site localized in the core of the minimal erythroid transcription sequence 10 bp downstream to the SCL binding site. SCL and GATA1 bind simultaneously to their respective sites of the core as multimeric complexes formed by SCL/E47/LMO2 on the one hand and by GATA1/LMO2 on the other. Binding of the two complexes to the core is stabilized by Lbd1, which forms a physical bridge between them. The paramount importance of the CF finger for GATA1 function is proved by the fact that GATA1 genes lacking the region encoding this domain are unable to rescue erythroid differentiation in $GATA1^{null}$ embryonic stem cells,[356] whereas mini genes containing only the CF of either GATA1 or GATA2 are sufficient to induce megakaryocytic differentiation of myeloid cell lines.[357] In addition to forming heterodimers with LMO2, CF can form complexes with Sp1 and PU.1, two factors essential for myelomonocytic differentiation. The GATA1–PU.1 complex is unable to bind DNA, so its function might be to establish either an erythroid- or a myeloid-permissive cellular environment depending on which factor is expressed at the highest concentration.[2] The presence of relatively higher concentrations of GATA1 would favor the formation of GATA1–LMO2 complexes leading to activation of erythroid-specific genes, whereas the presence of relatively higher concentrations of PU.1 would lead mainly to the formation of the transcriptionally inactive GATA1–PU.1 complexes.

Although early experiments on cell lines failed to identify any function for the amino-terminal domain of GATA1,[357,358] knock-in experiments in mice indicated that this domain, although dispensable for primitive erythropoiesis, is required for appropriate production of definitive red cells.[356] A truncated GATA1 gene lacking the amino-terminal domain is 10 times less efficient than the full-length gene in rescuing erythroid differentiation in $GATA1^{null}$ mice.[356] This experiment suggests that interaction of the amino-terminal domain of GATA1 with a yet to be identified partner(s) is required for optimal definitive erythropoiesis.

In addition to all the evidence pointing to GATA1 as exerting a predominant but ontogenetic-specific role in the control of erythroid differentiation, other evidence indicates that this gene exerts exquisite control in the differentiation of other hemopoietic lineages, such as megakaryocytes,[1] mast cells,[359] and eosinophils.[360] The mechanism used by one single factor in guiding differentiation along different lineages does not rely on specific domains in the GATA1 protein itself. In fact, the structure of all the GATA proteins is so well conserved among different family members and in evolution that $GATA1^{null}$ embryonic stem cells are rescued not only by reintroduction of the GATA1 gene itself but also by introducing any other member of the GAGA family, such as GATA3.[361] The lineage-specific action of GATA1 in regulating gene expression is achieved through the presence of lineage-specific regulatory sequences in the promoter regions of the target genes. Therefore, the relative concentration of GATA1, as opposed to the levels of a few key regulatory partners, may establish a lineage-permissive microenvironment. Furthermore, the existence of lineage-specific regulatory sequences in the GATA1 gene itself ensures that such concentrations are achieved only in the right cell. Although GATA1 is expressed in erythroid, megakaryocytic, mast, and eosinophilic cells, its level of expression differs greatly among the various cell types, with erythroid cells expressing the most. Three DNase hypersensitive sites (HS) have been recognized within the 8 kb upstream and the first intron of the murine GATA1 gene, defined as HSI, HSII, and HSIII. Targeted deletion

mutants in the mouse have shown that each of these sites functions as an enhancer in different cell types. HSI is required for GATA1 expression in megakaryocytes[362] and mast cells[359] and for upregulation of GATA1 expression in erythroid cells.[363] HSIII is capable of sustaining low levels of GATA1 expression in erythroid cells. HSII, which is dispensable for erythroid and megakaryocyte expression, is absolutely required for gene expression in eosinophils.[360] All of the 317 bp of HSI are required for GATA1 expression in megakaryocytes, but only the first 5′ 62 bp are needed for erythroid-specific reporter activity.[364] The HSI region contains a canonical minimal erythroid activation sequence, and point mutations in the GATA site, but not in the E-box, abolish HSI function in both erythroid and megakaryocytic cells. Of note, GATA1 mRNA has an unusually long half-live (>9 hours). Two GATA1 bands, corresponding to the native and processed (acetylated and phosphorylated) forms of the protein, have been detected by Western blot analysis.[365] The processed form binds DNA with higher affinity than the native form. Furthermore, although the half-life of the native form is short (approximately 0.5 hour) and stabilized by Epo, the processed form is extremely stable (half-life >6 hours) and Epo independent.[365] Because the cell cycle of hemopoietic cells in vivo is as short as 6 hours, erythroid cells accumulate GATA1 as mRNA and protein as they proliferate. As maturation is dependent on the levels of GATA1 expressed by cells, the cellular GATA1 content might represent the biologic clock that, by controlling the number of precursors, determines the cellular output of the differentiation process. This hypothesis suggests that Epo-induced GATA1 processing through the ubiquitin–proteasome pathway is an important element in the regulation of erythroid differentiation. On the other hand, the TRAIL–Bruton kinase death pathway has as an endpoint caspase 3, the protein specifically responsible for GATA1 cleavage. However, caspase 3 is unable to cleave GATA1 if the protein is complexed in the nucleus with the chaperone protein Hsp70. Epo-receptor signaling counteracts the apoptotic pathway by favoring Hsp70–GATA1 colocalization in the nucleus.[366] These biochemical studies detailing the biochemical link between Epo and TRAIL from one side and GATA1 from the other are consistent with studies indicating that Epo signaling also induces GATA1 phosphorylation at Ser310 and that this phosphorylation plays an important role in regulating GATA1 function in erythroid cell lines.[367,368] Although GATA1 mutants expressing only the native form of GATA1 do not have a detectable erythroid phenotype under steady-state conditions,[369] more studies on the response of these mice to erythroid stress will clarify the role of GATA1 processing in stress erythropoiesis.

Another gene of the GATA family important for erythroid differentiation is GATA2. Both GATA1 and GATA2 are expressed early in multipotential progenitors; however, their expression ratios change as the cells differentiate (Table 25–1),[370] suggesting that the ratio of these two factors may be important at specific stages of erythroid differentiation. Knock-out experiments with both of these genes have borne this out. Thus, in contrast to GATA2, which is expressed at high levels in early cells and affects expansion of all hematopoietic lineages,[349] GATA1 expression increases as differentiation advances and seems to be the obligatory factor required for survival and terminal differentiation of erythroid cells. In mice with targeted disruption of GATA1, erythropoiesis proceeds only up to the stage of proerythroblasts, which die early and fail to mature further.[371,372] Furthermore, transgenic mice with partial loss of function (knockdown alleles, GATA1^{low}) of GATA1 show that erythroid differentiation is dose dependent with respect to GATA1.[363] High levels of GATA1 are necessary to form complexes with its cofactor FOG1[353] and with the other proteins described above (LM02, SCLor Hsp70 during terminal erythroid differentiation.

The realization that minute differences in transcription factor concentrations are required for lineage specification under physiologic conditions supports the idea that the differentiation system allows more flexibility in both the choice and the reversibility of pathway commitment toward a specific lineage. For example, a CFU-E was thought to have no other choice than to became an erythroid cell or to die.[6] More recently, experiments with forced expression of transcription factors in fully committed or even mature cells have demonstrated that the system has some degree of plasticity and that forced expression of FOG1 into mast cells may turn them into erythroblasts,[373] whereas forced expression of GATA1 into common myeloid progenitor cells induces their transdifferentiation into MEP.[374] All of these manipulations were performed in vitro. Of interest, experimentally decreased expression of GATA1 in progenitor cell compartments in vivo does not alter the frequency of individual compartments (i.e., does not decrease MEP by increasing the granulocyte-monocyte progenitor) but results in alternative differentiation pathways. Although the numbers of cells phenotypically recognizable as MEP in these animals are much higher than normal, MEP with reduced GATA1 expression, unlike normal cells, have the potential also to differentiate into mast cells.[375]

Another factor with special importance in the erythroid lineage is the CACCC binding protein designated EKLF, which is expressed at all stages of erythropoiesis but binds preferentially to CACCC sites in β-globin promoter. Mice lacking EKLF (EKLF^{null}) die of a thalassemic-like defect due to severe deficiency of β-globin expression.[376] Microarray analysis of EKLF^{null} erythroid cells and promoter-specific expression of reported genes in EKLF^{null} cells have identified that the first *Gata1*-dependent molecular control of erythroid differentiation is followed by a second *Eklf*-dependent phase.[377,378] Primarily GATA1-dependent genes include, in addition to EpoR and those involved in the control of apoptosis, α-, and δ-globin. EKLF-dependent genes, in addition to β-globin[379,380] and AHSP, are represented by those required for appropriate membrane assembly, such as β-spectrin, ankyrin, and band 3 (but not α-spectrin). These results are consistent with the notion that, in erythroid differentiation, activation of α-globin gene expression precedes that of β-globin[381] and that loss of GATA1 binding sites in the promoter of the gene is found in α-thalassemia,[382] in the Greek nondeletion hereditary persistence fetal hemoglobin (guanine to adenine at nucleotide position −117 of γ globin),[383] and in δ-thalassemia (point mutation leading to G→A substitution at position +69 of the δ-globin gene),[384] whereas loss of EKLF binding site is present in other forms of hereditary persistence of fetal hemoglobin.

An intrinsic control on erythroid differentiation also is exerted by genes that, until repressed, prevent terminal cell maturation. The most studied of these genes is *Id1*.[385] which, as its name indicates, inhibits differentiation along almost all mesenchymal cell lineages, including the erythroid lineage.[386,387] ID1 appears to act between GATA1 and EKLF by preventing Eklf from executing its program.

As common transcriptional factors are present in erythroid and megakaryocytic cells, and bipotent erythroid/megakaryocytic progenitors exist both in vitro (in the form of cell lines) and in vivo,[52] exciting insights regarding subtleties in the molecular control of these two lineages by the same transcriptional factors have surfaced. Modified gene targeting strategy ("knockdown") of GATA1 uncovered a largely unanticipated role of this transcriptional factor in the control of proliferation and maturation of megakaryocytes.[363] In addition to GATA1, other important transcriptional factors essential for terminal megakaryocytic development are NF-E2[388] and its partner MafG.[389]

Nevertheless, the fact that several regulators are necessary for primitive (yolk sac), as opposed to definitive (fetal liver and bone marrow), erythropoiesis provides evidence that molecular control between these two hemopoietic sites is different and may include both ubiquitous and hematopoietic specific factors. In fact, evidence suggests that GATA1 transcription is differentially regulated in yolk sac cells compared to fetal liver erythroid cells, with alternative promoter use and an additional intron element requirement for promoter activation in fetal liver cells.[390]

In addition to transcriptional factors/oncogenes influencing erythropoiesis, targeted ablation and naturally existing mutations of hematopoietic growth factor receptors, especially of the tyrosine kinase family, have disclosed important insights into the control of erythropoiesis. Whereas deletion of the vascular endothelial growth factor (VEGF)/flk-1 receptor affects both endothelial and hematopoietic development[391] through its presumed presence in the hemangioblast, the common endothelial/hematopoietic stem cell, mutations affect-

ing the tyrosine kinase kit receptor (present in hematopoietic cells) or of its ligand KL (present in stromal cells) seem to predominantly affect erythropoiesis in the fetal liver and the adult animal. Mice with kit mutations (W mutations) leading to absence of or compromised kinase activity and steel mice with mutations of KL have disproportionate and severe abrogation of the late erythroid progenitors, CFU-E, and differentiated erythroid precursors resulting in anemia.[392] Studies showing cross-phosphorylation of EpoR following activation of kit/KL signaling may be relevant to the effect.[210] Mutations or targeted ablations of some downstream signaling substrates for kit or other receptors (i.e., Shp-2 phosphatase or gp130) seem to produce a hematopoietic picture not unlike the one produced by receptor mutations.[393,394]

Taken together, these studies have significantly expanded our understanding of the molecular level of hematopoietic development in general and of erythropoiesis in particular. The emerging picture is that certain genes, such as SCL, are absolutely required for hematopoietic development, whereas other genes, such as GATA2, c-myb, CBF, TEL, and some downstream signal transducing molecules, such as gp30 and Shp-2, are responsible for expansion and maintenance of a normal pool of fetal liver and adult hematopoietic progenitors. The participation of many of these molecules in multicomponent molecular complexes with protein/protein and protein/DNA interactions (i.e., LM02/Lbd1/SCL/E2A/GATA), during the early proliferative stages of hematopoiesis[395] may underlie their role in the proliferation and maintenance of immature progenitor/precursor pools in erythropoiesis. Other genes such as GATA1, its partner FOG1, and EKLF are necessary to direct high levels of function of erythroid-specific genes in cells already committed to terminal differentiation. Thus, a hierarchical requirement in the expression of specific regulators during early versus late erythroid differentiation or during yolk sac versus fetal liver/adult erythropoiesis is demonstrated. However, this does not exclude the involvement of some factors (i. e., SCL, TEL) at both early and late stages of erythropoiesis. In fact, more recent studies on conditional knock-outs have clarified that SCL exerts two different levels of control in the development of the hemopoietic system. First, SCL is required for the determination event that induces one (or few) mesenchymal cell(s) to become a hematopoietic stem cell(s) in the early embryos.[127] After this initial event has taken place, its presence becomes dispensable, as demonstrated by the fact that conditional SCL deletion in the adult animals impairs only erythropoiesis and megakaryocytopoiesis.[127,396] With information from innovative applications of molecular approaches becoming available at a fast pace, the list of regulators with a biologic impact on hematopoiesis/erythropoiesis is continuously expanding.

TRANSCRIPTIONAL AND POSTTRANSCRIPTIONAL FACTOR IMPAIRMENT IN DISORDERS OF ERYTHROPOIESIS

The transcription factor found most frequently altered in inherited and acquired human diseases of the erythroid and megakaryocytic lineage is GATA1. The mutations often involve the region of the gene encoding the NF domain. Mutations in the GATA1 NF domain interrupting its interaction with FOG1, such as V205M and G208S, are responsible for familial dyserythropoietic anemia and X-linked thrombocytopenia, respectively.[397,398] A different mutation at position 208 leading to G→A substitution is associated with dyserythropoietic anemia and macrothrombocytopenia.[399] Mutations in the NF terminal domain of GATA1 responsible for DNA binding, such as A216G[400] and D218G,[401] instead have been found associated with X-linked thalassemia and/or thrombocytopenia. The phenotype of X-linked thrombocytopenia was mimicked in mice by knock-in experiments of the mutant V205G GATA1 gene.[402] However, the same A216G mutation has been found associated with X-linked gray platelet syndrome, a mild bleeding disorder characterized by thrombocytopenia and large agranular platelets.[403] Furthermore, a mutation at codon 216 changing arginine to tryptophan (R216W) was detected in a 3-year-old boy with congenital erythropoietic porphyria, an autosomal recessive disorder usually due to mutations of the uroporphyrinogen III synthase gene (UROS). The boy also presented with microcytic anemia and red cell morphology and globin chain labeling values compatible with β-thalassemia and increased HbF levels (59.5%).[404] The different phenotype expressed by patients carrying mutations either in the FOG1 or the DNA binding portion of NF supported the notion that the two domains influence erythroid versus megakaryocytic maturation.[405] However, the observation that, in certain cases, a mutation in the same codon or even the same mutation results in a different phenotype suggests that the phenotype induced by mutations in the GATA1 gene are extremely sensitive to genetic heterogeneity outside the GATA1 locus. This hypothesis has been demonstrated in mice in which the same mutation induces embryonic lethality, thrombocytopenia, or myelofibrosis, depending on the mouse background in which it is harbored.[406]

On the other hand, frameshift and splice mutations encoding GATA1s, a protein lacking the amino-terminal domain, not only are associated with impaired inherited erythropoiesis[407] but also are found in patients with megakaryocytic leukemia in Down syndrome,[408,409] in newborns with transient myeloproliferative syndromes,[410] and in one adult patient with megakaryocytic leukemia.[411] A mutation equivalent to that found in patients with acute megakaryoblastic leukemia and Down syndrome was created in mice by *N*-ethyl-*N*-nitrosourea mutagenesis screening. The reduced expression of the full-length GATA1 was not compensated in mice by expression of GATA1s. The mutation was embryonic lethal in hemizygous males and induced thrombocytopenia in heterozygous females.[412] However, when introduced in mice the Gata1s mutation increased proliferation of a "unique" fetal stem/progenitor cell extinguished in adult life.[413] The association between mutation of GATA1 and development of leukemia support the concept described that GATA1 exerts an important control on the proliferation of hematopoietic progenitors. Reduced GATA1 expression, by increasing progenitor cell proliferation, may predispose hematopoietic cells to leukemia by favoring accumulation of secondary mutations. Alterations of hematopoietic proliferation appear to be achieved through quantitative, rather than structural, GATA1 alterations. The GATA1s protein is far less efficient than the full-length GATA1 in rescuing the phenotype of Gata-1^{null} embryonic stem cells,[414] and hypomorphic mutations in mice induce either leukemia[415] or a phenotype similar to idiopathic myelofibrosis,[416] depending on the severity of the reduction of the expression. Interestingly, the reduced content of GATA1 in megakaryocytes, through a yet to be identified molecular defect rather than the presence of ^{V617F}Jak2, distinguishes idiopathic myelofibrosis from all the other myeloproliferative abnormalities in humans.[417] (For a more complete review on the role of GATA factors in hematologic diseases, see reference 418.)

Another disease associated with abnormalities in the molecular machinery of red cell differentiation is represented by Diamond-Blackfan anemia, a rare congenital red cell aplasia characterized by anemia, bone marrow erythroblastopenia (lack of late erythroid forms), and congenital anomalies. The disease is associated with heterozygous mutations in the ribosomal protein S19 gene (RPS19) in approximately 25% of probands.[419] In a large cohort of 172 new families with familial history of Diamond-Blackfan anemia, mutations affecting the coding sequence of RPS19 or splice sites were found in 34 cases (19.7%), whereas additional mutations in noncoding regions were found in eight patients (4.6%). Mutations included nonsense, missense, splice sites, and frameshift mutations. More recently, de novo nonsense and splice-site mutations in another ribosomal protein, RPS24 (encoded by RPS24 [10q22-q23]), was identified in approximately 2% of RPS19 mutation-negative probands.[420] The molecular defect of the other families is yet to be uncovered. No correlation between the nature of mutations and the different patterns of clinical expression, including age at presentation, presence of malformations, and therapeutic outcome, has been documented. The lack of a consistent relationship between the nature of the mutations and the clinical phenotype implies that yet unidentified factors modulate the phenotypic expression of the primary genetic defect in

families with RPS19 mutations.[421] Two not mutually exclusive hypotheses had been proposed to explain the pathobiologic role of RPS19 (and RPS24) in the pathogenesis of the disease: (a) loss of unknown functions not directly connected with RPS19's structural role in ribosomes and (b) altered protein synthesis because of poor ribosome organization. The first hypothesis was suggested by findings based on a proteomic approach that identified numerous proteins bound to RPS19. In addition to FGF2, complement component 5 receptor 1, a nucleolar protein called RPS19 binding protein, and pim-1, the other RPS19-binding proteins fall in the following Gene Ontology categories: NTPases (ATPases and GTPases; 5 proteins), hydrolase/helicases (19 proteins), isomerases (2 proteins), kinases (3 proteins), splicing factors (5 proteins), structural constituents of ribosome (29 proteins), transcription factors (11 proteins), transferases (5 proteins), transporters (9 proteins), DNA/RNA-binding protein species (53 proteins), other (1 dehydrogenase protein, 1 ligase protein, 1 peptidase protein, 1 receptor protein, 1 translation elongation factor), and 13 proteins with unknown function.[422] However, more recent studies have identified that RPS19 plays an essential role in the biogenesis and maturation of the 40S small ribosomal subunit in human cells[423,424] because of reduced gene expression of clustered ribosomal proteins due to abnormal pre-mRNA processing.[425] Such a defective ribosomal gene expression results in alterations of the transcription, translation, apoptosis and oncogenic pathways.[426] Expression of RPS19 mRNA and protein decreases during terminal erythroid differentiation.[427] A mouse model of the disease has been generated by disrupting the endogenous Rps19 gene.[428] Cellular models of the disease have been established by siRNA technology against RP19 protein.[429–431]

CELLULAR DYNAMICS IN ERYTHROPOIESIS

The primary function of the mature red cell, which is the end product of erythropoiesis, is to transport oxygen efficiently through the circulation to the tissues. To achieve this goal, the adult marrow must release approximately 3×10^9 new red cells, or reticulocytes per kilogram per day.[432] This number of reticulocytes represents {1/100} of the total red cell mass and is derived from an estimated 5×10^9 erythroid precursors per kilogram.[432] In addition to maintaining homeostasis (i.e., a stable hematocrit), the erythron must be able to respond quickly and appropriately to increased oxygen demands, either acute (e.g., following red cell loss) or chronic (e.g., with hypoxia from pulmonary disease or a right-to-left cardiac shunt). It is well established that Epo is responsible both for maintaining normal erythropoiesis and for increasing red cell production in response to oxygen needs. However, the overall marrow response is complex and requires not only the participation of erythroid cells responsive to Epo but also a structurally intact microenvironment and an optimal iron supply within the marrow.

Epo stimulation elicits two types of measurable responses: changes in proliferative activity (including improved survival) and changes in maturation rates. The first detectable response to increased serum Epo is amplification of CFU-E and erythroid precursors, cells that are extremely sensitive to Epo. Because virtually all these cells are already in cycle, increases in their numbers cannot be achieved by increasing their fraction in cycle. Either additional divisions are involved or new cells are recruited to the CFU-E pool (from a pre-CFU-E pool). Additional divisions of CFU-E or precursor cells would increase their transit time within the marrow and potentially delay the delivery of new red cells to the periphery. Because a shortened maturation time has been observed instead and the proliferative potentials of CFU-E and proerythroblasts are finite, high levels of amplification cannot be achieved through this mechanism. Therefore, such needs are met by influx into the CFU-E and precursor pools of newly differentiating cells from earlier progenitor compartments.

Such a surge of newly produced cells has been observed in all previous experiments.[133,433,434] A rapid influx of fresh cells was particularly notable in polycythemic mice that were experimentally depleted of CFU-E and erythroid precursors at the time the stimulus was applied.[105,133] Because of the rapidity of response (i.e., within 24 hours in the polycythemic animals), it appeared that the orderly progression from BFU-E to CFU-E to proerythroblast had been compressed. Such acceleration of differentiation is possible through shortened intermitotic intervals, fewer mitotic divisions, or differentiation without divisions. This short circuiting in differentiation requires high serum levels of Epo and adequate numbers of BFU-E (i.e., these conditions are met in a previously hypertransfused, polycythemic animal stimulated by Epo or in marrow suddenly recovering from acquired pure erythroid aplasia). Once CFU-E and precursors are expanded through this mechanism, most persisting erythropoietic demands can be met through this pool without excess input from pre-CFU-E pools. Thus, acute demands for erythropoiesis are met by influx from pre-CFU-E pools through an accelerated differentiation and maturation sequence. In contrast, chronic demands (i.e., demands in chronic hemolytic anemia) are mainly satisfied through a greatly amplified late erythroid pool and with a minimum distortion in the differentiation sequence.[88,435] The fact that the kinetics of erythroid differentiation/maturation are different in acute versus chronic marrow regeneration is supported by differing qualitative changes in the newly formed red cells. An increase in i antigen and HbF expression as well as an increase in cells with higher mean corpuscular volumes is seen with an acute response, whereas these increases are minimal or less pronounced with chronic responses.[88,436] When severe anemia persists from birth onward, erythroid production can increase up to 10-fold above baseline.[435] This is possible not only because of maximally expanded erythropoietic pools but also because the sites of active erythropoiesis may extend to include those that support red cell differentiation during fetal life. Thus, although the marrow space in axial bones (vertebrae, pelvis, ribs, sternum, clavicles) is sufficient for normal erythropoiesis or for response to moderate anemia, the femur, humerus, spleen and/or liver, and (rarely) thymus may support red cell production in children with congenital hemolytic anemia (e.g., thalassemia major). Expanded erythropoiesis may lead to skeletal deformities, hepatosplenomegaly, or erythropoiesis in the soft tissues adjacent to bone.

Quantitative assessments of changes in erythroid progenitor cell pools in response to Epo stimulation can be made through cultures of bone marrow cells. Despite sampling errors, erythroid cultures can provide rough estimates of relative progenitor abundance within an aspirated marrow specimen and have shown consistent increases in the frequency of CFU-E in proportion to the level of Epo stimulation.[437,438] Conversely, with increases in the hematocrit or in polycythemic animals, a decrease in CFU-E frequency has been observed.[439,440] In contrast to CFU-E, the incidence of BFU-E was found to fluctuate less with either acute or chronic expansion of erythropoiesis, probably because a few BFU-E can generate progeny of several thousand cells. Furthermore, BFU-E can increase their fraction in cycle and thus increase the number of differentiated progeny without a significant change in their total numbers. Most BFU-E detectable in marrow or blood erythroid cultures probably represent a reservoir of progenitors not normally participating in day-to-day erythropoiesis. The parameters needed to maintain a healthy or appropriate BFU-E pool in hematopoiesis are not defined. That hematopoietic expansion is curtailed in mice with steel mutations and anemia develops in mice treated with anti-c-kit Ab antibody[441] suggest that adequate levels of normal KL may be crucial for early erythropoietic expansion.[134]

The rate of red cell production also can be accurately evaluated through ferrokinetics (i.e., study of iron incorporation into developing red cells). In addition, a marrow scan, typically with technetium Tc 99m, can document the extent of active erythropoiesis. However, these approaches seldom are necessary in clinical practice because estimates of erythropoiesis can be obtained from the reticulocyte index.[435] First, the observed percentage of reticulocytes is normalized for the hematocrit to calculate the total marrow output of reticulocytes. Alternatively, the absolute number of reticulocytes per microliter can be counted directly using fluorescent RNA labeling. However, because younger reticulocytes are prematurely released into the circulation under conditions of acute need, the total number of reticu-

locytes overestimates the true level of red cell production as measured by iron kinetics.[435] Therefore, a second correction is made to account for the maturation of early circulating reticulocytes, or "shift" cells (polychromatophilic red cells) when present in the blood smear. The resulting reticulocyte index gives excellent estimates of effective red cell production.

Although the presence, density, or both of EpoRs on developing erythroid cells determines the responses to Epo, other properties (e.g., surface antigens on BFU-E vs CFU-E vs end-stage red cells) may provide the basis for selective suppression of CFU-E versus BFU-E or selective immune destruction of red cells versus erythroblasts. For example, suppression of CFU-E or erythroblasts can occur in acquired pure red cell aplasia[442] or B19 parvovirus infection,[443] respectively, whereas BFU-E in both these conditions remain largely unperturbed. Thus, the boundary from BFU-E to CFU-E and erythroblast may be biologically important for the pathophysiology of these disease states. Furthermore, in acquired hemolytic anemia, selective destruction at a given stage of maturation (of red cells only or of both erythroblasts and red cells) can be observed depending on the type of antibody produced and the density of its antigen on maturing erythroid cells. Qualitative aberrations in the response of erythroid progenitors to cytokines or Epo may underlie the abnormalities of congenital erythroid aplasia (Diamond-Blackfan syndrome).[278] Analogous qualitative or functional defects can be observed in neoplastic erythropoiesis, as erythroid progenitors from patients with polycythemia vera and other myeloproliferative syndromes have altered sensitivities to Epo.[444] (see Alterations in ERO-R and its Signalling in Disorders of Erythropoiesis)

Detailed knowledge of the structural and functional properties of erythroid cells throughout their differentiation (see Transcriptional and Posttranscriptional Factor Impairment in Disorders of Erythropoiesis above) may provide significant insights into the pathogenesis of hematopoietic disorders affecting the red cell lineage.

CHAPTER 26

GRANULOCYTOPOIESIS AND MONOCYTOPOIESIS

Arati Khanna-Gupta and Nancy Berliner

GRANULOCYTOPOIESIS

Granulocytes-neutrophils, eosinophils, and basophils-are short-lived cells that are critical to both antimicrobial and inflammatory responses. The bone marrow produces granulocytes, especially neutrophils, at a prodigious rate to supply the baseline needs of circulating cells that survive in the peripheral blood only 3 to 6 hours. It also has the capacity to upregulate granulocyte production sharply in response to a wide range of stresses. The regulation of granulocyte production is controlled by a variety of cytokines that induce the myeloid differentiation program through the carefully orchestrated interaction of multiple general and myeloid-specific transcription factors. Understanding this intricate maturation sequence provides important insights into normal neutrophil responses to infectious, inflammatory, and allergic stresses, as well as into the dysregulation of differentiation contributing to myelodysplasia and leukemia.

Granulocyte Ontogeny

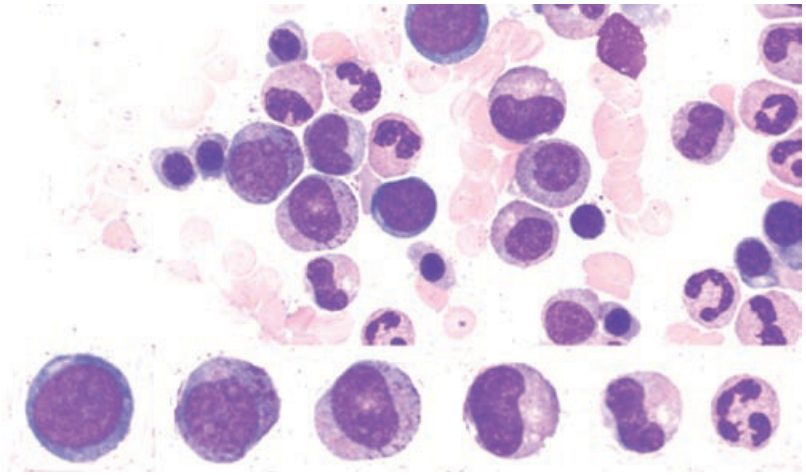
Stages of Neutrophil Differentiation

Granulocytes differentiate from early progenitors in the bone marrow in a process that takes 7 to 10 days. The cells pass through several identifiable maturational stages, during which they acquire the morphologic appearance and granule contents that characterize the mature granulocyte.[1,2] The earliest identifiable granulocyte precursor is the myeloblast, a minimally granulated cell with scant cytoplasm and a prominent nucleolus (Fig. 26–1). Transition to the promyelocyte stage is associated with the acquisition of abundant primary granules. Primary granules are found in both granulocytes and monocytes and contain many of the proteins necessary for intracellular killing of microbes. The transition to the myelocyte stage is associated with the acquisition of secondary or "specific" granules, which give the characteristic staining that differentiates neutrophils from eosinophils and basophils.

Neutrophil precursors account for approximately half of the cells in the marrow of normal persons, with a majority of these at the metamyelocyte stage and beyond.[3] Promyelocytes and myelocytes represent the primary proliferative pool of granulocyte precursors in the bone marrow. Beyond the myelocyte stage, cells mature as nondividing cells. Bands and segmented neutrophils constitute greater than 50% of the total granulocyte mass, primarily as a mobilizable pool of cells in the bone marrow. Only 5% of total neutrophils circulate in the periphery, where 60% are marginated in the spleen and on vessel walls. Mature neutrophils circulate in the peripheral blood for 3 to 12 hours and then migrate to the tissues, where they survive 2 to 3 days. Hence, the peripheral blood count reflects roughly 2% of the total neutrophil cell mass during approximately 1% of the neutrophil life span.

Biochemical events that accompany these physical changes include the sequential acquisition of primary granules and their content proteins (eg, myeloperoxidase, lysozyme, neutrophil elastase [NE], defensins, myeloblastin), secondary granules and their content proteins (lactoferrin, neutrophil collagenase, neutrophil gelatinase, neutrophil gelatinase-associated lipocalin [NGAL], transcobalamin 1), and tertiary granules containing neutrophil gelatinase (Table 26–1). The progressive gain of differentiated characteristics is accompanied by a loss of proliferative potential. This carefully coordinated process is disrupted in acute myeloid leukemias (AMLs), in which a block in the myeloid maturation pathway usually results in the circulation of immature blasts in the peripheral blood.

Surface Markers of Granulocytic Maturation



Stem cells have been characterized primarily by their marrow repopulating potential, as outlined in Chapters 19 and 20. Early granulocytic progenitors form hematopoietic colonies in vitro and their more differentiated progeny express specific cell surface proteins that are critically important to myeloid differentiation and function.[4,5] They mediate both the adhesion of precursors within the marrow and the vascular adhesion of mature neutrophils that is critical to normal neutrophil activation. Other proteins serve as receptors that recognize pathogens or as stimulatory peptides that facilitate activation of phagocytosis and killing of organisms. Appropriate expression of these surface proteins plays an important role in normal neutrophil function, and abnormalities of their expression are implicated in a wide range of diseases affecting the neutrophil compartment. For example, congenital abnormalities in the surface expression of integrin proteins are responsible for failure of neutrophil adhesion in leukocyte adhesion deficiency,[6] whereas acquired abnormalities of expression of the same proteins are hypothesized to underlie the abnormal peripheral circulation of immature precursors in myeloproliferative disease.[7] These markers also serve to help distinguish among the stages of myeloid commitment and maturation.

The phenotype of the early hematopoietic stem cells is $CD34^+/CD33^-$, with absence of lineage-specific markers. The common myeloid progenitor, colony-forming unit-granulocyte- erythrocyte-macrophage-megakaryocyte (CFU-GEMM), is characterized by the coexpression of CD33. CD33 is expressed at high levels on committed myeloid progenitors and on early precursors of both the granulocytic and monocytic lineages.[8] Expression of CD33 wanes with granulocytic maturation, and it is absent or nearly absent beyond the myelocyte stage. CD33 is a member of the sialic acid-binding Ig-like lectins (siglecs), which generally mediate cell-cell interactions and cell signaling.[9] The precise biologic function of CD33 itself is unknown.

Characteristic granulocyte markers acquired as the early myeloid progenitor cells become committed to the neutrophil lineage include CD45RA,[10–12] myeloperoxidase (MPO), and CD38, all of which are expressed on the myeloblast.[13] Further differentiation beyond the myelocyte stage is associated with acquisition of increased expression of CD16,[11] CD11b/CD18 (Mac-1),[11,14] and leukocyte alkaline phosphatase (LAP), all of which are expressed at high levels in mature neutrophils.

Neutrophil Granules and Their Content Proteins

The acquisition of granules and their content proteins are a critical part of the developmental program of the granulocyte.[15,16] Acquired at specific identifiable stages of neutrophil maturation, these intracellular and secretory organelles contain many of the requisite enzymes that mediate the oxidative and nonoxidative killing functions of the neutrophil (Table 26–1).[17–20]

	Myeloblast	Promyelocyte	Myelocyte	Metamyelocyte	Band	Segmented neutrophil
Proliferation	++	+++	+++	+/–	—	—

2°			+++	+		
3°				+++	+	

Figure 26–1 Neutrophil maturation stages with associated acquisition of stage-specific granules.

Primary (azurophilic) granules are acquired at the promyelocyte stage and contain a wide array of proteins, including myeloperoxidase, defensins, cathepsins, and elastase.[21,22] *Secondary* granules are secretory granules acquired at the transition to the myelocyte stage. Neutrophil secondary granules contain lactoferrin, the vitamin B_{12}-binding protein transcobalamin I, and the metalloproteinases (neutrophil collagenase and gelatinase), as well as NGAL.[22,23] With the exception of gelatinase, which also is expressed by monocytes, expression of the secondary granule proteins is restricted within the hematopoietic lineage to neutrophils. Secondary granules and the synthesis of their contents therefore constitute a definitive marker of commitment to terminal neutrophil maturation. As discussed later on, characteristic secondary granules are acquired at the same stage by eosinophils and basophils. *Tertiary* granules, containing primarily gelatinase, are formed during later stages of neutrophil maturation.[23,24] *Secretory vesicles* are formed by endocytosis and contain plasma proteins.[25,26]

On stimulation, the neutrophil first mobilizes secretory vesicles, which contribute their membrane proteins, including abundant integrin receptors, to the plasma membrane. They may thus increase cellular adhesion by upregulating surface integrin expression in response to selectin stimulation or inflammatory mediators.[16,27,28] Primary granules fuse with the phagosome and contribute to bacterial killing.[29] Secondary and tertiary granules have a complex function. They are secretory granules, releasing the matrix-modifying metalloproteinases collagenase and gelatinase into the extracellular milieu, enhancing neutrophil penetration into sites of inflammation.[30] The function of lactoferrin and transcobalamin I remains unconfirmed, but they are hypothesized to contribute to the antimicrobial response by sequestering iron and cobalamin, respectively, away from infecting organisms.[31–33] Secretion also results in the contribution of membrane proteins to the plasma membrane and is the source of the prominent upregulation of surface integrin receptor Mac-1 (CD11b/CD18) expression that occurs on neutrophil activation. Finally, they also fuse intracellularly with the phagosome to help promote bactericidal activity.

The fusion of azurophilic and peroxidase-negative granules allows for cross-exposure to their contents within the phagosome. These proteins are carefully sequestered in separate organelles, preventing premature activation and damage to the resting neutrophil; on fusion, the contents of the two granule subtypes cooperate in generating the antimicrobial response. Hydrogen peroxide, a by-product of NADPH oxidase in the secondary granule, in combination with MPO from the primary granules, produces hypochlorous acid, a highly toxic

Table 26–1 Neutrophil Granules: Major Classes and Contents

microbicidal agent.[34] Additionally, both neutrophil gelatinase and neutrophil collagenase (secondary granule proteins) are produced as zymogens and are converted to their active forms by the action of NE released from the primary granules.[35]

Current evidence largely supports the hypothesis that the content of the neutrophil granules is dictated primarily by the timing of synthesis of their respective content proteins. Recent studies have demonstrated that each distinct granule population is generated not by a sophisticated protein sorting mechanism but rather by a highly regulated transcriptional process that results in sequential gene expression.[36] For example, because myeloperoxidase and the other primary granule proteins are expressed between the promyelocyte and the myelocyte stages of neutrophil development, they are packaged into the primary granules. Secondary granule proteins such as lactoferrin (LF), on the other hand, are expressed between the myelocyte and the metamyelocyte stages and are hence packaged into the secondary granules.[16,36] Overexpression of the secondary granule protein NGAL in HL60 cells, a leukemic cell line that is arrested at the myeloblast stage of differentiation, resulted in its incorporation into primary granules,[37] lending empirical support to the concept that gene expression and protein sorting into granules are coordinate events. This hypothesis may, however, be a somewhat oversimplified view of granule protein sorting, because there is some overlap of expression between certain primary and secondary granule protein genes. Whereas secondary granule protein gene transcription appears to be coordinately regulated, the sequence of primary granule protein gene expression is much less synchronous. The defensins are expressed later than the other primary granule proteins, and defensin transcription appears to be regulated by the same transcriptional regulatory pathway as for the secondary granule proteins gelatinase and lactoferrin.[38] Indeed, the defensins are the only primary granule proteins that are absent in patients with neutrophil-specific granule deficiency. This suggests that defensin regulation would predict targeting to the secondary granule.[39–41] Consequently, how defensins become directed exclusively to the primary granule remains unclear.

CONTROL OF GRANULOPOIESIS

Granulocytes arise from pluripotent hematopoietic stem cells by a process of commitment, proliferation, and differentiation. Stem cells are long-lived cells capable of both self-renewal and differentiation to lineage-specific-committed progenitors. The process governing the cell fate decision that takes a stem cell down the path to lineage commitment and the subsequent factors that regulate lineage- specific differentiation have been the subjects of intense study for many years. Three models of hematopoietic differentiation have been proposed to address the mechanism underlying lineage commitment and differentiation of the pluripotent stem cell. The first or *inductive* model proposes that lineage commitment and differentiation are the results of external stimuli (eg, growth factors, stroma).[42] A second model, the *stochastic* model, emphasizes intrinsic cellular factors as being critical to hematopoiesis[43]; a third model combines the attributes of the first two.[44] It appears likely that the transition from a stem cell to a committed progenitor is largely stochastic, although the subsequent maturation from progenitor to precursor to mature neutrophil requires cytokines. Controversy remains as to whether cytokines and the bone marrow microenvironment play an instructive or a permissive role in influencing stem cell commitment and in inducing the proliferation and maturation of committed progenitors. As discussed subsequently, this complex issue has been elucidated in mice with homologous null mutations in specific cytokines and their cognate receptors, alone or in combination.

Cytokine Regulation of Myeloid Proliferation and Differentiation

Early progenitor cells express receptors for multiple cytokines, but expression becomes more restricted as the cell becomes committed to a specific lineage.[42] As a consequence of this broad range of cytokine receptor expression, early progenitors respond to combined growth factors, many of which show synergy of activity. The "early-acting" cytokines include the interleukins IL-1 and IL-6, stem cell factor (SCF), FLT3 ligand, and several others including granulocyte colony-stimulating factor (G-CSF). IL-3 is important in directing the pluripotent stem cell toward the myelomonocytic lineage, giving rise to the mixed myeloid progenitor (CFU-GEMM). Subsequent stages leading to commitment- and lineage-restricted differentiation are governed by more "late-acting" cytokines (Fig. 26–2).

The major cytokines mediating neutrophil maturation are G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF).[45] G-CSF not only supports the survival and proliferation of developing myeloid cells at all stages of differentiation but also increases the functional activity of mature neutrophils. Although the major role of G-CSF is thought to be the induction of neutrophil proliferation and differentiation, the G-CSF receptor (G-CSFR) is expressed on a wide range of cell types. In addition to myeloid progenitors and precursors at all stages of neutrophil differentiation, G-CSFR is expressed on platelets, monocytes, lymphocytes, and several nonhematopoietic cells, including endothelial cells and placenta.[46–49] The role of G-CSF as both an early- and late-acting cytokine is underscored by the successful use of G-CSF to mobilize early progenitors into the peripheral blood for stem cell collection and to speed neutrophil recovery following chemotherapy.[50]

The G-CSFR is a member of the cytokine receptor superfamily that signals through activation of the Jak-STAT (Janus kinase-signal transducer and activator of transcription) pathway and the Ras pathway. Ligand binding induces homodimerization of the receptor, leading to a cascade of downstream phosphorylation events. Dimerization leads to phosphorylation of associated JAK kinases that in turn phosphorylate STAT1 and STAT3. In addition, the activated G-CSFR also phosphorylates mediators of the Ras-mitogen-activated protein (MAP) kinase pathway by tyrosine phosphorylation of Shc.[51]

The importance of G-CSF in myeloid proliferation and differentiation has been studied in G-CSF-null[52] and G-CSFR-null mice.[53] Mice lacking G-CSF[52] or G-CSFR[53] had markedly decreased myeloid progenitors and impaired neutrophil production, with low circulating neutrophil counts. In addition, G-CSF-null mice had impaired neutrophil mobilization, and mature neutrophils from G-CSFR-null mice had increased susceptibility to apoptosis, supporting the role of the G-CSF pathway in sustaining the mobilization, survival, and function of mature neutrophils as well. However, despite all of these profound abnormalities, G-CSF/G-CSFR knock-out mice continued to make some neutrophils, suggesting that there are alternative overlapping cytokine pathways that support granulocyte development.[53]

GM-CSF also induces proliferation and differentiation of myeloid precursors. The GM-CSFR is a heterodimeric protein composed of an α- and a β-subunit. The α-subunit binds GM-CSF. The β-subunit is shared by the GM-CSFR and the receptors for IL-3, IL-5, and IL-6. The β-subunit does not bind ligand but is necessary for the high-affinity ligand binding to the αβ-heterodimer of each receptor. Signaling through the GM-CSFR also depends on the Jak-STAT pathway, signaling through Jak2, and also serves to activate the Ras-MAP kinase pathway.[54] Of interest, however, the GM-CSF-null mouse has no defect in hematopoiesis.[55] Mice with null mutations in both G-CSF and GM-CSF had more profound neutropenia in the perinatal period but the same levels of neutrophils in adulthood as those for mice lacking G-CSF only.[56]

Transcriptional Regulation of Myeloid Differentiation

Lineage-specific maturation of committed hematopoietic progenitors is ultimately driven by transcription factors, which have been hypothesized to be the final common pathway leading to commitment and differentiation of the pluripotent stem cell.[57] The role of transcription factors in cellular proliferation, differentiation, and survival of the stem cell during hematopoiesis in the mammalian bone marrow has

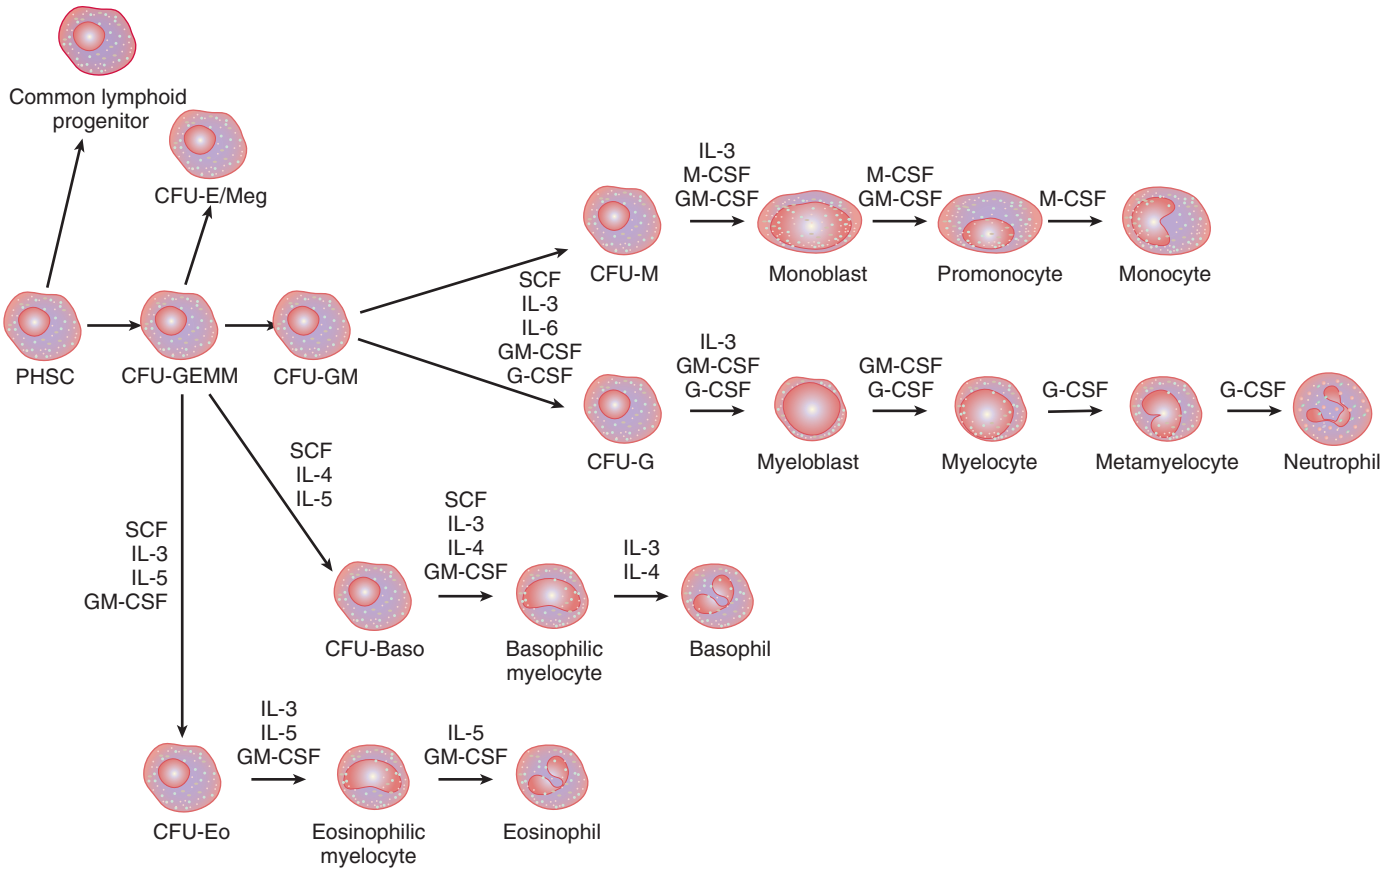

Figure 26–2 Cytokine regulation of granulocytic progenitors. been well established.[58,59] Studies of the regulation of individual genes that show tissue- and stage-specific myeloid expression have implicated a small number of transcription factors that are responsible for directing both phenotypical myeloid maturation and the expression of functionally important myeloid genes.[57,58,60–62] As described in detail subsequently, this role is underscored by the observations in AML, in which disruption of differentiation and defective myeloid-specific gene expression are linked to pathognomonic chromosomal translocations that result in the dysregulation of transcription factor expression.

Maturation of multipotent progenitor stem cells into specialized blood cells (lymphocytes, erythrocytes, neutrophils, monocytes, and eosinophils, among others) is regulated by a well-orchestrated interplay of transcription factors that are capable of instructing the expression of a specific set of genes within a specified lineage.[57,58,60,63] Gene knock-out technology and overexpression studies, in conjunction with newer techniques that involve the use of multicolor fluorescence-activated cell sorting (FACS), have aided in delineating several transcription factors critical to the development of specific hematopoietic lineages.[58,62,64] On the basis of these studies, critical transcription factors have been classified into two major categories. The first category includes factors such as stem cell leukemia transcription factor (SCL), GATA2, and acute myeloid leukemia transcription factor-1 (AML-1) that influence differentiation to all of the hematopoietic lineages; the second category comprises the master regulators of lineage development, including GATA1, PU.1, and CCAAT enhancer-binding protein-α (C/EBPα).[57] These factors not only promote lineage-specific gene expression but also suppress alternative lineage pathways. Fig. 26–3 summarizes the postulated role of several key transcription factors during hematopoietic development. Myeloid progenitors exhibit multilineage patterns of gene expression. In a recent study Laslo et al[65] elegantly demonstrated that cell fate determination is dependent upon subtle changes in expression levels of transcription factors, which regulate differential lineage maturation. For example, levels of PU.1 expression are increased by Egr-1/Nab-2 in developing macrophages; at the same time, Egr-1 represses the expression of the neutrophil specific Gfi-1 transcription factor, thereby simultaneously repressing the neutrophil development program (See Fig. 26–4).

Transcription Factors Regulating Myeloid Differentiation and Myeloid-Specific Gene Expression

AML-1. AML-1 (Runx 1) belongs to a family of highly conserved transcription factors that harbors a 128-amino-acid motif referred to as the Runt domain. The Runt domain functions in DNA binding, protein-protein interaction, ATP binding and contributes to nuclear localization.[66] This family of transcription factors, also known as the core binding factor (CBF) family, has been implicated in specification of cell fate and has a role in myeloid differentiation and lineage-specific granulocytic function.

AML-1 is the DNA-binding α-subunit of the CBF complex. Together with CBFβ, a widely expressed protein that enhances the DNA-binding affinity of the α-subunit, AML-1 binds the consensus DNA motif 5′ Pu ACCPuCA 3′ as a dimer.[67] Disruption of the

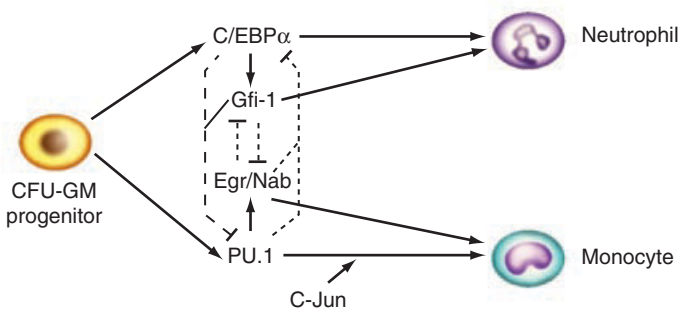

Figure 26–4 Transcription factor cross-talk affecting neutrophil and monocyte development.

AML1 gene in mice results in embryonic lethality resulting from a failure of definitive hematopoiesis in the fetal liver.[68] Although high levels of AML-1 expression have been reported in the early stages of myeloid differentiation, expression levels of AML-1 decrease beyond the promyelocytic stage of differentiation.[69] In concordance with its pattern of expression, AML-1 has been implicated in regulating a number of genes expressed early in the myeloid development pathway, including GM-CSF, macrophage colony-stimulating factor (M-CSF) receptor, myeloperoxidase, NE, and IL-3, among others.[69–72] In addition to activating lineage-specific myeloid markers, AML-1 has been shown to stimulate the G_1 to S transition in myeloid and lymphoid cell lines.[73]

A significant percentage (10%–20%) of human leukemias have been found to be associated with mutations in the *AML1* gene.[74] Most common of these is the t(8;21) translocation, which results in the AML-1-ETO (*e*ight *t*wenty-*o*ne oncoprotein) fusion protein. In AML-ETO, the Runt domain of AML-1 is fused in frame with the ETO transcriptional co-repressor.[75] The fusion protein has been hypothesized to function predominantly as a repressor that inhibits expression of genes that are normally activated by AML-1. For example, the tumor suppressor gene p14/p19(ARF), a critical AML-1 target gene that is necessary for the activation of p53 function, is normally activated by AML-1 but is repressed by AML-1-ETO.[76] The mechanisms underlying AML-1 function through its target genes are not yet fully understood.[77] Recent studies in sea urchins, however, have suggested that AML-1 regulates genes that contribute to chromatin architecture during cell proliferation.[66]

Studies involving mouse knock-in models of AML-1-ETO expression have indicated that the fusion protein alone is not sufficient to cause leukemia.[78] These animals are more susceptible to mutagen-induced AML, however, suggesting that AML-1-ETO is part of a multistep process that contributes to leukemogenesis.[79] Although the fusion partner of AML-1 (eg, ETO) may contribute to the role of the AML-1 fusion protein in leukemogenesis, the primary cause of the disease is thought to be the dysregulation of AML-1-specific target genes that are directly dependent on the Runt domain of AML-1.[80]

CCAAT Enhancer-Binding Protein Family of Transcription Factors. CCAAT enhancer-binding proteins (C/EBPs) are a family of basic region-leucine zipper (b-ZIP) transcription factors that recognize the consensus DNA-binding sequence 5′TKN NGYAAK3′ (Y = C or T; K = T or G) within the regulatory regions of target genes. C/EBP family proteins have been shown to bind DNA as either homo- or heterodimers. This family of transcription factors, which plays a crucial role in hematopoiesis, includes C/EBPα,-β,-γ, -δ,-ε, and -ζ (CHOP-GADD 153), all of which contain highly homologous carboxyl-terminal (C-terminal) dimerization (leucine zipper) domains and DNA-binding (basic region) motifs but differ in their amino-terminal (N-terminal) transactivation domains-with the exception of CHOP-GADD 153, which lacks this domain altogether.[81] Of interest, CHOP-GADD 153 can dimerize with and inhibit transactivation by C/EBPα,-β, and -ε and is found at a breakpoint in liposarcomas resulting in the TLS-CHOP fusion protein.[82]

With the exception of C/EBPε, which is expressed exclusively in the late stages of granulopoiesis and in T lymphocytes, the other C/EBP members are expressed in a wide variety of cells including liver, adipose tissue, lung, intestine, adrenal gland, and peripheral blood mononuclear cells and placenta.[81] Both C/EBPβ and C/EBPδ are expressed at high levels in late-stage granulocytes.[36] The C/EBP family members are known to exert pleiotropic effects in the tissues in which they are expressed. This may be due to their tissue- and stage-specific expression, their ability to dimerize with members of their own family and of the Fos/Jun and ATF/CREB families of transcription factors, and their ability to interact with other transcription factors such as nuclear factor-κB (NF-κB) and specificity protein-1 (Sp-1).[62]

The C/EBP factors have been implicated in regulating the differentiation of a variety of tissues. C/EBPα plays a role in adipocyte differentiation: Inhibition of C/EBPα blocks adipocyte differentiation, and overexpression of C/EBPα induces adipocyte differentiation.[83] Regulation of constitutive hepatic genes as well as acute-phase response genes in the liver involves several C/EBP family members, in particular, C/EBPα.[84] Modulation of myelomonocytic differentiation is also attributed to the activity of C/EBP family members.[81] The importance of this family of transcription factors in myeloid differentiation has been demonstrated by the study of hematopoietic

abnormalities observed in mice with targeted disruption of C/EBPα, -β, and -ε.

C/EBPα. C/EBPα has been postulated to be a master regulator of the granulopoietic developmental program. It is expressed at high levels throughout myeloid differentiation and has been shown to bind to the promoters of multiple myeloid-specific gene promoters regulating gene expression at many different stages of myeloid maturation. Although C/EBPα$^{-/-}$ mice die perinatally because of defects in gluconeogenesis that result in fatal hypoglycemia,[85] they also have a selective early block in the differentiation of granulocytes without affecting either monocyte/macrophage maturation or the differentiation of other hematopoietic lineages. Myeloid cells of C/EBPα$^{-/-}$ mice lack G-CSFR, and it has been postulated that lack of mature neutrophils in these mice may be due to the lack of G-CSFR.[86] However, the myeloid defect in C/EBPα$^{-/-}$ mice is more severe than that seen in G-CSFR$^{-/-}$ mice, suggesting that C/EBPα has additional functions vital to granulocytic maturation.

The C/EBP proteins all are expressed in multiple isoforms that are generated by both alternative transcription initiation and alternative splicing. C/EBPα itself is translated from two different start sites, yielding a 42-kd and a 30-kd isoform. Mutations in C/EBPα have been demonstrated in a subset (7%) of patients with AML with normal karyotypes. These mutations result from frameshifts in the N terminus of the C/EBPα gene resulting in the production of a nonfunctional protein. Studies by Tenen and colleagues have shown that the 30-kd isoform of C/EBPα (αp30) is preferentially formed in the setting of AML-associated mutations in C/EBP. In their studies, this isoform showed poor binding to target promoters and was presumed to act by decreasing C/EBPα DNA binding.[87] They concluded that the 30-kd isoform has a dominant negative activity that leads to a loss of C/EBPα function.[57,61] Additionally, the AML-ETO protein associated with the t(8;21) AML physically interacts with C/EBPα, thereby inhibiting the transactivation function of C/EBPα.[88]

The expression of C/EBPα is associated with growth arrest and differentiation of granulocyte precursor cells. This block in proliferation is thought to occur via the interaction of C/EBPα with the cyclin-dependent protein kinases cdk2 and cdk4, resulting in a block in cell proliferation by inhibiting these cell cycle kinases. In addition, C/EBPα inhibits E2F-dependent transcription, which in turn contributes to inhibition of cell proliferation and induction of differentiation associated with C/EBPα-induced granulopoiesis.[89,90]

C/EBPβ. Expression of C/EBPβ increases during myeloid maturation and has been shown to be important for monocyte/macrophage gene expression and development.[91] Mice lacking the C/EBPβ gene demonstrate decreased B-cell levels and defects in macrophage activation and function and are more prone to microbial infections.[92] The C/EBPβ knock-out studies reveal that this transcription factor is not essential for myeloid development per se, but knock-in of C/EBPβ into the C/EBPα locus of C/EBPα$^{-/-}$ mice rescues granulopoiesis.[93] Several monocyte/ macrophage-specific genes are activated by C/EBPβ, including the G-CSF receptor, lysozyme, CD11c, monocyte chemoattractant protein-1 (MCP-1), IL-6, IL-8, and nitric oxide synthase, among others.[60] Three isoforms of C/EBPβ are generated from a single transcript through the use of three translation initiation sites and a leaky ribosome scanning mechanism.[81,94] The shortest of these isoforms, initiated at the most 3′ AUG, results in the formation of LIP (*l*iver-enriched *i*nhibitory *p*rotein), which lacks the N-terminal activation domain present in full-length C/EBPβ and has been implicated as a negative regulator of C/EBPβ function.[93] It has been suggested that the ratio of C/EBPβ to LIP may affect cellular proliferation and differentiation.[95] The activity of C/EBPβ is regulated post-transcriptionally through protein-protein interactions and covalent modifications. For example, in early myeloid progenitor cells, C/EBPβ is found in an unphosphorylated state in the cytoplasm. However, on differentiation, C/EBPβ becomes phosphorylated and translocates to the nucleus.[96]

C/EBPγ. C/EBPγ is a ubiquitously expressed C/EBP family member that was first identified by its affinity for *cis*-regulatory sites in the Ig heavy chain promoter and enhancer. C/EBPγ contains a C/EBP-like b-Zip domain but lacks an N-terminal transactivation domain and can inhibit transcriptional activation of other C/EBP members in some cell types.[97] Impairment of natural killer (NK) cytotoxic activity and of interferon-γ production has been reported in C/EBPγ$^{-/-}$ mice.[98]

C/EBPδ. C/EBPδ is expressed at low or undetectable levels in several tissues of adult mice and humans. Expression has been shown to dramatically increase on induction with bacterial lipopolysaccharide and inflammatory cytokines, suggesting a role for C/EBPδ in acute-phase and inflammatory response. Double-knock-out experiments using C/EBPβ and C/EBPδ suggest a synergistic role for these two C/EBP family members in controlling terminal adipocyte differentiation.[99] Of interest, both C/EBPβ and C/EBPδ are expressed during late neutrophil development and have been postulated to play roles in late neutrophil gene expression.[36]

C/EBPε. CCAAT enhancer-binding protein ε (C/EBPε) is the most recently described C/EBP protein. The human C/EBPε gene resides on chromosome 14 and is transcribed by two alternative promoters, Pα (thought to function in mature neutrophils) and Pβ (thought to function in bone marrow).[100] A combination of differential splicing and alternate promoter usage results in four messenger RNA (mRNA) isoforms 2.6 kilobases and 1.3 to 1.5 kilobases in size, from which three proteins of 32.2 kd, 27.8 kd, and 14.3 kd have been described.[101] C/EBPε$^{-/-}$ mice produce hyposegmented granulocytes that are functionally defective. Late in life, these mice develop myelodysplasia. Absence of C/EBPε is thought to block the later steps in terminal differentiation of mature segmented granulocytes. Mutant mice usually survive 2 to 5 months and eventually succumb to low-pathogenicity bacterial infections.[101] C/EBPε thus plays a crucial role in terminal granulocytic differentiation.[100]

C/EBPε$^{-/-}$ mice have wild-type levels of the G-CSF receptor,[101,102] and the defects manifested in these mice are confined to late-stage gene expression associated with the function of the mature neutrophil. Recently it has been demonstrated that the ability of G-CSF to regulate myeloid differentiation is dependent on the induction of C/EBPε. Verbeek and colleagues[103] showed that the mRNA of several genes including p47 phox (a component of the neutrophil NADPH oxidase complex), as well as the secondary granule protein (SGP) genes, are either absent or abnormal in the bone marrow of C/EBPε$^{-/-}$ mice. These investigators further suggest that C/EBPε plays a critical role in the regulation of host antimicrobial defense.

Neutrophils from C/EBPε$^{-/-}$ mice have morphologic and biochemical features very similar to those observed in patients with neutrophil-specific specific granule deficiency (SGD). SGD is an extremely rare congenital disorder that is characterized by frequent and severe bacterial infections.[104,105] Patients with SGD have defects in neutrophil function including atypical nuclear morphology, impaired bactericidal activity, and abnormalities in neutrophil migration; they also lack both neutrophil and eosinophil secondary granule proteins.[105,106] Recent sequence analyses of genomic DNA from two patients with SGD revealed mutations within the C/EBPε gene, resulting in a mutant protein lacking the dimerization and DNA-binding domains and hence transcriptional activity.[86] Lack of functional C/EBPε activity has been postulated to underlie the observed pathology in these patients.[86,107]

C/EBPζ. C/EBPζ-C/EBP homologous protein (CHOP)-is a C/EBP family member that was originally isolated as the product of a gene induced in response to DNA-damaging agents. It has subsequently been shown to be induced by various extracellular or endoplasmic reticulum stresses. The basic region of CHOP is less well conserved than that of the other C/EBP family members, and CHOP does not seem to bind to canonical C/EBP *cis* elements.[94] CHOP has

been shown to interfere with the transcriptional activity of C/EBPβ in a manner dependent on its leucine zipper.[94]

PU.1. PU.1 is a member of the Ets family of transcription factors and is expressed abundantly in B cells and macrophages.[108] Expression of PU.1 has also been reported in granulocytes and eosinophils as well as in $CD34^+$ hematopoietic progenitor cells.[109] High levels of PU.1 expression in fetal livers of mice preferentially directs macrophage development, whereas low levels of PU.1 result in B-cell development.[110] C-Jun, another member of the b-Zip family of transcription factors, serves as a coactivator of PU.1 during macrophage development. It has been demonstrated that overexpression of c-Jun in myeloid progenitor cells results in macrophage development.[111,112] Recent studies have revealed that downregulation of c-Jun by C/EBPα is necessary for granulocytic maturation and appears to be the mechanism through which C/EBPα blocks macrophage development.[111] C/EBPα not only binds to the promoter of the c-*jun* gene and decreases its expression but also binds PU.1, thereby inhibiting its activity.[111]

PU.1-binding sites have been reported in almost all myeloid- specific promoters reported to date, including those for M-CSF, GM-CSF, and G-CSF receptors-all of which play critical roles in myeloid cell development.[60] PU.1 activity is modulated both by covalent modifications and by protein-protein interactions. For example, phosphorylation of PU.1 by casein kinase II or by JNK kinase leads to increased transcriptional activity.[113]

Abrogation of PU.1 expression in $PU.1^{-/-}$ mice results in perinatal lethality accompanied by the absence of mature monocytes/macrophages and B cells and delayed and reduced granulopoiesis.[114] Following in vitro differentiation, embryonic stem (ES) cells derived from $PU.1^{-/-}$ blastocysts fail to express mature myeloid cell markers, suggesting that PU.1 is not essential for the initial events associated with myeloid lineage commitment but is necessary for the later stages of development.

Growth Factor Independence-1 (Gfi-1). The Gfi-1 gene was first identified as a target of proviral insertion following infection with Moloney murine leukemia virus (MoMuLV) resulting in interleukin-2 (IL-2) factor independence in a rat lymphoma cell line (reviewed in[115]).Gfi-1 is a highly conserved gene that encodes a 55kD nuclear proto-oncogene that harbors six C_2H_2 type zinc finger domains at the carboxy terminus and a 20 amino acid stretch at the N-terminus known as the SNAG domain (reviewed in[115]). The SNAG domain which appears to be conserved in the Snail/Slug family of proteins, has been shown to confer transcriptional repressor activity on Gfi-1.[116] The human Gfi-1 gene is located on chromosome 1p22[117]and its closely related paralog Gfi1b maps to chromosome 9q34.[118] Gfi-1 is expressed at high levels in the thymus and bone marrow while Gfi1B expression is confined to the bone marrow and spleen.[119] Homozygous knockout of Gfi-1B results in embryonic lethality at day E15, despite the fact that myelopoiesis is normal. Death in these mice has been attributed to a failure of erythropoiesis and megakaryopoiesis.[120]

The essential role of Gfi1 in neutrophil differentiation became apparent only recently following two reports of gene disruption in mice.[121,122] Gfi1-null mice are severely neutropenic and eventually succumb to bacterial infections. In addition, these mice lack mature neutrophils and their granulocyte precursors are unable to differentiate into mature neutrophils upon induction with G-CSF. These cells also lacked SGP expression reminiscent of C/EBP−/− granulocytes. Gfi-1−/− bone marrow contained an atypical $Gr1^+Mac1^+$ myeloid precursor cell that appeared to share characteristics of both granulocyte and macrophage precursors. Ectopic expression of Gfi1 in ex-vivo sorted Gfi1−/− progenitor cells restored G-CSF mediated neutrophil maturation to these cells. These observations provide evidence for the critical role of Gfi1 in the neutrophil maturation program. Recent studies have further demonstrated that Gfi-1 together with C/EBPε synergize to transactivate the promoters of late myeloid genes. This synergy is lost in a patient with specific granule deficiency (SGD), who has a heterozygous substitution mutation in the C/EBPε gene and decreased levels of Gfi-1 in the bone marrow.[123]

Recently, heterozygous dominant negative mutations in the Gfi1 gene have been described in two patients with severe congenital neutropenia (SCN)[124] underscoring the role of Gfi1 in the neutrophil maturation pathway. It has been suggested that mutant Gfi1 in these patients alters the expression of elastase 2 (Ela2), mutations in which are commonly associated with SCN (see below). This observation confirms the vital role Gfi1 plays in human granulopoiesis.

CCAAT Displacement Protein. CCAAT displacement protein/cut (CDP) is a ubiquitously expressed, highly conserved, homeodomain protein with extensive homology to the *Drosophila* cut protein.[125] CDP has been shown to act as a repressor of developmentally regulated genes including the phagocyte-specific cytochrome heavy chain gene (gp91 phox), which is expressed exclusively in differentiating granulocytes.[126,127] Overexpression of CDP in 32Dcl3 myeloid cells blocks G-CSF-induced expression of SGP genes without blocking phenotypical maturation. CDP therefore acts as a negative regulator of stage-specific expression of both early and late neutrophil-specific genes.[128,129]

The CDP homeobox protein contains three highly conserved DNA-binding repeats referred to as *cut repeats* (CR1, CR2, CR3) and a homeodomain (HD), each of which is capable of recognizing and binding specific DNA motifs in target genes.[127,130–132] This may explain why the CDP molecule as a whole does not have a well-defined consensus DNA-binding sequence.[133] A recent study has shown that the cut repeats cannot bind DNA as monomers but in combination exhibit high DNA-binding affinity.[133] It has further been suggested that CDP-binding activity is restricted to proliferating cells, in which CDP target genes are repressed. These targets are upregulated as cells undergo cell cycle arrest and terminal differentiation, in association with a decrease in CDP binding.[126–129,134–136] Target genes of CDP include c-*myc*, c-*mos*, and the thymidine kinase (TK), cdk inhibitor p21(*WAF1*/*CIP1*), cystic fibrosis transmembrane conductance regulator (CFTR), transforming growth factor-β (TGF-β) type II receptor, gp91 phox, major histocompatibility complex (MHC) class I locus,[135,137–145] and neutrophil SGP genes.[128,129]

During myeloid differentiation, CDP binding has been shown to regulate genes that are expressed at widely disparate stages of differentiation. For example, it represses the gp91 phox gene, which is expressed at a much earlier time in myelopoiesis than is the case for the LF gene. The mechanism by which CDP mediates repression, and the means by which it modulates stage-specific gene expression at different stages of differentiation within a single lineage, are not fully understood. CDP is reported to have repressive activity associated with its ability to be displaced by a positive trans-acting factor involving the CR1 and CR2 cut repeats.[133] However, other modes of repressive activity involving the two active repression domains within the C terminus of CDP also have been reported.[125] Recently, CDP has been shown to function as a repressor of transcription via chromatin modification through recruitment of histone deacetylases (HDACs),[140] consistent with the notion that transcriptional silencing is associated with hypoacetylated histones.[143] Both acetylation and phosphorylation of CDP are post-transcriptional modifications that have been postulated to regulate CDP function.[144,145] Thus, differential modification, by phosphorylation or acetylation, of CDP-DNA complexes binding the promoters of target genes could result in the observed differential repression exerted by CDP during neutrophil development.

ROLE OF DEVELOPMENTALLY IMPORTANT NEUTROPHIL-SPECIFIC GENES IN DISEASE

Our understanding of the role of neutrophil-specific genes has been enhanced by the study of mice in which targeted disruption of a gene

Table 26–2 Differentiation-Specific Genes Implicated in Neutrophil Disorders

results in phenotypically important defects in neutrophil differentiation and function. Similarly, the importance of these genes has been underscored by the analysis of naturally occurring genetic events within these genes that result in human disease. The links between some genes and the diseases induced by their dysfunction may be anticipated by their important roles in neutrophil differentiation and function, whereas the pathophysiologic link between others and the diseases they induce remain elusive (Table 26–2).

Disruption of neutrophil transcriptional regulation is a recurring theme in the pathogenesis of leukemia. Nearly half of patients with AML have pathognomonic translocations resulting in the fusion of a transcription factor with a tissue-specific gene. These translocations have been shown to interfere with appropriate myeloid differentiation and emphasize the role of transcription factors in that process.[57,62]

As discussed previously, the same transcription factors that are implicated in the induction of neutrophil differentiation also direct the expression of genes encoding neutrophil-specific functional proteins. The link between morphologic differentiation and synthesis of neutrophil functional proteins is illustrated by the demonstration that disruption of C/EBPε signaling results in SGD, associated with both morphologic abnormalities and increased infections attributable to neutrophil functional defects.[85,99,107] It is intriguing that C/EBPε$^{-/-}$ mice share these abnormalities while also demonstrating a predilection for the development of myelodysplasia (ie, myelodysplastic syndrome [MDS]).[146] Although the development of MDS or AML has not been reported in patients with SGD, the deficiency is a rare disease described in less than a dozen patients, so a tendency to develop MDS/AML could easily be missed.

Other diseases have been linked to defects in functionally important neutrophil proteins. Abnormalities in integrin expression, notably, loss of the common β-chain of the integrin receptors, result in leukocyte adhesion deficiency,[6,147] and absence of any of the components of the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase leads to chronic granulomatous disease.[148]

Abnormalities in granule protein gene expression again underscore the complexity of the granulocyte functional program. Congenital absence of many individual granule proteins, including myeloperoxidase,[149] lactoferrin,[150] and transcobalamin,[151] has been described. In the absence of the more global defects seen in SGD, which presumably reflect more complex abnormalities than simple protein deficiency, these defects tend to be incidental laboratory findings with minimal or no associated pathology.

One prominent exception to that observation is the association between point mutations in the gene encoding NE (ELA2; neutrophil elastase) and severe congenital neutropenia (SCN), or Kostmann syndrome. The pathogenesis of SCN originally was sought in studies of G-CSFR, supported by the observation of a truncation mutation in G-CSFR in select patients with Kostmann syndrome.[152] It was later demonstrated that these were acquired mutations that may predispose the patient to secondary AML but did not constitute the pathologic basis for the neutropenia itself. Subsequent studies have implicated NE in the pathogenesis of SCN. NE is a primary granule protein that digests elastin and has been implicated in the pathogenesis of emphysema.[153] Recent linkage studies have linked heterozygous abnormalities in the NE gene to both SCN (Kostmann syndrome) and cyclic hematopoiesis.[154–156] The link between elastase and the control of neutrophil cell mass remains a mystery.

EOSINOPHIL PRODUCTION

Eosinophil precursors constitute approximately 3% of marrow progenitors, of which about two thirds are myelocyte precursors and the remainder mature eosinophils. Eosinophilic myelocytes are large cells with a single-lobed nucleus. The characteristic specific granules of eosinophils contain major basic protein, eosinophil cationic protein, eosinophil peroxidase, and eosinophil-derived neurotoxin. Eosinophils also contain primary granules that contain Charcot-Leyden crystal protein. Mature eosinophils are released into the marrow, where they circulate up to 18 hours before migrating to the tissues.[157]

Eosinophils proliferate and mature under the influence of IL-3, IL-5, and GM-CSF. Evidence suggests that these cytokines are secreted by T cells as the stimulus to eosinophil production in many disorders associated with eosinophilia. Recent studies of idiopathic hypereosinophilic syndrome have described activating mutations in the platelet-derived growth factor receptor-α (PDGFR-α) that result in constitutive tyrosine kinase activation and eosinophil proliferation.

Transcriptional regulation of eosinophilic differentiation is mediated through PU.1 C/EBPα and -β. Because these same factors serve to induce myeloid differentiation, the modulation of the signals determining the choice between these two lineages is not well defined. It has been proposed that levels of GATA-1 may be important in determining whether C/EBP expression induces the eosinophilic or the myeloid maturation program (see Chapter 45).[158]

BASOPHIL AND MAST CELL PRODUCTION

Basophils and mast cells mediate allergic responses, where they are the central cells involved in IgE-induced immune responses to parasites and other allergens. Both cell types are derived from marrow precursors, but they have a very different ontogeny (see Chapter 73).[159]

Basophils have a bilobed nucleus and characteristic intensely staining purple granules that may cover the nucleus. These granules contain glycosaminoglycans, predominantly heparin. Basophils differentiate from marrow progenitors and are released from the marrow as mature cells, where they circulate briefly, with a lifespan similar to that of neutrophils. Maturation is induced in response to IL-3, which serves both to induce basophilic differentiation and to mediate activation of mature basophils. Although IL-3 is the primary mediator of basophil development, studies of IL-3-null mice have demonstrated that it is not required for baseline production of basophils. It is, however, required for the induction of basophilia in response to parasitic infection.[160]Other cytokines that influence basophil proliferation include GM-CSF, IL-5, and SCF.

Mast cells arise from marrow precursors but are released into the circulation as immature cells. They circulate only briefly in the peripheral blood before migrating to the tissues, where they complete their maturation. There remains some question about whether mast cells and basophils arise from a common precursor.[161] In vitro studies showed that adding SCF to IL-3 to cultured CD34^{+} cells results in an increased proliferation and maturation of both basophils and mast cells but did not establish a common progenitor cell for the two lineages.[162] It is clear that SCF is especially effective in inducing mast cell proliferation; in fact, activating mutations in c-Kit, the SCF receptor, is the underlying molecular defect in most cases of systemic mastocytosis.

MONOCYTOPOIESIS

Monocyte Ontogeny

Stages of Monocyte Differentiation

Monocytes originate in the bone marrow from promonocytes, which constitute approximately 3% of the total cells in the normal marrow.[3] Promonocytes have round nuclei and basophilic cytoplasm. Differentiation occurs rapidly, with a maturation time of 50 to 60 hours, associated with two rounds of replication and morphologic maturation marked by progressive lobulation of the nucleus.[163,164] Stress-induced release of monocytes occurs primarily through their premature release from the proliferating pool.[152] Survival in the blood is short, approximately 8 to 72 hours.[165] Monocytes then enter the tissues, where they develop into macrophages that may survive 2 to 3 months. Tissue-fixed macrophages are found in the lung (alveolar macrophages), the liver (Kupffer cells), the spleen, and the central nervous system (glial cells).

Monocytes also may serve as precursors to a subset of dendritic cells. Dendritic cells are professional antigen-presenting cells that arise from both myeloid and lymphoid precursor cells.[166] The myeloid subset of dendritic cells arises from a precursor that can alternatively differentiate into macrophages.[167,168] Similar cells have been generated for immunotherapy by exposing peripheral blood monocytes to GM-CSF and IL-4 in vitro.[169]

Markers of Monocyte Maturation

Unique surface markers of monocyte maturation have been difficult to identify. In the mouse, the marker F4/80 was identified as a nearly universal marker of monocytes and macrophages; this antigen has been shown to be homologous to the human EGF module containing mucin-like hormone receptor 1.[170] The function of this receptor is unknown, because the knock-out mouse has no phenotype.[171] Monocyte precursor cells express the M-CSF receptor, lysozyme, the Fcγ receptor (II/III),[172] and the scavenger receptor.[173] Mature monocytes, like neutrophils, show high-level expression of CD11b/CD18. Following differentiation to macrophages, the cells acquire expression of macrosialin (CD68), a glycoprotein of unknown function that may play a role in lipoprotein metabolism.[174] Macrophages also express sialoadhesin, a member of the sialic acid-binding receptor family. Although its precise function has not been proved, sialoadhesin mediates binding to sialic acid moieties on cell surfaces and probably plays a role in macrophage cell-cell interactions and cell-extracellular matrix interactions.[175]

CD14 is a major functional surface protein of the monocyte/macrophage lineage.[176] CD14 is the receptor for lipopolysaccharide (LPS), leading to monocyte/macrophage activation.[177] More recent studies have suggested that CD14 also may have a role in apoptosis.[165]

Monocytes contain both primary (peroxidase-positive) and secondary (peroxidase-negative) granules. The primary granules of monocytes, like those of neutrophils, contain myeloperoxidase.[178] Secondary granule fusion with the membrane on stimulation of monocytes results in upregulation of Mac1 and p150,95 and is thought to play a role in adhesion and diapedesis of stimulated monocytes.[179]

Control of Monocytopoiesis

Cytokine Regulation of Monocyte Proliferation and Differentiation

The effects of colony-stimulating factor 1 (CSF-1), the primary regulator of mononuclear phagocyte production, are thought to be mediated by the high-affinity receptor tyrosine kinase CSF-1 receptor (CSF-1R), encoded by the c-*fms* proto-oncogene.[180] A total of five human or mouse mRNAs resulting from alternative splicing and the alternative use of the 3′ untranslated region resulting in three isoforms of the CSF-1 protein: a secreted proteoglycan, a secreted glycoprotein, and a membrane-spanning cell surface proteoglycan have been described.[181]

The phenotypes of Csf1-null mice and of mice harboring an inactivating mutation in the coding region of CSF-1 ($Csf^{op}/Csf1^{op}$) (osteopetrotic mice) are virtually identical; features include toothlessness, low body weight, low growth rate, and deficient tissue macrophages. Additionally, the mutant mice have defects in both male and female fertility.[180] Compared with their wild-type littermates, splenic erythroid burst-forming unit and high-proliferative-potential colony-forming cell levels in both $Csf1^{op}/Csf1^{op}$ and $Csf1^{-}/Csf1^{-}$ mice were significantly elevated, consistent with a negative regulatory role for CSF-1 in erythropoiesis and in the maintenance and proliferation of primitive hematopoietic progenitors. The circulating CSF-1 concentration in CSF receptor-null ($Csf1R^{-}/Csf1R^{-}$) mice was elevated 20-fold, in agreement with the previously reported clearance of circulating CSF-1 by CSF-1R-mediated endocytosis. Despite their overall similarity, several phenotypical characteristics of the $Csf1R^{-}/Csf1R^{-}$ mice were more severe than those of the $Csf1^{op}/Csf1^{op}$ mice. The results indicate that all of the effects of CSF-1 are mediated via the CSF-1R, but that additional effects of the CSF-1R could result from its CSF-1-independent activation.[182]

Signaling through the CSF-1R appears to be critical for monocyte/macrophage development. Although little is known about the events that lead to stimulation of a monocyte/macrophage specific array of genes, it is clear that several transcription factors, probably stimulated by M-CSF-related signaling events, play vital roles in the development of this lineage. It should be noted, however, that the ability of phorbol esters to induce monocytic differentiation of myeloid cell lines through activation of the protein kinases Cα and Cδ suggests a role for the PKC pathway in monopoiesis.[63]

IL-3, G-CSF, and tumor necrosis factor (TNF) all have been shown to synergize with M-CSF in the proliferation of macrophages.[183] G-CSF also has been shown to induce the increased release of monocytes; this is an indirect effect dependent on the presence of M-CSF.[184] Monocytes also have been demonstrated to have functional G-CSF receptors, although G-CSF appears to function mainly to decrease monokine secretion rather than to increase monocyte proliferation.[185]

Transcriptional Regulation of Monocyte Differentiation

Of the several transcription factors that regulate the development of the monocyte/macrophage lineage, the most well-established is PU.1 (discussed earlier), because abrogation of PU.1 expression in $PU.1^{-/-}$ mice results in perinatal lethality accompanied by the absence of mature monocytes/macrophages and B cells and delayed and reduced granulopoiesis.[114] A number of factors, the most notable of which is c-Jun, cooperate with PU.1 to regulate monocyte-specific genes.

c-Jun. The c-*jun* proto-oncogene encodes the transcriptional activator protein AP-1. As a member of the early response genes, c-*jun* is rapidly and transiently activated in response to external proliferative signals.[186] The expression of c-Jun as well as related family members JunB and JunD is upregulated during monocytic differentiation.[187] In addition, overexpression of c-Jun in M1, U937, or WEHI-B D^{+} myeloid cell lines, as well as in myeloid progenitor cells, was found to result in partial monocytic differentiation.[111,112,187] However, $c\text{-}Jun^{-/-}$ fetal liver cells are capable of reconstituting hematopoiesis in syngeneic recipients, suggesting that c-Jun is not required for myeloid development.[188] This finding may reflect a compensatory role played by other Jun family proteins.

As discussed, c-Jun serves as a coactivator of PU.1 during macrophage development. Recent studies have revealed that downregulation of c-*jun* by C/EBPα is necessary for granulocytic maturation and appears to be the mechanism through which C/EBPα blocks macrophage development[111] (Fig. 26–4). C/EBPα not only binds to the promoter of the c-*jun* gene and decreases its expression but also binds to PU.1, thereby inhibiting its activity.[111] Such transcription factor cross-talk resulting in subtle changes in the levels of transcription factors within a given lineage appears to be an emerging paradigm through which master regulators of lineage specification, such as C/EBPα and PU.1, direct lineage-specific development by directly upregulating lineage-specific genes as well as by blocking the progression of alternate lineages.[57]

Other Transcription Factors Modulating Monocyte Development

Egr-1. Egr-1 belongs to a family of zinc finger transcription factors, and is expressed in a number of tissues and at various points in development including the terminal stages of macrophage and neutrophil differentiation.[189,190] Egr-1 is necessary for monocytic differentiation of myeloid cell lines U937 and M1 and prevents factor-induced granulocytic differentiation of HL60 and 32Dcl3 cells.[178,179] Additionally, ectopic expression of Egr-1 in myeloid marrow progenitors was found to result in an increase in the number of CFU-M at the expense of CFU-G.191. However, mice lacking Egr-1 develop normal numbers of macrophages, a phenomenon attributed to the possible compensatory effects of other Egr family members.[181]

C/EBPβ. As discussed, expression of C/EBPβ increases during myeloid maturation and has been shown to be important for monocyte/macrophage gene expression and development.[90]

MafB and c-Maf. The transcription factors MafB and c-Maf belong to a family of basic-leucine zipper (b-Zip) factors that bind DNA as dimers.[193] The Maf proteins can dimerize with members of other b-Zip family proteins including c-Jun, fos, and NF-E2 in erythroid cells.[194,195] Ectopic expression of MafB in myeloblasts directed their expression to macrophages,[196] whereas overexpression of c-Maf in HL60 and U937 myeloid cells resulted in monocytic differentiation.[197]

CHAPTER 27

THROMBOCYTOPOIESIS

Alan B. Cantor

INTRODUCTION

Platelets, once regarded simply as "blood dust," are now recognized to play essential roles in hemostasis. Not only do they form a hemostatic plug and initiate thrombus formation in the event of vascular injury, but they also repair minute vascular damage that occurs on a daily basis. Platelets are also thought to be involved in wound healing and angiogenesis through delivery of key growth factors, such as vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor beta 1(TGF β1) to sites of vascular injury. Disorders associated with platelet production carry significant morbidity and mortality in humans because of hemorrhage, thrombosis, bone marrow fibrosis, bone marrow failure, and/or hematologic malignancy. Platelets are generated from their precursor cells, megakaryocytes, through a complex process. For a long time, the extreme rarity of megakaryocytes significantly hampered studies aimed at understanding the molecular mechanisms underlying platelet biogenesis. However, the purification and cloning of thrombopoietin (Tpo), the major megakaryocyte cytokine, in 1994 has enabled considerable progress to be made. These new insights provide an important foundation for improved diagnosis and treatment of disorders of thrombocytopoiesis. This chapter reviews the current understanding of megakaryocyte biology and platelet production, highlighting connections with human disease.

MEGAKARYOCYTE BIOLOGY

Megakaryocyte Development

Although platelets were described as early as the 1840s, it was not until 1906, in a seminal study by James Homer Wright, that their origin from megakaryocytes was first recognized.[1,2] Megakaryocytes are large polyploid cells that reside predominantly within the bone marrow during postnatal life. They are rare cells, constituting only approximately 0.1% of nucleated cells under normal steady-state conditions.[3] They develop from common bipotential megakaryocyte-erythroid progenitor (MEP) cells, which are themselves derived from common myeloid progenitor (CMP) cells, and ultimately from pluripotential hematopoietic stem cells (HSCs). Once committed to the megakaryocytic lineage, megakaryocyte progenitors undergo a series of dramatic maturational steps ultimately tailored to their final task of platelet production and release. These include changes in proliferative capacity, cell size, nuclear content, organelle biogenesis, membrane development, and cytoskeletal rearrangement. The large increase in cell size is linked to an unusual process termed *endomitosis*, in which cells replicate their DNA but fail to undergo cytokinesis (see Endomitosis discussion below). Mature megakaryocytes reach diameters of approximately 100 microns and contain DNA content as high as 128N.[4–8] They contain a multilobulated nucleus enclosed by a single nuclear membrane. Their abundant cytoplasm is filled with ribosomes, platelet-specific granules, mitochondria, and complex intracellular membrane systems. Although megakaryocytes reside predominantly within the bone marrow, they are also found in peripheral blood, spleen, and lung under normal conditions.[9–15] These extramedullary megakaryocytes release platelets, but their contribution to total thrombocytopoiesis is estimated to account for at most 7% to 15%.[14,16]

Megakaryocyte Progenitors

Like other hematopoietic progenitor cells, megakaryocyte progenitors can be cultured in vitro using semisolid media. Animal studies using these colony assays have allowed delineation of a hierarchal developmental pathway of megakaryocyte progenitor maturation based on proliferative potential, DNA content, morphologic criteria, and gene expression pattern (Fig. 27–1). This pathway can be conceptually divided into three broad stages: proliferating megakaryocytic progenitors, which contain normal DNA content (2N–4N); nonproliferating immature megakaryocytes (4N–8N DNA content); and nonproliferating mature megakaryocytes (DNA content 8N–128N). Within the proliferating megakaryocyte progenitor compartment, the earliest detectable cell is the megakaryocyte high-proliferative-potential colony-forming cell (MK-HPP-CFC), which is capable of generating macroscopically visible colonies containing a few thousand megakaryocytes. This corresponds to a proliferative capacity of approximately 8 to 10 replicative cycles. These cells require interleukin-3 (IL-3) and simultaneous activation of the protein kinase C and cyclic adenosine monophosphate (cAMP) signaling pathway.[17]

The burst-forming unit megakaryocyte (BFU-MK), which is thought to be a direct progeny of MK-HPP-CFC, is more mature than the MK-HPP-CFC, but retains a high degree of proliferative potential, developing "bursts" of individual colony-forming cells. These colonies contain approximately 100 to 500 megakaryocytes, representing approximately 5 to 7 replicative cycles. In humans, BFU-MK cells require mitogenic stimulation with IL-3 or granulocyte-monocyte (GM)–colony-stimulating factor (CSF) and synergistic signaling with stem cell factor (SCF; also called *kit-ligand*), interleukin-11 (IL-11), interleukin-1-alpha (IL-1α), and Tpo.[18–21] They are also resistant to treatment in vitro with 5-fluorouracil (5-FU).[18,20]
