The most mature proliferating cell is the colony-forming unit megakaryocyte (CFU-MK), which has very limited proliferative potential, representing only two to five cell divisions (4–32 megakaryocytes per colony).[22] This progenitor responds to a variety of single growth factors, such as IL-3 and GM-CSF, and coregulators such as SCF, fms-like tyrosine kinase 3 (FLT3) ligand, and Tpo.[19,23,24] They express early markers of differentiation such as glycoprotein IIb (GPIIb) and platelet factor 4 (PF4) before initiating endomitotic cell cycles.[5]

Immature Megakaryocytes: Promegakaryoblasts

Promegakaryoblasts are transitional cells intermediate between proliferating progenitor cells and post-mitotic, mature megakaryocytes.[25,26] These cells are not readily observed morphologically in vitro or in bone marrow specimens but can be identified by their expression of megakaryocyte- or platelet-specific markers, such as platelet peroxidase, platelet GPIIb/ glycoprotein IIIa (GPIIIa), and von Willebrand factor (vWF).[27,28] They have DNA content levels intermediate between proliferating progenitors and mature megakaryocytes. Promegakaryoblasts respond to a variety of cytokines in vitro including IL-3, SCF, interleukin 6 (IL-6), and Tpo, to produce large polyploid megakaryocytes.[4,29] At least three distinct subpopulations of promegakaryoblasts have been identified based on different physiochemical characteristics, morphology, antigen expression, and enzyme content.[4,28,30,31]

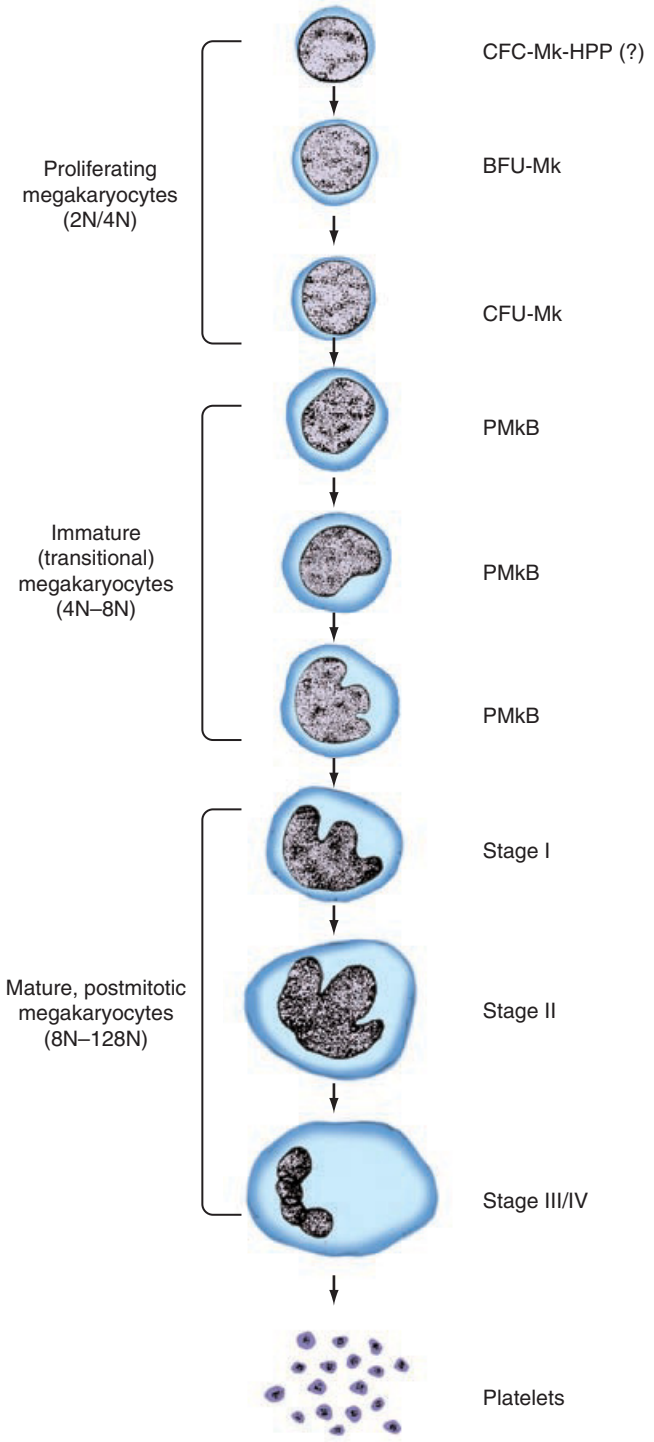

Figure 27–1 Cellular hierarchy of megakaryocyte development. Megakaryocytes can be conceptually divided into three stages: The proliferating progenitor cells, which have the typical 2N/4N DNA content; the immature megakaryocytes, which have an intermediate DNA content and are transitional between the progenitor cells and the more mature cells; and the mature, post-mitotic cells, which have an 8N to 128N DNA content. BFU-Mk, burst-forming unit megakaryocyte; CFC-Mk-HPP, colony-forming unit megakaryocyte high proliferative potential; CFU-Mk, colony-forming unit megakaryocyte; PMkB, promegakaryoblast.

Mature Megakaryocytes

Morphologically recognizable megakaryocytes exist in at least three distinct maturation stages as defined by their morphology (Fig. 27–2). The megakaryoblast (stage I) is characterized by a high nucleus-to-cytoplasm ratio and scanty basophilic cytoplasm, reflecting the large amount of protein synthesis occurring in these cells. The promegakaryocyte (stage II) is the cell in which the cytoplasmic volume and number of platelet-specific granules increase. The granular or "platelet shedding" megakaryocyte (stages III and IV) is the most mature cell. In reality, these stages likely represent a continuum.

Prospective Isolation of Megakaryocyte Progenitor Cells

Weissman and colleagues reported the prospective isolation of clonogenic committed megakaryocyte progenitor cells from the bone marrow of adult C57BLKa-Thy1.1 mice based on selection of a unique cell surface immunophenotype: c-kit$^+$Sca-1$^-$IL7Rα^-Thy1.1$^-$Lin$^-$CD9$^+$CD41$^+$FcγR^{lo}CD34$^+$D38$^+$.[32] This fraction represents approximately 0.01% of the total nucleated bone marrow cells and gives rise to CFU-MK and occasionally BFU-MK in colony assays. The ability to prospectively isolate pure populations of committed murine megakaryocyte progenitor cells should facilitate future studies of megakaryocyte development. Identification of a comparable set of surface markers for human megakaryocyte progenitors, if possible, would be of great usefulness.

Structure of Mature Megakaryocytes

Mature megakaryocytes contain a large multilobulated polyploid nucleus often situated toward the periphery of the cell. They have abundant cytoplasm, which contains platelet-specific secretory granules, alpha (α–) granules and dense granules (for more detailed discussion on platelet secretory granule development, see review by King and Reed[33]) (Fig. 27–3). The biogenesis of α-granules and dense granules begins in immature megakaryocytes, and both granule types develop concomitantly.[34] α-Granules are 200 to 500 nm in diameter and have a dense center and fine granular matrix.[35] Megakaryocytes synthesize many of the constituents of α-granules and target them to the granules. These include von Willebrand factor (vWF),[36] fibronectin,[36] P-selectin,[37] fibrinogen receptors, PF4,[38] coagulation factor V,[39] and plasminogen activator inhibitor type 1 (PAI-1),[40] among others. In addition, some constituents, such as fibrinogen, are taken up by megakaryocytes through endocytosis and/or pinocytosis and stored in α-granules.[41,42] Dense granules are 200 to 300 nm in diameter and consist of a halo encircling an electron opaque core.[35] They contain many soluble hemostatic factors such as serotonin, catecholamines, adenosine, adenosine diphosphate (ADP), adenosine triphosphate (ATP), and calcium. Their limiting membranes contain glycoproteins such as αIIbβ3, glycoprotein Ib (GPIb), and P-selectin, which are also present in α-granules, as well as unique membrane proteins such as granulophysin.[43–46] Multivesicular bodies (MVBs) serve as intermediates in the biogenesis of both α-granules and dense granules.[34,41] It has been proposed that they constitute a sorting compartment between α-granule and dense granule components.[34]

The megakaryocyte cytoplasm contains at least two complex membranous systems; the demarcation membrane system (DMS) and the dense tubular system (DTS) (see Fig. 27–3). The DMS consists of an extensive network of tubular and flattened membranous structures that interconnect with one another and communicate with the extracellular space.[47–50] Whole cell patch-clamp studies in living rat megakaryocytes have shown that they are electrophysiologically contiguous with the plasma membrane.[51] The open canalicular system (OCS) of platelets shares many features of the megakaryocyte

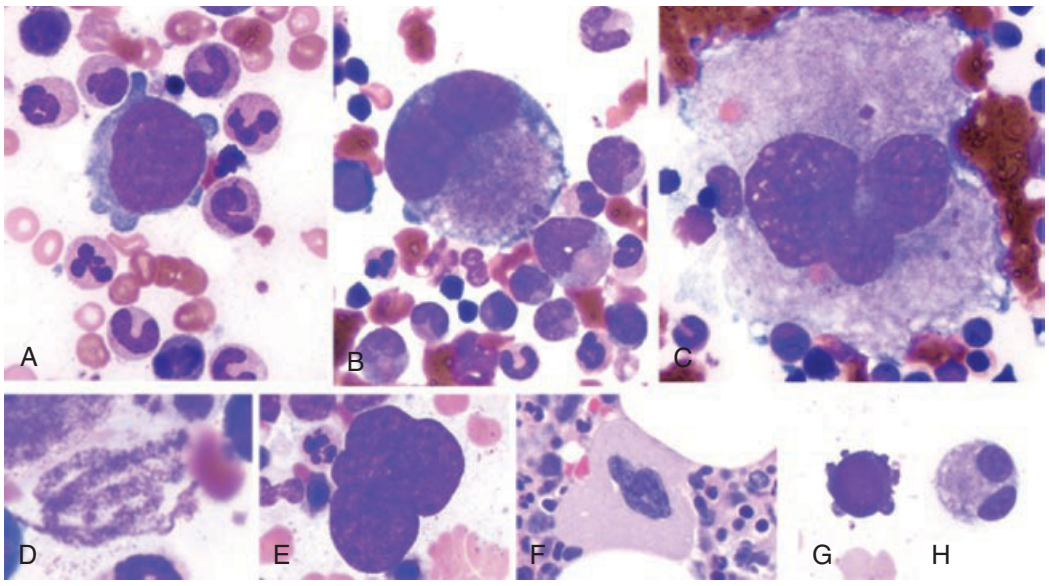

Figure 27–2 Megakaryopoiesis and megakaryocytes. **A,** Megakaryoblast (stage I) with intermediate ploidy level. Cytoplasm is scant. Note prominent cytoplasmic pseudopods. (**B**) Promegakaryocyte with early platelet production (stage II). (**C**) Mature, high ploidy megakaryocyte (stage III or IV) with abundant cytoplasm. Note cells traveling through cytoplasm. This is referred to as emperipolesis and is not uncommonly seen in large megakaryocytes. (**D**) Portion of megakaryocyte cytoplasm in long strand. Fragments of these can sometimes be seen in the blood and are referred to as *proplatelets*. (**E**) Megakaryocyte nucleus denuded of its platelets and cytoplasm. (**F**) Mature megakaryocyte seen in a tissue section of bone marrow biopsy. (**G**) Megakaryoblast from a patient with acute megakaryoblastic leukemia. Note cytoplasmic pseudopods. (**H**) Micromegakaryocyte from a patient with myelodysplasia. Note small, low ploidy (2–4N) nucleus, but mature cytoplasm.

DMS, and may represent a remnant of this structure.[35] The DMS serves as a vast membrane reservoir for proplatelet and platelet formation (see Platelet Biogenesis discussion below). The DTS of megakaryocytes is distinct from the DMS. Unlike the DMS, it fails to stain with surface membrane tracer dyes, indicating a lack of communication with the plasma membrane.[52] The DTS is thought to be a site of platelet prostaglandin synthesis.[53]

Ontogeny of Megakaryopoiesis

Hematopoiesis develops in distinct waves during embryonic development (see review by Tavian and Peault[54] for further details). In mammals, the first hematopoietic progenitors are found in blood islands of the yolk sac. These give rise to a distinct population of large erythrocytes, termed *primitive erythrocytes*, which express unique globin genes and retain their nucleus longer than adult-type or *definitive* erythrocytes. Definitive hematopoiesis arises later during embryogenesis from hematopoietic stem cells that develop de novo from the ventral aspect of the dorsal aorta in the aorta-gonad-mesonephros (AGM) region. These then seed the fetal liver, which serves as a major site of hematopoiesis during gestation. Eventually, hematopoiesis shifts to the bone marrow (and spleen in mice) where it is sustained postnatally.

Megakaryocyte progenitors have been detected in yolk sac as early as embryonic day 7.5 (e7.5) of mouse development.[55,56] They are capable of generating proplatelets and platelets after culturing in vitro.[55,56] Circulating platelets have been detected in the mouse embryo as early as e10.5.[56] Megakaryocytes cultured from early yolk sac have features somewhat distinct from those cultured from adult bone marrow, such as lower modal ploidy, smaller size, different cytokine requirements, and faster kinetics of platelet generation.[55] These unique progenitors disappear by e13.5. In addition, mixed erythroid-megakaryocyte colonies derived from the early yolk sac give rise to primitive erythrocytes. It has therefore been suggested that a separate wave of *primitive megakaryocytes*, akin to primitive erythrocytes, exists during early yolk sac stages of hematopoiesis.[55,56] These rapidly maturing megakaryocytes may prevent hemorrhage from the developing vasculature until definitive hematopoiesis is available to provide a steady supply of platelets.

Several pieces of evidence suggest that fetal liver megakaryocytes also have unique features compared to adult bone marrow-derived megakaryocytes. This could be because of either intrinsic differences in the progenitors, or possibly their interactions with different microenvironments. Megakaryocytes that develop from murine neonatal liver progenitors after transplantation into myeloblated mouse recipients are smaller and have lower ploidy levels than those derived from transplanted adult bone marrow.[57] However, these differences disappear by 1 month after transplant. In addition, several congenital disorders of megakaryopoiesis in humans, such as Down syndrome transient myeloproliferative disorder (DS-TMD) and thrombocytopenia and absent radius (TAR) resolve spontaneously after the newborn period, suggesting specific effects on fetal megakaryopoiesis (see GATA Family Transcription Factors discussion below). It is possible that these differences account for the delayed platelet engraftment often observed when umbilical cord blood is used as a source for hematopoietic stem cell transplantation in humans.[57]

Platelet Biogenesis

It has been estimated that each megakaryocyte produces between a few hundred to several thousand platelets.[13,16,58–60] The exact mechanism by which this occurs has been controversial, with several competing models proposed in the past. It was initially suggested that the DMS established platelet fields, which defined territories of prepackaged platelet contents.[61] These fields would generate platelets directly on breakdown of the megakaryocyte cytoplasm. However, prevailing evidence supports an alternate model in which platelets are released from dynamic megakaryocyte pseudopod extensions called *proplatelets*. This model was first proposed by Becker and DeBruyn in 1976,[62] and supported by ultrastructural studies later in the 1980s.[63–65] More recently, Italiano, Hartwig and their associates extended these earlier studies on proplatelet formation and platelet biogenesis using videomicroscopy of cultured murine megakaryocytes[66] (see Chapter 114 for detailed discussion and figures). These in-vitro experiments demonstrate that platelet biogenesis begins with a reorganization of unique cortical microtubules within the megakaryocyte to produce large pseudopodia structures from one pole of the megakaryocyte. This spreads across the megakaryocyte generating extensions that elongate into complex branching tubular proplatelet processes. During this time, organelles travel along microtubules within the shafts of the proplatelets and are loaded into the proplatelet tips where they are captured.[67] It is only at the tips of the proplatelets processes that platelets are shed. During proplatelet formation, extensive remodeling and branching occurs allowing for marked amplification of proplatelet ends. This phenomenon likely accounts for the ability of each megakaryocyte to generate such a large number of platelets. The DMS serves as an extensive membrane reservoir for these processes.[68,69]

Bone Marrow Spatial Cues and Megakaryocyte Maturation

There is mounting evidence that proliferation and terminal maturation of megakaryocyte progenitors occur in distinct spatial compartments within the bone marrow. In a simplified manner, the bone marrow space can be conceptually divided into distinct regions, a space adjacent to the cortical bone (an *osteoblastic niche*), an intermediate zone, and a *vascular niche* containing sinusoidal vessels lined with specialized bone marrow endothelial cells. HSCs are thought to reside in a quiescent state adjacent to the bone. Under appropriate conditions, they are recruited to generate hematopoietic multipotent progenitor cells, which leave the osteoblastic niche, perhaps in part

Inherited Causes of Thrombocytopenia

Although the most common cause of thrombocytopenia is immune thrombocytopenic purpura (ITP), it is important to maintain a high index of clinical suspicion for inherited disorders of thrombocytopoiesis. This is a particular problem as ITP is essentially a diagnosis of exclusion, and many inherited disorders mimic the macrothrombocytopenia seen in ITP. Making the correct diagnosis early is paramount, because it can spare patients unnecessary treatment with corticosteroids, other immunosuppressants, and/or splenectomy. In addition, it can be important in guiding decisions about surveillance for myelodysplasia or leukemia, screening for additional associated clinical problems, and/or possible family planning. Obtaining a careful family history, and sometimes obtaining blood counts on first-degree relatives, is important in fully evaluating patients with chronic thrombocytopenia. Associated abnormalities can provide important clues to the presence of a nonimmune familial thrombocytopenia. For instance, associated erythroid abnormalities and/or an X-linked inheritance pattern (GATA-1 mutations) (obligate females carriers can have dimorphic populations of platelets); leukocyte Dohle bodies, ± nephritis and sensineural hearing loss (Myh9 mutations); family history of myelodysplasia or myeloid leukemia (Runx-1 mutations); developmental delay, congenital cardiac anomalies, hand/face dysmorphogenesis (Paris-Trousseau/Jacobsen syndrome; Fli-1 [Ets-1] mutations); bleeding diathesis out of proportion to degree of thrombocytopenia (Bernard-Soulier syndrome). For a superb review of inherited thrombocytopenias and excellent diagnostic algorithm, see article by Balduini and colleagues.[281]

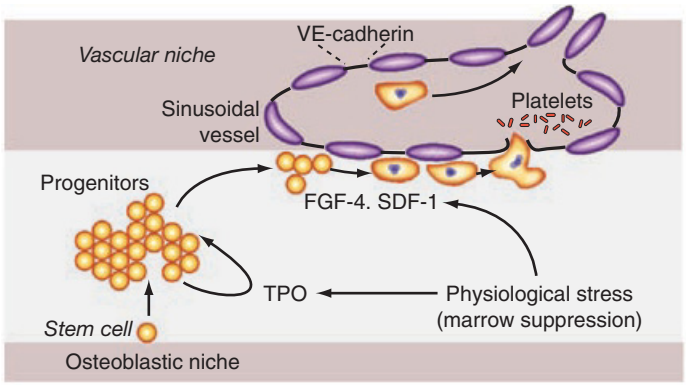

Figure 27–4 Model of terminal maturation of megakaryocytes at the bone marrow vascular sinusoid. Schematic diagram showing hematopoietic stem cells (HSCs) located predominantly adjacent to the cortical bone (osteoblast niche), megakaryocyte progenitors proliferating in the bone marrow space, and migration of progenitor cells to the vascular sinusoid (*vascular niche*) under the influence of chemokines such as stromal derived factor-1 (SDF-1) and fibroblast growth factor 4 (FGF-4). Once attached to the sinusoidal vascular endothelium, megakaryocyte progenitors cease proliferating, undergo terminal maturation and proplatelet formation, and shed platelets into the vascular sinusoidal space. TPO, thrombopoietin. VE, vascular endothelial. *(Reproduced with permission of Avecilla et al.[70])*

under the regulation of metalloproteinases such as matrix metalloproteinase type 9 (MMP-9). The multipotent progenitors are then subject to expansion and lineage commitment under the influence of various cytokines and likely other signaling molecules. This is where Tpo is postulated to affect megakaryocyte progenitor proliferation and survival. Rafii and coworkers have shown that the chemokines stromal derived factor-1 (SDF-1; also called CXCL12) and fibroblast growth factor-4 (FGF-4) promote migration and attachment of murine megakaryocyte progenitor cells (which express the receptor for SDF-1, CXCR4) to the vascular endothelium, where they physically attach, mature, and produce intercalating pseudopod structures.[70,71] In fact, exogenous SDF-1 and FGF-4 restores thrombopoiesis in $Tpo^{-/-}$ or Tpo receptor $(c\text{-}mpl)^{-/-}$ mice to near wild type levels. This occurs in the absence of enhanced megakaryocyte progenitor proliferation, and requires direct physical interaction with bone marrow endothelial cells. Based on these findings, Rafii and his colleagues have proposed a model in which megakaryocyte progenitors proliferate in an immature developmental state (in response to Tpo) in a nonvascular niche (Fig. 27–4). However, once the progenitors reach and adhere to the sinusoidal vessels in the vascular niche in response to chemokines, proliferation ceases, and terminal maturation and platelet release ensues. Work from other investigators supports this model. Multiple electron microscopy studies have captured megakaryocytes extending proplatelet processes through vascular endothelium and into bone marrow sinusoids.[62,63,72,73] Isolated megakaryocytes can be induced to form proplatelets after adhering to bovine corneal endothelial cells-derived extracellular matrix[74] or through binding of the megakaryocyte surface integrin $\alpha IIb\beta 3$ to fibrinogen, which is present in bone marrow vascular sinusoids.[75] Conversely, culture of megakaryocytes with bone marrow stromal cells inhibits megakaryocyte differentiation.[76,77]

CYTOKINE REGULATION OF THROMBOCYTOPOIESIS

Thrombopoietin Signaling

Thrombopoietin

It has been estimated that an adult human produces nearly 2×10^{11} platelets per day, and this number can increase four- to eightfold during times of increased demand.[16] The regulation of this process has been the subject of intense investigation. Kelemen first used the term *thrombopoietin* in 1958 to describe a humoral substance responsible for enhancing platelet production following the onset of thrombocytopenia.[78] However, it was not until 1994 that five independent groups succeeded in purifying and cloning the responsible cytokine, now known as Tpo (previously referred to as *c-mpl ligand*, megakaryocyte growth and development factor [MGDF] and megapoietin)[79–85] (see review by Kaushansky[86] for detailed discussion of the Tpo signaling system). The gene for thrombopoietin is located on chromosome 3q27. It encodes a 30 kd glycoprotein of 353 amino acids that can be divided into two structural domains; an amino terminal region with homology to human erythropoietin, and a carboxyl terminal region that contains multiple *N*- and *O*-linked oligosaccharides. The amino terminal 155 residues of human thrombopoietin share 21% sequence identity and 46% overall sequence similarity to human erythropoietin. This region mediates binding to the Tpo receptor (c-mpl). The carboxyl region does not share sequence homology with any known protein. Thrombopoietin is reported to enhance multiple stages of megakaryocyte maturation including cell size, cell ploidy, and platelet production.[79–81] The predominant sites of Tpo production are the liver and kidney, which secrete it constitutively.[80,83,87,88] Inducible expression of Tpo has been detected by more sensitive methods in bone marrow stroma and spleen in the setting of thrombocytopenia, although this likely accounts for only a minor fraction of total Tpo production.[87,89] Low level expression has also been reported in the amygdala and hippocampus of the brain.[90]

Thrombopoietin Receptor (c-mpl)

The receptor for Tpo (Tpo receptor; c-mpl) is the normal homologue of the oncogene v-mpl, the transforming gene of murine myeloproliferative leukemia virus.[91] It is a member of the type I cytokine receptor superfamily. Like the erythropoietin receptor, it is thought to function as a homodimer. The Tpo receptor is expressed on megakaryocyte progenitors, as well as earlier multipotential progenitors including MEPs, CMPs, and HSCs.[92–94] Tpo receptors are present on the surface of platelets at a estimated density of 20 to 200 receptors per platelet and bind Tpo with an affinity of 200 to 560 pM. Binding of Tpo to platelets plays an important role in the regulation of total body platelet mass by the Tpo-Tpo receptor system (see further discussion below). Both Tpo $receptor^{-/-}$ $(c\text{-}mpl^{-/-})$ and $Tpo^{-/-}$) knockout mice contain approximately 85% to 90% lower platelet and megakaryocyte numbers compared to wild type.[95–97] The structure of the megakaryocytes and platelets in these animals is normal, reinforcing the notion that Tpo signaling plays an important role in expansion and development of megakaryocyte progenitors, but not in terminal maturation and proplatelet release.[35] In addition, the residual platelet production in these mice suggests alternate cytokine, or possibly cytokine independent, pathways for thrombocytopoiesis. Interbreeding experiments of Tpo $receptor^{-/-}$ mice with knock-out mice for IL-3, IL-6, IL-11, or leukemia-inhibiting factor (LIF), or their receptors, show that these other cytokines are not responsible for the residual platelet production.[86]

Tpo Receptor Downstream Signaling Pathways

The Tpo receptor lacks intrinsic tyrosine kinase activity. Instead, ligand binding stimulates the cytoplasmic tyrosine kinase JAK2 (Janus-kinase 2) resulting in tyrosine phosphorylation of multiple targets, including STATs (signal transducers for activating transcription), Shc adaptor protein, and the Tpo receptor itself.[98] Additional signaling pathways activated upon Tpo receptor engagement include the mitogen-activated protein kinase (MAPK) p38, p42/p44 extracellular regulated kinase 1 and 2 (ERK1/ERK2), and phosphatidylinositol 3-kinase–Akt (PI3K-Akt) pathways.[98–101]

Several of these downstream signaling pathways have been shown to be functionally important in Tpo-mediated effects on megakaryopoiesis. Double STAT5a/STAT5b deficient mice have impaired

platelet production as well as defects in early multipotent progenitor cells.[102] Moreover, megakaryocyte-selective overexpression of a dominant negative mutant STAT3 in transgenic mice reduces platelet recovery following 5-FU–induced myelosuppression.[103] These findings suggest a functional role for STAT family members in thrombopoiesis.

Studies in primary megakaryocytes show a requirement for PI3-Akt signaling in Tpo-induced cell cycling.[99] This involves silencing of the Forkhead O (FOXO) family of transcription factors.[98] Activation of the p42/p44-MAPK plays an important role in Tpo-induced maturation and endomitosis.[101]

Lnk, an adaptor protein implicated in immunoreceptor and cytokine receptor signaling, has recently been shown to negatively modulate Tpo signaling in megakaryocytes.[104] Overexpression of Lnk decreases Tpo-dependent megakaryocyte growth and polyploidization in bone marrow (BM)-derived cultures. Conversely, loss of Lnk expression by gene targeting results in increased numbers of megakaryocytes and accentuated polyploidization compared to wild type controls. This correlates with enhanced and prolonged Tpo-mediated induction of STAT3, STAT5, Akt, and MAPK signaling pathways.

Tpo Signaling in Hematopoietic Stem Cells

It has recently been recognized that the Tpo-Tpo receptor signaling system is not only important for megakaryocyte proliferation and development but also plays a role in hematopoietic stem cell survival, self-renewal, and expansion.[105–108] Tpo receptor$^{-/-}$ HSCs compete poorly with wild type HSCs, even at a ratio of 10:1, in murine bone marrow competitive repopulation studies.[108] The role of Tpo signaling in HSC expansion is in part caused by its activation of the homeobox domain containing transcription factor HOXA9, through a mechanism involving phosphorylation and nuclear translocation of its partner protein, MEIS1.[109]

Congenital Amegakaryocytic Thrombocytopenia

A bi-allelic mutation in the thrombopoietin receptor gene causes congenital amegakaryocytic thrombocytopenia (CAMT). In this disorder, megakaryocytes are absent or greatly diminished in number in the bone marrow. Patients typically present shortly after birth with petechiae, bruising, or bleeding. Patients with severe CAMT are at high risk for developing full bone marrow failure, typically within the first few years of life.[110] This is consistent with a role of Tpo signaling in maintaining hematopoietic stems cells and/or multipotential progenitor cells. Interestingly, no mutations in the gene encoding Tpo itself have yet been reported in patients with CAMT. It should also be noted that in contrast to the humans, Tpo receptor$^{-/-}$ (as well as Tpo$^{-/-}$) mice do not develop bone marrow failure. The reason for this discrepancy is not known, but highlights important differences between human and mouse hematopoiesis.

Essential Thrombocythemia

Essential thrombocythemia (ET) is a chronic myeloproliferative disorder associated with sustained megakaryocyte hyperproliferation, thrombocytosis, and abnormal platelet function leading to either hemorrhage or thrombosis (for more complete description, see Chapter 71). In 2005, an acquired activating mutation in the JAK2 gene (V617F JAK2) was identified by four independent groups in a large proportion (23%–57%) of patients with ET[111–114] (see review[115]). The identical mutation has also been identified in several other myeloproliferative disorders including polycythemia vera (65%–97% of patients) and idiopathic myelofibrosis (35%–95% of patients). How the identical mutation leads to distinct clinical entities is not presently understood. Mutations leading to constitutive activation of the Tpo receptor,[116,117] and mutations leading to enhanced translation efficiency of the Tpo gene[86,118] have also been reported in rare cases of familial thrombocytosis.

Regulation of Platelet Mass by Thrombopoietin

Platelet counts are typically held at a relatively fixed level in humans, ranging from 150,000–400,000 platelets/mm.^{3} The maintenance of platelet number by the Tpo-Tpo receptor system involves an unusual homeostatic mechanism among hematopoietic cytokine-mediated regulation. This is sometimes referred to as the *Sponge model* (Fig. 27–5). Unlike other cytokines, Tpo is secreted predominantly in a

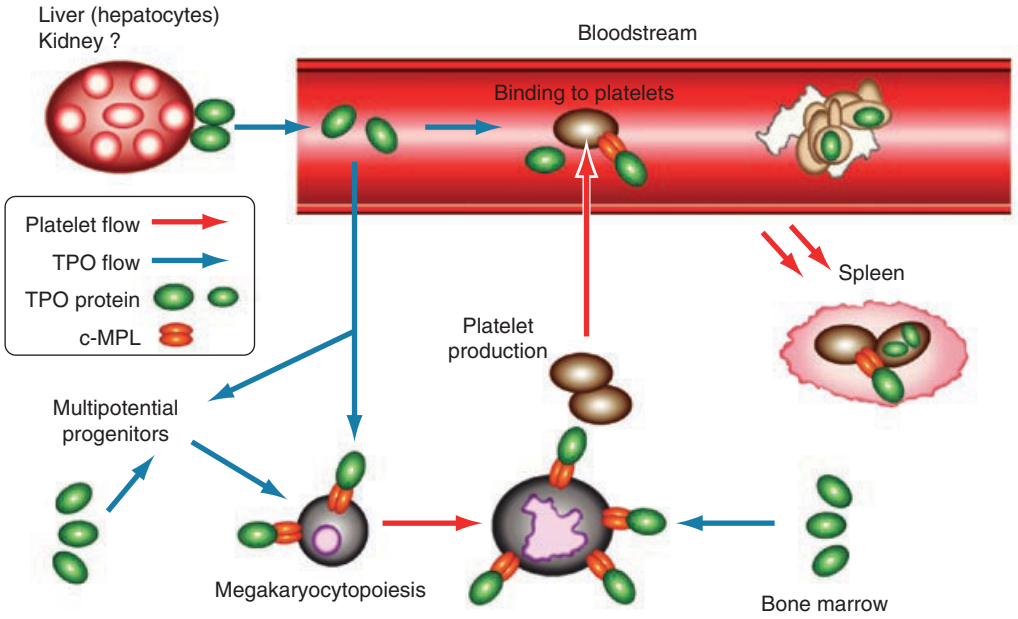

Figure 27–5 Regulation of platelet count by thrombopoietin: the *Sponge* model. Thrombopoietin (Tpo) is secreted at a constitutive rate primarily from liver and perhaps other sources such as the kidney, into the circulation. There, it binds with high affinity to Tpo receptors (c-mpl) present on the surface of platelets. The Tpo is then internalized by the platelets and degraded. Free Tpo (ie, Tpo not bound to platelets) enters the bone marrow and stimulates megakaryopoiesis. Thus, in the presence of high platelet counts, little free Tpo is available to stimulate megakaryopoiesis. Conversely, low platelet numbers lead to increased free Tpo and active megakaryopoiesis. The net result is preservation of total platelet mass.

constitutive manner, mostly from the liver and kidney. High-affinity Tpo receptors present on the platelet surface bind free Tpo and internalize it, where it is degraded.[86,119] Therefore, when platelet counts are low, less thrombopoietin is removed and more is available to stimulate megakaryopoiesis in the bone marrow. Conversely, when platelet counts increase above a given set point, they act as a "sink" for Tpo, binding and destroying it before it can stimulate megakaryopoiesis in the bone marrow. Thus, total platelet mass is preserved, rather than absolute platelet number. This may explain the mild-moderate thrombocytopenia seen in certain large platelet disorders, such as Bernard-Soulier syndrome (BSS).

Several pieces of evidence support this model. First, it has been known for more than 40 years that the peripheral blood platelet count varies inversely with plasma Tpo activity. Second, Tpo receptor deficient mice (c-mpl$^{-/-}$) have elevated levels of circulating Tpo, and this is reduced when the mice are transfused with washed platelets from normal mice.[95,120] Third, in contrast to platelets from Tpo-receptor deficient mice, platelets from normal mice bind purified radiolabeled Tpo and degrade it.[119–121] Fourth, Tpo levels are low to intermediate in normal individuals and in those with idiopathic thrombocytopenic purpura (where the bound Tpo is destroyed along with the platelets).[122] However, following chemotherapy, or in individuals with aplastic anemia, levels are markedly elevated.[122]

Although the model described above likely explains the predominant basal regulation of platelet number by the Tpo-Tpo receptor signaling system, overlying inducible mechanisms also probably exist. It has been shown that the Tpo gene is transcriptionally activated in bone marrow stroma and spleen during times of thrombocytopenia,[87,89] although the degree to which this can contribute to total Tpo levels is uncertain. In addition, IL-6 mediates upregulation of hepatic Tpo mRNA transcripts in inflammation-related thrombocytosis.[123]

Additional Cytokines Involved in Megakaryocytopoiesis

Although Tpo is the major cytokine regulating megakaryocytopoiesis, other cytokines have been shown to be active in vitro, particularly during earlier stages of megakaryocyte development. These include SCF,[19,124–128] IL-3,[124,126,129] IL-6,[124,128] IL-11,[81,129] LIF,[128] granulocyte colony-stimulating factor (GCSF),[128] and erythropoietin (Epo).[129] None of these factors are megakaryocyte-specific but act as synergistic coregulators with Tpo. Only SCF and Tpo have been shown to affect megakaryocyte development and platelet production in vivo using genetic ablation experiments in mice.[95,130] A thrombocytopenia phenotype has not been seen with knockout of IL-3, IL-6, IL-11 receptor, or LIF.

Cytokine Stimulation of Megakaryopoiesis for Clinical Use

Since the identification of Tpo as a major activator of megakaryocyte growth and maturation, there has been considerable interest in developing recombinant forms for clinical use in the treatment of chemotherapy-related thrombocytopenia and immune-mediated thrombocytopenia. Small pilot studies using a polyethylene glycol (PEG)ylated, truncated form of human Tpo (PEG-MGDF) showed activity in stimulating megakaryocyte growth and maturation, resulting in elevated platelet counts. However, some recipients subsequently developed thrombocytopenia because of the generation of a neutralizing antithrombopoietin antibody that cross-reacted with endogenous Tpo. The agent was therefore withdrawn from further testing. Since then, several nonimmunogenic thrombopoietic peptides and small, nonpeptide molecules have been under development (see recent review by Kuter).[131] A recent phase I/II placebo-controlled trial of AMG531, a synthetic molecule consisting of an immunoglobulin crystallizable fragment (Fc) linked to two identical peptide chains that activate the Tpo receptor, has been reported in a small series of adults with chronic, refractory immune thrombocytopenic purpura (ITP).[132] Nineteen of 28 patients (68%) treated at 1-mcg/kg and 3-mcg/kg doses in the combined studies experienced a response with an increase in the platelet count to the target range of 50,000 to 450,000 cells/mm^3 and at least twice the baseline count. The reported adverse effects consisted mostly of mild-moderate headache and transient decrease in the baseline platelet count after discontinuing treatment. No anti-AMG531 or antithrombopoietin antibodies were detected in the recipients. Further clinical study of this agent, as well as others in development, will be required before they can be recommended for clinical use. However, they represent a promising new development for the treatment of certain thrombocytopenic disorders.

IL-11 has multiple effects on in-vivo and in-vitro megakaryocytopoiesis.[21] It affects IL-3-dependent megakaryocyte colony formation and has a potent effect on megakaryocyte maturation. Administration of recombinant IL-11 to mice results in increased numbers of megakaryocyte progenitors, increased megakaryocyte polyploidization, and increased peripheral platelet counts.[133] Recombinant IL-11 has been approved for use in humans for the treatment of chemotherapy-induced thrombocytopenia.

ENDOMITOSIS

Endomitotic Cell Cycle

Megakaryocytes derive their name from their large and complex nuclei. This arises from an atypical cell cycle, termed the *endomitotic* cell cycle (see comprehensive review by Ravid et al [5])(Fig 27–6). Like normal diploid cells, the cycle begins with a G1 phase, followed by an S phase (DNA replication), and a G2 phase. The cells then enter an M phase, but unlike normal diploid mitotic cells, fail to complete anaphase B, telophase, or cytokinesis.[134] Instead they proceed directly to the next G1 phase and subsequent rounds of DNA replication. As DNA ploidy increases, multiple spindle poles and centrosomes form, but chromosome segregation is incomplete and asymmetric.[135,136] During each endomitotic cell cycle, the nuclear envelope breaks down, and later reforms as a single nuclear membrane around all of the sister chromatids.[134,137] The end result is a polyploid cell with a multilobulated nuclei encapsulated by a single nuclear membrane.[6,138] Mature human megakaryocytes have been observed to reach ploidy levels as high as 128N.[5–8] The term *endoreduplication* has at times been used erroneously to describe megakaryocyte polyploidization. Endoreduplication refers to a cell cycle that involves DNA replication but no entry into M phase.[139]

Role of Endomitosis in Thrombocytopoiesis

The advantage of megakaryocytes undergoing endomitosis remains unknown. It has been speculated that it provides a means for generating the abundant membrane, protein, biosynthetic cargo and energy required for the dramatic final stages of proplatelet elaboration and platelet release.[5] Several circumstantial pieces of evidence support this model. First, it is known that megakaryocyte DNA content correlates with megakaryocyte cell size, mRNA content, protein production, and eventual numbers of platelets released.[6,140–142] Second, an increased DNA content of megakaryocytes precedes increases in platelet count during recovery from acute thrombocytopenia.[6] Third, increases in cytoplasmic volume and maturation occur predominantly, if not completely, in stage II and III megakaryocytes, which do not synthesize DNA.[7,6,140,143–145] Fourth, in polyploid megakaryocytes (4N–32N), all alleles of the genes studied (ie, ITGA2B [GPIIb], VWF, ACTB [β-actin], HSPA1 [HSP70], MPL, FLI1, and ZFPM1 [FOG-1]) have been found to be transcriptionally active.[146]

Mechanisms of Endomitosis in Megakaryocytes

The molecular mechanisms mediating endomitosis in megakaryocytes are incompletely understood. Studies investigating endomitosis

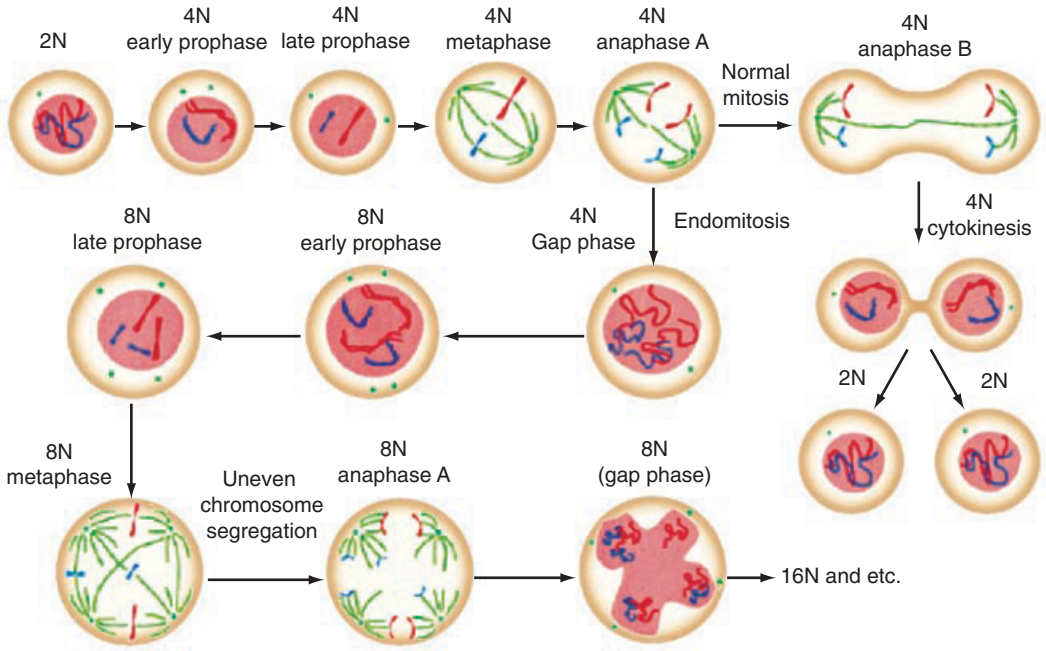

Figure 27–6 The endomitotic cycle in megakaryocytes. Schematic diagram depicting stages of the cell cycle in cells undergoing endomitosis (*bottom left*) versus normal mitosis (*right*). Endomitotic and mitotic cells share all stages of the cell cycle up until Anaphase A. Normal mitotic cells proceed through Anaphase B and complete cytokinesis, yielding two daughter cells each with 2N DNA content. In contrast, endomitotic cells fail to undergo Anaphase B or cytokinesis, and proceed to the next cycle following a Gap phase. Subsequent rounds produce multicentric spindles with uneven chromosome segregation. A single nuclear membrane (*shown in pink*) reforms after each round of endomitosis. Centrosomes are shown as blue dots. *(Reproduced by permission Ravid et al.[5])*

have been hampered by the rarity of megakaryocytes, difficulty separating direct effects from general perturbations of cell maturation, complications associated with synchronizing the cell cycle, use of transformed cell lines, and potential differences between rodent and human megakaryocytes.

Cyclins and Cyclin-dependent Kinases

Two classes of proteins control the cell cycle in mammalian cells. These are the cyclins, so named for their cyclical synthesis and degradation during the cell cycle, and cell division kinases (Cdks) (also known as *cyclin-dependent kinases*). Together these two families of proteins form a protein-kinase complex in which the regulatory unit is the cyclin and the catalytic unit is the Cdk. The role of these kinase complexes in cell cycle control is complex. At least seven members of the cyclin gene family and seven distinct Cdk genes have been identied.[147–149]

Given the importance of cyclins and Cdks in controlling cell cycle, they have been the focus of considerable attention in investigations of the mechanisms underlying megakaryocyte endomitosis. The most evidence probably exists for a role of the D-type cyclins in megakaryocyte endomitosis.[150,151] The D-type cyclins are unique in that their activity can be modulated by extracellular mitogens. Megakaryocytes express cyclin D3 and, to a lesser extent cyclin D1.[5] Levels of both of these factors increase after treatment with Tpo. Overexpression of cyclin D3 results in increased megakaryocyte ploidy in transgenic mouse models.[150] Complexes of cyclin D3 and its major kinase subunit, Cdk2, show high kinase activity in polyploid cells.[152] Antisense knockdown of cyclin D3 levels suppresses endomitosis and abrogates normal development of primary mouse megakaryocytes.[153]

Cyclin D1 is a direct target gene of GATA1, a transcription factor required for megakaryocyte polyploidization and maturation (see Transcriptional Control of Megakaryopoiesis below).[151,154] Overexpression of cyclin D1 in transgenic mice increases megakaryocyte modal ploidy compared to nontransgenic littermates, and the combination of cyclin D1 and CDK4 kinase activity restores polyploidization of GATA1 deficient murine megakaryocytes.[151,154] Conversely, enforced expression of p16(ink4a), a cell cycle inhibitor of Cdk4/6, blocks polyploidization in murine megakaryocytes.[154] p16(ink4a) is also potently repressed by GATA1.

Cyclin $E^{-/-}$ mice have impaired megakaryopoiesis with reduced modal ploidy.[155] These mice also have defective trophoblast development, another tissue dependent on endomitosis. Cyclin B1/CDC2 is a mitotic cyclin complex. Yeast strains deficient in cyclin B1 or CDC2 undergo an additional round of DNA replication without cytokinesis.[156,157] Several studies have shown that low levels of cyclin B1/CDC2 are required for progression of endomitosis in megakaryocytic cells lines.[153,158–160] However, studies of primary megakaryocytes have shown normal cyclin B1 and CDC2 levels and functional mitotic activity during endomitosis.[137]

Other Mitotic Kinases

Aurora-B kinase (also called *AIM1 kinase*) is involved in late anaphase and cytokinesis, and mRNA transcript levels of Aurora-B kinase have been reported to decrease during polyploidization of primary megakaryocytes and megakaryocytic cell lines.[161–163] This suggests that Aurora-B kinase may play a mechanistic role in megakaryocyte endomitosis. However, functional activity of Aurora-B kinase appears normal in late anaphase of endomitotic primary megakaryocytes, indicating that simple deficiency of Aurora-B kinase activation is an unlikely mechanism to explain endomitosis.[164,165] Polo-like kinase (PLK1) is a serine-threonine kinase required for assembly of the mitotic spindle, separation of chromosomes during anaphase, and exit from mitosis.[166–168] PLK1 mRNA and protein levels decrease during polyploidization of murine megakaryocytes, and enforced expression of PLK1 in primary murine megakaryocytes impairs endomitosis.[165] However, the effects of overexpression are modest, preferentially affect lower-ploidy megakaryocytes, and are complicated by alterations in cell cycle kinetics.

Spindle Checkpoint

During mitosis of normal diploid cells, a spindle assembly checkpoint prevents progression of anaphase until all of the chromosomes are

aligned with the mitotic spindle and each sister chromatid is properly attached to spindle microtubules originating from the opposing spindle pole. This ensures that each daughter cell receives the proper complement of chromosomes. The anaphase promoting complex (APC) is a multisubunit protein complex with ubiquitin ligase activity that regulates chromosome segregation and anaphase progression by targeting key factors for degradation. As some chromosomal missegregation occurs during megakaryocyte endomitosis, several groups have examined the expression levels and/or activity of certain APC components and associated factors. These studies have shown no significant difference in protein levels of the core APC protein CDC27 or the kinetochore associated signaling protein hsMAD2 in primary murine megakaryocytes undergoing polyploidization compared to nonendomitotic precursors.[165] Haploinsufficiency of BUBR1, a key component of the spindle checkpoint, perturbs megakaryocyte development and polyploidization in mice but does not cause alterations in circulating platelet counts.[169]

Microtubule Regulation

Microtubules play key roles in mitosis. Therefore, factors that regulate their assembly have also been interrogated as candidates involved in megakaryocyte endomitosis. PRC1 is involved in mitotic spindle elongation and cytokinesis. However, no differences in PRC1 levels were detected in primary murine megakaryocytes undergoing polyploidization compared to nonendomitotic precursors.[165] Stathmin is a microtubule depolymerizing factor that plays in important role in regulation of the mitotic spindle.[170] Levels of stathmin are inversely related to the level of ploidy of megakaryocytic cell lines and primary megakaryocytes.[171] Inhibition of stathmin in K562 cells increases their propensity to undergo endomitosis when induced to differentiate into megakaryocytes, and overexpression of stathmin prevents the transition from mitotic to endomitotic cell cycles.[170,171] Together, these findings support a possible role of stathmin in modulating endomitosis. Further studies will be required to fully dissect the molecular pathways involved in megakaryocyte endomitosis.

TRANSCRIPTIONAL CONTROL OF MEGAKARYOPOIESIS

Because platelets do not contain nuclei, all transcriptional regulation of platelet-specific genes must occur at the level of the megakaryocyte. Significant strides have been made recently in identifying key transcription factors involved in megakaryocyte development and platelet-specific gene expression. Importantly, mutations in several of these factors have been linked to various hematologic disorders providing significant new insights into the pathogenesis of these diseases (see Chapter 32 for additional discussion).

GATA Family Transcription Factors

GATA1

GATA transcription factors comprise a family of zinc finger proteins that bind the consensus DNA sequence (T/A))GATA(A/G). There are six known members of the GATA family in vertebrates. GATA1, -2, -3 play roles predominantly, although not exclusively, within the hematopoietic system. GATA4, -5,-6 are expressed in nonhematopoietic tissues and play diverse developmental roles within the cardiac, gastrointestinal, endocrine, and gonadal systems. Functionally important binding sites for GATA factors have been identified in cis-acting regulatory elements of essentially every megakaryocytic and erythroid gene that has been studied.[172] GATA1, the founding member of this family, is highly expressed in erythroid and megakaryocytic cells, and to a lesser extent in eosinophils and mast cells.[173] GATA1 plays an essential role in erythroid development, with loss of function resulting in blocked erythroid maturation and apoptosis of erythroid progenitor cells.[174] GATA1 is also required for megakaryocyte maturation and growth control. Lineage-selective loss of GATA1 in megakaryocytes results in marked thrombocytopenia in mice with platelet counts of only approximately 15% of wild type littermates.[175] Megakaryocytes are present in the mutant animals, but have a disorganized DMS, paucity of platelet-specific granules, reduced expression of multiple megakaryocyte-specific genes including GPIbα, GPIbβ, PF4, c-mpl, and p45 NF-E2, and marked hyperproliferation compared to wild type.[175,176] cDNA microarray studies of GATA1 deficient versus wild type murine megakaryocytes show a large number of potential GATA1 target genes, although evidence for direct targets has only been established for a few.[177] Mice containing reduced megakaryocyte-specific expression of GATA1 (GATA1^{low}) develop myelofibrosis as they age,[178] a frequent finding with disorders of megakaryocyte progenitor hyperproliferation. A GATA binding site mutation in the GPIbβ promoter has been described in a patient with BSS, a macrothrombocytopenia disorder characterized by deficiency of the GPIb/IX/V complex and a bleeding diasthesis.[179] Taken together, these findings suggest that GATA1 acts as master regulator of megakaryocyte maturation and proliferative control.

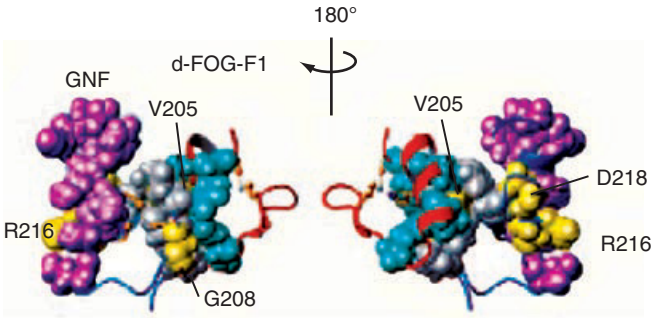

Figure 27–7 Structural basis of GATA1 N-terminal zinc finger mutations associated with familial hematologic disease. Solution nuclear magnetic resonance (NMR)-determined structure of the *N*-terminal zinc finger of murine GATA1 (GNF) complexed with zinc finger 1 of the Drosophila Friend of GATA (FOG) ortholog (U-shaped) (d-FOG-F1). The DNA binding surface of GNF is shown in purple, and the FOG-binding surface is shown in gray. Locations of the residues mutated in GATA1 related cytopenias are shown in yellow. V205 and G208 lie on the FOG contact surface, R216 lies on the GNF/DNA interface, and D218 lies between the two opposing surfaces. *(Reproduced by permission Liew et al,[279] copyright 2005, National Academy of Sciences.)*

Friend of GATA (FOG-1)

All vertebrate GATA factors contain two zinc fingers. The carboxyl zinc finger mediates high affinity DNA binding, whereas the amino zinc finger stabilizes the DNA interaction at certain double GATA sites.[180] Importantly, the amino zinc finger also interacts with Friend of GATA (FOG) proteins, a family of large multitype zinc finger transcriptional cofactors (see review by Cantor and Orkin[181] for more details). This interaction occurs on the surface of the zinc finger opposite to its DNA binding surface (Fig. 27–7).[182] FOG1 (also called *zfpm1*), the founding member, is expressed predominantly within erythroid and megakaryocytic cells.[183] Knockout of FOG1 in mice results in embryonic lethality because of severe anemia from a block in erythroid maturation similar to that observed in GATA1^{-} mice.[184] In addition, FOG1$^{-/-}$ mice have complete failure of megakaryopoiesis, establishing FOG1 as the first identified transcription-associated factor selectively required to generate the entire megakaryocyte lineage. FOG1's role in megakaryocyte and erythroid development requires direct physical interaction with GATA factors.[182,185,186] The discrepancy between the relatively late block in megakaryocyte development seen in GATA1 deficient animals and the complete loss of megakaryopoiesis in FOG1$^{-/-}$ mice is explained by overlapping FOG-dependent roles of GATA1 and GATA2 during early stages of megakaryopoiesis.[186]

Table 27–1 Reported GATA-1 Mutations in Hematologic Disease with Associated Clinical and Biochemical Features

Mutation	Thrombocytopenia	Platelet Features	Anemia	Erythroid Features	Other Features	FOG-1 Binding	DNA Binding	References
V205M	Severe	Large*	Severe, Fetal Hydrops	Dyserythropoiesis	Cryptorchidism	Markedly reduced	Normal	187
G208S	Moderate	Large, Decreased Platelet aggregation	None			Moderately reduced	Normal	188
G208R	Severe	Large*	Moderate	Dyserythropoiesis	Cryptorchidism**	Not Studied	Not studied	189
D218G	Moderate	Large, Decreased platelet aggregation	None	Dyserythropoiesis		Moderately reduced	Normal	190
D218Y	Severe	Large*	Severe		Platelets in carrier female expressed only WT allele	Markedly reduced	Normal	191
R216Q	Moderate	Large, normal platelet aggregation in vitro, but prolonged bleeding time; Gray platelet syndrome	Mild	Mild β-thalassemia	Splenomegaly	Normal	Decreased	192–195
R216W	Moderate	*	Mild	Mild β-thalassemia	Congenital erythropoietic porphyria	Not studied	Not studied	196
G332C***	None	Decreased platelet aggregation, Dysplastic megakaryocytes	Variable	Macrocytosis	Neutropenia	Not studied	Not studied	209

FOG-1, Friend of GATA.
*Function not studied.

X-linked Dyserythropoietic Anemia and Thrombocytopenia Caused by GATA1 Mutations

Over the past several years, germline GATA1 mutations that impair binding to FOG1 and/or DNA have been identified in several families with X-linked macrothrombocytopenia and/or anemia (GATA1 is located on the X chromosome in humans, as well as in mice). The first case, reported by Weiss and colleagues, involved a woman with mild chronic thrombocytopenia who had two pregnancies with male offspring that were both complicated by severe fetal anemia and thrombocytopenia requiring in-utero transfusions.[187] Bone marrow examination after birth revealed marked dyserythropoiesis and an overabundance of immature-appearing, dysplastic megakaryocytes that share many of the features of GATA1^{low} murine megakaryocytes. Remarkably, sequencing of the GATA1 gene from affected family members identified substitution of valine by methionine at codon 205 within the amino zinc finger. This mutation (GATA1 [V205M]) significantly impairs FOG1 binding but retains normal DNA affinity based on electromobility shift assays using synthetic oligonucleotides. This is consistent with the location of this residue on the surface of the zinc finger opposite the DNA binding face (see Fig. 27–7).

Since the initial report, several other GATA1 mutations have been linked to cases of familial X-linked macrothrombocytopenia with or without anemia (Table 27–1). These substitutions all impair FOG1 binding, although to different degrees. Substitution of glycine by serine at codon 208 (GATA1 [G208S]) results in moderate to severe thrombocytopenia, mild dyserythropoiesis, but no anemia.[188] Substitution of the same residue by arginine (GATA1 [G208R]) results in thrombocytopenia with anemia and severe dyserythropoiesis.[189] Similarly, substitution of aspartic acid by glycine at codon 218 (GATA1 [D218G]) leads only to thrombocytopenia, whereas substitution of this same codon by tyrosine (GATA1 [D218Y]) leads to severe thrombocytopenia, moderate anemia, and marked dyserythropoiesis.[190,191] The severity of the phenotype appears to correlate with the degree of FOG1 binding impairment, suggesting that megakaryocytic development is more sensitive to affinity changes in GATA1:FOG1 interactions than erythroid development.

X-Linked Thrombocytopenia and β-Thalassemia Caused by GATA1 Mutations

Mutations mapping to the DNA binding surface of the amino zinc finger of GATA1 have also been described (GATA1 [R216Q]).[192–194,195] As expected, this reduces DNA affinity to double (palindromic) GATA sites, but not single GATA sites. FOG1 binding is not substantially altered. Affected family members exhibit an X-linked β-thalassemia syndrome characterized by imbalance of α and β globin chain synthesis, reticulocytosis, and hemolysis. They also

have mild-moderate thrombocytopenia. In-vitro platelet aggregation studies are normal, but there is a prolonged bleeding time. Substitution of the same residue by tryptophan (R216W) produces thrombocytopenia, β-thalassemia intermedia, and congenital erythropoietic porphyria (CEP).[196] The CEP is likely caused by dysregulation of the GATA1 target gene uroporphyrinogen III synthase.

X-Linked Gray Platelet-Like Syndrome

Gray platelet syndrome (GPS) refers to a disorder of large platelets with absent or markedly reduced α-granules and/or α-granule proteins. Platelets from individuals with GATA1 (Arg261Gln) share some features with classical GPS.[195] Ultrastructural studies of platelets from a different family with GATA1 related X-linked macrothrombocytopenia (GATA1 [G208S]) also demonstrate hypogranular platelets that contain small vacuoles, likely representing membranes of empty α-granules.[197] However, the GATA1 mutant platelets also possess unique features such as masses of dense tubular system channels, dense double membranes, and platelets within platelets, not seen in classical GPS, suggesting a more general disorder of platelet biogenesis.

GATA1 Mutations in Down Syndrome Transient Myeloproliferative Disorders and Acute Megakaryoblastic Leukemia

Approximately 10% of children with Down syndrome (DS) (trisomy 21) are born with a transient myeloproliferative disorder (TMD), which is characterized by an abundance of circulating erythromegakaryocytic precursor cells, pancytopenia, and, in some cases, severe liver fibrosis. Remarkably, this myeloproliferative disorder resolves spontaneously over the first few months of life. In approximately 20% to 30% of cases, acute megakaryoblastic leukemia (AMKL) develops within a few years, sometimes preceded by a myelodysplastic phase. In 2002, Crispino and colleagues reported that DS-AMKL cells harbor acquired mutations in their GATA1 gene.[198] Since then, several groups have reproduced these findings and identified similar mutations in DS-TMD cells.[199–204] Although a wide spectrum of mutations have been found, including missense, deletion, insertion and splice-site mutations, they all involve exon 2 and result in the same outcome: generation of an amino terminal truncated protein (loss of amino acids 1–83) because of translation initiation from a downstream ATG codon (Fig. 27–8). This removes a region that functions as a transcriptional activation domain in transient transfection reporter assays.[205] The mutations are detectable in bone marrow from DS-AMKL patients but disappear when the patients enter remission, indicating a strong correlation between the mutated clone and the leukemic phenotype.[198] Mutations involving exon 2 of GATA1 are highly specific for DS-AMKL and DS-TMD, or AMKL with acquired trisomy 21. There is only one reported case of such a mutation in AMKL without trisomy 21,[206] and no mutations have been detected in DS-acute lymphoblastic leukemia or a large number of healthy individuals.

Analysis of stored neonatal blood spots shows the coexistence of several different GATA1 mutations (all resulting in the generation of GATA1s) in patients who subsequently developed DS-AMKL, suggesting an oligoclonal expansion.[207] In a few cases in which material was available, identical GATA1 mutations have been found in both the DS-TMD and DS-AMKL cells from the same patient. DS-AMKL cells often harbor additional genetics abnormalities, such as trisomy 8 or tetrasomy 21, not observed in DS-TMD cells. Taken together, these findings support a clonal evolution model of DS-AMKL, with GATA1 mutations associated with an early initiating event.

Knock-in mice that recapitulate the truncating GATA1 mutation show unexpected stage-specific effects on megakaryopoiesis.[208] During fetal liver hematopoiesis, the mutant megakaryocytes markedly hyperproliferate, similar to what is observed for GATA1 deficient megakaryocytes. However, during adult stage bone marrow hematopoiesis, megakaryopoiesis and thrombocytopoiesis appear normal. This suggests that the fetal liver and bone marrow microenvironments each interact differentially with the GATA1 truncated molecule. This might also explain the restriction of TMD to the neonatal period. Recently, a family was described with members containing a germline GATA1 gene splice site mutation (G332C) that results in exclusive production of a short isoform of GATA1, the GATA1s protein product.[209] Affected individuals exhibit a unique phenotype characterized by trilineage bone marrow dysplasia, macrocytic anemia and neutropenia. None of the family members have developed leukemia, suggesting that trisomy 21 plays a role in DS-TMD progression to DS-AMKL.

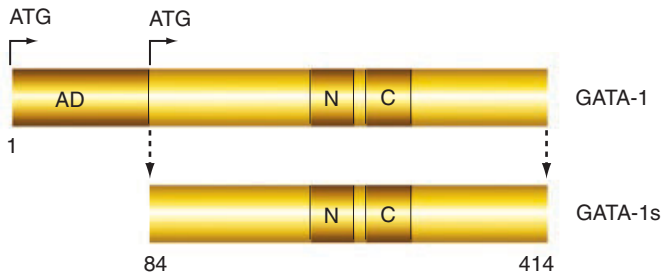

Figure 27–8 Generation of an amino terminal truncated isoform of GATA1 by mutations associated with Down syndrome transient myeloproliferative disorder (DS-TMD) and Down syndrome acute myelogenous leukemia (DS-AMKL). Schematic representation of full-length GATA1 is shown on top, and the truncated form (GATA1s) on bottom. The amino terminal transcriptional activation domain, as defined by reporter assays in transiently transfected cells, is indicated (*AD*). The amino (*N*) and carboxyl (*C*) zinc fingers are shown as gray boxes. In DS-TMD and DS-AMKL, mutations involving exon 2 of GATA1 (point mutations, deletions, insertions, and/or splice-site mutations) lead to exclusive translation from a downstream in-frame methionine at codon 84 producing the amino terminal truncated GATA1 protein (GATA1s). (Reproduced by permission Cantor.[280])

Interestingly, Santoro and his colleagues reported nearly 10 years ago that GATA1s is produced naturally at low levels in erythroid cells.[210] They proposed that this might serve a regulatory role during normal hematopoiesis by acting as a dominant negative molecule at specific times/environmental stimuli. Endogenous GATA1s has also been detected in normal mouse fetal liver megakaryocytes and adult human bone marrow megakaryocytes.[198,209] Thus, the ratio of GATA1 and GATA1s may play a role in developmental aspects of megakaryocytopoiesis, and acquired GATA1 mutations observed in DS-TMD and DS-AMKL, or germline mutations in the family described above, may perturb hematopoiesis by altering this ratio.

Ets Family Transcription Factors

A common feature of megakaryocyte-specific genes is the presence of tandem binding sites for GATA and Ets transcription factors in their promoters and enhancers.[211,212] The Ets transcription factor family is comprised of a diverse group of proteins that share a common *Ets* DNA-binding domain, which recognizes a GGAA core sequence.[213] More than 30 different Ets factors have been identified, at least 9 of which (Elf-1, Elf-2, Fli-1, Pu.1, TEL, GABPα, Ets-1, Ets-2, Elk-4) are expressed in megakaryocytes.[214,215] Functional studies have implicated several of these, including Fli-1, Ets-1, TEL, and GABPα, in megakaryocytopoiesis.

Fli-1

The role of Fli-1 has perhaps been best characterized of the Ets factors in terms of its functional role in megakaryocyte development.

Fli-1$^{-/-}$ mice die during embryogenesis from hemorrhage, likely because of both vascular defects and dysmegakaryopoiesis.[216] Colony assays in collagen-based semisolid media show an increased number of megakaryocyte progenitors in Fli-1$^{-/-}$ embryos versus wild type. However, the megakaryocytes from these colonies are small, contain high nuclear/cytoplasm ratio, and have hyperlobulated nuclei, disorganized platelet demarcation membranes, and reduced number of α-granules. Expression of the late megakaryocyte marker gene GPIX is markedly reduced, whereas expression of the early genes c-mpl and αIIb are normal or mildly reduced, consistent with a role of Fli-1 in late megakaryocyte maturation.[216,217] Fli-1 is involved in the synergistic transcriptional activation of several megakaryocyte-specific genes by GATA1 and FOG1.[218] Recent work by Poncz and coworkers shows that different Ets factors act in a stage-specific manner during megakaryocytopoiesis, with GABPα predominantly regulating genes active during early stages of megakaryocytopoiesis, and Fli-1 during later stages.[219]

Fli-1 has been implicated in the lineage commitment of bipotent erythroid-megakaryocyte progenitor cells to the megakaryocyte pathway. Fli-1 expression is downregulated as bipotent cells commit to the erythroid lineage, and its overexpression in the bipotent human erythroleukemia cell line K562 enhances the expression of several megakaryocyte-specific genes and induces a megakaryocyte phenotype.[220] In addition, functional cross-antagonism occurs between Fli-1 and the erythroid-specific transcription factor EKLF.[221,222]

Paris-Trousseau (OMIM 188925) and Jacobsen syndromes (OMIM 147791) are overlapping contiguous gene deletion disorders in humans involving the long arm of chromosome 11 (11q23).[223,224] The constellation of findings in these syndromes includes severe congenital cardiac abnormalities, trigonocephaly, mental retardation, dysmorphogenesis of the hands and face, and macrothrombocytopenia.[225] The etiology of the thrombocytopenia in these patients appears to be related to impaired platelet production, as platelet survival time is normal.[226] Examination of bone marrow reveals significant dysmegakaryopoiesis with an abundance of micromegakaryocytes and death of large numbers of megakaryocytes during late stages of maturation.[227] Peripheral blood platelets contain giant α-granules, which are thought to arise from aberrant α-granule fusion during prolonged residence in the bone marrow.[228] The minimal chromosome regions deleted in Paris-Trousseau and Jacobsen syndromes associated with thrombocytopenia includes the genes for the Ets factors Fli-1 and Ets-1.[216] Lentiviral expression of Fli-1 in CD34+ cells from patients with Paris-Trousseau thrombocytopenia rescues megakaryocyte differentiation in vitro, providing strong evidence that it is deficiency of Fli-1 that is the cause of impaired thrombopoiesis in these patients. Interestingly, Favier and colleagues have shown that in normal individuals expression of Fli-1 is mostly monoallelic in early megakaryocytic progenitors CD41^{+}/CD42^{-} cells), but predominantly bi-allelic in later stages.[229] They propose that the different populations of megakaryocytes seen in patients with Paris-Trousseau disorder arise from expression of the normal allele in the normally differentiating megakaryocytes, and the deleted allele (leading to complete loss of Fli-1 expression) in the dying population of megakaryocytes.

TEL (ETV6)

Generation of a fusion protein between TEL (ETV6) and Runx-1 (formerly called AML-1) is the most frequent chromosome translocation in childhood pre–B-cell acute lymphoblastic leukemia. Although TEL is required for the ontogeny of all definitive hematopoiesis,[230] a recent conditional knock-out study of the TEL gene in mice demonstrates its specific requirement for adult stage megakaryopoiesis.[231]

Runx-1

In 1999, Gilliland and colleagues used positional cloning to identify the genetic cause of a rare dominant disorder characterized by thrombocytopenia, an aspirin-like functional platelet defect, and increased risk of developing acute myelogenous leukemia (FPD/AML; OMIM 601399).[232–234] They identified nonsense mutations, intragenic deletions, or missense mutations on one allele of the gene for Runx-1 (formerly called AML-1 and CBFA2) that cosegregated with the disease in six separate pedigrees. These mutations all resulted in loss-of-function, indicating that haploinsufficiency of Runx-1 plays a causal role in this disorder. Bone marrow or peripheral blood from these patients contained reduced numbers of assayable colonies in megakaryocyte formation, indicating Runx-1 dosage affects megakaryocytopoiesis.

Runx-1 is a member of an evolutionarily conserved family of transcription factors that share a conserved 128 amino acid domain in their amino half with homology to Drosophila *runt* gene. This region mediates binding to DNA (consensus (C/T)G(C/T)GGT)) as well as to its heterodimeric binding partner CBF-β via protein-protein interactions (see review by Speck and Gilliland[235] for additional details). Runx-1 is the most frequently mutated transcription factors in human leukemia. In addition, acquired mutations in Runx-1 have been identified in significant number of patients with myelodysplastic syndrome (MDS), particularly those that progress to acute myelogenous leukemia (AML).[236–238] Homozygous knockout of either Runx-1 or CBF-β in mice is embryonic lethal because of a complete failure of definitive hematopoiesis.[239,240] This is thought to arise from a defect in the ontogeny of hematopoietic stem cells in the AGM region.[241–243] More recent studies using conditional knockout of Runx-1 in adult hematopoiesis demonstrate a specific role of Runx-1 in megakaryopoiesis.[244–246] Deletion of Runx-1 in adult mouse bone marrow results in up to an approximately 80% reduction in peripheral blood platelet numbers, without a bleeding diathesis. Bone marrow megakaryocytes are small, lack lobulated nuclei, have poorly developed demarcation membranes, and reduced polyploidization. These findings are reminiscent of the abnormal *micromegakaryocytes* seen in human myelodysplastic syndromes. Paradoxically, there is an increase in in-vitro megakaryocyte colony plating efficiency suggesting an expansion of early megakaryocyte progenitors. These effects are cell-autonomous. No defects are seen in the erythroid lineage. Reduced dosage of Runx-1's essential cofactor CBF-β also perturbs megakaryopoiesis in vivo.[247] Taken together, these findings indicate a specific role of Runx-1/CBF-β in megakaryocyte terminal maturation.

NF-E2 p45

NF-E2 is a heterodimeric transcription factor composed of two basic region-leucine zipper (bZip) subunits: a hematopoietic-specific 45 kd protein (p45) and a widely expressed 18 kd subunit (p18). NF-E2 p45 is expressed in erythroid, megakaryocytic and mast cell lineages.[248] In-vitro studies implicated NF-E2 p45 as a critical factor for β-globin expression. Unexpectedly, NF-E2 p45$^{-/-}$ mice were found to have only mild perturbations of the erythroid lineage. However, these mice fail to produce platelets secondary to a maturational arrest in the megakaryocyte lineage, and succumb to hemorrhage in the neonatal period.[249,250] Since the initial studies, NF-E2 p45 has been recognized as being a major regulator of late megakaryocyte maturation and platelet release. Interestingly, although NF-E2 p45$^{-/-}$ mice are severely thrombocytopenic, they have normal serum levels of thrombopoietin. In addition, megakaryocytes from these animals proliferate in vivo in response to thrombopoietin administration. These findings suggest that NF-E2 p45 regulates target genes independent of the action of thrombopoietin.

Several important target genes of NF-E2 p45 have been identified, including β-1 tubulin,[251,252] 3β-hydroxysteroid dehydrogenase (3β-HSD),[253] thromboxane synthase,[254] caspase 12,[255] and Rab27b.[256] β-1 tubulin, is a megakaryocyte-restricted isoform of β-tubulin that plays a key role in the marginal band structure of platelets and is essential for their discoid shape.[251,252,257] Deficiency of β-1 tubulin leads to spherocytic platelets. Heterozygosity for a polymorphism (Q43P, because of the double nucleotide substitution AG>CC) in the human

β1-tubulin gene is present in approximately 11% of individuals in a white northern European population, and correlates with a reduced risk of cardiovascular disease in men.[258] This can be caused by alterations in platelet structure and function. 3β-HSD catalyzes autocrine biosynthesis of estradiol within megakaryocytes, and plays an important role in proplatelet formation.[253]

p18 (also called mafK) is a member of a family of small maf proteins (mafF, mafG, mafK) related to the chicken v-Maf oncoprotein. Knockout of mafK, and the related mafF, in mice has no discernible phenotypes, whereas deficiency of mafG leads to mild thrombocytopenia.[259–261] Compound mafK::mafG null mice have profound thrombocytopenia, phenocopying NF-E2 p45 mice.[262] This indicates functional redundancy of the small maf family members in megakaryopoiesis.

SCL (Tal-1)

SCL (also known as Tal-1) is a member of the basic helix-loop-helix member of transcription factors and is expressed predominantly in megakaryocytic and erythroid cells. Dysregulated expression of SCL caused by chromosomal translocation is associated with certain cases of T-cell acute lymphoblastic leukemia. SCL forms obligate heterodimers with ubiquitously expressed E proteins (such as E12 and E47), which bind to E-box motifs (sequence CANNTG). It participates in multiprotein complexes that include E2A, GATA1, LM02, ldb1, and the repressor ETO2.[263,264] SCL$^{-/-}$ mice die during embryogenesis because of failure of all hematopoiesis and defective vasculogenesis.[265–267] However, conditional SCL knock-out models show a specific role for SCL in late stages of megakaryopoiesis and stress thrombopoiesis during adult hematopoiesis.[268,269] SCL-null megakaryocytes have disorganized demarcation membrane systems and reduced number of platelet granules. SCL modulates thrombopoiesis, in part, by direct transcriptional activation of NF-E2 p45.[269]

Other Transcription Factors

The transcription factors above have been studied the most in-depth in terms of their roles in megakaryocytopoiesis. Additional factors involved in megakaryocytopoiesis/thrombopoiesis have been identified, although their roles are just beginning to be explored. Gfi-1b is a member of a family of hematopoietic expressed zinc finger transcription factor proto-oncogenes (*Gfi*, for *g*rowth *f*actor *i*ndependent) that contain a unique 20 amino acid amino terminal transcriptional repressor SNAG domain. Knock-out of Gfi-1b in mice results in embryonic lethality because of severe anemia.[270] The fetal liver of mutant mice contains erythroid and megakaryocytic progenitors that are blocked in their maturation. Culture of these cells in the presence of thrombopoietin, in contrast to those from wild type animals, generates only small colonies and the cells are acetylcholinesterase negative (a marker of maturing megakaryocytes in mice). They contain markedly reduced mRNA transcript levels of vWF, NF-E2 p45, c-mpl and GPIIb, compared to wild type, suggesting a requirement for Gfi-1b in at least relatively early stages of megakaryopoiesis. Gfi-1 has been shown to repress target genes by recruitment of histone lysine methyltransferases.[271]

Warren and coworkers performed an N-ethyl-N-nitrosourea (ENU) mutagenesis screen in Tpo receptor$^{-/-}$ mice to identify factors that might influence thrombocytopoiesis. They identified two independent loss-of-function alleles of the transcription factor c-myb (substitution of valine for aspartic acid at residue 152 within the DNA binding domain, and residue 384 within the leucine zipper domain).[272] Both Tpo receptor$^{-/-}$ and wild type mice containing these mutations have supraphysiologic production of platelets because of excessive megakaryocytopoiesis, at the expense of erythroid and lymphocyte development.[273] Megakaryocytes from these animals have a 200-fold increased sensitivity to GM-CSF suggesting dysregulation of signaling pathways. Similar degrees of megakaryocytic hyperplasia and thrombocytosis occur in mice containing germline c-myb mutations that disrupt binding the transcriptional coactivator p300.[274] Thus, c-myb might play an important negative regulatory function in megakaryopoiesis and thrombocytopoiesis.

MICRORNAS IN MEGAKARYOPOIESIS

MicroRNAs are a recently discovered class of small (typically 19–25 nucleotide) noncoding RNAs that interact in a sequence-specific manner with mRNAs (typically in their 3′ untranslated region in mammals) and modulate gene expression through either enhanced mRNA decay or inhibiting translation. There is increasing evidence that they play significant roles in development and differentiation, likely by fine-tuning tissue-specific transcription factor expression. Each microRNA can have multiple target genes, and conversely, each mRNA can be subject to regulation by multiple micro RNA species. In addition, transcription of microRNAs is itself mediated by RNA polymerase II and subject to control by transcription factors. This raises the possibility of complex regulatory networks. Although examination of the functional significance of microRNAs in vivo is still at its infancy, there is some evidence that they play roles in hematopoietic development (see review by Shivdasani[275]). Croce and colleagues recently examined microRNA expression profiles in human CD34+ cells differentiated in vitro into megakaryocytes.[276] They identified a signature set of microRNAs including miR-10a, miR-126, miR-106, miR-10b, miR-17 and miR-20 that are downregulated during megakaryocyte differentiation. When they compared the microRNA expression profile of several megakaryoblastic leukemic cell lines to the differentiated CD34+ set, they found significant upregulation of several microRNAs including miR-101, miR-126, miR-99a, miR-135, and miR-20. Many of the miRs are predicted to target key transcription factors involved in megakaryopoiesis. Further work will be required to fully evaluate the functional significance, and any possible causal relationships, between these changes and altered megakaryocyte differentiation. However, it seems reasonable to speculate that microRNAs may play a role in modulating megakaryocyte differentiation.

CONCLUSION

Although the molecular details regarding the regulation and generation of platelets remain to be fully elucidated, considerable progress has been made over the past decade. This has been significantly facilitated by the isolation of Tpo and its receptor. Important models of thrombocytopoiesis have now been tested rigorously, yielding new insights into the final stages of platelet formation and shedding. These studies highlight the efficient mechanisms that have developed to satisfy the demands for dynamic and high-output platelet production. Several important transcription factors have been identified that regulate different stages of megakaryopoiesis, and mutations in these, and other genes, are beginning to be linked to human disorders of thrombocytopoiesis. The potential role of microRNAs is beginning to be explored. Although mouse models have played important roles in the analysis of these genes, it is becoming clear that they do not always faithfully recapitulate human disease. In addition, several studies have documented important differences between rodent and human platelets including differences in size, circulating numbers, and DMS ultrastructural features.[277] Thus, some caution must be exercised when extrapolating results of mouse studies to human thrombocytopoiesis. The advent of megakaryocyte in-vitro differentiation systems using human embryonic stem (ES) cell and/or CD34$^+$ cells should provide important tools for future studies geared toward dissecting human disorders of megakaryopoiesis and thrombocytopoiesis.[278]

CHAPTER 28

INHERITED FORMS OF BONE MARROW FAILURE

Melvin H. Freedman

INTRODUCTION

Bone marrow failure is defined as decreased production of one or more of the major hematopoietic lineages on an inherited basis (Table 28–1). The rather outdated term "constitutional" is often used interchangeably with "inherited" and similarly implies that a genetic abnormality causes the bone marrow dysfunction, especially when it occurs in two or more members of the same family or is associated with physical abnormalities. The designation "congenital" has a looser connotation and refers to conditions that manifest early in life, often at birth, but does not connote a particular causation. Congenital marrow failure is not necessarily inherited, therefore, and may be caused by acquired factors such as viruses, drugs, and environmental toxins.

Because hematopoiesis is an orderly but complex interplay of stem and progenitor cells, growth factors, marrow stromal elements, and positive or negative cellular and humoral regulators, marrow failure can potentially occur at a number of critical points in the hematopoietic lineage pathways. For the inherited marrow disorders, current theory holds that genetic mutations interfere with hematopoiesis and cause the marrow failure. The discovery of several abnormal genes, each associated with a specific inherited marrow failure syndrome, gives credence to this theory. Modifying genes and acquired factors may also be operative and interact with the genetic mutations to produce overt disease with varying clinical expression. Hence, the conditions shown in Table 28–1 can be transmitted as a simple Mendelian disorder determined primarily by one or more mutant genes with inheritance patterns of autosomal dominant, autosomal recessive, or X-linked types. Alternatively, some or all of these can be multifactorial disorders caused by an interaction of multiple genes and multiple exogenous or environmental determinants.

The incidence of the inherited marrow failure disorders can be approximated from experience at large centers. For example, data from the Children's Hospital Medical Center, Boston, and the Prince of Wales Hospital, Australia, show that the inherited syndromes comprise about one-third of cases of pediatric marrow failure, and that Fanconi anemia (FA) represents about two-thirds of the inherited forms.[1,2]

BI-LINEAGE AND TRI-LINEAGE CYTOPENIAS

Fanconi (Aplastic) Anemia

Background

Fanconi anemia (FA) is inherited in an autosomal recessive manner in 99% of cases. Rarely, it is transmitted in an X-linked recessive mode, caused by a mutant *FANCB* gene. Its overall prevalence is 1 to 5 cases per million with a carrier frequency of 1:200 to 300 in most populations.[3] It occurs in all racial and ethnic groups. Spanish Gypsies have the world's highest prevalence of FA with a carrier frequency of 1 : 64 to 1 : 70 for a common founder mutation.[4] A founder effect has also been demonstrated in South African Afrikaners in whom one specific mutation is common,[5] as well as in Ashkenazi Jews.

Although the original report in 1927 by Dr. Guido Fanconi described pancytopenia combined with physical anomalies in three brothers,[6] a summary of the large body of published information on 1,206 cases over the ensuing years has underscored the clinical variability of the condition.[7] Basically, FA is a chromosomal fragility disorder characterized by cytopenias, progressive bone marrow underproduction, variable developmental anomalies and a strong propensity for cancer. At presentation patients may have (a) typical physical anomalies but normal hematology; (b) normal physical features but abnormal hematology; or (c) physical anomalies and abnormal hematology, the so-called classic phenotype that fits the original description (Fig. 28–1). There can also be sibling heterogeneity in presentation with discordance in clinical and hematological findings, even in affected monozygotic twins. All patients show abnormal chromosome fragility most easily seen in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin and enhanced by adding clastogenic agents.

Approximately 75% of patients are between 3 and 14 years of age at the time of diagnosis of Fanconi anemia, with a mean of 6.5 years in males and 8 years in females.[7,8] It is noteworthy that 4% are diagnosed in the first year of life and 9% at 16 years of age or older.

Etiology and Genetics

A breakthrough in the search for FA genes evolved from the important observation that fusion of normal cells with FA cells resulted in correction of the abnormal chromosome fragility, a process known as complementation.[9] It was further demonstrated that cell fusion studies from several unrelated FA patients could also produce the corrective effect on chromosomal fragility by complementation, which led directly to subtyping of patients into discrete complementation groups.[10–13] As of 2008, 13 complementation groups (termed types A, B, C, D1/BRCA2, D2, E, F, G, L, J, M, N, and I) have been distinguished on the basis of these somatic cell hybridization experiments, with Fanconi anemia type A accounting for over 65% of the cases analyzed.[14]

The identification of the 13 subtypes facilitated the cloning of all 13 corresponding FA or *FANC* genes by 2007. The first gene, *FANCC* on chromosome 9q22.3, was discovered in 1992 in Toronto,[15] and then the other genes, corresponding to each of the other complementation groups, were subsequently cloned: *FANCA* on 16q24.3[16]; *FANCB* on Xp22.31[17]; *FANCD1/BRCA2* on 13q12.3[18]; *FANCD2* on 3p25.3[19]; *FANCE* on 6p21.3[20]; *FANCF* on 11p15[21]; *FANCG* on 9p13[22]; *FANCJ/BACH1/BRIP1* on 17q22[23]; *FANCL* on 2p16.1[24]; *FANCM* on 14q21.3[25]; and *FANCI* on 15q26.1.[26] A 13th FA gene, *FANCN* (or *PALB2*), maps to 16p12.[27] Of patients tested, 70% have mutant *FANCA*, 10% *FANCC*, 10% *FANCG*, 5% *FANCE*, and 2% or less for the others.

Knock-out mouse models of FA provide insight into the role of individual mutations. Knockouts of *Fanca*[28] and *Fancg*[29] and two different knockouts of *Fancc*[30] have been generated. The phenotype of these mutant mice is identical and consists of cellular sensitivity to DNA cross-linking agents, abnormal G_2-M progression of the cell cycle similar to FA patients, and hypoplasia of the gonads. Also, hematopoietic progenitor cells from *Fancc* knock-out mice in tissue culture display cytogenetic abnormalities and an increased risk of malignant transformation.[31] *Fancc* –/– progenitor cells are also hypersensitive to inhibitory cytokines and show impaired hematopoietic colony growth and increased apoptosis.[30,32,33] Marrow failure in

Fancc knock-out mice can be induced by treatment with the DNA-damaging agent mitomycin C.[34,35] The stem cells in these mice are intrinsically defective and show impaired ability for long-term reconstitution in recipient mice.[36,37] *Fancd2* knock-out mice serve as an informative murine model of FA-related epithelial cancer.[38]

Cells and cell lines from Fanconi patients are phenotypically similar regardless of the complementation group that they represent. The hypothesis, therefore, that wild-type Fanconi proteins function in a common cellular pathway was substantiated by data showing that proteins A, B, C, E, F, G, and M form a single large nuclear protein complex as an important first step in the DNA damage response pathway.[39–43,17,25] The essence of this elaborate, complicated pathway as it relates to FA is described. For additional details, see the thorough review of the FA pathway of genomic maintenance.[44] Activation of this protein complex by DNA damage or cell cycle progression results in the conversion of the downstream FANCD2 protein from an unubiquitinated (unubiquitinylated) isoform to a monoubiquitinated isoform,[44] a process mediated by FANCL ubiquitin ligase.[24] Monoubiquitination does not occur if the protein complex upstream of FANCD2 is not intact or if FANCL is mutated, and therefore Fanconi cells from patients with these mutations do not show monoubiquitinated FANCD2. In normal cells following monoubiquitination, FANCD2 localizes to nuclear foci where it forms complexes with other DNA-repair proteins such as BRCA1 and RAD51, and interacts with BRCA2[45,46] to complete the final steps of the DNA repair pathway. FANCI protein associates with FANCD2 as a complex and together localize to chromatin in response to DNA damage.[26] Biallelic mutations of *FANCI* cause FA.[47] PALB2 (or FANCN) is a nuclear binding partner of BRCA2. Biallelic mutations of *PALB2* also cause FA.[27]

As summarized,[46] there are important protein-protein interactions between FA proteins and non-FA "binding partners" for cell survival. FANCC and FANCD2 form complexes with members of the STAT family of transcription factors in cytokine-mediated biological responses. Secondly, heat shock proteins serve several cell survival functions, and FANCC specifically facilitates the anti-apoptotic role

Figure 28–1 Classic phenotype of Fanconi anemia. Patient has pigmentary changes around the neck, shoulders and trunk, short stature, absent radii and absent thumbs bilaterally, microcephaly, and low-set ears.

of hsp 70. Finally, GSTP1 is an enzyme that detoxifies byproducts of redox stress and xenobiotics and FANCC enhances GSTP1 activity in cells exposed to apoptosis inducers.

A genotype-phenotype study examined the consequences of mutations of *FANCC* in patients.[48] Kaplan-Meier analysis showed that IVS4 or exon 14 mutations define poor-risk subgroups clinically and are associated with earlier onset of hematologic abnormalities and poorer survival compared to patients with the exon 1 mutation and to the non-*FANCC* population. This was confirmed in a 20-year follow-up perspective by the International Fanconi Anemia Registry (IFAR).[49] A specific mutation in *FANCC* (IVS4+4A→T) is associated with multiple birth defects and early-onset hematology problems in Ashkenazi Jews[50] but the same mutation results in a mild phenotype in Japanese.[51] Another report showed that FA patients with mutations in the *FANCG* gene are at high risk for a poor hematologic outcome.[52] FA patients with biallelic mutations in *BRCA2* are distinctive in the severity of the physical phenotype, the association with VATER syndrome, and early onset and high rates of leukemia and specific solid tumors.[53] It is clear that FA patients with null mutations are more severely affected than patients with hypomorphic mutations independent of the mutant gene involved.[50]

Pathophysiology

Wild-type FA proteins are part of a cluster of survival signaling molecules that protect against genotoxic insult and suppress apoptosis signaling.[46] Biallelic inactivation of any of the known genes causes FA and the pro-survival benefit is lost. This underlies the phenotype of clinical FA but does not explain or unify the relationship between congenital anomalies, bone marrow failure, the predisposition to cancer, and chromosome fragility.

Two theories of the pathophysiology of FA relate to either defective DNA repair or an inability of FA cells to remove oxygen-free radicals that damage cells. An extensive body of published data was generated mostly in the 1980s, but the data are still relevant today. The strongest evidence supporting an oxygen metabolism deficiency is the G_2 phase cell cycle defect of FA cells, consisting of both a phase transit delay and/or a complete arrest.[54] This finding is reduced when FA cells are grown at low oxygen levels, and a similar defect can be induced in normal cells grown at high oxygen levels.[55,56] This phenotype cannot be induced by treatment with DNA cross-linking agents, suggesting that it is not related to a DNA repair defect. A comprehensive summary of the literature is available,[7] and a more recent interpretation has been published.[57]

The best evidence supporting the theory that the primary defect is in DNA repair comes from our understanding of the critical role of FANC proteins in the DNA damage response pathway. There were also experiments in the 1980s in which the frequency of mutations induced by 8-methoxypsoralen plus near-ultraviolet radiation at the *HPRT* locus was lower in FA cells than in controls.[58,59] These results could indicate that FA cells cannot repair cross-links through the normal pathway involving mismatch repair, or recombinational repair following bypass of the lesion, or both. Similar studies that assayed the repair of cross-linked herpes simplex virus DNA following transfection found that FA cells, unlike controls, were able to repair cross-linked DNA only under conditions of multiple infection.[60] Because multiplicity reactivation is dependent on recombinational repair, it can be inferred that FA cells are defective in an excision repair pathway.

To reconcile the evidence of defective oxygen metabolism with the data demonstrating involvement of the DNA repair system in the pathology of FA cells, we speculate that proteins closely involved in DNA repair are particularly sensitive to oxidative damage. The biallelic gene inactivation in FA could either make the repair pathway sensitive to oxidative damage or cause a transient increase of oxidative damage to which the repair machinery is particularly sensitive. The findings that wild-type FANCA and FANCG proteins are redox-sensitive and are multimerized and/or form a nuclear complex in response to oxidative stress and damage are pertinent.[61]

Hematologic dysfunction in FA is evident at the hematopoietic progenitor level in bone marrow and peripheral blood. The frequencies of CFU-E, BFU-E and CFU-GM colony-forming cells are reduced fairly consistently in almost all patients after aplastic anemia ensues,[62–66] as well as in a few patients before the onset of aplastic anemia.[67] Although FA marrow cells show normal transcripts for the α and β chains of the GM-CSF/IL-3 receptor and for c-kit protein, there is a deficient proliferative response of CFU-GEMM, BFU-E and CFU-GM progenitors in response to GM-CSF plus stem cell factor (c-kit ligand) or IL-3 plus stem cell factor.[68] Because all hematopoietic lineages are affected in these studies, the basic defect is likely at the hematopoietic stem cell level. Cure of FA marrow failure by hematopoietic stem cell transplantation supports this view. Confirmatory data for defective stem cells in FA using long-term bone marrow cultures were reported by one group[69] but not confirmed by another.[70] Decreased colony numbers in these studies can be interpreted as the result of an absolute decrease in progenitors. In support of this, Buchwald documented decreased numbers of $CD34^+$ cells in *Fancc* −/− mice (M. Buchwald, personal communication). Decreased numbers of assayable hematopoietic colonies may also be a result of adequate numbers of progenitors that have faulty proliferative properties and cannot form colonies *in vitro*.

Additional factors are operative in FA bone marrow failure. Telomeres, the non-encoding DNA at each end of chromosomes, shorten with each round of cell division in normal human somatic cells. Their length is a reflection of the mitotic history of the cell. Telomerase, a ribonucleoprotein reverse transcriptase that can restore telomere length, is variably present in hematopoietic progenitors. Leukocyte telomere length is significantly shortened in FA patients but there is increased telomerase activity,[71] suggesting an abnormally high proliferative rate of progenitors, which ultimately leads to their premature senescence. In parallel, apoptosis has surfaced as an important mechanism in some inherited marrow failure syndromes. Increased marrow cell apoptosis has been demonstrated in FA patients[72] and in knockout mouse models[32] and is mediated by Fas, a membrane glycoprotein receptor containing an integral death domain. FA cells exposed to TNF-α, interferon-γ, mip-1α, Fas ligand, and double-stranded RNA undergo exaggerated apoptotic responses.[32,73,74]

Studies of cytokines in FA patients have shown varied abnormalities. Although FA fibroblasts showed no deficiencies in stem cell factor or M-CSF production, variability ranging from diminished production to augmentation of production of IL-6, GM-CSF and G-CSF has been observed in different patients.[75] A consistent finding that may relate directly to pathogenesis is diminished IL-6 production in FA patients and markedly heightened abnormal TNF-α generation.[76]

Clinical Features

History and Physical Examination

The presence of characteristic congenital physical anomalies alone or in combination with signs, symptoms, complications, and laboratory confirmation of bone marrow failure makes a diagnosis of FA straightforward. However, FA patients may lack anomalies. The older historical terms *Estren-Dameshek aplastic anemia* and *constitutional aplastic anemia type II* referred to such patients. With the introduction of clastogenic stress-induced chromosomal breakage analysis as a confirmatory test for FA, data from the IFAR showed that 39% of 202 patients tested had aplastic anemia and anomalies, and 30% had aplastic anemia without anomalies.[77] A summary of 1206 published cases of FA also documented that 25% of patients had no anomalies.[7] Twenty-four percent of patients in the IFAR had anomalies only, and 7% had neither anomalies nor hematologic abnormalities. Hence, the Estren-Dameshek cases that lack anomalies should not be considered as a separate entity but as part of the pleiotropic continuum of FA.

Table 28–2 shows the characteristic physical abnormalities and their approximate frequency. The most common anomaly is skin hyperpigmentation, a generalized brown melanin-like splattering,

Table 28–2 Characteristic Physical Anomalies in 1,206 Fanconi Anemia Patients*

Anomaly	Frequency (%)
Skin pigment changes and/or café au lait spots	55
Short stature	51
Upper limb abnormalities (thumbs, hands, radii, ulnae)	43
Hypogonadal and genitalia changes (mostly male)	35
Other skeletal findings (head/face, neck, spine)	30
Eyes/lids/epicanthal fold anomalies	23
Renal malformations	21
Gastrointestinal/cardiopulmonary malformations	11
Hips, legs, feet, toes abnormalities	10
Ear anomalies (external and internal), deafness	9

Alter BP: "Inherited Bone marrow Failure Syndromes" In Nathan DG, Orkin SH, Look AT, Ginsberg D (eds.): Nathan and Oski's Hematology of Infancy and Childhood, 6th ed. Philadelphia WB Saunders, 2003, p 280.

which is most prominent on the trunk, neck, and intertriginous areas and which becomes more obvious with age. Café-au-lait spots are common alone or in combination with the generalized hyperpigmentation, and sometimes with vitiligo or hypopigmentation. The skin pigmentation should not be confused with hemosiderosis-induced bronzing in transfusion-dependent patients who have not been adequately iron-chelated.

One half of patients are less than the third percentile for height. In some patients, growth failure is associated with endocrine abnormalities. In one report, spontaneous overnight growth hormone secretion was abnormal in all patients tested, and 44% had a subnormal response to growth hormone stimulation.[78] Approximately 40% of patients also have overt or compensated hypothyroidism, sometimes in combination with growth hormone deficiency.[79]

Malformations involving the upper limbs are common—especially hypoplastic, supernumerary, bifid, or absent thumbs. Hypoplastic or absent radii are always associated with hypoplastic or absent thumbs in contrast to the thrombocytopenia with absent radii (TAR) syndrome in which thumbs are always present. Less often, anomalies of the feet are seen including toe syndactyly, short toes, a supernumerary toe, clubfoot, and flat feet. Congenital hip dislocation and leg abnormalities are occasionally seen.

Males often have gonadal and genital abnormalities including an underdeveloped penis or micropenis, undescended, atrophic, or absent testes, hypospadias, phimosis, and an abnormal urethra. Female patients occasionally have malformations of the vagina, uterus, or ovary.

Many patients have a Fanconi "facies," and unrelated patients can resemble each other almost as closely as siblings. The head and facial changes vary but commonly consist of microcephaly, small eyes, epicanthal folds, and abnormal shape, size, or positioning of the ears. Approximately 10% of FA patients are developmentally retarded.

Renal anomalies occur but require imaging for documentation. Ectopic, pelvic, or horseshoe kidneys are detected often, as are duplicated, hypoplastic, dysplastic, or absent organs. Occasionally, hydronephrosis or hydroureter is present.

A scoring system was developed for the probability of an accurate diagnosis of FA using discriminating clinical and laboratory variables in patients enrolled in the IFAR whose diagnosis was confirmed by clastogenic stress-induced chromosomal breakage analysis.[77] The scoring system was useful in proving that diepoxybutane (DEB)-induced chromosomal breakage results could be correlated with common FA findings. DEB testing is considered by the IFAR to be the gold standard for diagnosis, but mitomycin C testing is still used in many laboratories.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings. A cardinal feature is the gradual onset of bone marrow failure usually in the first decade of life, with declining values in one or more hematopoietic lineages. Of 754 FA patients followed prospectively by the IFAR, 80% had hematologic abnormalities other than acute leukemia or MDS.[49] The cumulative incidence of these abnormalities by 40 years of age was 90%. Patients with FANCC mutations appeared to have the earliest onset of changes and the highest incidence.[49] Thrombocytopenia usually develops initially, with subsequent onset of granulocytopenia and then anemia. Severe marrow aplasia eventually ensues in most cases but the full expression of pancytopenia is variable and evolves over a period of months to years. The development of aplastic anemia can be accelerated by intercurrent infections or by drugs such as chloramphenicol. Within families, there is a tendency for the hematologic changes to occur at approximately the same age in affected siblings.

The red cells are macrocytic with mean cell volumes often above 100 fl even before the onset of significant anemia. Erythropoiesis is characterized by increased HbF and increased expression of i antigen, but not necessarily both features in individual cells. The increased HbF production is not clonal and has a heterogeneous distribution. Ferrokinetic studies indicate that most patients have an element of ineffective erythropoiesis as part of the marrow failure. Red blood cell lifespan may be slightly shortened but this is a minor component, if any, of the anemia.

In the early stages of the disease, the bone marrow can show erythroid hyperplasia, sometimes with dyserythropoiesis, myelodysplastic changes, and even megaloblastic-appearing cells. As the disease progresses, the marrow becomes hypocellular and fatty, sometimes in a patchy manner, and shows a relative increase in lymphocytes, plasma cells, reticulum cells, and mast cells. With full-blown marrow failure, the morphology on biopsy is identical to severe acquired aplastic anemia.

A summary of the literature on FA heterozygotes indicates that parents of FA children may have physical abnormalities such as short stature but without hematologic disease.[7] Heterozygote carriers may also have increased levels of HbF, decreased natural killer cell counts and diminished reactivity to mitogen stimulation. In chromosome breakage assays with DEB, FA heterozygotes may have a higher mean breakage value compared to controls but individual testing shows overlap with normal values. Except for FA families with BRCA2 mutations, there is no apparent increased risk of cancer in relatives of FA patients.

Abnormal Chromosome Fragility. A major finding is abnormal chromosome fragility seen readily in metaphase preparations of peripheral blood lymphocytes cultured with phytohemagglutinin. The karyotype shows "spontaneously" occurring chromatid breaks, rearrangements, gaps, endoreduplications, and chromatid exchanges in cells from homozygote FA patients. Cultured skin fibroblasts also show the abnormal karyotype underscoring the constitutional nature of the disorder. The abnormal lymphocyte chromosome patterns and the number of breaks per cell have no direct correlation with the hematological or clinical course of individual patients.

Spontaneous chromosomal breaks are occasionally absent in true cases of homozygote FA.[77] The clastogenic stress-induced chromosomal breakage analysis was introduced, in part, to circumvent this problem and to bring specificity to testing for FA. Chromosomal breakage is strikingly enhanced compared with controls if clastogenic agents (DNA crosslinking compounds) such as DEB or mitomycin C (MMC) are added to the cultures.[80] Indeed, homozygote Fanconi cells are hypersensitive to many oncogenic and mutagenic inducers such as ionizing radiation, SV40 viral transformation, and alkylating and chemical agents including cyclophosphamide, nitrogen mustard, and platinum compounds.[8] For definitive diagnostic purposes, the IFAR has defined FA as increased numbers of chromosome breaks/cell after exposure to DEB[80] with a range of 1.06 to 23.9 compared to the normal control range of 0.00 to 0.05. The abnormal chromosome breakage can be used to make a prenatal diagnosis of FA.[81]

Diagnostic testing can be performed on fetal amniotic fluid cells obtained at 16 weeks' gestation or on chorionic villus biopsy specimens at 9 to 12 weeks. A very high degree of prenatal diagnostic accuracy has been obtained by looking at both spontaneous and DEB-induced breaks in fetal tissue.[81] DEB testing of heterozygote carriers is unreliable for diagnosis because there is overlap of results with the normal range.[7]

Somatic Mosaicism. Ten percent to 15% of patients with clinical FA do not show increased chromosome breakage when tested with DEB or mitomycin C. These patients usually have hematopoietic cell somatic mosaicism as a result of a molecular genetic correction in a stem cell resulting in 1 normal allele.[82–85] The mechanisms for this phenomenon include gene reversion, gene conversion, mitotic recombination and compensatory frameshifts. The end result is mixed populations of somatic cells, some with 2 abnormal alleles and some with 1. If FA is strongly suspected, a skin biopsy is performed to assess chromosomal breakage in cultured fibroblasts.

Immunoblotting for *FANCD2*. An accurate diagnostic and subtyping assay for FA has been introduced.[86] Primary lymphocytes or fibroblasts are assayed after exposure to mitomycin C or radiation for *FANCD2* by immunoblot, which distinguishes the unubiquitinated and monoubiquitinated forms. The testing is useful in 3 situations for screening FA defects.[46] In FA patients with diagnostic mitomycin-induced chromosomal breakage assays, *FANCD2* mutations are presumed if no full-length *FANCD2* is detected by immunoblotting. If *FANCD2* is detected but is not monoubiquitinated, mutations of one of the core complex proteins are predicted. If *FANCD2* is detected and *is* monoubiquitinated, *BRCA2* or *FANCJ* mutations are expected. Monoubiquitination of *FANCD2* is normal in other bone marrow failure syndromes and chromosomal breakage disorders.

Other Findings. Wild-type FA genes can be transfected into FA T cells using retroviral vectors.[87,88] If a specific wild-type FA gene corrects (complements) the abnormal chromosome breakage in an FA patient's T cells on exposure to DEB, the mutant gene is identified. The mutant gene can also be identified by flow cytometry. FA cells exposed to alkylating agents arrest in the G_2/M phase of the cell cycle. The transduced wild-type FA gene that reduces G_2/M arrested cells pinpoints the mutant gene.

A simple, fast, sensitive, and specific biochemical test for FA has also been described,[89] but there are several methods and each requires validation. The vast majority of FA patients have stable, elevated levels of serum α-fetoprotein expressed constitutively that are independent of liver complications and of androgen therapy. Levels are also unchanged after hematopoietic stem cell transplantation.

Predisposition to Malignancy

A major feature of the FA phenotype is the propensity to develop cancer. The chromosome fragility, the defects in DNA repair, the genomic instability, and the cellular damage that occur in FA patients translate into an enormous predisposition for malignancy.[90,91] Since there are at least 13 genetic mutations that are operative in FA, the disorder is a critical human model of the genetic determinants of hematologic cancers and malignant solid tumors. FA is a member of two categories of cancer predisposition syndromes. The first group is comprised of disorders of DNA repair that include ataxia telangiectasia, xeroderma pigmentosum, and Bloom syndrome. The close relationship between FA and ataxia telangiectasia, for example, is underscored by data showing convergence of signaling pathways in both conditions.[92] The second group of predisposition syndromes consists of other inherited marrow failure disorders described herein that show a propensity for malignant myeloid transformation and/or solid tumors.

The magnitude of the risk of malignancy in FA is detailed in two comprehensive reports. The first is a complete survey of literature from 1927 to 2001 that identifies 1301 published cases of FA.[91] Of these, 200 patients had one or more cancers, a crude rate of 17%. The median age for all cancers in these patients was 16 years of age, which is strikingly different from the median age of 68 for the same types of cancer in the general population.

There were 68 patients with a total of 80 solid tumors. The most frequent solid tumors were squamous cell carcinomas of the head, neck, and upper esophagus, followed by carcinomas of the vulva and/or anus, and lower esophagus. Twelve patients were described who developed cancer after bone marrow transplantation. All 12 patients had oral carcinoma, mainly of the tongue, and one case had an additional vulva carcinoma. Liver tumors, benign and malignant, occurred in 37 patients (23 hepatomas, 13 adenomas, and 1 not specified). All of the hepatoma patients and all adenoma cases except one had received androgen therapy for aplastic anemia. Androgen administration has therefore been implicated in liver tumor pathogenesis, as well as in the etiology of peliosis hepatis, which consists of blood-filled hepatic sinusoids in the liver. Indeed, peliosis hepatis is reversible when androgens are stopped, and tumors may regress.

The second report that describes the malignant risk in FA is the 20-year prospective observational study by the IFAR.[49] The findings corroborate the literature survey[91] in terms of type of cancer and site. Of the 754 registered FA patients, 120 (16%) developed hematologic cancer (AML, MDS, or ALL). Based on current data,[49,90,91] the crude risks irrespective of age are about 5% for MDS and up to 10% for leukemia. The cumulative incidence of leukemia by 25 years of age is about 10%. Previous observations by the IFAR showed that the risk of developing MDS and AML was higher for patients in whom a prior clonal marrow cytogenetic abnormality had been detected.[93] Monosomy 7, rearrangement or partial loss of 7q, rearrangements of 1p36 and 1q24-34, and rearrangements of 11q22-25 were the most frequently recurring cytogenetic changes. There is also a high incidence of abnormalities involving chromosomes 2, 6, 8, 5, and 21.

Additional data indicate that patients with partial trisomies and tetrasomies of chromosome 3q in marrow cells also have a high risk of developing MDS and AML.[94] Similar to the literature review[91] and another source,[95] the IFAR verified that the risk of developing hematologic and non-hematologic cancer increased with advancing age, but it did not show an age-related plateau for the risks for MDS and AML, possibly because both diagnoses were analyzed together. When interpreting the significance of cytogenetic clonal abnormalities in FA patients, note that clonal variation is frequent including appearances of new clones, disappearance of established clones, and clonal evolution.[95]

Differential Diagnosis

Patients with hematological abnormalities and characteristic physical anomalies are not difficult to diagnose, especially if there are previously affected siblings. Distinguishing FA from acquired aplastic anemia on clinical grounds can be difficult if the FA patient lacks physical anomalies. In this situation, the clastogenic stress-induced chromosomal breakage analysis using DEB or MMC will specifically identify FA and lead to the correct diagnosis. Although not widely available yet, screening by *FANCD2* immunoblotting or by retroviral-mediated transfer of corrective wild-type *FANC* genes into patient cells is also diagnostic.

Although neutropenia is a consistent feature of Shwachman–Diamond syndrome (SDS), anemia and/or thrombocytopenia is seen in more than 50% of the patients and can be confused with FA. Since growth failure is also a manifestation of SDS, differentiating between the two disorders can initially be difficult. The major difference between them is that SDS is a disorder of exocrine pancreatic dysfunction that produces gut malabsorption. This can be confirmed by fecal fat analysis, by pancreatic stimulation studies using intravenous secretin or cholecystokinin that confirm markedly impaired enzyme secretion, and by showing reduced levels of serum trypsinogen and isoamylase. Computed tomography ultrasonography or magnetic resonance imaging of the pancreas may also demonstrate fatty changes

within the body of the pancreas. Other skeletal distinguishing features found in some SDS patients are short flared ribs, thoracic dystrophy at birth, delayed bone maturation, and metaphyseal dysostosis of the long bones. Chromosomes do not show spontaneous breaks in SDS, and there is no increased breakage after clastogenic stress using DEB or MMC. Specific diagnostic confirmation is obtained by demonstrating the mutant *SBDS* gene.

Dyskeratosis congenita (DC) shares some features with FA including development of pancytopenia, a predisposition to cancer and leukemia, and skin pigmentary changes. However, the pigmentation pattern is somewhat different in DC and manifests with a lacy reticulated pattern affecting the face, neck, chest, and arms, often with a telangiectatic component. At some point, usually in the first decade, DC patients also develop dystrophic nails of the hands and feet, and, somewhat later, leukoplakia involving the oral mucosa, especially the tongue. Other findings seen only in DC and not in FA are teeth abnormalities with dental decay and early tooth loss, hair loss, and hyperhydrosis of the palms and soles. Although there are contradictory data regarding chromosomal fragility in DC, DEB testing has not shown any difference between patients and controls, which contrasts sharply with FA patients. In the X-linked form of DC, mutations can be identified in the *DKC1* gene. The *TERC* or *TERT* or *TINF2* gene mutation confirms the dominant form of the disorder. The *NOP10* mutation accounts for autosomal recessive DC.

Congenital amegakaryocytic thrombocytopenia and TAR syndrome both present in the neonatal period with an isolated decrease of platelets. A neonatal hematologic presentation is atypical for FA, as less than 5% of patients are diagnosed in the first year of life. Neither of the thrombocytopenic syndromes shows chromosome fragility, which separates them from FA, and a mutated *MPL* gene is diagnostic of congenital amegakaryocytic thrombocytopenia. In the TAR syndrome, thumbs are always preserved and intact despite the absence of radii, whereas in FA, the thumbs are hypoplastic or absent when the radii are absent.

Schimke immunoosseous dysplasia is characterized by spondyloepiphyseal dysplasia with exaggerated lumbar lordosis, renal dysfunction, hypothyroidism, and cytopenias including lymphopenia. The syndrome is cause by a mutated *SMARCAL1* gene.

The Nijmegen chromosome breakage syndrome is a rare disorder characterized by stunted growth, microcephaly, a distinctive facies, café-au-lait spots, immunodeficiency, and a predisposition to lymphoid malignancy. The genetic defect is a mutant *NBS1* gene whose wild-type protein product is involved in DNA repair. Because these patients show increased chromosomal sensitivity to DEB and MMC, they can mimic and be confused with FA.[96] Genetic testing is diagnostic.

Natural History and Prognosis

The most serious early event for most FA patients is bone marrow failure. The exceptions are patients with biallelic *BRCA2* mutations who manifest early-onset AML, brain tumors, and Wilms tumors. Judging from the literature, the risk for FA patients developing solid malignant tumors, liver tumors, acute leukemia and MDS is at least 15%, but it is likely higher in older patients. Treatment for cancer imposes additional problems and probably increases the risk for additional cancers secondary to therapy.

Despite these major issues, prognosis for FA patients is improving. Older literature describing an early demise of FA patients is flawed because it did not take into account the diversity in clinical and hematological phenotype. Early diagnosis can now be made before the onset of serious marrow failure or malignant transformation, and survival from the time of diagnosis is longer. Also, current management, especially hematopoietic stem cell transplantation (HSCT), has dramatically changed prognosis. From cases reported in the last decade, the projected median survival is greater than 30 years of age.[7] Some middle-aged patients with presumably hypomorphic mutations are not diagnosed as FA until severe complications from treatment in cancer occur.[97] Despite delayed menarche, irregular menses, and early menopause, older female FA patients can be sexually active; at least 20 patients have become pregnant resulting in 21 living infants as well as miscarriages.[7] Four FA males were also reported to be fathers despite the high incidence of underdeveloped gonads and abnormal spermatogenesis reported in FA males overall.[7]

Therapy

Because of their clinical and psychosocial complexity, FA patients should be supervised by a hematologist at a tertiary care center using a comprehensive and multidisciplinary approach. On the initial visit, the following should be performed: a careful physical examination with emphasis on physical anomalies; complete blood counts and chemistries; serum α-fetoprotein level; and diepoxybutane (and/or mitomycin C) chromosome fragility testing on peripheral blood lymphocytes on patients and siblings. When the diagnosis is confirmed, HLA tissue typing on patient and family members should be performed and arrangements made for determining the mutant gene. Imaging studies should also be made to search for internal anomalies described in History and Physical Examination section. When all the results are catalogued, a follow-up visit with the family is arranged to discuss management options and prognosis.

If the patient is stable and has only minimal to moderate hematological changes and does not have transfusion requirements, a period of observation is indicated. Blood counts should be monitored every 1 to 3 months, and bone marrow aspirates and biopsies should be performed annually for morphology and cancer cytogenetics to identify the emergence of a malignant clone or overt transformation to MDS or AML. Spectral karyotyping (SKY), fluorescent in situ hybridization (FISH), and comparative genomic hybridization can enhance the diagnostic capability on marrow cells. Depending on the types of congenital anomalies, subspecialty consultations, for example with orthopedic surgery, can be arranged during this interval.

Growth is followed clinically, and when growth velocity or stature falls below expectations, endocrine evaluation is needed to identify growth hormone deficiency. Impaired glucose tolerance, hyperinsulinemia, and diabetes mellitus occur more commonly in FA[79] and should be screened for annually or biannually depending on the degree of hyperglycemia found on initial testing. Screening for hypothyroidism also should be performed annually. Screening for cancers associated with FA should be initiated at least annually. Dentists, oral surgeons, or head and neck surgeons should be recruited to screen for head and neck squamous cell carcinomas. The risk in untransplanted FA patients is 700-fold that of the general population.[90] After stem cell transplantation, the oral cavity should be examined every 3 months for signs of malignant change, because cancers can occur within a year of the procedure.[98] Beginning at menarche, all women with FA should undergo gynecologic screening annually, because the risk of gynecologic squamous cell carcinoma is 4000-fold that of the general population.[90]

Hematopoietic Stem Cell Transplantation (HSCT)

HSCT is currently the only curative therapy for the hematological abnormalities of FA. The best donor source is an HLA-matched sibling in whom thorough screening has excluded a diagnosis of FA. Initial efforts to transplant FA patients using standard preparative regimens and graft-versus-host prophylaxis were plagued by two serious and often lethal problems: severe cytotoxicity from chemotherapy, and exaggerated graft-versus-host disease (GVHD). HSCT protocols were subsequently modified for FA patients and the outcomes improved substantially. Protocol refinements are ongoing internationally and several approaches are being studied.

Pooled published data on HSCT using HLA-matched sibling donors show a survival of greater than 80% in FA patients less than 10 years of age, and greater than 65% for FA patients of all ages. The multicenter Italian experience reflects these optimistic outcomes.[99] Using a conditioning regimen of low-dose cyclophosphamide (median 20 mg/kg in most patients) and thoracoabdominal or total body irradiation (median dose 500 cGy), survival for 27 consecutive patients at 36 months was 81.5%.

Some transplantation centers have eliminated irradiation in the preparative regimen because of concern for secondary cancer, especially squamous cell carcinoma of the head and neck or genitourinary tract. A retrospective study of 37 FA patients conditioned with low-dose cyclophosphamide plus thoracoabdominal irradiation also identified almost a twofold risk of acute GVHD compared with a cohort of non-FA patients with aplastic anemia transplanted without irradiation conditioning.[100] This risk increased to sevenfold in patients younger than 12 years old.

Reduction in immunosuppression by eliminating radiation is best suited for transplants using genotypically-matched related donors determined by DNA-based molecular methodology. Several reports from 2005 and 2006 reflect this trend.[101–103] Comparable outcomes were seen with protocols using low-dose cyclophosphamide alone (60 or 80 mg/kg),[101] busulfan (6 mg/kg) plus cyclophosphamide (40 mg/kg),[102] and cyclophosphamide (60 mg/kg) plus anti-thymocyte globulin (40 mg/kg/day for 4 doses).[103] There is a growing trend for incorporating fludarabine, a purine anti-metabolite with potent immunosuppressive properties, into conditioning regimens instead of irradiation for FA transplants.[104]

For FA patients who do not have an HLA-A, B, and DRB1-identical sibling donor for HSCT, a search for a matched unrelated donor should be initiated. Because of the heightened graft-versus-host response observed in FA patients, the survivals and cure rates are not as good compared to matched sibling donor HSCT. Even when matched unrelated marrow is fully compatible with the recipient at the DNA level (*molecular match*), these transplants are still problematic. Two reports on outcomes of 69 and 29 FA patients, respectively, transplanted with matched unrelated or alternate donors yielded probabilities of survival of about 33%.[105,106] These outcomes decline sharply to approximately 10% if patients are transplanted with advanced MDS or AML, proven or probable fungal infections, or prior gram-negative infections. Additional risk factors are patients older than 10 years, prior use of androgens, the number of physical anomalies, and female donors.[105] There is evidence that fludarabine-based protocols yield improved outcomes in FA transplantations with unrelated and alternate donors sources.[107–110]

Unless the increased risks associated with alternate donors improve, it is not recommended currently that FA patients undergo this type of HSCT if their clinical and hematological status is stable. Although open to debate, indications to proceed with an alternate donor HSCT include (a) failure to respond adequately to androgen therapy and/or cytokine treatment resulting in severe cytopenia or an impending need for chronic transfusional support; (b) presence of a persistent high risk cytogenetic clone in bone marrow cells, for example, monosomy 7; (c) overt malignant transformation to MDS or AML; and (d) a high risk mutation (FANCC IVS4, FANCC exon 14, or BRCA2).

Cord blood cells, naturally enriched with hematopoietic stem and progenitor cells, are being increasingly used as a donor source. The first cord blood transplantation was reported in 1989 for a FA patient using a matched sibling donor.[111] Since then, cord blood collections and transplants have increased quickly for a variety of indications including more FA patients.[112,113] Using cord cells from related or unrelated donors, engraftment and survival is comparable to related or unrelated bone marrow, although engraftment is slower with cord blood. The incidence of acute and chronic GVHD is reduced with cord blood grafts even in 1 to 2 HLA antigen mismatched transplants.

G-CSF-mobilization and collection of peripheral blood CD34+ cells from FA patients prior to onset of severe pancytopenia[114] has not attained broad application. These cells in theory can be used as targets for gene therapy, or cryo-preserved and infused later when severe marrow failure ensues, or as an autologous rescue after chemotherapy in the event of leukemic transformation.

Molecular technology has led to *preimplantation genetic diagnosis* (PGD) in order to find an HLA-matched donor for transplantation for a FA patient.[115] A couple, both carriers of the IVS4+4A→T mutation in the FANCC gene, had an affected child requiring a hematopoietic stem cell transplantation. Using single-cell PCR technology, isolated cells from several blastomeres fertilized in vitro were each tested for HLA type and for presence of the mutation. HLA- compatible normal blastomeres were then transferred and implanted in utero resulting in one success and the subsequent birth of a matched unaffected sibling. Cord blood from such a PGD-selected healthy sibling has been used successfully for a HSCT of the affected sibling.[116,117] The notion of "designer babies" has sparked ethical debate.[118]

Despite the successes of HSCT in correcting the marrow failure of FA patients, there is a subset of survivors who develop secondary cancers, particularly squamous cell carcinoma of the head and neck.[98] These malignancies reflect the ongoing genetic susceptibility of FA nonhematopoietic tissue to cancer despite successful transplantation for marrow failure.[119] Conditioning regimens clearly play a role in heightening the risk of transformation.

Hematopoietic Growth Factors

The role for recombinant granulocyte colony stimulating factor (G-CSF) therapy for FA has not been defined. A multicenter clinical trial examined the effect of prolonged administration of G-CSF to 12 FA patients with neutropenia.[120] The patients were treated with varying subcutaneous dosages daily or every other day for 40 weeks. By week 8 of the study, all patients had an increase in absolute neutrophil numbers and 4 had an increase in platelet counts. Additionally, four patients who were not being transfused had a significant increment in hemoglobin levels and a fifth patient lost a transfusion requirement. Concurrent with the impressive improvements in hematology, 8 of 10 patients who finished 40 weeks of G-CSF treatment showed increases in the percentage of marrow and peripheral blood CD34+ cells.

Since genomic instability and a marked predisposition to leukemia and cancer are features of FA, the wisdom of using a growth-promoting cytokine on a long-term basis for this disorder continues to be an issue.[121] In the G-CSF study,[120] one patient had a marrow clonal cytogenetic abnormality (48 XXY, +14) without MDS or AML at week 40 of treatment. Therapy was stopped and within 3 months the +X, +14 clone disappeared but monosomy 7 appeared in 11% of metaphases and increased over the ensuing months, prompting bone marrow transplantation. Unlike the monosomy 7, the appearance of the +X, +14 clone while the patient was receiving G-CSF treatment and its disappearance when cytokine was discontinued must be put into the context of FA, per se, in which clones, seemingly unstable, are known to appear and disappear spontaneously.[95]

Another study examined the long term efficacy and safety of G-CSF in 4 FA patients.[121] Three had an increase in neutrophil numbers, a reduction in number and severity of infections, and improvement in clinical status. However two of the responders developed monosomy 7 and showed immature cells in peripheral blood.

Thus, G-CSF when used alone in FA can usually induce an increase in absolute neutrophil numbers and occasionally boost platelet counts and hemoglobin levels. However, there appears to be a heightened risk of developing cytogenetic abnormality such as monosomy 7.

GM-CSF can also induce an increase in neutrophils in FA using a starting dose of 250 μg/m^2/day subcutaneously. Of 7 patients treated, 6 had a 7- to 25-fold increase in neutrophils that was sustained with minimal side effects.[122]

Combination cytokine therapy consisting of G-CSF 5 μg/kg once daily with erythropoietin 50 units/kg administered subcutaneously or intravenously three times a week was given to patients without a matched donor for transplantation.[123] Androgen therapy was added if the response was inadequate. Of 20 patients treated, all but 1 had improved neutrophil numbers, 20% achieved a sustained rise in platelets, and 33% had an increase in hemoglobin levels. Although more than half of the responders lost the response after one year as a result of progression of marrow failure, the requirement for androgen therapy could be delayed by about a year. A trial of interleukin-11 for patients with inherited marrow failure and thrombocytopenia failed to increase platelet numbers (Dr. James Croop, personal communication).

Androgens

Androgen therapy has been used to treat FA for more than four decades. The overall response rate in the literature is about 50%[7] heralded by reticulocytosis and a rise in hemoglobin within 1 to 2 months. If the other lineages respond, white cells increase next, followed by platelets, but it may take many months to achieve the maximum response. When the response is deemed maximal, the androgens should be slowly tapered but not stopped entirely. Accepted indications for treating with androgens are one or more of the following: hemoglobin level less than 8 g/dL or symptoms from anemia; platelet count less than 30,000/mm^3; and neutrophil count less than 500/mm^3.

Oxymetholone, an oral 17-α alkylated androgen, is used most frequently at 2 to 5 mg/kg once a day with the lower dose preferred initially. Although unproven, corticosteroids are commonly added to offset the androgen-induced growth acceleration and to prevent thrombocytopenic bleeding by promoting vascular stability. For this purpose, 5 to 10 mg of prednisone is given orally every second day. If an injectable androgen is preferred to decrease the risk of liver toxicity and growth of tumors, nandrolone decanoate, 1 to 2 mg/kg/week is given intramuscularly followed by the application of local suitable pressure and ice packs to prevent the development of hematomas. There are insufficient comparative data on the efficacy of the attenuated androgen, Danazol, compared to oxymetholone to make a recommendation. Claims of reduced masculinizing side effects in female FA patients treated with Danazol as compared to oxymetholone have not been substantiated in clinical trials.

Almost all patients relapse when androgens are stopped. Those few who successfully discontinue treatment are often in the puberty age range when temporary "spontaneous hematological remissions" have been observed to occur. A subset of patients on long-term androgens eventually become refractory to therapy as marrow failure progresses. Potential side effects include masculinization, which is especially troublesome in female patients, and elevated hepatic enzymes, cholestasis, peliosis hepatis, and liver tumors. Those receiving androgens should be evaluated serially with liver enzyme profiles every 2 to 3 months and ultrasonography and/or CT scan of liver, every 6 to 12 months. If liver enzymes increase to threefold normal of if abnormalities appear on imaging, the androgen dose should be decreased or stopped.

It is strongly recommended by many transplant centers that an FA patient not receive androgens if it is known that the patient has a matched donor available. Prior use of androgens pre-transplantation adversely affects outcome after the transplantation.[105]

Future Directions

The premise for gene therapy in FA is based on the assumption that corrected hematopoietic cells would have a growth advantage. Strengthening this supposition are FA patients with hematopoietic somatic mosaicism who show spontaneous disappearance of cells with the FA phenotype.[82–85] These patients have two populations of leukocytes, one sensitive to mitomycin C and the other with normal resistance to mitomycin C.[85] These *mosaic* patients may show spontaneous hematologic improvement suggesting that hematopoiesis was derived from stem cells with a normal phenotype. In the context of gene therapy, there is evidence that even one genetically corrected hematopoietic stem cell may be able to repopulate the marrow of a FA patient.[125]

Despite encouraging preclinical studies over a decade ago using retroviral vectors that showed wild-type *FANCC* and *FANCA* could be integrated into normal and FA CD34$^+$ cells,[126–128] the ensuing clinical trials in *FANCC* and *FANCA* patients were disappointing.[129] A central problem is suboptimal wild-type gene integration into FA cells in culture. Because of the apoptotic phenotype, FA cells die rapidly in vitro before efficient gene transfer is accomplished. Lentiviral vectors that can infect noncycling human cells were deemed the solution[130] but obstacles persisted. Recently, there is evidence that FA marrow cell survival in vitro can be ameliorated by using specific culture conditions that limit oxidative stress.[131] Using these conditions, gene-corrected marrow cells using retroviral vectors survived in culture longer than 4 months and showed long term engraftment in NOD/SCID mice.[131] There is also interest in transposons, non-viral vectors that have been used successfully for gene delivery in murine models and may hold promise for human genetic diseases.[132]

Shwachman-Diamond Syndrome

Background

Shwachman-Diamond syndrome (SDS) is an autosomal recessive multisystem disorder characterized by exocrine pancreatic insufficiency and varying degrees of bone marrow failure.[133–138] There may be additional features including short stature and skeletal abnormalities. The mutant gene responsible for this complex, pleiotropic phenotype has been identified[139] and has been confirmed in 90% of patients with the classic presentation. To date, though, no unifying pathogenesis has been able to account for all of the multisystem features of SDS. Chromosomes are normal and there is no increased breakage with clastogenic stress testing in contrast to FA patients. None of these patients have cystic fibrosis; sweat chloride levels are normal. Many families have been identified with at least two affected children, and published studies of segregation ratios and family pedigrees support an autosomal recessive mode of inheritance.

Etiology, Genetics, and Pathophysiology

The identification of SDS-associated mutations on chromosome 7q11 in a previously uncharacterized gene termed "*SBDS*" was the entry point for studies on the molecular basis for SDS.[139] There is an adjoining pseudogene (*SBDSP*) with 97% homology but it contains deletions and nucleotide substitutions that disrupt its coding potential. Recombination occurs whereby segments of *SBDSP* become incorporated into wild-type *SBDS* and interfere with its function.

These recombinational events result in 3 common gene conversion mutations in exon 2 that account for 75% of *SDS* alleles. A nonsense mutation, 183_184TA>CT, introduces an in-frame stop codon (K62X); a splice-site mutation, 258+2T>C, is predicted to result in premature truncation of the SBDS protein by frameshift (C84fs3); and an extended conversion mutation, 183_184TA>TA+258+2T>C, encompasses both mutations. In the Toronto database of 210 SDS families, 89% of unrelated SDS individuals carry a gene conversion mutation on one allele and 60% carry conversion mutations on both alleles. Thus, the vast majority of patients are compound heterozygotes with respect to K62X and C84fs3. Additional rare mutations in the *SBDS* gene have been identified in SDS patients. These include dozens of insertion, deletion, and missense mutations which have not arisen from gene conversion events.

SBDS is a member of a highly conserved protein family of previously unknown function with putative orthologs in diverse species including archaea and eukaryocytes. The gene encodes a 250 amino acid protein product whose phylogeny is shared with proteins that are enriched for RNA metabolism and/or ribosome-associated functions.[140] The SBDS protein can be detected in human cell nuclei and in cytoplasm but is concentrated within nucleoli providing supportive evidence for its role in RNA processing.[141] The pathophysiological link between exocrine pancreatic insufficiency, physical anomalies, partial to complete marrow failure and propensity to myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML) should soon be clarified. SBDS forms a protein complex with nucleophosmin, a multifunctional protein implicated in ribosome biogenesis and leukemogenesis.[142] Biallelic targeted disruption of the mouse ortholog Sbds leads to arrested embryonic development and early lethality.[143]

Regarding the bone marrow failure, initial studies in the 1970s and early 1980s showed reduced CFU-GM and BFU-E colony growth in most patients compatible with a defective stem cell origin

Fanconi Anemia: Hematology and Oncology Details Worth Noting

Because 25% of FA patients do not have physical anomalies, cases may not be recognized until they present with aplastic anemia, MDS, AML, single cytopenias or macrocytic red cells. Thus, FA should be part of the differential diagnosis in children and adults with unexplained cytopenias. Similarly, the diagnosis of MDS or AML in patients less than 1 year to 30 years of age should prompt consideration of FA as the underlying problem. Patients with AML or solid tumors who exhibit excessive sensitivity to chemotherapy or radiotherapy should also be tested for FA. Cases of "acquired" or "idiopathic" aplastic anemia who fail to respond to immunosuppressive therapy with ATG and cyclosporine may also have FA.

The relative risk of AML in FA patients is 800-fold; the frequency of MDS has not been defined in these patients. Although MDS may precede overt transformation to AML, this is not predictable in FA and the temporal relationship between the two is unclear. Data from patients who have annual bone marrow testing for morphology and cytogenetics may show clonal chromosomal abnormalities with or without morphologic evidence of MDS. Isolated cytogenetic clones without signs of MDS in FA are perplexing because they may come and go without progression to leukemia. In some cases, isolated clones have persisted *without* overt marrow transformation for more than 12 years. Findings of clones with cytogenetic abnormalities commonly associated with MDS, however, such as –7 or +8 warrant careful evaluation. There is a striking association between chromosome 3q26q29 amplifications and rapid progression to MDS or AML. The identity of the duplicated material may have to be confirmed by FISH or SKY or by comparative genomic hybridization because G-banding may not be completely informative.

When interpreting marrow morphology and cytogenetic findings the following must be noted. Bone marrow morphology often appears dysplastic in FA patients. Marrow cell dysplasias, such as nuclear/cytoplasmic dyssynchrony, hypolobulated megakaryocytes, and binucleated erythroid cells, are often seen in patients with FA and must be distinguished from MDS. Such marrow dysplasia is commonly seen in the inherited marrow failure syndromes and is not necessarily a sign of impending AML. The distinction between benign and malignant cytology should be established by an experienced morphologist with familiarity of these disorders.

Androgen therapy induces a rise in hemoglobin and sometimes platelets and neutrophils in about 50% of FA patients. A subset of responders becomes refractory over time. MDS and AML are not prevented by androgen treatment. There are 5 complications of androgen therapy that require consideration.

1. *Peliosis hepatis* is a cystic dilation of hepatic sinusoids that fill with blood and can be life-threatening if they rupture. They may be clinically silent or produce right upper quadrant pain. Liver function tests are normal. Imaging is the safest way to diagnose the abnormality. The lesions may regress after stopping the androgens.
2. *Androgens also damage hepatocytes* nonspecifically. This may be manifest as cholestatic jaundice or elevated liver enzymes. Stopping androgen therapy will usually lead to complete resolution. Hepatic cirrhosis may develop in patients on continued androgen therapy. If resolution of enzyme elevation does not occur after androgen withdrawal, a liver biopsy is indicated.
3. *Hepatocellular adenomas* are associated with androgen therapy. These are benign, non-invasive tumors. They can, however, rupture, leading to life-threatening bleeding. FA patients may develop these tumors rapidly but they can be readily detected by imaging. The tumor may regress after stopping the androgens. If persistent, surgical resection or radiofrequency ablation may be necessary.
4. *Hepatocellular carcinoma* (HCC; hepatoma) occurs with androgen use and some studies have suggested that FA patients on treatment may be at increased risk for HCC. The HCC associated with androgens characteristically does not produce α-fetoprotein in serum, distinguishing it from de novo HCC. Patients developing HCC should discontinue androgen therapy.
5. Androgen therapy for FA patients is recognized by hematopoietic stem cell transplanters as an important *adverse prognostic factor* for those receiving a transplant. Several centers with experience in FA transplants firmly recommend that androgens *not* be given to any FA patients unless a suitable donor is not available.

There is up to a 700-fold increase in the incidence of head and neck squamous cell carcinoma in patients with FA. The cumulative risk is 14% for patients surviving to 40 years of age. The biological behavior of these cancers in FA is aggressive with early lymph node metastases and soft tissue invasion. The risk is heightened after hematopoietic stem cell transplantation and is partly related to acute and chronic GVHD. Tobacco and alcohol use, especially together, also increases the cancer risk and total abstinence from both is strongly recommended. Surveillance should begin aggressively by 10 years of age on a semiannual basis by an experienced professional in the field of dentistry, oral surgery, or head and neck surgery.

Similar to the heightened risk of the head and neck sites, there is a 4000-fold risk of genital tract squamous cell carcinoma in women with FA. Cervical, vaginal, vulvar and anal cancers have been recorded. Annual exams for all FA women should begin at age 16 years or at menarche and must include a Papanicolaou (Pap) smear and reactive testing for human papilloma virus (HPV). HPV DNA is detected in 84% of squamous cell carcinoma specimens from various anatomic sites in FA patients compared to 36% of specimens from non-Fanconi controls. Prevention of HPV should become a reality with the availability of the HPV vaccines (example, Gardasil quadrivalent cervical cancer vaccine, Merck Pharmaceuticals).

of the marrow failure.[144] Recent investigations have characterized a much more extensive hematopoietic phenotype (Table 28–3).[145–149] SDS marrow has decreased numbers of $CD34^+$ cells as well as an impaired ability for $CD34^+$ cells to form multilineage hematopoietic colonies in vitro confirming that they are intrinsically defective.[145] The bone marrow stroma is also markedly defective in terms of its ability to support and maintain normal hematopoiesis.[145] Patients' marrow cells over-express Fas, the membrane receptor for Fas ligand, and show increased patterns of apoptosis after preincubation with activating anti-Fas antibody,[146] pinpointing this as a central pathogenetic mechanism for the marrow failure. An additional finding is abnormal telomere shortening in patient leukocytes,[147] reflecting premature cellular aging and likely representing compensatory stem cell hyperproliferation. Lymphoid immune function is also impaired; most SDS patients show decreased numbers or diminished function of B cells, T cells, or NK cells.[148] Marrow microvessel density is increased[149] reflecting neovascularization, a hallmark of malignant tumors, acute leukemia, and MDS. Overexpression of p53 protein

Table 28–3 Hematopoietic Phenotype in Shwachman-Diamond Syndrome

- Decreased marrow CD34+ cells[a]
- Decreased colonies from CD34+ cells[a]
- Abnormal telomere shortening of leukocytes[b]
- Increased apoptosis of marrow cells[c]
- Apoptosis is mediated by Fas pathway[c]
- Marrow stromal cell function is impaired[a]
- Lymphoid immune function is abnormal[d]
- Marrow microvessel density is increased[e]
- Marrow cell upregulation of specific oncogenes[f]

Table 28–4 Clinical Features and Strict Diagnostic Criteria for Shwachman–Diamond Syndrome

Essential Features for Diagnosis	% Patients	References
• Pancreatic insufficiency (decreased digestive enzymes)	100%	151–153
• Hematologic cytopenias:		151,152,155,156
Neutropenia	88%–100%	
Thrombocytopenia	24%–70%	
Anemia	42%–66%	
Pancytopenia	10%–44%	
Supportive Diagnostic Features		
• Short stature	50%	151
• Skeletal abnormalities:		154
Delayed bone maturation	100%	
Metaphyseal dysplasia	44%–77%	
Rib cage anomalies	32%–52%	
• Hepatomegaly/elevated enzymes	<50%	152
• Poor oral health (caries, ulcers, tooth loss)	>50%	*
• Learning and behavioral problems	>50%	*

*Unpublished data.

has also been demonstrated in bone marrow biopsies from patients[150]; this may represent an early indicator of significant DNA genetic alteration, which is a crucial step in leukemogenesis.

Clinical Features

History and Physical Examination

The many manifestations that occur in varying combinations are shown in Table 28–4; however, the criteria for clinical diagnosis are very specific and strict.[151] Patients must have two essential features for diagnosis: exocrine pancreatic insufficiency *and* one or more hematological cytopenias. Other features like short stature, skeletal abnormalities, hepatic enlargement or impairment, poor oral health, and learning and behavioral problems are supportive of the diagnosis, but cannot substitute for the pancreatic or hematological changes.

The pancreatic pathology is caused by failure of pancreatic acinar development (Fig. 28–2). Pathologic studies reveal normal ductular architecture but extensive fatty replacement of pancreatic acinar tissue, which can be visualized by computed tomography, ultrasonography, or by magnetic resonance imaging. Pancreatic function studies using intravenous secretin or cholecystokinin, confirm the presence of markedly impaired enzyme secretion averaging 10% to 14% of normal but with preserved ductal function.[152] Patients may also have reduced serum trypsinogen and isoamylase levels.[153] Decreased isoamylase levels in children older than three years of age, in particular, are highly sensitive and very specific for the diagnosis.

The vast majority of patients have symptoms of malabsorption from birth caused by the pancreatic insufficiency. The absence of steatorrhea, however, does not exclude a diagnosis of SDS. Approximately 50% of patients appear to exhibit a modest improvement in enzyme secretion with advancing age.[152] Many older patients with SDS actually develop pancreatic sufficiency with normal fat absorption when assessed by 72-hour fecal fat balance studies.

The most conspicuous physical findings relate to the pancreatic insufficiency and malabsorption, especially short stature, which is

another consistent feature of the syndrome. When treated with pancreatic enzyme replacement, most patients show a normal growth velocity yet remain consistently below the third percentile for height and weight, indicating an intrinsic growth defect. Some patients have evidence of delayed puberty. The occasional adult achieves the 25th percentile for height. The clinical picture can also be dominated by complications related to the cytopenias. Bacterial and fungal infections, in particular, secondary to neutropenia as well as immune deficiency[148] can be problematic.

Skeletal abnormalities are present in all SDS patients with mutant SBDS.[154] Some patients present at birth with thoracic dystrophy, and others have short, flared ribs. Metaphyseal dysostosis of the long bones is a common radiological abnormality (44%–77% of patients) and is thought to be quite specific, particularly in the femoral head and the proximal tibia. These changes may not be detectable until after 12 months of age. The etiology of the metaphyseal changes is unclear. In most patients these bony lesions fail to produce any symptoms. However, the integrity of the growth plate may be affected which in turn may result in skeletal growth disturbances and joint deformities, particularly in the knees and hips. In 100% of patients, there is delayed appearance of secondary ossification centers resulting in delayed bone maturation.[154]

As summarized,[136] there are additional clinical features that are seen very infrequently in SDS. Endocrine abnormalities include insulin-dependent diabetes, growth hormone deficiency, hypogonadotropic hypogonadism, and hypothyroidism (Dr. Akiko Shimamura, Seattle, unpublished observations). Cardiomyopathies have been noted in some cases. Psychomotor delay of varying severity, urinary tract anomalies, renal tubular acidosis, and cleft palate also occur.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings. Data from 4 publications (Table 28–4) accurately represent the spectrum of hematologic findings.[151,152,155,156] In 1 series,[156] neutropenia was present in virtually all patients on at least one occasion. It can be chronic, intermittent or cyclic although there are no published data on the periodicity of the cycles. Neutropenia has been identified in some SDS patients in the neonatal period during an episode of sepsis. Anemia, usually normochromic-normocytic, was recorded in up to 66% of patients,[156] and thrombocytopenia in up to 70%.[155] Fetal hemoglobin was elevated in 75% of patients at some stage during the disease course.[156] Whether this reflects stress hematopoiesis and/or ineffective erythropoiesis concomitant with chronic infections, or represents MDS in evolution has not been clarified. Reticulocyte responses were inappropriately low for the levels of hemoglobin in 75% of patients.[156]

More than one lineage can be affected, and pancytopenia was observed in up to 65% of cases.[155] The pancytopenia can be severe as a result of full-blown aplastic anemia (Fig. 28–3). However, bone marrow biopsies and aspirates vary widely with respect to cellularity; varying degrees of marrow hypoplasia and fat infiltration are the usual findings, but marrows with normal or even increased cellularity have also been observed.[152,156] The severity of neutropenia does not always correlate with bone marrow cellularity, nor is the severity of the pancreatic insufficiency concordant with the hematological abnormalities.

Patients with SDS are particularly susceptible to severe infections including otitis media, bronchopneumonia, osteomyelitis, septicemia, and recurrent furuncles. Overwhelming sepsis is a well-recognized fatal complication of this disorder, particularly early in life. SDS neutrophils may have a defect in mobility, migration and chemotaxis that does not appear to be caused by malnutrition.[157] Lithium in some manner appears to restore chemotaxis.[158] There appears to be a diminished ability of SDS neutrophils to orient toward a gradient of *N*-formyl-methionyl-leucyl-phenylalanine.[159] An unusual surface distribution of concanavalin A has also been reported that reflects a cytoskeletal defect in SDS neutrophils.[160] Whatever the magnitude of the chemotaxis abnormality is in vitro in SDS, neutrophil recruitment into abscesses or empyemas ensues robustly in vivo.[161]

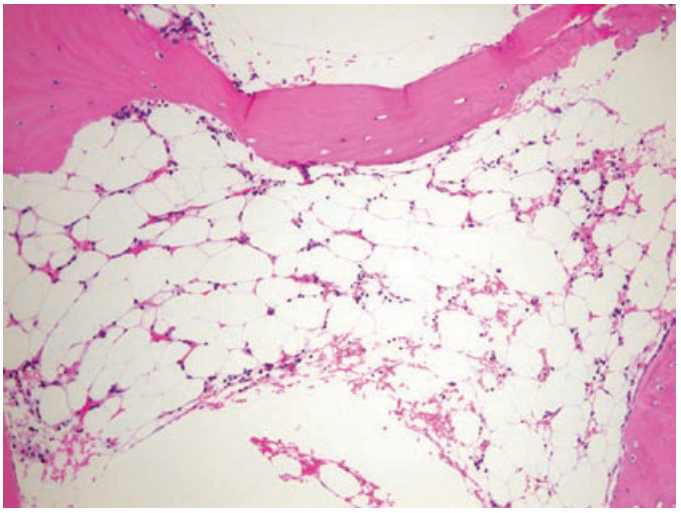

Figure 28–3 Bone marrow biopsy in severe Shwachman–Diamond syndrome showing striking hypocellularity, fatty changes, and tri-lineage aplasia. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

Immune Dysfunction. Impaired immune function can be significant in SDS and underlie recurrent infections even if neutrophils are at a protective level.[148] Patients have variations of B-cell abnormalities with one or more of the following: low IgG or IgG subclasses, low percentage of circulating B lymphocytes, decreased in vitro B-cell proliferation, and lack of specific antibody production. Patients may also have T-cell abnormalities: low percentage of circulating T lymphocytes or subsets or NK cells, and decreased in vitro T-cell proliferation.

Leukemia, Myelodysplasia, and Clonal Cytogenetic Changes. Like six other inherited bone marrow failure disorders, SDS predisposes patients to MDS and acute myeloid leukemic transformation.[135,138] The crude rate for MDS or acute myeloid leukemia (MDS/AML) in patients with SDS was 8% in one case series (7 of 88 patients)[151] and 33% in a smaller case series (7 of 21).[156] It was 5% in approximately 200 SDS cases reported in the literature prior to 1990, and 10% in more than 300 patients who had not received G-CSF reported through 2000.[162] Of 55 SDS patients followed prospectively in the French Severe Chronic Neutropenia Registry, 7 patients developed MDS or AML with an estimated risk of 19% at 20 years and 36% at 30 years.[163] A literature search revealed 54 SDS cases with MDS/AML of whom 37 developed cytogenetic abnormalities and/or morphologic dysplasia and/or increased numbers of marrow blast cells.[138] Clearly, the propensity for malignant myeloid transformation is very high compared to the general population, but is probably not as high as in Fanconi anemia.

There is an increased frequency of marrow cell clonal cytogenetic abnormalities as an isolated finding in SDS. The incidence is roughly estimated to be 7% to 41% based on pooled published data.[136] In a 2005 review,[138] reports of marrow cytogenetic abnormalities were compiled on 40 SDS patients who showed no evidence of malignant transformation. Isochromosome 7q [i(7q)], an extremely uncommon finding rarely described in MDS or AML in patients without SDS,[164] was seen in 44% of SDS patients. This high occurrence suggests that it is a fairly specific marker for SDS and might be related to the mutant gene on 7q(11).

Other chromosome 7 abnormalities were seen in 33% of the SDS patients and included monosomy 7, i(7q) combined with monosomy 7, and deletions or translocations involving part of 7q. The prognostic significance of the cytogenetic changes requires prospective monitoring for clarification. Of the patients with i(7q), progression to MDS with excess blasts or to AML has rarely been reported.[135,138]

Similarly, SDS patients with del (20q) almost never evolve into MDS/AML. In a prospective 5-year follow-up study of SDS patients, no progression to overt transformation was seen in 2 patients with del (20q), 1 patient with i(7q), and 1 with combined del (20q) and i(7q).[165] Similarly, no progression was seen in six additional patients with i(7q) from several hospitals in the United Kingdom.[166] In contrast, approximately 40% of patients with the other chromosomal 7 abnormalities progress to either high grade MDS or to AML.[138]

An ongoing issue is the risk of MDS or AML in SDS patients while receiving G-CSF therapy for severe neutropenia. In the report of 14 patients with congenital disorders of myelopoiesis who developed MDS/AML (n = 13) or a clonal cytogenetic abnormality (n = 1) while receiving G-CSF, two of the study group had SDS.[167] Of 16 SDS patients enrolled in the Severe Chronic Neutropenic International Registry in 2003 who received G-CSF therapy, 2 developed MDS and 1 developed a marrow cytogenetic clonal change (Dr. Cornelia Zeidler, personal communication). The concern is that G-CSF therapy may have played a role in the malignant transformation.

***SBDS* Gene and MDS/AML.** Wild-type *SBDS* must play a critical role in preventing leukemic myeloid transformation because up to 1/3 of SDS patients develop MDS/AML. To address whether an acquired mutant *SBDS* gene is associated with leukemic transformation in de novo AML, 77 AML marrow samples at diagnosis or relapse were analyzed for *SBDS* mutations and none were identified.[168] To see if a subset of previously undiagnosed SDS patients presented for the first time with AML, 48 AML marrow samples were studied at remission but no *SBDS* mutations were found.[168] SDS patients with MDS/AML have common *SBDS* mutations,[168] and a genotype-phenotype study of 21 cases of SDS with MDS/AML showed no relationship (Linda Ellis, RN, Toronto, personal communication). Thus the link between mutant *SBDS*, hematologic cancer, and upregulated oncogenes[169] including *LARG*, *TAL1*, and *MLL* is undetermined.

Although molecular and cellular parameters do not distinguish SDS patients with clonal cytogenetic changes from SDS patients without clonal changes,[165] it is remarkable that SDS marrows from almost all patients demonstrate many characteristic features seen in MDS.[138] These include impaired marrow stromal support of normal hematopoiesis,[145] increased marrow cell apoptosis mediated by the Fas pathway,[146] p53 protein over expression,[150] telomere shortening of leukocytes,[147] increased marrow neovascularization,[149] and high frequency of cytogenetic clonal abnormalities.[138] It is possible that preleukemia in SDS is established in utero.

Differential Diagnosis

The syndrome of refractory sideroblastic anemia with vacuolization of bone marrow precursors, or Pearson syndrome, is clinically similar to SDS but very different in bone marrow morphology.[170] Severe anemia requiring transfusions rather than neutropenia is often present at birth and by 1 year of age in all cases. In contrast to SDS, the major marrow morphologic findings are ringed sideroblasts with decreased erythroblasts and prominent vacuolation of erythroid and myeloid precursors. The disorder shares clinical similarities with SDS because of exocrine pancreatic dysfunction in both. Malabsorption and severe failure to thrive occurs in approximately one-half of cases within the first 12 months of life. Qualitative pancreatic function tests show depressed acinar function and reduced fluid and electrolyte secretion. Approximately 50% of reported cases die early in life from sepsis, acidosis, and liver failure; the others appear to improve spontaneously with reduced transfusion requirements. At autopsy, the pancreas shows acinar cell atrophy and fibrosis; fatty infiltration as seen in SDS is not a prominent feature. The need for long-term pancreatic enzyme replacement is unclear. These patients have a diagnostic deletion of mitochondrial deoxyribonucleic acid (mtDNA).[171] mtDNA encodes enzymes in the mitochondrial respiratory chain that are relevant to oxidative phosphorylation, including the reduced form of nicotinamide-adenine dinucleotide dehydrogenase (NADH), cytochrome oxidase, adenosine triphosphatase (ATPase), and transfer ribonucleic acids (tRNAs) and ribosomal RNAs.

SDS shares some manifestations with Fanconi anemia such as marrow dysfunction and growth failure, but SDS patients are readily distinguished because of pancreatic insufficiency with a resultant malabsorption syndrome, fatty changes within the pancreatic body that can be visualized by imaging, characteristic skeletal abnormalities not seen in Fanconi patients, and normal DEB clastogenic stress testing. Mutational analysis for mutant *SBDS* is definitive, but 10% of classic clinical SDS cases do not have a mutant *SBDS*.

Natural History and Prognosis

Because of the broad pleiotropy in SDS, the number of undiagnosed patients with mild or asymptomatic disease is unknown. Hence, overall prognosis may be better than previously thought. The majority of *SBDS* mutations represent hypomorphic alleles with reduced but variable protein expression.[172] Also, there is phenotypic heterogeneity in patients carrying identical *SBDS* mutations.[173] Therefore, until more information is forthcoming, the natural history and prognosis are not yet defined.

From a literature review, the projected median survival of SDS patients was calculated as 35 years.[7] During infancy, morbidity and mortality are mostly related to malabsorption, infections, and thoracic dystrophy. Later in life, the major problems are hematological or complications related to their treatment. Cytopenias tend to fluctuate in severity, never fully resolve, and show no genotype-phenotype relationship.[174] Spontaneous remissions do not occur after symptomatic cytopenias ensue or after MDS/AML.

Therapy

Patient management is ideally shared by a multidisciplinary team consisting of a hematologist and a gastroenterologist as core members, and other subspecialists such as a dentist and a psychologist as required. The malabsorption component of SDS responds to treatment with oral pancreatic enzyme replacement with meals and snacks using guidelines similar to those for cystic fibrosis. Supplemental fat-soluble vitamins are also usually required. When monitored over time, approximately 50% of patients convert from pancreatic insufficiency to sufficiency because of spontaneous improvement in pancreatic enzyme secretion.[151,175] This improvement is particularly evident after four years of age. A long term plan should be initiated to monitor changes in peripheral blood counts that require corrective action and to look for early evidence of malignant myeloid transformation. The latter requires serial bone marrow aspirates for smears and cytogenetics, and marrow biopsies. One recommendation is to do marrow testing annually.[135]

Growth Factors and Other Strategies

G-CSF given for profound neutropenia has been very effective in inducing a clinically beneficial neutrophil response.[167,176–179] Crossover treatment using GM-CSF initially, followed by G-CSF later for a form of childhood neutropenia has shown efficacy from both,[179] but they have not been compared in SDS patients.[179] Of 35 SDS patients enrolled in the Severe Chronic Neutropenia International Registry in 2003, 16 evaluable cases received G-CSF; 14 of the 16 patients had brisk neutrophil responses that were sustained in some cases for more than 11 years (Beate Schwinzer, Hannover, personal communication).

A small number of patients have been treated with corticosteroids with hematologic improvement in 50%. A smaller number received androgens plus steroids in the manner of treating Fanconi anemia

and improved marrow function was also noted. Isolated cases treated with androgens alone, cyclosporine, or erythropoietin do not allow broad therapeutic conclusions. Anemia and thrombocytopenia are managed with transfusions of red cells or platelets as needed.

Hematopoietic Stem Cell Transplantation (HSCT)

At present, the only curative option for severe marrow failure in SDS is allogeneic hematopoietic stem cell transplantation. As of mid 2006, 58 patients who had received HSCT were reported in the literature.[180–182] Indications were marrow failure, MDS or leukemia, and there was a mix of sibling and matched unrelated donors. The French Registry reported a 60% overall survival of SDS patients following HSCT.[182] The European Transplantation Group similarly had a 65% overall survival. Analysis[136] of the reported experience[180–182] yielded the following: 21 of 25 transplanted patients for marrow failure were cured, but only 6 of 14 with MDS and 2 of 6 with leukemia survived.

A note of caution is sounded regarding HSCT for SDS. Left ventricular fibrosis and necrosis without coronary arterial lesions have been reported in 50% of SDS patients at autopsy,[183] suggesting that there may be an increased risk of cardiotoxicity as well as other problems with the intensive preparatory chemotherapy used in HSCT. Indeed, 2 pertinent reports[184,185] and a recent literature review[138] emphasized that complications are more common in SDS patients who receive chemotherapy or undergo transplantation than in non-SDS patients with aplastic anemia. Complications include cardiotoxicity, neurological and renal complications, veno-occlusive disease, pulmonary disease, post-transplant graft failure, and severe GVHD. The heightened risk for patients with SDS after transplantation can be explained in three ways; (1) the presence of the SDS marrow stromal defect that is not corrected by the allograft and might be aggravated by the conditioning regimen, (2) increased sensitivity to chemotherapy and radiation resulting in massive apoptosis in various organs, or (3) performing HSCT relatively late and at an advanced disease stage. A reduced-intensity conditioning regimen shows promise for SDS HSCT[186] but has not been extensively used yet.

Future Directions

Mutant *SBDS* causes SDS in 90% of clinically diagnosed patients. The hunt for additional causative mutant genes in the other 10% should demonstrate that SDS is genetically heterogeneous and expand our understanding of pathogenesis. Several other clinical and basic research questions in SDS must be addressed. First, the function of the *SBDS* gene has to be deciphered. How SBDS protein maintains normal hematopoiesis and protects from apoptosis as well as cancer is unclear. The complete clinical phenotype, natural history and risk factors for the development of complications need to be determined. There is also a need to understand the mechanism for the heightened sensitivity of SDS patients to chemotherapy and irradiation and to develop low-intensity regimens for HSCT. Research should continue on the efficacy of innovative drugs such as anti-apoptotic agents in increasing the growth potential of hematopoietic stem cells and relieving the severity of cytopenia. Determining risk factors and molecular events during malignant myeloid transformation might prompt strategies for prevention and screening for complications.

Dyskeratosis Congenita

Background

Dyskeratosis congenita (DC) is an inherited multisystem disorder of the mucocutaneous and hematopoietic systems in association with a wide variety of other somatic abnormalities.[187] The diagnostic ectodermal component invariably consists of the triad of reticulate skin pigmentation of the upper body, mucosal leukoplakia, and nail dystrophy. The skin and nail findings usually become apparent in the first 10 years of life, whereas the oral leukoplakia is seen later. These manifestations tend to progress as patients get older.

DC is also an inherited bone marrow failure syndrome in which aplastic anemia occurs in about 50% of cases, usually in the second decade of life. Patients also have a predisposition to develop cancer and myelodysplastic syndromes. Because of the cluster of abnormalities involving skin and bone marrow and the predilection to cancer, DC resembles Fanconi anemia. However, the genetics, gene mutations, and physical abnormalities of patients with both conditions are quite different and hence the two diseases should be considered as totally discrete entities.

Etiology, Genetics, and Pathophysiology

The inheritance pattern is genetically heterogeneous. Approximately 73% of DC patients in the literature are males, compatible with an *X-linked recessive* trait.[7] Approximately 16% of cases are sporadic female patients, familial cases with affected male and female siblings in one generation, and cases with known parental consanguinity that fit an *autosomal recessive* inheritance pattern. An *autosomal dominant* mode fits the remaining 11% of cases that occur in families with affected male and female members in consecutive generations. The DC Registry at Hammersmith Hospital, London, is less certain about the modes of inheritance.[187] Of 228 DC families, 158 have only a single affected individual (123 male, 35 female) and it is not possible to infer the inheritance pattern.[188]

From the literature, the autosomal dominant group seems to have clinically milder manifestations, and the autosomal recessive group appears to have more physical anomalies and a higher incidence of aplastic anemia and cancer. In one series, the actuarial probability of male patients developing aplastic anemia was 94% by 40 years of age.[189]

The X-linked recessive form of DC maps to Xq28 and many mutations have been identified in the *DKC1* gene, which codes for the nuclear protein dyskerin.[190] Dyskerin is critically involved in the telomere maintenance pathway. It is a component of small nucleolar particles that are important in ribosomal RNA processing. The autosomal dominant form of DC is caused by germline mutations in the *TERC* gene, the *TERT* gene, or the *TINF2* gene. *TERC* encodes the RNA component of telomerase that is also involved in telomere maintenance.[191] Indeed, very short telomeres have been demonstrated in peripheral blood cells of all patients with autosomal dominant, autosomal recessive, and X-linked recessive forms of the disorder[192] and is a marker for the genetic abnormalities.[193] Defective telomere maintenance leading to heightened cellular apoptosis is a central pathogenetic mechanism for these 3 forms of DC.[194,195] The *TERT* gene encodes a reverse transcriptase that adds telomere repeats of the ends of each chromosome. *TERT* and *TERC* work together in telomere maintenance. *TINF2* encodes a component of the shelterin telomere protection complex and when mutated impairs telomere maintenance and causes DC.[196] Autosomal recessive DC has been linked to mutations in the telomerase-associated protein NOP10.[197]

Most studies of the pathogenesis of the aplastic anemia in DC have shown a marked reduction or absence of CFU-GEMM, BFU-E, CFU-E and CFU-GM progenitors.[62,63,198,199] Long-term bone marrow cultures were used to study hematopoiesis in three patients with DC[199]; hematopoiesis was severely defective in all with a low frequency of colony-forming cells and a low level of hematopoiesis in long-term cultures. The function of DC marrow stromal cells was normal in their ability to support growth of hematopoietic progenitors from normal marrow in all 3 cases, but generation of progenitors from DC marrow cells seeded over normal stroma was reduced, strongly suggesting that the defect in DC is of stem cell origin.

Thus, the marrow failure in this disorder may be a result of a progressive attrition and depletion of hematopoietic stem cells which manifests as pancytopenia when patients are in their mid-teens. Alternatively, the marrow dysfunction may not be a simple conse-

Figure 28–4 Dystrophic nails in dyskeratosis congenita.

quence of a limited stem cell pool but may represent a failure of replication and/or maturation.

Clinical Features

History and Physical Examination

Clinical manifestations in DC often appear during childhood. The skin pigmentation and nail changes typically appear first, mucosal leukoplakia and excessive ocular tearing appear later, and by the mid-teens the serious complications of bone marrow failure and malignancy begin to develop. In rare cases the marrow abnormalities may appear before the skin manifestations. The main causes of death relate either to bone marrow failure or to malignancy with an additional risk of fatal pulmonary complications. The actual median age at death is 20 years for males with X-linked and sporadic DC and those with autosomal recessive DC.[7] Autosomal dominant DC patients have a milder disease and survive longer.

The DC Registry data show the prevalence of somatic abnormalities in families with classic DC.[187,189] The phenotype in female cases varies considerably but many share the same features as male cases. Cutaneous findings are the most consistent feature of the syndrome. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is a common finding (89%). The degree of pigmentation increases with age and can involve the entire skin surface. There may also be a telangiectatic erythematous component. Nail dystrophy of the hands and feet is the next most common finding (88%) (Fig. 28–4). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia usually involves the oral mucosa (78%), especially the tongue (Fig. 28–5), but may also be seen in the conjunctiva, anal, urethral, or genital mucosa. Hyperhidrosis of the palms and soles is common, and hair loss is sometimes seen. Eye abnormalities are observed in approximately 50% of cases.[200] Excessive tearing (epiphora) secondary to nasolacrimal duct obstruction is common. Other ophthalmologic manifestations include conjunctivitis, blepharitis, loss of eyelashes, strabismus, cataracts, and optic atrophy. Abnormalities of the teeth, particularly an increased rate of dental decay and early loss of teeth, are common. Skeletal abnormalities such as osteoporosis, avascular necrosis, abnormal bone trabeculation, scoliosis, and mandibular hypoplasia are seen in approximately 20% of cases.[201,202] Genitourinary abnormalities include hypoplastic testes, hypospadias, phimosis, urethral stenosis, and horseshoe kidney. Gastrointestinal findings, such as esophageal strictures, hepatomegaly, or cirrhosis, are seen in 10% of cases.[203] A subset of patients develop pulmonary complications with reduced diffusion capacity and/or a restrictive defect.[189] In fatal cases, lung tissue shows pulmonary fibrosis and abnormalities of the pulmonary vasculature.

Laboratory Findings

Peripheral Blood, Bone Marrow, and Immunological Findings. Approximately 50% of the X-linked male DC patients and 70% of the autosomal recessive patients develop aplastic anemia, usually in the teenage years. It occurs in the autosomal dominant patients as well but much less frequently. Most of these patients already have manifestations of DC, but some younger patients can develop marrow failure before the clinical onset of the mucocutaneous manifestations. The initial hematological change is usually thrombocytopenia or anemia, or both, followed by full-blown pancytopenia caused by aplastic anemia. The red cells are often macrocytic and the fetal hemoglobin can be elevated. Oddly, early bone marrow aspirations and biopsies may be hypercellular; however, with time the cellular elements decline with a symmetrical decrease in all hematopoietic lineages. Ferrokinetic studies at this point are consistent with aplastic anemia. Some patients with DC have immunologic abnormalities including reduced or elevated immunoglobulin levels, reduced B- and/or T-lymphocyte numbers, and reduced or absent proliferative responses to phytohemagglutinin.[189]

Chromosome Fragility Findings. There is a large body of contradictory information regarding chromosomal fragility and instability in DC. Spontaneous chromosome breaks in patients' lymphocytes were

Figure 28–5 Leukoplakia of the tongue in dyskeratosis congenita.

reported in some studies but were not confirmed. Similarly, excessive spontaneous and clastogenic-induced sister chromatid exchange in patient lymphocytes were observed by some investigators but not by others. Finally, a definitive study demonstrated that there was no significant difference in chromosomal breakage between patient and normal lymphocytes with or without exposure to bleomycin, diepoxybutane, MMC, and γ radiation.[204] This contrasts sharply with Fanconi anemia cells and distinguishes one disorder from the other.

However, Dokal argues that DC is a chromosome "instability" disorder of a somewhat different type than Fanconi anemia.[189] Primary skin fibroblasts in culture are abnormal in morphology and doubling rate and show numerous unbalanced chromosome rearrangements such as dicentrics, tricentrics and translocations in the absence of clastogenic agents. These findings provide evidence for a defect that predisposes patient cells to developing chromosomal rearrangements and possibly DNA damage.

Predisposition to Cancer and Myelodysplasia

Cancer develops in about 10% to 15% of patients, usually in the third and fourth decades of life. Similar to Fanconi anemia in which malignant tumors and MDS or AML are seen, DC patients are predisposed to MDS as well as to solid tumors but much less so. The literature was summarized on cancers in 43 DC patients including 35 X-linked and sporadic males, 6 autosomal recessive cases, and 2 autosomal dominant patients.[7] Most of the cancers were squamous cell carcinoma or adenocarcinoma, and the oropharynx and gastrointestinal tract were involved most frequently. One patient had three separate primaries in the tongue, nasopharynx, and rectum, one had esophageal and cheek carcinomas, and one had separate nasal and tongue malignancies.[205] Thus, the sites of most of the cancers involve areas known to be abnormal in DC, such as mucous membranes and the gastrointestinal tract. Four male patients were identified with MDS of 148 in the DC Registry.[189] Two had refractory anemia and 2 had refractory anemia with excess blasts.

Differential Diagnosis

Several physical findings can be used to distinguish Fanconi anemia from DC clinically. The following abnormalities are seen only in DC and not Fanconi anemia: nail dystrophy, leukoplakia, abnormalities of the teeth, hyperhydrosis of palms and soles, and hair loss. There are overlap syndromes that share some of the features of DC. The Hoyeraal–Hreidarsson syndrome is a multisystem disorder affecting mostly boys who manifest aplastic anemia, immunodeficiency, microcephaly, growth retardation, and cerebellar hypoplasia. The syndrome is caused by mutations in *DKC1* and hence is a severe variant of X-linked DC. The Revesz syndrome consists of dystrophic nails, leukoplakia, aplastic anemia, cerebellar hypoplasia, growth retardation, microcephaly, and bilateral exudative retinopathy. Mutant *TINF2* was identified in revese syndrome[196] and hence is an autosomal dominant variant of DC.

Natural History and Prognosis

In classical DC, nail dystrophy and skin pigmentation present first, often in the first 10 years of life. Bone marrow failure usually follows in the teenage years and twenties. The primary cause of death is either from hemorrhage secondary to thrombocytopenia or sepsis from severe neutropenia. In the 10% of cases who develop cancer or MDS, the disease or its treatment can prove fatal. Pulmonary complications can develop in 20% of cases and be life-threatening. However, considerable clinical heterogeneity exists even within the same family, and some patients live into their forties with only moderate nail changes and mild cytopenias.

Therapy

Management of aplastic anemia is similar to that for Fanconi anemia. Androgens, usually combined with low-dose prednisone, can be expected to induce improved marrow function in about 50% of patients. If a response is seen and deemed to be maximal, the androgen dose can be slowly tapered but not stopped. As in Fanconi anemia, patients can become refractory to androgens as the aplastic anemia progresses. There is no evidence that immunosuppressive therapy is effective for this disorder. A small number of patients were reported who responded to G-CSF therapy with significant increases in absolute neutrophil counts.[206–209] Similarly, two other patients received GM-CSF therapy which resulted in improved neutrophil numbers.[210,211] G-CSF with erythropoietin resulted in a trilineage hematologic response in one patient.[212] G-CSF plus androgens has led to splenic peliosis and rupture in DC and is not recommended.

Although the reports are scanty, cytokine therapy appears to offer potential benefit, at least in the short-term, especially for improving granulopoiesis.

Hematopoietic Stem Cell Transplantation

A relatively small number of patients with DC have undergone HSCT using standard myeloablative protocols, mostly with matched related donors.[7] Of these patients, approximately 50% survived longer than 3 years after HSCT. Vascular lesions and fibrosis involving various organs occurred in these patients in both early and late periods after transplantation and carried a high mortality rate. DC patients may be more susceptible to endothelial damage,[189,213,214] which occurs after HSCT as a result of various factors including the conditioning regimen, cyclosporine A, infectious disease, GVHD, and cytokine storm. Another striking complication for DC patients after HSCT is bronchopulmonary disease. An inherent propensity for pulmonary disease[189] explains the high incidence (up to 40%) of early and late fatal pulmonary complications after HSCT. These unusual complications, uniquely seen in DC,[213] have not been reported in other inherited bone marrow failure syndromes such as Fanconi anemia. DC is a disorder involving a subtle degree of chromosomal instability with a predisposition to chromosomal rearrangements,[189] rather than to gaps and breaks as seen in Fanconi anemia. Flawed telomere maintenance in virtually all cases of DC sheds additional light on the hypersensitivity to irradiation and chemotherapy found in these patients. The increased hypersensitivity of DC patients

to transplant conditioning can be related to the telomere shortening from DC combined with the accelerated telomere shortening that occurs after HSCT.[215]

The increased predisposition to posttransplant complications, especially pulmonary and vascular, the chromosomal instability, and the tendency to develop tumors highlight the need to avoid certain conditioning agents such as busulfan and irradiation. The strategy of using low-intensity fludarabine-based protocols for HSCT has produced encouraging results for DC patients.[216–218] These regimens appear to be well tolerated and allow prompt engraftment without significant complications. The long-term risk of the conditioning regimen inducing cancer in predisposed DC transplant survivors is still to be determined.

Future Directions

Although 5 mutated genes for the three forms of dyskeratosis congenita are known, prospects for gene therapy are not imminent. The identification of other DC genes should clarify how the activity, transport, and stability of telomerase and other ribonucleoprotein complexes interact and influence hematopoietic stem cell function.

Amegakaryocytic Thrombocytopenia

Background

Amegakaryocytic thrombocytopenia or congenital amegakaryocytic thrombocytopenia (CAT or CAMT) is an autosomal recessive syndrome that presents in infancy with isolated thrombocytopenia caused by reduced or absent marrow megakaryocytes with preservation initially of granulopoietic and erythroid lineages.[219] Aplastic anemia subsequently ensues in approximately 45% of patients, usually in the first few years of life. The diagnosis depends on the exclusion of all other specific causes for thrombocytopenia in early life. The mutant gene has been identified and confirms that sporadic and familial cases are inherited in an autosomal recessive manner. *CAMT* is a distinct genetic entity, but mutations in several other genes have been described in a number of inherited thrombocytopenias that must be considered in the differential diagnosis (Table 28–5).

Etiology, Genetics, and Pathophysiology

The defect in *CAMT* is directly related to mutations in *MPL*, the gene for the thrombopoietin receptor that maps to 1p34.[220–222] Carriers of the mutant gene have normal blood cell counts; affected individuals have mutations in both alleles. Some patients have inherited two different *MPL* mutations resulting in a compound heterozygous state.[220,223,224] Inheritance of homozygous *MPL* mutations also occurs.[223]

Mutations have been found throughout the *MPL* gene including nonsense, missense, frameshift, and splicing mutations. A genotype-phenotype correlation was identified in 23 CAMT patients whereby two prognostic groups were established, types I and II.[225] Frameshift and nonsense mutations produce a complete loss of function of the thrombopoietin receptor in type I with persistently low platelet counts and a fast progression to pancytopenia. Since thrombopoietin also has an anti-apoptotic effect on hematopoietic stem cells,[226] impaired stem cell survival explains the evolution of type I CAMT into aplastic anemia. Type II CAMT with missense and splicing mutations is characterized by a milder course, a transient increase in platelet counts during the first years of life, and delayed onset, if any, of pancytopenia, indicating residual receptor function.

Table 28–5 Inherited Thrombocytopenia Disorders

Disorder	Genetics*	Mutant Gene	Platelet Size†	Features	References
Amegakaryocytic thrombocytopenia	AR	*MPL*	Normal	± physical anomalies	222
Thrombocytopenia absent radii	AR	Unknown	Normal	Physical anomalies	219
MYH9-related thrombocytopenia					238

*AD = autosomal dominant; AR = autosomal recessive.
†Platelet size: small, MPV <7 fL; normal, MPV 7–11 fL; large/giant, MPV >11 fL.

Informative serial studies of hematopoiesis using clonogenic assays were performed in a female infant with CAMT.[227] Initially, when the only hematologic abnormality was isolated thrombocytopenia, the number of clonogenic hematopoietic progenitors was comparable to controls, including the number of megakaryocyte precursors, CFU-MK (CFU-Meg). As the disease evolved into aplastic anemia over an 11-month period, the peripheral blood counts declined, and colony numbers from four classes of progenitors also declined in parallel. When added to the marrow cultures, patient plasma was not inhibitory to control or to patient colony growth. Similarly, no cellular inhibition of hematopoiesis was observed when the patient's marrow was cultured after depleting the sample of T lymphocytes or after adding them back. Stromal cells established in short-term and long-term cultures of the patient's marrow showed normal proliferative activity and yielded a "fertile" marrow microenvironment for patient and control marrow colony growth. The data suggested that the central problem in CAMT was an intrinsic hematopoietic stem cell defect rather than an abnormality of the marrow milieu. The findings are consistent with current knowledge about *MPL* mutations.

Another study demonstrated measurable numbers of CFU-MK progenitors in vitro from five patients with CAMT in response to IL-3, GM-CSF, or a combination of both.[228] The identification of megakaryocyte progenitors in these patients agrees with the data described above when patients are studied early in the course of the disease. Another report described the effect of recombinant human thrombopoietin on CFU-MK colony formation from a patient with CAMT in which there was a defective response.[229] The patient's serum thrombopoietin level was significantly elevated as compared to controls, and the patient's marrow cells did not express mRNA for *MPL*. The pathophysiology of CAMT in this case was directly attributable to these findings and consistent with current evidence.

Plasma thrombopoietin levels in patients with CAMT are always elevated and are amongst the highest seen in any patient population.[221,230] The detectable immunoreactive material retains full biological activity.[230]

Clinical Features

History and Physical Examination

Almost all patients present with a petechial rash, bruising, or bleeding in the first year of life. Most cases are obvious at birth or within the first 2 months. Roughly 30% of the patients have characteristic physical anomalies that do not fit with other specific syndromes; the other patients have normal physical and imaging features. Some affected sibships manifest both normal and abnormal physical findings in the same family. As in Fanconi anemia, CAMT patients with and without anomalies should be considered as part of the clinical spectrum of one entity.

The commonest manifestations in those with anomalies are neurologic and cardiac. Findings related to cerebellar and cerebral atrophy are a recurrent theme and developmental delay is a prominent feature in this group. Patients may also have microcephaly and an abnormal facies. Congenital heart disease with a variety of malformations can be detected, including atrial septal defects, ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate.

Laboratory Findings

Thrombocytopenia is the major laboratory finding with normal hemoglobin levels and white blood cell counts initially. Although there are usually measurable but reduced platelet numbers, peripheral blood platelets may be totally absent. Those that can be identified are of normal size and appearance. Similar to other inherited bone marrow failure syndromes, red cells may be macrocytic. HbF can be increased and there may be increased expression of i antigen. Bone marrow aspirates and biopsies show normal cellularity with markedly reduced or absent megakaryocytes (Fig. 28–6). In patients who develop aplastic anemia, marrow cellularity is decreased with fatty replacement, and the erythropoietic and granulopoietic lineages are symmetrically reduced.

Predisposition to Leukemia

Some patients with CAMT have developed MDS or acute myeloid leukemia.[7,223] One male with a normal physical appearance had amegakaryocytic thrombocytopenia from day 1 of life, developed aplastic anemia at 5 years of age, responded poorly to androgens and steroids, and then evolved into AMML at age 16 with death at age 17. A female had thrombocytopenia at 2 months of age, pancytopenia at 5 months, and thereafter developed a preleukemic picture with clonal abnormalities involving chromosome 19. The patient described herein[227] had thrombocytopenia at 6 months of age, developed progressive aplastic anemia over the next 2 years, acquired monosomy 7 in marrow cells at 5 years of age, and then evolved into MDS with an activating *ras* oncogene mutation in hematopoietic cells. Hence, the current evidence shows that CAMT is another inherited marrow failure disorder that is preleukemic. The risk or incidence of malignant conversion is difficult to determine because of the rarity of the disease and paucity of published data dealing with this issue.

Differential Diagnosis

If CAMT presents beyond the neonatal age group, a marrow aspirate and biopsy will point to the diagnosis, and mutational analysis will confirm it. (Certified mutation analysis for *MPL* can be obtained at Gene Dx, Gaithersburg, MD.) If CAMT presents at birth or shortly after, it must be distinguished from other causes of severe neonatal thrombocytopenia. Usually, these are caused by increased peripheral destruction of platelets and marrow sampling is not the customary first step.

Passive transplacental passage of IgG antiplatelet antibodies into fetal circulation can cause rapid destruction of fetal platelets. This occurs in two circumstances: a maternal autoimmune disease such as idiopathic thrombocytopenic purpura (ITP) or systemic lupus erythematosus (SLE); and in neonatal alloimmune thrombocytopenia by alloimmunization of the pregnant mother to fetal antigens inherited from father but absent in the mother. In the former situation, mother has thrombocytopenia or a past history of such; in the latter

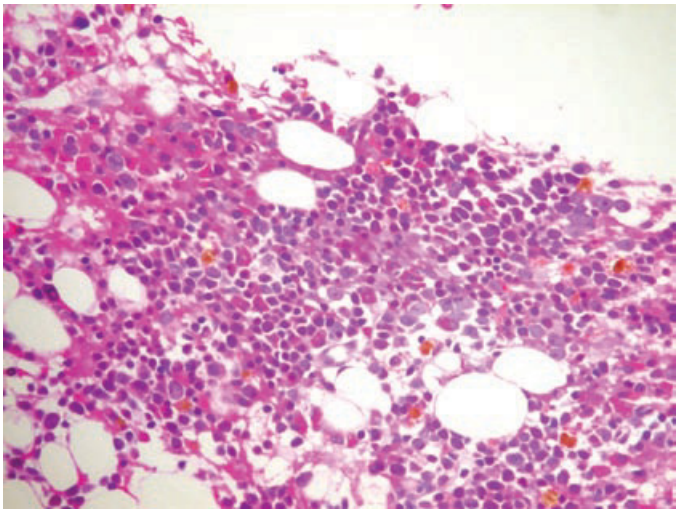

Figure 28–6 Low-power view of a bone marrow aspirate from a newly diagnosed patient with congenital amegakaryocytic thromobocytopenia. The 3 findings are normal celllularity, normal granulopoiesis and erythropoiesis, and absent megakaryocytes. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

situation, mother has a normal platelet count and serum antibodies to human platelet alloantigens.

TAR syndrome is distinguished from CAMT because in TAR the radii are absent. Peripheral blood chromosomes are not characterized by increased fragility with DEB or MMC clastogenic stress testing in CAMT, which distinguishes it from Fanconi anemia. Several severe systemic neonatal infections collectively designated as the TORCH syndrome are associated with thrombocytopenia but are usually obvious clinically. Increased platelet destruction also occurs in newborns with giant benign hemangiomas of skin, liver or spleen, the so-called Kasabach-Merritt syndrome.

In an infant or young child with a CAMT clinical diagnosis but without mutant *MPL*, other inherited forms of thrombocytopenia have to be addressed (Table 28–5). These can generally be classified according to inheritance pattern (autosomal dominant, autosomal recessive, or X-linked), size of the platelets (small, normal, or large/giant), and presence or absence of associated clinical features. Identification of the specific mutant gene for each disorder confirms the diagnosis.

Therapy and Prognosis

Historically, treatment has been unsatisfactory and the mortality rate from thrombocytopenic bleeding, complications of aplastic anemia, or from malignant myeloid transformation has been very close to 100%. For that reason, HLA typing of family members should be performed as soon as the diagnosis is confirmed to see if a matched related donor for a HSCT exists. If not, a search for a matched unrelated donor or for cord blood cells should ensue as soon as the seriousness of the clinical picture dictates. The need for transfusional support is a cogent indication.

Platelet transfusions should be used discretely. Platelet numbers should not be a sole indication; clinical bleeding is a more appropriate trigger for the use of platelets. Single-donor filtered platelets are preferred to multiple unfiltered random donor platelets in order to minimize sensitization, and if HSCT is a realistic possibility all blood products should be free of cytomegalovirus.

Corticosteroids have been used for thrombocytopenia with no apparent efficacy. For aplastic anemia, androgens in combination with corticosteroids may induce a temporary partial response but the effect is short-lived and does not prevent mortality.

Based on the in vitro augmentation of megakaryocyte progenitor colony growth in response to IL-3, GM-CSF, or both, a phase I/II clinical trial was initiated for five patients with CAMT.[228] IL-3 but not GM-CSF resulted in improved platelet counts in two patients and decreased bleeding and transfusion requirements in the other three. GM-CSF had no benefit when given after IL-3 pretreatment. Prolonged IL-3 administration in two additional patients also resulted in platelet increments. This pilot study illustrates that IL-3 may have been an important adjunct to the medical management of CAMT but it was not adopted broadly and is no longer available. Thrombopoietin has not been tried for the treatment of severe Type I CAMT and would likely fail because endogenous thrombopoietin levels are markedly increased and the mutated thrombopoietin receptor is nonfunctional.

CAMT can be cured by HSCT.[223,231–236] Most of the published cases have had successful outcomes. Matched sibling donor sources are best, even if the donor is a carrier with one mutant allele.[235] Alternate donor sources are more problematic. Reduced-intensity conditioning regimens for CAMT and other inherited marrow failure disorders hold promise to lessen transplant-related morbidity and mortality.[237]

Future Directions

As summarized,[219] novel therapy may be available shortly for type II CAMT patients who retain some MPL function. MPL agonist antibodies can be engineered in the laboratory that bind and activate partially functional thrombopoietin receptors. CAMT is also a candidate disease for gene therapy as restoration of wild-type *MPL* would provide in vivo selection of corrected hematopoietic stem cells.

Other Genetic Syndromes

Bone marrow failure can occur in the context of several specific nonhematologic syndromes, and also in familial settings that do not exactly correspond with the entities already described.

Down Syndrome

Down syndrome, or constitutional trisomy 21, has a unique association with aberrant hematological abnormalities. Three seemingly related events can occur.[245] In the neonatal period, a myeloproliferative blood picture with large numbers of circulating blast cells has been observed in approximately 10% of these infants. The blasts show somatic *GATA1* mutations[246] and apparently are clonal but, remarkably, disappear spontaneously over several weeks in most cases. The term "transient leukemia" is often used to reflect this unusual natural history.

Secondly, in 20% to 30% of these cases, "true" acute megakaryoblastic leukemia (AMKL) appears later and requires oncologic management. Acute lymphoblastic and myeloblastic leukemias are also seen in Down syndrome, but AMKL is the most common form of the myeloblastic leukemias and is estimated to be 500 times greater in children with Down syndrome than in normal children.[245]

Thirdly, the onset of AMKL is frequently preceded by an interval of MDS characterized by thrombocytopenia, abnormal megakaryocytopoiesis, megakaryoblasts in the marrow, and an abnormal karyotype, commonly trisomy 8.[247,248] In addition to the propensity for leukemia, a few patients have been reported with aplastic anemia. Alter summarized five of these aplastic cases,[7] three of whom died of marrow failure and two who responded to androgen therapy.

Dubowitz Syndrome

This is an autosomal recessive disorder characterized by a peculiar facies, infantile eczema, small stature, and mild microcephaly. The face is small with a shallow supraorbital ridge, a nasal bridge at the same level as the forehead, short palpebral fissures, variable ptosis, and micrognathia.[249] This is a rare disorder and incidence rates for complications are difficult to establish, however, there appears to be a predilection to cancer as well as hematopoietic disorders in Dubowitz syndrome.[250] Patients have developed acute leukemia, neuroblastoma, and lymphoma.[250–252] Approximately 10% of patients also develop hematopoietic abnormalities varying from hypoplastic anemia, moderate pancytopenia, and full-blown aplastic anemia.[250,253]

Seckel Syndrome

Sometimes called "bird-headed dwarfs," patients with this autosomal recessive developmental disorder have marked intrauterine and postnatal growth failure and mental deficiency, severe microcephaly, a hypoplastic face with a receding forehead and chin, a prominent curved nose, and low-set and/or malformed ears.[254] These patients can be distinguished from those with Fanconi anemia on the basis of a negative DEB clastogenic chromosome stress test. About 25% of cases develop aplastic anemia or malignancies.[7,255–257] One form of Seckel syndrome is caused by a mutant *ATR* gene, and another by a mutant *PCNT2* gene. Different loci for 2 additional forms have also been identified demonstrating genetic heterogeneity.

Reticular Dysgenesia (Dysgenesis)

This is an immunologic deficiency syndrome coupled with congenital agranulocytosis.[258] The mode of inheritance is probably autosomal

recessive but an X-linked mode is also possible in some cases. The disorder is a variant of severe combined immune deficiency (SCID) in which cellular and humoral immunity are absent and patients also have severe lymphopenia and neutropenia. Because of profoundly compromised immunity, the syndrome presents early with severe infection at birth or shortly thereafter. A striking feature is absent lymph nodes and tonsils and an absent thymic shadow on radiograph. In addition to lymphopenia and neutropenia, anemia and thrombocytopenia may be present. Bone marrow specimens are hypocellular with markedly reduced myeloid and lymphoid elements. Clonogenic assays of hematopoietic progenitors consistently show reduced to absent colony growth, indicating that the disorder has its origins at the pluripotential lympho-hematopoietic stem cell level.[259–262] The only curative therapy is HSCT.[261–263]

Schimke Immunoosseous Dysplasia

Schimke immunoosseous dysplasia is an autosomal recessive disorder caused by mutations in the chromatin remodeling protein SMARCAL1.[264,265] Patients manifest spondyloepiphyseal dysplasia with exaggerated lumbar lordosis and protruding abdomen.[266] There are pigmentary skin changes and abnormally discolored and configured teeth. Renal dysfunction can be problematic with proteinuria and nephrotic syndrome. The R561C missense mutation in the *SMARCAL1* gene is associated with a mild phenotype.[266] Approximately 50% of patients have hypothyroidism, 50% have cerebral ischemia, and 10% have bone marrow failure with neutropenia, thrombocytopenia, and anemia. Lymphopenia and altered cellular immunity are present in almost all patients. One case underwent a successful bone marrow transplantation.[267]

Noonan Syndrome

Noonan syndrome (NS) is a development disorder characterized by the "Noonan facies" (hypertelorism, ptosis, short neck, low-set ears), short stature, congenital heart disease, and multiple skeletal and hematologic abnormalities. NS is an autosomal dominant disorder with genetic heterogeneity. Heterozygous mutations in *PTPN11* which encodes SHP-2 cause about 50% of NS cases.[268] There is a resultant gain of function of SHP-2, a protein tyrosine phosphatase that positively modulates RAS signaling. Germline *KRAS* mutations also cause NS.[269,270] A variant of neurofibromatosis type 1 caused by mutations in the *NF1* gene results in a phenotypic overlap disorder with NS, the so-called neurofibromatosis-Noonan syndrome.[271] Remarkably, mutations of *PTPN11*, *RAS*, and *NF1* also are found in children with juvenile myelomonocytic leukemia (JMML), an aggressive hematologic cancer requiring hematopoietic stem cell transplantation.[272] JMML also occurs in NS patients but it regresses spontaneously without treatment. As summarized,[7] several NS patients developed amegakaryocytic thrombocytopenia, and one other patient manifested pancytopenia and a hypocellular marrow.

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is an autosomal recessive syndrome characterized by metaphyseal dysostosis, short-limbed dwarfism, and fine, sparse hair. Additional skeletal findings include scoliosis, lordosis, chest deformity, and varus lower limbs. Aganglionic megacolon and other gastrointestinal abnormalities have been reported.[7] Most cases in the literature are Finnish or Amish. Mutations in the RNA component of RNase MRP cause CHH.[273,274] Macrocytic anemia is seen in over 80% of cases.[275] Most are mild and self-limited but some patients show a severe, persistent anemia resembling Diamond–Blackfan anemia. Neutropenia has been reported in 25% of CHH cases[7,276] and lymphopenia in 65%. Lymphomas and other cancers also occur at an increased frequency.[7]

Familial Forms of Marrow Failure

Bone marrow failure can cluster in families, but many of these cases cannot be readily classified into discrete diagnostic entities such as Fanconi anemia. Baseline chromosome breakage is almost always normal in these non-Fanconi syndromes but clastogenic stress testing with DEB or MMC is required for clarification. The phenotype of these conditions can be complex with varying combinations of cytopenias, macrocytosis, elevated levels of HbF, hypocellular bone marrows, immunologic deficiency, physical malformations, and predisposition to leukemia. The marrow failure is the result of a complex interplay of genetic and environmental influences that are likely specific to each affected family. Alter's practical approach to nosology is to divide the disorders into inheritance patterns, and then subdivide them into those with and without physical anomalies.[7]

Some families show an **autosomal dominant** mode of inheritance of marrow dysfunction associated **with physical anomalies**. The *WT syndrome* is characterized by successive generations of affected family members who have radial-ulnar hypoplasia, abnormal thumbs, short fingers, and fifth finger clinodactyly.[277,278] Pancytopenia or thrombocytopenia, sometimes with leukemia, occurs in some of the affected. The *IVIC syndrome*[279–281] or oculo-oto-radial syndrome[282] manifests with radial ray hypoplasia, absent thumbs or hypoplastic radial carpal bones, impaired hearing, strabismus, mild thrombocytopenia in about 50% of cases, and sometimes imperforate anus. The *ataxia-pancytopenia syndrome* is a combination of cerebellar atrophy and ataxia associated in affected family members with varied manifestations of anemia, aplastic anemia, MDS, AML, monosomy 7 in marrow cells, and immune deficiency.[283–285] Other autosomal dominant syndromes with anomalies include a family with marrow failure, ALL, skin pigmentation, warts, immune dysfunction, and multiple spontaneous abortions[286]; successive generations of family members with unilineage cytopenia or pancytopenia with vascular occlusions[287]; and proximal fusion of the radius and ulna, and aplastic anemia or leukemia.[288] The latter syndrome was associated with a mutation in a gene involved in bone marrow morphogenesis, *HOXA11*.[240,289]

Autosomal recessive inheritance **with physical anomalies** and marrow dysfunction also occurs. Consanguinity can result in a syndrome of microcephaly, mental retardation, skin pigmentation, short stature, and pancytopenia, possibly with a clonal cytogenetic marker in bone marrow cells.[290] A second example of this inheritance mode presents with central nervous system anomalies such as the Dandy–Walker syndrome or ventricular dilatation and asymmetry, and aplastic anemia.[291] Two cousins had oculocutaneous albinism, microcephaly, facial dysmorphia, immunodeficiency, neutropenia, and thrombocytopenia.[292] Three siblings with consanguineous parents had facial dysmorphia, steatorrhea, increased skin folds, congenital heart disease, vesicoureteral reflux, decreased cellular immunity, and severe neutropenia but normal chromosomes.[293] Seven families with a specific pattern of inheritance have been reported: five sporadic, one consanguineous, and one with affected siblings. Diaphyseal dysplasia and anemia were observed in all of the families.[294–296]

Autosomal dominant inheritance of a wide-ranging pattern of disordered marrow function can be seen **without physical anomalies**. Successive generations have been described with the following: "acquired" aplastic anemia in 4 families comprised of 9 patients with an affected parent, aunt, or uncle[297]; aplastic anemia in a mother and neutropenia and thrombocytopenia in her offspring[298]; aplastic anemia, AML and monosomy 7 in various family members[299]; and hypoplastic anemia in a parent and offspring with either myelofibrosis, AML, MDS, or pancytopenia, all associated with the acquired Pelger-Huet anomaly.[300]

Marrow dysfunction can also be inherited in an **autosomal recessive mode without physical anomalies.** One example encompasses pancytopenia, immune deficiency, multiple cutaneous basal cell and squamous cell carcinomas, oral telangiectasias, and neck and chest poikiloderma.[301] Another pattern includes immune deficiency, pure red cell aplasia and/or neutropenia, and unusual crystalloid structures seen by electron microscopy in neutrophils.[302] In one generation of a large maternal kindred, there were 8 members with aplastic anemia, AML and monosomy 7.[303] Thrombocytopenia was reported in 2

adult siblings with a Robertsonian translocation t (13;14).[304] Xeroderma pigmentosum can be associated with aplastic anemia,[305] as well as MDS,[306] and AML.[307,308]

An **X-linked inheritance without physical anomalies** is suggested by a syndrome affecting males in successive generations with one or more of pancytopenia, AML, ALL, and light chain disease but without physical anomalies.[309] The X-linked lymphoproliferative syndrome is a well-documented genetic disorder associated with the Epstein-Barr virus that causes malignant infectious mononucleosis and fatal aplastic anemia.[310,311] In most patients a mutant *SH2D1A* gene can be demonstrated. A mutant *XIAP* gene accounts for other cases.

Therapy for Familial Marrow Failure

Because these disorders are rare, broad conclusions about management are difficult to formulate. For full-blown aplastic anemia with a hypocellular, fatty marrow, curative therapy with HSCT remains the first choice if a suitable donor is identified. In the familial cases, potential stem cell donors must be thoroughly assessed clinically, hematologically and by marrow morphology, clonogenic activity, and cytogenetics to ensure that latent or masked marrow dysfunction is not present. If a matched donor is not available, principles of medical management used for Fanconi anemia and for acquired aplastic anemia should be used.

UNI-LINEAGE CYTOPENIAS

Diamond-Blackfan Anemia

Background

Diamond-Blackfan anemia (DBA), or congenital hypoplastic anemia, is an inherited form of pure red cell aplasia.[312,313] The syndrome is heterogeneous with respect to inheritance patterns, clinical and laboratory findings, in vitro data, and therapeutic outcome. Although it was formerly believed that 80% of DBA cases were sporadic, molecular studies in conjunction with data on family members for red cell adenosine deaminase levels, red cell macrocytosis, and congenital anomalies suggest that approximately 45% of cases[314,315] are autosomal dominant with variable penetrance.[316,317] Recessive inheritance was inferred in more than 30 families published in the literature in which there were affected siblings with normal parents, affected cousins, or consanguinity.[7] However, these cases have not been confirmed as autosomal recessive.[314] Some of these may be autosomal dominant with non-penetrance[318] or from gonadal mosaicism.[319] DBA likely represents a family of disorders with different genetic and molecular etiologies that share the common hematological phenotype of pure red cell aplasia. Based on data from a European registry of DBA patients, the suspected incidence of the disorder in Europe is approximately 7 cases per million live births.[317]

The uniform diagnostic criteria for all cases are (a) normochromic-macrocytic anemia presenting in 90% of cases in the first 12 months of life; (b) profound reticulocytopenia; (c) normocellular marrow with a selective, marked deficiency of red cell precursors; (d) increased serum levels of erythropoietin; (e) normal or slightly decreased white cell counts; and (f) normal, decreased, or increased platelet counts. Fetal hemoglobin is usually increased with a fetal G-γ/A-γ pattern, is distributed heterogeneously, and is associated with increased expression of red cell i antigen as well as with fetal levels of red cell glycolytic and hexose monophosphate shunt enzyme activities.

Etiology, Genetics, and Pathophysiology

In most DBA cases, cytogenetic findings are normal although alterations of chromosomes 1 and 16 have been reported.[320,321] Discovery of a balanced reciprocal translocation t(x;19) in a sporadic female case of DBA[322] and the identification of microdeletions on chromosome 19 in some other DBA patients[323] localized a gene responsible for DBA to 19q13.2. Cloning of the 19q13 breakpoint region revealed a mutated gene encoding ribosomal protein (RP) S19 associated with the ribosomal 40S subunit.[324] Subsequent studies identified mutations in one allele for the gene in 25% of patients.[325–327]

The exact function of this protein in ribosome biogenesis is still poorly understood. The yeast homolog of RPS19 is required for the maturation of the 3′ end of 18S rRNA, failure of which results in the accumulation of faulty pre-40S ribosome subunits.[328] Extraribosomal functions have been ascribed to RPS19 in addition to the post-apoptotic mediation of monocyte chemotaxis.[329] RPS19 has been shown to interact with a novel nucleolar protein S19-binding protein (S19BP),[330] fibroblast growth factor 2,[331] and the PIM-1 oncoprotein.[332] PIM-1 is an ubiquitous serine-threonine kinase whose expression can be induced in erythropoietic cells by several growth factors including erythropoietin. Thus, for the first time, a link between erythropoietic growth factor signaling and RPS19 was identified.

In 25% of cases with mutant *RPS19*, the prevailing opinion is that the disorder results from protein haploinsufficiency.[333] In support of this, two classes of *RPS19* mutations have been described: quantitative defects resulting in undetectable protein, and hotspot mutations leading to loss of function.[333] Additional links between *RPS19* and erythropoiesis have now been clearly established. When *RPS19* is knocked down in cellular models,[334–336] defective erythropoiesis results. In addition, wild-type gene transfer corrects the defective erythropoiesis in *RPS19*-deficient DBA $CD34^+$ cells resulting in a 3-fold increase in erythroid colony growth.[337] In yeast, the introduction of *RPS19* mutations found in DBA results in a defect in the processing of pre-rRNA similar to that observed in DBA cells with decreased expression of *RPS19*.[328]

There is recent evidence that *RPS19* mutations lead to downregulation of multiple ribosomal protein genes as well as downregulation of genes involved in translation in DBA cells.[338] These data coupled with earlier reports establish the important relationship between *RPS19* and erythroid proliferation and maturation.[339,340]

In DBA patients without *RPS19* mutations, a second DBA locus has been mapped to chromosome 8p22-p23 in approximately 35% of cases,[341] but a candidate gene, tentatively called *DBA2*, has not been identified. There are DBA patients with neither mutant RPS19 nor linkage to 8p22-p23. In approximately 2% of *RPS19* mutation-negative probands, de novo nonsense and splice-site mutations can be identified in another ribosomal protein, RPS24. The gene *RPS24* (*DBA3*) maps to 10q22-q23.[342] A third mutant ribosomal protein gene, *RPS17*, has also been decribed[343] strengthening the theory that impaired translation may be the pathogenetic explanation for DBA. At the 9th annual DBA International concensus conference in 2008, two additional ribosomal protein gene mutations were described, *RPL5* and *RPL11*.[344] Thus, at least 6 genetic mutations account for DBA.

Initial reports of humoral, cellular, or microenvironmental inhibitors of erythropoiesis in DBA could not be confirmed. Claims for immune-mediated erythroid suppression in DBA would need to satisfy strict criteria: patients must be newly diagnosed, untreated, and not previously transfused; the in vitro testing system must be completely autologous using only patient cells and serum; and any degree of inhibition must be totally selective for the erythroid lineage. Since almost none of the reports met these criteria, the notion of an immune pathogenesis of DBA shifted to alternate possibilities.

A large body of evidence indicates that the erythroid progenitor compartment is intrinsically defective in DBA.[345–350] Cultures of DBA marrow using standard clonogenic assays for CFU-E and BFU-E progenitors consistently have shown reduced or absent colonies in most DBA patients, and intermediate, normal, or occasionally increased numbers in the rest. The DBA erythroid progenitors are relatively insensitive to Epo in vitro[348] and to burst-promoting activity,[351] but the hyporesponsiveness to Epo can be corrected in some cases by the addition of glucocorticoids in vitro[352] or by clinically

administering prednisone.[353] A recent report localized the DBA defect down-stream of the erythropoietin receptor.[354]

The data underscore the fact that the intrinsic defect of DBA erythroid progenitors is an inability to respond normally to inducers of erythroid proliferation and/or differentiation. Confirmation of the overall defect was demonstrated by showing that $CD34^+$ DBA progenitors differentiated normally along megakaryocytic and granulocytic pathways but aberrantly along the erythroid lineage.[355] Accelerated programmed cell death (apoptosis) plays a central role in this pathogenesis[356] as it does in many if not all inherited marrow failure disorders. A role for induction of apoptosis by the Fas-Fas ligand system in DBA was suggested because of elevated serum soluble Fas ligand in patients compared to controls.[357] Based on the various patterns of erythroid colony growth seen with DBA patients, a model for the aberrant erythropoiesis was developed that proposes maturational arrests at varying sites along the differentiation pathway.[313]

Recombinant interleukin-3 (IL-3)[358] and Steel factor (SCF) in combination with Epo[359–361] may increase the in vitro clonogenicity of DBA bone marrow progenitors from unfractionated cell preparations. The size and number of DBA BFU-E colonies are dramatically increased by adding IL-3 to the cultures.[358] One study showed a growth response of BFU-E from 4 patients to SCF alone or in combination with IL-3, GM-CSF, or conditioned media.[359] Another study described a lack of response of enriched $CD34^+$ progenitors to IL-3, GM-CSF and erythroid potentiating activity (EPA) in 10 DBA patients, but SCF in combination with IL-3 promoted BFU-E colony growth in 3 patients.[355] A further report described heterogeneity in vitro in 10 patients with normal, intermediate or absent responses to SCF.[360] Additional data showed that 15 of 16 DBA marrow cultures had increased erythropoiesis, often to normal levels, in the presence of SCF compared to cultures lacking SCF.[361] The human ligand for flt-3 apparently has no effect on DBA marrow colony growth. However, addition of IL-9 to SCF, IL-3, and Epo does potentiate DBA BFU-E growth.[362]

There are significant age-related changes in erythroid and granulopoietic progenitors in DBA patients.[363] Despite profound anemia, 7 of 10 patients studied within 1 year of diagnosis had normal numbers of CFU-E and BFU-E that showed a normal response to cytokines. In contrast, 12 of 14 patients followed more than 3 years had decreased erythroid progenitors and, in 7 cases, decreased CFU-GM. The data are consistent with the idea that the DBA defect involves other hematopoietic lineages and worsens with time.

Strong support for this conclusion comes from a detailed study that examined the interaction between DBA $CD34^+$ cells and the hematopoietic microenvironment using long-term bone marrow cultures.[364] Stromal adherent layers from DBA patients did not show evidence of any morphological, phenotypic, or functional abnormality and the stroma sustained the proliferation of normal $CD34^+$ cells. A major finding was an impaired capacity of DBA $CD34^+$ cells in the presence of normal stromal cells to proliferate and differentiate along not only the erythroid pathway but also along the granulocytic-macrophage pathway. These results indicate an intrinsic defect of a hematopoietic progenitor with at least bi-lineage potential that places it earlier than previously suspected and which was only unmasked by testing in long-term cultures. These findings were extended with evidence in long-term culture initiating assays for a trilineage defect in DBA refractory to treatment.[365] The data broaden the definition of DBA and explain generalized marrow dysfunction and hypoplasia in some cases of DBA that have puzzled investigators for years.

The in vitro findings raised speculation that DBA is caused by one or more receptor-ligand abnormalities involving various growth-promoting cytokines such as Epo, IL-3, and SCF. Studies have failed to identify any of these putative abnormalities. DBA lymphocytes produce high levels of IL-3, DBA marrow stromal cells express mRNA for SCF, and DBA patients have measurable serum levels of SCF and have SCF receptors on marrow cells.[366] Moreover, molecular studies have not disclosed mutations in genes for c-kit (SCF receptor) or SCF.[367–369] Thus, current thinking based on cases with mutant *RPS19* is that haploinsufficiency of RPS19 protein either quantitatively or qualitatively accounts for DBA. A second theory in DBA without mutant *RPS19* is that an intracellular defect exists in signal transduction or in a transcription factor acting early in differentiation. Such anomalies could account for the increased tendency of DBA erythroid progenitors to undergo apoptosis upon Epo deprivation in vitro.[356]

Clinical Features

History and Physical Examination

DBA registries with longitudinal data,[315,317,370–374] and a summary of published cases[7] provide comprehensive information about clinical aspects of the disorder. Aside from findings associated with anemia, about one-half of infants at presentation look healthy and are normal physically. Unless the patient develops cardiac failure as a result of anemia, hepatosplenomegaly and edema are absent.

Both sexes are equally affected. Although the majority of published patients are white, DBA has been recognized in several ethnic groups, including African blacks, Arabs, East Indians, and Japanese. Pregnancy, birth history, or both are often abnormal. In a survey from the French and German DBA registries of 64 pregnancies in 26 women with DBA,[375] complications were seen in 42 pregnancies (66%) and included abortion, preeclampsia, in utero fetal death, in utero growth retardation, retroplacental hematoma, and preterm delivery. Thirteen of 34 children born alive had DBA.

From 30% to 47% of patients present with one or more congenital defects.[315,317,370–374] Most of these phenotypic abnormalities belong to the following categories: (a) craniofacial dysmorphism, including hypertelorism, microcephaly, microphthalmos, congenital cataract or glaucoma, strabismus, microretrognathism, and a high-arched palate or cleft palate; (b) prenatal or postnatal growth failure, independent of steroid therapy; (c) neck anomalies; these may consist of a pterygium coli, or the fusion of cervical vertebrae with flaring of the trapezius muscle (Klippel-Feil syndrome) giving a Turner syndrome appearance; there may also be the Sprengel deformity (congenital elevation of the scapula) as an isolated anomaly, or a combination of the two anomalies; and (d) thumb malformations, such as bifid thumb (Fig. 28–7), duplication, subluxation, hypoplasia, or absence of the thumb. There is a characteristic association of triphalangeal thumbs with DBA (Fig. 28–8) commonly referred to as "Aase syndrome II" or "Aase-Smith syndrome." In addition, some patients have a flat, hypoplastic thenar eminence, weak or absent radial pulses, or both, which probably represent variations of the thumb malformations.

Some patients have a characteristic facial appearance. The facies of DBA is said to consist of tow-colored hair, snub nose, wide set eyes, thick upper lip, and an intelligent expression.[376] Another facies observed in two unrelated girls of markedly different ancestries consists of small heads, almond-shaped eyes with a slight antimongoloid slant, a "carp-like" smile, and pointed chins.[313] These patients resemble each other more than they resemble their own family members (Figs. 28–9A and 28–9B). Some patients with DBA have a phenotype indistinguishable from Treacher-Collins syndrome, a disorder of ribosome biogenesis caused by *TCOF1* mutations.[314,377,378]

Various other anomalies are occasionally reported in association with DBA. There may be urogenital malformations, such as dysplastic or horseshoe kidneys, duplication of ureters, or renal tubular acidosis. There may also be congenital heart disease, mainly ventricular and atrial septal defects, or hypogonadism, ear malformations, mental retardation, congenital hip dislocation, cartilage-hair hypoplasia with T-cell dysfunction, or tracheoesophageal fistula.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings. The main hematological findings in DBA are summarized in Table 28–6. The anemia is usually profound at the time of diagnosis. Hemoglobin levels average 6.5 g/dL in patients diagnosed in the first 2 months of life

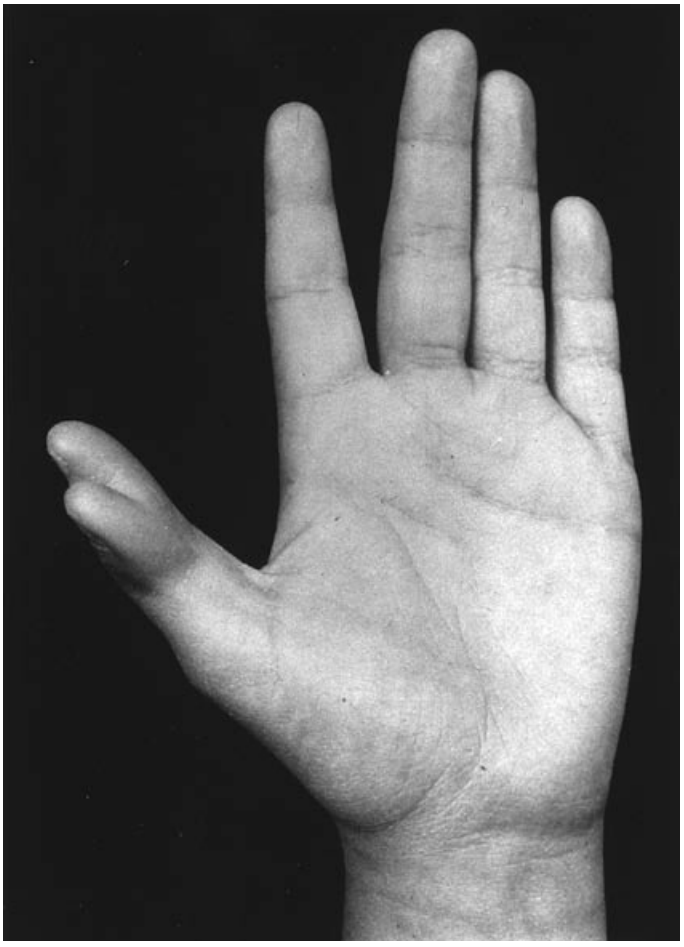

Figure 28–7 Bifid thumb in Diamond-Blackfan anemia.

Figure 28–8 Radiograph of a triphalangeal thumb in Diamond-Blackfan anemia.

A B

Figure 28–9 Similar Diamond-Blackfan facies in two unrelated girls of different ancestries consisting of a small head, almond-shaped eyes with slight antimongoloid slant, a "carp-like" smile, and a pointed chin.

Table 28–6 Hematological Features of Diamond-Blackfan Anemia at Diagnosis

Hematologic Parameters	Lab Findings
Mean hemoglobin value (range):	
Newborns under 2 months of age[a]	6.5 g/dL (1.7–9.1 g/dL)
Children 2 months of age or older[a]	4.0 g/dL (1.8–7.4 g/dL)
Mean corpuscular volume (MCV)	Usually increased for age
Reticulocytes	Markedly decreased (<1%)
White cell count	Normal or slightly decreased
Platelet count	Normal or increased
Fetal hemoglobin	Increased (>5% after 6 months of age)
Red cell i antigen	Expression increased beyond first year of life
Red cell enzymes	Fetal pattern
Red cell adenosine deaminase activity	Elevated in 40%–90% of cases
Bone marrow morphology:	
In >90% of cases	Marked reduction or absence of erythroid precursors
In 5–10% of cases	Slightly reduced or normal number of proerythroblasts with or without maturation arrest
In all patients	Normal cellularity; normal myeloid and megakaryocytic lineages

[a]Toronto series (n = 21). See reference 313.

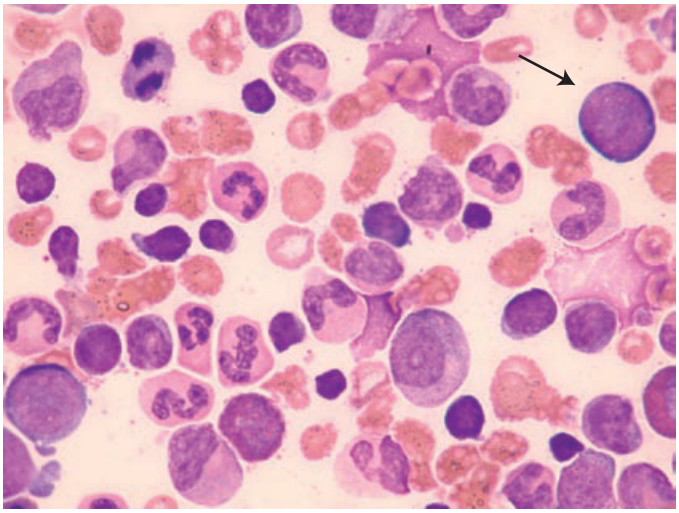

Figure 28–10 High-power view of a bone marrow aspirate from a newly diagnosed infant with Diamond-Blackfan anemia. The findings are active granulopoiesis, normal lymphoid activity for age, and an isolated pronormoblast (*arrow*) with total absence of early-, intermediate-, and late-stage nucleated red cells. *(Photocmicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

(range of 1.7–9.1 g/dL) and 4.0 g/dL (range of 1.8–7.4 g/dL) in those diagnosed later. Macrocytosis is seen in the vast majority of patients with the mean corpuscular volume (MCV) being above the expected values for age. The peripheral blood smear may show, in addition to macrocytes, a mild degree of nonspecific anisocytosis and poikilocytosis. The aregenerative component of the anemia is reflected by the absence of both polychromasia and nucleated red cells on the blood film. Decreased red cell production is confirmed by absence of a reticulocyte response and by characteristic findings on bone marrow examination.

In more than 90% of patients, the bone marrow aspirate is normocellular, but erythroblasts are markedly decreased or absent. Proerythroblasts, if present, account for less than 3% of all nucleated elements, with a myeloid:erythroid ratio of >10:1 (Fig. 28–10). In 5% to 10% of cases, proerythroblasts may be present in normal numbers, with or without a maturation arrest. The other cell lines are normal. White cell counts and platelet counts are usually normal at diagnosis, but platelets may be decreased, or increased and with normal function. Mild to moderate neutropenia, thrombocytopenia, or both may occur later in the course of the disease, particularly in multitransfused patients who have hemosiderosis and secondary hypersplenism. Progression of the single-lineage erythroid deficiency of DBA into pancytopenia and severe aplastic anemia is rare but occurs.[365,379] Of 36 deaths reported to the American DBA Registry (DBAR), 1 died from severe aplastic anemia.[314]

Erythrocyte Findings. Erythrocytes in DBA express a number of fetal characteristics.[380] The level of hemoglobin F (HbF) is increased persistently even during remission. It remains at a level of 5% to 10% after the age of 6 months and has a heterogeneous distribution in red cells. The HbF has a specifically fetal amino-acid profile, with a high glycine:alanine ratio (G-γ:A-γ). Similarly, the i antigen, which normally disappears from the erythrocyte surface by 1 year of age, is expressed at near fetal levels in older patients with DBA.

The precise cause of this fetal-like erythropoiesis is unclear.[381,382] It is clearly distinct from the fetal erythropoiesis implicated in various types of leukemia, notably in juvenile myelomonocytic leukemia in which the fetal red cells presumably arise from the leukemic clone. The situation in DBA may be analogous to that in other forms of bone marrow failure and in the hematological recovery phase following bone marrow transplantation.[381] In all of these conditions, the fetal (or "stress") erythropoiesis may represent an accelerated recapitulation of red cell ontogeny in the face of an increased demand for new red cells in peripheral blood.

Red cell enzymes often display an abnormal pattern of activity.[383] Enzymes, such as enolase, glyceraldehyde-3-phosphate dehydrogenase, phosphofructokinase, and glutathione peroxidase, have increased activity in patients with DBA compared to those in normal children and adults or in patients with transient erythroblastopenia of childhood. For some enzymes, this increased activity is comparable to cord blood red cells. In apparent contradiction, carbonic anhydrase isoenzyme B, which is not normally present in fetal red cells, was detected in hemolysates from three patients with DBA.[380] Also, the red cells of two of the three patients had adult hexokinase isoenzyme distribution by isoelectric focusing.

Abnormalities in purine and pyrimidine metabolism are reflected by increased activity of red cell adenosine deaminase (ADA) in many patients with DBA.[384–387] Also, increased orotidine decarboxylase (ODC) activity is seen in some patients.[387] ADA activity is raised in DBA erythrocytes, but not in cord blood red cells from normal newborns or from patients with any of several hematologic conditions associated with "stress" erythropoiesis. Thus, this enzymatic abnormality cannot be due simply to a "reversion" to fetal erythropoiesis. Red cell ADA activity was initially reported to be elevated in up to 90% of patients with DBA and to be elevated occasionally in some of their nonanemic relatives. However, in subsequent studies, ADA levels were found to be raised in only 40% of patients. Raised ADA activity may also be detected in some hemolytic anemias and acute leukemias which limits the utility of this assay as a specific diagnostic marker for DBA. However, increased ADA activity does appear to be useful in differentiating DBA from transient erythroblastopenia of childhood on a biochemical basis,[383–387] and for epidemiologic testing of DBA pedigrees to identify family members with a mild phenotype.[315]

Miscellaneous Laboratory Findings. Serum levels of various factors involved in red cell production, such as erythropoietin, iron, vitamin

B_{12}, and folate, are appropriately elevated in DBA. These findings are compatible with any form of chronic hypoplastic anemia. Riboflavin levels are normal in the serum but not in the erythrocytes. This observation initially aroused interest since experimental riboflavin deficiency may be corrected by corticosteroids similar to DBA. However, administration of large doses of riboflavin to several DBA patients did not result in a hematopoietic response.

Red cell serology is usually unremarkable at the time of diagnosis, but alloantibodies are frequently detected in chronically transfused patients. Two infants developed hypoplastic anemia, either in conjunction with or following a bout of Rh hemolytic disease.[388,389] In one of them,[388] the hypoplastic anemia was transient. It was proposed that the Rh antibody had specificity not only for mature red cells but also for reticulocytes and erythroid progenitors thereby causing temporary erythropoietic suppression of the bone marrow. The second patient[389] presented with a brisk hemolytic anemia that initially masked the presence of DBA. DBA became manifest 5 weeks postnatally when the Rh hemolytic disease had resolved. Fetal DBA with hydrops fetalis has been reported.[390]

Differential Diagnosis

Transient Erythroblastopenia of Childhood

In clinical practice, after excluding a viral etiology, particularly parvovirus B_{19}, transient erythroblastopenia of childhood (TEC) is usually the only diagnosis that is confused with DBA (Table 28–7). Both entities share the same morphologic findings in the bone marrow. However, TEC is a self-limited disorder with an excellent prognosis and needs no specific therapy except for red cell transfusions in the most profoundly anemic patients.[391] The definition of TEC includes the following features: (a) gradual onset of pallor in previously healthy children usually 1–4 years of age (85% of cases); (b) normochromic-normocytic anemia with varying reticulocytopenia unless recovery has already ensued; (c) marrow erythroid hypoplasia (60% of cases), or aplasia (10% of cases), or a recovery picture (30% of cases); (e) spontaneous recovery usually within 4 to 8 weeks without recurrence, with rare exceptions.[392]

There are some additional important features of TEC. It can occur in siblings simultaneously and in seasonal "clusters" from June to October and from November to March. Of concern are the transient neurologic changes that can accompany TEC and which appear to be linked to the disorder. Affected children may have one or more of the following: hemiparesis, papilledema, abnormal extraocular movements, seizures, and unsteadiness of gait. The affected patients in the published reports recovered without sequelae, and the precise relationship of these neurologic changes to the pathogenesis of TEC has not been determined.

It was claimed initially that only the erythroid lineage was affected in TEC and all other hematopoietic lineages were normal. Although the mechanism is not clear, significant neutropenia also occurs in many patients with TEC, being associated in some with hypocellular marrows or with a granulopoietic maturational arrest. The neutropenia may be caused by a common pathogenetic mechanism that produces anemia. Increased numbers of $CD10^+$ lymphoid cells have been observed in bone marrow of some TEC patients but the interpretation of this finding is not clear.[393,394] An unusual presentation of TEC as a leukoerythroblastic anemia has been recorded.[395]

Although one case of TEC was caused by parvovirus B19,[396] there are no data that firmly incriminate other infectious agents in the etiology of TEC, although a history of a preceding viral-like illness can be obtained in more than half of the patients. The most plausible explanation proposed to date is that TEC is caused by transient immunosuppression of erythropoiesis,[397] and possibly of granulopoiesis in those with neutropenia. Most supportive evidence for this thesis comes from in vitro studies. Two reports described an inhibitory effect of TEC serum and fractionated IgG on erythroid colony growth that disappeared as TEC improved.[398,399] An IgG inhibitor of erythropoiesis was discovered in one case, and an IgM inhibitor in a second patient.[397] A summary of other published studies[400] suggests that over 60% of TEC patients have autologous or allogeneic serum inhibitors of erythroid colony formation. Autologous or allogeneic cell-mediated immune suppression of erythropoiesis has also been identified in about 25% of cases.[397,400,401] All of the in vitro studies have generated varying patterns of erythroid colony growth in TEC. Colony numbers can be normal, but reduced numbers of BFU-E and CFU-E progenitors have been recorded in 30% and 50% of cases, respectively.

Therefore, TEC has an autoimmune pathogenesis. There are data that indicate that TEC cases are allelic with DBA on chromosome 19q13.2 but are not caused by mutations of the *RPS19* gene.[402] The transient nature of TEC is similar to other autoimmune hematologi-

Table 28–7 Distinguishing Features Between Diamond–Blackfan Anemia (DBA) and Transient Erythroblastopenia of Childhood (TEC)

	DBA	TEC
Etiology	Genetic	Acquired
Immune-mediated	None	Common
Family history	About 10%	Occasional siblings with concurrent TEC
Antecedent history	None	Viral infection
Age at diagnosis	90% by 1 year	6 months–4 years
Physical anomalies	About 50%	None
Neurologic findings	None	Occasional
Transfusion dependence	Yes, if steroid-refractory	None
Course	Chronic	Full recovery
Risk of cancer	Increased	Not increased
Risk of MDS/leukemia	Increased	Not increased
Laboratory findings at diagnosis:		
RBC size	Macrocytic	Normocytic
HbF	Increased	Normal[a]
i antigen	Increased	Normal[a]
RBC enzyme activities	Fetal levels	Adult levels[a]
RBC adenosine deaminase	Increased in 40%–90%	Normal

[a]During recovery, values may be increased.

cal disorders of childhood, such as idiopathic thrombocytopenic purpura and some cases of autoimmune hemolytic anemia. The decreased activities of virtually all red cell enzymes in TEC compared to controls probably relate to the aged population of peripheral blood erythrocytes being tested.[391]

Viral Etiologies of Erythroid Failure

Regarding viral causes of non-DBA red cell aplasia, Epstein-Barr virus, hepatitis virus, human T-cell leukemia virus-1, and human immunodeficiency virus-1 have all been implicated and should be excluded if the etiology of the anemia remains unclear. Parvovirus B_{19} stands out as a major causal agent of red cell aplasia in the context of an underlying chronic hemolytic anemia in infants and children with chronic congenital and acquired forms of immunosuppression. The fetus is uniquely susceptible to parvovirus infection and in utero transmission is a well-documented cause of nonimmune hydrops fetalis. Parvovirus infection should be ruled out in every case of childhood red cell aplasia by serial measurements of serum IgM and IgG, and by bone marrow examination for the characteristic giant pronormoblasts. Parvovirus may also be detected in marrow by gene amplification using the polymerase chain reaction and confirmed by direct in situ hybridization.

Predisposition to Malignancy

Although not generally regarded as a preleukemic or precancerous condition, DBA is clearly associated with hematologic cancer and with solid tumors. The link between DBA and hematologic cancer is more understandable from the data described herein that implicate an early pluripotent marrow progenitor in the pathobiology of DBA.[364,365] As summarized,[314] 10 DBA cases developed acute myeloid leukemia, 2 developed MDS, 1 had acute lymphoblastic leukemia, and 1 had non-Hodgkin lymphoma. There have also been reports of neoplasms including three cases of osteogenic sarcoma, two cases each of hepatocellular carcinoma, breast carcinoma, and Hodgkin disease, and one case each of gastric carcinoma, vaginal melanoma, and malignant fibrous histiocytoma. Although the actuarial risk of cancer in DBA is unknown, the risk exists and hence DBA is considered to be a cancer predisposition syndrome. The published cases implicate several possible operative factors including transfusional iron overload, use of androgens, immunosuppression from corticosteroids, thymic and skeletal irradiation during childhood as "therapy" for DBA in one case, and cyclophosphamide "treatment" in another. Although some DBA patients with mutant *RSP19* developed cancer,[314] there are insufficient data to predict a cancer genotype.

Natural History and Prognosis

Historically, the only treatment for DBA was blood transfusions. Without this, patients died of anemia. When corticosteroids were introduced as an effective therapy for DBA, all patients were assigned to one of the two therapeutic interventions and the "natural history" of the disorder took on a different dimension. A notable example is the phenomenon of spontaneous remission that occurs in about 20% of cases that allows patients to discontinue whatever treatment they are receiving, either chronic transfusion therapy or corticosteroids. The DBAR has some actuarial data showing that 75% remit prior to their 10th birthdays, and in most cases the remission is sustained.[403] It appears that an equal number of patients remit from either corticosteroids or transfusions. A relapse of DBA requires reintroduction of treatment.

The overall actuarial survival for DBA patients greater than 40 years of age is 75% ± 4.8%.[403] For those in sustained spontaneous remission, it is 100%; for corticosteroid responders it is 57% ± 8.9%; and for transfusion-dependent patients it is 8.9%. Causes of death mostly relate directly to the development of cancer or its treatment, complications from corticosteroid-induced immunosuppression, stem cell transplant-related complications, and transfusional hemosiderosis.

Therapy

In younger children and infants, it is important to determine whether the red cell aplasia is DBA or TEC (Table 28–7). Until a firm diagnosis is established, the initial treatment in children is almost always the use of transfusions. This allows the flexibility to complete the viral work-up and other investigations, and to await a spontaneous remission if the anemia is caused by TEC or another self-limited condition. The principle to follow if transfusions are used is to aim for a moderate but not full correction of anemia so that erythropoiesis is not suppressed and recovery from TEC not delayed. Most patients with TEC usually recover within a few weeks after receiving only one transfusion. Occasionally, recovery from TEC is slow and starts to mimic DBA in chronicity. If there is confusion about the proper diagnosis, it is appropriate to withhold corticosteroids in favor of a further transfusion in order to allow more observation time. Demonstration of a mutant ribosomal protein gene would clinch the diagnosis, but only in about 25% of patients.

Transfusions

Before the first transfusion, it is recommended that a full red cell phenotype be performed on the patient. This information will be valuable for prevention and management of alloantibody formation caused by sensitization. For patients in whom corticosteroids are either ineffective or excessively toxic, a regular program of red cell transfusions is usually required. During the course of this program, a small number of steroid-resistant patients may show sensitivity to corticosteroids when re-treated, or even proceed to a spontaneous transient or prolonged remission. If not, leukocyte-depleted packed red cells are given monthly to keep the hemoglobin concentration at a level compatible with normal activity. CMV-negative packed cells should be used if stem cell transplantation is contemplated. The nadir should not be less than 6 g/dL. Several complications may arise from transfusions such as blood-borne infections and sensitization, but the major long-term threat is iron overload, which causes delayed puberty, growth retardation, diabetes mellitus, hypoparathyroidism, and eventually liver cirrhosis and cardiac failure. These complications can be delayed, and possibly prevented, by the early administration of an iron chelator. Deferoxamine (Desferal), administered with a battery-powered pump as a daily 12-hour subcutaneous infusion, has been the main chelator for the past 3 decades. However in a randomized trial of Desferal or deferasirox (Exjade), a once-daily oral iron chelator, in patients with transfusional iron overload, the two chelators showed similar efficacy.[404] It is predicted that Exjade will replace Desferal as the chelator of choice. The oral iron chelator deferiprone (L1) has caused significant neutropenia and death in one case[405] in DBA and is not recommended (Dr. Jeffrey Lipton, public communication).

As long as Desferal remains the main chelator, there are uncertainties about the optimal age at which to start it for patients with transfusion-dependent anemia. There have been reports of abnormal linear growth and metaphyseal dysplasia in thalassemia major patients treated with deferoxamine before the age of 3 years.[406] This adverse event has prompted recommendations for starting therapy later. However, a progressively rising serum ferritin level or, more accurately, excessive hepatic iron concentration obtained by biopsy after 1 year of regular transfusions would be appropriate indications to commence chelation. The daily starting subcutaneous infusion dose of Desferal should not exceed 50 mg/kg. Ascorbate supplementation should be considered if there is sustained loss of efficacy of Desferal, especially if tissue ascorbate concentrations are reduced.[407]

Corticosteroids

Steroid responsiveness is present in 50% to 75% of DBA patients. Upon administration of prednisone at a dose of 2 mg/kg/day in three

divided doses, reticulocytosis is usually seen within 1 to 4 weeks, and is followed by a rise in hemoglobin concentration. Once the hemoglobin level reaches 9.0 to 10.0 g/dL, prednisone can be slowly tapered by reducing the number of daily doses. If a single daily dose of prednisone maintains the desired hemoglobin level, the dose can be doubled and given on alternate days but this may not prevent significant steroid toxicity.

The dose of prednisone can be further reduced by small decrements on a weekly basis, or more slowly, until the minimal effective dose is determined. This dose is extremely variable. A few patients can be maintained on minute, nonpharmacologic doses, whereas other patients need large doses that preclude long-term therapy because of serious side effects like cushingoid features, pathologic fractures, cataracts, growth failure, diabetes, and avascular necrosis of the femoral or humeral heads. There is no known predictor of steroid responsiveness, nor any way to anticipate the type of individual responses. In general, a corticosteroid dose-equivalent of prednisone, 0.5 mg/kg/day, is suggested as a maximum "maintenance" dose after the initial dose of 2 mg/kg/day.[314]

There are several patterns of response to corticosteroid therapy, some of which may occur at different times in the same patient.[317] Most children who respond to steroids cannot be completely weaned off the medication and become steroid dependent. About one-third of these patients, however, enter steroid-free remission after a prolonged period of treatment.[317] Between 1% and 5% of responders immediately enter a durable steroid-independent remission. However, late relapses, sometimes precipitated by an infectious illness or by hormonal changes such as in pregnancy or with the use of birth control pills, are not uncommon. In other cases, a progressive resistance to steroids occurs, requiring escalating doses of prednisone or alternative therapy. Following a relapse, some patients are responsive to steroids again, whereas others are refractory to subsequent trials. Initial insensitivity to steroids is observed in 36% of cases.[317] In over 60% of patients long-term steroid therapy is hampered by the development of resistance or by side effects of the treatment. In adolescent responders on long-term steroids, an option is to stop prednisone temporarily to allow a normal growth spurt. Infants with DBA on steroids are at risk for pneumocystis pneumonia and should be given prophylactic antibiotics.

High-Dose Methylprednisolone. Megadose steroid therapy for patients refractory to conventional prednisone induced a sustained erythroid response leading to transfusion independence in 8 of 13 DBA patients.[408] Eleven had been treated with 100 mg/kg/day intravenously, and 2 additional patients with 30 mg/kg/day orally. Another report showed only a transient response in 1 of 8 patients after intravenous treatment with 30 mg/kg/day and a sustained response after a higher dosage (100 mg/kg/day) in 3 of 8 patients, but side effects were weight gain, oral moniliasis, increase in hepatic transaminases, transient hyperglycemia, and bacteremia related to central venous access.[409] A conclusive study[410] of nine refractory DBA patients using megadose oral methylprednisolone showed no response in five cases, and a partial or complete response in the other four in the initial 4 to 8 weeks of therapy, but all of these relapsed with a taper and became transfusion-dependent. Thus, none of the cases exhibited a clinically significant or durable response.[410]

Cytokine Therapy

Because of the "corrective" effect on erythropoiesis by IL-3 in vitro, clinical trials were introduced for steroid-refractory and steroid-dependent DBA patients and for those in whom BMT was considered too risky.[411–415] The early enthusiasm generated by sustained remissions in some patients was tempered by the realization that IL-3 is effective in only a very small number of cases of steroid-refractory, transfusion-dependent DBA. Of 49 patients treated with IL-3 in a European multicenter compassionate-need study, only 3 children had a significant response with sustained remissions off therapy.[414] A comparison of individual patient characteristics confirmed that patients who had never achieved significant in vivo erythropoiesis in response to steroids or during a spontaneous remission were highly unlikely to respond to IL-3. Thus, the overall response rate in all published studies averages 10–20%. Currently, there are no IL-3 or other growth factor clinical trials in North America for DBA. Serum Epo levels are elevated in DBA and attempts at treatment with high-dose Epo have been ineffective.

Hematopoietic Stem Cell Transplantation (HSCT)

HSCT is a therapeutic option for DBA but risks must be weighed against benefits on a case-by-case basis. The fundamental issue centers on the defined mortality rate with HSCT when used for a non-lethal medical disorder, at least a disorder that is non-lethal in the short-term. In steroid-responsive patients on low-dose maintenance, and in properly transfused and adequately chelated patients, quality of life is not threatened by life-threatening complications. Thus, the decision for intervention with HSCT in this setting is difficult.

Nevertheless, experience has broadened since the first BMT was performed for DBA in 1976.[416] Preparative regimens, supportive measures, and graft-versus-host disease management have progressively become more refined thereby reducing overall risks of the procedure. For consideration in the decision-making, though, there are still lethal risks[417,418]: interstitial pneumonia, cardiac failure, fatal complications associated with chronic graft-versus-host disease, graft failure, graft rejection and sepsis. Results from the International Bone Marrow Transplant Registry show a 64% 3-year probability of overall survival of 61 transplanted DBA patients.[419] The American DBA Registry[420] and the Aplastic Anemia Committee of the Japanese Society of Pediatric Hematology[373] report an 87.5% and an 85% survival, respectively, but with a caution that alternative donors pose a much higher risk than matched sibling donors.[420] From the DBAR database, the survival rate for patients under the age of 10 years receiving matched related HSCT is greater than 90%.

This success has sparked a big interest in preimplantation genetic diagnosis (PGD) with in vitro fertilization to "create" HLA-matched, non–*RPS19*-mutated sibling donors, and a number of patients worldwide have been successfully transplanted using umbilical cord-derived stem cells from donors produced in this way. The religious, ethical, and economic questions generated by PGD to find a healthy matched donor for DBA and other inherited marrow failure transplantations is ongoing.[116–118,429–432] Related and unrelated umbilical cord blood as a stem cell source has been used for DBA HSCT with favorable results.[314,421–426]

Other Therapeutic Options

Two options deserve consideration. The first, cyclosporin-A (CSA), has been reported to produce remission in some DBA patients in whom standard prednisone therapy had failed.[433–436] In one report, 4 of 8 steroid-refractory patients responded to CSA and remained transfusion-independent for a 12-month follow-up.[436] The second option arose from a report of an adult DBA patient whose anemia remitted during pregnancy and was sustained during breast feeding, suggesting that prolactin effected the improvement. Metoclopramide, an inducer of prolactin release, was subsequently administered and sustained the hemoglobin for several years.[437] A subsequent case report confirmed efficacy of metoclopramide for DBA.[438]

A number of other uncontrolled therapeutic trials have been performed in steroid-refractory patients using various medications and treatments with varying success in a few patients. The medications include: androgens, riboflavin, vitamin B_{12}, folate, iron and other "hematinic" agents, 6-mercaptopurine, cyclophosphamide with antilymphocyte globulin, and antithymocyte globulin alone. Administration of the amino acid leucine was effective in a DBA patient (D. D. Pospisilova, public communication). There is a case report claiming efficacy of valproic acid for DBA,[439] and another report of an 8-month transfusion-free remission after rituximab therapy.[440] Plasmapheresis has also been tried. Splenectomy, employed in the past, shows no effect on erythropoiesis but may be helpful in transfused patients with proven hypersplenism.

Future Directions

Registries and DBA patient databases will continue to broaden our understanding of the genetic origins and epidemiology of DBA. Specimen collection and distribution to qualified research laboratories globally will identify the remaining DBA genes. Genetically-based DBA diagnosis and pedigree analysis will underscore the broad dimensions of the DBA phenotype, from clinically silent to life-threatening severe. Genotype-phenotype correlations will facilitate HSCT donor selection, allow counseling for reproductive options, and predict for cancer risk.

Kostmann Syndrome/Congenital Neutropenia

Background

Severe chronic neutropenia (SCN) and recurrent serious infections are features of a heterogeneous group of disorders of myelopoiesis including congenital neutropenia, cyclic neutropenia, and idiopathic neutropenia. Kostmann syndrome (KS) is an inherited subtype of congenital neutropenia with onset in early childhood of profound neutropenia (absolute neutrophil count <200/μL), recurrent life-threatening infections, and a maturation arrest of myeloid precursors at the promyelocyte-myelocyte stage of differentiation. The initial description of KS included several neutropenic patients in a large intermarried Swedish kinship.[441,442] An autosomal recessive mode of inheritance in 24 cases was deduced by inference because of hematologically normal parents with two or more neutropenic children in several families. It is now clear that KS and congenital neutropenia are genetically heterogeneous despite a shared hematologic phenotype. The cloning of the neutrophil elastase 2 gene (*ELA2*) and the identification of heterozygous mutations in patients with the KS phenotype support an autosomal dominant inheritance in many cases.[443] Homozygous germline *HAX1* mutations have been identified in autosomal recessive patients, including some from Kostmann's original pedigree.[444]

Congenital neutropenia and KS are indistinguishable hematologically. "Congenital neutropenia" is a term that usually refers to a single "sporadic" case in a family, and may or may not be inherited in the same mode as KS. Many sporadic cases, though, have heterozygous mutations of *ELA2*.[445] The option to "lump" or "split" the two disorders is debatable, but in this chapter, the terms "KS" and "congenital neutropenia" are used interchangeably. These disorders are rare with an estimated frequency of one to two cases per million with equal distribution for gender.

The Severe Chronic Neutropenia International Registry (SCNIR) was established in 1994 to catalogue the clinical features and to monitor the clinical course, treatment, and disease outcomes in patients with SCN.[446] The Registry is a valuable resource for clinical data because of the large numbers of patients entered into its worldwide database. Patient data are submitted internationally to the coordinating centers at the University of Washington, Seattle, and the Medizinische Hochschule, Hannover. As of 2004, short-term and long-term information dating back to 1987 on a total of 1,163 patients was available for analysis. Of the total, 422 patients were classified as having congenital neutropenia including KS.

Etiology, Genetics, and Pathophysiology

The discovery of heterozygous mutations in the ELA2 gene encoding neutrophil elastase in 22 of 25 sporadic and dominantly-inherited patients with congenital neutropenia was the entry point for understanding the molecular basis of the disorder in many patients.[443] As experience with genetic testing has broadened it appears that 60% to 80% of cases have spontaneously-occurring or inherited point mutations in ELA2 and, less commonly, mutations in other genes.[445] ELA2 encodes neutrophil elastase, a glycoprotein synthesized in the promyelocyte/myelocyte stages and packed in the azurophilic cytoplasmic granules. It is released in response to infection and inflammation. The wild-type neutrophil elastase diffusely localizes throughout the cytoplasm but the mutated protein in cases of congenital neutropenia abnormally concentrates in the nucleus and plasma membrane. Mutant *ELA2* also occurs in all cases of classical cyclic neutropenia, but the mutations cluster in exon 4 or 5 on the gene on chromosome 19p13.3 or at the junction of exon 4 with intron 4. Patients with congenital neutropenia have mutations more widely distributed over exons 2, 3, 4, and 5.[443,447]

In congenital neutropenia, mutant *ELA2* results in impaired survival of myeloid progenitor cells.[447] Neutrophil elastase mutations alone may not be sufficient to cause the congenital neutropenia phenotype. This conclusion is based on 2 siblings with congenital neutropenia who inherited the same heterozygous mutation from their unaffected, hematologically normal father. In contradiction, in vivo confirmation of the pathogenic role of the mutations in neutropenia was demonstrated in a healthy father of a congenital neutropenia patient; he was mosaic for his daughter's mutation, and his myeloid precursors with the mutation were selectively lost during myelopoiesis or failed to mature to neutrophils.[448]

The exact mechanism by which mutant *ELA2* causes neutropenia is under intense study.[449–454] There are several lines of evidence that mutant ELA2 protein triggers accelerated apoptosis of developing neutrophil precursors.[450] Mutant protein leads to cytoplasmic accumulation of non-functional protein, disturbance of cellular trafficing, and activation of unfolded protein response in congenital neutropenia neutrophils.[454] Downregulation of lymphoid enhancer-binding factor 1 (LEF-1), a feature of KS, interferes with myeloid maturation and imposes additional interference on granulopoiesis.[455] In addition, decreased expression of Bcl-2 was observed in Kostmann myeloid progenitor cells along with constitutive mitochondrial release of cytochrome C, and excessive cellular apoptosis.[454] Of note, administration of G-CSF restored Bcl-2 expression and improved survival of myeloid progenitor cells.

In autosomal recessive KS patients caused by mutant *HAX1*, there is a deficiency of the mitochondrial protein HAX1 which normally functions in signal transduction and cytoskeletal control. Normal HAX1 protein is critical for maintaining the inner mitochondrial membrane potential and protecting against apoptosis in myeloid cells.[444]

A constitutively activating mutation in the Wiskott-Aldrich syndrome protein encoded by the *WASP* gene was discovered in 5 males from a three-generation family.[456] The phenotype of the resulting X-linked immunodeficiency syndrome was comprised of severe neutropenia from birth, bacterial infections, monocytopenia, and shifts of lymphocyte subsets. Bone marrow morphology showed a selective maturation arrest at the promyelocyte/myelocyte stage similar to KS. Mutant *WASP* leads to constitutive activation of the WASP protein because of disruption of an autoinhibitory domain in the wild-type protein. This increased WASP protein activity produces marked abnormalities of cytoskeletal structure and dynamics.[457]

Mutations in the protooncogene *GFI1* also cause congenital neutropenia with the Kostmann syndrome phenotype.[458] Wild-type *GFI1* is a transcriptional repressor of *ELA2* and when mutated, repressor activity is disabled and *ELA2* is overly expressed. This leads to premature apoptosis and reduced proliferation of granulopoietic cells.[459]

A constitutive point mutation was discovered in the extracellular domain of the G-CSF receptor in a patient with congenital neutropenia who also had a mutant *ELA2* gene.[460] The receptor mutation affected ligand-receptor complex formation with severe consequences for intracellular signal transduction; the patient was totally unresponsive to G-CSF therapy. As demonstrated in vitro and then clinically, corticosteroids combined with G-CSF produced a corrective action through synergistic activation of STAT5 and the patient responded to G-CSF therapy.[461] Three subsequent reports of patients with cell-surface G-CSF receptor mutations were also refractory to G-CSF therapy and suggest that this may be a common finding in cases unresponsive to treatment.[462–464]

In patients with KS who are treated with G-CSF, transformation to MDS and/or AML (MDS/AML) is associated in most cases with *acquired* G-CSF receptor (CSF3R) point mutations.[465–468] These CSF3R nonsense mutations result in the truncation of the C-terminal cytoplasmic region, a subdomain that is crucial for G-CSF induced maturation.[469,470] The acquired mutation is directly operative in the conversion to MDS/AML. In murine models, the mutation results in impaired ligand internalization, defective receptor downmodulation, and enhanced growth signaling that produces an exaggerated hyperproliferative effect in response to G-CSF.[471,472–474] This also confers resistance to apoptosis and enhances cell survival[475] that favors clonal expansion in vivo.[473] The clinical interplay between G-CSF and the receptor mutation was underscored in the report of a patient with congenital neutropenia on G-CSF who developed the receptor mutation and AML.[476] When G-CSF was stopped, the blast count in blood and in marrow fell to undetectable levels on two occasions without giving chemotherapy although the mutant receptor was persistently detectable during the remissions. These acquired receptor mutations appear at varying time points after G-CSF therapy is started.[468,477]

Regarding the cellular pathology of KS, many cell culture studies performed in the 1970s and 1980s provided clonogenic data that pointed to intrinsically defective granulocytic progenitors.[478] Further reports confirmed this and excluded other possible pathogenetic factors.[477,479–482] To summarize: (1) KS marrow myeloid colony growth is defective,[481,482] (2) Western blot and in vitro bioassays show that KS serum contains normal or increased levels of G-CSF,[479,480] (3) endogenous KS G-CSF has normal biologic activity,[477] (4) G-CSF receptors are expressed in slightly increased numbers on myeloid cells from KS patients,[480] and (5) the binding constant for G-CSF to its receptor in KS is normal.[477]

Clinical Features

History and Physical Examination

Approximately half the patients develop clinically impressive infections within the first month of life and almost all others develop them by 6 months. Skin abscesses are common but deep-seated tissue infections and septicemia also occur. SCNIR data illustrate examples of every conceivable form of bacterial and fungal infection in the pre-cytokine era. Especially troublesome in survivors were recurrent episodes of otitis media and pneumonia, advanced gingival-stomatitis sometimes with tooth loss, and in the extreme, gut bacterial flora overgrowth leading to malabsorption requiring total parenteral nutritional therapy. In contrast to some of the other inherited bone marrow failure syndromes, physical malformations are not a feature. Birth weights are generally unremarkable and physical examination is normal. There are a small number of reports of short stature, microcephaly, mental retardation, and cataracts but the association with KS does not appear to be strong. Data from the SCNIR indicate that some patients with KS develop bone demineralization that may be an intrinsic component of the disorder[445,480]; it has been observed before and during G-CSF therapy. The underlying pathogenesis is unclear but patients can develop bone pain and unusual fractures.

Laboratory Findings

Peripheral Blood and Bone Marrow Findings. Neutropenia is profound and persistent in KS, usually less than 200/μL, but often absolute. A small number of patients appear to have intermittent cycling patterns with regular periodicity that mimic classic cyclic neutropenia.[443] A compensatory two to four-fold increase in monocytes is seen, sometimes accompanied by eosinophilia. At diagnosis, platelet numbers are normal or increased, and hemoglobin values are usually normal. In survivors in the pre-cytokine era, anemia of chronic disease associated with recurrent infections and inflammation were common. Aside from neutropenia, humoral and cellular immunity is completely normal.

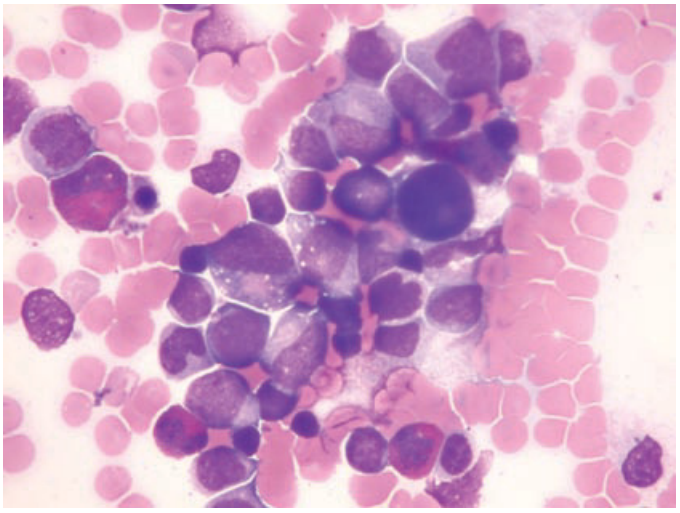

Figure 28–11 High-power view of a bone marrow aspirate from a patient with Kostmann syndrome (congenital neutropenia) prior to a G-CSF therapy. The findings are a "maturation arrest" with recognizable myeloblasts, promyelocytes, myelocytes, occasional metamyelocytes, but total absence of band forms and neutrophils. *(Photomicrograph prepared by Dr. Mohamed Abdelhaleem, Toronto.)*

Bone marrow specimens are usually normocellular. The striking classical finding is a maturation arrest at the promyelocyte or myelocyte stage of granulocytic differentiation with a paucity of more mature elements. Promyelocytes may have atypical nuclei and the cytoplasm may be vacuolated. Neutrophils and bands are usually absent (Fig. 28–11). Marrow eosinophilia and monocytosis is common. The other hematopoietic lineages are normal, active, and undisturbed.

Predisposition to Leukemia and MDS

In 1997, the SCNIR provided its first report on patients with congenital neutropenia on G-CSF therapy who developed MDS/AML.[484] Since then, there has been progressive enrollment of new patients into the SCNIR from North America, Europe, and Australia and there has also been in parallel an annual accrual of new patients with congenital neutropenia and Shwachman-Diamond syndrome on G-CSF that evolved into MDS/AML.[485] From 1987 to year-end 2005, data at the SCNIR confirmed that 65 patients with congenital neutropenia and 5 with Shwachman-Diamond syndrome developed MDS/AML while taking G-CSF.[445] The crude rate of MDS/AML conversion was 11.5% for the 70 patients (70 cases among 611 exposed), with an average follow-up of 5 to 6 years. The leukemic transformation occurred in patients with *ELA2* mutations, in unclassified congenital neutropenia cases, and in Shwachman-Diamond syndrome, but not in patients with *GFI1* mutations, *WASP* mutations, Barth syndrome, or in glycogen storage disease type 1b.

To determine if the incidence of MDS/AML in the SCNIR patients is related to G-CSF dosage or duration of therapy, or to other patient demographics, a detailed analysis was conducted on data received up to December 31, 1998, on 352 patients with congenital neutropenia treated with G-CSF,[485] and then again on data received up to 2000 on 374 patients.[486] In the second more recent analysis, the hazard of MDS/AML increased significantly during the period of observation on G-CSF, from 2.9% per year after 6 years to 8.0% per year after 12 years. The cumulative incidence of MDS/AML was 21% after 10 years. The risk of MDS/AML increased with the dose of G-CSF. Less responsive patients, defined as those requiring greater than 8 μg/kg/d of G-CSF, had a cumulative incidence of MDS/AML

of 40% after 10 years, compared to 11% of more responsive patients. The data were interpreted as indicating that a poor response to G-CSF defines an "at-risk" population and predicts an adverse outcome. The data do no necessarily support a cause-and-effect relationship between development of MDS/AML and G-CSF therapy; the results may only mean that patients requiring higher G-CSF therapy have a more severe disease phenotype. A report from the French Severe Chronic Neutropenia Study Group confirmed that increased exposure to G-CSF with respect to dose and duration in congenital neutropenia patients was associated with a heightened risk of MDS/AML[487] but they do not speculate on the mechanism.

Conversion to MDS/AML in congenital neutropenia patients receiving G-CSF is associated with one or more cellular genetic abnormalities that provide insight into the pathobiology of the transformation, and may be useful in identifying patients who are at high risk. The cellular genetic changes are acquired after starting G-CSF and occur singly or in combinations. Remarkably, the abnormalities have predictably similar characteristics in most patients and underscore a fairly specific multistep pathogenesis in the evolution into MDS/AML. As summarized herein, 60% to 80% of patients with congenital neutropenia (but not with SDS) have a heterozygous mutation in the gene encoding neutrophil elastase.[445] At varying time points after starting G-CSF therapy, about half of the congenital neutropenia patients who transform acquire the same activating RAS oncogene mutation, namely a GGT (glycine) to GAT (aspartic acid) substitution at codon 12.[488] More than 90% of patients who transform also show an acquired cytogenetic clonal alteration in bone marrow cells, usually −7 or 7q-, but also +21.[484–489] Occasionally chromosome 7 and 21 abnormalities occur in the same cell. Over 80% of patients develop one or more G-CSF receptor point mutations. The detection of these mutations places patients at high risk for malignant conversion, but the time course from detection of mutations to overt MDS/AML varies considerably and may take years.[445]

The role of G-CSF in myeloid transformation in these patients is obscured because of their predisposition to AML as a component of the natural history. There were three case reports of patients who developed AML prior to the use of hematopoietic growth factors[490–492] and one more recent patient diagnosed with acute leukemia prior to starting G-CSF.[493] Because most patients with congenital neutropenia died at a young age from bacterial sepsis or pneumonia in the pre-cytokine era, the true risk of patients with congenital neutropenia developing MDS/AML was not clearly defined. As a rough estimate, in the literature there were 128 cases of congenital neutropenia reported and the 3 cases of AML[490–492] up to 1989, the first year that G-CSF was available for general use, leading to a crude estimated risk of leukemia of 2%.

Although patients requiring greater than 8 μg/kg/day of G-CSF to attain safe neutrophil levels are an "at risk" group for MDS/AML, there is no definitive evidence that G-CSF directly causes malignant transformation. G-CSF may simply be an "innocent bystander" that corrects the neutropenia, prolongs patient survival, and allows time for the malignant predisposition to declare itself. Alternatively, G-CSF may accelerate the propensity for MDS/AML in the genetically altered stem and progenitor cells in congenital neutropenia. G-CSF may rescue malignant clones that would otherwise be destined for apoptosis. An axiom of oncogenesis is that rapidly dividing cells are more susceptible to mutational events. Since therapeutic G-CSF provides a powerful proliferative signal for marrow cells, it is a reasonable hypothesis that congenital neutropenia marrow progenitors acquire new mutations. From the evidence cited herein, acquisition of a G-CSF receptor mutation in the face of therapeutic G-CSF in congenital neutropenia can provide the hyper-responsive replicative scenario[471,472–474,494] that can relentlessly evolve into MDS/AML. Is recombinant human G-CSF a carcinogen? This would seem highly unlikely. As a physiologic regulator of hematopoiesis, it would be unexpected for G-CSF to break molecular bonds and cause DNA damage, even when used in therapeutic dosages. It is noteworthy that MDS/AML has rarely been seen in other categories of SCN patients on long-term G-CSF therapy.

Differential Diagnosis

The commonest cause of isolated neutropenia in very young children is viral-induced marrow suppression. An antecedent history of good health, the occurrence of a viral illness, and the transient nature of the neutropenia distinguishes this disorder from KS/congenital neutropenia. Autoimmune neutropenia of infancy is recognized as a fairly specific syndrome of early childhood. Low neutrophil numbers are often discovered during the course of routine investigation for a benign febrile illness. The illness abates but the neutropenia persists, sometimes for months and occasionally for years. A marrow biopsy is normocellular and an aspirate shows active granulopoiesis up to the band stage; neutrophils may be normally represented, reduced or absent. The neutropenia is caused by increased peripheral destruction and the diagnosis is confirmed serologically by demonstrating antigranulocyte antibodies.[495] The prognosis is good, the neutropenia is self-limited albeit protracted, and patients seldom develop serious bacterial infections as a result of it. Other infrequent acquired causes of severe, isolated neutropenia in this age group include marrow suppression from a drug or toxin, and neutrophil sequestration as part of a hypersplenism syndrome.

Of the inherited forms of neutropenia, Shwachman-Diamond syndrome can also manifest as isolated neutropenia but can be identified because of growth failure, the malabsorption component caused by pancreatic insufficiency, fatty changes in the pancreas seen on computed tomography scanning, and characteristic skeletal abnormalities. Glycogen storage disease type 1b and Barth syndrome are also in the differential diagnosis. Neutropenia can also be a prominent part of antibody deficiency syndromes and/or cellular immunodeficiency disorders (Table 28–8); investigation of chronic neutropenia of childhood should include an immunoglobulin electrophoresis, T-cell proliferative studies, and quantitation of T-cell subsets and NK cell activity. Cyclic neutropenia is distinguished by predictable symptomatology, especially mouth sores every 21 days in classic cases, often associated with chronic gingivitis. A complete blood count 2 or 3 times a week for 4 to 8 weeks will demonstrate the diagnostic oscillation pattern with the 21-day nadir. Familial cases of neutropenia with an autosomal dominant mode of inheritance also occur; parents and siblings of all cases should be screened with a complete blood count. When severe neutropenia is diagnosed in the newborn period, the cause may be passive transfer transplacentally of IgG anti-neutrophil antibodies from mother. This can occur if mother has an autoimmune disorder with neutropenia, or by alloimmunization caused by fetomaternal incompatibility for a neutrophil-specific antigen.

Therapy and Prognosis

Before the introduction of G-CSF as a specific therapy of KS and other forms of severe chronic neutropenia, there was limited treatment. Antibiotics were the mainstay of management for active infection and for prophylaxis. Attempts to mobilize neutrophils in KS with lithium had limited application.[496]

Cytokine Therapy

G-CSF has supplanted all other forms of management since more than 90% of KS patients respond. The SCNIR has consistently recommended that it should be initiated as front-line treatment when the diagnosis is established.[480,497] GM-CSF in crossover trials with G-CSF for KS is not as effective and does not induce a neutrophil response consistently. If the ANC remains below 1.0×10^9/L after initiation of G-CSF at 5 μg/kg/dose once a day subcutaneously, the dose should be escalated to 10 μg/kg/dose and then by increments of 10 μg/kg/dose at 14-day intervals until a response is seen. As soon as the ANC can be maintained at 1.0×10^9/L or above, the G-CSF dose does not have to be increased further since the occurrence of bacterial infection is reduced dramatically with an ANC at this level. The G-CSF dose can be reduced if the ANC increases to 5.0×10^9/L or above in order find the lowest dose necessary for maintaining a

neutrophil count at 1.0×10^9/L or greater. Nonresponders are defined as patients who do not respond to G-CSF levels exceeding 120 μg/kg/dose. Partial responders show an increase of their ANC to 0.5 to 1.0×10^9/L, with the highest dose, but they still suffer bacterial infections. In these patients the dose of G-CSF cannot be increased because of the large volume and frequency of injections required. In some of these patients a combination of G-CSF with stem cell factor (SCF) can induce a further increase in the ANC, but the potential allergic side effects of SCF have limited the use of this treatment combination to hospitalized patients with severe infections who also receive concomitant antihistaminic medication.[498] The only currently available treatment for patients who do not respond to G-CSF treatment alone or in combination with SCF is HSCT.

All patients on G-CSF therapy should be seen by a physician every 3 to 6 months. Patients requiring more than 8 μg/kg/day are at higher risk for MDS/AML and should be reviewed more often. Blood counts (white blood cells, hemoglobin, platelets, and differential blood counts) should be obtained and a physical examination performed at least every three months, including assessment for weight and height in pediatric patients, and documentation of intercurrent infections. Bone marrow examination for morphology and cytogenetics is recommended once a year to search for acquired cytogenetic abnormalities such as monosomy 7 or trisomy 21.

In the SCNIR report in 2003, a sustained hematological response in patients treated with G-CSF for more than 12 years was confirmed.[480] With therapy, neutrophil counts rise in more than 90% of SCN patients and are maintained at a plateau for protracted periods resulting in vast clinical benefits. In no instance has there been marrow or hematopoietic lineage "exhaustion" or depletion with G-CSF therapy. The overall safety of long-term administration of G-CSF is reviewed in detail.[477,480,484,497]

Hematopoietic Stem Cell Transplantation (HSCT)

Prior to the use of G-CSF, HSCT was tried in a small number of KS patients with mixed success. Data from the International Bone Marrow Transplantation Registry are limited and series is heterogeneous with regard to donor source and clinical status of patients at the time of the procedure.

A report from the SCNIR summarizes its experience with HSCT for KS.[499] Of 29 who were transplanted, 18 had transformed to MDS and/or AML and the dual goal was to cure the malignancy and the neutropenia. Only 3 of the 18 were successful. The causes for failure included mismatched transplants, progressive refractory AML, serious illness at the time of the procedure, and transplants performed in desperation. The other 11 patients underwent HSCT for reasons other than malignant transformation, mostly because of no response or only partial response to G-CSF. Eight patients received stem cells from an HLA-matched sibling after conditioning mainly with busulfan/cyclophosphamide alone or with additional immunosuppression. In sharp contrast to the MDS/AML group, 9 of the 11 were cured with resolution of neutropenia.

Since the SCNIR report in 2000, there have been several additional publications describing experiences with single or multiinstitutional HSCT for a variety of indications using matched-related or MUD marrow or cord blood with variable outcomes.[476,500–505] In general, the best scenario for a curative HSCT is when the procedure is performed prior to developing MDS/AML, using a matched-related donor, and when the patient is in good physical condition. In a small series of 6 transplanted patients for MDS or AML, 2 with MDS who underwent the procedure without being given induction chemotherapy survived, whereas 4 with AML given induction chemotherapy had significantly more morbidity and died post-transplant, raising questions about conditioning strategies for these patients.[504]

The discovery of an isolated marrow clonal cytogenetic abnormality without other evidence of MDS or AML in patients with congenital neutropenia raises management issues. One option is to perform HSCT if there is a matched donor as soon as feasible. This has generally been recommended for patients with −7, 7q-, or +21. The a priori argument is that the chance for cure is higher when the patient is well and with a low burden of malignancy. The problem with this decision centers on not knowing the tempo of progression from the cytogenetic change to clearcut MDS or AML. Thus, there may not be a need to rush to transplant in all patients. Instead, one recommendation is to lower the G-CSF to the lowest dose that maintains neutrophil counts greater than 0.5×10^9/L and to monitor the patient regularly for change with blood counts and by serial marrow testing.

Opinions vary about the best way to manage patients with non-cytogenetic evidence of clonal disease but without overt hematologic malignancy. This would include acquisition of a G-CSF receptor mutation or an activating RAS oncogene mutation in marrow from a patient with congenital neutropenia taking G-CSF who shows no other signs of MDS or AML. In one patient with an isolated G-CSF receptor mutation, a hematopoietic stem cell transplant was performed to eliminate the risk of leukemic conversion.[499] Debate about this form of management remains open, and watchful waiting is an acceptable option.

Bisphosphonates for Osteoporosis

Bone density measurements of congenital neutropenia patients on G-CSF show varying degrees of osteopenia or osteoporosis in about 50% of cases. Most of these are subclinical and asymptomatic, but some patients complain of bone pain and have fractures. In a small series of 5 congenital neutropenia cases treated with bisphosphonates, 4 remodeled and re-expanded fractured vertebrae during treatment and no side effects were seen on follow-up.[506] Bisphosphonates appear to be effective treatment for these patients.

Future Directions

Mutational analysis of congenital neutropenia patients will continue to be informative. Thus far, genotype-phenotype relationships have not been possible and will require further accrual of data. It is also not yet clear if there is an association between specific mutations and the risk of evolution to MDS and acute leukemia, but studies are ongoing to try to answer this clinical question. At present, diagnosis of cyclic and congenital neutropenia still depends primarily upon observations of serial blood cell counts, but it is expected that mutational analysis of the *ELA-2* gene will become a routine part of diagnosis and prognosis for these patients in the years ahead. Since apoptosis is a central mechanism of neutropenia in these patients, it is expected that the term "maturation arrest" will soon be replaced by "accelerated apoptosis" as a descriptive term for the marrow findings. It appears that cellular models involving transfection of the mutant genes into human myeloid cell lines provide evidence of how neutropenia occurs. Potentially, these models can also be used to examine new approaches to preventing apoptosis and serve to provide clues to new and more effective therapies. Considerable data now suggest that the effectiveness of G-CSF in the treatment of various forms of severe chronic neutropenia is related to anti-apoptotic effects in addition to its effects on stimulating and expanding myeloid cell production.

Other Inherited Neutropenia Syndromes

Barth Syndrome

Barth syndrome is a rare multisystem metabolic disorder inherited in an X-linked recessive mode.[507] It is the first human disease in which the primary causative factor is an alteration in cardiolipin remodeling. Cardiolipin is a component of the inner mitochondrial membrane necessary for proper functioning of the electron transport chain. The findings in typical cases are cardiomyopathy of the dilated type, skeletal myopathy, growth failure, 3-methylglutaconic aciduria, and neutropenia. The neutropenia has been termed "classic cyclic neutropenia" but documentation is lacking. Absolute neutrophil counts are variable, but total agranulocytosis has been recorded.[508] Marrow morphology shows a maturation arrest at the myelocyte stage.[507] By

Table 28–8 Miscellaneous Inherited Neutropenia Disorders*

Diagnosis	Genetics†	Mapping	Mutant Gene	Additional Features
WHIM syndrome	AD	2q21	*CXCR4*	Warts, ↓IgG, myelokathexis
Hyper IgM syndrome, type 1	X-L	Xq26	*CD40L*	↓IgG, IgA, IgE, autoimmune cytopenias
Hermansky-Pudlak syndrome, type 2	AR	5q14.1	*AP3B1*	↓IgG, partial albinism, platelet dysfunction
Griscelli syndrome, type 2	AR	15q21	*RAB27A*	Hemophagocytosis, partial albinism
Chediak-Higashi syndrome	AR	1q42.1-q42.2	*LYST(CHS1)*	Immunodeficiency, neurologic dysfunction, partial albinism

*Data compiled from Online Mendelian Inheritance in Man (OMIM; ncbi.nlm.nih.gov/omim) 193670, 308230, 608233, 607624, and 214500 and reference 520.
†Genetics: AD, autosomal dominant; AR, autosomal recessive; X-L, X-linked recessive.

electron microscopy, mitochondria show concentric, tightly packed cristae and occasional inclusion bodies; these are seen in various tissues including granulocyte precursors. Female carriers are healthy and hematologically normal, likely because of extreme skewing of X-inactivation.[509] The initial impression that Barth syndrome is a lethal infantile disease has to be modified. Age distribution in 54 living patients ranges from 0 to 49 years and peaks around puberty.[510]

The Barth syndrome gene was mapped to Xq28 which led to the cloning of the *G4.5* (*TAZ*) gene[511] and the various mutations that account for the phenotype. The *TAZ* gene produces several different mRNAs which predict resultant proteins called *tafazzins*. The role of the tafazzins is under study. Mutations in *TAZ* result in a decrease in tetralinoleoyl species of cardiolipin and an accumulation of monolysocardiolipin within cells.[512] This is a sensitive and specific marker for Barth syndrome.[513] Clinically, the cardiomyopathy dominates the clinical picture, but gingivitis, oral problems, and bacterial sepsis can be problematic. The mechanism of neutropenia has not been characterized. There are anecdotal reports that G-CSF is highly effective in correcting the neutropenia.

Glycogen Storage Disease Type 1b

Glycogen storage disease (GSD) type 1b is an autosomal recessive disorder that results from a deficiency of the glucose-6-phosphate translocase enzyme caused by mutations in the *G6PT1* gene. This enzyme transports glucose-6-phosphate into the lumen of the endoplasmic reticulum where it is hydrolyzed into glucose and inorganic phosphate.[514] Absence of the translocase, therefore, results in an inability to liberate glucose from glucose-6-phosphate. Consequently, patients with GSD type 1b are susceptible to fasting hypoglycemia and lactic acidosis, and have hepatomegaly, poor linear growth, delayed pubertal development, and other systemic complications.[515]

Depending on the type of mutations of *G6PT1*, patients with GSD 1b may or may not be neutropenic. Neutrophil dysfunction with defective chemotaxis and an impaired respiratory burst is an additional feature. Patients are consequently susceptible to recurrent infections and to inflammatory bowel disease. Infections most commonly involve the skin, perirectal area, ears, and urinary tract; however, severe or life-threatening infections, such as sepsis, pneumonia, and meningitis, may also occur. The most frequently isolated organisms include *Staphylococcus aureus*, group A streptococci, *Streptococcus pneumoniae, Escherichia coli,* and *Pseudomonas* species.

Neutropenia is often[516] but not always[514] associated with a hypocellular marrow and a maturation arrest at the myelocyte stage. Neutrophil apoptosis appears to be a central mechanism of the granulop oietic failure.[517] G-CSF therapy is extremely effective in almost all GSD 1b patients.[514,518] Marrow cellularity increases, the ANCs increase exuberantly, and impaired oxygen radical formation is corrected. The SCNIR has long-term prospective data on 29 GSD 1b patients receiving G-CSF therapy.[514] Forty percent had splenomegaly prior to starting G-CSF, with 81% developing splenomegaly by the first year of treatment and 100% by 3 years. Hypersplenism occurred in 5 patients, two of whom required splenectomy; in the other 3, hypersplenism resolved by reducing the G-CSF dose. Histology of the removed spleens showed extramedullary hematopoiesis. None of the SCNIR patients developed leukemia, but AML was reported in one non-registry case of GSD 1b while on G-CSF therapy.[519]

Kostmann Syndrome/Congenital Neutropenia: G-CSF versus HSCT as First-line Therapy

Therapeutic options for newly-diagnosed patients with KS must be constantly reevaluated. Since the inception of the Severe Chronic Neutropenia International Registry (SCNIR) in 1994, the recommendation for treating new KS patients with G-CSF has not wavered.[446,480] This opinion was underscored in a recent review[445] because more than 90% of KS patients show a robust neutrophilic response to G-CSF treatment. HSCT has been regarded as "salvage" therapy for patients who acquire G-CSF receptor mutations, clonal cytogenetic abnormalities, RAS mutations, or overt MDS/AML, or who fail to respond to G-CSF altogether.

This opinion requires ongoing review in light of the startling annual accrual of KS patients on G-CSF who transform to MDS/AML, usually with a fatal outcome regardless of treatment. The hazard of MDS/AML has increased over time from 2.9% per year after 6 years of therapy to 8% per year after 12 years on G-CSF.[486] After 10 years of therapy the cumulative incidence is 21% for MDS/AML. Remarkably, for those patients requiring 8 micrograms/kg/day of G-CSF or greater the cumulative incidence for MDS/AML after 10 years is 40%. Clearly, this is a strategic issue.

Discussions with stem cell transplant physicians have centered on the following. For KS patients transplanted with a fully matched donor *prior* to transforming to MDS/AML and in stable health, the chance for cure is at least 85%, possibly higher. The SCNIR data support this estimate.[499] Not only is the neutropenia fully corrected by HSCT, but the risk of MDS/AML is also eliminated. The onerous burden of daily subcutaneous injections is removed, the financial expense is relieved, and the side effects of G-CSF are prevented. Clearly, an 85% cure rate stacks up favorably against the 21% to 40% cumulative incidence of incurable MDS/AML in those on G-CSF over time. HSCT is a reasonable option as front-line therapy for these patients instead of G-CSF, and the option should be discussed fairly and sensibly with newly diagnosed patients and families.

Other Inherited Neutropenias

There are other inherited neutropenia disorders associated with specific mutant genes but they do not necessarily have the Kostmann marrow phenotype, nor is their pathophysiology necessarily similar (Table 28–8). Immune deficiency appears to be an important component of these syndromes. Unlike congenital neutropenia, these miscellaneous forms tend to have distinguishing physical abnormali-

ties such as partial albinism, and are not predisposed to MDS/AML.

Thrombocytopenia With Absent Radii (TAR)

Background

TAR syndrome was first described in 1929,[521] defined by Hall et al. in 1969,[522] and subsequently reviewed.[219,523,524] The two essential features of TAR syndrome are hypomegakaryocytic thrombocytopenia and bilateral radial aplasia with thumbs present. It is one of a group of inherited hematologic disorders that include Fanconi anemia and Diamond-Blackfan anemia with radial ray anomalies. The manifestation of the phenotype vary widely and patients can manifest with abnormalities involving skeletal, skin, gastrointestinal, brain, renal and cardiac systems. Most of the genetic evidence supports an autosomal recessive mode of inheritance for TAR syndrome because many families have been observed with more than one affected sibling. Each child in 2 sets of identical twins had TAR[525,526] whereas one of a pair of fraternal twins had the syndrome.[527] The possibility of autosomal dominant inheritance with variable penetrance for TAR syndrome has also been raised.[523,524,528] Almost always, parents of TAR patients are phenotypically normal. Females with TAR syndrome can conceive and give birth to hematologically and phenotypically normal offspring.

Three cases of acute myeloid leukemia[529–231] and one case of acute lymphoid (*lymphoidic*) leukemia[532] in TAR syndrome patients have been reported. Using a denominator of about 250 published cases of TAR,[7] four leukemic episodes (1%–2% crude rate) suggests a predisposition to hematologic cancer.

Etiology and Pathophysiology

Thrombocytopenia in TAR syndrome is the result of a defect in megakaryocytopoiesis and thrombocytopoiesis.[533] The gene responsible for the disorder has not been identified. However, an interstitial deletion of 200 kb on chromosome 1q21.1 in 30 TAR patients and 25% unaffected parents has been identified.[534] Whereas targeted disruptions of several *Hox* genes result in abnormal development of the mouse radius, the normal genomic sequences for human *HoxA10*, *HoxA11* and *HoxD11* were determined and sequenced in 10 TAR syndrome patients and the results were identical to normal controls.[535] In contrast to congenital amegakaryocytic thrombocytopenia, mutational screening of coding and promoter regions of the *MPL* gene by sequence analysis was normal in 10 TAR syndrome patients.[536,537]

Thrombopoietin levels in plasma or serum are consistently elevated in TAR syndrome thereby excluding a cytokine production defect as a cause for thrombocytopenia in this disorder.[537–539] Marrow CFU-Meg (CFU-Mk) progenitors are either absent,[533] or are present in low to normal frequencies[537,539] but are composed of small colonies in vitro[539] with abnormal morphology.[534] CFU-GM and BFU-E colony growth is often increased.

In a detailed study of $CD34^+$ cells, the thrombocytopenia of TAR syndrome was associated with a dysmegakaryocytopoiesis characterized by cells blocked at an early stage of differentiation.[537] Cells expressing CD41 without CD42 accumulated behind the block, and there was a decrease in c-mpl transcripts and mpl protein. The response of platelets to adenosine diphosphate or to the thrombin receptor agonist peptide, SFLLRN (TRAP), is normal in TAR patients.[538] However, in contrast to controls there is no in vitro reactivity of platelets from TAR patients to recombinant thrombopoietin as measured by testing thrombopoietin-synergism to ADP and TRAP in platelet activation.[538] Thrombopoietin-induced tyrosine phosphorylation of platelet proteins in this setting is completely absent or markedly decreased. The results indicate that there is a lack of response to thrombopoietin in the signal transduction pathway of c-mpl.

Figure 28–12 Radial aplasia with preservation of the thumb in a newborn with TAR syndrome.

No recurrent chromosomal changes are seen in TAR syndrome. Some karyotypic abnormalities found in a few patients are of unclear significance.[524] Despite one report of non-hematologic cancer in a presumed TAR patient whose lymphocytes demonstrated radiation hypersensitivity,[540] abnormal chromosomal breakage is not seen in TAR syndrome.[524]

Clinical Features

History and Physical Examination

The diagnosis is made in the newborn period because of the absent radii, and in about half of patients because of a petechial rash and overt hemorrhage such as bloody diarrhea. Patients have bilateral radial aplasia (Fig. 28–12) with preservation of thumbs and fingers on both sides. Additional upper extremity deformities include radial clubhands, hypoplastic carpals and phalanges, and hypoplastic ulnae, humeri, and shoulder girdles. Syndactyly and clinodactyly of toes and fingers are also seen. Characteristic findings include a selective hypoplasia of the middle phalanx of the fifth finger and altered palmar contours. Upper extremity involvement ranges from isolated absent radii to true, often asymmetric, phocomelia. The lower extremities are involved in about half of cases.[524] Malformations include hip dislocation, coxa valga, femoral torsion, tibial torsion, abnormal tibiofibular joints, small feet, and valgus and varus foot deformities. Abnormal toe placement is commonly seen, especially the fifth toe overlapping the fourth. Like upper limb involvement, lower extremity deformities range from minimal involvement to complete phocomelia. An asymmetric first rib, a cervical rib, cervical spina bifida, and a fused cervical spine can occur, but trunk involvement is usually minimal. Micrognathia has been associated with the TAR syndrome in up to 65% of cases.

Cardiac abnormalities occur in 15% of the patients.[219] The commonest are atrial septal defect, tetralogy of Fallot, and ventricular septal defect. Capillary hemangiomas are common (24%) as well as

redundant nuchal folds. Genitourinary tract malformations are detected in 23% of cases. About 95% of patients have short stature, 76% have macrocephaly, and 53% show facial dysmorphism. Two recent reports highlight structural brain abnormalities.[541,542] Additional findings are dorsal pedal edema, hyperhydrosis, and gastrointestinal disturbances such as diarrhea and feeding intolerance; almost one-half of patients are intolerant of cow's milk.[524]

Prenatal diagnosis can be made by ultrasound imaging of absent radii with thumbs present[543] and by quantitating platelet numbers obtained by fetoscopy or cordocentesis. In one case after the diagnosis was made, a prenatal in utero platelet transfusion was given to effect a safe delivery.[544]

Laboratory Findings

Thrombocytopenia as a result of bone marrow underproduction is a consistent finding. Marrow specimens show normal to increased cellularity with decreased to absent megakaryocytes. The erythroid and myeloid lineages are normally represented. When a few megakaryocytes can be identified in biopsies, they are small, contain few nuclear segments, and show immature nongranular cytoplasm. If platelet counts increase spontaneously in patients after the first year of life, megakaryocytes increase in parallel and appear more mature morphologically. At diagnosis, leukocytosis is seen in the majority of patients and is sometimes extreme to over 100,000/μL with a "left shift" to immature myeloid forms. The cause of this leukemoid reaction is unclear but it is usually transient and subsides spontaneously. If anemia is present, the likeliest etiology is from blood loss caused by thrombocytopenia. When platelet numbers are adequate for study, their size is generally normal and routine testing of function is unremarkable,[545] although some patients may show abnormal platelet aggregation and storage pool defects.[546–548] Unlike some of the other inherited marrow failure syndromes, red cell size and fetal hemoglobin levels are normal.

Differential Diagnosis

There are important clinical differences that distinguish TAR syndrome from Fanconi anemia. In Fanconi patients, when radii are absent, the thumbs are hypoplastic or absent. Fanconi patients do not have skin hemangiomas like some TAR patients, whereas TAR patients do not show abnormal skin pigmentation like 55% of Fanconi patients. Confirmation of Fanconi anemia is made by the clastogenic chromosome stress test showing increased fragility and by mutational analysis. TAR patients do not have increased chromosomal breakage.

Some infants with trisomy 18 have absence or hypoplasia of radii and thrombocytopenia. Similar to Fanconi anemia, however, thumbs are absent in trisomy 18 if radii are absent, and the disorder can also be distinguished from TAR syndrome cytogenetically. As summarized,[219] there are several syndromes with radial abnormalities but with *normal* platelet counts that can be diagnosed by mutational gene analysis. These include Roberts syndrome (mutant *ESC01*), Holt-Oram syndrome (mutant *TBX5*), and the clinical spectrum of three disorders caused by mutant *RECQL4* (Rothmund-Thomson syndrome, Baller-Gerold syndrome, and the RAPADILINO syndrome).

Therapy and Prognosis

The risk of hemorrhage is greatest in the first year of life. Deaths are usually caused by intracranial or gastrointestinal bleeding. If patients survive the first year, platelet counts spontaneously increase inexplicably to levels that are hemostatically safe and which do not require platelet transfusional support. A minority of patients have sustained, profound thrombocytopenia that does not improve spontaneously. A summary of published cases of TAR syndrome[7] shows an actuarial survival curve plateau of 75% by age 4 years. Many of these publications antedated the modern use of platelet transfusions so the survival is likely much better currently. TAR patients do not evolve into marrow failure with pancytopenia but may develop acute leukemia in 1% to 2% of cases.

Platelet Transfusions

As in other inherited marrow failure disorders associated with thrombocytopenia, platelet transfusions should be used judiciously. Clinical bleeding or prophylaxis for orthopedic surgical procedures is an appropriate indication. Persistent platelet counts below 10,000/μL may require preventative platelet transfusions on a regular basis, especially in the first year of life when the expectation is that a spontaneous improvement in platelet number will ensue with time in most infants. Single donor platelets are preferred to multiple random donor platelets to minimize the risk of alloimmunization. HLA-partially-matched or fully-matched donors for platelets may be required if patients become refractory to transfusions.

Other Therapies

Supportive management is the mainstay but in exceptional situations profound, persistent life-threatening thrombocytopenia can be successfully treated by HSCT.[549] The role of thrombopoietin therapy in the management of TAR patients is unclear. Elevated serum thrombopoietin levels at baseline[538] may predict for a poor response to the cytokine therapy. IL-11, another thrombopoietic cytokine, has not been studied in clinical trials; however, endogenous IL-11 serum levels in TAR patients are also elevated.[538] One child had a moderate, increase in platelet numbers while receiving IL-6,[550] but its use causes fevers and chills and its clinical development has been halted. Androgens, corticosteroids, and splenectomy are ineffective therapies for TAR syndrome.

Congenital Dyserythropoietic Anemias

Background

The designation *congenital dyserythropoietic anemia* (CDA) refers to a family of inherited refractory anemias characterized by marrow erythroid multinuclearity, ineffective erythropoiesis, and secondary hemosiderosis. The ineffective erythropoiesis is reflected by marrow erythroid hyperplasia, inappropriately low reticulocyte counts for the level of hemoglobin, and intramedullary red cell destruction. Splenomegaly and chronic or intermittent jaundice are additional features. Granulopoiesis and thrombopoiesis are normal. Although these disorders are not bone marrow failure syndromes per se, they are genetically transmitted and result in anemia with a blunted erythropoietic response.

Three forms of CDA have been described as well as a number of variants.[551] An arbitrary classification used in practice is based on the inheritance pattern, the peripheral blood and bone marrow morphology, and the serologic findings in each case. The distinguishing features of the three classical types of CDA are as follows:

- Type I: Autosomal recessive; macrocytosis; megaloblastic erythroid precursor cells; 2% to 5% binucleated erythroid precursor cells; internuclear chromatin bridges; negative Ham test.
- Type II: Autosomal recessive; normocytosis; normoblastic erythroid maturation; 10% to 35% binucleated late normoblasts; positive Ham test.
- Type III: Autosomal dominant; macrocytosis; megaloblastic erythroid maturation; giant multinucleated erythroid precursors with up to 12 nuclei per cell; negative Ham test.

The designation "type IV" has been used for decades to classify cases of morphologic type II CDA with a negative Ham acidified

Inherited Marrow Failure and Malignant Hematopoietic Transformation

Historically, the inherited marrow failure syndromes were classified as "benign" hematology in order to contrast sharply with hematologic cancer. Patients with Kostmann syndrome/congenital neutropenia, Shwachman-Diamond syndrome, Fanconi anemia, dyskeratosis congenita, congenital amegakaryocytic thrombocytopenia, Diamond-Blackfan anemia, or TAR syndrome often died early in life from complications of cytopenias. However, in the current era of advanced supportive care and availability of recombinant cytokines and other effective therapeutics, patients with these conditions usually survive the early years of life and beyond. With the extended life span of patients, a new natural history for some of these disorders is evident. One of the most sobering observations is that the seven disorders cited above confer an inordinately high predisposition to MDS and AML. Thus, the distinction between "benign" and "malignant" hematology in the context of the inherited marrow failure disorders has become blurred, and a new clinical and hematologic continuum is evident.

Carcinogenesis occurs as a multistep sequence of events that is driven by genetic damage and by epigenetic operative factors. In the traditional view, the initiation of cancer starts in a normal cell through mutations from exposure to carcinogens. In the proliferative phase that follows, the genetically altered, initiated cell undergoes selective clonal expansion that enhances the probability of additional genetic damage from endogenous mutations or DNA-damaging agents. Activation of protooncogenes, inactivation of tumor-suppressor genes, or inactivation of genomic stability genes may be central in this process. Finally, during malignant conversion and cancer progression, malignant cells show phenotypic changes, gene amplification, chromosomal alterations, and altered gene expression.

With respect to the seven inherited marrow failure syndromes that are predisposed to develop hematologic cancers, there is reason to believe that leukemogenesis is also a multistep process. The first genetic "hit" or leukemia-initiating step may be the syndrome-specific inherited genetic abnormality itself, which initially manifests as the single- or multiple-lineage marrow failure state. The "predisposed" progenitor, already initiated, could conceptually develop decreased responsiveness to the signals that regulate homeostatic growth, terminal cell differentiation, or programmed cell death. Leukemic promotion and progression with clonal expansion leading to MDS or AML could then ensue readily. Since many of the mutant genes that produce the inherited marrow failure syndromes have been discovered, the nature of the leukemogenic-initiating events in these conditions should become evident.

Three of the syndromes illustrate the point. The best example is the multistep evolution of leukemic transformation over time in patients with congenital neutropenia while taking G-CSF. The acquisition of activating RAS oncogene mutations, cytogenetic abnormalities involving primarily –7, 7q- and +21, and G-CSF receptor mutations in the majority of patients who transform is remarkable.

Other than clonal cytogenetic changes, we know little about the timeline or sequence of events that characterize the malignant phenotype of Shwachman-Diamond syndrome. It is striking, though, that the syndrome from early age already shares many of the findings of de novo adult MDS including abnormal hematopoietic colony growth, abnormally short leukocyte telomeres, elevated apoptotic index mediated by FAS/FAS ligand, an abnormal immune system, an aberrant marrow microenvironment that shows impaired support of normal hematopoiesis, and marrow neoangiogenesis. Many if not all of these findings may evolve in utero.

Finally, Fanconi anemia has a "short cut" mechanism to leukemic conversion. Biallelic mutant genes from conception result in genomic instability, compromised DNA repair and chromosome breakage. The opportunities for hematologic cancer in this setting are infinite. Actuarial data from the IFAR[93] showed that the risk of acquiring clonal cytogenetic abnormalities was 67% by 30 years of age in patients with bone marrow failure. The actuarial risk of MDS or AML was 52% by 40 years of age. This steady tempo of leukemic evolution implies a stepwise acquisition over time of additional, critical genetic "hits" prior to overt MDS/AML.

serum test.[552,553] There are also several other forms of CDA that are distinct from CDA types I, II, III, and IV. These other forms have been identified in 3 or more families and have been tentatively classified into CDA groups (not types) IV, V, VI, and VII.[554,551] The growing number of variants[555–562] underscore the complex nature of CDA and the need to reclassify these disorders accurately when the molecular basis for the various types and groups becomes clear.

Etiology, Genetics, and Pathophysiology

The gene for CDA I was mapped to chromosome 15q15 using homozygosity linkage mapping in a cluster of highly inbred Israeli Bedouins.[563] The gene responsible, *CDAN1*, was then identified.[564] The gene product, codanin-1, may be involved in nuclear envelope integrity, conceivably related to microtubule attachments. The gene for CDA II (*CDAN2*) has not been identified but it maps to 20q11.2.[565] Nor has the gene for CDA III (*CDAN3*) been discovered, but there is close linkage of the locus at 15q21.[566]

The defect that accounts for each type of CDA is found in all of the erythroid progenitors rather than in a subpopulation of cells.[567,568] Some pertinent biochemical abnormalities are related to the etiology of CDA I,[569–573] but little more is known about pathogenesis. In comparison, the pathogenesis of CDA II has been almost completely clarified. At the stem cell level, in vitro culture of CDA II erythroid progenitors produces CFU-E and BFU-E colonies with erythroblast multinuclearity.[567] Initially, studies of peripheral blood CDA II red cells identified a number of chemical abnormalities including unbalanced globin chain synthesis,[571] increased membrane glycolipids,[574] and altered red cell membrane protein patterns demonstrated by two-dimensional electrophoresis.[573] Furthermore, glycoproteins on CDA II red cells were found to have an abnormal carbohydrate structure leading to aberrant reactivity with anti-i sera.[575] Additional data suggested that the IgM antibody responsible for hemolysis in the acidified-serum lysis test (Ham test) recognizes an abnormal glycolipid structure sharing homology with the i and I antigens.[576] Thus, a variety of data predicted that abnormalities in the glycosylation pathway were involved in the etiology of CDA II.

Indeed, there are two distinct defects in the glycosylation enzymatic pathway that occur in CDA II:[577,578] α-mannosidase II deficiency and *N*-acetylglucosaminyl transferase II deficiency, although the genes encoding these proteins were excluded as the CDA II mutation.[579] As a result of the former abnormality, addition of new sugar moieties to the oligosaccharide core structure is impaired. A defect, probably in the promoter region of the gene encoding for α-mannosidase II, has been identified. There is also a report that multinucleated erythroblasts are formed in vitro when normal bone marrow is cultured with an inhibitor of α-mannosidase II.[577] Also, low levels of *N*-acetylglucosaminyl transferase II, the enzyme responsible for addition of an *N*-acetylglucosamine residue to one of the arms of the core, result in glycoproteins with truncated oligosaccharides.

A third enzymatic defect has been described in a variant case of CDA II.[580] Low levels of the membrane-bound form of galactosyl

transferase, involved at various stages of oligosaccharide synthesis, severely affect processing and lead to the presence of primitive high-mannose core structures on glycoproteins.[580]

All three of these enzymatic deficiencies lead to abnormal oligosaccharides on major erythrocyte proteins such as the anion transporter, Band 3.[581,582] In addition to its other functions, this glycoprotein plays a critical role in the organization of the membrane skeleton that determines normal red cell strength, flexibility, and shape. Abnormal glycosylation of Band 3 may cause it to cluster on the cell surface.[583] Such clustering could cause disruption of the structural network of the erythrocyte and its precursors, thereby leading to their premature demise.

Defective glycosylation on the red blood cell surface may also affect the regulation of complement on the surface of erythrocytes. Enhanced functional activity of the alternative pathway C3 convertase and of the membrane attack complex may result from the improper glycosylation of glycophorin A, which has been proposed to serve as a complement regulatory protein.[584]

CDA III is the rarest of the three classical forms of CDA and little is known about its pathophysiology. However, in some dominantly inherited and sporadic cases of CDA III, electron microscopy reveals that an occasional erythroblast section contains stellate or branching electron-dense intracytoplasmic inclusions.[585–587] These are morphologically indistinguishable from those in HbH disease and consists of precipitated β-globin chains. In one sporadic case with such inclusions, the α:β globin chain synthesis ratio was 0.76 and DNA studies demonstrated the presence of four α genes and excluded two of the common mutations of nondeletion α thalassemia.[585]

Clinical Features

History, Physical Examination, and Laboratory Findings for Each CDA Type

Some features are shared by all forms of CDA and some features are specific for each type. In general, for all types there is a wide variation in age of onset of clinical problems related to CDA. Most patients are diagnosed in late childhood or adolescence; however, a few CDA cases have been reported in newborn infants presenting with hydrops fetalis.[588–590] Clinical manifestations may include intermittent jaundice and dark urine caused by increased hemoglobin catabolism, or signs and symptoms of anemia. Rarely, hyperbilirubinemia without anemia may be the initial presentation of CDA patients. The degree of splenomegaly and hepatomegaly is quite variable. Cholelithiasis may be present as a consequence of chronic hyperbilirubinemia. In some older patients, evidence of hemosiderosis (skin hyperpigmentation, diabetes mellitus, hypogonadism, or delay of secondary sexual characteristics) is often present. It is noteworthy that hemosiderosis occurs in both transfused and nontransfused CDA patients. In the latter, iron overload is a direct consequence of high plasma iron turnover and low iron utilization by normoblasts caused by ineffective erythropoiesis. Gastrointestinal absorption of iron is also increased. Large series of patients with CDA I and CDA II, respectively, illustrate the spectrum of clinical manifestations of these disorders.[591–594]

CDA Type I. CDA I is inherited in an autosomal recessive manner. The disorder is caused by biallelic mutant *CDAN1*. In several reported families, more than one sibling was affected, and the disorder has been seen in fraternal and identical twins. The onset of anemia, jaundice, or other symptoms may be noted at any age especially in neonates. Eighty percent of infants in a recent large series required blood transfusions during the first month of life.[595] One case was reported with fetal anemia requiring intrauterine exchange transfusions at 28 and 30 weeks' gestation.[596] Affected patients often manifest some degree of icterus and splenomegaly.

CDA I has been associated with a variety of congenital anomalies. As summarized,[551] the following have been catalogued: patches of brown skin pigmentation, syndactyly in the feet, absence of phalanges and nails in the fingers and toes, an additional phalanx, duplication or hypoplasia of metatarsals, short stature, pigeon chest deformity, varus deformity of hips, flattened vertebral bodies, a hypoplastic rib, congenital ptosis, Madelung deformity, and deafness. The pigmentation, syndactyly and absence of phalanges and nails are not common in CDA I patients but appear to be quite specific for this subtype. Dysmorphic features are seen in up to 65% of patients. Three siblings from a Bedouin family presented with neonatal pulmonary hypertension.[597] In a French family, three siblings had sensorineural deafness and a lack of motile sperm cells.[564]

The degree of anemia is usually mild to moderate (hemoglobin in the range of 6.6 to 11.6 g/dL), and red cells appear macrocytic. Peripheral blood red cell morphology is characterized by anisocytosis and poikilocytosis, and occasionally Cabot rings are seen. Cabot rings appear to be unique to CDA I and are not seen in types II and III. White blood cells and platelets are normal. Examination of the bone marrow reveals erythroid hyperplasia with some megaloblastic erythropoiesis, and a small number of erythroblasts with dyserythropoietic features. The unique morphologic abnormality seen in CDA I is the presence of chromatin bridges between nuclei of two separate erythroblasts, a reflection of impaired cellular division (Fig. 28–13). This internuclear bridging of erythroblasts seen with light microscopy is also a common feature in myelodysplastic syndromes. Electron microscopy reveals additional abnormalities that include widening of the nuclear membrane pore space with cytoplasmic invagination into the nucleus, separation of nuclear chromatin, and chromatin condensation, all of which give the general appearance of a spongy nucleus (Fig. 28–14). Dyserythropoiesis seems limited mostly to more mature red cell precursors. In contrast to CDA II, there are no unique serologic features.

The defect in CDA I is at the stem cell level. The numbers of CFU-E and BFU-E colonies are normal but they contain a mixture of normal and abnormal cells when examined by electron microscopy.[598] This suggests that the abnormality is expressed variably in the mature progeny of each stem cell. Erythroid precursors also demonstrate S phase arrest and morphologic features of apoptosis.[599] In some CDA I patients, hemoglobin A_2 levels are increased. Also, some cases show unbalanced globin chain synthesis. Patients do not have thalassemia and the cause of these findings is not known.[551]

CDA Type II (HEMPAS). CDA II is commonly known as HEMPAS, an acronym for *H*ereditary *E*rythroblastic *M*ultinuclearity with a *P*ositive *A*cidified *S*erum test.[600] It is inherited in an autosomal recessive manner but the mutant gene is not known. There is overlap of some clinical and laboratory manifestations between CDA I and CDA II, but there are three major differences. The first is that the magnitude of anemia is usually more severe and patients, especially children, often require red cell transfusions.[593] Peripheral blood red cells are usually normocytic but show anisocytosis and poikilocytosis (Fig. 28–15). The second difference is that the bone marrow in CDA II reveals more abnormal erythroblasts with binuclearity in up to 35% late erythroblasts, as well as multinuclearity, and abnormal lobulation (Fig. 28–16). These nuclear abnormalities are seen only in the late erythroblasts, not in basophilic erythroblasts. Karyorrhexis is commonly observed, and pseudo-Gaucher cells may be present representing the ingestion of debris by histiocytic cells from ineffective erythropoiesis. Electron microscopy of late erythroblasts also reveals an excess of endoplasmic reticulum parallel to the cell membrane, giving the appearance of a double cell membrane (Fig. 28–17).[601,602] A third difference, which is also a pathognomonic finding, is that CDA II red cells are lysed by acidified (pH 6.8) sera obtained from approximately 30% to 60% of fresh ABO-compatible sera from normal persons (Ham test), but there is no lysis when red cells are incubated with the patient's own acidified serum. This lysis is a result of a naturally occurring IgM antibody that recognizes an antigen on CDA II cells and binds complement; this antibody can be removed by preincubating normal sera with HEMPAS erythrocytes. However, the specific HEMPAS antigen recognized by this antibody is not known. In contrast to HEMPAS, the erythrocytes of patients with paroxysmal nocturnal hemoglobinuria (PNH) undergo lysis when the acidified serum is from the PNH patient or from

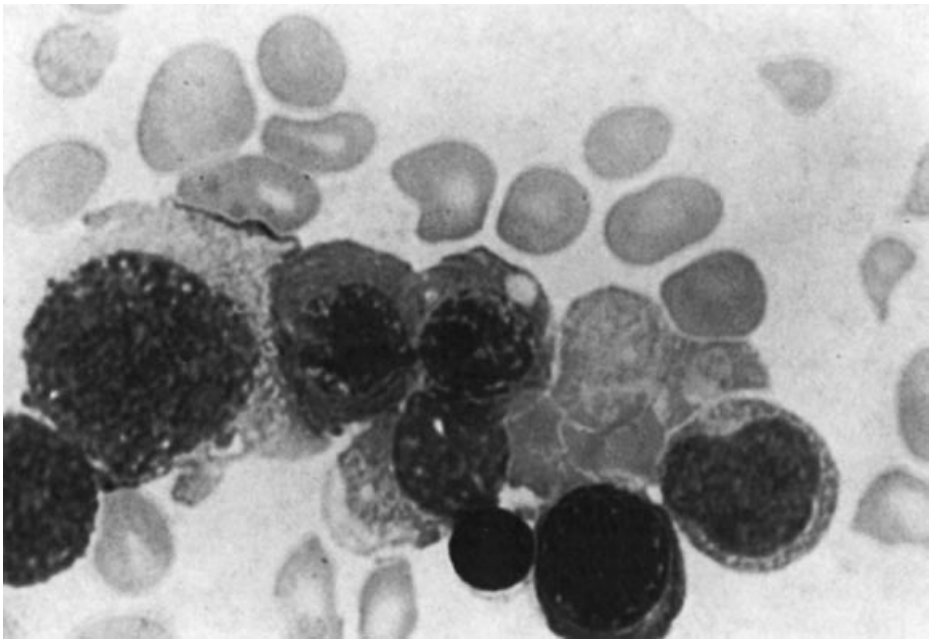

Figure 28–13 Bone marrow from patient with type I CDA. Erythroblasts are connected by internuclear bridges between two cells. *(Provided by Dr. Jean Shafer, Rochester, NY).*

normal donors. Another difference is that PNH erythrocytes undergo lysis in isotonic sucrose, (sugar water test), whereas HEMPAS red cells do not lyse in isotonic sucrose.

The erythrocytes from patients with CDA II also exhibit an increased agglutinability and lysis to anti-i and anti-I sera and manifest increased expression of both antigens. These surface antigens are complex carbohydrate structures found predominantly on fetal and adult red cells, respectively. Increased expression of i antigen can be demonstrated on all red cells in CDA II using fluorescent labels. Relatives of patients with CDA II who have normal marrows but increased agglutinability to anti-i appear to be heterozygote carriers of this disorder.[603] HEMPAS erythrocytes bind a normal amount of complement (C1), but more antibody and less C4 than normals.[604] This causes binding of an excess of C3 and hemolysis.

The number of erythroid progenitors is probably normal in marrow and blood. Although one study found only normal morphology of the erythroblasts produced in culture,[605] subsequent studies reported multinuclearity similar to that seen in the bone marrow.[606] As in CDA I, the defect in CDA II is in the erythroid progenitor cell and is expressed variably in more mature erythroblasts.

CDA II patients may develop progressive, lifelong iron overload even in the absence of transfusions,[533] and approximately 20% develop cirrhosis as a consequence. Splenomegaly is a feature in the majority of CDA II cases. A number of other clinical associations with CDA II have been reported such as mental retardation, Sweet syndrome, von Willebrand disease, and Dubin-Johnson syndrome, among others.[607–609] Rather than true associations, it is likely that the majority represent coincidental occurrences. An adult patient was reported with an extramedullary hematopoietic mass in the posterior mediastinum that was a result of marrow expansion associated with ineffective erythropoiesis.[610] In a retrospective study of 41 patients, coinheritance of Gilbert syndrome was associated with a significantly increased risk of hyperbilirubinemia and early-onset gallstone formation.[594]

CDA Type III. Based on reported CDA cases, type II is the most common, type I is next, and CDA III is the rarest of the three major forms. In contrast to the other major forms, CDA III is inherited as an autosomal dominant disorder[611–614] although sporadic cases have also been described.[615,616] These latter cases with hematologically normal parents and relatives may represent autosomal recessive inheritance, or may have been caused by spontaneous dominant mutations.[617] In a Swedish family with 31 cases inherited in an autosomal dominant mode, an excess number of cases of monoclonal gammopathy and myeloma have occurred.[618] Also, an adult patient with CDA III was described with T-cell non-Hodgkin lymphoma.[619] These cases, plus a case of Hodgkin disease occurring in an additional patient,[620] may indicate an increased incidence of lymphoproliferative disease in CDA III.

In CDA III, splenomegaly is usually minimal or absent. The anemia is usually mild to moderate, but transfusion-dependent patients have been observed.[621] The circulating red cells can be normal or mildly macrocytic. Bone marrow examination shows erythroid hyperplasia. Giant erythroblasts with up to 12 nuclei are the most distinctive feature of CDA III observed on light micro-

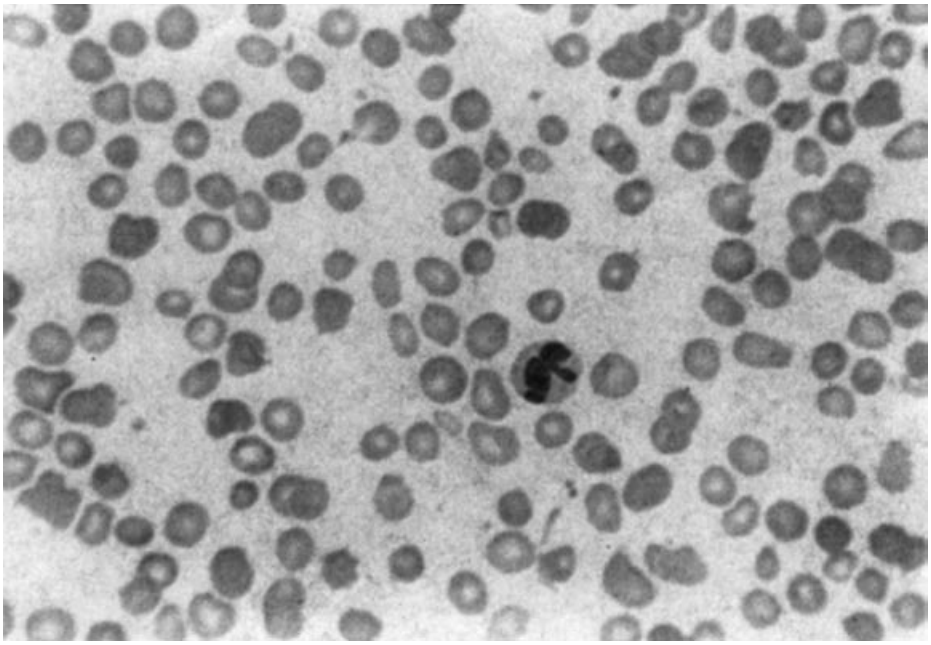

Figure 28–15 Peripheral blood smear from a patient with CDA type II. Note the marked variation in size and shape.

scopic examination of the bone marrow. These may appear similar to some of the large multinucleated cells seen in CDA II (Fig. 28–16). Abnormally large lobulated nuclei and discordance in nuclear maturation are also found. Although they are hallmarks of CDA III, these findings are not pathognomonic and may be seen in erythroleukemia. Electron microscopy demonstrates nuclear clefts and blebs, autolytic areas within the cytoplasm, and iron-filled mitochondria.

The acidified-serum lysis test is negative in CDA III. Agglutination and lysis of erythrocytes to anti-i antibody has only been examined in a few cases of CDA III with conflicting findings.[615,617] Serum thymidine kinase was measured in 20 CDA III patients and 10 healthy siblings.[622] Elevated thymidine kinase was found in all 20 cases but was normal in the siblings. It is suggested that measuring thymidine kinase levels can allow clinicians to discriminate between affected individuals and healthy siblings without performing a marrow aspirate.

Other CDAs, Nonclassifiable and Classifiable. Dozens of cases of CDA have been reported that do not conform with the classification of types I, II, III, and IV (Ham test-negative type II).[556,623] The major features of some of the earlier variant cases were reviewed[624] and representative findings are summarized here. In two kindreds, apparent CDA IV was inherited in an autosomal dominant mode. Long-lasting erythroblastosis occurring after splenectomy of type IV patients has been attributed to impairment of the denucleation of erythroblasts.[624] Unbalanced globin-chain synthesis with excess production of α-chains was documented in several patients. In one kindred, a disorder with features of both thalassemia and hereditary erythroid multinuclearity was dominantly transmitted.[625] In other cases there were also differences in the degree of agglutination by anti-i antibodies and in the concentrations of hemoglobins F and A_2.

Possible cases of CDA have been observed with lifelong anemia, which were probably inherited.[626] These were characterized by marked aniso- and poikilocytosis and occasional teardrop and fragmented

erythrocytes in the peripheral blood. Hyperplastic marrows showed megaloblastoid features without multinuclearity or ringed sideroblasts,[626] but a case with prominent ringed sideroblasts was also described.[627] Neutropenia or thrombocytopenia has been observed in some of these patients. Cytogenetic studies of marrow revealed no clonal chromosomal abnormalities. Reticulocyte response to anemia was absent or inappropriately low in all. Most case studies of parents failed to reveal abnormalities, suggesting an autosomal recessive mode of transmission.

In an attempt to sort out some of these CDAs, a phenotypebased classification was proposed that assigns patients to 1 of 4 groups (not types) designated group IV, V, VI, and VII.[551] To qualify for inclusion in this classification, each group contains cases from three or more unrelated families. The features of each are as follows:

CDA group IV. This group has severe anemia, transfusion dependence from birth, marked erythroid hyperplasia, normoblastic or mild to moderate megaloblastic changes, up to 8.0% marrow erythroblasts with markedly irregular or karyorrhectic nuclei, and an absence of precipitated protein within erythroblasts by electron microscopy. An infant with group IV CDA presented with hydrops fetalis. The spleen is enlarged. The inheritance is not clear.

CDA group V. Patients have normal or near-normal hemoglobin levels, a normal or slightly elevated MCV, and an increased serum unconjugated bilirubin. The marrow shows marked erythroid hyperplasia, and normoblastic or mild to moderate megaloblastic changes. The spleen may be palpable. The condition has been previously described as "primary shunt hyperbilirubinemia." Inheritance is variable and appears to be autosomal recessive in some cases but possibly autosomal dominant or X-linked in others. In CDA group V, the bone marrow macrophages phagocytose morphologically normal but functionally abnormal erythroblasts.

CDA group VI. This group is characterized by marked macrocytosis (MCV 119–125 fL) with little or no anemia and grossly megaloblastic erythropoiesis. There may be mild jaundice and an increased serum bilirubin. The differential diagnosis includes orotic aciduria and thiamine-responsive anemia. Vitamin B_{12} and red cell folate levels are normal.

CDA group VII. These patients have severe transfusion-dependent anemia from birth, marked erythroid hyperplasia, normoblastic or nonspecific dysplastic changes, markedly abnormal nuclear shapes in many erythroblasts, and intraerythroblastic inclusions resembling precipitated α globin chains. The inclusions do no react with monoclonal antibodies against α and β globin chains. The diagnosis requires the exclusion of β-thalassemia trait in the parents.

Differential Diagnosis

Dyserythropoiesis with erythroblast multinuclearity is seen with other hematologic disorders but these can be readily distinguished from CDA. The megaloblastic anemias have a different clinical presentation and are identified in the laboratory by the presence of hypersegmented neutrophils, decreased red cell folate values, or reduced serum levels of vitamin B_{12}. The myelodysplastic syndromes may manifest as an isolated refractory anemia but they often present with bi- or tri-lineage cytopenias that contrast sharply with CDA. The FAB and WHO myelodysplastic syndrome subsets may also show marrow granulocytic and megakaryocytic morphologic abnormalities, the presence of myeloblasts, ringed sideroblasts, and clonal cytogenetic changes. Erythroleukemia (AML, M6) is another cause of marked dyserythropoiesis but typically there is pancytopenia, the erythroblasts are avidly positive for the periodic acid-Schiff stain, and the marrow cells may show a clonal cytogenetic marker. The β-thalassemia syndromes differ from CDA by the presence of marked microcytosis with elevated levels of hemoglobin A_2, fetal hemoglobin, or both.

Therapy and Prognosis

In general, the CDAs are associated with a favorable long-term prognosis. For example, CDA I can be diagnosed late in life.[628] One case was associated with a relatively benign course over a 30-year follow-up.[629] Anemia is typically mild in most cases of CDA and requires no intervention, but in more severe presentations, especially those requiring transfusional support, splenectomy may be beneficial. Most of the experience showing an improvement in hemoglobin levels after splenectomy has been in CDA II; the benefit of splenectomy in CDA I is less clear.[621,630,631] Splenectomy may cause a persistent thrombocytosis in CDA types I and II and contribute to the development of Budd-Chiari syndrome[551] and to portal vein thrombosis.[552]

Treatment of all forms of CDA with androgens, corticosteroids, vitamin E, vitamin B_{12}, folic acid, pyridoxine, or iron is ineffective in ameliorating the anemia. Iron therapy is also contraindicated because of the underlying propensity for hemosiderosis secondary to ineffective erythropoiesis, transfusional iron overload, and increased gut iron absorption. Even if regular red cell transfusions are not initiated, patients should be routinely monitored for evidence of iron overload. Iron chelation with daily subcutaneous infusions of deferoxamine (Desferal) has been underused in CDA even though deaths have been recorded from hemochromatosis. The value of the oral iron chelators deferiprone (L1) and deferasirox (Exjade) has not been defined yet for the CDAs.

Phlebotomy has been carried out to remove iron in CDA patients but this could result in a worsening of the anemia and theoretically enhance gut iron absorption. An additional concern is that CDA patients seem predisposed to hepatic cirrhosis irrespective of body iron burden.[632] The pathogenesis of this is unclear.

Interferon α-2a, interferon α-2b, and peg-interferon α-2a increase hemoglobin levels in CDA I patients who require repeated transfusions for moderately severe anemia.[551,633,634] Erythrokinetic studies demonstrate a striking reduction of ineffective erythropoiesis in patients receiving interferon, and electron microscopy shows a reduction in nuclear structural abnormalities. Interferon therapy should also be considered in moderately anemic CDA I patients prior to treatment of iron overload by phlebotomy. CDA type II patients do not respond to interferon α.[551]

Hematopoietic stem cell transplantation has been curative in a few severe cases of CDA including transfusion-dependent CDA type I,[635] CDA type II,[636] Ham test–negative CDA type II,[637] and an unclassified CDA.[638]

Asymptomatic extramedullary hematopoiesis may mimic tumors of the mediastinum, abdomen, and vertebral column.[610,639,640] Because of the increased red cell production that occurs, the development of sites of extramedullary hematopoiesis may result in an amelioration of the degree of anemia.[641] Technetium-99m sulfur colloid scintigraphy is useful in delineating the extent of these regions.[640]

Future Directions

Identification of the various mutant genes for the CDA types will facilitate a more precise classification than the phenotype-based system used currently. The wild-type protein product of *CDAN1* requires further research to clarify its function in health, and its role in producing CDA type I when mutant. CDA types I and II mimic thalassemia and show unbalanced globin chain synthesis; this requires explanation. Strategies are required for managing iron overload similar to those for Diamond-Blackfan anemia and thalassemia major. In this regard, the therapeutic benefit of the oral iron chelators deferiprone and deferasirox should be explored fully.

CHAPTER 29

APLASTIC ANEMIA

Neal S. Young and Jaroslaw P. Maciejewski

Aplastic anemia (AA), the paradigm of bone marrow failure syndromes, is most simply defined as peripheral blood pancytopenia and a hypocellular bone marrow (Fig. 29–1). From epidemiologic and clinical features, pathophysiologic studies, and response to therapy, AA is a distinctive disease. However, the diagnosis of AA requires excluding other causes of pancytopenia (Table 29–1). AA can occur as a primary hematologic disorder, most often idiopathic, or apparently result from various proximate causes, including obvious physical and chemical toxins but also drugs and viruses that can act indirectly. Although AA is usually characterized by a severe diminution in bone marrow function that affects all the hematopoietic lineages, granulocyte, platelet, and red blood cell (RBC) levels may not be depressed uniformly, and less severe degrees of marrow hypoplasia and odd combinations of bicytopenias and monocytopenias can occur. AA can be especially difficult to distinguish from hypocellular forms of myelodysplasia, a diagnostic dilemma that can rest on real biologic similarities. Even typical AA can vary in its clinical presentation and course, from a fulminant illness marked by continuous or recurrent hemorrhage and major infections to an indolent process manageable by transfusion therapy alone.

HISTORY

The study of bone marrow failure dates to 1888, when Paul Ehrlich described a young woman who died after an explosive short illness marked by severe anemia, bleeding, and high fever. As a pathologist, Ehrlich was struck by the absence of nucleated RBCs and the fatty quality of the femoral marrow.[1] Vaquez and Aubertin, in a 1904 case report of "pernicious anemia with yellow marrow," named the disease and emphasized a pathophysiology of "*anhematopoiesis*."[2] Cabot stressed the marrow's distinctive pathology and the need for its examination in making the diagnosis.[3] Tissue from patients with early cases of AA could only be examined at autopsy, and in practice, pancytopenia was often equated with AA. The etymologic root of the term *aplastique* is the Greek verb πλ¿ϑω, to create and give shape to(¿πλαζτκ(, the adjective, unformed). Inferences about the cause of the disease were made from the bone marrow appearance. The aplastic variety of pancytopenia was distinguishable from secondary cellular or regenerative pernicious anemias, and AA was recognized as primary and caused by failed blood cell production.[2] Pathologically, the watery, yellow marrow seen at autopsy uniquely characterized the aplasia, but the limited and rather general clinical signs were less helpful in distinguishing this type of aregenerative marrow failure from other anemias.[4]

CLASSIFICATION

AA is a major sequela of irradiation and exposure to cytotoxic chemotherapy. It has been associated with the use of chemicals and drugs, viral infections, and other diseases (Table 29–2). Most patients have an idiopathic form of the disease, meaning that the cause is unknown. Too strict a division of cases into categories can obscure important pathophysiologic relationships. Historically, the relation between clinical associations and causation can be neither direct nor reliable. Thus the basis for assigning a particular case to a particular cause has depended on the history. How closely is the patient questioned? How biased are the inquiries? How conscientiously is a possibly significant but distant toxic exposure sought? How exaggerated is a brief episode?

EPIDEMIOLOGY

Incidence

The largest and most comprehensive study of the epidemiology of bone marrow failure was the International Aplastic Anemia and Agranulocytosis Study (IAAAS), conducted in Europe and Israel from 1980 to 1984.[5] This study was performed prospectively and applied strict case definition to pathologically confirmed cases. Using stringent criteria, the overall annual incidence of AA was 2 cases per 1 million people. Other subsequent studies of similar design have confirmed this figure.[6] The incidence rates reported in the IAAAS are threefold to fourfold lower than rates reported in many earlier, mainly retrospective, and far less well-designed surveys.

A remarkable feature of the epidemiology of AA is the unexplained geographic variation in its incidence. The incidence of AA in Bangkok and two rural regions of Thailand has been accurately determined using the same methods as employed by the IAAAS researchers in Europe and Israel; the annual incidence was 4.0 cases per 1 million people in the capital and 5.6 cases per 1 million people in the northeastern province of Khonkaen.[7] The incidence in 21 Chinese provinces has been estimated to be 7.4 cases per 1 million people annually,[8] and in the Sabah province of Malaysia, a retrospective analysis suggested a rate of 5 cases per 1 million people.[9] From published, hospital-based series, personal communications, and first-hand observations, AA appears most prevalent in less developed specific regions of the world, including Vietnam, Indonesia, Russia, the former Soviet republics, Iran, Iraq, Pakistan, India, Mexico,[10] certain regions of Latin America,[11] and Africa, where it is probably underdiagnosed.[12] There are no major sex or racial differences in the occurrence of AA.[5,7,13]

Geographic and Age Distribution

AA is a disease of the young. (Fig. 29–2) Most patients present between 15 and 25 years of age or older than 60 years of age.[14,15]

Epidemiologic Clues to Causality

Population-based studies have investigated possible causal associations. Drugs are implicated in only approximately 25% of cases of AA[5] in the west; in Thailand, AA was attributed to drug exposure in only approximately 15% of cases.[16,17] There are associations with chemical exposures, exposures to viruses, hepatitis, and occupation.[18] There is evidence that geographic variation in AA might result from environmental causes[17,19,20] and also genetic predisposition.[21]

Genetic Aspects

More than one case of acquired AA in a single family is a rare occurrence. In children and young adults, acquired AA should be distin-

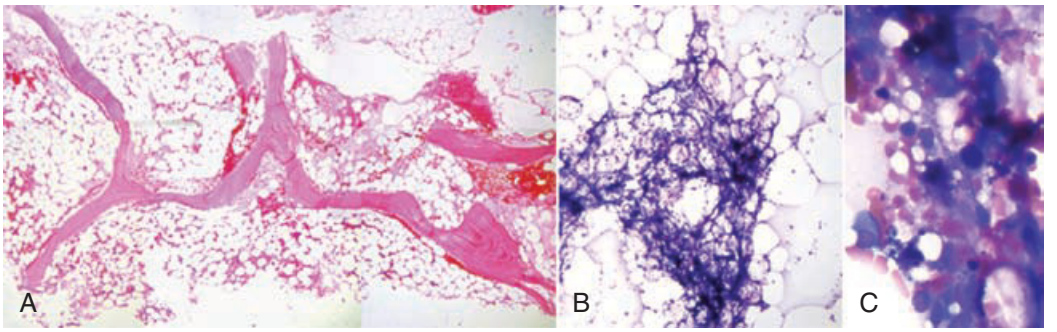

Figure 29–1 BONE MARROW MORPHOLOGY IN SEVERE APLASTIC ANEMIA (A–C). Bone marrow biopsy specimen, of sufficient length (**A**) shows severe hypocellularity. The corresponding aspirate (**B, C**) shows empty marrow spicules and residual stoma including lymphoid cells, plasma cells, histiocytes and mast cells.

Table 29–1 Differential Diagnosis of Pancytopenia

Pancytopenia with Hypocellular Bone Marrow
Acquired aplastic anemia
Inherited aplastic anemia (Fanconi anemia and others)
Some myelodysplasia syndromes
Rare aleukemic leukemia (acute myelogenous leukemia)
Some acute lymphoblastic leukemias
Some lymphomas of bone marrow
Pancytopenia with Cellular Bone Marrow
Primary bone marrow diseases
Myelodysplasia syndromes
Paroxysmal nocturnal hemoglobinuria
Myelofibrosis
Some aleukemic leukemias
Myelophthisis
Bone marrow lymphoma
Hairy cell leukemia
Secondary to systemic diseases
Systemic lupus erythematosus, Sjögren syndrome
Hypersplenism
Vitamin B_{12}, folate deficiency (familial defect)
Overwhelming infection
Alcohol
Brucellosis
Ehrlichiosis
Sarcoidosis
Tuberculosis and atypical mycobacteria
Hypocellular Bone Marrow ± Cytopenia
Q fever
Legionnaires disease
Mycobacteria
Tuberculosis*
Anorexia nervosa, starvation
Hypothyroidism

*Pancytopenia in tuberculosis only rarely is associated with a hypocellular bone marrow at biopsy or autopsy. Marrow failure in the setting of tuberculosis is almost always fatal; exceptional patients probably had underlying myelodysplasia or acute leukemia.

Other drugs and chemicals
Viruses
Epstein-Barr virus (infectious mononucleosis)
Hepatitis virus (non-A, non-B, non-C, non-G hepatitis)
Parvovirus (transient aplastic crisis, some pure red cell aplasia)
Human immunodeficiency virus (acquired immunodeficiency syndrome)
Immune diseases
Eosinophilic fasciitis
Hyperimmunoglobulinemia
Thymoma and thymic carcinoma
Graft-versus-host disease in immunodeficiency
Paroxysmal nocturnal hemoglobinuria
Pregnancy
Idiopathic aplastic anemia
Inherited Aplastic Anemia
Fanconi anemia
Dyskeratosis congenita
Shwachman-Diamond syndrome
Reticular dysgenesis
Amegakaryocytic thrombocytopenia
Familial aplastic anemias
Preleukemia (eg, monosomy 7)
Nonhematologic syndromes (eg, Down, Dubowitz, Seckel)

guished from the inherited forms of bone marrow failure such as Fanconi anemia and dyskeratosis congenita. Identification of patients with Fanconi anemia has important therapeutic implications. Patients with constitutional AA can lack typical physical anomalies, and the pancytopenia can develop after childhood (see Chapter 28), mimicking the acquired disease.

A few histocompatibility types have also been associated with AA, most consistently human leukocyte antigen (HLA)-DR2.[22–24] HLA-DR subtypes have proved useful in predicting response to immunosuppressive therapy; in a large cohort of US AA patients, HLA-DR15 was associated with the presence of the paroxysmal nocturnal hemoglobinuria (PNH) clone and responsiveness to immunosuppression.[24] In Japanese patients, the presence of the *DRB*1501* allele was strongly associated with hematologic responses to cyclosporine[25] and with the probability of relapse[22] and cyclosporine dependence.[26] Haplotypes associated with clozapine-induced agranulocytosis have been linked to the heat-shock protein variants encoded within the large major

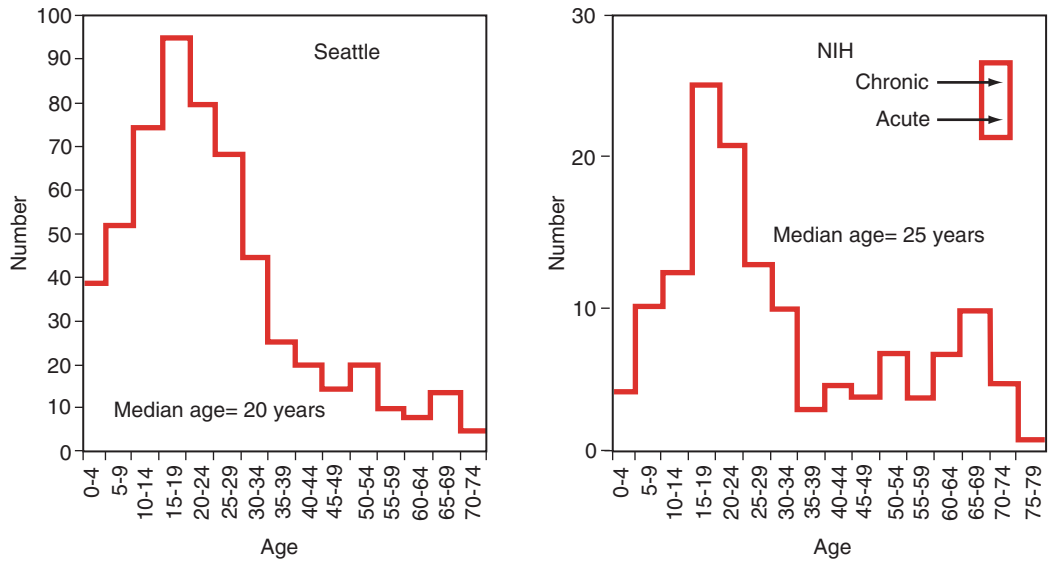

Figure 29–2 Distribution of aplastic anemia by age. For the patients at the University of Washington, a major transplantation center, the age given is at the time of first treatment. For the patients at the National Institutes of Health (NIH), where immunosuppressive therapy is offered, the age given is at the time of diagnostic bone marrow biopsy. Acute disease is defined as less than 3 months between diagnosis and presentation at NIH, and chronic disease is defined as more than 3 months. *(Seattle statistics are courtesy of Rainer Storb, University of Washington.)*

histocompatibility gene region.[27] Genetic predisposition may be responsible for some idiosyncratic reactions to drugs and chemicals leading to the development of AA. Polymorphisms in cytokine genes, associated with an increased immune response, also are more prevalent in AA: a nucleotide polymorphism in the tumor necrosis factor α (TNF-α; *TNF2*) promoter at −308,[26,27] homozygosity for a variable number of dinucleotide repeats in the gene encoding γ-interferon (IFN-γ), and polymorphisms in the interleukin 6 (IL-6) gene.[28] Genome wide transcriptional analysis of T cells from aplastic anemia patients has implicated components of innate immunity in aplastic anemia, including Toll-like receptors and natural killer cells,[29] for which there is some preliminary experimental support.[30,31]

ETIOLOGY AND PATHOGENESIS

Hematopoiesis in Bone Marrow Failure

Stem Cells

A consistent laboratory finding for patients with AA is a very low number of hematopoietic progenitor cells.[28,32,33] Colony formation by bone marrow cells of AA patients remains unresponsive, even to high levels of hematopoietic growth factors.[29,34] The total number of progenitors in a marrow sample is reduced, and the number of colony progenitor cells assayed from a purified CD34 population is low.[32] In humans, a stem-cell surrogate assay that assesses cells capable of colony formation after more than 1 month in long-term bone marrow culture is available; these long-term culture-initiating cells (LTC-ICs) share the frequency, phenotype, and kinetic properties of true stem cells. Studies indicate a profound deficiency in LTC-IC numbers in all patients with severe AA.[30,31,35] At clinical presentation, the number of LTC-ICs is usually less than 10% of normal; combined with a reduction in total marrow cellularity to 10% or less, the stem-cell number is estimated to be reduced to 1% or less than normal in patients with AA (Fig. 29–3).

One peculiar feature of white blood cells in AA is short telomeres.[36,37] Telomere shortening was initially most easily attributed to stem-cell exhaustion. However, the discovery, first by linkage analysis in large pedigrees, that the X-linked form of dyskeratosis congenita was caused by mutations in *DKC1* and subsequently purposeful identification of mutations in *TERC* in some autosomal dominant patients with this constitutional marrow failure syndrome indicated a genetic basis for telomere deficiency. Central to the repair machinery is an RNA template, encoded by *TERC,* on which telomerase, a reverse transcriptase encoded by *TERT,* elongates the nucleotide repeat structure; other proteins, including the *DKC1* gene product dyskenin, are associated with the telomere repair complex. Systematic surveys of DNA disclosed first *TERC*[38,39] and later *TERT* mutations[40] in some patients with apparently acquired AA, including older adults. Family members who share the mutation, despite normal or near normal blood counts, have hypocellular marrows, reduced CD34 cell counts and poor hematopoietic colony formation, increased hematopoietic growth factor levels, and of course short telomeres; however, their clinical presentation is much later than in typical dyskeratosis congenita, and they lack typical physical anomalies.[38,40] Chromosomes are also protected by several proteins that bind directly to telomeres, and polymorphisms in their genes (*TERF1, TERF2*) are also more or less prevalent in AA compared to healthy controls.[41] A few patients also have heterozygous mutations in the Shwachman-Bodian-Diamond syndrome (*SBDS*) gene. Almost all children with this form of constitutional AA are compound heterozygotes for mutations in *SBDS,* and their white cells have extremely short telomeres;[42] however, the *SBDS* gene product has not been directly linked to the telomere repair complex or to telomere binding. A parsimonious inference from all these data is that inherited mutations in genes that repair or protect telomeres are genetic risk factors in acquired AA, probably because they confer a quantitatively reduced hematopoietic stem cell compartment that may also be qualitatively inadequate to sustain immune-mediated damage.[43] However, telomeres are short in one-third to one-half of AA patients,[36,37] but mutations have only been identified in less than 10% of cases.

Stromal and Hematopoietic Growth Factors

Stromal cell function is usually not defective in cases of AA.[28] Adherent cells from patients support hematopoiesis by normal CD34 cells, whereas no hematopoietic colonies develop when patients' CD34 cells are cultured in the presence of normal stroma[36,44] (Fig. 29–4). Stromal cells cultured from patients' bone marrow generally produce normal quantities of hematopoietic growth factors.[37] Serum levels of erythropoietin,[39] thrombopoietin,[40] granulocyte colony-stimulating factor (GCSF),[41] and granulocyte-macrophage colony-stimulating

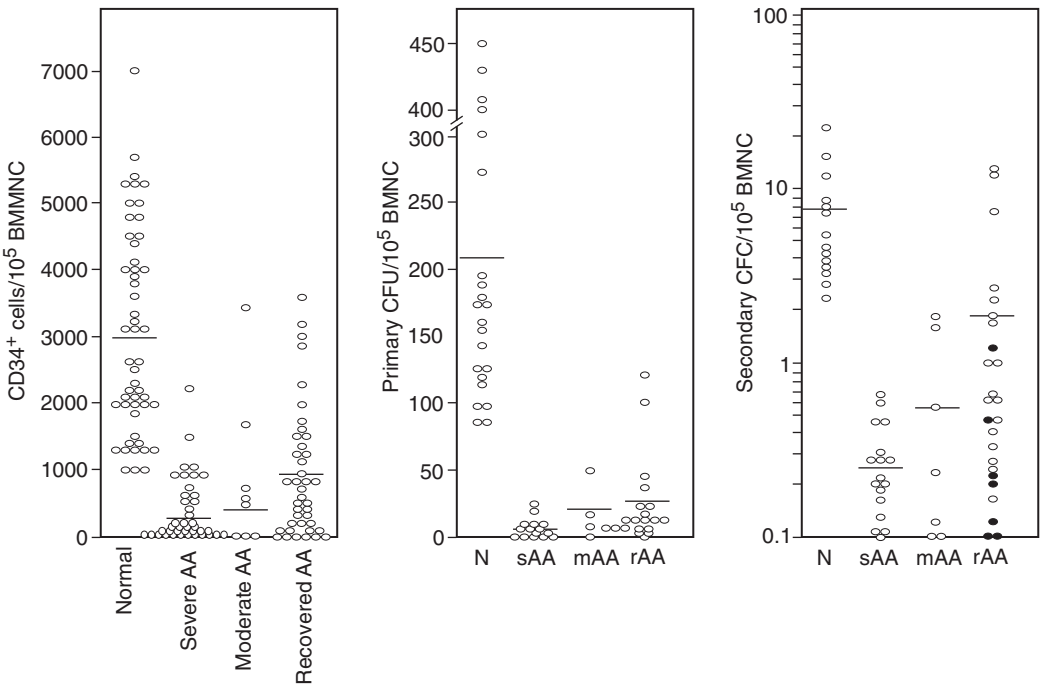

Figure 29–3 The numbers of CD34 cells, primary colony-forming cells (CFC), and long-term culture-initiating cells (LTC-ICs) were measured in the bone marrow of aplastic anemia patients. Each dot represents an individual patient's sample studied. Severe aplastic anemia (sAA) includes patients at presentation, cases refractory to immunosuppressive therapy, and patients who relapsed after a period of recovery. Primary CFC were measured in short-term methylcellulose cultures. Secondary CFC after long-term bone marrow cultures reflect LTC-IC numbers. BMNC, blood mononuclear cell; CFU, colony-forming unit; mAA, moderate aplastic anemia; N, normal; rAA, recovered from aplastic anemia.

factor (GM-CSF) are almost always normal or elevated.[42] Cytokines that act at very early stages of hematopoiesis have been studied as possible etiologic factors in the pathobiology of AA. Blood levels of FLT3 ligand are highly elevated in AA,[43] stem cell factor (SCF) levels are modestly decreased,[45] and SCF stromal cell production is normal.[45] Adequate stromal function is implicit in the success of marrow transplantation in AA because important stromal elements remain of host origin.

PATHOPHYSIOLOGIC PATHWAYS LEADING TO APLASTIC ANEMIA

Direct Hematopoietic Injury

The most common form of AA is iatrogenic; transient marrow failure often follows treatment with cytotoxic chemotherapeutic drugs or irradiation (Fig. 29–5). Certain chemical or physical agents directly injure proliferating and quiescent hematopoietic cells. However, patients with community-acquired AA rarely have a history of exposure to such physicochemical agents. Even benzene, which can act as a particularly inefficient cytotoxic chemical, is an infrequent cause of AA in developed countries.[5] Therapeutic drugs are associated with acquired AA, and in some instances, they can directly cause marrow damage. However, compared with chemotherapeutic agents, which are delivered in high doses, relatively low total quantities of ingested drug apparently cause idiosyncratic hematologic reactions. In addition to their direct toxic effects, chemicals and viruses can induce complex immune reactions leading to bone marrow failure in persons with AA (see Fig. 29–5).

Immune-Mediated Marrow Failure

In the 1970s, Mathé and colleagues[46] observed unexpected improvement of pancytopenia after failed marrow transplantation. They speculated that the immunosuppressive conditioning regimen, intended to allow engraftment of the donor marrow, might instead have promoted the recovery of host marrow function.[46] The effectiveness of diverse treatments that reduce lymphocyte number or block T-cell function, and the superior results obtained when agents are

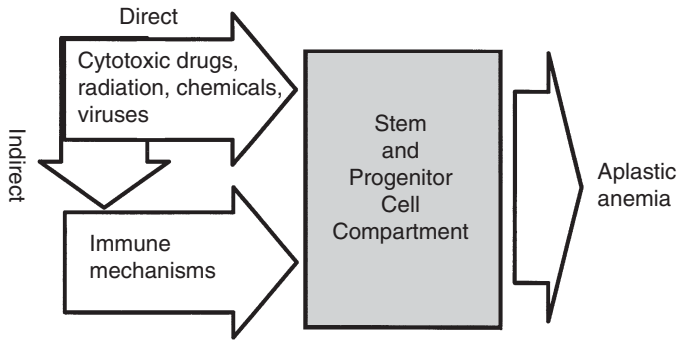

Figure 29–5 Possible causes of direct and indirect bone marrow failure in patients with aplastic anemia (AA).

combined strongly suggest that such therapeutic success is caused by the immunosuppressive effects of the drugs employed. AA shares numerous clinical and pathophysiologic features with other autoimmune disorders that all are characterized by T-cell–mediated, tissue-specific organ destruction. Like AA, these disorders tend to occur in younger persons and show geographic variation in incidence. The late immune events that dominate at the time of clinical presentation—cytotoxic lymphocyte activation, cytokine production, and specific target cell elimination—are common to many autoimmune disorders.

Immune system destruction of marrow occurs in animal models of graft-versus-host disease (GVHD) and in humans with transfusion-associated GVHD, in which AA is the invariable cause of death.[47] Very small numbers of effector cells, which have been conveyed by residual lymphocytes contained within the transfusion product[48] or with solid organ transplants,[49] are sufficient to mediate GVHD under these conditions. AA is associated with rheumatologic syndromes, such as eosinophilic fasciitis,[50] and with systemic lupus erythematosus, which can appear or worsen with pregnancy.[51] AA occasionally occurs in individuals with hypogammaglobulinemia or congenital immunodeficiency syndrome,[52] thymoma, thymic hyperplasia,[53] and thymic carcinoma.[54]

Laboratory support for the immune hypothesis first came from coculture experiments in which mononuclear cells from AA patients' blood or bone marrow were shown to suppress in vitro colony formation by hematopoietic progenitor cells. Removal of T cells from the patient samples sometimes improved colony formation in vitro.[55] Peripheral blood and bone marrow samples from patients were shown to produce a soluble factor that inhibited hematopoiesis,[56–58] ultimately identified as IFN-γ.[59] Patients' T cells[60,61] overproduced IFN-γ and tumor necrosis factor (TNF), two cytokines that inhibit hematopoietic proliferation.[62] Increased expression of IFN-γ was detected in samples from most AA patients.[63,64] Constitutive expression of Tbet, a transcriptional regulator that is critical to Th1 polarization, was present in a majority of AA patients[33] Patients' blood and marrow also contained elevated numbers of activated cytotoxic lymphocytes.[65] The activity and levels of these cytotoxic cells decreased appropriately with antithymocyte globulin (ATG) therapy.[66,67] Cytotoxic T lymphocytes (CTLs) that contain IFN-γ can be measured by flow cytometry and correlate with disease activity.[68]

The lymphokines IFN-γ and TNF suppressed proliferation of early and late hematopoietic progenitor and stem cells.[62] These effects were far more potent when these lymphokines are secreted into the marrow microenvironment than when they were simply added to the cultures,[69] consistent with their localization in the marrow of patients. Although IFN-γ and TNF can suppress hematopoiesis by effects on cell proliferation, an important component of their inhibitory activity is cell death by induction of apoptosis: Both lymphokines induced expression of the Fas receptor on CD34 progenitor cells; triggering of the Fas receptor by its ligand initiates a fatal process of apoptosis.[70,71] Apoptosis of hematopoietic cells in AA is suggested by the findings of high Fas receptor expression[72] and increased numbers of apoptotic cells[73] in patients' bone marrow. Immune-mediated cell cycle blockade and apoptosis can lead to the dramatic elimination of hematopoietic progenitor and stem cells in patients with AA.

The early immune system events that must precede the global destruction of hematopoietic cells are not clear. Involvement of CD4 lymphocytes has been suggested and a more specific class II haplotype has been identified among Japanese patients.[26] Clones of HLA-DR–restricted T cells derived from a few patients have been shown to proliferate in response to marrow cells.[74,75]

Molecular analyses of the T-cell receptor repertoire have been used to study the T-cell responses in AA.[76] Oligoclonal skewing of a large number of CTL repertoire consistent with the presence of expanded immunodominant clones has been observed, suggesting the presence of an ongoing CTL response.[77–79] Using the unique region of the variable portion of the β-chain of the T-cell receptor, immunodominant CTL clones have been identified and their levels correlated with the hematologic parameter.[79] Similar clonotypic sequences have been observed in patients matched for certain HLA restriction elements, a finding suggestive of the response to common or closely related antigens. Clonotypic sequences derived from the T-cell receptor may serve in the future as a molecular marker for the activity of disease and indicate the presence of specific antigens driving the immune response.[76,80]

Radiation

Marrow aplasia is a major acute toxic effect of radiation;[81,82] both stem and progenitor cells are damaged (Fig. 29–6). The dose-related occurrence of pancytopenia 2 to 4 weeks after exposure to radiation is caused by injury of actively replicating progenitor cells. Mortality from hematologic toxicity is a function of the marrow's ability to tolerate depletion of hematopoietic cells and damage to the stem cell. The capacity for recovery of hematopoietic function after even massive single irradiation exposures is considerable, reflecting the resistance of the quiescent stem cell to damage and the enormous marrow repopulating potential of even a greatly reduced stem cell pool. At intermediate radiation doses around the median lethal dose (LD_{50}), at which marrow toxicity limits survival, supportive efforts can drastically alter outcome. Autopsies of atomic bomb victims in Japan showed acellular bone marrows in the first weeks of the explosion, but there frequently was regenerating bone marrow in those who survived longer.[83] The histologic picture of radiation-mediated aplasia includes necrosis, nuclear pyknosis and karyorrhexis, nuclear lysis, and ultimately cytolysis; the associated phagocytosis, marked congestion, and hemorrhage are rapidly followed by fatty replacement.[84] Bone marrow hypoplasia occurs with radiation doses higher than 1.5 to 2 Gy to the whole body. Precise LD_{50} figures for humans do not exist, and estimates are based on the limited direct human data and extrapolation from animal experiments. The LD_{50} is highly dependent on the quality of medical care, and improved support may double the tolerated radiation dose.[85] From assessment of the outcome of radiation accidents and high-dose therapeutic irradiation, the LD_{50} has been estimated at approximately 4.5 Gy,[86,87] an almost mythical figure sometimes called the Shields Warren number (see Fig. 29–6).

Although the principles of management of pancytopenia after a single large dose of irradiation are similar to those for treating AA in general, some unique points should be made concerning immediate evaluation and long-term prognosis. The type and intensity of the source of radiation and the distance and shielding of the subject are the major determinants of radiation injury; because of the nature of the exposure, these factors are often difficult to assess. Early recognition of the nature of the accident provides the best opportunity for dosimetry by accident reconstruction and can allow employment of blocking, displacement, or chelation agents. Exposure correlates well with the degree of pancytopenia.[88] Because lymphocytes are particularly sensitive to radiation, their rate of decline can be used to estimate the dose of total body exposure to a level of approximately 3 Gy.[88]

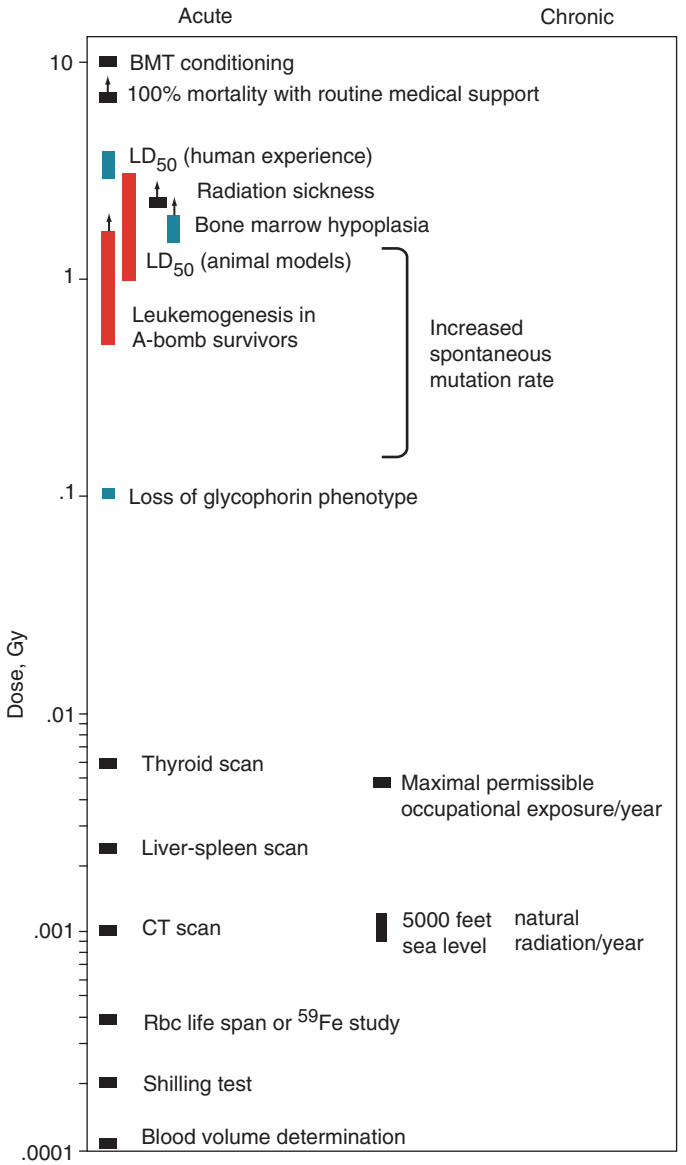

Figure 29–6 Scale of whole-body radiation doses. A Gray (Gy) is a measure of absorbed dose equivalent to 1 J/kg unit mass, and 1 Gy equals 100 rads. Radiation represents radiant energy. When absorbed by biologic tissue, radiant energy causes release of electrons and molecular ionization, which result in further energy release. Radiant energy can directly break chemical bonds and indirectly damage macromolecules through generation of high-energy free radical forms. The relationship between increased mutation rate and radiation dose is very approximate *(hatched bars).* Measurement of the phenotype of an autosomal recessive gene such as for glycophorin would be expected to be a very sensitive indicator. Because malignant transformation is almost certainly a two-step process, increased leukemogenesis is probably an underestimation of the effect of radiation on a single gene. Even the extensive data on the atomic bomb survivors of Hiroshima are subject to statistical errors because of the small number of cases; a linear or exponential curve fit gives various results, and very high doses of radiation may not be associated with as high a risk of leukemia because of stem cell death. Other data that can bear on mutation frequency lie outside the range shown. In a patient with ankylosing spondylitis who underwent irradiation of the spine, leukemogenesis was observed at relatively low doses (doubling of the leukemia rate can be extrapolated to approximately 7 Gy), but such individuals can be predisposed to leukemia. An increased risk of thyroid cancer after irradiation of the mediastinum in childhood occurred at approximately 4 Gy. BMT, bone marrow transplantation; CT, computed tomography; LD_{50}, median lethal dose; Rbc, red blood cell.

At higher doses, the fall in granulocytes and the severity of thrombocytopenia and reticulocytopenia can be used as gauges.[89] After the Chernobyl radiation accident, measurements of dicentric chromosomes were used to estimate dose, which correlated better with neutrophil than with lymphocyte kinetics. The cytogenetic alterations in stem cells are dose related, irreversible, and probably cumulative in increasing the probability of leukemic transformation.[90] The survival of some patients who received doses higher than 9 Gy suggests in retrospect that autologous marrow reconstitution may occur in most persons who survive the immediate consequences of radiation exposure.[91]

Pancytopenia may be a late consequence of a single radiation dose,[92] but AA is not well documented as a delayed event after radiation exposure. Of 156 cases of AA in Japan in the 20 years after the atomic bomb explosions, only 13 individuals had received more than a 1-rad dose, and of the 3 individuals who had been heavily irradiated, only 1 had typical AA.[93]

A variety of hematologic abnormalities are associated with chronic low-level radiation exposure, most commonly lymphocytosis, neutropenia, immature or dysmorphic white blood cells (WBCs), and giant platelets (see Fig. 29–6). Cytogenetic abnormalities accumulate with time after chronic exposure, but they may not be reliably related to dose.[94] Repeated low doses of radiation can damage bone marrow and have been associated with AA in special circumstances,[95] but even in these circumstances, only a small proportion of exposed individuals developed hematologic disease.[96] AA does not appear to be more frequent among nuclear power plant or thorium processing factory workers or among residents living close to the plants.[97] Excessive numbers of deaths from AA were reported after therapeutic irradiation of the spine for ankylosing spondylitis,[98] although later analysis has suggested that the risk may have been overestimated.[99] Despite occasional instances in which marrow failure developed years after radiation therapy and chemotherapy,[100] AA was not found in unexpected numbers in a large population of cancer patients who had received therapeutic irradiation.[101] Bone marrow failure has not been observed with abnormally high frequency among persons exposed to higher natural background radiation.[102] Excessive deaths from AA did occur among North American radiologists who died between 1948 and 1961.[103]

Drugs and Chemicals

AA is frequently associated with medical drug use (Table 29–3).[104] At the end of the 19th century, chemicals were linked to marrow function through observations of benzene effects on workers. Establishment of a relationship between the analgesic amidopyrine and agranulocytosis in the early 20th century and an apparent epidemic of AA after the introduction of chloramphenicol in the 1960s also supported this concept. Initially suggested by the accumulation of case reports, drug associations have been established in formal case-control population-based epidemiologic studies. In the IAAAS, relative risks were estimated for individual drugs and large classes of pharmaceutical agents, including nonsteroidal antiinflammatory drugs (NSAIDs), drugs affecting thyroid function, certain cardiovascular agents, some psychotropics, and sulfa-based antibiotics (Table 29–4).[5] Approximately 25% of the cases of AA identified in the IAAAS could be attributed to drug use. Drug use as a risk factor was also assessed by similar methods in Thailand,[105] where the incidence of AA is higher than in the West.[7] Surprisingly, chloramphenicol was not shown to be a risk factor; only sulfonamide exposure reached statistical significance, and the etiologic fraction for drugs in AA was only approximately 15%.[105]

Associations between drug exposure and AA can be divided into two classes. Drugs used in cancer chemotherapy are selected for their cytotoxicity, and their regular, dose-dependent induction of marrow aplasia is an expected effect. Most AA associated with medical drug use in the community is described as idiosyncratic, meaning that its occurrences are unexpectedly rare. Many of the drugs implicated in AA also appear to cause other, milder forms of marrow suppression

Table 29–3 Classification of Drugs and Chemicals Associated with Aplastic Anemia

I. Agents that regularly produce marrow depression as a major toxic effect when used in commonly employed doses or normal exposures
Cytotoxic drugs used in cancer chemotherapy
Alkylating agents (busulfan, melphalan, cyclophosphamide)
Antimetabolites (antifolic compounds, nucleotide analogs) antimitotics (vincristine, vinblastine, colchicine)
Some antibiotics (daunorubicin, doxorubicin [Adriamycin])
Benzene (and less often benzene-containing chemicals: kerosene, carbon tetrachloride, Stoddard solvent, chlorophenols)
II. Agents probably associated with aplastic anemia but with a relatively low probability relative to their use
Chloramphenicol
Insecticides
Antiprotozoals (quinacrine and chloroquine)
Nonsteroidal antiinflammatory drugs (including phenylbutazone, indomethacin, ibuprofen, sulindac, diclofenac, naproxen, piroxicam, fenoprofen, fenbufen, aspirin)
Anticonvulsants (hydantoins, carbamazepine, phenacemide, ethosuximide)
Gold, arsenic, and other heavy metals such as bismuth and mercury
Sulfonamides as a class
Antithyroid medications (methimazole, methylthiouracil, propylthiouracil)
Antidiabetes drugs (tolbutamide, carbutamide, chlorpropamide)
Carbonic anhydrase inhibitors (acetazolamide, methazolamide, mesalazine)
D-Penicillamine
2-Chlorodeoxyadenosine
III. Agents more rarely associated with aplastic anemia
Antibiotics (streptomycin, tetracycline, methicillin, ampicillin, mebendazole and albendazole, sulfonamides, flucytosine, mefloquine, dapsone)
Antihistamines (cimetidine, ranitidine, chlorpheniramine)
Sedatives and tranquilizers (chlorpromazine, prochlorperazine, piperacetazine, chlordiazepoxide, meprobamate, methyprylon, remoxipride)
Antiarrhythmics (tocainide, amiodarone)
Allopurinol (can potentiate marrow suppression by cytotoxic drugs)
Ticlopidine
Methyldopa
Quinidine
Lithium
Guanidine
Canthaxanthin
Thiocyanate
Carbimazole
Cyanamide
Deferoxamine
Amphetamines

Table 29–4 Drugs Associated with Aplastic Anemia in the International Aplastic Anemia and Agranulocytosis Study*

Drug	Stratified Risk Estimate (95% CI)	Multivariate Relative Risk Estimate (95% CI)
Nonsteroidal analgesics		
Butazones	3.7 (1.9–7.2)	5.1 (2.1–12)
Indomethacin	7.1 (3.4–15)	8.2 (3.3–20)
Piroxicam	9.8 (3.3–29)	7.4 (2.1–26)
Diclofenac	4.6 (2.0–11)	4.2 (1.6–11)
Antibiotics		
Sulfonamides†	2.8 (1.1–7.3)	2.2 (0.6–7.4)
Antithyroid drugs	16 (4.8–54)	11 (2.0–56)
Cardiovascular drugs		
Furosemide	3.3 (1.6–7.0)	3.1 (1.2–8.0)
Psychotropic drugs		
Phenothiazines	3.0 (1.1–8.2)	1.6
Corticosteroids	5.0 (2.8–8.9)	3.5 (1.6–7.7)
Allopurinol	7.3 (3.0–17)	5.9 (1.8–19)
Gold	29 (9.7–89)	

CI, confidence interval.

*The multivariate model included the following factors: age, gender, geographic area, date of interview, reliability of the patient, person interviewed, transfer from another hospital, history of blood disorder or tuberculosis, exposure to benzene and related chemicals, and use of other suspected drugs.

†Other than trimethoprim-sulfonamide combination.

From Kaufman DW, Kelly JP, Levy M, Shapiro S: The Drug Etiology of Agranulocytosis and Aplastic Anemia. New York, Oxford University Press, 1991.

such as neutropenia. Although difficult to prove, some dose relationship probably does exist even for idiosyncratic reactions. In most case reports, patients received normal or high doses of the agent, usually for a period of weeks to months. Drug-induced aplasia cannot be distinguished by history from idiopathic forms of the disease; the clinical course, including the favorable response to immunosuppressive therapy, of patients with histories of drug exposure are the same as in idiopathic disease.[106]

The low probability of developing AA after a course of drugs may be a reflection of the gene frequency for metabolic enzymes (for direct chemical effects) or immune response genes (for immune-mediated marrow failure) in the population. The rarity of idiosyncratic drug reactions could then arise from the infrequent combination of unusual circumstances: exposure, genetic variations in drug metabolism, the physical properties of the agent, enzymatic pathways that chemically alter the drug, and the susceptibility of the host to the action of a toxic compound. Many drugs and chemicals, especially if they have limited water solubility, must be enzymatically degraded before conjugation and excretion. Degradative pathways for xenobiotics are complex, specific, redundant, and interrelated. Intermediate metabolites in complex degradation pathways can be toxic, highly reactive, and responsible for some adverse effects of the primary agents. Examples of detoxifying enzyme systems directly applicable to bone marrow failure and that also demonstrate genetic variability include arylhydrocarbon hydroxylase (eg, benzene toxicity), epoxide hydrolases (eg, phenytoin toxicity), *S*-methylation (eg, 6-mercaptopurine, 6-thioguanine, azathioprine) and *N*-acetylation (eg, sulfa drugs). The role of genetic background was shown in experiments using cells of a patient with carbamazepine-associated AA. Only after generation of reactive metabolites from the incriminated agent by rat microsomes were the patient's lymphocytes killed in a dose-dependent, drug-specific pattern.[107] These metabolites were not toxic to normal donors' cells and displayed intermediate toxicity toward cells of the patient's mother.

Benzene

Benzene is convincingly linked to AA.[108–111] Benzene myelotoxicity can be placed between the predictable effects of chemotherapeutic agents and idiosyncratic drug reactions. Industrial emissions add greatly to the biologic sources of ambient benzene. Significant benzene exposure can also occur outside of industry. Although the concentrations of benzene to which consumers are exposed are orders of magnitude lower than those observed in industrial workers, the effect of low-dose chronic exposure is uncertain, but genetic variations in the metabolizing enzymes may influence susceptibility to marrow suppression at these levels.[109] Benzene metabolites are also generated from the diet.[110]

Water-soluble products of benzene metabolism such as phenols, hydroquinones, and catechols mediate the toxicity to the marrow. Benzene and its intermediate metabolites covalently and irreversibly

bind to bone marrow DNA, inhibit DNA synthesis, and introduce DNA strand breaks. Benzene acts as a "mitotic poison" and as a mutagen. Acutely, the more mature, actively cycling marrow precursor cells are preferentially damaged over the more primitive progenitors.[111] Intermittent exposure may be more damaging to the stem cell compartment than is continuous exposure.[111] Marrow stroma can also be damaged by benzene.[112]

The range of hematologic disease attributable to benzene is broad, from relatively frequent mild alterations in blood counts to AA or leukemia. Studies of exposed North American workers earlier in the 20th century suggested that the risk of AA was 3% to 4% in men exposed to concentrations higher than 300 ppm and that 50% of individuals exposed to 100 ppm developed some blood cell count depression.[113] The prevalence of some form of marrow suppression with heavy exposure can be high; more than 10% of workers developed leukopenia, and with improved hygiene, the figure was lowered to 0.5%.[114] Leukopenia, anemia, thrombocytopenia, and lymphocytopenia are common consequences of benzene; other manifestations include macrocytosis, acquired Pelger-Huet anomaly, eosinophilia, basophilia, and less often, polycythemia, leukocytosis, thrombocytosis, or splenomegaly. The marrow is usually normocellular but can show hypocellularity or hypercellularity;[113] a hypercellular phase can precede complete aplasia. In addition to hypocellularity, chronically exposed workers can have marrow necrosis, fibrosis, edema, and hemorrhage.[115] AA and acute myelogenous leukemia (AML) have occurred in the same person,[116] and pancytopenia preceded acute leukemia in one-fourth of industrial workers.[117] Marrow failure and leukemia in benzene workers can manifest decades after exposure.

Aromatic Hydrocarbons

The common perception that other molecules resembling benzene or containing a benzene ring can also cause marrow suppression is not well supported. Neither the closely related alkylbenzenes nor pure toluene or xylene are established marrow toxins. Often, an aromatic hydrocarbon has been implicated by the clinician as a causative agent for AA for lack of another apparent cause. For some substances, toxicity can result from the presence of benzene as a contaminant of the synthesis of the molecule or in the petroleum distillates used to dissolve the compound. However, the total number of AA cases reported with aromatic hydrocarbon exposures is small when the large populations exposed to this heterogeneous group of chemicals are considered. For example, surveys of AA patients found that only 2% to 6% of cases were associated with insecticide exposure.[17,118,119] The significance of a handful of case reports associated with insecticide exposure in the context of the vast use of these compounds is questionable. However, the very high prevalence of aromatic hydrocarbons in daily life would greatly amplify even a small individual risk. Pesticides and insecticides have been associated with AA for decades, with almost 300 medical case reports appearing in the medical literature.[120] The most frequently cited insecticides are chlordane, lindane, and dichlorodiphenyltrichloroethane (DDT). For the miscellaneous aromatic hydrocarbons, case reports also greatly outnumber series of patients, and systematic epidemiologic surveys have shown mixed results. Significant excesses of cases of AA were found in workers in the printing industry (odds ratio [OR] = 6.2), in lumber and wood products industries (OR = 3.7), in agriculture workers (OR = 2.4), and in construction workers (OR = 2.0).

Chloramphenicol

Structural similarity of chloramphenicol to amidopyrine, a drug known to cause agranulocytosis, led to early prediction of possible hematotoxicity.[121,122] During the period of its unrestrained use, chloramphenicol was considered the most common cause of AA in the United States,[123] accounting for 20% to 30% of total cases and 50% of drug-associated cases.[124–126] Estimates of the risk of AA after a course of chloramphenicol ranged from 1 case per 20,000[125] to 1 case per 800,000 people.[127] Based on these figures, a course of chloramphenicol was estimated to increase the risk of AA 13-fold. Although the introduction of chloramphenicol into the American market was perceived as having increased the total number of cases of AA,[123,128] this assumption was only weakly supported by epidemiologic data, and the mortality from AA remained essentially constant during the period of chloramphenicol's introduction and extensive use and after the withdrawal of chloramphenicol from the market. In series reported from the United States and Europe, of a total of 394 patients, only 1 was found to have ingested the drug.[18,129] Chloramphenicol has not been associated with AA in Thailand, despite its high rate of use there. In Hong Kong, where the use of chloramphenicol is almost 100 times higher than in the West, drug-associated AA occurs infrequently.[130] The early epidemiologic surveys stressed excessive dosage, high blood levels, repeated or intermittent courses, young age, and oral route of administration as particular risks for chloramphenicol marrow toxicity. However, in a series of 600 cases, most patients had received a dose of less than 10 g.[131]

At ordinary doses, a pattern of reversible alterations in erythropoiesis occurs in most patients treated with chloramphenicol.[132] In vitro, chloramphenicol can decrease hematopoietic colony formation[133] or diminish colony size,[134] although usually at doses greater than those achieved in patients. Inhibition of marrow stromal cell proliferation[135] and the production of growth factors[136] have also been reported. There is no consistent evidence of abnormal marrow sensitivity to the drug in affected individuals. Chloramphenicol was also claimed to produce marked chromosome abnormalities in WBCs.[137] Others have proposed that chloramphenicol toxicity is the result of covalent binding of the drug to reactive oxidative metabolites, such as an oxalic acid derivative produced by P450 cytochrome-mediated oxidative dehalogenation to produce a chloramphenicol-free radical and hydroxylamine intermediate, all capable of acylating proteins.

Nonsteroidal Antiinflammatory Drugs

Compared with chloramphenicol, it took far longer to associate phenylbutazone with AA.[138] Mortality estimates have ranged from 1 case per 100,000 to 1 case per 1 million treatment courses.[139] The use of other NSAIDs is associated with case reports of AA. A large case-control led investigation in Europe confirmed the risk of AA with phenylbutazone use and identified even higher probabilities with other NSAIDs.[140] There was a suggestion of increased risk with drugs taken regularly for a prolonged period at very high doses, and in some cases, hematologic reactions were reproduced on repeat exposure.

Neuroleptics and Psychotropic Drugs

A variety of drugs used to treat disorders of the central nervous system have been associated with AA: the hydantoins and carbamazepine, antidepressants, tranquilizers, and felbamate. The marketing of felbamate was severely affected by the occurrence of aplasia in more than 30 patients.[141] Monitoring of drug blood levels and peripheral blood counts in patients receiving carbamazepine was recommended despite fewer than two dozen AA cases reported by 1982.[142] Doubt about the validity of many cases reported in the literature, as well as several large series of patients who did not develop hematologic toxicity[143] and an estimated AA case rate of approximately 1 in 200,000 treated patients,[144] have led to questions concerning the relationship between carbamazepine and AA.

Gold and Heavy Metals

Gold salts have an extraordinarily high frequency of fatal adverse reactions, estimated at 1.6 cases per 10,000 prescriptions. Dose-dependent leukopenia is common, but several dozen cases of AA have been reported.[145] In the IAAAS, exposure to gold salts was the most

Table 29–6 Severity of Aplastic Anemia as Defined by Laboratory Studies

Severe aplastic anemia
Bone marrow cellularity <30%
Two of three peripheral blood criteria:
Absolute neutrophil count <500 cells/mm^3
Platelet count <20,000 cells/mm^3
Reticulocyte count <40,000 cells/mm^3
No other hematologic disease
Moderate aplastic anemia
Patients with pancytopenia who do not fulfill the criteria of severe disease

significant drug association for developing AA, with a relative risk of 29 and an excess risk of 23 cases per 1 million users in 1 week.[5] Spontaneous recovery rarely occurs.[146] Patients have been successfully treated with stem-cell transplantation or immunosuppressive therapy; chelation therapy usually has not been helpful.[147] High concentrations of gold salts inhibit hematopoietic colony formation in vitro.[148] There is some evidence for a dose relationship.[149]

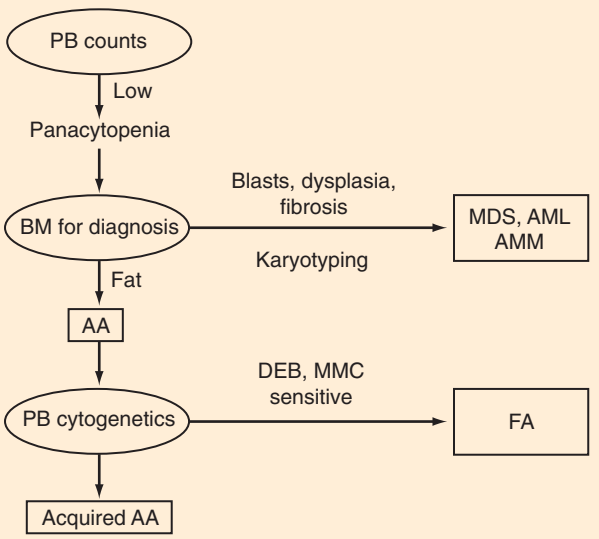
Arsenic poisoning can result in neutropenia, anemia, and thrombocytopenia.[150] Organic arsenicals, originally used in the treatment of syphilis (arsphenamine) and now as antihelminthic (arsenamide), have also been associated with AA.[151]

TYPICAL AND ATYPICAL PRESENTATIONS

Most patients with AA seek medical attention for symptoms that occur as a result of low blood counts (Fig. 29–7 and Table 29–5). All of the blood elements can be depressed, or a decrease in a single lineage can dominate the clinical picture. However, the differential diagnosis of pancytopenia includes a variety of diseases (see Table 29–1). Except for complaints related to the blood counts, most patients do not have systemic symptoms. Weight loss, persistent fever, pain, and loss of appetite point to an alternative diagnosis.

Bleeding is the most alarming manifestation of pancytopenia and most frequently sends the patient to a doctor. Thrombocytopenia usually does not cause massive bleeding. Instead, the patient reports easy bruisability and the appearance of red spots, especially over dependent surfaces; gum bleeding with tooth brushing and episodic nosebleeds are common. Heavy menstrual flow or irregular vaginal bleeding can occur in younger women. In AA associated with PNH, there are reports of red or dark urine that is caused by free hemoglobin, but visible bleeding from the genitourinary and gastrointestinal tracts is rare on presentation in AA. Extensive hemorrhage from any organ can occur but usually late in the course of the disease and almost always associated with infections, drug therapy (eg, corticosteroids), or invasive procedures.

The ability to adapt to a gradual reduction in hemoglobin concentration is remarkable. The anemic patient might mention fatigue, lassitude, shortness of breath, or ringing in the ears, but some individuals can tolerate astonishingly low hemoglobin levels without complaint. Even abrupt cessation of erythropoiesis leads to only a slow decline in hemoglobin (approximately 1 g/dL each week).



Infection is an uncommon presentation in patients with AA. The sore throat of agranulocytosis is not often observed, presumably because other alarming symptoms appear earlier.

Retrospective studies of AA associated with drugs and viruses and the observation of the occasional patient with serially monitored blood counts suggest a latent period of 6 to 8 weeks between the inciting event and the onset of pancytopenia.[152] The interval can be more prolonged when pancytopenia is well tolerated or moderate. For purposes of diagnosis and management, a history of blood diseases in other family members is very important and should trigger appropriate genetic tests for constitutional causes.

Findings on physical examination usually reflect the severity of the pancytopenia (Table 29–6). However, patients with severe disease can look remarkably well. The patient can present with subtle variations from normal or with a dramatic, even toxic appearance. Petechiae are often present over the pretibial surface of the lower leg and the dorsal aspects of the forearm and wrist; a few petechiae can be seen in the oropharynx and on the palate. Scattered ecchymoses typi-

Diagnostic Algorithm in Aplastic Anemia

AA, aplastic anemia; AML, acute myelogenous leukemia; AMM, agnogenic myeloid metaplasia; BM, bone marrow; DEB, diepoxybutane; MDS, myelodysplastic syndrome; MMC, mitomycin C; PB, peripheral blood.

cally appear in areas exposed to minor trauma. With severe thrombocytopenia, retinal hemorrhages can be present on funduscopic examination, there can be gingival oozing or blood in the nares, and hemorrhage can be apparent at the uterine cervical os. The stool can contain traces of heme. Pallor is common and is best appreciated on the mucosal membranes and palmar surfaces. The new patient can be febrile, but specific or localizing signs of infection are uncommon on presentation. Cachexia, splenomegaly, and lymphadenopathy are not associated with AA, and these findings should strongly suggest another diagnosis. The examiner should look carefully for café au lait spots and other physical anomalies of Fanconi anemia and for leucoplakia and nail changes of dyskeratosis congenita in children *and* adults. Acquired AA is usually a diagnosis of exclusion, and evidence from the history or physical examination of another major disease suggest secondary pancytopenia; an exception is drug-associated aplasia, as in the patient with chronic rheumatoid arthritis.

Several atypical presentations of AA should be pointed out. A physician might encounter an elderly patient with pancytopenia in whom subsequent bone marrow examination reveals dysplastic features (box on Diagnostic Algorithm in Aplastic Anemia and Table 29–7). Although the history of the illness in a newly diagnosed patient is short—in the range of months—a few patients recall a long history of bruisability, anemia, and low blood-cell counts reported to them by previous physicians during routine examinations. These patients can have a moderately severe, chronic disease that is stable for years. Pancytopenia from childhood should suggest a constitutional AA. Some patients can be diagnosed incidentally and show remarkable few symptoms despite severely depressed blood counts.

CLINICAL ASSOCIATIONS

A number of clinical syndromes, usually revealed through a careful history and physical examination, are associated with AA (see box on Diagnostic Algorithm in Aplastic Anemia and Tables 29–2 and 29–3).

Table 29–7 Bone Marrow Morphologic Findings that Discriminate Myelodysplasia from Aplastic Anemia

Characteristic*	Myelodysplasia	Aplastic Anemia
Cellularity	Usually normal to increased	Decreased
Erythropoiesis		
Megaloblastic	Very common	Common
Dyserythropoietic	Very common	Unusual
Maturation defects	Common	Not found
Ringed sideroblasts	Common	Not found
Myelopoiesis		
Monocyte prominence	Very common	Unusual
Mid-myeloid predominance	Very common	Unusual
Increased blasts	Yes	Not found
Megakaryocytes		
Atypical morphology	Very common	Not found

*Ringed sideroblasts and myeloblasts are observed by definition in some of the myelodysplastic syndromes. Dyserythropoietic red blood cell precursors show bizarre forms with multiple or irregular nuclei. Megakaryocytes can show defective nuclear polyploidization and increased internuclear spaces, or they can be small with only a few nuclei and peculiar granulation.

Adapted from Bagby GC: The preleukemic syndrome (hematopoietic dysplasia). In Shahidi NT (ed): Aplastic Anemia and Other Bone Marrow Failure Syndromes. New York, Springer-Verlag, 1990, p 199, which provides percentages for myelodysplasia.

Posttransfusion Graft-Versus-Host Disease

Almost uniformly fatal AA is a constant feature of transfusion-associated GVHD, produced by the transfusion of competent lymphocytes into immunodeficient hosts, including children with congenital syndromes, cancer patients receiving high-dose chemotherapy, and patients with adoptive cellular immunotherapy for leukemia.[47] Rarely, posttransfusion GVHD occurs in an apparently immunocompetent recipient in the special circumstance in which the donor is homozygous for an HLA haplotype also shared by the recipient, as can occur among first-degree family members. Small numbers of lymphocytes are sufficient to produce the syndrome, which is surprisingly resistant to immunosuppressive therapy. Pancytopenia with marrow hypoplasia is an almost constant feature of posttransfusion GVHD. Runt disease in animals is a model of this immune-mediated marrow failure syndrome.[153,154]

Pregnancy

Pregnancy is common in the age groups most susceptible to marrow failure, and in many cases, its association is probably only coincidental. The true frequency of AA in pregnancy is unknown, but from the number of cases reported it appears rare,[155–157] although bone marrow hypoplasia may be relatively common during pregnancy. A causal relationship is suggested by the temporal relationship between the onset of pancytopenia and that of pregnancy and by resolution after delivery and spontaneous or induced abortion; some patients have developed AA that remitted after each delivery. Survival rates for AA in pregnancy have been relatively high for the mother (83%) and baby (75%), with most pregnancies successful (69%).[157] Hemorrhage is the most common cause of death from AA during pregnancy. The published data are insufficient to guide the management of the pregnant woman with AA, especially because it is clear that AA in some cases is serendipitously diagnosed and can persist beyond parturition. However, in one series,[158] successful pregnancies were reported, and the mortality rate was low. A woman who desires a child can be maintained with transfusions, with the understanding that any clinical deterioration is a criterion for interruption or termination of the pregnancy. The hazard of pregnancy to the woman who has recovered from idiopathic AA is unknown, but most hematolo-

gists, recognizing the risk of relapse, advise patients not to become pregnant, especially if thrombocytopenia and a PNH clone are present.[158]

Post Hepatitis Aplasia Anemia

The association of AA and acute, apparently viral hepatitis is not rare. Several hundred cases have been reported.[159–162] A prior history of hepatitis is recognized in 2% to 9% of AA patients in Western series.[163,164] Uncomplicated viral hepatitis is frequently associated with mild blood cell count depression, but severe pancytopenia with marrow aplasia is a rare sequela, estimated at less than 0.07% of total pediatric hepatitis cases[165] and 2% of patients with non-A, non-B hepatitis.[166] However, in patients, usually children, who develop hepatic failure after fulminant seronegative hepatitis, approximately one-third develop AA at the time of liver transplantation.[167]

Hepatitis-associated AA has several peculiar features.[160–162,168,169] Typically, an uneventful episode of apparent viral hepatitis in a young man is followed in 1 to 2 months, during convalescence from the liver inflammation, by very severe pancytopenia. Depression of blood cell counts during the course of hepatitis is common; leukopenia, atypical lymphocytosis, erythroid macrocytosis, and thrombocytopenia mimic in milder forms the hematologic changes of AA. However, posthepatitis AA has a very poor prognosis, with early estimates of mortality of 90% at 1 year,[160] and a history of hepatitis in AA has been considered an indication for early marrow transplantation. Patients with posthepatitis AA can successfully undergo marrow transplantation without an increased risk of veno-occlusive disease.[170] Patients with hepatitis-associated aplasia have markers of immune system activation and respond well to intensive immunosuppressive therapy.[161,171]

The putative viral agent in posthepatitis AA is unknown. Almost all cases have been non-A, non-B, non-C,[172,173] and non-G hepatitis by serology;[161] nor have hepatitis E or B19 parvovirus been convincingly associated.[174] Posthepatitis AA is linked to fulminant hepatitis of childhood and acute seronegative hepatitis. Acute viral hepatitis that is seronegative differs clinically from hepatitis C disease; parenteral exposure is not a risk factor, liver functions abnormalities are more severe during the acute phase, and late complications are more common.[175]

Postmononucleosis Aplastic Anemia

Acute infection with Epstein-Barr virus (EBV) causes infectious mononucleosis that is commonly associated with neutropenia and other hematologic abnormalities[176–178] but, like acute hepatitis, is only rarely complicated by AA.[179–181] However, EBV can be involved in the cause of AA more frequently than originally appreciated, because a large number of primary EBV infections are unrecognized.[180,182,183] Pancytopenia can be first observed during the acute mononucleosis syndrome or shortly after disappearance of symptoms. Some patients have recovered spontaneously, and others have recovered after therapy with corticosteroids or ATG. EBV can occasionally be demonstrated in the bone marrow cells of patients with apparently idiopathic AA, in association with serologic evidence of a primary or reactivated viral infection. Some patients with EBV-associated AA can respond to antiviral therapy.[180,184–186] For those with severe disease, conventional therapeutic interventions should be implemented early.

Hemophagocytic Syndrome

The marrow is hypocellular in approximately one-third of cases with hemophagocytic syndrome. In this disorder, there can be progression from marrow hypercellularity to aplasia; myelofibrosis is also common. Pancytopenia occurs in 74% of cases. Anemia is a universal finding; thrombocytopenia (91%) and neutropenia (65%) are also common.[187] In contrast to typical AA, these patients appear systemically ill, with fever and constitutional symptoms, and peripheral blood-cell count depression is often associated with abnormalities of other organ systems: hepatosplenomegaly, lymphadenopathy, cutaneous eruptions, and pulmonary infiltrates.[187–189] Hemophagocytic syndrome is associated with a large variety of diseases, including immunodeficiency, malignancy, and infections. In the infectious category, viral infections are most common and include EBV, cytomegalovirus, herpes simplex, and herpes zoster.[187,190] B19 parvovirus, HIV-1, and bacterial and parasitic infections also have been associated with hemophagocytosis. Hemophagocytosis is often observed on supravital[191] or Wright-Giemsa staining[152] of the marrow of patients with idiopathic AA, and it is also a morphologic feature of graft rejection after marrow transplantation.[192] In virus-associated hemophagocytosis, there is evidence of immune system activation. The sera of patients contain high levels of IFN-γ, TNF-α, IL-6, soluble CD8, and soluble interleukin 2 (IL-2) receptor, and T cells overproduce IFN-γ in vitro.[193] The clinical response to cyclosporine is consistent with a T-cell–mediated pathophysiology of hematopoietic failure.[194]

Paroxysmal Nocturnal Hemoglobinuria and Aplastic Anemia

There is a strong association between AA and PNH (see Chapter 30).[195] These diseases frequently are diagnosed concurrently or sequentially in the same individual, and they share similar clinical and pathologic features (ie, pancytopenia and marrow hypocellularity). The presence of an expanded PNH clone is associated with HLA-DR15 and has been reported as a good prognostic factor for the responsiveness to immunosuppressive therapy.[24,196–199] Marrow failure can be present at the onset of PNH or can develop after diagnosis. In a retrospective review, marrow failure was especially prevalent among young patients, occurring in 58% of them.[200] In a cooperative study from France of 220 patients with PNH (defined by a positive Ham test), there was a previous history of AA in 30%, and for the remainder, the actuarial risk of developing pancytopenia was estimated at 14% at 4 years.[201] Conversely, AA can evolve into PNH months or years after successful immunosuppressive treatment; many patients have only a positive Ham test or a population of granulocytes lacking glycophosphoinositol-linked proteins. In one study, a presumptive diagnosis of PNH based on flow cytometry was made in almost 50% of AA cases at presentation,[202] and at least one-third of all AA cases probably contain PNH clones.[203–205] Longitudinal studies of patients with de novo PNH[206] or PNH developing from AA[207] indicate a low probability of spontaneous remission, and in many patients, the contribution of the PNH clones remains stable for years. Hemolytic disease can develop in approximately one-third of these patients or 10% of AA patients.[203]

In the setting of marrow failure, PNH could develop as a result of an intrinsic growth or survival advantage for the somatically mutated cell or because of extrinsic selection of cells bearing the *PIGA* defect; most evidence favors the latter possibility. Supporting an extrinsic mechanism are the presence of multiple genetically different *PIGA* mutations in a single patient;[208] apparent in vivo selection for the development of PNH-like lymphocytes occurs in lymphoma patients treated with alemtuzumab (Campath-1), a monoclonal antibody that incidentally recognizes a glycophosphoinositol-linked protein;[209] and lack of a growth advantage for *PIGA* knock-out cells in vitro[210] and in vivo.[211] Increased rates of apoptosis within phenotypically normal, compared with PNH CD34, cells derived from the same patient are consistent with selective escape of the mutated cells from an immune attack.[212,213]

Collagen Vascular Diseases

AA is a component of the collagen vascular syndrome called eosinophilic fasciitis.[214–216] This severe, scleroderma-like disease is characterized by fibrosis of subcutaneous and fascial tissue, localized

skin induration, eosinophilia, hypergammaglobulinemia, and an elevated erythrocyte sedimentation rate. The rheumatologic symptoms of fasciitis respond to corticosteroids, but the associated AA has a very poor prognosis. A few patients have survived after bone marrow transplantation or immunosuppressive therapy. More rarely, AA has complicated systemic lupus erythematosus and rheumatoid arthritis, but in many cases, the role of concomitant drug therapy is confounding.[217] Rarely, AA can accompany Sjögren syndrome,[218] multiple sclerosis,[219] and immune thyroid disease.[219] AA occasionally occurs in individuals with hypogammaglobulinemia or congenital immunodeficiency syndrome,[52] thymoma, or thymic hyperplasia.[53,54]

LABORATORY EVALUATION

Peripheral Blood

In typical cases of AA, all the blood cell counts are depressed. The blood smear usually shows obvious paucity of platelets and leukocytes but normal RBC morphology; toxic granulations can be present in neutrophils. Automated cell counting shows erythrocyte macrocytosis and a normal red cell distribution of width. Platelet size is normal and not increased as in immune peripheral destruction, but the low number can cause greater heterogeneity of size. Prior transfusions alter platelet numbers, relative reticulocyte counts, and hemoglobin values. Although relative lymphocytosis is very common, most patients also have decreased absolute numbers of monocytes[220] and lymphocytes. The severity of AA can be graded based on the peripheral blood cell counts (see Table 29–6 and box on Diagnostic Algorithm in Aplastic Anemia).

DIAGNOSIS OF APLASTIC ANEMIA

Although the ultimate diagnosis of AA rests on the interpretation of an adequate bone marrow biopsy specimen, important clues to the cause of pancytopenia can be obtained from the history, physical examination, and laboratory data. Pancytopenia that is not primarily hematologic in origin but secondary to other disease processes is usually an obvious diagnosis. Patients with severe liver disease and splenomegaly, systemic lupus erythematosus, or overwhelming sepsis can have low blood cell counts, but their clinical presentation is not subtle. Similarly, bone marrow aplasia follows cytotoxic drug therapy for cancers and is an anticipated and transient toxic effect for a variety of nonmalignant diseases. In the challenging case, obvious medical causes of pancytopenia usually have already been excluded. Pancytopenia almost never results from peripheral blood cell destruction alone. In AA, the blood smear does not show reticulocytes, band forms, or the large platelets typical of increased compensatory bone marrow efforts.

Acquired AA is a disease of the young, as is constitutional aplasia. Patients with Fanconi anemia often, but not always, have physical abnormalifies. In the absence of a suggestive family history or the presence of physical anomalies, the distinction between acquired and constitutional disease depends on the results of a clastogenic-stress culture of peripheral lymphocytes (for Fanconi anemia) and increasingly on genetic testing for mutations in the fanconi anemia (FA), telomere repair, and other genes.

In most older patients, the major differential diagnosis is between AA and myelodysplasia. There is a gray area between hypocellular myelodysplasia and moderate aplastic anemia, and competent hematologists might not agree on the final diagnosis. Bone marrow cytogenetics can help in establishing the proper diagnosis.

Myelofibrosis can also produce pancytopenia, but the bone marrow is not aspirable, the spleen is often enlarged, and the peripheral blood smear shows characteristic abnormalities. Acute leukemia in children and the elderly can manifest as bone marrow hypocellularity, requiring a careful search for lymphoblasts or myeloblasts, including phenotypic analysis by flow cytometry. Peripheral blood flow cytometry for glycophosphoinositol-anchored proteins should be performed to diagnose PNH (see Chapter 30).

The patient's history can provide clues, such as benzene exposure for myelodysplasia and acute leukemia or a suspicious drug history for AA. Discontinuation of exposure to the incriminated drugs or chemicals is mandatory, and in some instances, patients may then recover. However, given the difficulty of assigning blame with absolute certainty to environmental agents, we treat all patients similarly and do not advocate protracted observation for possible spontaneous recovery. For patients with severe disease (see Table 29–6), suitable and early preparation for bone marrow transplant should be undertaken or immunosuppression begun, whereas for those with moderate disease, the clinical status should be evaluated, and serial blood cell counts are required to assess progression of the disease.

BONE MARROW

The marrow must be assessed quantitatively and qualitatively for cellularity and the morphology of residual cells (Fig. 29–8 and see Fig. 29–1). Marrow aspiration and biopsy should always be performed, and the core specimen should be at least 1 cm long. There should be no compromise in obtaining adequate specimens and no hesitation in performing a second procedure if required.

Bone marrow cellularity is best estimated from the core biopsy. Point counting under microscopic cross hairs in many parts of a histologic section[221] is the most accurate method of determining cellularity, but hematologists commonly rely on visual estimation only.[222] A crude "eyeball" approximation is almost always adequate in severe aplasia, because the hematopoietic content of the marrow specimen is usually close to zero. Estimates of marrow cellularity based on examination of the aspirate smear and biopsy specimen are correlated, but dilution of the aspirate by sinusoidal blood often occurs, and the aspirate can be hypocellular when the biopsy specimen is hypercellular[223] or can show focal areas of active hematopoiesis.[224] Normal marrow cellularity decreases considerably with age, a variation that is of some importance in assessing the older patient with aplasia or myelodysplasia. In autopsy samples from normal, young children, approximately 80% of the marrow space of the iliac crest is cellular (range, 60% to 100%);[225] marrow from the sternum, vertebrae, and long bones is usually 100% cellular in infants;[226] for sternal aspirates, cellularity ranges from 35% to 80%.[227] Marrow cellularity gradually decreases from age 20 to 70 years and more precipitously in the very elderly, to approximately 30% in the eighth decade of life.[225] For practical purposes, the lower limit of normal marrow cellularity in adults is accepted at approximately 30%, but the differences at the extremes of life should be recalled when evaluating infants and the elderly. In most patients with AA, total marrow cellularity is extremely low, but there can be significant residual lymphocytosis. The increase in marrow fat in aplasia is caused by increases in the size and number of individual fat cells. "Hot pockets" of hematopoiesis can be present.[228] The marrow tends to contract centripetally with age, and a similar process can be observed in pathologic states, so the sternal bone marrow can be more cellular than iliac crest samples.

Examination of the bone marrow (Figs. 29–8 and 29–9 and see Fig. 29–1) is basic for the diagnosis of most primary hematologic causes of pancytopenia (see Table 29–1 and box on Diagnostic Algorithm in Aplastic Anemia). Information can be gained by observing the marrow aspirate itself. A fatty, even watery specimen can usually be aspirated without difficulty from an aplastic patient, whereas a truly dry tap is more typical of a packed or fibrotic bone marrow. The morphology of individual cells is best seen in the Wright-Giemsa–stained aspirate smear, and the architecture of the marrow is appreciated in a biopsy section. In acellular specimens, the only cells visible are usually lymphocytes, plasma cells, and stromal elements—fibroblastoid and histiocytic cells. Some degree of dyserythropoiesis is common, usually the megaloblastoid features of macrocytosis and some nuclear-cytoplasmic maturation asynchrony, but sometimes more complex degenerative changes in nuclei and cytoplasm can be

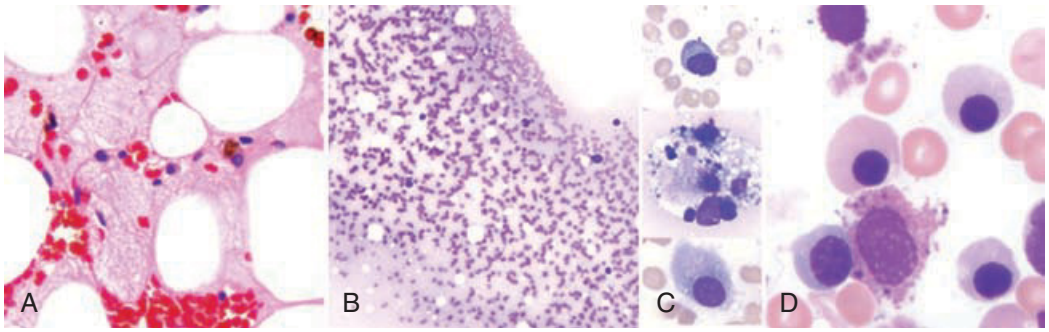


Figure 29–8 SOME MORPHOLOGIC FEATURES OCCASIONALLY OBSERVED IN PATIENTS WITH APLASTIC ANEMIA. (A–D). Empty marrow with eosinophilic ground substance consistent with serous atrophy or stomal injury (**A**), possibly indicative of marrow damage. Scanty marrow aspirate in severe disease (**B**) showing only rare nucleated elements many of which are from blood. Presence of plasma cells, histiocytes and osteoblasts (**C**) confirms marrow nature of aspirate. Note: sometimes the histiocytes can show hemophagocytosis. Megaloblastoid erythropoiesis (**D**) is sometimes seen in aplastic anemia and in recovery.

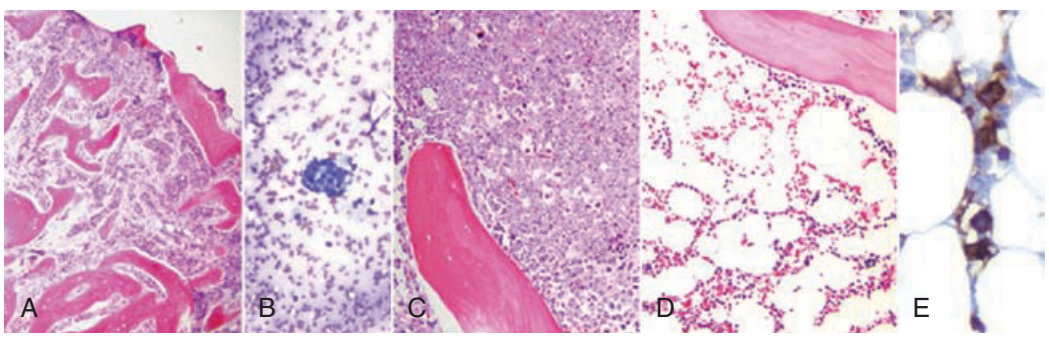

Figure 29–9 MORPHOLOGY OF OTHER DISEASES THAN MAY MANIFEST WITH PANCYTOPENIA. (A–E). Bone marrow biopsy from patient with pancytopenia showing myelofibrosis and osteosclerosis associated with metastatic prostate cancer (**A**). The aspirate was hypocellular but did show occasional tumor clusters (**B**). Another case where the patient presented with pancytopenia and was found to have a bone marrow packed with lymphoma cells (**C**). Hairy cell leukemia can present with pancytopenia and with a hypocellular bone marrow (**D**) difficult to distinguish from aplastic anemia. The diagnosis rests on identifying a B-cell infiltrative process with immunohistochemical stains (**E,** CD20).

observed by light[229] and electron[230] microscopy (see Fig. 29–8). These features are common to AA and myelodysplasia (see Table 29–7), which can be very difficult to distinguish.[231] Hemophagocytosis of RBCs can also be seen in AA. Examination of the cells close to the spicules of a sparse aspirate smear can disclose a distinctive population of leukemic blasts; increased numbers of myeloblasts are not seen in AA and are evidence of aleukemic leukemia or herald the evolution of leukemia from pancytopenia.[232] Lymphoid aggregates, nests of tumor cells, granulomas, and infectious particles can be apparent on examination of the fixed biopsy specimen.

Karyotyping of marrow cells is diagnostically important. Unfortunately, the yield of cells from a hypocellular marrow can be inadequate to perform cytogenetic analysis. Chromosome analysis is usually normal in AA[231] but frequently reveals a clonal abnormality in myelodysplasia.[233,234]

Radiographic Measures of Bone Marrow Function

Magnetic resonance imaging (MRI) with spin-echo sequences can be useful in the study of bone marrow disease. On T1-weighted spin-echo images, fatty marrow appears bright and cellular marrow exhibits a lower density signal (see Fig. 29–9). The high fat content of aplastic bone marrow can be readily appreciated on MRI. Magnetic resonance (MR) spectroscopy, which detects the type of fat signal, has shown diverse patterns among AA patients.[235] MRI is complementary to tissue sampling, allowing a large area of marrow to be visualized and fat content to be roughly quantified. The technique appears to be worthwhile in diagnosis, because the patterns of fat and cell distribution appear to differ between aplasia and hypocellular myelodysplasia, and in prognosis, to monitor improvements in hematopoiesis after treatment.[236]

DIFFERENTIAL DIAGNOSIS OF PANCYTOPENIA

AA is not the most common cause of pancytopenia (see Table 29–1). In one study of 100 pancytopenic cases, a diagnosis of AA could be made in only 19, despite prescreening for systemic or malignant diseases.[237] A rational diagnostic algorithm can be very helpful in establishing a correct diagnosis (see box on Diagnostic Algorithm in Aplastic Anemia). Pancytopenia is unlikely to be the presenting feature of hypersplenism in cirrhosis or of Evans syndrome in systemic lupus erythematosus. Findings on physical examination can point strongly toward another diagnosis. For example, the patient with myelofibrosis usually has splenomegaly, whereas a large spleen is very unusual in AA. Although vitamin B_{12} and folate deficiencies have been reported to be associated with erythroid hypoplasia,[238] this must be an exceedingly rare event. For the practicing hematologist, the most important and difficult choice of diagnoses in pancytopenic patients is among the primary bone marrow disorders. An empty bone marrow is usually obvious, but diagnostic

confusion arises from the equivocal character of moderate AA, alterations in the marrow appearance in patients with chronic disease, and real overlaps among AA, myelodysplasia, and leukemia.

In moderate AA, the modest depression of marrow cellularity can muddle the single most reliable diagnostic criterion. Bone marrow cellularity is imprecisely quantitated at best, and further uncertainty is introduced by large sampling errors. "Hot spots" of hematopoietic activity in an otherwise acellular specimen reflect biologic heterogeneity in the pattern of cell loss. In patients with a syndrome of transient pancytopenia, spontaneous recovery occurs within a few months; although the blood cell counts can be severely depressed, the marrow is much more commonly normal or hypercellular than hypoplastic. In patients with chronic bone marrow failure, serial bone marrow specimens may not be identical because of sampling error or because the original disease was misdiagnosed or has changed its character. Some patients with AA are not pancytopenic; they do not have uniform depressions of RBC, WBC, and platelet production, despite an empty bone marrow, and their clinical course is dominated by failure in two cell lines or a single hematopoietic lineage. Related conditions such as pure red cell aplasia, amegakaryocytic thrombocytopenia, and agranulocytosis, although usually distinctive in their clinical presentation, can evolve into more generalized marrow failure. In the absence of better markers, sometimes the only accurate diagnosis is a description of the clinical features and the specific marrow morphology.

A hypocellular bone marrow often precludes the proper morphologic diagnosis. This problem can be especially evident in the case of a myelodysplastic syndrome with hypoplastic bone marrow (see Table 29–7). In addition to the clinical features, more sophisticated laboratory studies can be helpful. Bone marrow cytogenetics, if positive for chromosome abnormalities, can facilitate the diagnosis of leukemia or myelodysplastic syndrome. Conventional bone marrow examination is not helpful in differentiating AA from Fanconi anemia or dyskeratosis congenita (see Chapter 28).

TREATMENT

AA should be considered a medical emergency. Lives are lost, mainly because the grave consequences of severe pancytopenia go unrecognized. The ultimate benefits of definitive therapies such as transplantation or immunosuppression will be unrealized if the patient succumbs to an early clinical catastrophe. A haphazard transfusion policy increases the risk of graft rejection after marrow transplantation, but an overly conservative approach to transfusion can jeopardize the patient's life and increase morbidity. Supportive management therefore requires meticulous attention to the daily problems that occur as a consequence of pancytopenia and appreciation of their impact on the ultimate possibilities for cure or amelioration of AA. AA can be cured by replacement of stem cells, by bone marrow transplantation, and by immunosuppressive therapy. Androgens and hematopoietic growth factors have secondary roles (box on Treatment Algorithm in Aplastic Anemia).

Supportive Management

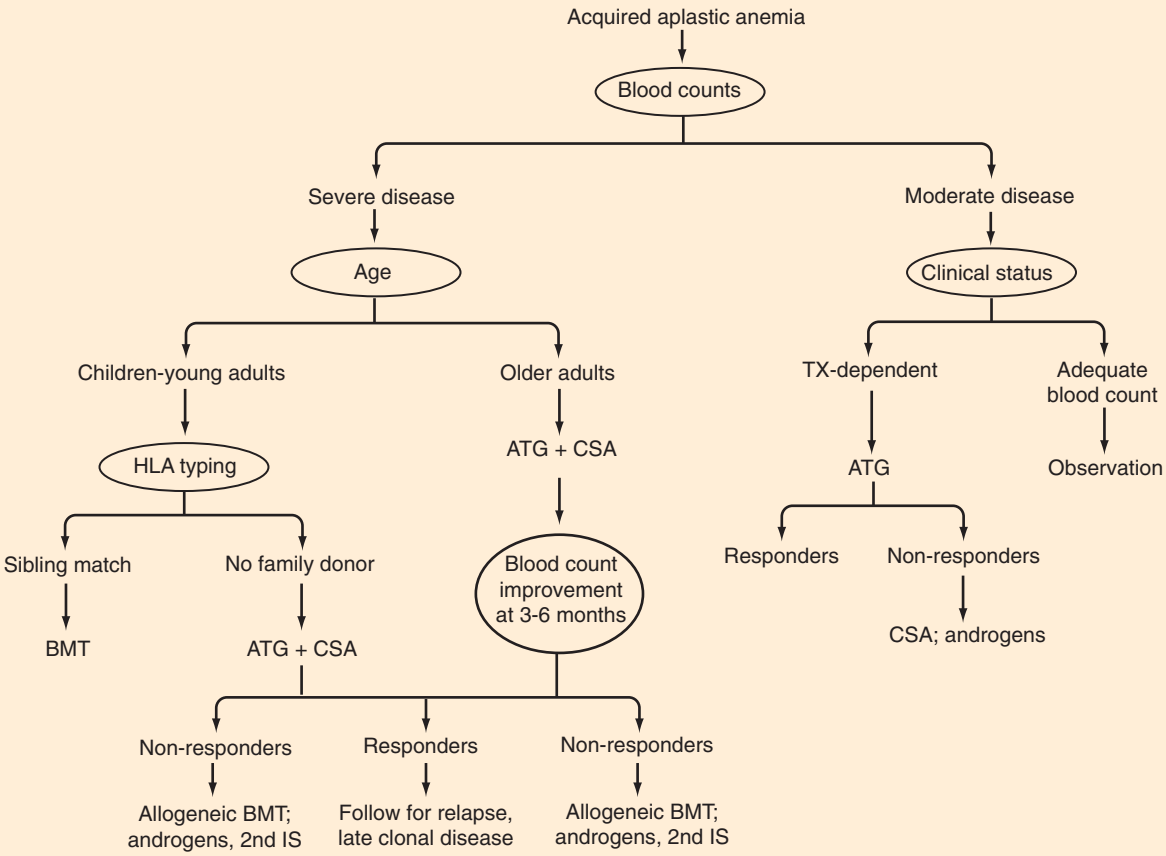
Bleeding

Bleeding was historically a common symptom in AA, and death from hemorrhage occurred frequently in the premodern era. Platelet transfusions have substantially improved survival in patients with this disease. Measurable correction of the platelet count by transfusion almost always alleviates the minor mucocutaneous bleeding common in thrombocytopenic patients. Major bleeding usually is not caused by thrombocytopenia alone, and ancillary explanations for massive hemorrhage should be sought. The bleeding time improves after erythrocyte transfusion in patients with anemia, and there is a strong inverse correlation between the hematocrit and bleeding.[239] The treatment of serious hemorrhage should include correction of severe anemia and RBC transfusions.

Modern transfusion practice has made platelets readily available and safe to administer. Other than cost and convenience, the major problem related to platelet transfusions is the development of alloimmunization in the recipient.[240,241] The life span of the transfused platelet in the circulation is dramatically shortened by host antibodies, almost always directed to HLA-A and HLA-B antigens. Alloimmunization is suggested by poor recovery of the 1-hour posttransfusion platelet count and confirmed by finding specific HLA antibodies in serum.[242,243] Refractoriness can often be overcome by selection of HLA-matched donors, but 6% to 39% of perfectly HLA-matched transfusions fail.[243] Alloimmunization can be prevented or delayed by the use of single-donor platelets rather than pooled platelets,[244] and by physical leukocyte depletion by filtration or ultraviolet treatment of blood products[245–247] Avoidance of platelet transfusions except when there is active bleeding is another alternative to prevent alloimmunization, but the dose relationship between exposure to different donors' platelets and the probability of developing refractoriness are not clearly established,[243] and only after more than 40 units have been administered does the risk of alloimmunization clearly increase.[248]

Prophylactic transfusion of platelets is not standard.[249,250] The primary indication for platelet prophylaxis is to prevent intracranial hemorrhage, but the risk of this complication in the chronically thrombocytopenic patient, although real, is low. Prophylactic platelet transfusions have not been shown to alter survival.[249–251] Nevertheless, the beneficial effects of avoiding bleeding complications and improving the quality of life justifies their use.[252] Maintenance of platelet counts higher than 20,000 platelets/μL decreases bleeding episodes,[253,254] but the threshold is based on an old study showing reduction in days of bleeding and serious hemorrhage among children with acute leukemia.[255] Although the 20,000 platelets/μL value has long been used to trigger transfusion, many reports have suggested little difference in the risk of bleeding over a wide range of platelet counts between 5000 and 100,000 platelets/μL.[256,257] In one study of a rigorous transfusion policy during induction therapy, fatal or severe bleeding episodes were rare and did not occur in patients with platelet counts higher than 10,000 platelets/μL; the worst bleeding episodes in these cases were associated with refractoriness to platelet transfusions.[258] In a randomized trial of patients with AML, the risk of major bleeding was no different when 10,000 or 20,000 platelets/μL was chosen as the threshold, whereas the lower value led to a 20% reduction in platelet use.[259] Any prophylaxis program must be modified to address the individual patient, but a goal of maintaining platelet counts higher than 5000 platelets/μL is reasonable.

Major surgery can be accomplished in the setting of thrombocytopenia. In one study, blood loss and morbidity rates were low even at platelet counts of less than 30,000 platelets/μL.[260]



Anemia

Other than to reduce the risk of graft rejection after receiving an allogeneic transplant, there is no reason to allow a patient to suffer the symptoms of anemia. After equilibrium is achieved, a constant amount of blood will be required to maintain a given hemoglobin concentration. Physically fit individuals are usually not symptomatic at hemoglobin concentrations higher than 7 g/dL; patients with underlying cardiovascular disease should be maintained at a higher level (≥9 g/dL). Iron chelation should be used in patients with unresponsive chronic anemia who have a reasonable expectation of survival.

Alloimmunization as a result of blood product administration increases the probability of graft rejection and mortality after marrow transplantation. Blood products from a potential marrow donor such as a sibling or a parent (who share histocompatability antigens) should be avoided. Small numbers of transfusions do not have a major deleterious effect on survival. The 5% risk of graft rejection after transplantation in entirely untransfused patients was increased to 15% with receipt of 1 to 40 units and to higher than 25% only in more heavily transfused patients.[261] An increased rate of graft rejection was observed in patients who had received more than 10 units

of erythrocytes or 40 or more units of platelets and would be anticipated to be lower with leucocyte-depletion methods of platelet preparations.[262] Speed in arranging tissue typing and transfer to an appropriate center has a greater impact on the survival of the patient than the judicious transfusion of a few units of RBCs to a severely anemic patient or platelets to a bleeding patient. Transfusions should not be withheld in an older patient in whom immunosuppressive therapy will be the first-line therapy.

Infection

There are very few specific reports of infections and their therapy in patients with AA.[220,263] The duration of neutropenia is the major difference between the neutropenia of bone marrow failure and that induced by cytotoxic chemotherapy. With longer periods of neutropenia, the probability of serious bacterial or fungal infection increases. A second major difference is that neutropenia is part of a complex of problems associated with malignant disease and its therapy. In AA, the immune system is activated, and with the exception of intravenous catheter placement, the integument is preserved. Studies of cancer patients have usually identified a low-risk category of neutropenia, determined by the relatively brief period of neutropenia; by this criterion, almost all unresponsive patients with AA are at high risk.

In classic studies of leukemic children, neutropenia was shown to increase susceptibility to bacterial infections, and the number of infectious episodes was quantitatively correlated with the degree and duration of neutropenia.[264,265] Susceptibility to infection is extremely high with an absolute neutrophil count of less than 200 platelets/μL, and this value has been used to define a category of very severe AA.[266] As severe granulocytopenia becomes prolonged, infection is inevitable.

Recommendations for initiation of empirical antibiotic therapy are similar for AA patients and other patients with neutropenia. The cardinal rule is, if the absolute neutrophil count is less than 500 cells/μL and infection is suspected, broad-spectrum parenteral antibiotic therapy should begin immediately. Any regimen can need modification based on results of cultures, new symptoms or signs, or a deteriorating clinical course. Bacteremia is present in only 20% of febrile neutropenic episodes, and in only approximately 40% of those can a microbiologic cause or localizing physical findings be identified.[267,268] Early discontinuation of antibiotics when cultures are unrevealing in persistently neutropenic patients is dangerous.

Patients often remain febrile despite antibiotic therapy, or fever reappears. In the absence of additional microbiologic data or clinical clues from the patient's complaints or physical examination, antifungal therapy should be instituted in patients who have remained febrile despite adequate antibacterial therapy. Current infectious disease guidelines recommend introduction of antifungal therapy after five days,[269] but earlier addition can be advisable in the AA patient, especially if there are findings on chest tomography and a positive test for galactomannan protein. Fungemia during an initial febrile episode is rare, but fungal infection becomes more likely with repeated courses of antibiotics and ultimately is the major cause of death in AA patients in whom definitive therapy fails.[270] *Candida* and *Aspergillus* species account for almost all fungal diseases in AA.[270] Early aggressive treatment of neutropenic patients can reverse fungal

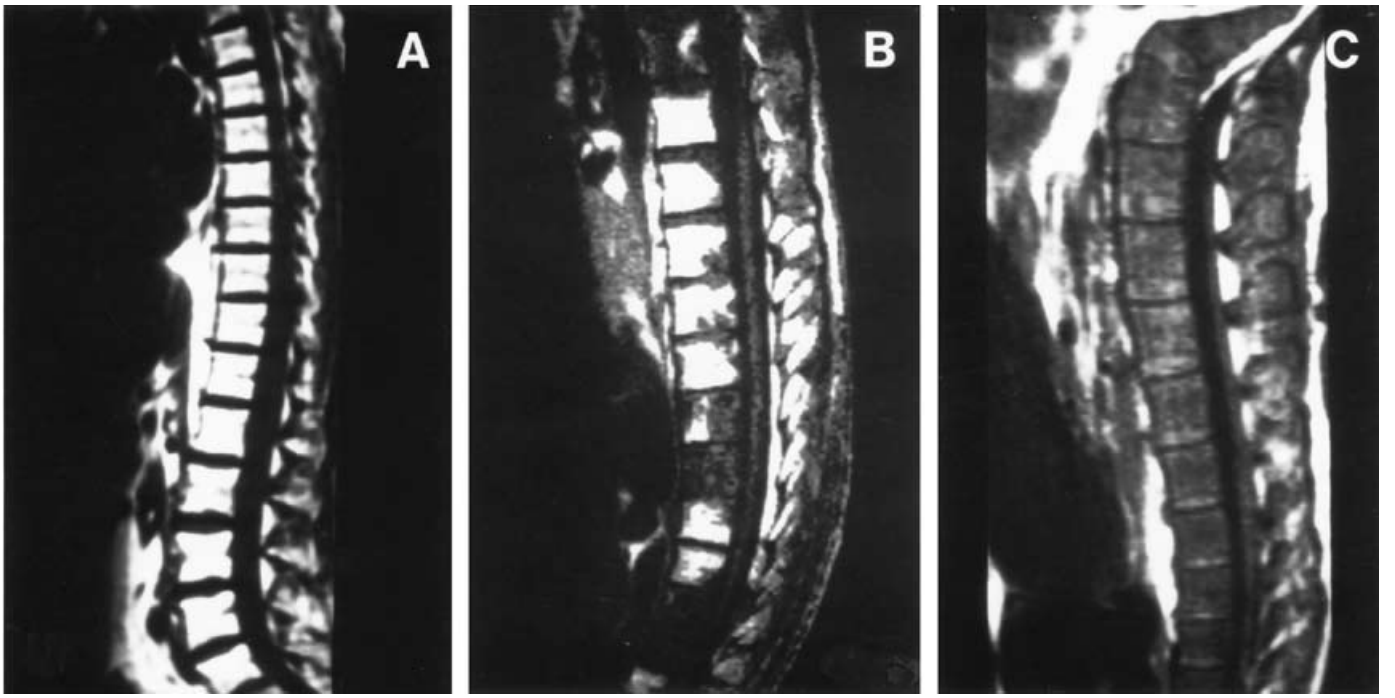

Figure 29–10 Magnetic resonance imaging of bone marrow (**A**) in a young man with severe aplastic anemia, (**B**) in a middle-aged woman with severe aplastic anemia, and (**C**) in a middle-aged woman with myelodysplasia.

disease, as demonstrated in individual cases[271] and by comparison of autopsy series.[272] Large randomized trials have shown that newer antifungal agents such as voriconazole and caspofungin are less toxic and as effective or superior compared to amphotericin and liposomal amphotericin for treatment of both persistent neutropenic fever and established *Candida* and *Aspergillus* infection.[273–276]

Polymorphonuclear cells have a relatively brief life span in the circulation and their major activity is in infected tissue. There are no simple measures of the therapeutic efficacy of WBC transfusions. The absolute neutrophil count is not measurably increased by standard transfusions. Nonetheless, several controlled trials performed in the 1970s reported improved survival in patients who received granulocyte transfusions; the negative studies were criticized because of the relatively low numbers of granulocytes transfused ($<10^{10}/m^2$/day).[277–279] Granulocyte transfusions are expensive and associated with serious toxicity: severe febrile reactions, pulmonary capillary leak syndrome, an increased risk of infection, and inevitable alloimmunization. A meta-analysis of published studies suggested that granulocyte transfusions helped in patients with sepsis unresponsive to antibiotics if adequate cell numbers were administered (2 to 3×10^{10}/day), donor and recipient were compatible, and the patients treated were unlikely to have imminent improvement in marrow function.[280] Later studies suggested that if sufficient numbers of granulocytes can be harvested, granulocyte transfusions could be beneficial in the management of refractory infections in neutropenic patients.[281]

Cytokines offer a strategy for increasing the efficiency of donor harvests. Administration of GCSF to normal donors greatly increases the yield of leukapheresis without adverse effects on the volunteers.[282,383] The addition of dexamethasone to GCSF results in granulocyte yields higher than GCSF or dexamethasone alone.[284,285] Excellent results can be obtained from community donors,[286] and the use of allocompatible granulocytes (as determined by lymphocytotoxicity screening assay) can further improve clinical results of granulocyte transfusions.[286] Large numbers of neutrophils can be obtained, allowing dramatic increases in the absolute granulocyte levels in neutropenic recipients, which can improve clinical outcomes; case reports and phase I and II studies have suggested that GCSF (GCSF plus dexamethasone)-mobilized granulocyte transfusions can be helpful in the treatment of life-threatening fungal infections in severely neutropenic patients.[287–291]

Definitive Therapy

Hematopoietic Stem Cell Transplantation

Allogeneic bone marrow transplantation from an HLA-matched sibling donor provides curative therapy for AA patients (Fig. 29–10 and Tables 29–8 and 29–9). Bone marrow transplantation in AA is the subject of a large number of reports and reviews.[292–296] Cytokine-mobilized peripheral blood also has been used successfully as a stem cell graft.[297–299] The convenience of this method probably has led to its substitution for marrow harvesting as the major method of stem cell collection in many circumstances, but whether results for patients with AA for both sources are equivalent remains uncertain[300] (see box on Treatment Algorithm in Aplastic Anemia).

The first studies of allogeneic bone marrow transplants conclusively demonstrated their value compared with conventional supportive therapy. In a controlled trial reported by the International Aplastic Anemia Study Group, patients with severe disease who received transplants early had an actuarial survival rate of more than 60%, compared with approximately 20% in patients who received androgens and blood transfusions only.[301] Results with marrow transplantation have improved over time because of a combination of factors: progressive modification of conditioning regimens and lower procedure-related early mortality, improved transfusion support and antibiotic regimens, and the introduction of cyclosporine as prophylactic therapy for GVHD. Analysis of the International Bone Marrow Transplant Registry data showed that 5-year survival rates climbed from 48% in the years 1976 to 1980 to 66% is 1988 to 1992.[302] Some hospitals now report very high rates of survival: 89% in Seattle at 8 years,[303,304] 79% in Baltimore,[305] 89% and 95% at Viennese centers.[306,307] Registry data indicate lower survival values as the general experience for the same period, with 64% of patients who received transplants during the period of 1985 to 1991 alive at 5 years after the procedure.[308] Between 1990 and 1994, the European Group for Bone Marrow Transplantation (EGBMT) reported a 72% survival rate at 3.5 years.[309] In the latest update of the EGBMT, the long-term survival had further improved over the past 5 years to 80%[310,311] In the most favorable subgroup—untransfused or minimally transfused, young, uninfected patients—survival rates of 80% to 90% should be routinely achieved (see Fig. 29–10).[312] Overall,

Table 29–8 Results of Matched Sibling Donor Allogeneic Marrow Transplantation for Aplastic Anemia

Institution/Study	Years of Study	*N*	Age (median in years)	Graft Rejection/Failure	Acute GVHD	Chronic GVHD	Actuarial Survival

Therapy for Aplastic Anemia

After the diagnosis of acquired AA has been established, treatment options must be identified, considered carefully, and chosen with alacrity (see box on Treatment Algorithm in Aplastic Anemia). For patients with moderate disease (see Table 29–6), an expectant approach can be chosen based on a stable course and adequate blood counts, or for patients dependent on transfusion support, ATG (40 mg/kg/day for 4 days) can be given. Intradermal sensitivity testing with 50 ng/mL of ATG solution should be performed, and patients showing an immediate reaction should be desensitized. After assessment of the response, patients who improve should be monitored for hematologic signs of relapse, and nonresponders can be offered alternative therapy, such as androgens or cyclosporine. Daclizumab, a humanized monoclonal antibody to the IL-2 receptor, improved blood counts and relieved transfusion requirements in 6 of 16 patients who were able to be evaluated; this outpatient regimen had little toxicity.[82] In severe disease for which the prognosis with blood transfusion and antibiotic support alone is very poor, bone marrow transplantation from a histocompatible sibling or immunosuppression are accepted and effective therapies. Although large, retrospective analyses have shown that long-term survival rates from transplantation or immune therapy are equivalent, each has its own advantages and disadvantages. For children, bone marrow transplantation remains the treatment of choice if an appropriate family donor is available, because these patients have a low rate of GVHD, and the marrow disease is cured by stem cell replacement. The risk of therapy-related cancers can be increased, especially in children, after marrow transplantation. Adults with AA also successfully receive transplants, although the risk and severity of chronic GVHD and other treatment-related complications increase with age. Bone marrow transplantation has been performed in patients older than 50 years of age, and it is a reasonable approach in a younger adult, especially with more severe degrees of neutropenia.

Most patients with AA do not have an HLA-matched sibling donor, and immunosuppression is the treatment of choice in these cases. Patients with severe disease should receive a combination of ATG and cyclosporine. We recommend a regimen consisting of 40 mg/kg/day of horse ATG on days 1 to 4, followed by cyclosporine for 6 months at a dose of 12 mg/kg. Corticosteroids are added in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate serum sickness. Improvement should be expected within 6 months. This regimen has produced hematologic responses in approximately 70% of treated patients, who then have an excellent 5-year survival rate.

Although immunosuppressive therapy is relatively nontoxic, patients frequently relapse and require further treatment; however, relapse is not associated with a poor prognosis. A more serious problem is the development of late-onset hematologic clonal diseases, PNH (which may not be clinically significant), myelodysplastic syndrome, and rarely, acute myeloid leukemia. Immunosuppression can be considered ameliorative therapy in which bone marrow destruction may continue and abnormal stem cell clones develop.

For patients in whom immunosuppressive therapy fails, there are a number of options. For children, alternative donor bone marrow transplantation should be seriously considered; at the best centers, survival rates now are almost as good as with sibling donors. Adults do less well, primarily because of transplant-related mortality from the intensive conditioning regimen. Some patients respond to androgen therapy, and others to combinations of growth factors. Repeated immunosuppression in a patient in whom a first course of ATG and cyclosporine has failed is successful in about 30% of cases. High-dose cyclophosphamide can also be effective therapy for AA at presentation and in those patients refractory to ATG.

Patients with severe AA should not be subjected to useless early trials of corticosteroids or hematopoietic growth factors as the primary treatment. For the occasional patient who must decide between bone marrow transplantation and immunosuppression, the advice of experts familiar with this disease and careful counseling of the patient are advisable. Age and severity of neutropenia are decisive factors. A limited number of transfusions can be necessary to optimize the patient's condition before definitive therapy and are acceptable. Single-donor platelets should be given and can be obtained from HLA-compatible donors. In severely neutropenic patients, GCSF therapy can decrease the risk of life-threatening infections. In the absence of overt bleeding, platelet counts as low as 5000 cells/μL appear to be safe.

the survival rates reported from major centers are approximately 70%.[313,314]

Graft rejection and GVHD are the major complications of allogeneic transplantation in AA. Graft rejection is a major predictor of posttransplantation survival. In one study of transplantations performed between 1981 and 1986, 29% of deaths resulted from graft rejection, the single most common cause of mortality.[315] The rate of graft rejection decreased with intensification of the immunosuppressive conditioning regimen from 15% to 4% in Europe[315] and from 35% to between 10% and 15% in Seattle[316] and has remained stable in the past decade.[317] Graft rejection can be caused by the pathophysiology of AA, a finding supported by the unexpectedly high proportion of failures in unprepared patients receiving syngeneic transplants[318–321] and even in adequately preconditioned patients receiving syngeneic transplants.[322,323] In a group of untransfused patients who received allogeneic stem cells, the incidence of graft rejection was 10%, indicating that AA patients may be particularly sensitive to alloimmunization.[324] Nevertheless, the influence of the number of transfusions on graft rejection is relative, and modest numbers of blood donations (<40 units in the International Bone Marrow Transplant Registry experience[261] and less than 10 units of erythrocytes or 40 units of platelets in Seattle[262]) did not greatly increase the risk of graft rejection.

Matched Sibling Donor (Hematopoietic Stem Cell Transplantation [see Table 29–8])

Intensification of immunosuppressive conditioning regimens with the use of total-body[261,325,326] or lymphoid irradiation,[327,328] cyclosporine,[261,305] or ATG[303] reduces the risk of graft rejection. Such measures, however, have not been shown to influence long-term survival.[261,329,330] The effect of the conditioning program on graft rejection probably is achieved through elimination of the recipient's lymphocytes and of subsequent mixed hematologic chimerism, which is associated with rejection.[331,332] More rapid regeneration of bone marrow grafts has been observed when cyclosporine[3] was used,[333] and second transplantations have been successful when ATG was added to the conditioning regimen.[334] The effect of ATG or cyclosporine in the conditioning regimen on the rate of graft rejection has been tested in randomized studies.[303,335,336] Conditioning regimens that do not include irradiation now regularly achieve engraftment and avoid many of irradiation's long-term complications, especially late cancers. In a recent series of 81 patients who were prepared by cyclophosphamide plus ATG, sustained engraftment was achieved by 96%, and three of the four patients who rejected were successfully retransplanted; 88% of patients survived long-term.[85] The combination of cyclophosphamide plus fludarabine, with or without ATG,

has achieved high rates of graft acceptance and survival even in heavily transfused patients who were transplanted with mobilized peripheral blood stem cells, months after proving refractory to immunosuppressive drugs.[86,87] The use of methotrexate and cyclosporine has not improved rates of GVHD compared with cyclosporine, but surprisingly, methotrexate was associated with a better survival rate for patients with AA transplanted from matched sibling donors.[337] Overall, the reported rejection rates range between 10% and 15%, account for 14% of deaths in the first 100 days after transplantation and 23% of deaths thereafter.[313]

Rates of chronic GVHD vary and are related to patient selection and treatment regimens. Historically, age is the major risk factor for the development of chronic GVHD. The incidence of chronic GVHD ranged from 19% for patients between 0 and 10 years old to 46% for those between 11 and 30 years old and to 90% for patients older than 31 years in an older Seattle series.[338] With improved treatment regimens, patients have fared better, but additional studies have confirmed a higher incidence and more serious consequences of GVHD in older patients.[339,340] Children have a lower probability of suffering and dying from chronic GVHD.[341] In an EGBMT analysis, a significant survival difference was observed between those younger than 20 years of age (65%) and those older than 20 years of age (56%), but there was no survival difference between patients 21 to 30 years old and those 31 to 55 years old.[329] Young adults have fared better in other series,[342,343] although morbidity from severe GVHD disease was far more prevalent in the young adults than in children (43% versus 10%).[342,343] Overall, the acute GVHD rate between 1991 and 1997 was approximately 20% for patients younger than 20 years of age and 40% for those older than 40 years of age. In general, similar numbers were cited for chronic GVHD.[313]

In summary, excellent survival rates and low morbidity in younger patients make allogeneic bone marrow transplantation the treatment of choice for children and adolescents. Older adults have a higher risk of transplant-related morbidity and mortality. Younger adults have a good opportunity for cure with transplantation but face more complications than children. In addition to age, a prolonged interval between diagnosis and transplantation, multiple transfusions, and serious infections before transplantation are poor risk factors.

Matched Unrelated and Nonhistocompatible Family Donors (see Table 29–9)

Until recently, the lack of an HLA genotypically identical sibling donor has precluded marrow transplantation, excluding approximately 70% of patients with AA from access to this therapeutic option. Alternative potential donors include relatives who are phenotypically matched or partially matched and HLA phenotypically matched but unrelated volunteers. Although phenotypically identical family donors are occasionally available, mismatched family members and matched but unrelated donors represent a much larger pool.[344]

Haplotype sharing between parents occasionally has allowed identification and successful transplantation between phenotypically matched relatives.[345,346] Long-term survival after even one-locus-mismatched family donation is inferior to genotypically matched transplants, mainly because of graft rejection and GVHD. In the large European experience, for phenotypically identical family matches, the actuarial survival rate was 45%; for patients with a single-locus mismatch, it was 25%; and for those with two to three loci mismatched, the survival rate was 11%.[347,348] In a report from Seattle,[346] although all patients who received fully HLA-matched transplants survived, those with mismatches at one or more loci had a much poorer outcome, and even with total-body irradiation added to the conditioning regimen, the survival rate was only 50%. Most large studies of unrelated donors have shown inferior long-term survival and higher rates of complications such as graft rejection,[349] GVHD,[350,351] and delayed immune system reconstitution.[352] Even more than in standard sibling transplants, age is a crucial risk factor in unrelated transplants and probably more important than the level of match, conditioning regimen, or use of T-cell depletion.[344,348,353–355] For patients with AA who received unrelated transplants and who were enrolled in the National Marrow Donor Program, the survival rate at 2 years was 29%.[356] In the EGBMT's 1994 report, the survival rate for 110 recipients of marrow grafts from other than a matched sibling was 34%, approximately one-half of the rate of standard transplantation.[309] Superior results were obtained at Children's Hospital in Milwaukee, where T-cell depletion of the donor graft was combined with a rigorous conditioning program of cytosine arabinoside, cyclophosphamide, and total-body irradiation. For 28 transfused and previously treated children with severe AA, a survival rate of 54% was reported at a median follow-up of almost 3 years, with no incidence of chronic GVHD.[357] Similar results have been reported in a series of 154 transplantations performed in patients between the ages of 1 and 46 years of age (median, 17 years of age), with delayed transplantation (>3 years after diagnosis), HLA-A or HLA-B mismatch, and age being poor risk factors.[358] In a meta-analysis,[359] for fully matched, unrelated recipients, the survival rate was 25% to 50%, with rates of graft failure and GVHD of 0% to 50% and 28% to 100%, respectively. The degree of match clearly impacts the outcome of the unrelated bone marrow transplantation.

Despite progress, matched but unrelated transplantation is associated with a high mortality rate, and perhaps refractory, high-risk patients are therefore often selected for this procedure. It is likely the poor results may be a consequence of this referral bias. However, alternative-donor transplantation is feasible; the rare phenotypic match from within the family may be equivalent to a sibling donor, but with other family members or unrelated donors, there is a high risk of transplantation-related mortality. Because unrelated-donor transplantation takes months to arrange, it should be considered early. At the best centers, alternative-donor transplantation represents an option, especially for the young patient with very severe pancytopenia in whom immunosuppressive therapy has failed. In Japan, an unrelated but matched transplant has been reported to produce better results in refractory pediatric cases when used early rather than after repeated courses of immunosuppression.[360] In an analysis from Seattle, patients who failed one or more courses of immunosuppression had an overall survival rate of 36% at 3 years.[361]

Introduction of transplantation with less intense conditioning (ie, nonmyeloablative transplantation) and cord blood transplantation are promising therapeutic concepts that can help to improve the results of unrelated transplantation in AA and make the procedure available to a higher number of patients.

Late Complications of Bone Marrow Transplantation

Very late complications after transplantation include effects on growth and development, as well as on the function of endocrine, neurologic, and other organ systems.[362,363] A high rate of secondary malignancies has been recorded after transplantation. In a National Cancer Institute retrospective analysis of almost 20,000 transplantations, the risk of late-onset cancer was eightfold higher at 10 years than in the general population and even higher for young patients, for whom the risk of malignancy was increased approximately 40-fold.[364] Multivariate analysis suggested that high-dose radiation was a risk factor for the development of malignancies. For AA, among 320 patients who received transplants in Seattle, 4 developed cancer, leading to a calculated risk 7 times higher than for normal controls.[365] In a recent update, 12% of patients who survived more than 2 years after transplantation developed solid tumors.[366] In a French survey, 4 of 147 AA patients developed solid tumors, an 8-year cumulative incidence rate of 22%.[367] In an analysis of 700 transplantation patients with AA and Fanconi anemia, the risk of developing a secondary malignancy was 14% at 20 years. The hazard of lymphoid malignancies decreased with the time after transplantation, whereas the risk of solid tumors progressively increased.[368] Secondary solid tumors developed in the radiation fields of 5 of 147 AA patients whose conditioning regimens included irradiation of the thorax and

abdomen.[369] In general, the rates of secondary malignancies after bone marrow transplantation for AA and other diseases are similar.[370] Immune events such as acute GVHD, treatment with ATG or monoclonal antibodies, and total-body irradiation have been related to the development of secondary malignancies.[370] Patients with these secondary cancers have a poor prognosis.[371] The risk of cancer after bone marrow transplantation must be evaluated in the context of other therapeutic options, especially immunosuppression, because a significant risk of late malignancy exists in AA patients independent of transplantation therapy. The risk of malignancy in the large registry of the EGBMT was equivalent for patients who received immunosuppression and those who underwent transplantation. Compared with the general European population, the relative risk of malignancy was calculated at 5.15 for AA patients treated with immunosuppression (confidence interval [CI]: 3.26–7.94) and at 6.67 (CI: 3.05–12.65) for patients receiving transplants.[372] Overall, the rate of malignancy after bone marrow transplantation has been calculated to be 3.8-fold higher than in the age-matched population.[373]

Immunosuppression

Antithymocyte Globulins

Immunosuppressive therapy is an effective alternative treatment for patients who are not candidates for bone marrow transplantation (Table 29–10 and see box on Treatment Algorithm in Aplastic Anemia). Immunoglobulin preparations made from the sera of horses (less frequently from rabbits) immunized against human thymocytes are the mainstays of current regimens.[374–378] Rabbit and horse ATGs are licensed for use in the United States as ATGAM (Pfizer) and Thymoglobulin (Genzyme), respectively.

The efficacy of antilymphocyte globulin (ALG) in marrow failure was discovered serendipitously in the late 1960s, when Mathé[46] observed recovery of autologous hematopoietic function in patients who received antilymphocyte serum as conditioning for marrow transplantation. In a collection of European cases from Basel, Paris, and Leiden in which patients were treated with different serum preparations and with a variety of dose regimens, sustained hematologic improvements occurred in 12 (41%) of 29 patients with severe AA, and the 1-year survival rate of the entire group was 55%.[379] In a multicenter study, Swiss ALG was clearly superior to androgen treatment, with a significantly better response rate (70% versus 18%) and 1-year survival rate (76% versus 22%).[380] Similar results were also obtained in a randomized study of ATG versus supportive care.[381] In a large multicenter American trial, 47% of patients improved.[382] Review of published results from Europe and North America suggests that approximately one-half of patients treated with ATG and ALG show hematologic improvement, broadly defined as an end to transfusion dependence and an improvement in a neutrophil number to a level protective against infection.[374] Response rates vary from 20% to 85%.[374]

The putative cause of AA is not a factor that predicts response. Virus-associated[161,180] and drug-induced aplasia[383,384] respond similarly as compared to idiopathic disease. Cytogenetic abnormalities do not preclude a response because AA with chromosome abnormalities[385–387] and some cases of frank myleodysplasia[388] can be responsive to immunosuppressive therapy. The response rate to ATG or ALG is not improved by the addition of androgens[389] or very high doses of corticosteroids.[390]

A hematologic response to ATG is usually apparent within several months of therapy; in some cases, all blood counts rise dramatically, and in others, increases in platelets or RBCs can be delayed (see box on Treatment Algorithm in Aplastic Anemia). The average time to improvement in neutrophil number is 1 to 2 months.[382] Transfusion independence occurs approximately 2 to 3 months after initiation of treatment.[391,392] Continued improvement without further therapy commonly occurs after 3 months; nevertheless, clinical status by 3 months is strongly correlated with long-term survival. Blood cell counts above the critical values for severity and platelets and reticulocyte counts of more than 50,000 cells/μL are highly prognostic.[382,393,394] Patient selection is important; in general, survival correlates with disease severity,[395,396] and in particular, with a low neutrophil count.[266,329,393] Patients who develop trisomy 8 frequently maintain responsiveness to immunosuppression.[397]

ATG has three major toxic effects: immediate allergic phenomena, serum sickness, and transient blood cell count depression (see Fig. 29–10). Fever, rigors, and an urticarial cutaneous eruption are common on the first or second day of ATG therapy, and these symptoms respond to antihistamines and meperidine therapy. Anaphylaxis is rare but can be fatal.[398] A positive immediate wheal-and-flare reaction to the cutaneous application of a 50 mg/mL of stock solution of horse ATG can be predictive of massive histamine release on systemic infusion, and desensitization with gradually increasing doses of horse ATG administered intradermally, subcutaneously, and then intravenously has permitted use in allergic individuals.[398] Corticosteroids are administered in moderate doses (1 mg/kg of prednisone or methylprednisolone) during the first 2 weeks to ameliorate the symptoms of serum sickness. Doses of ATG and ALG have varied from 5 to 50 mg/kg, and the duration of administration has varied from 4 to 28 days. It is more rational to administer equivalent doses of horse ATG by the schedule originally employed in Europe (40 mg/kg/day for 4 days); antiserum will then have reached low levels in the circulation by the time host antibody appears.[399] A short course of therapy is easier to administer, associated with less serum sickness, and equally effective as the same dose given over a more prolonged course. Thymoglobulin, rabbit ATG, has been approved for use in the United States. Rabbit ATG is more potent by weight than horse

Table 29–10 Intensive Immunosuppression in Severe Aplastic Anemia

Study	*N*	Median Age (years)	Response	Relapse	Clonal Evolution	Survival
German[448]	84	32	65%	19%	8%	58% at 11 years
EGMBT[63]	100	16	77%	12%	11%	87% at 5 years
NIH[62]	122	35	61%	35%	11%	55% at 7 years
Japan*[64]	119	9	68%	22%	6%	88% at 3 years
NIH**[73]	104	30	62%	37%	9%	80% at 4 years

*With androgens and ± granulocyte colony-stimulating factor (G-CSF).
**With mycophenolate mofetil.
Only studies of >20 enrolled patients are tabulated. Responses to immunosuppressive therapy are usually partial; blood counts may not become normal, but transfusions are no longer required, and the neutrophil count is adequate to prevent infection. Relapse is usually responsive to further immunosuppressive therapies. Clonal evolution is to dysplastic bone marrow changes and/or cytogenetic abnormalities. For details, see accompanying text.

ATG, and the dose used is in the range of 2 to 5 mg/kg daily for 4 to 5 days (Thymoglobulin at 3.5 mg/kg for five days). Rabbit ATG may cause more leukopenia.

Antilymphocyte globulins are immunosuppressive. ATGs contain a heterogeneous mix of antibody specificities for lymphocytes, including reactivity to antigens such as CD2, CD3, CD4, CD8, CD25 (the receptor for IL-2), and HLA-DR.[400–402] Horse sera fix human complement efficiently, and all preparations are T-cell cytotoxic in vitro, with little difference among ATGs or among lots for lymphocyte killing in vitro.[401] In vitro, antilymphocyte globulins efficiently inhibit T-cell proliferation and block IL-2 and IFN-γ production and IL-2 receptor expression.[403] ATG induces Fas-mediated apoptosis of T cells, especially after activation.[404] In monkeys, ATG suppresses cutaneous allograft rejection.[402] Studies of rabbit ATG in rhesus monkeys undergoing kidney transplantation have indicated that persistence of specific antibodies may be responsible for a chronic anergic state and tolerance induction.[405] In patients, the administration of ATG results in rapid reduction in the number of circulating lymphocytes, usually to less than 10% of starting values, and lymphocytopenia persists for several days after discontinuing therapy. Although lymphocyte numbers return to pretreatment values by 3 months, reductions in activated lymphocyte numbers in recovered patients persist.[66,406–408] It seems likely that these inhibitory effects on T cells are responsible for the efficacy of antilymphocyte globulins in AA. Nevertheless, the ability of ATG to stimulate lymphocyte function by acting as a mitogen may also have a role in their therapeutic efficacy. ATG provoked IL-2 nd hematopoietic growth factor production by peripheral blood mononuclear cells,[409] later identified as GM-CSF[61,409,410] and IL 3 (IL-3).[405] T cells cloned after stimulation produced GM-CSF or IL-3 (or both), and less frequently, they produced IL-2 and IFN-γ.[411] Administration of ATG after human marrow transplantation is associated with increased serum levels of IL-3.[412] ATG also binds to bone marrow precursor[413] and progenitor[414] cells[415] and may modestly directly enhance hematopoiesis, possibly through binding to CD45RO, a molecule capable of promoting tyrosine phosphatase signaling.[416]

Reliable methods to predict which patients will respond to ATG are lacking. In some cases, inhibitory activity of lymphocytes on hematopoiesis is no longer detected after successful ATG therapy.[417,418] In one study, CD8 T cells obtained from patients before treatment inhibited autologous hematopoietic colony formation, whereas CD8 lymphocytes isolated from the same patients after recovery were not active.[419] Good correlations were reported between the clinical response to immunosuppression and improvement in hematopoietic colony formation in vitro after T-cell depletion.[57,417] These findings have not been confirmed by others.[191,394,420–422] The lymphocyte stimulatory effects of ATG have been associated with positive clinical outcomes by some[423] but not by others.[409] Flow cytometric detection of intracellular IFN-γ expression in lymphocytes correlates with the responsiveness to ATG.[68]

Cyclosporine

Several groups[424–431] reported success with cyclosporine therapy combined with androgens in individual patients with AA, in many of whom other therapies had failed. Several studies suggested efficacy of cyclosporine in patients refractory to ALG or ATG alone, with salvage rates of approximately 50%.[432–437] The use of cyclosporine as initial therapy was promoted by a large French cooperative randomized study in which low but equivalent response rates were observed compared with standard ATG therapy.[438] However, in a randomized German trial,[404] cyclosporine was clearly inferior to ATG as measured by response and survival rates.

The optimal regimen has not been determined. In the United States, cyclosporine has usually been employed in high doses (12 mg/kg/day for adults and 15 mg/kg/day for children), with adjustment according to plasma drug concentrations and serum creatinine levels. In Europe, lower doses (3 to 7 mg/kg/day) have been reported to be equally efficacious.[439,440] Hematologic improvement can occur in a few weeks or months. A 6-month trial is warranted. Remissions, when achieved, usually have been durable, but some patients experience relapse when cyclosporine is discontinued. Most patients who relapse will respond to the reinstitution of cyclosporine.[439–442] Some patients require maintenance treatment.[429,432]

Cyclosporine has considerable toxicity. Hypertension and azotemia are the most common serious side effects; hirsutism and gingival hypertrophy are also frequent complaints. Increasing serum creatinine levels are an indication for dose reduction. Chronic cyclosporine nephropathy characterized by interstitial fibrosis and tubular atrophy can be irreversible. The risk of nephropathy is increased by high doses and longer duration of therapy and occurs more commonly in older than in younger patients. Cyclosporine, especially in combination with corticosteroids, converts patients with AA to a temporary immunodeficiency state and puts them at high risks for opportunistic infections. Monthly aerosolized pentamidine prophylaxis can prevent *Pneumocystis carinii* pneumonia in patients receiving cyclosporine. Convulsions, possibly related to hypomagnesemia, are another serious complication of cyclosporine therapy.

Combined or Intensive Immunosuppressive Therapy

The combination for the treatment of AA of an agent that lyses lymphocytes (ATG) with a drug that blocks lymphocyte function is rational (see Table 29–10). The strategy resulted in a striking increase in the response rate to immunosuppressive therapy observed in a German randomized trial in which patients were treated initially with a combination of ATG and cyclosporine or ATG only. The addition of cyclosporine led to higher hematologic response rates and more complete responses than were observed with ATG alone: 65% versus 39% and 70% versus 46% at 3 and 6 months, respectively.[443] In the European randomized trial of ATG and cyclosporine versus cyclosporine alone for nonsevere AA, a superior response rate was achieved with the combination regimen.[444] In a National Institutes of Health (NIH) study of combination ATG and cyclosporine therapy[393,445] and in a multicenter European study of ATG and cyclosporine,[446,447] the hematologic response rates at 1 year were 60% to 80%. In a long-term follow-up report from NIH, although the responses plateaued, few late deaths were reported.[393] In all the trials, the 5-year survival rates for responding patients have been between 80% and 90%. In the 11-year follow-up of the German randomized ATG versus ATG plus cyclosporine trial, patients who received the combination showed a better response rate and failure-free survival, but overall survival, perhaps linked to the efficacy of salvage regimens, was not different in both groups.[448] In elderly patients, the response rates to cyclosporine alone, ATG alone, and a combination were higher than 50%, but there was no difference in the outcome between regimens.[449]

Immunosuppressive therapy has been intensified in other regimens. In Europe, repeated courses of ATG are commonly given in an effort to induce hematologic improvement.[395,450–452] A longer course of ATG (28 days versus 10 days) appeared to produce more complete responses in a North American multicenter trial.[382] The addition of high-dose methylprednisolone to ATG has been associated with very high response rates in some trials.[45,453,454] In patients refractory to the initial therapy with ATG and cyclosporine, a repeat course of ATG is often administered as a salvage regimen and can rescue a proportion of patients. Rabbit ATG for patients refractory to the first course of ATG. In addition to inducing a response in 30% of patients, their survival was excellent (97% within the median follow-up of more than 900 days), unexpected for refractory disease.[455]

Cyclophosphamide

Since the initial pilot series of 11 patients who received high doses of cyclophosphamide (45 mg/kg/day for 4 days) without stem cell

rescue,[456] a larger cohort ($n = 19$) of newly diagnosed AA patients has been reported with an overall response rate similar to that achieved with ATG therapy.[457] After cyclophosphamide therapy, blood cell counts were reported to be normal, and there was no evidence of relapse or late complications. These favorable but uncontrolled, single-institution, phase II results prompted a randomized trial in which ATG plus cyclosporine was compared with cyclophosphamide and cyclosporine. However, because of the excess toxicity in the cyclophosphamide-treated patients (invasive fungal infections or death in 6 of 15 versus 0 of 16[458]), the study was terminated. In an update of the results, although the response rate was comparable, the development of clonal disorders was observed in the cyclophosphamide arm, and relapses were observed.[459] Cyclophosphamide has been associated with a lower relapse rate, but comparison with ATG is difficult because most of the cyclophosphamide-treated patients may not achieve normal counts for 2 years after the therapy—a period in which a significant proportion of relapses occurs with ATG.[457]

Corticosteroids

Methylprednisolone in modest doses (1 mg/kg/day) is usually administered during ATG and ALG therapy to ameliorate the symptoms of serum sickness. Very-high-dose ("industrial strength") steroids are delivered boluses of 6-methylprednisolone given intravenously in dosages of 20 mg/kg/day on days 1 to 3, 10 mg/kg/day on days 4 to 7, 5 mg/kg/day on days 8 to 11, 2 mg/kg/day on days 12 to 20, and 1 mg/kg/day until day 30, followed by a maintenance regimen. Such high-dose regimens can be effective, especially in recently diagnosed patients.[191,452,460] High-dose methylprednisolone also has been added to ATG therapy, with inconsistent results. ATG therapy is associated with better response rates and many fewer associated toxic effects than high-dose steroid therapy and is generally preferable as initial therapy. Modest doses of corticosteroids do not have roles in the treatment of AA except in combination with ATG. There is little evidence of their effectiveness in reversing marrow failure or improving hemostasis, and even limited courses of steroids can contribute to the development of aseptic vascular necrosis and the increase in the rate of fungal infections.[461]

Late Complications of Immunosuppressive Therapy

Relapse after immunosuppressive therapy is common. In the European experience, in 719 patients treated with immunosuppressive therapy, the actuarial rate of relapse among 358 responders was 35% at 14 years; relapse was more common among patients who had initial rapid responses.[462] Approximately one-half the patients who relapsed responded to a second course of immunosuppression, but survival rates were lower for patients who experienced relapse than for those who did not. In the large NIH cohort of 112 patients, relapse, defined as a need for treatment, was even more common, with a risk estimated at 35% at 7 years for responders; however, survival was unaffected by the occurrence of relapse. Pancytopenia occurred in a minority of patients, and most patients responded to further therapy, usually reinstitution of cyclosporine.[207,393] These observations are consistent with a view of AA as a chronic immunologic disease that might not be cured by a single course of immunosuppressive therapy.

A much more serious complication is the development of late-onset clonal hematologic disorders. The syndromes include PNH, myelodysplasia, and AML.[463–485] Some of these events can represent part of the natural history of AA. Before recent improvements in treatment, leukemia was considered an unusual complication,[466] but late-onset clonal disorders do not appear to simply be the result of the introduction of immunosuppressive therapy. In a series of 156 patients treated with androgens, there was a 10% actuarial probability of developing PNH; in addition, five cases of late-onset myelodysplasia and one of non-Hodgkin lymphoma were observed.[467] In retrospective analyses performed by the EGBMT, of 223 long-term survivors after immunosuppression, 19 developed PNH (13% risk at 7 years), and 11 developed myelodysplastic syndrome, which in 5 years later evolved to AML (combined risk of 15% at 7 years).[468] In single-center series, estimated rates of late-onset clonal disease have ranged from 9% (at 6 years)[390] to 57% (at 8 years).[469] Children appear to be at similar risk for the development of clonal complication as adults, and evolution to myelodysplastic syndrome can occur in responders and in refractory patients.[470,471] Myelodysplastic syndrome that develops after AA can transform to acute leukemia[463] but can also be surprisingly indolent.[472] In a series from the NIH, in 29 patients with AA who developed a chromosome abnormality, monosomy 7 and trisomy 8 were the most common defects observed. Clinically, monosomy 7 was more likely to occur in primarily refractory patients and had a poor prognosis, whereas patients with trisomy 8 remained responsive to cyclosporine and had excellent survival.[473] Similarly, AA patients who develop 13q− appear to have a good prognosis and retain responsiveness of their counts to continued immunosuppression.[474] Overall, the frequency of the development of a new chromosome abnormality was estimated to be approximately 15% at 7 years.

A PNH clone can be detected in up to 50% of patients on their presentation. Approximately 10% to 15% of patients will develop the hemolytic or thrombotic form of PNH;[203] and in most, the proportion of PNH cells remains stable and low. Immunosuppressive therapy does change the size of the PNH clone. In an analysis of a large cohort of PNH patients, those with a history of AA constituted a larger group than those with primary hemolytic PNH.[203]

Immunosuppression Versus Bone Marrow Transplantation

Immunosuppression and transplantation are both effective therapies for AA (Figs. 29–11 and 29–12). Lack of a matched sibling donor, the expense and availability of transplantation, and risk factors such as active infections, advanced age, or a heavy transfusion burden lead most patients to automatically undergo treatment with ATG and cyclosporine.[475] For a few patients with AA, a choice does exist between transplantation and immunosuppressive therapy. Marrow transplantation offers a permanent cure. Its disadvantages are cost, procedure-related morbidity and mortality (especially GVHD in older patients), and an increased incidence of solid organ malignancies. Immunosuppressive therapy is easier and initially cheaper. However, many patients do not achieve normal blood cell counts and remain at high risk for relapse and the more serious complications of late-onset clonal hematologic disease, especially myelodysplasia.

Retrospective analyses of the large number of European patients reported to the EGBMT show consistently improved results with both therapies but have repeatedly failed to demonstrate a survival advantage for transplantation over immunosuppression.[329,476–478] The latest 5-year survival rate quoted was higher than 80% for both treatments.[479] Single-center studies are similar. Certain categories of patients, defined by neutrophil number and age, probably benefit from one therapy or the other. In the EGBMT analyses, marrow transplantation yielded superior results in children younger than 10 years old and in younger patients with a neutrophil count of less than 400 cells/μL, whereas immunosuppressive therapy was superior for adults 40 years old or older. For patients of intermediate age and a neutrophil count of less than 300 cells/μL, transplantation results in a more favorable outcome compared with immunosuppressive therapy.[315] Superior results with matched sibling transplantation in children have been reported by others.[266,473–483]

Much improved results with matched sibling and with unrelated matched transplantation were reported from Seattle.[484] However, older individuals are likely to fare less well than children undergoing transplantation.[293,484] A cutoff of 40 years of age was adopted for consideration of transplantation in one review. In some cases, an unsuccessful trial of immunosuppression can be followed by stem cell

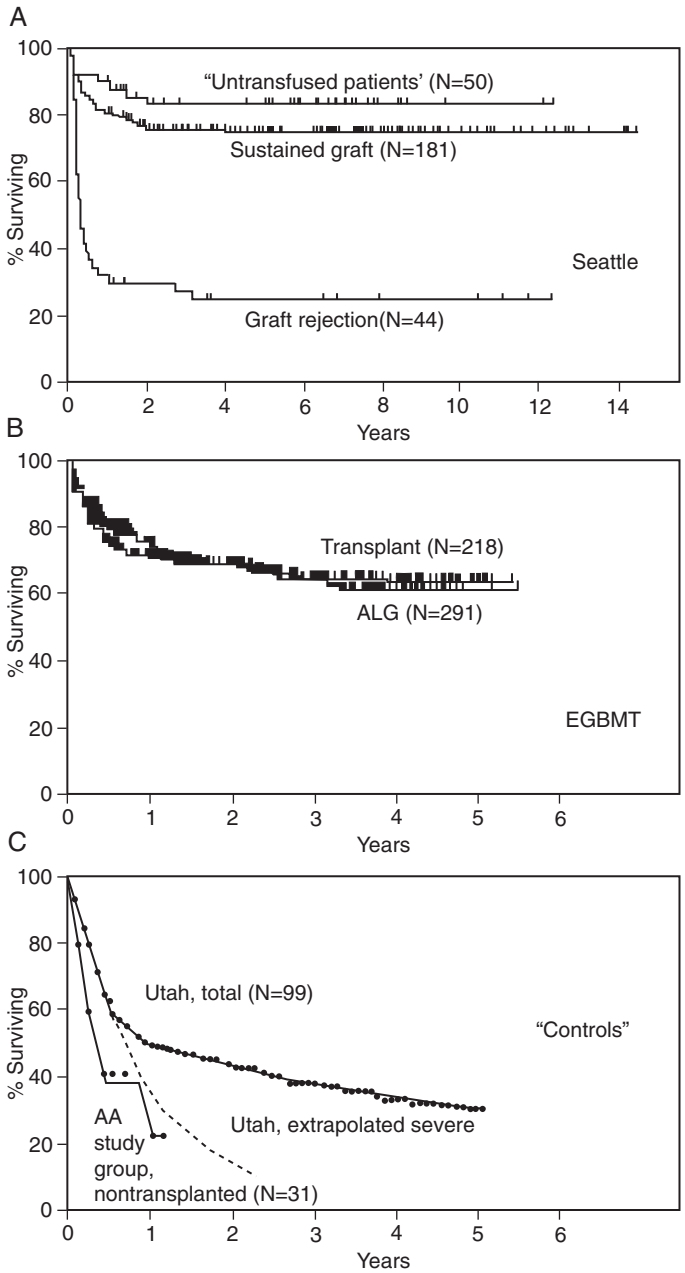

Figure 29–11 Actuarial survival rates for patients with aplastic anemia (AA). (**A**) Data on bone marrow transplantation from the University of Washington. (**B**) Data from the European Group for Bone Marrow Transplantation on bone marrow transplantation versus immunosuppression with antilymphocyte globulin (ALG). (**C**) Natural history as indicated by survival with supportive and other treatments. Two groups are illustrated. Extrapolated survival curves for patients with severe disease are derived from retrospective reviews from the University of Utah of 101 records collected from the late 1940s to early 1970s. The patients received blood transfusions and, later in this period, also received platelets. Almost all were treated with corticosteroids, and one-half were also treated with androgens. Data for patients who did not receive transplants come from a multicenter study of the efficacy of marrow transplantation performed in the early 1970s; this control group was treated with androgens.

transplantation from a sibling donor.[485] For the more risky matched unrelated donor transplant, the decision to undergo this procedure can be difficult, but outcomes are improving. Increasingly children who have failed a single course of immunosuppression and adults refractory to multiple courses of ATG are offered this procedure.

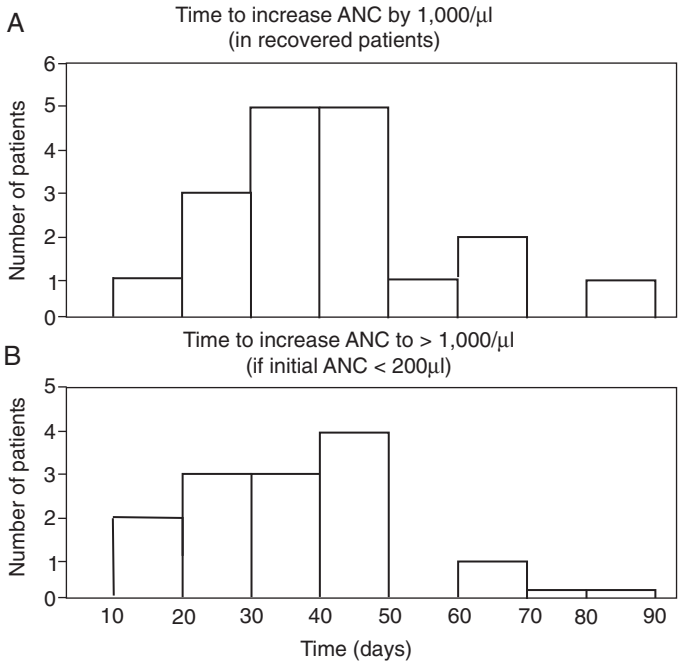

Figure 29–12 Time to response after treatment with antilymphocyte globulin (ATG). (**A**) Distribution of patients with severe aplastic anemia by time to achieve an increase in the absolute neutrophil count of 1000 cells/mm^3. (**B**) Distribution of patients with an initial absolute neutrophil count of less than 200 cells/mm^3 by time to achieve an absolute neutrophil count of 1000 cells/mm^3. ANC, absolute neutrophil count.

Androgens

Testosterone and synthetic anabolic steroids appeared to be major advances in the treatment of AA when they were introduced in the 1960s.[239,486] The high response rates in some early series may be retrospectively attributed to the inclusion of patients with moderate acquired and constitutional AA. For severe AA, controlled trials in general have not demonstrated efficacy, as measured by survival rates[487] or hematologic improvement.[382] When added to immunosuppressive therapies, androgens failed to result in any increase in response rates.[389] In Europe, a modest survival advantage was observed only in women with severe neutropenia who received combined therapy.[488]

Although marrow transplantation or immunosuppressive therapy is generally preferred, certain androgen regimens have their advocates. These investigators have reported response rates and prolonged survivals[467] similar to those observed with ATG.[489] Androgens continue to be helpful in some patients when used as a second-line therapy. Most hematologists have observed patients who appeared to respond or even to develop hormone dependence.[490,491] Androgen therapy is popular in Asia[492–495] and Mexico[496] because it is inexpensive and seemingly effective. Various preparations of androgens in different doses have resulted in virtually identical response rates of 35% to 60% after 6 months of therapy.[497]

Useful androgens include nandrolone decanoate, oxymetholone, and danazol; unfortunately, their popularity and abuse by athletes has led to restrictions of their availability and manufacture. The hemoglobin response frequently is more impressive than improvements in granulocyte or platelet levels. An adequate trial is considered to be a full dose given for at least 3 months. Complications occur infrequently, although some are serious and can limit effective therapy, especially in the elderly.[498] The associated liver cholestasis is usually reversible. Hepatotoxicity (eg, bile duct proliferation, peliosis, atypical hepatocyte hyperplasia, tumors) can occur but is less common with parenteral formulations.[499] Children appear to tolerate

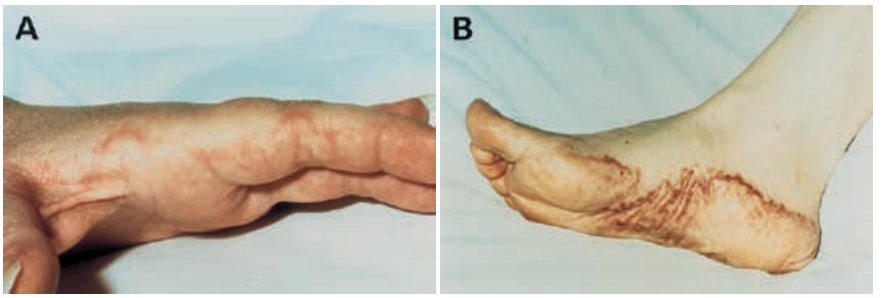

Figure 29–13 Cutaneous eruptions of serum sickness.

high doses of androgens without lasting effects on growth or maturation.[500]

Hematopoietic Growth Factors

Although hematopoietic growth factor production is normal or increased in most patients with AA, pharmacologic stimulation with very high doses of cytokines can be effective through a direct effect on residual stem cells, promoting marrow recovery, or by increasing progenitor cell activity and allowing patients to survive long enough to respond to other, more definitive therapies.[501,502]

Neutropenia most often leads to serious and life-threatening infections. GCSF and GM-CSF are capable of increasing neutrophil counts in patients with AA.[503–505] Controlled trials with these agents have not been performed, and data demonstrating that growth factor administration alone decreases the incidence of serious infections or improves survival are lacking. In general, neutrophil responses to growth factors are transient, dependent on their continuous administration, and usually restricted to patients with quantitatively less severe forms of AA. Nevertheless, occasional bilineage and trilineage responses have been observed.[506] Children can be more sensitive to the effects of prolonged administration of GCSF.[504,507]

A concern has been the possibility that prolonged administration of GCSF might increase the probability of late clonal disease, especially monosomy 7. In retrospective analyses of Japanese children and adults[508,509] with severe AA, this syndrome appeared to occur most frequently among patients who had received growth factor.[510,511] Although not initially observed among European patients in GCSF protocols, a recent retrospective analysis has suggested a higher risk of myelodysplasia associated with GCSF use.[512] The mechanism of GCSF's relationship to monosomy appears to be selection of aneuploid cells bearing an isoform of GCSF; these cells are less sensitive to GCSF, but once triggered by the cytokine proliferate and do not differentiate.[513] Regardless of toxic or late effects, growth factors, often are inappropriately employed as the first-line therapy in AA, for which they have not been shown to be useful. Such practices lead to unfortunate delays in the institution of definitive therapy.[514]

Anemia and pancytopenia in rare patients have responded to prolonged administration of high doses of erythropoietin. Clinically meaningful hematologic responses to the administration of single cytokines have been limited in marrow failure syndromes, but combinations of growth factors might be more effective because of physiologic or pharmacologic synergism. Some complete remissions have been reported with GM-CSF and erythropoietin[386] and with IL-3 and GCSF.[515] In a large, randomized protocol, the combination of GCSF and high doses of erythropoietin improved hemoglobin values, mainly in patients with moderate disease.[516]

Growth factors have also been combined with definitive medical therapy for the purpose of improving neutrophil counts during the early phase of immunosuppression. Often, therapy with GCSF or GM-CSF is instituted because the neutropenic patient is febrile and unresponsive to antibiotics; its value in these circumstances is unknown. A brief course of GM-CSF before or concurrent with ALG has not added appreciable benefit in two small trials.[517,518] A few case reports have suggested that the combination of a growth factor with cyclosporine might rescue patients with refractory disease,[519–521] but a randomized trial showed GCSF and cyclosporine to be inferior to ALG and cyclosporine as a front-line therapy for AA.[522] Prolonged GCSF was part of the EGBMT's trial of intensive immunosuppression,[446] but whether the excellent hematologic responses and survival rates could be attributed to the use of growth factor or to the sequential courses of immunosuppression was unclear. A subsequent randomized trial to determine the efficacy of GCSF showed higher neutrophil counts but no differences in the rates of infection or survival.[523]

In the absence of convincing evidence of short- or long-term benefit, growth factor use in AA is dictated by the individual physician's judgment. Most severely neutropenic patients who are persistently or seriously infected undergo a therapeutic trial in the hope of achieving clinical benefit. Some patients with disease refractory to other forms of treatment can also receive prolonged courses of cytokines in the hope of raising the low neutrophil count. Preferably, the use of growth factors over long treatment periods, especially in patients who are not severely neutropenic, should be in the context of a formal study. Physicians and patients should be aware of possibly significant risks associated with such treatment.

New thrombopoietic factors are currently under development, including AMG531, an engineered thrombopoietin-derived synthetic growth factor, and an oral c-mpl agonist, elthrombopag.[524] Both agents have shown significant activity in raising platelet counts in immune thrombocytopenic purpura. AMG531 is currently being tested in thrombocytopenic patients with myelodysplastic syndrome (MDS). These agents might be applied in refractory cases of AA, possibly in combination with GCSF.

PROGNOSIS

The initial blood cell counts of a patient with AA are the most important indicators of prognosis. The most popular criteria used to define severe disease are the presence of two of the following three: neutrophil count of less than 500 cells/μL, platelet count of less than 20,000 cells/μL, and corrected reticulocyte level of less than 1% (<40,000 cells/μL).[301] More complicated formulas are less easy to use and often only quantitate the obvious.[525] In a comparative study of prognostic indices, decreasing blood cell counts during the first 3 months of therapy were uniformly associated with death within 5 years, and stable or improved blood cell counts correctly predicted long-term survival for 75% of patients. Of the prognostic indices, the simple criteria described previously were the most accurate at 6 months, correctly predicting poor survival for 85% of patients with 100% sensitivity after 6 months.[526] In a long-term follow-up study of 122 patients treated with an ATG plus cyclosporine combination at the NIH, blood count improvement (no longer meeting severity criteria) and the robustness of the platelet and reticulocyte response correlated with long-term survival.[393] One modification to the standard criteria is useful. Although bleeding was a major cause of death in the past, infection kills the overwhelming proportion of patients today. In the large European cooperative trials, a category of *supersevere* AA has been defined by an extremely low absolute neutrophil count (<200 cells/μL).[266] Relapse does not appear to affect the probability of survival;[393] clonal evolution, especially monosomy 7, is a poor prognostic factor.[473]

Bone marrow examination is subject to sampling error, and cellularity is not usually quantitated; for these reasons, blood cell counts have been more readily correlated with survival than gross marrow appearance.[527] A predominance of lymphoid cells in the bone marrow has been associated with a bad prognosis in some studies,[229] and the presence of residual hematopoiesis, particularly erythropoiesis, with a good outlook in others.[528,529]

The rate of spontaneous recovery is difficult to estimate, but most observers believe it to be low. Untreated severe disease is almost invariably fatal. In contrast, moderate AA has a good prognosis, and some patients with minimal blood cell count depression recover normal blood cell counts with limited or no therapy.[530] Nevertheless, in an older series of pediatric patients treated mainly with transfusions, only 3% of 334 were judged to be cured,[128] and among African patients who received transfusions, corticosteroids, and androgens, the mortality rate was 56% at 1 year and 72% after 18 months.[12] Interpretation of older publications is complicated by uncertainties concerning diagnosis and the inclusion of a large proportion of patients with moderate disease. In a randomized study from the contemporary era, none of 21 patients assigned to supportive care improved during 3 months of observation.[381]

CHAPTER 30

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Robert A. Brodsky

INTRODUCTION

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal hematopoietic stem-cell disorder that has fascinated hematologists for more than a century because of its protean clinical manifestations and captivating pathophysiology. One of the earliest descriptions of PNH was by Dr. Paul Strübing, who in 1882 described a 29-year-old cartwright who presented with fatigue, abdominal pain, and severe nocturnal paroxysms of hemoglobinuria that were exacerbated by excess alcohol, physical exertion, and iron salts.[1] Strübing deduced that the hemolysis was occurring intravascularly as the patient's plasma turned red following severe attacks of hemoglobinuria. Decades later his prescient deduction was confirmed. Later reports by Marchiafava and Micheli led to the eponym, Marchiafava-Micheli syndrome, but it was Enneking, in 1925, who introduced the term *paroxysmal nocturnal hemoglobinuria*.[2]

In 1937, Thomas Ham found that PNH erythrocytes were hemolyzed when incubated with normal, acidified serum.[3] This seminal discovery resulted in the first diagnostic test for PNH, the acidified serum or Ham test. The cell lysis following acidified serum appeared to be complement dependent because heat inactivation abrogated the reaction; however, it was not until 1954, with the discovery of the alternative pathway of complement activation, that complement was formally proven to cause the hemolysis of PNH red cells.[4] Following the emergence of specific diagnostic tests, additional disease manifestations such as venous thrombosis, bone marrow failure, and development of myelodysplastic syndromes and acute leukemia were associated with PNH. These nonerythroid manifestations of the disease foreshadowed the discovery that PNH results from the clonal expansion of a mutated hematopoietic stem cell.

In the 1980s, roughly 100 years after Strübing's initial description of the disease, it was discovered that PNH cells display a global deficiency in a group of proteins affixed to the cell surface by a glycosylphosphatidylinositol (GPI) anchor. Interestingly, several of the missing proteins (eg, CD55 and CD59) are important complement regulatory proteins. A few years later, the genetic mutation (*PIGA*) responsible for the GPI-anchor protein deficiency was discovered,[5] and most recently, a humanized monoclonal antibody that inhibits terminal complement activation has been shown to ameliorate hemolysis and disease symptoms in PNH patients.[6] Although the pathophysiology of many of PNH's clinical manifestations are now understood, the mechanism of thrombosis, the mechanism of clonal dominance, and the close association with aplastic anemia continue to be areas of intense investigation. PNH is an extremely rare condition; however, the risk for developing PNH in patients with acquired aplastic anemia is 20% to 30%. In addition, 20% to 65% of patients with aplastic anemia harbor a small to moderate PNH population at diagnosis.[7,8] Understanding the factor(s) that promote the clonal outgrowth of diseases such as PNH should give insight into the genesis of other clonal hematologic malignancies.

PATHOPHYSIOLOGY

The Glycosylphosphatidylinositol Anchor

Covalent linkage to GPI is an important means of anchoring many cell-surface glycoproteins to the cell membrane.[9–11] Alkaline phosphatase was the first GPI-anchor protein recognized after it was discovered that cell surface alkaline phosphatase could be removed by a bacterial enzyme, phosphatidylinositol-specific phospholipase C (PIPLC).[12] PIPLC cleaved the phosphate from phosphatidylinositol and left the enzyme with full activity after its release, suggesting that the protein structure was unperturbed. This fundamental observation led to the discovery of dozens of GPI-anchored proteins.

The GPI anchor consists of a highly conserved glycan core (ethanoloamine-*P*-6Manα1-2Manα1-6Manα1-4GlcN) linked to the 6-position of the D-*myo*-inositol ring of phosphatidylinositol (Fig. 30–1). The anchor is synthesized in a stepwise manner in the endoplasmic reticulum membrane involving at least 9 reactions and more than 20 different genes (Table 30–1).[11] The first step in GPI anchor biosynthesis is the transfer of *N*-acetylglucosamine (GlcNAc) from uridine diphosphate (UDP)-GlcNAc to phosphatidylinositol (PI) to yield GlcNAc-PI. This step is catalyzed by GlcNAc-PI α1-6 GlcNAc transferase, an enzyme whose subunits are encoded by seven different genes: *PIGA,*[5] *PIGC,*[13] *PIGH,*[14] *GPI1,*[15,16] *PIGY,*[17] *PIGP,* and *DPM2.*[18] In the second step, GlcNAc-PI is deacetylated by the gene product of *PIGL* to form glucosamine (GlcN)-PI.[19] GPI anchor assembly continues in the endoplasmic reticulum with acylation of the inositol and stepwise addition of mannosyl and phosphoethanolamine residues. The preassembled GPI is linked to nascent proteins that contain a C-terminal GPI-attachment signal peptide, displacing it in a transamidase reaction.[20] The GPI-anchored protein (AP) then transits the secretory pathway to reach its final destination at the plasma membrane. If the GPI anchor is not attached to the protein, it is degraded intracellularly, probably in lysosomes.[21,22]

Given the numerous gene products involved in GPI anchor assembly, it seemed improbable that PNH would be the consequence of a single genetic mutation. However, after intense scrutiny of this pathway, it became apparent that in all PNH cases, the defect could be attributed to mutations in the *PIGA* gene, whose product is essential for the first step of GPI anchor biosynthesis. Later it was determined that the *PIGA* gene is on the X chromosome and that its product is part of a complex that transfers *N*-acetylglucosamine to phosphatidylinositol to form GlcNAc-PI.[16] Thus, a single "hit" will generate a PNH phenotype because males have only one X chromosome, and in females one X chromosome is inactivated through lyonization. Conceivably a mutation in any one of the genes in this pathway would cause the disease; however, other genes involved in GPI anchor biosynthesis are located on autosomes (see Table 30–1). Inactivating mutations in these genes would have to occur on both alleles to produce the PNH phenotype. Recently, a rare autosomal recessive disease that manifests with seizures and venous thrombosis was found to be caused by a point mutation near the start codon of *PIGM.*[23] The mutation resulted in a partial but severe deficiency of GPI-anchored proteins.

Acetylcholinesterase from erythrocytes and alkaline phosphatase from leukocytes were the first GPI-anchored proteins shown to be missing in PNH. Since then, more than a dozen GPI-anchored proteins with heterogeneous expression on hematopoietic cells have been found to be missing in PNH (Table 30–2). The functions of these cell surface GPI-anchored proteins are manifold; they can serve as complement regulatory proteins, enzymes, blood group antigens, receptors, and adhesion molecules. Membrane inhibitor of reactive lysis (CD59) and decay accelerating factor (CD55)—both complement regulatory proteins—are the most widely expressed GPI-

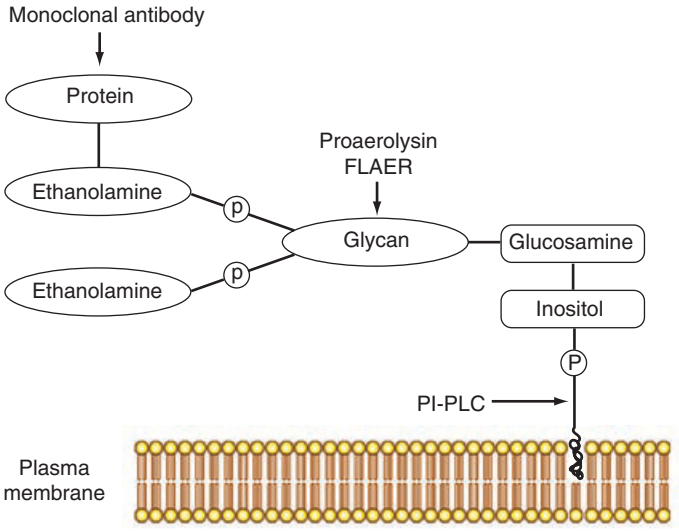

Figure 30–1 Structure of the glycosylphosphatidylinositol (GPI) anchor. Phosphatidylinositol is inserted into the lipid bilayer of the plasma membrane. The glycan core, which serves as the binding site for aerolysin, proaerolysin, and FLAER, consists of a molecule of *N*-glucosamine, three molecules of mannose, and a molecule of ethanolamine. The representative protein (eg, CD55, CD59, etc.) is covalently attached through an amide bond to an ethanolamine on the terminal mannose. Individual monoclonal antibodies used for the diagnosis of PNH (eg, CD55, CD59, etc.) bind to the protein, but not the GPI anchor. Phosphatidylinositol-specific phospholipase C (PIPLC) cleaves the phosphate from phosphatidylinositol and leaves the enzyme with full activity after its release.

Table 30–1 Genes Involved in GPI Anchor Biosynthesis

Number	Gene	Location
1	PIG-A*	Xp22.1
2	PIG-C*	1q23.3
3	PIG-H*	14q11-q24
4	PIG-P*	21q22.2
5	GPI1 (PIG-Q)*	16p13.3
6	PIG-L	17p12
7	PIG-M	1q22
8	PIG-N	18q21
9	PIG-B	15q21-q22
10	PIG-F	2q16-p21
11	PIG-O	9
12	GPI8 (PIG-K)†	1p22.2-p22.3
13	GAA1 (GPAA1)†	8q24.3
14	PIG-S†	17
15	PIG-T†	20q12-q13
16	DPM1	20q13.1
17	DPM2	9q33
18	DPM3	1q21.2
19	SL15 (MPDU1)	17p13.1
20	PIG-U†	20q11

Table 30–2 Cell Surface GPI-Anchored Protein Absent on PNH Blood Cells

Antigen	Hematopoietic Lineage	Classification
CD55—decay accelerating factor	All blood cells	Complement regulator
CD59—membrane inhibitor of reactive lysis	All blood cells	Complement regulator
CD58—lymphocyte function associated antigen-3	All blood cells	Adhesion molecule
Acetylcholinesterase	Red cells	Enzyme
CD14—monocyte differentiation antigen	Granulocytes, monocytes, macrophages	Endotoxin-binding receptor
CD16—Fcγ receptor III	Granulocytes, NK cells	Receptor
CD66b	Granulocytes	Adhesion
Neutrophil alkaline phosphatase	Granulocytes	Enzyme
CD87—urokinase (plasminogen activator) receptor	Monocytes, granulocytes	Receptor
Leukocyte alkaline phosphatase	Granulocytes	Enzyme
CDw52—Campath-1 antigen	Lymphocytes, monocytes	Unknown
CD24	B lymphocytes, granulocytes	B cell differentiation
CD48	All leukocytes	Adhesion molecule
CD73—ecto-5′-nucleotidase	Some B and T lymphocytes	Enzyme
Dombrock-Holley/Gregory-bearing protein	Red cells	Blood group antigen
Folate receptor	Myeloid and erythroid cells	Receptor

anchored proteins and can be found on all hematopoietic lineages including $CD34^{+}CD38^{-}$ progenitor cells.[24] Certain proteins, CD58 (LFA3) and CD16 (FcγRIII), may exist in both GPI-linked and transmembrane forms.

PIGA Gene

Investigators in Osaka, Japan, first identified the gene that was defective in PNH.[5] The gene was isolated by expression cloning and named *PIGA* (**p**hosphatidyl**i**nositol-**g**lycan complementation class **A**). *PIGA* was then cloned into an expression vector and transfected into GPI-deficient cell lines derived from PNH patients; cell surface expression of all the missing GPI-anchored proteins was restored, confirming that *PIGA* mutations are responsible for causing PNH.[25,26] Since this seminal discovery, somatic mutations of the *PIGA* gene have been found in all PNH patients to date.[27–31] Little to no GPI anchor is made when the *PIGA* gene is mutated. Consequently, the translated protein (eg, CD59, CD55, etc.) residing in the cisterna of the endoplasmic reticulum cannot be attached to the GPI anchor and is degraded in situ.[32]

The human *PIGA* gene contains 6 exons, 5 introns, and extends over 17 kb (Fig. 30–2); it encodes for a protein that contains 484 amino acids (60 kd). In humans, there is a single copy of the gene located on the short arm of the X chromosome (Xp22.1), although an intronless pseudogene has been found on chromosome 12q21.[33,34] A wide range of somatic mutations interspersed throughout the entire coding region of the *PIGA* gene have been described in PNH patients. There are no true mutational "hot spots," although exon 2, which contains almost half of the coding region, is the exon where most mutations occur. Most *PIGA* mutations are small insertions or deletions, usually one or two base pairs, which result in a frameshift in the coding region and consequently a shortened, nonfunctional product. Although *PIGA* function is abolished by these frameshift mutations, missense mutations, where the product of the mutated *PIGA* gene has some residual activity, have also been described. In most patients studied, a single (monoclonal) *PIGA* mutation has been discovered. However, two different mutations (biclonal) and in one case four separate *PIGA* mutations have been found in PNH patients.[35]

PNH Stem Cell

PNH is a clonal hematopoietic disorder similar to myelodysplastic syndrome (MDS), chronic myelocytic leukemia, and acute myeloid leukemia. The first evidence to support the notion that PNH arises through the mutation of an abnormal multipotent hematopoietic stem cell was derived from glucose 6-phosphate dehydrogenase studies on the red cell of women with PNH.[36] Subsequently, flow cytometric analyses revealed that all hematopoietic lineages—myeloid, erythroid, and lymphoid—were involved. Furthermore, *PIGA* mutations found in granulocytes match those found in other lineages,[25,37] and $CD34^{+}CD38^{-}$ progenitor cells have been shown to be missing GPI-anchored proteins in PNH patients.[38] Thus, the "hit" in PNH clearly involves a multipotent hematopoietic stem cell and may even involve an earlier stem cell than diseases such as chronic myelocytic leukemia, MDS, or acute leukemia. In the latter disorders, B cells are sometimes derived from the leukemia clone, but T cells are seldom involved. In PNH, both B cells and T cells have been shown to be derived from the malignant clone.

PNH Red Cells

PNH cells can display one of three phenotypes (Fig. 30–3): cells with normal expression of GPI-anchored proteins (type I cells), cells with intermediate expression of GPI anchor proteins (type II cells), and cells with no expression of GPI anchor proteins (type III cells). These three populations are most easily seen in the erythrocyte and granu-

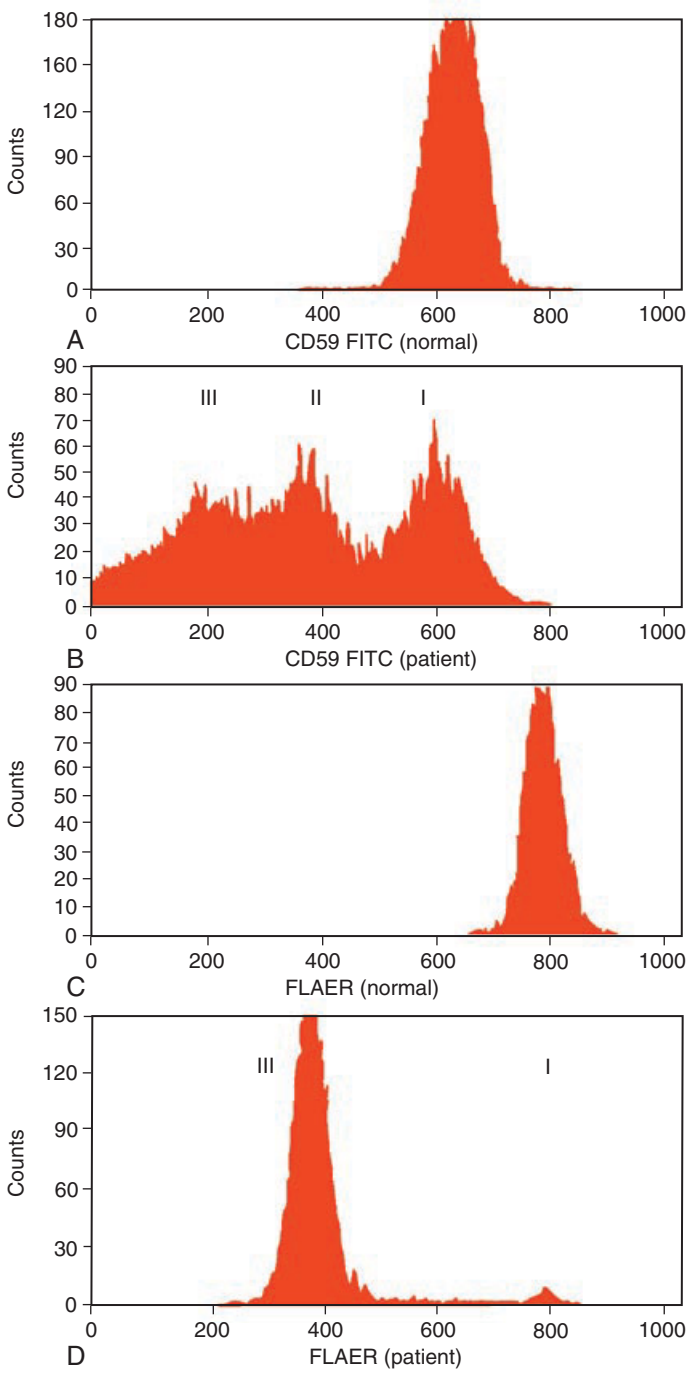

Figure 30–2 Flow cytometric analysis or peripheral blood cells from a paroxysmal nocturnal hemoglobinuria (PNH) patient. (**A**) Fluorescence intensity of erythrocytes from a healthy control after staining with anti-CD59. (**B**) Fluorescence intensity of erythrocytes from an untransfused PNH patient after staining with anti-CD59. Type II cells are "blended" between the type I (normal) and type III cells. (**C**) Fluorescence intensity of granulocytes from a healthy control stained with FLAER. (**D**) Fluorescence intensity of granulocytes from the same PNH patient as **B** following staining with FLAER. Note that the granulocytes are almost exclusively type III cells. A small population of type I granulocytes is present.

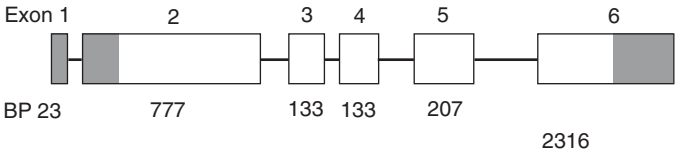

Figure 30–3 Structure of the human *PIGA* gene. Boxes represent exons; intervening lines represent introns. Shaded areas show noncoding regions.

locyte populations. Patients with three discreet granulocyte populations (type I, type II, and type III cells) usually have more than one PNH clone. The type II cells are usually the consequence of a missense mutation, whereas the type III cells commonly result from frameshift mutations caused by small base pair insertions or deletions. However, in many PNH patients the type II cells are not a distinct population, but represent a "spectrum" between the type III and type I cells (see Fig. 30–3). This finding may be an artifact as many of these patients will have few to no type II granulocytes; thus, the correlation between phenotype and genotype is best for PNH granulocytes and/or when the type II erythrocytes represent a circumscribed population.

CLINICAL FEATURES

Hemolytic Anemia and Hemoglobinuria

Hemolysis in PNH results from the increased susceptibility of PNH red cells to complement. Complement consists of a battery of proteins that circulate in the plasma. These proteins are part of the innate immune system and are important for antibody-mediated immunity.[39] Normally, membrane proteins regulate the activation of the complement system and protect cells from the deleterious effects of activated complement. PNH red cells are more vulnerable to complement-mediated lysis because of a reduction, or complete absence, of membrane inhibitor of reactive lysis (CD59) and decay accelerating factor (CD55), both of which are GPI-anchored.

CD59 is a 19,000 molecular weight glycoprotein that directly interacts with the membrane attack complex (MAC) to prevent lytic pore formation by blocking the aggregation of C9.[40,41] CD55, a 68,000 molecular weight glycoprotein, functions to accelerate the rate of destruction of membrane-bound C3 convertase. Hence, CD55 reduces the amount of C3 that is cleaved, and CD59 reduces the number of MAC that is formed. Of the two, CD59 is more important in protecting cells from complement. Red blood cells from individuals with the Inab phenotype, a blood group antigen, lack CD55, yet these individuals have no clinical hemolysis.[42] In contrast, a patient with a congenital deficiency of CD59 was shown to have a compensated hemolytic anemia.[43] Furthermore, incorporation of CD59 onto PNH erythrocytes was shown to ameliorate acidified serum lysis to a greater extent than incorporation of CD55.[44]

The classic manifestation from which PNH derives its name—paroxysmal bouts of reddish, brownish, or "cola-colored" urine that strikes predominantly overnight—is described by a minority of PNH patients. Most PNH patients have no noticeable hemoglobinuria or have intermittent episodes of hemoglobinuria with no relation to the time of day. Early speculation that the nocturnal hemoglobinuria was a function of a mild drop in pH that occurs with sleep has not been validated. Patients with a history of hemoglobinuria are more likely to have a large PNH clone and less likely to have a markedly hypocellular bone marrow.

Although hemolysis is often the most conspicuous feature in patients with classical PNH, many patients, particularly those with coexisting bone marrow failure, exhibit mild to barely detectable hemolysis. The hemoglobin concentration can range from normal to severely depressed. The reticulocyte count is often elevated but usually lower than expected for the degree of anemia. Patients with PNH manifest all the usual clinical and laboratory signs of chronic hemolytic anemia: weakness, fatigue, pallor, and dyspnea on exertion. In patients with prominent hemolysis, the magnitude of fatigue can be out of proportion to the degree of anemia. Morphologically, the red cells appear normal, although some cases display mild to moderate poikilocytosis and anisocytosis. The haptoglobin levels are usually low, and the lactate dehydrogenase (LDH) is frequently elevated, sometimes greater than 3000 IU/L, depending on the degree of hemolysis.

Multiple factors influence the degree of hemolysis in PNH, including the size and type of the PNH clone and the degree of complement activation. In general, the percentage of PNH erythrocytes correlates with the degree of hemolysis. However, the type of PNH erythrocytes may also influence the degree of hemolysis. Type III erythrocytes are more readily lysed than type II erythrocytes and almost always constitute a larger percentage of the PNH red cells. Thus, patients with a large percentage of type III erythrocytes tend to have more hemolysis than patients with a large percentage of type I or type II cells. Finally, hemolysis is frequently exacerbated by infections (especially gastrointestinal infections), surgery, strenuous exercise, excessive alcohol intake, blood transfusions, and anything else that initiates complement activation.

Smooth Muscle Dystonia and Nitric Oxide

Many clinical manifestations of PNH are readily explained by hemoglobin-mediated nitric oxide scavenging.[45,46] Failure of complement regulation on the PNH erythrocyte membrane leads to intravascular hemolysis resulting in the release of large amounts of free hemoglobin into the plasma. Free plasma hemoglobin leads to increased consumption of nitric oxide resulting in manifestations that include fatigue, abdominal pain, esophageal spasm, erectile dysfunction, and possibly thrombosis. Indeed, hemoglobinuria, thrombosis, erectile dysfunction, and esophageal spasm are more common in patients with large PNH populations (>60% of granulocytes) than in patients with relatively small PNH populations. In a study of 49 PNH patients diagnosed using flow cytometry, Moyo and colleagues demonstrated that large PNH clones were associated with an increased risk for thrombosis, hemoglobinuria, abdominal pain, esophageal spasm, and male impotence.[47] Thus, many of the clinical manifestations of PNH appear to be a direct consequence of intravascular hemolysis, leading to the release of free hemoglobin, scavenging of nitric oxide, and smooth muscle dystonias.

Renal Manifestations

PNH patients can experience renal manifestations that resemble those observed with sickle cell anemia.[48] Perturbed tubular function and declining creatinine clearance are found in a high percentage of patients. Radiologically, patients can exhibit large kidneys, cortical infarcts, cortical thinning, and papillary necrosis. PNH patients display marked hemosiderin deposition in the proximal tubules; however, microvascular thrombosis can be responsible for many of the renal abnormalities in PNH.[48] Acute renal failure following massive hemolysis occurs infrequently and usually resolves in days to weeks.

Thrombosis and PNH

Thrombosis is an ominous complication of PNH and the leading cause of death from the disease. It occurs in approximately 40% of PNH patients and almost invariably involves the venous system. Patients with a large percentage of PNH cells and classical symptoms (hemolytic anemia and hemoglobinuria) have a greater propensity for thrombosis than patients with a small percentage of PNH cells.[47,49–51] According to logistic regression modeling, for a 10% change in PNH clone size, the odds ratio for risk of thrombosis is estimated to be

1.64.[47] Patients with PNH granulocyte clones of greater than 60% appear to be at greatest risk for thrombosis. The mechanism of thrombosis in PNH is not entirely understood and probably multifactorial, but similar to other manifestations of the disease, it is probably related to the GPI anchor protein deficiency. Indeed, nitric oxide depletion has been associated with increased platelet aggregation, increased platelet adhesion, and accelerated clot formation.[46] In an attempt to repair damage, PNH platelets undergo exocytosis of the complement attack complex.[52] This results in the formation of microvesicles with phosphatidylserine externalization, a potent in-vitro procoagulant. These prothrombotic microvesicles have been detected in the blood of PNH patients.[53] Fibrinolysis can also be perturbed in PNH given that PNH blood cells lack the GPI-anchored urokinase receptor.[54] Lastly, tissue factor pathway inhibitor (TFPI), a major inhibitor of tissue factor, has been shown to require a GPI-anchored chaperone protein for trafficking to the endothelial cell surface.[55] Although the mechanism of thrombosis in PNH is not entirely clear, the sites of venous thrombosis in PNH are manifold with the abdominal veins and the cerebral veins being the most commonly involved regions.

Liver

Hepatic vein thrombosis (Budd-Chiari syndrome) is the most common site of thrombosis in PNH and is frequently a fatal complication.[47,56,57] Moreover, PNH is probably the condition that confers the highest risk for developing hepatic vein thrombosis.[58] The clinical manifestations of hepatic vein thrombosis include abdominal pain, hepatomegaly, jaundice, ascites, and weight gain.[59] The onset of symptoms can be abrupt or insidious. Hepatic vein thrombosis in PNH tends to inexorably progress with periodic exacerbations followed by intervals of relatively stable disease. Although some patients live many years with the condition, it frequently results in death. The best noninvasive tests to confirm the diagnosis include computed tomography scanning, magnetic resonance imaging, and ultrasonography. Thrombosis can involve the small hepatic veins, large-sized hepatic veins, or both. Thrombolytic therapy has been used successfully to restore venous patency and reverse the hepatic congestion; however, because of the potential danger of this approach, it should be used judiciously.[60] Patients with acute onset disease, preserved platelet counts (>50,000 cells/mm^3), and large vessel involvement are the best candidates for thrombolysis. For patients with massive ascites who are not suitable candidates for thrombolytic therapy, transjugular intrahepatic portal-systemic shunting or surgical shunting can successfully palliate some patients. Orthotopic liver transplantation has also been performed in a few cases; however, this is not routinely recommended as the underlying disease leads to prompt relapse.[61]

Portal vein thrombosis is also common in PNH and can occur with or without hepatic vein thrombosis.[47,57,62,63] Patients frequently present with nausea, vomiting, abdominal pain, and liver dysfunction. Management is similar to that of hepatic vein thrombosis.

Other Abdominal Veins

Venous thrombosis in PNH has been described in all abdominal and retroperitoneal venous systems including the splenic veins,[64] mesenteric veins, renal veins, and the inferior vena cava.[65] Thrombosis of minor veins can also occur and can be difficult to diagnose because of the protean manifestations and their relapsing and remitting nature.[66] Often such patients present with recurrent, severe abdominal pain crises sometimes mimicking intestinal obstruction. The consequence of these microthromboses can sometimes be visualized with esophagogastroduodenal endoscopy or colonoscopy. Patients with intestinal thromboses can present with ischemic colitis and can be misdiagnosed as having Crohn's disease. Upper gastrointestinal bleeding can be caused by esophageal or gastric varices that develop as a consequence of portal hypertension or splenic vein thrombosis.

Cerebral Veins

Cerebral veins, particularly the sagittal veins and sinuses, are also highly prone to thrombosis in PNH.[47,57,63,67] Patients can present with severe headaches and/or focal neurologic deficits depending on the location of the thrombosis. Similar to hepatic vein thrombosis, cerebral vein thrombosis is an ominous complication that can result in substantial morbidity and mortality. Magnetic resonance imaging to carefully examine the cerebral blood flow is helpful in establishing the diagnosis.

Other Sites

Dermal venous thrombosis can occur virtually anywhere on the body but seem to have a predilection for the face and upper extremities. Patients usually complain of pain, discolorations and swelling. The lesions can reach several centimeters in diameter and are firm and tender. Necrosis and the formation of a black eschar can occur. Anticoagulation and warm compresses can ameliorate the attacks. Pulmonary emboli and deep venous thrombosis have also been reported in PNH but are uncommon; arterial thrombosis is rare.

CLONALITY AND BONE MARROW FAILURE

PIGA Mutations in Aplastic Anemia and Myelodysplastic Syndrome

Small to moderate PNH clones are found in up to 70% of patients with acquired aplastic anemia, demonstrating a pathophysiologic link between these disorders.[7,8,68,69] Typically, less than 20% GPI anchor protein-deficient granulocytes are detected in aplastic anemia patients at diagnosis, but occasional patients can have larger clones.[8] DNA sequencing of the GPI anchor protein-deficient cells from aplastic anemia patients reveals clonal *PIGA* gene mutations.[29] Moreover, many of these patients exhibit expansion of the *PIGA* mutant clone and progress to clinical PNH. Although it was once thought that PNH evolving from aplastic anemia is more benign than classical PNH, this observation can be a consequence of lead time bias, as many of these patients eventually develop classical PNH symptoms.

GPI anchor protein-deficient cells have also been reported in patients with MDS,[7,69] but sequencing of the *PIGA* gene to establish clonality has not been performed in most of these studies. MDS patients reported to have small PNH populations tend to be classified as refractory anemia and often have the following characteristics: a hypocellular marrow, human leukocyte antigen (HLA)-DR15 positivity, normal cytogenetics, moderate to severe thrombocytopenia, and a high likelihood of response to immunosuppressive therapy.[69,70] Thus, it is possible that many of these patients have moderate aplastic anemia rather than MDS. Distinguishing hypoplastic MDS from aplastic anemia is often difficult; however, quantitative analysis of bone marrow CD34 positive cells is useful for discriminating between these two entities.[71]

PIGA Mutations in Healthy Controls

PNH is an uncommon disease, with only two to five new cases per million US inhabitants annually; however, *PIGA* mutations can be found in the blood from virtually all healthy controls.[37,72,73] Araten and coworkers used flow cytometric analysis of blood from 9 healthy controls and found an average of 22 GPI anchor protein-deficient granulocytes per 10^6 cells, yet none of these subjects developed PNH. GPI anchor protein-deficient lymphocytes have also been detected in patients with lymphoid malignancies or rheumatoid arthritis after treatment with alemtuzumab (Campath-1H). Alemtuzimab is a

monoclonal antibody that recognizes CD52, a GPI-anchored protein expressed on monocytes, B cells, and T cells.[74–77] None of these patients developed PNH; furthermore, when the alemtuzimab was discontinued, the GPI anchor protein–deficient cells regressed.

How can such a common mutation, *PIGA,* be so specific for PNH, yet so rarely result in disease? One hypothesis to explain the close relationship between PNH and aplastic anemia, and the mechanisms whereby the PNH clone achieves dominance, involves a "two-step" model. This model proposes that hematopoietic stem cells randomly and spontaneously acquire *PIGA* mutations at a very low frequency (step one). Step two in this model proposes that the immunologic attack that targets hematopoietic stem cells in aplastic anemia spares PNH cells, ostensibly because they lack GPI-anchored proteins.[78,79] Indeed, *PIGA* mutant cells are found at low frequency in most healthy controls.[37,72,73,76] More recent data suggest that most, if not all, *PIGA* mutations in healthy controls arise from colony-forming cells rather than hematopoietic stem cells[37]; thus, the relevance of these mutations is unclear. Furthermore, there is no direct evidence to support a GPI-anchored protein being the target of the immune attack in aplastic anemia. Importantly, this two-step model does not explain the similarly high incidence of MDS in aplastic anemia patients.[80,81]

An alternative hypothesis that could explain the predisposition of patients with aplastic anemia to develop both PNH and MDS has been proposed. MDS and PNH evolving in the setting of aplastic anemia could be analogous to the *field cancerization effect* described in aerodigestive and other solid tumors to explain second primary tumors in the affected tissue.[82,83] That is, a single insult to the marrow, such as generalized toxic damage or a genetic predisposition, may be responsible for bringing about different forms of marrow disorders; these disorders can occur alone, simultaneously, or sequentially.[84,85] In aplastic anemia, the bone marrow injury may primarily trigger an autoimmune attack on the hematopoietic stem/progenitor compartment, perhaps by exposing cryptic epitopes through molecular mimicry, or by sending a "danger" signal. In primary PNH or MDS, the injury may primarily produce a genetic mutation that leads to clonal dominance of the affected clone.[86–88] In other patients, bone marrow injury may induce both an autoimmune hematopoietic attack and a clonal genetic mutation that present either simultaneously or sequentially. Examples of simultaneous presentation are the aplastic anemia/PNH overlap and hypoplastic MDS. Lastly, a third hypothesis proposes that additional mutations occurring in *PIGA* mutant stem cells are required for clonal expansion PNH.[89–91] These hypotheses may not be mutually exclusive; thus, further investigation is needed to fully understand the mechanism of clonal dominance in PNH.

Clinical observations also provide clues to understanding clonal dominance in PNH and the relationship between aplastic anemia and PNH. Up to 30% of aplastic anemia patients treated with conventional immunosuppressive therapy (antithymocyte globulin and cyclosporine) will develop PNH or MDS, usually several years after therapy.[81,92] In contrast, allogeneic bone marrow transplantation appears to eliminate the risk for developing PNH in patients with aplastic anemia. These data suggest that secondary clonal disorders (PNH and MDS) are part of the natural history of aplastic anemia. Although immunosuppressive therapy unequivocally prolongs survival, it does not prevent these late complications. High-dose cyclophosphamide therapy for severe aplastic anemia appears to result in more durable and complete remissions than conventional immunosuppression, but it is premature to conclude that this approach eliminates the risk for developing PNH.[93–95]

Clonal Transformation

PNH patients, similar to aplastic anemia and MDS patients, are at increased risk for clonal transformation;[96] however, the incidence of leukemic transformation in PNH is less than that of MDS. Abnormal cytogenetics can be found in up to 20% of PNH patients.[97] MDS and acute myeloid leukemia are the most common malignancies to evolve from PNH; the leukemic cells arise from the GPI anchor-deficient clone in most, but not all cases.[98,99]

NATURAL HISTORY

The natural history of PNH ranges from indolent to severely debilitating and life-threatening.[47,56,57] Females and males are equally affected with the median age of diagnosis being 40 years old. The median survival from time of diagnosis is 10 to 15 years. Thrombosis, severe pancytopenia, evolution to MDS or leukemia, older age, and thrombocytopenia at diagnosis portend a poor prognosis. Older literature, where patients were diagnosed with PNH based on the Ham test or sucrose hemolysis test, reported on the occurrence of spontaneous long-term remissions in up to 10% of PNH cases[57]; however, in patients diagnosed with PNH based on flow cytometric assays, spontaneous remissions are extremely rare.[47]

LABORATORY EVALUATION

Blood

Peripheral blood counts in PNH patients vary from severe pancytopenia to normal. Virtually all patients will present with anemia, frequently with mild macrocytosis. Thrombocytopenia and/or neutropenia are also common. A mild to moderate reticulocytosis is usually present in patients with the classical form of the disease; however, in patients with hypoplastic PNH (also known as *aplastic anemia/PNH overlap*), the reticulocyte count can be reduced. Similarly, in patients with hypoplastic PNH, the biochemical profile can be normal, but in patients with large PNH clones the indirect bilirubin and LDH are significantly elevated. In patients with vigorous hemolysis, it is not uncommon for the laboratory to report the specimen as "hemolyzed."

Bone Marrow

Bone marrow cellularity can be hypocellular, normocellular, or hypercellular. In patients with classical PNH (not arising from or coinciding with aplastic anemia), the marrow is usually normocellular to hypercellular with erythroid hyperplasia. Mild to moderate dyserythropoiesis is common. Stainable iron is frequently absent because of iron loss associated with the intravascular hemolysis. Cytogenetic abnormalities can be found in up to 20% of patients.

DIAGNOSIS

Complement-Based Assays

The Ham test and the sucrose hemolysis test (sugar water test) were two of the first assays used to diagnosis PNH. Both assays are performed on erythrocytes and discriminate PNH cells from normal cells based on a differential sensitivity to the hemolytic action of complement. In the Ham test, complement is activated by acidification of the serum. This results in lysis of PNH erythrocytes but not normal erythrocytes.[3] The Ham test is relatively specific for PNH, but is not very sensitive.

Complement is also activated in a low ionic strength sucrose-containing medium. Preferential lysis of PNH erythrocytes through the activation of complement in this sucrose-containing medium forms the basis for the sugar water test.[100] This assay is easier to perform and is more sensitive than the Ham test but not as specific; other hemolytic anemias and even leukemias can produce false positive results. The complement lysis assay in which complement is activated with antibody will also detect PNH erythrocytes.[101] These complement-based red cell assays are important from a historical

perspective, but should no longer be used to establish the diagnosis of PNH.

GPI Anchor-Based Assays

Most laboratories use monoclonal antibodies against specific GPI-anchored proteins in conjunction with flow cytometry to diagnose PNH. Anti-CD59 is most commonly used because it is widely expressed and is displayed on all hematopoietic lineages. Anti-CD55, anti-CD14, anti-CD16, anti-CD67, and a variety of other monoclonal antibodies can also be used to establish the diagnosis. Flow cytometry offers several advantages over complement-based assays for diagnosing PNH: It measures the size of the PNH clone in the various cell lineages, it is more sensitive and specific, and it is less affected by blood transfusions. It is noteworthy that rare congenital deficiencies of CD59 and CD55 can lead to a false positive test for PNH if only one monoclonal antibody is used. This, coupled with the variable expression of GPI-anchored proteins on different hematopoietic lineages, accounts for the recommendation that at least two different monoclonal antibodies, directed against two different GPI-anchored proteins, on at least two different cell lineages, should be used to diagnose a patient with PNH. Solely screening patients' red cells for PNH can lead to falsely negative tests, especially in the setting of a recent hemolytic episode or a recent blood transfusion. As granulocytes and monocytes have a short half-life and are not affected by blood transfusions, the percentage of PNH cells in these lineages best reflects the size of the PNH clone.

Aerolysin Assays

A fluorescein-labeled proaerolysin variant, 5 *Fl*ourescent *Aer*olysin FLAER, is increasingly being used as a flow cytometric assay to diagnose PNH.[102,103] Aerolysin is the principal virulence factor of the bacterium *Aeromonas hydrophila*. It is secreted as an inert protoxin termed, proaerolysin, that binds selectively and with high affinity to the GPI anchor.[104,105] After binding to its receptor (the glycan portion of the GPI anchor), the C-terminal peptide of proaerolysin is cleaved by cell proteases. This activates the toxin and leads to the formation of heptameric channels that insert into the membrane and kill the cell.[106] PNH cells are resistant to aerolysin and proaerolysin because PNH cells lack GPI-anchored proteins. FLAER binds to the GPI anchor without forming channels and gives a more accurate assessment of the GPI-anchor deficit in PNH than anti-CD59.[102] Because the GPI anchor is the major determinant for binding FLAER, it allows for the direct assessment of GPI anchor expression on virtually all cell lineages.[8,102,103] Red cells are a notable exception; this may be because both normal and PNH red cells express large amounts of glycophorin, a protein shown to bind aerolysin weakly.[107] Nevertheless, in mononuclear cells FLAER eliminates the need for multiple lineage-specific monoclonal antibodies. These properties make FLAER more reliable for detecting the diminutive PNH populations often found in patients with aplastic anemia.[8]

THERAPY

Introduction

Some PNH patients can be managed conservatively with supportive care alone. The major exceptions are patients with hypoplastic PNH (especially those who also meet criteria for severe aplastic anemia) and patients with life-threatening thromboses or debilitating hemolysis and smooth muscle dystonias. Cytopenias in patients with hypoplastic PNH are usually caused by immune suppression of hematopoiesis; thus, the management of these patients should be similar to those with acquired aplastic anemia. Classical PNH patients manifesting with recurrent thrombosis and/or severe intravascular hemolysis are particularly challenging to manage. For these patients, eculizumab or bone marrow transplantation are reasonable therapeutic options.

Immunosuppressive Therapy

PNH patients with a hypoplastic bone marrow, low reticulocyte count, and pancytopenia (hypoplastic PNH) will frequently respond to immunosuppressive therapy.[108,109] The response rate in this group is more than 50%. In fact, finding a minor population of PNH-like cells in severe aplastic anemia may predict for response to immunosuppressive therapy.[110] The impaired hematopoiesis that occurs in hypoplastic PNH may respond to antithymocyte globulin and/or cyclosporine, but the PNH clone is not affected.[109] In some cases, immunosuppressive therapy has ameliorated the aplasia but with preferential expansion of the PNH clone.[111] Immunosuppressive therapy does not appear to benefit patients with classical PNH.

Management of Anemia

The cause of anemia in PNH is often multifactorial. In patients with hypoplastic PNH, bone marrow failure, usually because of autoimmunity, is the major etiologic factor for anemia. Patients with hypoplastic PNH may respond to immunosuppressive therapy. However, in patients with cellular bone marrows, elevated reticulocyte counts, and a high LDH (classical PNH), intravascular hemolysis is the major mechanism of anemia. Traditionally, these patients were given a trial of adrenocorticosteroids. Prednisone therapy (0.5 mg to 1 mg/kg/day) can reduce hemolysis and increase hemoglobin levels in some patients. If possible, the prednisone dose should be tapered to 10 mg to 20 mg on alternate days to reduce the toxicities from chronic steroid therapy. If no salutary effect is observed after 1 to 2 months of therapy, prednisone should be discontinued. Danazol can also be effective in some patients with classical PNH.[112] Erythropoietin is rarely beneficial. Iron deficiency caused by intravascular hemolysis can also contribute to the anemia of PNH; thus, in patients with absent iron stores, iron replacement therapy is indicated. Folic acid supplementation is also recommended in PNH because of the high red cell turnover. Some patients are refractory to therapy and can require periodic red cell transfusions. These patients should receive group-specific blood and blood products. Washing the red cells with saline, once advocated to minimize hemolysis after transfusion in PNH, is unnecessary.[113]

Eculizumab

Eculizumab is a humanized monoclonal antibody against C5 that inhibits terminal complement activation (Fig. 30–4) and will likely become the treatment of choice in patients with classical PNH. A 12-week open-labeled trial of eculizumab in 11 PNH patients demonstrated that the drug reduced intravascular hemolysis and transfusion requirements.[6] A recent international double-blind, randomized, controlled trial in PNH patients demonstrated that eculizumab was effective in stabilizing hemoglobin levels and reduced transfusion requirements in patients with classical PNH.[114] Blockade of the complement cascade at C5 preserves the early activity of the complement cascade that is necessary for the opsonization of microorganisms and clearance of immune complexes;[39] however, as terminal complement blockade can be associated with an increased risk for *Neisserial* infections, all patients in this study were vaccinated against *Neisseria meningitides* 2 weeks before receiving the study drug. The study randomized 87 PNH patients to receive either placebo ($n = 44$) or eculizumab ($n = 43$) administered intravenously at 600 mg weekly for 4 weeks, 900 mg the following week, and then 900 mg every 2 weeks for a total of 6 months. The primary endpoints were hemoglobin stabilization and reduction in units of transfused blood. Eligible PNH patients were required to be red cell transfusion dependent with a platelet count of >100,000 per mm^3 and an LDH level >1.5 times

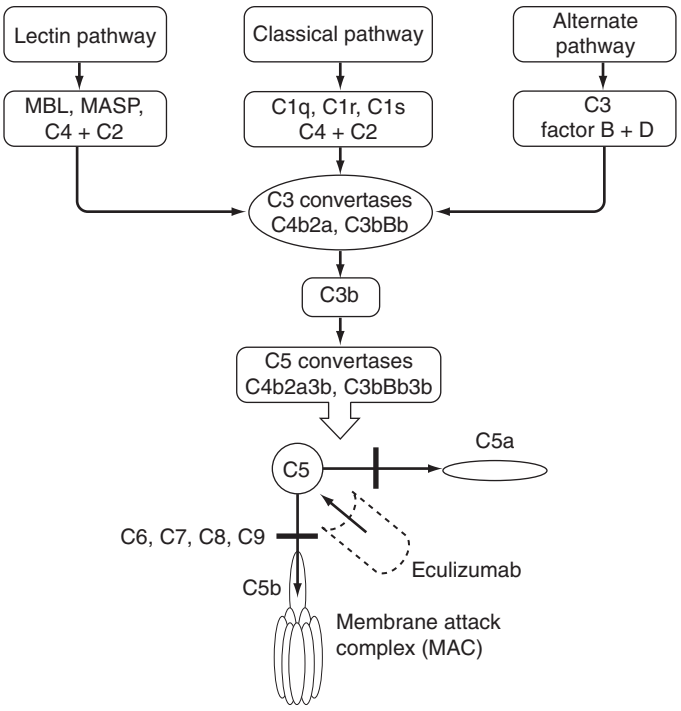

Figure 30–4 Overview of the complement cascade. Classic, alternative, and lectin pathways converge at the point of C3 activation. The lytic pathway is initiated with the formation of C5 convertase and leads to the assembly of the C5, C6, C7, C8, (*n*) C9 membrane attack complex. Eculizumab is a monoclonal antibody that binds to C5, thereby preventing the formation of C5a and C5b. C5b is the initiating component of the membrane attack complex (MAC). FITC, fluorescein isothiocyanate.

the upper limit of normal. Hemoglobin stabilization was maintained by 48.8% patients in the eculizumab-treated group and 0% in the placebo-treated group ($P < 0.001$). A median of 0 units of packed red cells were transfused in the eculizumab-treated group compared with a median of 10 units in the placebo-treated group ($P = 0.001$). The eculizumab-treated group also showed significant improvements in quality of life and a significant decrease in LDH levels. The most common adverse events reported for eculizumab-treated patients were headache, nasopharyngitis, back pain, and upper respiratory tract infections. Thus, in patients with classical PNH, eculizumab is highly effective in decreasing intravascular hemolysis; the drug greatly improves quality of life and reduces or eliminates the need for blood transfusions. Importantly, eculizumab also mitigates the smooth muscle dystonias that are often associated with PNH by reducing plasma free hemoglobin levels. Eculizumab is not yet approved by the FDA; however, on approval and further investigation, it is likely that eculizumab will become the recommended initial therapy for patients with classical PNH. Patients with hypoplastic PNH are less likely to respond to eculizumab, because bone marrow suppression, rather than complement-mediated hemolysis is the major mechanism of anemia. Whether eculizumab will decrease the risk for thrombosis and improved survival in PNH remains to be determined.

Thrombosis

Thrombosis is often the most pernicious complication of PNH and usually represents an indication for long-term anticoagulation. In patients with acute onset abdominal vein thrombosis, thrombolytic therapy has been successfully employed.[60] However, in some patients, thrombolytic therapy and/or anticoagulation is relatively contraindicated because of severe thrombocytopenia. Managing PNH patients on chronic warfarin therapy is often challenging. Platelet counts are usually mildly to moderately reduced and sometimes erratic. Furthermore, maintaining a therapeutic international normalized ratio (INR) is difficult in some patients because of frequent PNH attacks that can be associated with anorexia, nausea, and vomiting. The use of oral contraceptives and pregnancy can exacerbate the proclivity for thrombosis in PNH and should be considered high risk.

Bone Marrow Transplantation

Allogeneic hematopoietic stem cell transplantation is the only curative therapy for PNH.[115–117] Because of the substantial morbidity and mortality of this procedure and the sometimes indolent natural history of PNH, bone marrow transplantation (BMT) should only be offered to patients with more severe forms of the disease. Younger patients with severe pancytopenia or life-threatening thrombosis who have an HLA-identical sibling are the best candidates for this approach. The International Bone Marrow Transplant Registry (IBMTR) reported a 2-year survival probability of 56% in 48 recipients of HLA-identical sibling transplants between 1978 and 1995. The median age was 28 years. The majority of the deaths in this study occurred within 1 year of transplantation. One of seven recipients of alternative donor allogeneic transplants reported to the IBMTR during this period was alive 5 years after transplant. Both nonmyeloablative syngeneic BMT and nonmyeloablative stem cell transplants from HLA-matched siblings have been performed in PNH patients.[115,116,118] Interestingly, the latter approach, but not the former, appears to cure the disease, suggesting that there is an important *graft-versus- PNH* effect with bone marrow transplantation. Future use of bone marrow transplantation to treat PNH may be curtained once eculizumab becomes more widely available.

APPROACH TO DIAGNOSING PNH

PNH has an estimated incidence of 2 to 5 per million in the United States. This, coupled with its protean manifestations, make diagnosing PNH a challenge for even the most astute diagnostician. However, given the ease and specificity of modern diagnostic assays, the most important attribute a physician can possess in diagnosing PNH is to maintain a high level of suspicion and to be cognizant of the various presentations of the disease. A small sample of peripheral blood sent to an experienced flow cytometric laboratory is usually sufficient to establish or exclude the diagnosis of PNH. These assays are fast, reliable, and inexpensive. If monoclonal antibodies are used to establish the diagnosis, it is imperative that two or more antibodies be used on at least two different lineages. Assaying granulocytes is the most reliable method to diagnose PNH as they are not affected by blood transfusions. I prefer to use FLAER over monoclonal antibodies on granulocytes and monocytes because of the improved sensitivity and specificity; anti-CD59 is the most reliable marker on erythrocytes.

Classical PNH is usually more conspicuous than hypoplastic PNH. Patients typically present with a direct antiglobulin negative hemolytic anemia, hemoglobinuria, and mild to moderate cytopenias. Obscure paroxysms of back pain, abdominal pain, fatigue and/or headaches are often present. The bone marrow is typically normocellular to mildly hypercellular with intense erythroid hyperplasia and mild to moderate dyserythropoiesis. Bone marrow iron stores are frequently, but not always, absent. PNH patients can also present with abrupt, severe abdominal pain and jaundice caused by thrombosis. All patients presenting with unexplained hepatic vein, portal vein, mesenteric vein, or portal vein thrombosis should be screened for PNH.

It is important to distinguish PNH from MDS. Most patients with refractory anemia should be screened for PNH, especially those with moderate to severe cytopenias and a hypocellular bone marrow. In addition, all patients diagnosed with aplastic anemia should be screened for PNH. In rare instances idiopathic myelofibrosis or autoimmune hemolytic anemias can mimic PNH. Patients with a history of aplastic anemia—especially those managed with immunosuppres-

sive therapy—should be monitored closely for the outgrowth of PNH.

APPROACH TO TREATMENT

Classification of PNH: Classical PNH Versus Hypoplastic PNH

I find it useful to classify PNH patients as either "classical" or "hypoplastic." This can usually be accomplished by ordering a complete blood count, reticulocyte count, LDH, peripheral blood flow cytometry for PNH, and a bone marrow aspirate, biopsy, and cytogenetics. Patients with classical PNH tend to have mild to moderate cytopenias, a normocellular to hypercellular bone marrow, an elevated reticulocyte count, a markedly elevated LDH, and a relatively large PNH granulocyte population (>30%). In contrast, hypoplastic PNH patients present with manifestations similar to that of aplastic anemia or hypoplastic MDS. These patients typically present with moderate to severe cytopenias, a hypocellular bone marrow (<25% cellularity), a decreased corrected reticulocyte count, a normal or mildly elevated LDH, and a relatively small (<20%) PNH granulocyte population. Most, but not all, patients can be readily subdivided into classical versus hypoplastic PNH, a distinction that aids with therapeutic decisions.

Hypoplastic PNH

Because bone marrow failure is the major risk for patients with hypoplastic PNH, I direct my therapy toward the pancytopenia. If, in addition to the PNH, the patient fulfills criteria for severe aplastic anemia (see Chapter 29), appropriate therapeutic options include allogeneic bone marrow transplantation, high-dose cyclophosphamide, or antithymocyte globulin and cyclosporine. Young patients (ie, <30 years of age) with an HLA-matched sibling should be transplanted; for older patients and for those without an HLA-matched sibling, high-dose cyclophosphamide or antithymocyte and cyclosporine is appropriate. I prefer to use high-dose cyclophosphamide because of the improved quality and duration of remissions. If the patient's cytopenias do not fulfill criteria for severe aplastic anemia, supportive care or a trial of immunosuppressive therapy is appropriate.

Classical PNH

Symptoms in patients with classical PNH vary from mild, to severely debilitating, to acutely life-threatening. Hence, therapy should be directed toward the specific manifestations (eg, anemia, thrombosis, etc). Allogeneic bone marrow transplantation, preferably from an HLA-matched sibling, is appropriate for patients with severely debilitating or acutely life-threatening disease. In general, these are patients with recurrent thrombosis or those with clonal evolution to either MDS or acute leukemia. Patients with less severe disease should not be transplanted because of the relatively high morbidity and mortality of the procedure. Antithymocyte globulin (ATG) and cyclosporine or high-dose cyclophosphamide does not appear to benefit patients with classical PNH.

Anemia

All patients with classical PNH should be placed on folic acid (1 to 2 mg/day). Patients with absent iron stores, usually because of chronic intravascular hemolysis, should be treated with oral iron supplementation. Pending FDA approval, eculizumab is likely to become the standard-of-care to treat patients with classical PNH. It is the only drug demonstrated in a randomized study to benefit PNH patients. Eculizumab has been shown to decrease the need for transfusions, decrease paroxysms, and improve quality of life in patients with classical PNH; however, it has not been shown to benefit patients with hypoplastic PNH.

If eculizumab is unavailable, a trial of prednisone (0.5 to 1.0 mg/day) can occasionally decrease hemolysis and increase hemoglobin levels. If a salutary effect is not achieved within 6 to 8 weeks, the steroids should be discontinued. In responding patients the steroids should be tapered to the lowest dose that still provides a beneficial effect. Alternate day steroids can help decrease the risk of deleterious long-term side effects. Danazol (400 mg/day) can also decrease hemolysis; if no response is observed after 8 weeks, the drug should be discontinued.

Thrombosis

Patients who present with acute life-threatening or organ-threatening thrombosis should be considered for thrombolytic therapy. In patients with chronic, insidious thrombosis, anticoagulation with heparin followed by long-term warfarin anticoagulation should be initiated. Meticulous monitoring of warfarin levels in PNH patients is warranted, as the risk for bleeding complications is high. Erratic oral intake during PNH attacks, and underlying liver dysfunction can lead to volatility in the INR. In addition, most PNH patients have thrombocytopenia. Thus, the potential risks and benefits of anticoagulation must be scrupulously considered, especially in patients with platelet counts below 50,000 cells/mm^3.

CHAPTER 31

ACQUIRED DISORDERS OF RED CELL AND WHITE CELL PRODUCTION

Jaroslaw P. Maciejewski and Ramon V. Tiu

PURE RED CELL APLASIA

Acquired pure red cell aplasia (PRCA) is characterized by the presence of an acquired severe normochromic, most frequently normocytic, anemia associated with a complete disappearance of reticulocytes and erythroid precursors in the marrow and normal production of myeloid cells and platelets. Consequently, it is presumed that the defect lies within erythroid precursors and not within stem cells as seen in aplastic anemia. Initially described by Kaznelson in 1922,[1] PRCA is a rare bone marrow failure disorder without geographic or racial predilection. All ages can be affected but, if present in children, it is called transient erythroblastopenia of childhood (TEC) and may be difficult to distinguish from congenital causes of anemia, mainly Diamond–Blackfan anemia (DBA). Former nosology included various terms such as erythrophthisis, chronic hypoplastic anemia, pure red cell agenesis, and primary red cell anemia.

ETIOLOGY AND CLASSIFICATION

Acquired forms of PRCA must be distinguished from congenital forms of PRCA, which usually manifest themselves early in life (see Chapter 28). Acquired PRCA occurring in childhood may be difficult to distinguish from DBA. As an acquired disease, PRCA may be a primary disorder or secondary to a variety of systemic diseases, including a number of hematologic diseases (Table 31–1).

Pathogenesis

The inciting events in the development of PRCA are not known. However, as with idiopathic aplastic anemia, viruses or exposure to chemicals can serve as potential triggers (Fig. 31–1). Theoretically, a viral infection could lead to depletion of erythroid precursors. Studies of B19 parvovirus (see later) suggest such an etiology. Because hematopoietic stem cells are not affected by B19 parvovirus, myeloid cells and platelets are normally produced and upon clearance of the virus, normal erythroid production can resume. Similarly, in immune-mediated PRCA, the mechanism of erythroid inhibition may vary and may include (a) antibodies to proteins specific to erythroblasts, (b) direct cytotoxic T-lymphocyte (CTL)-mediated killing of erythroid precursors, and (c) production of soluble products by CTLs such as inhibitory or proapoptotic cytokines that directly affect the erythroid series.

Historically, initial studies concentrated on examining the effects of soluble serum inhibitors of erythropoiesis. These investigations revealed a decline in erythroid colony formation in the presence of patient serum or failure to induce erythroid colony formation in the presence of erythropoietin.[2,3] Such serum inhibitors can be found in 40% of patients with PRCA.[2–4] In 60% of patients, erythroid colony formation can be induced in vitro with hematopoietic growth factors.[2–4] The inhibitory activity is localized to the immunoglobulin (IgG) fraction and disappears upon achieving a clinical remission. The antigenic targets for autoantibodies have not been well characterized, but various stages of erythroid differentiation can be affected (also called PRCA type A) as seen in the reduction of BFU-E or CFU-E.[5,6] In certain cases of antibody-mediated PRCA, the involvement of the complement system is a prerequisite to disease causation.[7] Perhaps, the exception and a model for antibody-induced red cell aplasia is the identification of PRCA associated with antierythropoietin antibodies (also called PRCA type B) in rare cases.[8,9] Consistent with the specificity of the antibodies, myeloid colony formation is not impaired, making it unlikely that a more ubiquitous inhibitory cytokine mediates the specific erythroid inhibition.

In recent years, experimental and clinical observations have suggested that PRCA may be mediated by CTLs, which specifically recognize and kill erythroid precursors similar to CTL-mediated killing of cells in aplastic anemia.[10–12] Although such a T cell-mediated antierythroid response is likely to be polyclonal, rare instances of T-cell large granular lymphocyte (T-LGL) leukemia associated with PRCA or erythroid inhibition may represent an extreme form of the clonal continuum of CTL responses (see T-Cell Large Granular Lymphocyte-Associated). In addition to CTLs expressing α/β TCR, T cells with a γ/δ TCR can mediate PRCA.[13,14] The antigens/antigenic peptides triggering such a response have not been well described.[15,16] Similarly, natural killer (NK) cells have also been implicated in mediating cytotoxicity directed against erythroid precursors.[17,18] NK cells like γ/δ T-lymphocytes and unlike α/β CTL do not rely on MHC-restricted cytotoxicity, but may utilize killer-cell inhibitory receptors (KIRs).[19,20] KIRs inhibit cytolysis when they encounter a cell bearing HLA class I molecules. A lack of appropriate KIRs may predispose cells to increased attack by NK cells or γ/δ CTL. Physiologic down-regulation of KIR has been implicated in the pathogenesis of PRCA in a patient with concomitant γ/δ T-LGL clonal proliferation.[13,21] An alternative NK-cell cytotoxic mechanism independent of KIR has been reported in healthy individuals.[22]

Peripheral T-helper lymphocyte polarization has been implicated in the pathogenesis of PRCA.[16,23] Polarization toward the Th2 functional subtype (IL-4) during disease relapse and normalization of Th1/Th2 ratio after effective treatment has been reported in both monoclonal gammopathy of undetermined significance (MGUS) and thymoma-associated PRCA. Further studies have shown increased *C-MAF* gene expression in relapsed PRCA associated with Th2 polarization, a mechanism that may help explain the alteration in Th1/Th2 balance.[16]

PRIMARY PURE RED CELL APLASIA

Primary PRCA occurs in the absence of any underlying disorder. It may be acute and self-limited or may be a chronic and refractory condition. Acute forms are uncommon. Most cases are protracted and chronic, unlike TEC, which is an acute and self-limited disorder. Most of the cases of classical primary PRCA are autoimmune in origin, but a significant proportion will remain idiopathic in origin in spite of an exhaustive workup.

Table 31–1 Classification of Pure Red Cell Aplasia

Congenital (DBA)		
Primary	Autoimmune Idiopathic	
Secondary	Thymoma[8,9,32–34]	
	Hematologic malignancies	CLL[24,25]
		T-LGL/chronic NK-LGL leukemia[10,11,17,18,28–31]
		Myeloma[435]
		NHL[436,437]
		MDS[438]
		ALL[439–441]
	Solid tumors	Renal cell carcinoma[442]
		Thyroid cancer[443]
		Various adenocarcinomas[444,445]
	Infections	Parvovirus B19[50]
		EBV,[59] Mumps
		HIV,[61] HTLV-1[28]
		CMV[60]
		Viral hepatitis (Hep A,[55,56,446] Hep C[57,58])
		Leishmaniasis[240]
		Gram+ systemic infections eg, staphylococcemia
		Meningococcemia
	Autoimmune conditions	SLE[74]
		RA[69]
		Sjögren's syndrome[71,72]
		Mixed connective tissue disease[66]
		Autoimmune hepatitis[447]
		Anti-Epo antibodies[448,449]
		ABO-incompatible BMT
		Minor incompatibility[93–98]
	Drugs and chemicals	
	Pregnancy[43,44]	
	Severe nutritional deficiencies[450,451]	
	Renal failure[452]	

ALL, acute lymphoblastic leukemia; BMT, bone marrow transplantation; CLL, chronic lymphocytic leukemia; CMV, cytomegalovirus; DBA, Diamond–Blackfan anemia; EBV, Epstein–Barr virus; HTLV-1, human T-lymphotrophic virus; MDS, myelodysplastic syndrome; NHL, non-Hodgkin lymphoma; NK-LGL, natural killer large granular lymphocyte; RA, refractory anemia; SLE, systemic lupus erythematomus; T-LGL, T-cell large granular lymphocyte.

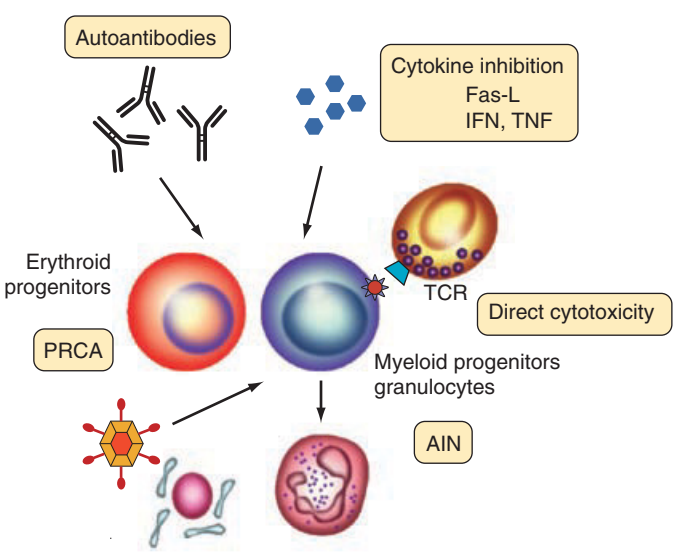

Figure 31–1 Pathogenesis of pure red cell aplasia.

SECONDARY FORMS OF PURE RED CELL APLASIA

Clinical Associations

B-Cell Chronic Lymphocytic Leukemia-Associated PRCA

In B-cell chronic lymphocytic leukemia (CLL), PRCA can be observed in up to 6% of cases.[10,24,25] The underlying pathogenetic mechanisms are not clear and the inhibition of the erythroid series does not appear to be mediated by a soluble factor.[26,27] The distinction between whether the PRCA is a result of the primary B-cell CLL disease or its therapy becomes difficult in circumstances when PRCA presents as a late event. In most cases, PRCA cannot be attributed simply to infiltration of the marrow by the lymphoma.

T-Cell Large Granular Lymphocyte-Associated PRCA

Although neutropenia is a typical finding in T-LGL leukemia, PRCA with varying degrees of erythroblastopenia can also be observed in 10% to 15% of patients with T-LGL leukemia.[11,28–31] In such a setting, PRCA is often accompanied by red cells with an increased mean corpuscular volume. T-LGL leukemia with PRCA may respond to oral cyclophosphamide, cyclosporine A (CsA), methotrexate, and in refractory cases therapy to antithymocyte globulin (ATG). It is possible that PRCA associated with T-LGL leukemia represents an extreme form of the T-cell–mediated disease that, if polyclonal, might be classified as idiopathic PRCA.

Thymoma-Associated PRCA

Thymoma is associated with PRCA; thus a chest x-ray or CT scan should be included in the workup for PRCA. Antibodies with direct inhibitory effects against erythroid precursors may be present,[8,9,32–34] T cell-mediated inhibition of erythropoiesis has also been implicated in the pathogenesis of PRCA associated with either benign or malignant thymomas.[35–38] Thymectomy is the usual initial treatment approach[34]; however, incomplete responders, nonresponders, and patients who relapse are common,[38] necessitating additional therapies in the form of azathioprine,[39] intravenous immunoglobulins (IVIg),[40] and CsA.[41]

Pregnancy-Associated PRCA

Pregnancy-associated PRCA is a self-limited syndrome that may occur at any age of gestation.[42] It has a high risk for relapse during subsequent pregnancies and can be safely managed with either blood transfusions or corticosteroids.[43,44] Patients with other forms of PRCA may also be more prone to relapse during pregnancy.[45]

Parvovirus B19 and Other Viral-Induced PRCA

Parvovirus B19 is a single-stranded DNA virus, which in normal individuals causes fifth disease (erythema infectiosum) in children and arthropathy in adults.[46–49] The cellular receptor for the virus is the P antigen, a blood group antigen also responsible for the agglutination reaction that occurs in the presence of the virus. Detection of parvovirus B19–specific IgM without anti–parvovirus B19 IgG supports the diagnosis of acute infection whereas the parvovirus–B19 specific IgG suggests immunity.[50] Addition of parvovirus B19 in vitro to cultures of erythroid progenitor cells completely abolishes erythroid colony formation.[47,48] Primary infection causes life-long immunity; however, it is possible that a latent virus may persist in a healthy individual for years.

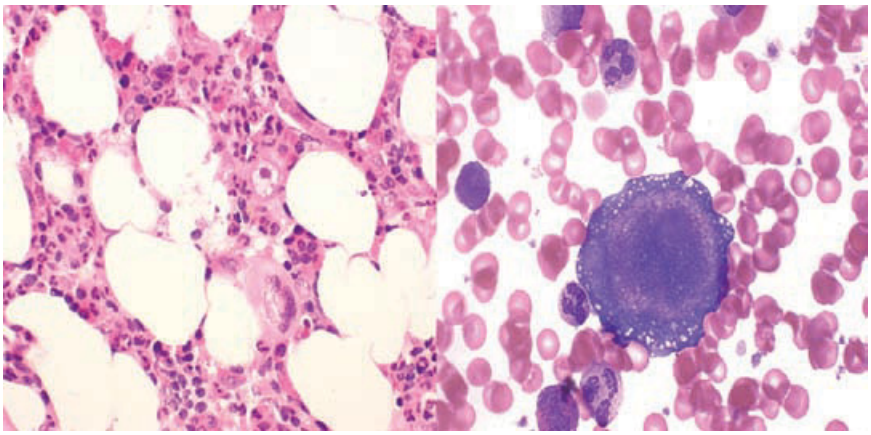

Figure 31–2 Parvovirus B19–mediated pure red cell aplasia.

A transient aplastic crisis is a typical complication of a primary parvovirus B19 infection in patients with increased red cell turnover (usually chronic hemolysis, eg, hemoglobinopathies, and hereditary disorders of red blood cell [RBC] membrane, eg, hereditary spherocytosis).[51–53] In typical cases, the occurrence of acute reticulocytopenia results in a sudden drop in hemoglobin (Hgb)/hematocrit (Hct) levels as RBC destruction continues but is unsupported by a suppressed marrow. Occasionally, characteristic giant pronormoblasts may be seen in marrow aspirates (Fig. 31–2). This disorder is often self-limiting with the evolution of a protective IgG response. Viral titers in the serum of affected patients may be high. Supportive transfusions may be needed during the acute phase of the disease.

A more chronic form, parvovirus B19–related PRCA, may develop in immunocompromised patients as, for example, in AIDS. In such cases, IVIg can produce remarkable responses. High doses of IVIg are required (>2 g/kg) as an insufficient dose may not produce the desired effect. DNA dot blot hybridization is the best diagnostic test for the detection of viremia. Parvovirus B19 can also be detected by polymerase chain reaction (PCR), a routinely available test, but this method may provide a high rate of false positive results. However, if negative, it excludes B19 parvovirus–mediated disease.[50] Improved tests have been developed that allow for the detection of neutralizing antibodies and infectivity of parvovirus B19.[54]

Several other viral infections including viral hepatitis (A[55,56] and C[57,58]), Epstein–Barr virus (EBV),[59] cytomegalovirus (CMV),[60] human T-lymphotrophic virus–1 (HTLV-1),[28] and HIV[61] have been implicated as causative agents of PRCA. Little is known about the exact mechanisms underlying these disorders but they likely involve T cell-mediated suppression as observed during HTLV-1 infection[28] and EBV or antibody-mediated destruction of red cell precursors, as in hepatitis C-induced PRCA.[57,58] Frequently, the presence of multiple comorbidities and medications makes it difficult to pinpoint the exact causative agent.[61,62]

Connective Tissue Disease-Associated PRCA

The majority of connective tissue diseases associated with PRCA are autoimmune in nature. Several rheumatologic diseases have been associated with PRCA including adult-onset Still disease,[63,64] dermatomyositis,[65] mixed connective tissue disease,[66] polymyositis,[67] rheumatoid arthritis,[68,69] Sjögren syndrome,[70–72] and systemic lupus erythematosus.[73–75] The pathogenesis of the PRCA in this setting may vary and includes (a) autoantibody-mediated erythroid inhibition,[76] (b) autoantibody directed against erythropoietin,[77] and (c) CTL-mediated killing of erythroid precursors.[73]

Drug-Induced PRCA

Various chemical agents and drugs have been associated with PRCA. The mechanisms responsible for erythroid inhibition may be diverse depending on the offending agent (Table 31–2) but may include induction of antibodies targeting the drugs or drugs bound to cellular and plasma proteins. Another possible mechanism involves drug-mediated triggering of T-cell responses, or direct toxicity to the erythroid series as seen with diphenylhydantoin.[78]

Table 31–2 Drugs and Chemicals Implicated in Pure Red Cell Aplasia

Alemtuzumab[151]	Erythropoietin[448,449]	Phenytoin[78,482,483]
Allopurinol[453,454]	Estrogens[468]	Procainamide[484–486]
α-Methyldopa[455]	Fludarabine[469]	Ribavirin[487,498]
Aminopyrine[456]	FK506[470]	Rifampicin[489]
Azathioprine[457,458]	Gold[471]	Sulfasalzine[490,491]
Benzene[459]	Halothane[472]	Sulfathiozole[492]
Carbamazepine[460]	Interferon-α[473,474]	Sulindac[493]
Cephalothin[461]	Isoniazid[475–477]	Tacrolimus[494]
Chloramphenicol[462]	Lamivudine[62]	Mycophenolate mofetil[487]
Chlorpropamide[463,464]	Linezolid[478]	Thiamphenicol[495]
Cladribine[465]	Maloprim[479]	Ticlopidine[496,497]
Cotrimoxazole[466]	Penicillin[480]	Valproic acid[194,498]
D-Penicillinamine[467]	Phenylbutazone[481]	Zidovudine[499]

Erythropoietin Antibody-Associated PRCA

Erythropoietin is produced mainly by the kidneys and to a limited extent by the liver. Recombinant erythropoietin is used in the treatment of anemias of various origins, including, for example, anemia of chronic disease, renal disease, and a variety of bone marrow failure syndromes, particularly MDS. Cases of PRCA have developed as a consequence of antibody formation against endogenous erythropoietin[79] or while receiving treatment with recombinant erythropoietin.[80–82] The latter condition has been referred as to epoietin-induced PRCA or epo-PRCA. The first three cases of epo-PRCA were reported between 1988 and 1998,[81,83] with 13 cases subsequently reported in France between 1998 and 2000 mainly related to exposure to epoietin-alpha (Eprex; 92%) and epoietin-beta (NeoRecormon; 8%).[84] The exact pathogenesis remains unclear but may be related to the formation of neutralizing antierythropoietin antibodies. There are several risk factors to the development of epo-PRCA, including subcutaneous route of administration, use of epoietin-alpha stabilized in a human serum albumin (HAS)-free formulation, use of silicone oil as lubricant in prefilled Eprex syringes, and use in patients with chronic renal disease.[85,86] All these factors increase the immunogenic potential of the antierythropoietin antibodies. This observation has lead to the modification in the storage, handling, and administration of Eprex favoring IV administration, especially with Eprex stabilized with HAS-free formulation and avoidance of the subcutaneous (SQ) non-HAS stabilized Eprex for patients with chronic renal disease. Of note is that cases of epo-PRCA occurring after intravenous epoietin

administration have been described.[80,87] Diagnostic criteria have also been proposed incorporating major features (treatment with epoietin for at least 3 weeks, decrease in Hgb by 0.1 g/dL per day without transfusions or transfusion need of about 1 unit/week to keep hemoglobin level stable, reticulocyte count $<10 \times 10^9$/L, no major drop in white blood cell [WBC] and platelet counts), minor features (skin and systemic allergic reactions), and accessory investigations (eg, bone marrow showing normal cellularity and <5% erythroblasts with evidence of maturation block, and serum assay showing presence of antierythropoietin antibodies and evidence of neutralizing capacity).[80] All major criteria are required for diagnosis while minor features must be confirmed by additional confirmatory tests, usually in the form of bone marrow biopsy and neutralizing antierythropoietin antibody detection. The most commonly used tests to detect antibodies are enzyme-linked immunosorbent assay (ELISA), radioimmunoprecipitation assay (RIPA), and surface plasmon resonance. Once antibodies are detected, their neutralizing ability is tested using in vitro bioassay. Following establishment of diagnosis, management should include discontinuation of exogenous erythropoietin, administration of immunosuppressive agents, or, in cases of anemia secondary to renal insufficiency, renal transplantation. It is possible to use and regain response to recombinant erythropoietin once antierythropoietin antibodies have disappeared.[88]

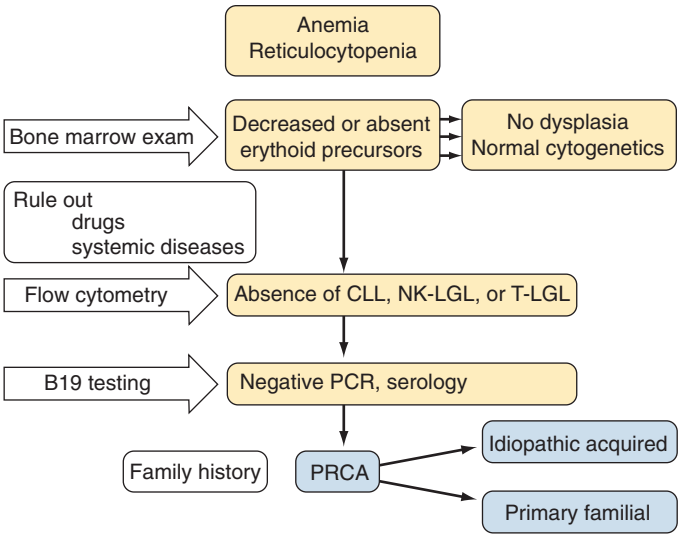

Figure 31–3 Diagnostic algorithm in pure red cell aplasia.

PRCA Post Allogeneic Stem Cell Transplantation

In contrast to HLA matching, ABO-blood group incompatibility plays a minor role in the success of allogeneic hematopoietic stem cell transplantation. However, PRCA may be associated with major ABO incompatibility between the donor and recipient, leading to inhibition of donor erythroid precursors by residual host isoagglutinins. This complication is more commonly observed following the use of nonmyeloablative conditioning regimens. PRCA may also be resistant to the withdrawal or decrease of immunosuppression, or donor-lymphocyte infusions. Responses to rituximab,[89,90] erythropoietin,[91] and azathioprine[91] have been reported. A case responsive to purified $CD34^+$ cell infusion has also been reported.[92] Resolution of PRCA is generally associated with decrease and subsequent disappearance of host isoagglutinins.[93–98]

PRCA Post Radiation Therapy

In rare circumstances, PRCA may be associated with prior radiation therapy. The cases described usually involve radiation therapy being administered to a patient with an underlying thymoma not previously associated with PRCA.[99,100]

CLINICAL MANIFESTATIONS OF PRCA

Anemia is the leading symptom of PRCA and can be severe at diagnosis as the fall in hemoglobin occurs over a protracted period of time and patients often exhibit a good degree of adaptation. Arrest of erythropoiesis is obvious with a profound reticulocytopenia. In children, TEC is usually diagnosed during evaluation of a febrile illness. In primary, idiopathic PRCA, physical signs other than those of anemia are usually absent. In secondary PRCA, the physical findings are consistent with the underlying primary disease.

LABORATORY EVALUATION

A complete blood count with differential, peripheral smear review, reticulocyte count, and a bone marrow examination remain the cornerstone in the diagnosis of PRCA. The classic hematologic picture of PRCA includes a complete blood count showing a normocytic, normochromic anemia (anemia associated with T-LGL leukemia is often macrocytic) with normal WBC and platelet count. The reticulocyte count is significantly reduced to less than 1% (a reticulocyte level >2% is not compatible with the diagnosis of PRCA) (Fig. 31–3). The bone marrow examination generally shows absence of the erythroid lineage and normal appearance of granulocytic and monocytic precursors and megakaryocytes. Erythroid precursors, if present, are usually less than 1%, and only a few residual proerythroblasts or basophilic erythroblasts may be seen. Blast cell numbers and cellularity are within normal limits. There are no dysplastic changes, ringed sideroblasts, or reticulin fibrosis. Cytogenetics is normal. In some cases, neutropenia,[101] mild thrombocytopenia, eosinophilia,[16] thrombocytosis,[16] leukocytosis, or relative lymphocytosis may be seen. Cytogenetic abnormalities, if present, may indicate concomitant myelodysplasia and is a poor prognostic marker for both response to treatment and propensity to leukemic transformation.[102,103] In the natural history of PRCA, ineffective erythropoiesis characterized by maturation arrest at the proerythroblasts or basophilic erythroblast stage may be observed and signifies either partial response to treatment or initial recovery from treatment or a prelude to the development of full-blown PRCA.[104]

It is important to exclude vitamin B_{12} and folate deficiencies, and depending on the etiology and associated disease, other blood and bone marrow findings may be seen. The presence of giant and vacuolated pronormoblasts in the bone marrow examination should raise the suspicion for parvovirus B19 infection.[50] The presence of large granular lymphocytosis, neutropenia and/or thrombocytopenia, expansion of $CD3^+CD8^+CD57^+$ T cells, clonal cytotoxic T-cell receptor (TcR) gene rearrangement, expansion of specific TcR Vβ region family gene segment, and splenomegaly may point toward concomitant T-LGL leukemia,[105,106] B cell lymphocytosis, especially of the $CD5^+/CD19^+/CD20^+/CD23^+/cyclinD^-/SmIg^{-dim}$ phenotype with concomitant lymphadenopathy, hepatosplenomegaly, hypogammaglobulinemia, and thrombocytopenia, may be very suggestive of a B-cell CLL. Other laboratory findings that may help point to a secondary cause of PRCA includes the presence of monoclonal gammopathy.[16] Parvovirus B19 DNA titers (DNA hybridization and amplification techniques) may show high levels of the virus at 10^{12} genome copies per milliliter but it is important to note that serologic (IgM and IgG) titers are usually absent.[50] Erythropoietin antibodies,[84] antinuclear antibodies,[107,108] and/or complement consumption may point toward a specific disease mechanism.[109] A radiographic workup may also be useful in the clinical workup as chest x-ray or CT scan may show evidence of a thymoma.

Table 31–3 Therapy of Pure Red Cell Aplasia and Its Results

DIFFERENTIAL DIAGNOSIS

PRCA can be easily differentiated from aplastic anemia and other types of bone marrow failure syndromes. A distinction between MDS with erythroid hypoplasia and idiopathic PRCA may be more difficult. In childhood, TEC has to be distinguished from DBA but a history of normal blood counts, late onset of manifestation, and transient disease course are characteristic of TEC.

THERAPY

The distinction between primary and secondary forms of PRCA is essential as many secondary types have specific and very effective therapies (Table 31–3). All potentially offending drugs should be discontinued and drug-associated PRCA should remit within 3 to 4 weeks. Nutritional deficiencies (B_{12} and folic acid) should be excluded and treated if present. The therapy of primary and secondary forms of PRCA refractory to the treatment of an underlying disease may be challenging and should include a sequential trial of various immunosuppressive agents until a response is achieved. Spontaneous remissions have been reported.

Surgery or Radiation

In cases associated with thymoma, thymectomy is the usual initial treatment of choice prior to immunosuppression and may induce remission with return of erythropoiesis 4 to 8 weeks in about 30% to 40% of patients.[110–112] Patients who remain refractory following surgery should be treated as patients with idiopathic PRCA. The removal of a thymoma may improve responsiveness to immunosuppressive therapy.[111] Thymectomy in the absence of a thymoma in other forms of PRCA is not recommended. In circumstances where surgical resection of thymoma is contraindicated, radiation therapy with or without chemotherapy may be administered.[113]

Medical

Supportive

Supportive care includes blood transfusions and iron chelation with deferasirox (Exjade). Deferasirox is a new once-daily, oral iron chelator developed for treating transfusional iron overload syndromes used in a variety of hematologic disorders, including thalassemia and sickle cell anemia, and works primarily by promoting fecal excretion of iron. Side effects may include diarrhea, renal failure, and, rarely, agranulocytosis.[114,115]

Immunosuppression

Prednisone therapy at a dose of 1 mg/kg is associated with significant response rates (approximately 40%) and should constitute the initial therapeutic approach.[103] Initial responses are generally observed after 4 to 6 weeks.[102,116] A slow taper of prednisone is suggested over a period of 3 to 4 months. The disease may relapse and the minimal maintenance dose of corticosteroids may need to be established to maintain the desired hemoglobin levels.[117] Trials of prednisone therapy without clinical response longer than 8 weeks are not warranted.[102,103,116]

Alternative therapies may include cyclosporine, oral cyclophosphamide, azathioprine, antithymocyte globulin (ATG), rituximab, and alemtuzumab (Table 31–3). Erythropoietin and darbepoietin[118,119] are usually not effective as a sole agent but may hasten recovery following an adequate trial of cyclophosphamide. No randomized trials exist to favor a particular treatment based on efficacy. The choice of therapy may be influenced by clinical clues. For example, the presence of large granular lymphocytes may suggest the use of CsA, hypogammaglobulinemia may be corrected with IVIg, whereas detection of hypergammaglobulinemia or monoclonal protein may suggest a choice of rituximab. Most refractory cases may require administration of ATG. The age of the patient may influence a choice of the cytotoxic agent, which may pose a significant risk for the development of secondary leukemias, especially with a prolonged administration.

Danazol is a synthetic attenuated androgen that has been used for many years for the treatment of a variety of hematologic disorders mainly myelofibrosis.[120] Usually given at 200 mg PO BID, the maximum dose per day is 600 mg. It has been used to treat PRCA either as a single agent or in conjunction with steroids or other agents and have shown efficacy in PRCA of various etiologies.[121–124] The main adverse events reported include liver transaminitis and vascular liver tumors.

IVIg (Gammagard, Octagam, Panglobulin) given at 1 to 2 g/kg IV for 5 days is also effective in several types of PRCA.[125–128] Higher doses of usually 2 g/kg of IVIg for 5 days are necessary for the treatment of parvovirus B19 virus-induced PRCA. In AIDS patients with parvovirus B19 virus-induced PRCA, a regimen consists of induction therapy with 1 g/kg daily for 1 to 2 days followed by 1 g/kg for 2 days. If the patient relapses, then maintenance therapy with IVIg 0.4 to 1.0 g/kg q 4 weeks is recommended.[129]

Azathioprine is an imidazolyl derivative of mercaptopurine that inhibits DNA synthesis by inhibition of purine metabolism. In PRCA, it may be given at a dose of 2 to 3 mg/kg/day IV and has been found to be effective in patients nonresponsive to cyclophosphamide.[39,130]

Oral cyclophosphamide may be started at a dose of 50 mg PO daily, with a maximal dose of no more than 150 mg daily. Blood

counts should be monitored and the dose may be escalated accordingly. Trials of therapy longer than 3 months without signs of response are not warranted. Monitoring of the reticulocyte count may allow for the early assessment of response. Often, a delayed response may be seen when cyclophosphamide is withdrawn, which reflects the fine balance between adequate immunosuppression and cytotoxicity.[3,4,103,116,131,132]

Rituximab given at 375 mg/m^2 intravenous infusion weekly for 4 weeks has been found to be efficacious in PRCA. PRCA in a variety of settings, including B-cell CLL, EBV-associated posttransplant lymphoproliferative disorder (EBV-PTLD), ABO-incompatible allogeneic hematopoietic stem cell transplantation for acute myeloid leukemia, and hairy cell leukemia variant, has been successfully treated.[89,133–136] Owing to the fact that it is specific for B cells alone, cases of nonresponders to rituximab have been reported and attributed to an alternative T-cell–mediated pathogenesis.[137] In cases refractory to immunosuppressive agents affecting T-cell function, rituximab or low-dose alemtuzumab constitutes reasonable options. Rituximab is effective in patients with PRCA owing to ABO incompatibility following bone marrow transplantation.[89,90]

CsA can be administered at a dose of 5 to 10 mg/kg orally (PO) daily in divided doses. CsA can be combined with prednisone at doses of 20 to 30 mg PO. The trough levels of CsA should be monitored and the dose adjusted to achieve a level between 200 and 300 μg/mL. An adequate trial of therapy is considered 3 months of therapy. The response rates may be as high as 60% to 80%. After a response is achieved, the therapy should be continued for 6 months followed by a slow taper.[102,103,138–144]

Horse ATG may be given to refractory cases at a dose of 40 mg/kg IV daily × 4 days with prednisone at 1 mg/kg. Rabbit ATG (thymoglobulin) may be given a dose of 2.5 to 3.5 mg/kg daily IV for 4 or 5 days with prednisone at 1 mg/kg. Concomitant prednisone should be administered and then tapered over 2 to 3 weeks. A therapeutic response should occur within 3 months post therapy, although responses at or beyond 6 months may be observed.[8,102,103,116,145–147]

Daclizumab, an anti–interleukin 2 receptor antibody (Zenapax, anti-CD25 mAb), may constitute a good alternative to ATG as it does not require hospitalization and is well tolerated. In a recent trial, a dose of 1 mg/kg IV was administered every 2 weeks. The therapy should be given for at least 3 months. It is possible that combination with CsA may increase the response rate but no data exist as to the observed response rates.[148,149]

Methotrexate, an antimetabolite, at low doses (7.5–15 mg/week PO) is useful in treating PRCA, especially in patients with concomitant LGL leukemia. The responses are generally sustained and therapy is well tolerated. Methotrexate may be given in conjunction with other therapies like CsA.[12,102]

Alemtuzumab (Campath, anti-CD52 mAb) is a recombinant DNA-derived humanized monoclonal antibody directed against the cell surface glycoprotein CD52, which is expressed on the surface of normal and malignant B- and T-lymphocytes. It can be given IV or SQ every other day with an initial dose of 3 mg, and subsequent doses can be increased until response is obtained. The usual cumulative dose before response is usually between 200 and 400 mg. Alemtuzumab has been tested in a variety of lymphoproliferative disorders including diffuse large B-cell lymphoma, B-cell CLL, and T-cell LGL leukemia. Similarly, PRCA occurring in the context of these conditions previously unresponsive to therapy with steroids, CsA, and even cytoxan has been shown to be responsive to this agent. Alemtuzumab can be given either intravenously or subcutaneously.[150–152]

Hematopoietic Stem Cell Transplantation

Despite advances in immunosuppressive regimens, subsets of patients with PRCA remain refractory and are very difficult to treat. As with other bone marrow failure disorders with autoimmune pathogenesis like aplastic anemia, hematopoietic stem cell transplantation (HSCT) is an important treatment option especially for refractory and relapsed PRCA cases. Matched sibling donor allogeneic HSCT results in restoration of normal hematopoiesis in patients with refractory PRCA.[153–155] In another case, a patient with relapsed PRCA underwent matched sibling donor allogeneic HSCT combined with donor lymphocyte infusions resulting in full donor engraftment and subsequent return of normal hematopoiesis, suggesting a graft-versus-autoimmunity effect as the likely mechanism for response.[156]

PROGNOSIS

The prognosis of secondary PRCA depends upon the underlying disease. Idiopathic PRCA may be very refractory to treatment. Ultimately, remission may be achieved in a significant proportion (approximately 68%) of patients, especially when sequential regimens are used. Spontaneous remissions are observed in 5% to 10% of cases. Relapses are common especially during the first year postremission but are usually responsive to the same regimen that induced remission.[102,116] Chronic, low-dose immunosuppressive therapy may be needed in certain cases that have relapsed. In one study, median survival was reported to be 14 years.[116] Unlike a megakaryocytic thrombocytopenic purpura, evolution to aplastic anemia is rare[111,157] in PRCA and, moreover, very few patients (3%–5%) evolve into acute leukemia.[102,116]

DISORDERS OF NEUTROPHIL PRODUCTION

Neutropenia is a common condition. The majority of cases are secondary to a variety of etiologies, including systemic or hematologic diseases. In this chapter we will describe a primary, isolated form of neutropenia in which other hematopoietic lineages are not affected. In such a setting, neutropenia may be the result of peripheral destruction or perhaps less frequently, the result of the absence of myeloid progenitors in the marrow. Neutropenia may be initially noted during workup for fever and infections or may be an incidental finding on a routine CBC. The cut-off value for the diagnosis of neutropenia is an absolute neutrophil count (ANC) of less than 1500 cells/μL. This value is generally accepted as a definition for neutropenia for all ages and ethnic backgrounds except for newborn infants.[158] Clinically, the most concerning consequence of neutropenia is the propensity to develop infections. ANC is the best parameter to assess the severity of neutropenia; however, the correlation between ANC and the propensity for infection is variable in different circumstances and determined by marrow neutrophil reserves, duration of neutropenia, and clinical context.[159–162] This is best illustrated in patients with chronic benign neutropenia of childhood and infancy, where patients may have ANC as low as less than 250 cells/μL and yet they may be devoid of infections or only have mild infections.[163–165] Instead of ANC, it is the bone marrow neutrophil pool reserve that serves as the most suitable determinant of risk for infection, best evaluated through a bone marrow biopsy. In the setting of neutropenia, should the bone marrow examination reveal depleted neutrophil reserves, the ANC level correlates with the risk of infection. In contrast, if bone marrow shows adequate neutrophil reserves, then ANC levels are not predictive of the risk of developing a serious infection.

CLASSIFICATION OF ACQUIRED NEUTROPENIAS

Neutropenia as a primary disease should be distinguished from inherited forms of neutropenia, which commonly present during early childhood (see Chapter 28), and secondary forms of neutropenia associated with systemic disorders. In addition, idiopathic neutropenia is distinct from the constitutional or familial benign neutropenia frequently seen in African Americans,[166,167] Yemenites, and Falashah Jews or black Bedouins.[168] The degree of neutropenia is often mild and there is no propensity to develop infections. This condition is described in Chapter 50. Most cases of neutropenia are secondary to

Table 31–4 Classification of Neutropenia

Congenital	
Primary	Autoimmune neutropenia
	Pure white cell aplasia
	Idiopathic
	Thymoma
	Hematologic malignancies, eg, T-LGL leukemia
	Infections/postinfectious
	Viral
	Measles,[215] mumps, roseola,[216,217] rubella,[501] RSV, influenza[214]
	Hepatitis A,[209] B,[209,210] and C[58]
	CMV,[218,219,502] EBV,[211–213] HIV[224,225]
	Parvovirus[221–223]
	Bacterial
	Tuberculosis[235,236]
	Brucellosis[232–234]
	Tularemia[231]
	Typhoid fever [230]
	Rickettsial
	Rocky Mountain spotted fever[503]
	Ehrlichiosis.[242,243]
	Fungal
	Histoplasmosis[237,238]
	Parasitic
	Malaria,[239] leishmaniasis[240,424]
	Autoimmune conditions, eg, SLE[504,505], RA[506]
	Drugs and chemicals
	Neutropenia associated with immunodeficiency[314,320]
	Severe nutritional deficiencies[247,248]
	Neutropenia due to increased margination
	Iatrogenic, eg, hemodialysis[321,322]

CMV, cytomegalovirus; EBV, Epstein–Barr virus; RA, refractory anemia; RSV, respiratory syncytial virus; SLE, systemic lupus erythematomus; T-LGL, T-cell large granular lymphocyte.

a variety of disorders. Primary autoimmune neutropenia (AIN) and idiopathic neutropenia are less common. We will limit our description to isolated forms of neutropenia (Table 31–4).

Primary Neutropenia

Most neutropenias are secondary to various hematologic conditions and systemic diseases. However, in a small proportion of cases, an inciting cause cannot be identified despite intensive testing. Such idiopathic cases are most likely autoimmune in nature.

Chronic Idiopathic Neutropenia in Adults

Chronic idiopathic neutropenia in adults compared to those in infancy and early childhood has lesser tendency toward spontaneous remission although it does generally remain clinically benign. There may be concomitant anemia or thrombocytopenia that may portend a higher incidence of splenomegaly, infectious complications, and antineutrophil antibodies (ANAs) that are complement fixing.[169] The bone marrow biopsy may show evidence of arrest in myeloid maturation and mild hypercellularity. ANAs may be seen in 36% of patients, suggesting an immunologic pathogenesis.[169]

Idiopathic neutropenias may be chronic and benign in nature or may be associated with significant morbidity. In certain instances immune neutropenia may be associated with hemolytic anemia or with immune thrombocytopenia, but these forms likely represent a distinct nosologic entity. Idiopathic neutropenia can occur at any age, including early childhood. Such cases may be difficult to distinguish

from hereditary neutropenia syndromes. AIN may be associated with moderate and severe depression of neutrophil counts. Monocytosis is frequently present.[160,161] Some cases present with splenomegaly, which is to be distinguished from cytopenias associated with hypersplenism in Felty syndrome.[170] The frequency of infectious complications does not correlate with the severity of neutropenia, and patients with severe depletion of neutrophils may remain asymptomatic for long periods of time.

Conceptually, AIN may be due to peripheral autoimmune destruction of neutrophils due to lineage-specific inhibition of myeloid precursors, with its extreme form being pure white cell aplasia (Fig. 31–3). Consequently, increased peripheral destruction is associated with marrow hypercellularity and an increased number of myeloid precursors or, if myeloid progenitors are the targets, decreased myeloid precursors and a myeloid maturation arrest. Autoimmune ANAs have been implicated in the pathogenesis of AIN and could be mediated by both peripheral destruction of neutrophils and inhibition of myelopoiesis.[171,172] The antigens involved in these processes include neutrophil antigens NA1, NA2, ND1, ND2, and NB1 (Table 31–5). Both IgG and IGM antibodies have been implicated. Neutrophil-specific antibodies can be detected using many assays, including specific ELISA, opsonization,[173,174] leukoagglutination,[175] and direct antibody binding.[176] There are several proposed effector mechanisms as to how ANA can result in neutropenia or affect neutrophil integrity. For example, ANA may act as opsonins and directly enhance neutrophil destruction.[174] Alternatively, ANA can indirectly activate, complement, and facilitate opsonization.[177] Immune complexes may also bind to the neutrophil Fc portion, leading to increased neutrophil clearance by the reticuloendothelial system,[178] and finally, ANA may recognize and damage myeloid precursors.[179] The currently available diagnostic assays used to detect ANA are generally based on immunofluorescence and agglutination assays. The former allows for the detection of IgM and IgG antibodies from a suspected patient that are attached to normal donor neutrophils detected by flow cytometry performed with patient's serum and antihuman IgG. The results may be reported as strongly positive, weakly positive, or absent. The second technique, called agglutination assay, utilizes serum that leads to agglutination of normal neutrophils into either small or large clumps. These tests may help suggest an underlying immunologic process but cannot establish the definite. If there is a high index of suspicion that ANA is the causative factor, some authors suggest that a minimum of two methods be used to detect ANA, namely granulocyte agglutination test (GAT) and granulocyte immunofluorescence test (GIFT).[180]

In addition to antibodies, T-cell responses may be associated with neutropenia. The most extreme example of such responses is T-cell LGL leukemia associated with neutropenia and polarized proliferation of CTL (see later). In AIN, CTL responses are polyclonal and are often accompanied by the simultaneous presence of antibodies. It is likely that specialized CTL clones are capable of recognizing and killing myeloid precursors, interrupting granulocyte production. Consequently, some of the cases of AIN may be amenable to therapy with immunosuppressive agents directed against T cells.

Chronic Benign Neutropenia of Infancy and Childhood

Chronic benign neutropenia of infancy and childhood is considered the most common cause of chronic neutropenia in the pediatric age group. The majority of cases are autoimmune in nature and show clinical overlap with childhood idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia. It is therefore considered a type of AIN.[181–186] An incidence of 1:100,000 has been reported in a childhood population in Scotland.[185] This form of neutropenia typically presents in children less than 3 years of age, with a median age of 8 to 11 months and with a predominance of females.[181,183,184] The CBC usually shows an ANC of less than 250 cells/μL with normal morphology and normal hemoglobin and platelet count. Occasionally monocytosis, eosinophilia, and mild thrombocytopenia may be present. In this condition, neutropenia is due to chronic depletion of mature granulocytes and is accompanied by a compensatory myeloid left shift in the marrow.[163–165] Most frequent clinical signs and symptoms are oral infections, including bothersome ulcers, but these are often associated with additional functional defects of neutrophils, and cellulitis of the labia majora. Of importance is the normal neutrophil count at birth and absence of a history of familial forms of neutropenia. The etiology of this condition is unknown but the pathogenesis involves ANAs, detectable in the majority of patients.[183,164,181] The antibodies are generally directed against similar antigens seen in adult AIN, especially those involving NA, NB, and ND loci. In about 25% of cases, the antibody is against an allele of neutrophil FcγRIII opsonin receptor called NA1.[181,183,184] Immunosuppressive therapy leads frequently to responses supporting the immune pathogenesis of this disease. Although the neutrophil count can be severely depressed, serious infectious complications are uncommon and therefore treatment to raise the ANC is generally not indicated except if recurrent infections occur. Antibiotics are useful to treat infections and G-CSF has been shown to be effective in elevating neutrophil counts.[187]

SECONDARY FORMS OF NEUTROPENIAS

Clinical Associations

Drug-Induced Neutropenia/Agranulocytosis

Drug-induced neutropenia is common.[188] The association was first described by Kracke in 1931 when agranulocytosis was observed in patients taking aminopyrine. The incidence in various studies is 1.0 to 3.4 cases/million per year.[188–193] Drugs may induce granulocytopenia by (a) direct toxicity leading to inhibition of myelopoiesis frequently observed in drugs like valproic acid,[194] carbamazepine,[195] and β-lactam antibiotics[196,197]; (b) immune-mediated (either antibody/complement-mediated) as seen with penicillin and antithyroid drugs[198–200] or immune complex mediated (quinidine)[201] destruction of myeloid progenitors and mature neutrophils; and (c) induction of CTL responses.[202] Genetic predisposition due to polymorphisms in various genes coding for cytokine and cytokine receptors as demonstrated for clozapine with tumor necrosis factor (TNF) and HLA polymorphisms as well as possibly variants of genes coding for a variety of metabolizing enzymes also plays a role.[203,204] Of interest are drugs that directly antagonize important vitamin cofactors necessary in normal bone marrow development. Neutropenia observed in patients treated with trimethoprim-sulfamethoxazole is due to the inhibitory effects on granulopoiesis by trimethoprim, owing to its antifolate action, which is reversed by folinic acid.[205] A similar finding can be seen with methotrexate owing to its antifolate action.

Most patients present with either asymptomatic neutropenia discovered on routine examination or symptomatic neutropenia with infectious complications including fever, angular stomatitis, or pneumonia. The reported mortality rates vary from 1% to 25%. Most patients recover without further complications. It has been estimated that drugs account for 72% of cases of agranulocytosis. The usual time to development of overt neutropenia is around 1 to 2 weeks and it resolves upon discontinuation of the offending drug within 10 to 14 days,[206] although time to recovery may vary depending on whether bone marrow hypoplasia is present (10 days) or not (14 days).[207] The recovery in neutrophil counts is usually preceded by increases in peripheral blood monocytes and immature granulocytes.[208] The International Aplastic Anemia and Agranulocytosis Study (IAAAS) has identified the most commonly associated agents and the relative odds ratios for developing agranulocytosis (Table 31–6).[193] In some instances, the severity of neutropenia is related to the dose and duration of the therapy. The therapy includes discontinuation of the potentially offending agents. In some instances associated with infections or prolonged recovery, G-CSF may be administered.

Table 31–6 Drugs Associated With Agranulocytosis

	Etiologic Fraction	
	Agranulocytosis	Aplastic Anemia
Overall	64%	62%
IAAAS	12%	27%
US	72%	17%
Thailand	70%	2%

Drugs associated with agranulocytosis (IAAAS and other drugs of interest)

Acetyldigoxin[507]
ACE inhibitors[508,509]
Allopurinol[510–512]
Amodiaquine[513]
Benzafibrate[514]
β-Lactam antibiotics[189]
β-Blockers[507,515]
Carbamazepine[516]
Cinepazide[415,517]
Corticosteroids[518]
Cotrimoxazole[205] Other sulfonamides
Dipyridamole[507]
Deferasirox (Exjade)[519]
Dypirone[408,193]
Histamine-2 receptor antagonist[520]
Indomethacin[188]
Isoniazid[521,522]
Macrolides[523,524]
Mefloquine[525]
Nifedipine[526]
Phenytoin[527,528]
Procainamide[529,530]
Salicylates[531]
Sulfasalazine[532,533]
Sulfonylureas[179,534]
Tetracyclines[193]
Thenalidine[418,419]
Thyrostatics[535–537]
Troxerutine[193]

Neutropenia as a Manifestation of Systemic Diseases

Postinfectious Neutropenia

Neutropenia is commonly associated with viral infections, particularly in children. Various mechanisms have been implicated in neutropenia associated with systemic viral infections, including inhibition of hematopoiesis, granulocyte sequestration, margination, and peripheral destruction. Neutropenia generally improves when the viremia resolves. Neutropenia has been associated with hepatitis A,[209] B,[209,210] and Cvirus,[58,209] EBV,[211–213] influenza,[214] measles,[215] roseola,[216,217] CMV,[218–220] and parvovirus B19 infections.[221–223] Neutropenia is also frequently encountered in patients with AIDS, with approximately 70% of patients being neutropenic during their illness.[224,225] The mechanisms vary and may include antibody formation against neutrophils,[226–228] direct viral inhibition of hematopoietic progenitor cells, abnormal expression of growth factors and other cytokines, and inhibitory effects exerted by HIV-infected accessory cells.[229] The HIV virus not only suppresses hematopoiesis but also increases the risk of acquiring other infections. Furthermore, therapy with antiretroviral agents may dramatically decrease neutrophil counts (Table 31–4).

Systemic bacterial, fungal, and parasitic infections can be accompanied by neutropenia, including typhoid fever,[230] tularemia,[231] bru-

cellosis,[232–234] mycobacterial infections,[235,236] histoplasmosis,[237,238] malaria,[239] leishmaniasis,[240,241] and ehrlichiosis.[242,243] The pathogenesis include margination and sequestration of leukocytes as observed in malaria, where there is reduction in the circulating polymorphonuclear neutrophil (PMN) pool and enlargement of the marginating PMN pool, primarily in the spleen and lung. Neutropenia can be present during sepsis, especially in newborns or debilitated individuals.[244,245] In such situations, neutropenia may be due to inhibition of hematopoiesis by inflammatory cytokines, exhaustion of marrow reserves, or redistribution.[246]

Neutropenia in Nutritional Deficiency and Nutritional Excess

Malnutrition, dietary restrictions, malabsorptive states, and concomitant intake of inhibitory drugs are just a few common causes of nutritional deficiencies that may lead to neutropenia. Vitamin B_{12} and folate deficiency frequently associated with megaloblastic anemia can also manifest with neutropenia. Lack of these essential vitamin cofactors results in the impairment of normal DNA synthesis, leading to abnormal granulopoiesis. A frequently observed morphologic feature is the presence of hypersegmented neutrophils.

Copper deficiency may also be associated with neutropenia.[247,248] Possible mechanisms may include arrest in maturation of neutrophil development as shown in studies in mice,[249] and increased antineutrophil antibody formation.[250,251] Most cases have been found in malnourished infants, in patients with zinc intoxication[252,253] and malabsorption states,[254,255] and in persons receiving total parenteral nutrition without adequate copper supplementation.[256,257] Copper deficiency is often accompanied by a normocytic anemia while platelet counts are invariably normal.[258] Other clinical and laboratory manifestations associated with copper deficiency include presence of ringed sideroblasts in the bone marrow,[259,260] macrocytic anemia,[261] low ceruloplasmin levels,[259] myeloneuropathy,[262] and skeletal abnormalities.[263]

Zinc intoxication in the absence of concomitant copper deficiency has also been associated with neutropenia generally in conjunction with severe anemia. A dysregulation in calprotectin metabolism has been suggested as a mechanism. Calprotectin, also known as the S100A8/A9 or MRP8/14 complex, is a major calcium-binding protein present in the cytosol of neutrophils, monocytes, and keratinocytes that increases during inflammatory states.[264]

Neutropenia Associated With Metabolic Disorders

Various acquired or inherited metabolic conditions may be associated with neutropenia. For example, neutropenia has been observed in patients with ketoacidosis and hyperglycemia, orotic, or methylmalonic aciduria.[265–268] Similarly, glycogen storage disease type Ib is commonly associated with neutropenia responsive to myeloid growth factors.[269–272]

Acquired Neonatal Neutropenias

Neutropenia has been described in infants of hypertensive mothers. In this syndrome, the ANC can be severely depressed for 1 to 30 days postpartum.[273–275] This type of neutropenia is associated with an increased risk of early-onset sepsis in neonates,[276] a prolonged duration of neutropenia, and an increased risk of neonatal nosocomial infections.[277] Granulocyte kinetic investigations suggested that the neutropenia is the result of diminished neutrophil production. An inhibitor released by the placenta and present in cord blood serum has been shown to play a role in this syndrome.[273,278]

Moderate to severe neutropenia has been also observed secondary to IgG antibodies transferred from mother to infant. This is a condition called isoimmune neonatal neutropenia or neonatal alloimmune neutropenia. In most cases, antibodies are directed against antigens on neutrophil FcγRIIIb (anti-NA1, anti-NA2, and anti-SH)[279] and NB1,[280,281] but in rare circumstances, maternal neutrophil-specific isoantibodies are also produced when there is deficiency of the FcγRIIIb gene.[282–286] The incidence of this condition can be as high as 2:1000 live births.[287] In both neutropenia occurring in hypertensive mothers and isoimmune neonatal neutropenia, differentiation from congenital forms of neutropenia may be difficult. Treatment with G-CSF is usually effective in neutropenia of infants of hypertensive mothers but higher doses may be needed as preeclampsia-associated inhibitor of rhG-CSF may be present.[275,288,289] IVIg[290] and G-CSF[279,291] are both effective for treatment of isoimmune neonatal neutropenia.

Neutropenia and Hypersplenism

Hypersplenism may be associated with neutropenia, but in most instances other cytopenias will also be present. However, hypersplenism may be a sign of diseases that can result in neutropenia, such as in T-LGL leukemia[105,106,292] and Felty syndrome.[293,294] Other than direct sequestration, another potential mechanism leading to neutropenia may be increased neutrophil apoptosis that normalizes after splenectomy.[295] Recently a high incidence of *Helicobacter pylori* infection has been noted among individuals with neutropenia and splenomegaly. A potential role for the bacterium in the pathogenesis of the splenomegaly is being explored. Conversely one can hypothesize that the bacterium may be the culprit in the development of the neutropenia.[296] Splenectomy either laparoscopically[297] or through laparotomy[298] may be effective in most cases. Although in situations precluding splenectomy, intraoperative splenic artery embolization is also effective.[299,300]

Pure White Cell Aplasia

Pure white cell aplasia (PWCA) is a rare condition with pathophysiologic overlap with some forms of AIN associated with myeloid suppression. Similar to PRCA, the pathogenesis may vary and includes antibody-mediated suppression of granulopoiesis,[198,301] T-cell–mediated suppression of granulopoiesis, direct myelotoxicity as seen with certain drugs,[302] opsonization of neutrophil precursors in the bone marrow leading to its destruction by macrophages within the bone marrow,[302] and formation of antibody–drug complex that may damage myeloid progenitors.[303] A bone marrow examination reveals either a total absence of myeloid precursors or arrest at the promyelocyte stage, with megakaryocytes and the erythroid series remaining quantitatively and qualitatively normal. In many cases, a thymoma is present.[304,305] PWCA, if associated with thymoma, has a variable clinical outcome. The complete absence of granulocytic precursors portends a poor response to both immunosuppression and thymectomy and is often fatal, whereas the presence of a maturation arrest at the promyelocyte stage may respond to immunosuppressive therapy.[301,305–308] PWCA has been described in connection with imipenem-cilastatin,[309] ibuprofen,[310] and chlorpropramide.[179] The discontinuation of the offending drug leads to rapid improvement. Recently, PWCA has also been associated with primary biliary cirrhosis.[311]

Therapeutic options may include azathioprine,[301] G-CSF combined with plasmapheresis especially if the disease process is antibody mediated,[312] methylprednisolone,[309] IV cyclophosphamide combined with plasmapheresis and G-CSF,[313] and thymectomy.[304] Severe depression of counts may require ATG therapy (see later).

Neutropenia Associated With Immunologic Abnormalities

Acquired and inherited defects of the cellular and humoral immune system may be accompanied by secondary neutropenias. In the

inherited immunodeficiency syndromes, the initial presentation is in children and may be associated with failure to thrive. X-linked agammaglobulinemia (XLA) is a primary immunodeficiency disorder caused by mutations in the gene for Bruton tyrosine kinase (BTK) expressed in both myeloid and B cells that result in the absence of development of B lymphocytes and hypogammaglobulinemia. Neutropenia is seen in 15% to 26% of patients with X-linked agammaglobulinemia and most suffer from upper respiratory tract infection.[314–316] The exact pathogenetic mechanism is not clear but is believed to be related to the crucial role of BTK in myeloid survival under stress.

Neutropenia is seen in 40% to 50% of patients with X-linked hyper-IgM syndrome,[317] and has been associated with defects of myelopoiesis. The most common form of hyper IgM syndrome is due to mutations in the CD40 gene. This defect also leads to a decrease in IgG and IgA. In addition to chronic anemia, children suffer from various infectious complications. They typically lack ANAs and show an arrest at the promyelocyte–myelocyte stage of neutrophil development.[318] Allogeneic HSCT has been curative in some instances.[319]

Common variable immunodeficiency is also frequently associated with neutropenias that can be either chronic or episodic.[320] In addition, hyper- and hypogammaglobulinemia and T- and NK-cell abnormalities of various etiologies (both inherited or acquired) can also be associated with neutropenia.

Other Iatrogenic Forms of Neutropenia

Hemodialysis, which is critical in the care of end-stage renal disease patients, can result in neutropenia.[321,322] One important mechanism postulated is through activation of the plasma complement pathway by dialyzer cellophane membranes and generation of C5a (desarg) that causes reversible neutrophil aggregation, resulting in transient neutropenia.[321,323] Similar mechanisms to explain neutropenia have been noted in other clinical settings, including leukapheresis[324] and cardiopulmonary bypass surgery.[325]

LABORATORY EVALUATION

Laboratory studies aim at the identification of the primary causes of neutropenia, as outlined in Figure 31–4. Idiopathic and autoimmune neutropenia remains, in most instances, diagnoses of exclusion. A careful history, including family history and initial age of first abnormal counts, help to distinguish familial neutropenias (see Chapter 28). Should primary causes such as drugs or systemic diseases be identified, the diagnostic evaluation will concentrate on disease-specific tests. In addition to a complete blood count and differential, which will help establish the severity of neutropenia and tests to diagnose a specific disorder such as T-LGL leukemia, a bone marrow examination may be required. Lack of morphologic or cytogenetic signs of primary hematologic diseases (eg, myelodysplastic syndromes or aplastic anemia) and peripheral destruction will be supported by the observation of left shift and myeloid predominance. Inhibition of myeloid production is exemplified by an increased E:M ratio.

In some instances, auxiliary tests may help identify the cause of the neutropenia, including vitamin B_{12}, zinc, folate, or copper levels. Determination of immunoglobulin levels may be helpful to establish the presence of immunodeficiency. Detection of ANAs has a limited significance as most of the currently available routine tests are not very sensitive and may not be specific. The presence of antibodies, however, may be helpful and support the diagnosis of autoimmune forms of neutropenia.

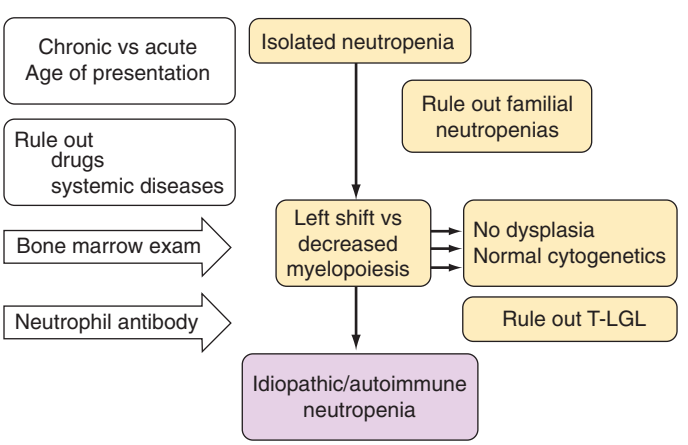

Figure 31–4 Evaluation of primary and secondary neutropenia.

DIFFERENTIAL DIAGNOSIS

Differential diagnostic consideration aims to distinguish primary from secondary forms of neutropenia and to exclude familial hematologic diseases. Suspicion of neutropenia secondary to a primary hematologic disorder requires a bone marrow examination that may be consistent with early form of aplastic anemia or myelodysplastic syndrome (MDS).

THERAPY

In secondary neutropenias, the therapy is aimed at the primary disease. If potentially offending drugs are present, they should be discontinued. G-CSF (4–10 μg/kg SQ per day until ANC is above 500 cells/μL) may be used for both severe cases of primary and secondary neutropenias.[272,326,327] It may help to speed up recovery but if the primary cause persists, it will have only a temporary effect. The use of antibiotics may be useful for the treatment of certain infections. Primary or idiopathic neutropenias most often have an autoimmune cause. Prednisone (1 mg/kg PO QD for 3 months) may be used as first-line therapy,[311] but other B-cell–targeted agents may be needed, including rituximab (375 mg/m^2 IV every week for 4 weeks).[328,329] IVIg (2 g/kg IV for 5 days) is effective in certain cases of PWCA.[330] Cytotoxic therapies like cytoxan (50–100 mg PO QD for 3–6 months) may be difficult to administer owing to their inherent myelotoxicity. In cases of neutropenia secondary to lupus or rheumatoid arthritis, such agents may be effective but the distinction between neutropenia due to the myelosuppressive effects of previous or concurrent treatments for increased activity of the autoimmune disease is necessary. Finally, similar to the treatments applied for T-LGL leukemia, T-cell–targeted approaches, such as CsA, can be used (1–1.5 mg/kg PO BID and titrated to maintain a trough level of 250–400 ng/mL).[331,332] A trial of at least 6 weeks is recommended. Similarly use of ATG has also been effective for cases of PWCA[333] and other idiopathic forms of neutropenia.[334] Methotrexate is effective in treating neutropenia related to Felty syndrome (5–7.5 mg/week for 1–2 months)[335] and T-LGL leukemia.[172,336] Of note is that in many instances isolated neutropenias may be asymptomatic and therapy may not be needed. Alemtuzumab has been used with success in treating thymoma-associated PWCA and other cases of neutropenias.[337–339]

LARGE GRANULAR LYMPHOCYTE LEUKEMIA

Large granular lymphocyte leukemia is a chronic clonal lymphoproliferation of cytotoxic T cells (T-LGL) or NK cells (NK-LGL), often associated with cytopenias, including neutropenia, red cell aplasia, and thrombocytopenia. Pancytopenia is less frequently encountered and may be related to splenomegaly. T-LGL leukemia may be an indolent disorder and present with leukopenia or with lymphocytosis. LGLs observed on a peripheral smear are characteristic of LGL but their frequency can vary.

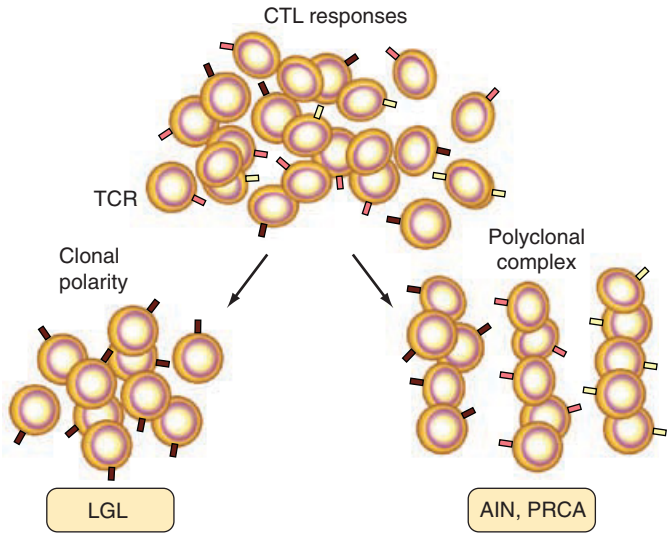

Figure 31–5 Pathophysiology of cytotoxic T-lymphocyte responses.

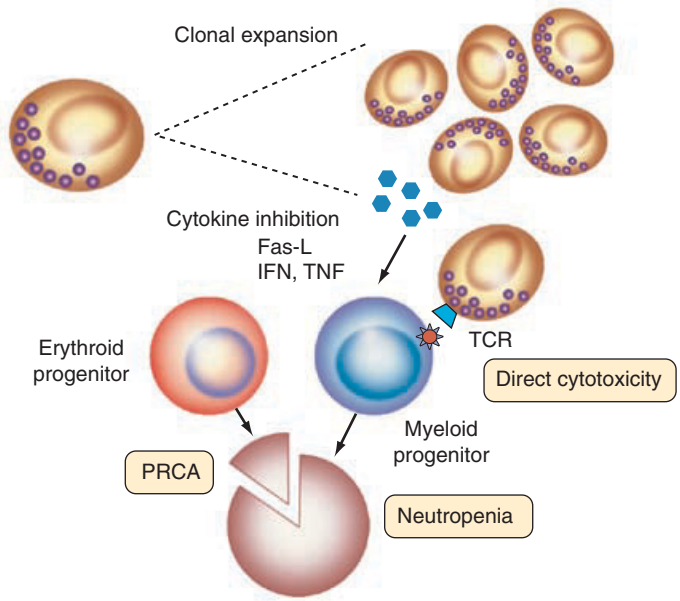

Figure 31–6 Pathophysiology of cytopenias in T-cell large granular lymphocyte leukemia.

T-LGL leukemia results from a proliferation of cytotoxic T cells (CTL) and often resembles reactive CTL expansion. It is frequently associated with other autoimmune disorders, including rheumatoid arthritis, Crohn disease, multiple sclerosis, and many hematologic conditions including MDS. Most reactive processes are polyclonal but immunodominant CTL clones may be present making a distinction between true T-LGL and reactive process difficult (Fig. 31–5). A reduction in the variability of the CTL repertoire can occur in the elderly, and clonal or oligoclonal CTL expansions may be more frequent in older individuals. If asymptomatic, this disorder has been termed monoclonal clonopathy of unclear significance (MCUS).

PATHOGENESIS

Inciting Events

T-LGL leukemia frequently arises in the context of a reactive polyclonal CTL expansion undergoing transformation in a manner similar to that proposed for CLL.[340,341] It is possible also that in T-LGL leukemia, one of the effector CTL clones may be initially driven by an exciting antigen, may transform and consequently the cells fail to undergo apoptosis. The initial or initiating polyclonal response may be a component of the pathophysiologic process associated with infectious agents, rheumatoid arthritis, or other autoimmune disorders.

An initial T cell-mediated process may be responsible for cytopenias in the absence of clonal predominance. In concurrence with this hypothesis, the clinical spectrum of T-LGL is determined by the specificity of the TcR: for example, if myeloid precursors are targets of clonal CTL, neutropenia will be a clinical manifestation. Conversely, if erythroid progenitors are affected, patients will present with anemia (Figs. 31–1 and 31–6). However, unlike the cytopenias that resolve following immunosuppression, the CTL clone may persist at a certain level, suggesting that other disease mechanisms involving soluble factors play a role in the development of the cytopenias. Various soluble agents including Fas-ligand (Fas-L), and perforin have been implicated in the pathophysiology of the cytopenias in T-LGL leukemia.[342–344]

Clonal Transformation

Clinically, T-LGL leukemia does not behave as a typical leukemia: excessive accumulation of malignant cells is often absent and progression to a more malignant phenotype is rare (for clinical review, see references 105 and 345). Instead, the expanded clone in T-LGL leukemia resembles a normal antigen-activated $CD8^+CD57^+$ effector-cell; both normal and malignant LGL constitutively express perforin and Fas-L and can suppress neutrophil development in vitro.[343,346–348] Gene expression studies have shown that the T-LGL leukemia clone exhibits upregulation of cytotoxic proteases and adhesion molecules and downregulation of protease inhibitors.[346,347] Typical clonal LGL cells seem to be terminally differentiated and cannot be effectively expanded in vitro by polyclonal mitogens (unpublished observations).

It is likely that a polyclonal CTL response predates the outgrowth of the immunodominant T-LGL leukemia clone (see Fig. 31–3). The putative transforming event most likely involves a memory cell that feeds into the mature effector CTL compartment.[349] Under normal physiologic circumstances, activated effector T cells are deleted after antigen-driven expansion by Fas-mediated apoptosis. The failure of an activated memory and/or effector clone to undergo apoptosis may result in its persistent expansion.[350–353] LGL leukemia cells express high levels of Fas/Fas-L, yet themselves are resistant to Fas-mediated apoptosis.[354] It is conceivable that persistent LGL leukemia cell expansion may result from this resistance to homeostatic apoptosis. In addition to the high surface expression of Fas/Fas-L, soluble Fas-L has been detected in sera from T-LGL leukemia patients and may contribute to the induction of apoptosis of neutrophil precursors in the bone marrow.[336]

An LGL clone persists mostly in the G_0/G_1 phase of cell cycle[348] and clonal transformation may also be due to a constitutive overexpression of prosurvival and antiapoptotic transcription factors. STAT3 has been shown to be involved in cellular transformation along with an active Src family kinase[355] and appears to be constitutively activated in T-LGL leukemia cells.[356,357] In addition, a constitutive activation of an Src family kinase in T-LGL leukemia (likely Lck or Fyn) has been reported that may be related to this increased STAT phosphorylation.[358] It has been proposed that STAT3 activation in T-LGL may inhibit apoptosis downstream of Fas receptor signaling by induction of MCL-1, a member of the BCL-2 family of antiapoptotic proteins.[356] This finding is further supported by data showing that blockade of STAT signaling in T-LGL cells leads to the reversal of Fas resistance. Similarly, constitutive activation of the ERK mitogen activated protein kinase pathway seem to play a role in survival of NK-LGL leukemia cells.[359] ERK was found to be constitutively activated in T-LGL as well.[358]

Extreme Clonal Expansion and the Nonrandom Nature of the T-Cell Large Granular Lymphocyte Leukemia Clone

Molecular analysis of the TcR repertoire in T-LGL leukemia has revealed a spectrum of expansion of the T-cell clone in individual patients. In some cases, up to 98% of the peripheral $CD8^+$ repertoire consists of only one clone, a surprising finding given the absence of immunodeficiency among LGL leukemia patients. In healthy controls, even the most predominant clones, most likely reactive to ubiquitous antigens, constitute only up to 1.4% of the entire TCR repertoire.[360] Thus, detection of an extreme degree of clonal expansion is an important pathologic sign. Similarly, because of the vast diversity of the physiologic TcR repertoire, the probability of isolation of identical CDR3 clonotypes in different individuals is extremely low. We have encountered only a few shared clonotypes even when identical twins were compared. Therefore, occurrence of identical and highly similar clonotypes between individual LGL leukemia patients or strikingly homologous clonotypes within the TcR repertoire of an individual patient may lead to the recognition of identical target antigens.[360] This notion might be further supported if patients with identical or highly similar clonotypes share some HLA features, leading to the display of identical antigenic peptides. It is possible that structurally similar clonotypes present in some patients with T-LGL arise in the context of initial polyclonal CTL response and the initial transformation step is not random (see Fig. 31–3). Once a pathogenic immunodominant clonotype is identified and characterized, its sequence can be used for the design of clonotypic Taqman PCR. This quantitative method may be employed to track the immunodominant clone throughout the course of therapy and thus may potentially predict an impending relapse.[360]

Putative Viral Culprits

While no particular virus has been singled out, according to evidence to date, HTLV-1 (or a related retrovirus) and/or a member of the γ-herpesvirus family are interesting candidates implicated in the pathogenesis of LGL leukemia.[361–365] For instance, patients with NK-cell LGL are often seropositive for the p21e envelope protein of HTLV-1, known to activate the ERK pathway. HTLV epitope mapping has demonstrated a strong reactivity against env p21e protein, with particular specificity for the BA21 epitope. However patients seroreactive for this epitope were negative for HTLV. Consequently, it has been hypothesized that a cellular or retroviral protein with homology to BA21 may play a major role in LGL etiology.[361] In addition, rabbit and bovine LGL infected with alcelaphine herpes virus-1 or bovine herpes virus-2, respectively, have been shown to display several properties of human T-LGL, such as poor proliferation after mitogen stimulation, constitutive ERK activation, and constitutive Lck and Fyn kinase activity.[366]

CLINICAL PRESENTATION AND PHYSICAL FEATURES

Patients with T-LGL leukemia present at a median age of about 55 years, with an equal male/female distribution. The clinical course may be indolent and chronic. Patients are asymptomatic in one-third of cases. The most common clinical presentation is neutropenia (observed in approximately 85% of patients) often accompanied by infections or neutropenic fever.[105,106,292,345,367–369] However, in contrast to neutropenia associated with other hematologic disorders, LGL leukemia patients may remain surprisingly free of infectious complications for extended periods of time regardless of the depressed ANC. Despite the extreme clonality within the T-cell population (suggesting a decreased antigen recognition spectrum), opportunistic infections are rare. Other single-lineage cytopenias, including PRCA and immune-mediated thrombocytopenia, accompany T-LGL leukemia less frequently than neutropenia.[12,367,368,370,371] In some patients, neutropenia, anemia, or pancytopenia may occur at different time points throughout the course of the disease.[372] Pancytopenia may be related to splenomegaly reported in 20% to 50% of patients. Hepatomegaly is present in a minority of patients (10%–20%). Lymphadenopathy and B symptoms may also occur; however, this is uncommon.[345] It has been reported that pregnancy can improve neutropenia in women with LGL leukemia.[373] Clinical transformation to a more malignant form is rare. The clinical presentation of NK-cell LGL lymphocytosis is very similar to that seen in T-LGL leukemia with regards to lymphocyte counts, associated conditions, treatment responses, and survival although in some reports there is a lower incidence of neutropenia and anemia.[374]

Clinical Overlap and Associations

In some clinical circumstances, natural or pathologic immune responses can resemble T-LGL expansions. For example, responses to viruses such as CMV or EBV, although of an oligoclonal or polyclonal nature, may display a strong clonal dominance mimicking at times a true clonal process.[377] Consequently, polarized CTL responses in the context of infections have to be distinguished from true LGL leukemia.

T-LGL leukemia can occur concomitantly with several autoimmune diseases. Rheumatoid arthritis is likely the most common association occurring in one-third of patients with T-LGL leukemia, but other diseases such as ulcerative colitis, Sjögren syndrome, SLE, multiple sclerosis, and a number of other (auto)immune conditions have been described.* Felty syndrome is characterized by neutropenia with rheumatoid arthritis and splenomegaly; 80% of cases express the *HLA-DR4* allele, a finding also observed in T-LGL leukemia.[386] This common immunogenetic link and similar patterns of cytotoxic clonal expansion with T-cell infiltration suggest that Felty syndrome and T-LGL represent components of the same disease process.[378,387–389] In addition, PRCA and immune-mediated thrombocytopenia may also be associated with LGL lymphoproliferation.† Clonal expansions that characterize T-LGL leukemia can appear similar to oligoclonal CTL responses elicited by strong immunodominant antigens, including certain viruses[389–392]—thus the distinction between T-LGL leukemia and a reactive lymphoproliferative process. LGL leukemia has also been described after bone marrow and solid organ transplantation, perhaps initiated by an alloantigen or an infectious agent such as EBV.[393–398]

LGL-like expansions may also be present in other hematologic disorders, including MDS, aplastic anemia, and paroxysmal nocturnal hemoglobinuria,[369,399–403] and may coincide with a number of lymphoproliferative disorders as well.[379,404–406] In MDS, the prognosis is usually determined by the presence of MDS, but the presence of LGL may provide a rational target for immunosuppressive therapy. In MDS, T-LGL leukemia has been reported to negatively impact the outcome of therapy directed against the CTL clone.[402] LGL leukemia has also been described in conjunction with hemolytic anemia following bone marrow transplantation, perhaps a process initially driven by an alloantigen or infectious agent such as EBV.[31] As with infections, distinction between an LGL leukemia and reactive lymphoproliferation may be blurred. For example, neutropenia may be associated with various degrees of clonality, with an LGL leukemia representing the most extreme form of this process.

LABORATORY DIAGNOSIS

Diagnostic criteria remain a subject of considerable discussion (Table 31–7). Traditionally, LGL lymphocytosis (identified by morphology and flow cytometry) is a significant diagnostic criterion.[292,379] However, not all clonal cells display the typical morphology and some

*See references 105, 106, 292, 368, 372, and 376–383.

TcR rearrangement	TCR-γ PCR Southern blot

patients present with leukopenia. Consequently, an LGL count of greater than 2000/μL of blood has been abandoned as a strict diagnostic requirement, and lower numbers such as 0.400/μL of blood have been proposed.[105,407] Most investigators consider the presence of an expanded homogeneous $CD3^+$, $CD16^+$, $CD28^-$, $CD57^+$ cell population as diagnostic of LGL leukemia; in almost all patients the expanded clone is $CD8^+$ (only very rarely $CD4^+$)[105,408–410] and in the majority of cases this population also expresses CD57, but LGL cases without this marker have been observed.[105,410] In addition, clinically aggressive T-LGL leukemia is characterized by expression of CD26.[411] In most cases of LGL leukemia, CD94 is expressed at increased levels and other receptors for class I MHC molecules are abnormally expressed.[412–414] Some investigators have suggested that a pool of $CD8^+$ memory cells exists that lack CD57 expression but feed into the mature CD57 effector compartment.[408,415] The size of the abnormal clone defining T-LGL leukemia remains controversial. It is likely that the size of the leukemic T-cell population influences the detection of the clonal TCR γ-chain (G) rearrangement by PCR or Southern blotting; thus, such tests are considered mandatory for diagnosis.[416,417] These methods may detect a clonal population that represents 15% of the cell population but it is also likely that smaller CTL expansions may be consistent with latent T-LGL detected only if more precise methods are used. T-LGL can express CD4, but both $CD4^+$ as well as double positive $CD4^+/CD8^+$ cases are rare. Cytogenetic analyses are not useful although cases with chromosomal aberrations have been described.[418,419]

Flow cytometric analysis of Vβ utilization pattern with antibodies directed against most of the Vβ-chain types may be helpful in making the diagnosis. The Vβ family expansion by flow cytometry does not prove clonalily but it may help assess the contribution of the F-LGL clone to the $CD8^+$ or $CD4^+$ population (Fig. 31–7).

Rare immunophenotypic variants of T-LGL exist that coexpress CD4 and CD8, lack both of these markers, or utilize γ/δ TCR instead of α/β TCR chains. Vβ flow cytometry has been used to assess the size of the LGL clone and its Vβ utilization; Vβ usage can be identified in 80% of patients. The current Vβ antibody panel does not cover 25% to 35% of the Vβ spectrum. In usual cases, T-LGL does not express CD56 antigen; the presence of this marker has been associated with a more aggressive clinical phenotype.[420] A monotypic expression pattern of KIR can be found with monoclonal antibodies to CD157b, CD158a, and CD158e (corresponding to the most prevalent KIR genes) in about 50% of patients.[421]

Additional supportive tests include a reticulocyte count, which is low in cases presenting with red cell aplasia. The MCV is usually

Approach to the Diagnosis and Treatment of Acquired Pure Red Cell Aplasia, Acquired Neutropenia, and T-LGL Leukemia

Acquired pure red cell aplasia (PRCA) is characterized by reticulocytopenia but diagnosis is based on the morphologic absence of erythroid precursors in the bone marrow. Congenital forms of PRCA, including Diamond–Blackfan anemia, need to be distinguished when presenting in young children. In adults, primary idiopathic disease has to be differentiated from secondary forms of red cell aplasia associated with hematologic diseases such as B-cell chronic lymphocytic leukemia (CLL), myeloma, T-cell large granular lymphocyte (T-LGL) leukemia, and parvovirus B19–associated chronic reticulocytopenia or acute transient aplastic crisis. The diagnosis of parvovorus B19 infection can be made on the basis of the presence of parvovirus B19–specific IgM and by DNA hybridization techniques. Parvovirus B19–specific polymerase chain reaction (PCR) can help rule out an ongoing infection. This diagnosis is important as therapy with IVIg (2 g/kg IV for 5 days) can be curative. The therapy of secondary red cell aplasia includes treatment of the underlying condition. It is also important to distinguish red cell aplasia from myelodysplastic syndromes, which can be associated with erythroid hypoplasia but carry a significantly worse prognosis.

In cases with thymoma, thymectomy is the usual initial treatment approach; however, incomplete responders, nonresponders, and patients who relapse are common, necessitating the addition of immunosuppressive therapy. In patients with idiopathic PRCA, therapy includes immunosuppressive agents such as prednisone (1 mg/kg PO for 3 months), cyclosporine A (CsA; 5–10 mg/kg PO daily in divided doses for 3 months), or oral cyclophosphamide (50–150 mg PO QD for 3 months). Second-line therapies include ATG (if horse ATG, 40 mg/kg IV daily for 4 days with prednisone at 1 mg/kg, and if rabbit ATG, 2.5–3.5 mg/kg daily IV for 4 or 5 days with prednisone at 1 mg/kg) or rituximab (375 mg/m^2 IV every week for 4 weeks).

Neutropenia may be associated with severe infections, but the risk associated with neutropenia depends on its clinical context, severity, and duration. The management of neutropenia must account for its clinical presentation and the risk of possible life-threatening complications and includes supportive care, clinical monitoring, and implementation of prophylactic antibiotics and/or hematopoietic growth factors. Neutropenia in childhood may be due to congenital diseases, be associated with viral infections, or be immune mediated. These three etiologies are usually self-limiting. In adults, most neutropenias are secondary to other conditions, including hematologic or systemic diseases. In general, drug reactions are a very common cause of neutropenia. Idiopathic or autoimmune neutropenia as a primary disease is a diagnosis of exclusion. The pathogenesis involves T-lymphocyte/natural killer–mediated inhibition of myelopoiesis or antineutrophil antibodies. Immunosuppressive therapy may be employed and includes prednisone (1 mg/kg PO QD for 3 months), methotrexate (5–7.5 mg/week for 1–2 months), CsA (1–1.5 mg/kg PO BID and titrated to maintain a trough level of 250–400 ng/mL), IVIg (2 g/kg IV for 5 days), cyclophosphamide (50–100 mg PO QD for 3–6 months), or rituximab alone (375 mg/m^2 IV every week for 4 weeks) or in conjunction with myeloid growth factors.

T-LGL is a chronic, often indolent clonal lymphoproliferation of cytotoxic T cells associated with immune-mediated cytopenias. It may be a part of a continuum of reactive cytotoxic T-cell responses ranging from polyclonal, oligoclonal, to monoclonal expansions as seen in T-LGL. Persistent antigenic drive or dysfunction of the homeostatic termination of clonal T-cell expansion may be involved, and the abnormal cytotoxic T lymphocyte (CTL) in LGL is not entirely autonomous. The pathophysiology of cytopenias includes cytokine effects and direct antigen-specific cytotoxicity. Most patients present with neutropenia. PRCA and pancytopenia are less common. Hemolytic anemia and pancytopenia may be the result of splenomegaly present in a significant minority of patients. B symptoms and lymphadenopathy are uncommon and many patients remain asymptomatic. The diagnosis is established according to the presence of characteristic LGL lymphocytosis, but in some patients the LGL count may not be very high. The immunophenotype is CD3$^+$, CD8$^+$, CD57$^+$, CD16$^+$, CD56$^-$, and CD28$^-$. CD56 antigen-expressing LGL may be characterized by a more aggressive course. Some cases may coexpress CD4 and CD8. The diagnosis includes detection of T-cell receptor rearrangement. In most instances, expansion of the involved Vβ family may be detected using Vβ flow cytometric clonotyping. T-LGL is often associated with autoimmune diseases, including rheumatoid arthritis and Felty syndrome. T-LGL can accompany myelodysplasia and, in rare instances, aplastic anemia or paroxysmal nocturnal hemoglobinuria. Reactive, often viral infection–associated, CTL proliferation may be difficult to document. Asymptomatic cases are monitored, and development of systemic symptoms or symptomatic cytopenias may prompt therapy. Current treatments include immunosuppressive agents such as prednisone, CsA (1–1.5 mg/kg PO BID then adjusted to maintain a trough level of 250–400 ng/mL for 8–10 weeks), oral methotrexate (10 mg/m^2 week for 21 months), or cyclophosphamide (50–100 mg/day for 3–6 months). Chronic long-term therapy may be more effective than high-dose combination chemotherapy applied in B-cell lymphomas. Second-line treatments may involve alemtuzumab or ATG. The prognosis is generally good and transformation to a more aggressive lymphoproliferative disorder is rare.

high. Serologic studies or DNA titer to detect evidence of EBV infection is usually not needed but may be helpful to distinguish reactive immunologic responses. The rheumatoid factor is frequently positive. Antinuclear antibodies and ANAs may also at times be positive.[422,423]

Unless additional hematologic diseases, such as MDS, are suspected, bone marrow examination may not be required. Bone marrow biopsy and aspirate should be obtained in cases of pancytopenia or involvement of several lineages. Morphologic hallmarks of MDS and cytogenetic analysis may help establish a diagnosis of MDS.

DIFFERENTIAL DIAGNOSIS

Differential diagnostic considerations include reactive processes such as viral infections. Occasionally, MDS may be present simultaneously or serve as an alternative diagnosis; T-cell oligoclonality may accompany MDS.

THERAPY

A significant proportion of patients will be asymptomatic and the diagnosis may be totally coincidental. Should the patient be asymptomatic, therapy may be delayed. Lymphocytosis may be significant but absolute lymphocyte counts more than 40,000/μL are unusual. Symptomatic splenomegaly may be an indication for splenectomy. Pancytopenia may be a result of splenomegaly and the procedure aids in the treatment of a hemolytic anemia that can be present in some patients.

Patients may tolerate significant degrees of neutropenia for many years. Indications for treatment include neutropenic complications or transfusion-dependence (Fig. 31–8). G-CSF therapy will increase counts in some patients, but a significant proportion of patients will be refractory or would have delayed response.[225,424–426] Of interest is the observation that high-dose therapy with typical lymphoma regimens such as CVP or CHOP may be ineffective and therefore should not be used. Cases refractory to bone marrow transplantation have

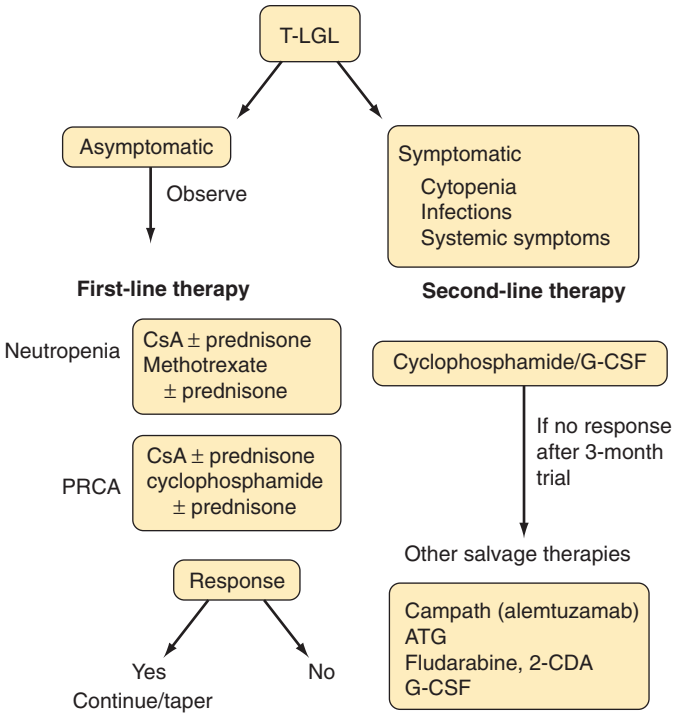

Figure 31–8 Therapy of T-cell large granular lymphocyte leukemia.

been described.[427] Monotherapy with prednisone may relieve some of the symptoms and improve neutropenia but remissions are usually not durable. CsA given at 1 to 1.5 mg/kg PO BID then adjusted to maintain a trough level of 250 to 400 ng/mL represents a reasonable first-line therapy; however, a course of sufficient duration has to be given, with a response expected after 8 to 10 weeks of therapy.[331,428] Weekly oral methotrexate given at 10 mg/m^2 PO weekly has been used successfully.[428,429] Patients with LGL leukemia–associated PRCA may be better treated with oral cyclophosphamide instead of methotrexate with a dose between 50 and 100 mg/day. In LGL leukemia with associated PRCA, responses may be delayed and the PRCA may recur after discontinuation of cyclophosphamide therapy, or if insufficient treatment (<6–8 weeks) was administered. Therapy with cyclophosphamide in neutropenic patients may be difficult due to myelosuppression. In most refractory cases, ATG has been also used with success.[430] In recent years, successful therapy with alemtuzamab has been reported.[431] Allogeneic HSCT has also been used successfully in some cases.[432,433]

Relapses are frequent but usually responsive to the previously effective therapy. Certain patients may require low-dose maintenance therapy with CsA. In some cases, remarkable improvement of cytopenia can be achieved with splenectomy.[434]

PROGNOSIS

LGL leukemia is a chronic condition and may be indolent. In general, mortality is low. Transformation to more aggressive forms of lymphomas or leukemias is uncommon. In cases of T-LGL leukemia associated with a primary hematologic disease such as MDS, the prognosis is dependent on the therapy of the underlying problem.

CHAPTER 32

THROMBOCYTOPENIA DUE TO DECREASED PLATELET PRODUCTION

Alan M. Gewirtz

In this chapter we consider the diagnosis, pathogenesis, and treatment of platelet production (thrombopoiesis) abnormalities. To accomplish this goal, it is useful to first briefly review the biology of megakaryocyte development, a topic that is treated in much greater detail in Chapter 27 of this book. Platelets are the direct progeny of megakaryocytes; as such, disorders of megakaryocyte development are important causes of thrombocytopenia.

In 1906, J. Homer Wright, using only a microscope and histochemical stains, formulated the seminal hypothesis that platelets were derived from bone marrow megakaryocytes.[1] His insightful observations proved correct and were the beginning of a long, technically difficult, and still incomplete investigation into the processes that control megakaryocyte development and the production of platelets. Having said this, however, it is still clear that the study of thrombopoiesis has come a very long way and much has been revealed about the cellular, biochemical, and molecular aspects of this process.[2]

Megakaryocytes, like all formed elements of the peripheral blood, are ultimately derived from undifferentiated hematopoietic stem cells that exist in a developmental continuum (see Chapter 20).[3] Through a series of still incompletely understood events, stem cells undergo an asynchronous division that gives rise to two daughter cells. One daughter cell remains a stem cell, fulfilling the requirement for self-renewal of the stem cell compartment, and the other commits to developing within a given lineage, likely through the induction of specific transcription factors such as GATA-1, FOG-1, and FLI-1, in the case of megakaryocytes,[4,5] and perhaps by downmodulation of other transcription factors, such as c-myb.[6,7] Lineage-committed *progenitor cells* are characterized by a loss of "plasticity" and a remarkable capacity for proliferation. The latter is required because approximately 15×10^6 megakaryocytes/kg body weight must be available to produce the roughly 100×10^9 new platelets that are needed daily to maintain a normal platelet count of 150 to 400×10^9/L.[8] As progenitor cell divisional activity proceeds, maturation, as defined by the acquisition of lineage-specific proteins, ensues, largely under the control of the hematopoietic cytokine thrombopoietin.[2,9,10] After a variable number of mitoses, proliferative activity eventually declines, giving rise to many daughter cells, which are known as *precursors*. Precursor cells are essentially postmitotic and are capable of one or two additional cell divisions at most. They are often morphologically identifiable as belonging to a given lineage and are primarily engaged in the terminal maturation steps that allow them to function as competent members of their lineage. In the case of megakaryocytes, precursor cells undergoing nuclear endoreduplication to increase their ploidy (to a mean of approximately 16 N), a characteristic unique to cells of the megakaryocyte lineage.[4,11–17] Nuclear endoreduplication is accompanied by an increase in megakaryocyte cytoplasm and thereby the number of platelets that an individual megakaryocyte can produce.[14]

As discussed in Chapter 27, the process of platelet formation, or thrombopoiesis, occurs during megakaryocyte terminal maturation.[18,19] It is initiated by the development of the demarcation membrane system in the megakaryocyte's cytoplasm.[20] Among the functions of the demarcation membrane system is delineation of platelet fields. These fields are filled with the granules and proteins that ultimately make up the contents of mature platelets. The latter are shed from pseudopods that mature megakaryocytes extend through endothelial cell junctions into the lumen of marrow capillaries. The pseudopods fracture, because of shear stress in the lumen of these capillaries, and release shards of megakaryocytic cytoplasm, or proplatelets, that are the immediate antecedents of circulating platelets. A fully mature megakaryocyte is estimated to produce approximately 1 to 1.5×10^3 platelets. The molecular regulation of this process is beginning to be better understood. It has been shown, for example, that the apoptosis-stimulating gene Bax promotes platelet production.[21] Interestingly**,** very recent evidence suggests that the lifespan of circulating platelets is also regulated by the apoptosis proteins. Using the strategy of ethylnitrosourea (ENU)-inducted mutations, Mason and colleagues have recently demonstrated that mutations in the Bcl-x_L gene lead to synthesis of a form of the protein that no longer inhibits Bax, and that this in turn leads to accelerated platelet death and a heritable form of thrombocytopenia (Fig. 32–1).[22]

Failure in the process of either megakaryocytopoiesis or thrombopoiesis will result in thrombocytopenia. Under either circumstance, platelet production is characterized as "ineffective," either because there is an absolute decrease in available megakaryocyte cytoplasm (failure of megakaryocytopoiesis) or because cytoplasmic development is defective (failure of thrombopoiesis). Selective impairment of megakaryocytopoiesis may also result from damage to the progenitor cell compartment (the burst-forming units–megakaryocyte [BFU-MK] or colony-forming units–megakaryocyte [CFU-MK]; see Chapter 27) or, rarely, from a compromised ability to synthesize thrombopoietin, the chief cytokine regulator of this compartment (Fig. 32–2).[23] Inherent or acquired defects in megakaryocyte precursor cells may lead to ineffective thrombopoiesis.[23,24] The relative effectiveness of platelet production can be calculated by measuring platelet mass turnover, which is defined as the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes.[8,25–27] A disparity between cytoplasmic mass and platelet delivery to the peripheral blood (platelet count divided by platelet survival, corrected for splenic pooling) is the hallmark of ineffective platelet production (Fig. 32–3). Table 32–1 shows the typical kinetic characteristics of diseases characterized by ineffective platelet production.

An examination of the peripheral blood smear is the first step in the initial assessment of patients who present with thrombocytopenia. The presence of platelet clumps, indicative of pseudothrombocytopenia, or abnormally large, or small, platelets can be very useful in generating a differential diagnosis, as can the presence of inclusion bodies in neutrophils. Nevertheless, the current gold standard for diagnosing thrombocytopenia due to ineffective platelet production is a bone marrow aspirate and biopsy. At the moment, direct visualization of the marrow and its cellular contents is the only way to judge the quantity and quality of the megakaryocyte population (Fig. 32–4). However, noninvasive methods for making a diagnosis of ineffective platelet production are being developed. For example, the concentration of serum glycocalicin, the soluble fragment of glycoprotein (GP) Ib, has been shown to be significantly diminished in patients with platelet production abnormalities when compared with normal control subjects.[28] Reticulated platelets, like red blood cell reticulocytes, contain RNA. It has been suggested that as is true for red blood cell reticulocytes, the presence of residual RNA in platelets indicates that they have been newly formed.[28,29] Thus, they may be

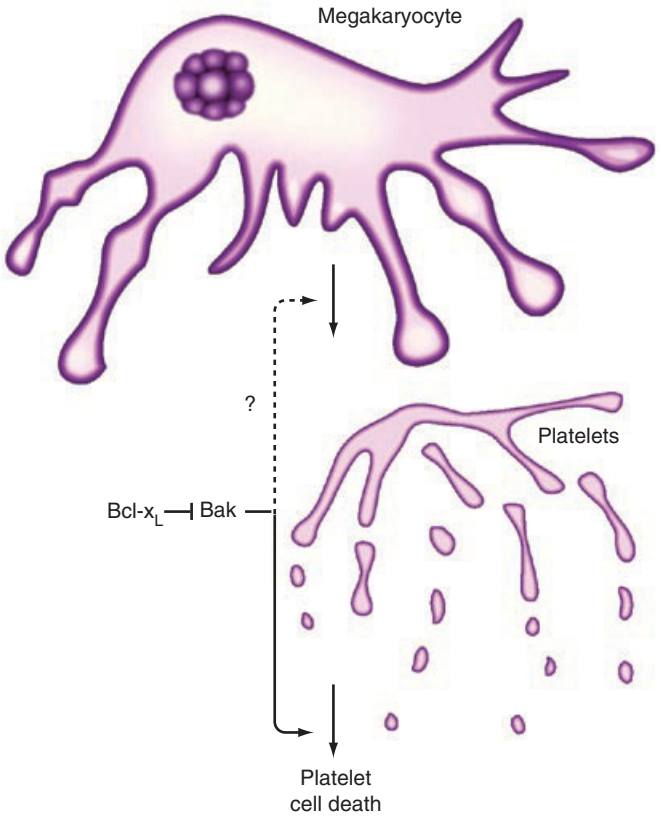

Figure 32–1 Bcl-x_L and platelet life span**.** Mason et al[22] subjected mice to ethylnitrosourea (ENU) mutagenesis and screened their first-generation offspring for platelet deficiency. They identified two mutations in the gene encoding the antiapoptotic factor *Bcl-x_L* that give rise to a dominantly inherited reduction in platelet count. Bcl-x_L appears to promote platelet survival through inhibition of the proapoptotic activity of Bak. Bax promotes production of platelets,[21] and overexpression of antiapoptotic Bcl-xL impairs the fragmentation of megakayocytes.[289] *(Adapted from Qi B, Hardwick JM: A Bcl-xL timer sets platelet life span. Cell 128(6):1035, 2007.)*

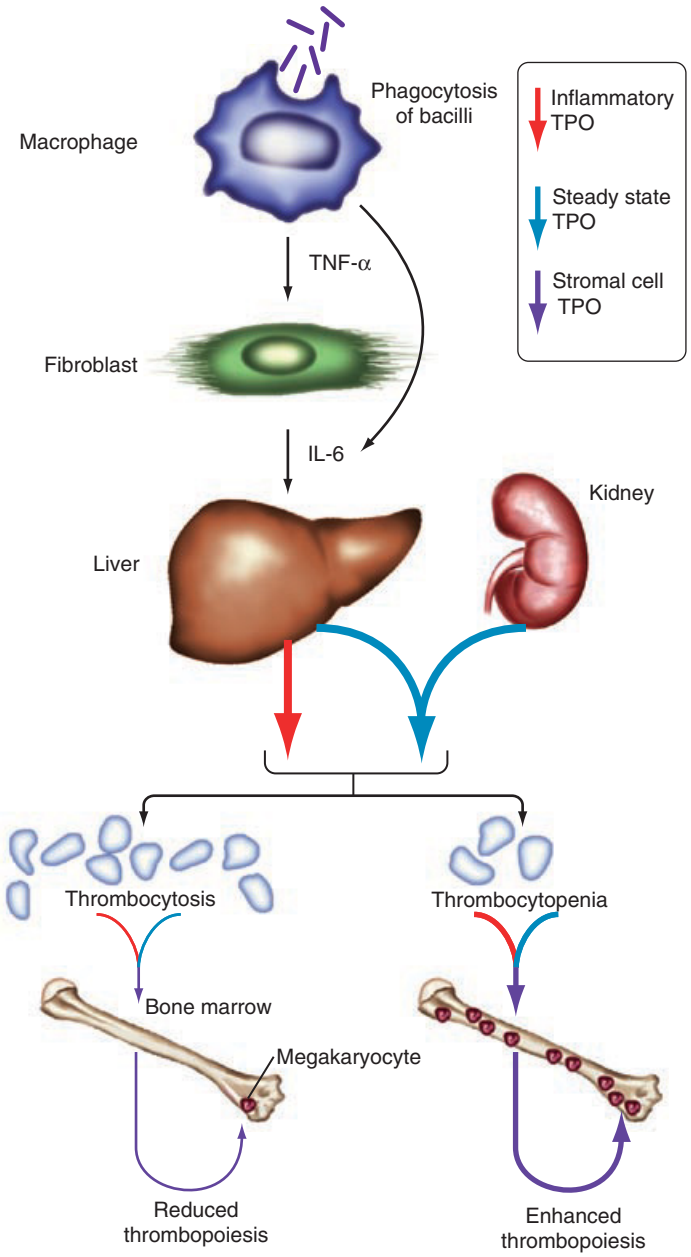

Figure 32–2 The regulation of thrombopoietin levels. A steady-state amount of hepatic thrombopoietin (TPO) is regulated by platelet c-Mpl receptor–mediated uptake and destruction of the hormone. Hepatic production of the hormone is depicted. Upon binding to platelet c-Mpl receptors, the hormone is removed from the circulation and destroyed, which reduces blood levels. In the presence of inflammation, IL-6 is released from macrophages and, through TNF-α stimulation, from fibroblasts and circulates to the liver to enhance thrombopoietin production. Thrombocytopenia also leads to enhanced marrow stromal cell production of thrombopoietin, although the molecular mediator(s) of this effect is not yet completely understood. *(Adapted from Kaushansky K: The molecular mechanisms that control thrombopoiesis. J Clin Invest 115(12):3339, 2005.)*

useful for assessing the dynamics of platelet production, under baseline conditions and after marrow insults such as chemotherapy or irradiation.[30–33] Platelet RNA can be detected by staining with dyes such as thiazole orange,[29] and it has been suggested that assessing the mean thiazole orange staining can be used to construct a reticulated platelet maturation index.[30] Although appealing in concept, the ultimate usefulness of this assay remains to be determined, because staining artifacts[34] and paradoxically low reticulated platelet counts in cases of disorders characterized by peripheral destruction may complicate the interpretation of such results.[29,34] Yet another approach to assessing platelet production is the measurement of serum thrombopoietin levels. Thrombopoietin is synthesized constitutively in the liver and then binds to its receptor c-MPL on megakaryocytes and platelets. Accordingly, in patients with disorders in which megakaryocytes are reduced in the marrow, thrombopoietin levels rise.[29,34–37] However, the wide variation in "normal" thrombopoietin concentrations in serum make this determination somewhat problematic as well. Some of this variability may be attributed to the fact that TPO synthesis is inducible in marrow stromal cells, perhaps by platelet α-granule proteins.[38,39] Reports attesting to the increased reliability and precision of measuring several of these parameters at once have appeared,[30,40] but it remains unclear whether the expense and time involved will prove cost-effective when compared with the relative simplicity of a bone marrow examination.

CONGENITAL OR HEREDITARY PLATELET PRODUCTION DISORDERS

Once thought rare, congenital or hereditary thrombocytopenias are becoming increasingly recognized and their molecular genetic bases more clearly understood. They vary in severity as an indirect function

Table 32–1 Typical Kinetic Profiles in Patients With Thrombocytopenia Due to Production Abnormalities

	Megakaryocytes				Platelets		
Category	Cell No. ($\times 10^6$/kg)	Cytoplasmic Volume (fL)	Cytoplasmic Mass ($\times 10^{11}$ fL/kg)	Concentration (Platelets/mm^3)	Volume (fL)	Survival (Days)	Mass Turnover ($\times 10^5$ fL/mm^3/day)
Normal	15 ± 4	12,000 ± 1,700	1.8 ± 0.4	250,000 ± 40,000	8.7 ± 0.8	9.6 ± 0.6	3.2 ± 0.5
Decreased Megakaryocytopoiesis —Damaged marrow	2	14,000	0.3	22,000	9.1	5.2	0.7
Ineffective production							
Autosomal dominant	49	9,400	4.6	64,000	8.9	8.4	1.1
Wiskott-Aldrich syndrome	20	9,000	1.8	40,000	4.0	5.0	0.4
Vitamin B_{12} deficiency	51	8,900	4.5	62,000	8.5	8.4	0.8
Preleukemia	18	13,300	2.4	16,000	9.0	6.7	0.4

Adapted from Thompson A, Harker L: Quantitative platelet disorders. In Manual of Hemostasis and Thrombosis. Philadelphia, FA Davis, 1983, p 65.

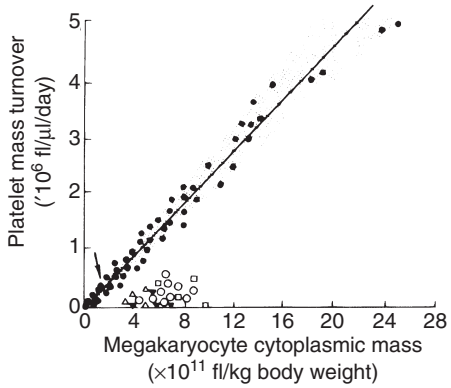

Figure 32–3 Ineffective platelet production. In thrombocytopenia, the relationship between marrow megakaryocyte cytoplasmic mass and the turnover of platelet mass in the peripheral blood is usually direct. Platelet mass turnover represents the product of the mean megakaryocyte cytoplasmic volume multiplied by the total number of marrow megakaryocytes. The results in normal subjects are indicated by the *arrow*, and the *stippled area* represents 95% of confidence limits in thrombocytopenic patients with effective production. Ineffective thrombocytopoiesis is identified as a disparity between available marrow substrate (megakaryocyte cytoplasmic mass) and delivery of platelet mass to the peripheral blood (platelet mass turnover). Results in patients with autosomal dominant thrombocytopenia (*open circles*), Wiskott–Aldrich syndrome (*open triangles*), megaloblastic anemia (*open squares*), and preleukemia (*closed triangles*) are characterized by ineffective platelet production. *(Data from Thompson A, Harker L: Quantitative platelet disorders. In: Manual of Hemostasis and Thrombosis. Philadelphia, FA Davis, 1983, p 65.)*

of age, so that the most severe forms are diagnosed, not surprisingly, in newborns and infants, whereas the least clinically significant are diagnosed in adults. The congenital thrombocytopenia syndromes have been the subject of a number of authoritative reviews.[41,42] Because profound thrombocytopenia is a common problem in sick newborns, it is important to note that in this population, thrombocytopenia is typically due to sepsis, viral infections, perinatal asphyxia, or immunologic causes.[43,44] It has been estimated that less than 5% of cases of neonatal thrombocytopenia are due to inherited or congenital disorders of platelet production.[45] It is also worth noting that Fanconi anemia, congenital aplastic anemia, and other marrow failure syndromes involving multiple lineages may also manifest initially, though uncommonly, as an isolated thrombocytopenia (see Chapter 28).

Congenital thrombocytopenias can be classified in a number of ways, including clinical features (e.g., age of onset and severity of bleeding), platelet size (large, normal, small),[41] or by mode of inheritance and genetic mutation (Table 32–2).[42] The latter may be considered the most modern approach and perhaps ultimately the most informative with regard to etiology.

AUTOSOMAL DOMINANT THROMBOCYTOPENIA

Autosomal dominant thrombocytopenia can be encountered with or without other congenital abnormalities.[46–51] Patients with isolated thrombocytopenias usually have only modest reductions in their platelet counts, with normal platelet morphology and normal numbers of megakaryocytes. These individuals rarely have clinical symptoms related to their thrombocytopenias.

Patients with autosomal dominant thrombocytopenia may be relatively more common than previously believed. Many cases are not diagnosed until adulthood, again because these patients usually are asymptomatic, although exceptions have been reported.[52] The most important reason for recognizing these disorders is that patients may be misdiagnosed as having immune thrombocytopenic purpura (ITP) and treated for that disorder.[42,46] A detailed family history may be useful, as family studies of 54 patients referred with the diagnosis of refractory ITP showed that these patients had autosomal dominant thrombocytopenia with large platelets, normal megakaryocytes, and normal platelet survival.[49] Treatment is usually not indicated. Corticosteroids are ineffective, although splenectomy occasionally results in a modest response.[53]

THROMBOCYTOPENIA SYNDROMES ASSOCIATED WITH *MYH9* GENE MUTATIONS

The nonmuscle myosin heavy-chain IIA gene, *MYH9*, is found on chromosome 22q.[14,16,52,54] *MYH9* is expressed in platelets and upregulated during granulocyte differentiation.[52,55,56] Quite recently, May–Hegglin anomaly (Online Mendelian Inheritance in Man [OMIM] 155100), Fechtner syndrome (OMIM 153640), Sebastian syndrome (OMIM 605249), and Epstein syndrome (OMIM 153650) have all been found to be associated with mutations of this gene. These disorders share a characteristic triad of thrombocytopenia, macrothrombocytes, and neutrophil inclusions termed *Döhle-like bodies*.

The May–Hegglin anomaly, also called familial thrombocytopenia with leukocyte inclusions, was the first of these syndromes to be recognized and was in fact described almost 100 years ago. The thrombocytopenia associated with May–Hegglin anomaly is usually mild to moderate and, as just noted, is associated with giant platelets whose volumes may actually exceed those of red blood cells.[57] Up to one-third of platelets have volumes between 30 and 80 fL. Although

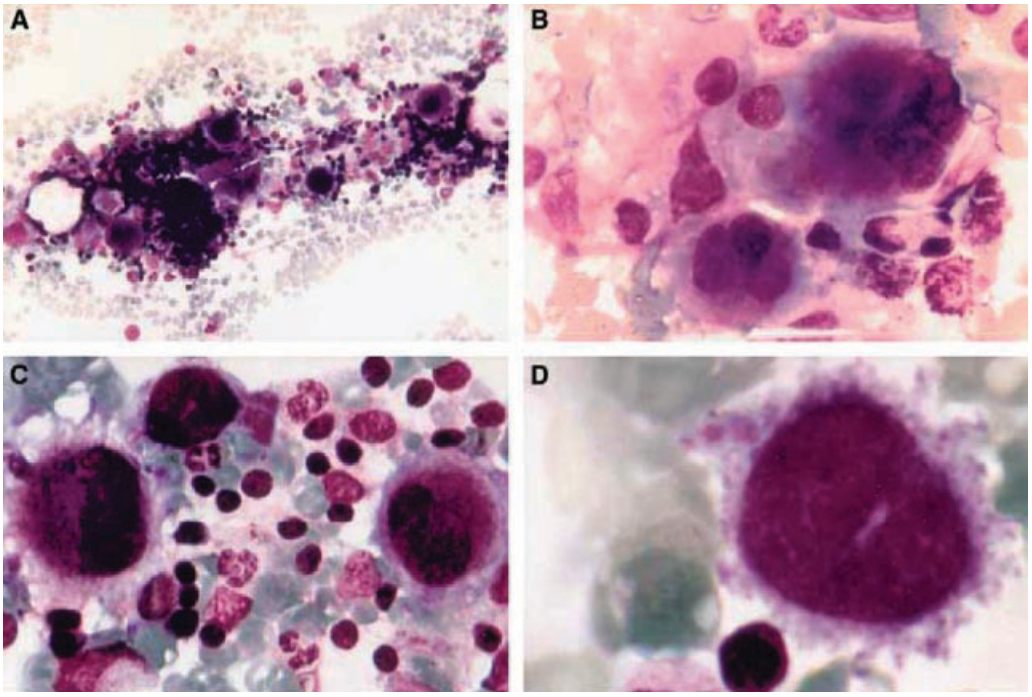

Figure 32–4 Marrow aspirate obtained from a child with thrombocytopenia and dysmegakaryocytopoiesis. The megakaryocytes are small and hypolobular, with diminished cytoplasm. Cells are viewed at magnifications of 250× (**A**), 1000× (**B**), 200× (**C**), and 1600× (**D**). *(From van den Oudenrijn S et al: Three parameters: Plasma thrombopoietin levels, plasma glycocalicin levels, and megakaryocyte culture, distinguish between different causes of congenital thrombocytopenia. Br J Haematol 117:390, 2002.)*

Table 32–2 Inherited Thrombocytopenias Classified by MYH9 Mutations and Associated Findings

Syndrome	Gene Mutation	Chromosome Location	Associated Findings
MYH9-related thrombocytopenia			
May–Hegglin anomaly	MYH9	22q11	Neutrophil inclusions, sensorineural hearing loss, nephritis, cataracts
Fechtner syndrome	MYH9	22q11	
Epstein syndrome	MYH9	22q11	
Sebastian syndrome	MYH9	22q11	
Mediterranean thrombocytopenia Bernard–Soulier carrier	GPiBB possibly others	17pter-pt2	None
Bernard–Soulier syndrome	GP1BA, GP1BB	17pter-pt2	None
Velocardiofacial/DiGeorge syndrome (CATCH22)	?GP1BB	22q11	Cancer facial, parathyroid, and thymus anomalies, cognitive learning impairment
Familial platelet discordant/acute myeloid leukemia	AML1	21q22.2	Myelodysplasia, acute myeloid leukemia
Chromosome 10THC22	?FL/14813	lop12-11.2	None
Paris–Trousseau thrombocytopenias/ Jacobsen syndrome	?FLIt	11q23	Psychomotor retardation, facial anomalies (Jacobsen syndrome)
Gray platelet syndrome	Unknown	Unknown	None
Congenital amegakaryocytic thrombocytopenia	MPL	1p34	Marrow failure during second decade
Thrombocytopenia and absent radii	Unknown	Unknown	Shortened absent radii bilaterally
Thrombocytopenia and radial synostosis	*HOXA11*	7prs-p14.2	Fused radius, incomplete range of motion
Wiskott–Aldrich syndrome	*WAS*	Xp11.23-p11.22	Immunodeficiency, eczema, lymphoma
X-linked thrombocytopenia	*WASI*	Xp11.23-p11.22	None
GATA-1 mutation	*GATA1*	Xp11.23	Anemia, dyserythropoiesis, thalassemia

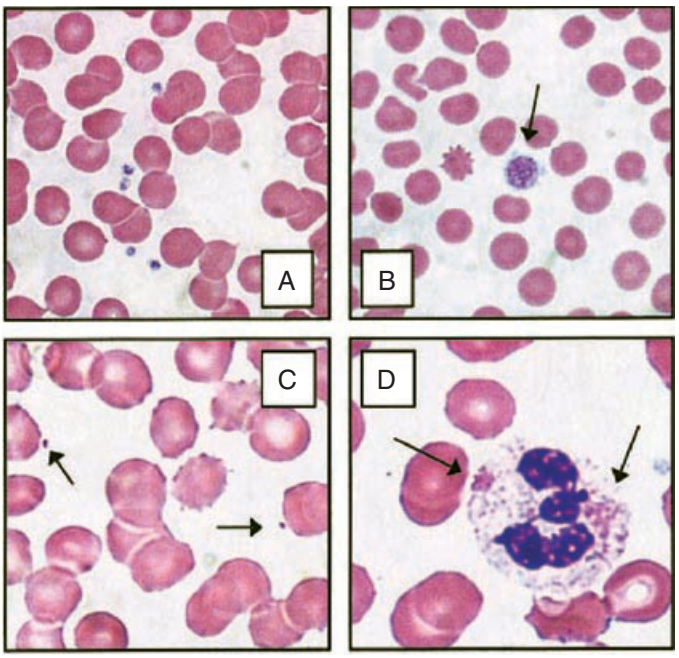

Figure 32–5 Peripheral blood platelets. **A**, Normal blood smear. **B**, Macrothrombocyte. The platelet depicted (*arrow*) is larger than the average erythrocyte. **C**, Microthrombocytes (*arrows*) are typical of those seen in Wiskott–Aldrich syndrome or X-linked thrombocytopenia. **D**, Döhle-like bodies in the cytoplasm of neutrophils (*arrows*) are seen in the May-Hegglin anomaly. All photomicrographs originally made at a magnification of 100× (Wright–Giemsa stain). *(From Drachman JG: Inherited thrombocytopenia: When a low platelet count does not mean ITP. Blood 103:390, 2004.)*

the platelets are large, they exhibit no intrinsic structural abnormalities and have normal surface membrane proteins.[58] Because marrow megakaryocytes are morphologically normal and platelet survival has been shown to be normal or modestly decreased in most cases,[59,60] ineffective production is the likely cause of the thrombocytopenia. The mechanism by which the giant platelets are formed in May–Hegglin anomaly and in other macrothrombocytopenias is not known with certainty, but recent studies suggest that abnormalities in the Rho-ROCK-myosin-IIA signaling pathway play a role.[61] Abnormal fragmentation of megakaryocyte pseudopods may also be involved.[59] The other characteristic of May–Hegglin anomaly is the presence of cytoplasmic inclusions in the patient's neutrophils, eosinophils, and, less commonly, monocytes. Morphologically, the inclusions resemble the classic Döhle bodies found in neutrophils from patients with acute inflammatory conditions, but unlike Döhle inclusions, they are present throughout the lifespan of affected individuals (Fig. 32–5). The inclusions appear bright blue on Wright–Giemsa staining and are composed largely of mutated nonmuscle myosin heavy-chain IIA, an important cytoskeletal contractile protein in hematopoietic cells.[55] Because the thrombocytopenia is modest and bleeding times are variable, treatment is usually not required.[62] Platelet transfusions have been given for thrombocytopenia, but their role is not clear.[63,64] Pregnancy is not difficult to manage and normal vaginal deliveries in these patients should be possible.[65]

May–Hegglin-like variants have also been described (Fechtner, Sebastian, and Epstein syndromes). All have mild macrothrombocytopenia.[51] They are distinguished according to whether the individual's neutrophils contain the Döhle-like inclusion bodies and whether the patient manifests abnormalities similar to Alport syndrome, such as nephritis, sensorineural hearing loss, and cataracts.[66,67] The clinical distinction of these syndromes can be quite difficult because within the same family and indeed the same individual, expressions of nephritis and hearing loss can be variable as a result of other as yet unidentified environmental factors. Fortunately, the bleeding tendency in affected individuals is mild, likely because the platelet mass in these patients is nearly normal, and functional defects are equally mild.

Macrothrombocytopenia is frequently discovered during routine testing of an asymptomatic individual. Diagnosis can be aided by examination of the peripheral blood smear, and identification of neutrophilic inclusions and giant platelets. As noted, individuals with mutations of *MYH9* and associated syndromes do not have life-threatening bleeding events. Nevertheless, genetic counseling should be offered to affected kindreds, if for no other reason than that platelet function-compromising drugs should be avoided as well as potentially dangerous treatments for presumed ITP.[42,66] For periods of hemorrhagic stress, such as trauma or surgery, platelet transfusions would be useful for uncontrolled bleeding.

MEDITERRANEAN MACROTHROMBOCYTOPENIA (OMIM 153670)

Not every macrothrombocytopenia is caused by mutations in the *MYH9* gene. Mediterranean macrothrombocytopenia,[68] common in people of Southern European extraction, has been assigned to an as yet unidentified gene mutation on the short arm of chromosome 17 through linkage analysis of affected families.[69] The degree of thrombocytopenia in affected individuals is generally mild to moderate, with platelet counts ranging from 70,000 to 150,000/μL. Flow cytometric analysis of platelets has shown decreased expression of the GPIb/IX/V complex in a high percentage of affected individuals, and sequencing of the *GPIBA* gene has revealed an Ala156Val mutation in the GP1b in almost all families examined.[69] Functional defects, if any, are minor, so bleeding is not a problem in these individuals. In virtually all respects, the clinical phenotype and the molecular genetics of the condition are essentially identical to what is observed in carriers of the Bernard–Soulier syndrome, an autosomal recessive thrombocytopenia described below. Because there is no bleeding tendency related to the thrombocytopenia, no therapy is required. Nonetheless, recognition of this entity is in the patient's interest, because it will avoid interventions that are potentially harmful, such as platelet transfusions. In addition, genetic counseling is suggested for couples in which both mother and father are affected, because of the possibility of having a child with Bernard–Soulier syndrome.

MACROTHROMBOCYTOPENIA ASSOCIATED WITH VELOCARDIOFACIAL SYNDROME (OMIM 192430) AND DiGEORGE SYNDROME (OMIM 188400)

Patients with the velocardiofacial and DiGeorge syndromes have a host of congenital abnormalities affecting their skeletal, cardiac, endocrine, neurologic, and immune systems.[70,71] Collectively, these disorders are known by the acronym CATCH22 (*c*ardiac *a*bnormality, *T*-cell deficit, *c*left palate, *h*ypocalcemia due to a chromosome *22* deletion).[4,72,73] Mild thrombocytopenia, unassociated with a bleeding diathesis, is frequently observed in affected individuals. Similar to Mediterranean macrothrombocytopenia, the platelet abnormality found in these conditions appears to be due to a deletion in one of the four genes that comprise the von Willebrand receptor locus (*GP1BA*, *GP1BB*, *GP5*, and *GP9*) on chromosome 22q11.[74] Whereas *GP1BA* is affected in the Mediterranean variant, in these cases *GP1BB* is deleted.[74] As of today, thrombocytopenias due to deletions or mutations of *GP5* and *GP9* have not been described; it is possible that mutations in one or both of the other two genes will be identified, causing similar disorders (ie, *GP9* and *GP5*). No therapy is necessary for the thrombocytopenias seen in these patients. Genetic counseling considerations are the same as those for patients with Mediterranean macrothrombocytopenia.

FAMILIAL PLATELET DISORDER WITH ASSOCIATED MYELOID MALIGNANCY (OMIM 601399)

The autosomal dominant thrombocytopenia known as familial platelet disorder with associated myeloid malignancy was first described in 1985.[47,74] Its genetic basis has only recently been deciphered.[75] Patients with this disorder have mild to moderate thrombocytopenia. The platelets appear normal morphologically, but an aspirin-like aggregation defect has been documented, and bleeding times are prolonged. Linkage analysis narrowed the defect to an interval on human chromosome 21q22.1–22.2.22 which greatly assisted in identification of the responsible genetic abnormality; a gene identified as *AML1*, now known as *CBFA2*.[75] *CBFA2* is a hematopoietic transcription factor that plays an important role in regulating cell development. Nonsense mutations, or an intragenic deletion of one *CBFA2* allele, are now known to be responsible for the condition. It is of interest that in mice, similar lesions of *CBFA2* cause a more global disruption of hematopoiesis.[76,77] In humans, the numbers of assayable CFU-MK are diminished, but not the progenitors of other lineages.[75] Why the defect results only in thrombocytopenia in humans is not certain. It is also unclear why these defects predispose patients to developing acute myeloid leukemia.[78] Bleeding in these patients can be treated in the usual manner, but the high likelihood of leukemic transformation has led some investigators to suggest that these patients should undergo bone marrow transplantation.[42] This could be problematic in an affected family because, if unrecognized, a sibling HLA-matched donor might transmit the disease again. At least one case has been reported of a transplant from a sibling in which the donor and recipient subsequently developed donor-derived leukemia.[79]

PARIS–TROUSSEAU SYNDROME (OMIM 188025) AND JACOBSEN SYNDROME (OMIM 147791) MACROTHROMBOCYTOPENIA

The autosomal dominant macrothrombocytopenias Paris–Trousseau and Jacobsen syndromes are associated with deletions of the distal portion of chromosome 11,11q23–24.[78–82] In children with Jacobsen syndrome, in addition to the platelet abnormalities, psychomotor retardation and facial and cardiac abnormalities are also seen.[79] Affected individuals have only a mild bleeding diathesis. Platelets in patients with this disorder are larger than normal and are characterized by giant granules that stain red with Giemsa. Megakaryocytes are increased in the marrow but are dysplastic; micromegakaryocytes with small hypolobulated nuclei are present.[78,81] It is believed that the paucity of larger, more mature cells is due to their spontaneous lysis. Mutations of the Ets family transcription factor gene, *FLI1*, have been implicated in the etiology of Paris–Trousseau thrombocytopenia. This association has been made because of morphologic similarities observed in the megakaryocytes of mouse embryos in which *fli1* has been genetically deleted,[78] and because the *FLI1* gene has been mapped to the region deleted in Paris–Trousseau and Jacobsen syndrome thrombocytopenia. Very recently, Wenger and colleagues reported a female patient with an approximately 10 Mb interstitial deletion involving chromosome 11 and with many of the features of Jacobsen syndrome.[83] The karyotype of the patient was 46,XX,del(11)(q24.1q24.3). The interstitial deletion was found to be in the distal portion of 11q, and included FLI-1 but not JAM-3, a finding that should assist in determining the critical genes involved in these syndromes.

GRAY PLATELET SYNDROME (OMIM 139090)

The gray platelet syndrome is a rare congenital bleeding disorder in which thrombocytopenia is associated with increased platelet size and decreased α-granule content.[79,84,85] It is the latter phenomenon that causes the platelets to appear gray after histochemical staining. The decrease in granule content is not due to an inability to synthesize the granule proteins but rather to an inability to transport and incorporate the proteins into the α granules.[86–88] Examination of patient blood smears will reveal not only gray platelets but also gray polymorphonuclear neutrophils.[89] The granules of the polymorphonuclear neutrophils have decreased or abnormally distributed secretory constituents in a manner analogous to that seen in the platelets. Secondary granules in polymorphonuclear neutrophils are also decreased in number, as assayed by immunoelectron microscopy. Although many affected families demonstrate clear autosomal dominant inheritance, several reports have documented affected children born of apparently healthy parents. Accordingly, a recessive form of this disorder may also exist.[89] The bleeding tendency in this syndrome generally varies from mild to moderate, and no specific treatment is usually needed.[84,90]

Sex-linked forms of gray platelet syndrome have also very recently been recognized by Tubman et al, who identified a family with gray platelet syndrome that segregated as a sex-linked trait.[91] Affected males had a mild bleeding disorder, thrombocytopenia, and large agranular platelets characteristic of the gray platelet syndrome. Obligate female carriers were asymptomatic but had dimorphic platelets on peripheral smear. Associated findings included mild erythrocyte abnormalities in affected males. Linkage analysis revealed a 63 cM region on the X chromosome between markers G10578 and DXS6797 which segregated with the platelet phenotype and included the GATA1 gene. Sequencing of GATA1 revealed a G-to-A mutation at position 759 corresponding to amino acid change Arg216Gln. Interestingly, this mutation has been previously described as a cause of X-linked thrombocytopenia with thalassemia (XLTT) but not of gray platelet syndrome. These investigators hypothesized that XLTT is within a spectrum of disorders constituting the gray platelet syndrome, and further proposed that GATA1 is an upstream regulator of the genes required for platelet α-granule biogenesis. Other formes frustes of this disease have also been reported.[92–94]

AUTOSOMAL RECESSIVE THROMBOCYTOPENIAS

Congenital Amegakaryocytic Thrombocytopenia (OMIM 604498)

Profound thrombocytopenia in an otherwise well newborn (<10,000 platelets/L) should always raise the question of whether the baby has congenital amegakaryocytic thrombocytopenic purpura (CAMT).[95–97] The diagnosis is first entertained when an apparently well newborn develops easy bruising or bleeding soon after birth. Milder forms are sometimes discovered in the course of routine screening examinations. As with any recessive disorder, neither parent will have an abnormality of platelet count or function, and the family history is likely to be negative as well. A bone marrow examination will reveal markedly diminished or absent megakaryocytes. CAMT is a progressive disorder, so even children with milder forms will develop worsening thrombocytopenia, as well as leukopenia and anemia, toward the end of the first decade of life. By the second decade, pancytopenia is likely to have developed. Other marrow failure syndromes, such as Fanconi anemia, aplastic anemia, or dyskeratosis congenita might be confused with CAMT.

The differential diagnosis for severe congenital thrombocytopenia includes thrombocytopenia with absent radii syndrome (TAR)[98] and Wiskott–Aldrich syndrome (WAS). These conditions can often be distinguished from CAMT on the basis of associated skeletal hypoplasia of the arms, in the case of TAR, and microthrombocytes, in the case of WAS. Neonatal alloimmune thrombocytopenia, which may present with profound thrombocytopenia due to the transfer of maternally derived antiplatelet antibodies at the time of delivery, should also be included in the differential diagnosis.[9] Neonatal alloimmune thrombocytopenia is most often due to the maternal absence of an epitope on GPIIIA (PlA1).[99] Typically, alloimmune thrombo-

cytopenias are self-limited and resolve as the maternal antibodies degrade. In addition, these children will have normal numbers of megakaryocytes in their bone marrows.

The molecular lesions responsible for CAMT have been identified as composite mutations affecting both alleles of the thrombopoietin receptor gene, c-*MPL* (chromosome 1p34).[100–103] HOXA11 mutations have also recently been described.[104] The definitive diagnosis of CAMT is based on identification of one of these mutations. Many *MPL* mutations have been described in CAMT patients. New mutations are recognized with some frequency.[105] They are located in exons 2, 3, 4, 5, 6, 10, and 12 and a splice-junction mutation of intron 10. Some of these mutations, such as nonsense or frameshift types, will completely abrogate receptor function. Single amino acid substitutions may allow some receptor function to remain. The severity of the disease correlates directly with the degree of receptor impairment. The evolution of CAMT into complete marrow failure can be explained by the recognition that, in addition to being required for megakaryocyte maturation, thrombopoietin, and of course its receptor, are required for maintenance of the stem cell compartment.[9,106] Accordingly, even milder forms of CAMT will evolve, because minimal MpL function is apparently insufficient to maintain the integrity of the stem cell compartment.[9]

Treatment options for children with CAMT are limited. For acute bleeding episodes, platelet transfusions are indicated and effective. Over time, however, platelet alloimmunization is likely to be a problem. For this reason, and because this is ultimately a disease of stem cells, allogeneic stem cell transplantation is the only potentially curative, long-term solution.[107] The disease would clearly be a good candidate for genetic therapies that would either replace or correct the defective gene.

Thrombocytopenia With Absent RADII Syndrome (OMIM 274000)

Thrombocytopenia with absent radii (TAR) syndrome is typically an autosomal recessive disorder, though other forms of transmission have been recorded, including dominant transmission from an affected parent to offspring (Chapter 28).[108,109] In one recent report, all of 30 patients examined manifested a common interstitial microdeletion of 200 kb on chromosome 1q21.1, which was detected using microarray-based comparative genomic hybridization. Analysis of the parents revealed that the deletion occurred de novo in 25% of affected individuals. Inheritance of the deletion along the maternal as well as the paternal line was also observed. Because the deletion was not detected in a cohort of control individuals, it was argued that this microdeletion could play an important role in the pathogenesis of TAR syndrome. It was further hypothesized that TAR syndrome is not only associated with a deletion on chromosome 1q21.1 but that the phenotype develops only in the presence of an additional, as-yet-unknown modifier (mTAR).[110]

Patients typically are of short stature, but the syndrome's most striking physical manifestation is a pathognomonic absence of radii with intact thumbs (Fig. 32–6). In affected individuals, muscles that normally attach to the radius are inserted instead onto the carpal bones of the hands. Other skeletal malformations, including absence or malformation of the ulnar bones and abnormalities of the humerus, shoulder joint, and lower extremities, are also frequent. Cardiac malformations, in particular the tetralogy of Fallot and atrial septal defects, occur in one-third of patients. Mental retardation has also been reported in approximately 7% of affected individuals, presumably on the basis of cerebral hemorrhage. Single case reports of TAR-associated hypoplasia of the cerebellum, horseshoe kidney, and both of the abnormalities have been reported.[111] Symptomatic milk allergy has been observed frequently and may cause severe bloody diarrhea.[112]

Thrombocytopenia of TAR patients is most severe perinatally, with counts ranging from 15,000 to 30,000/mm^3. The low platelet counts may be further exacerbated by any significant intercurrent stress, including infection, surgery, or even the gastrointestinal disturbances that accompany milk allergies. Such episodes are often accompanied by a myeloid leukemoid reaction. Eosinophilia is noted in approximately 50% of patients and is particularly common, not surprisingly, in patients with milk allergies. Anemia related to bleeding, or hemolysis, is typical in the first year of life. Interestingly, the thrombocytopenia improves with age, so that children who survive the first year or two of life are believed to have normal life spans.[109,113]

A bone marrow aspirate will show decreased or absent megakaryocytes. Those megakaryocytes that are present are often small, basophilic, and vacuolated. Erythroid hyperplasia is sometimes observed, presumably in anemic patients. Recent studies on the megakaryocyte progenitor cell compartment and c-*MPL* expression in six patients have found CFU-MK numbers to be markedly reduced and very primitive progenitor cells to have increased, suggesting an inability

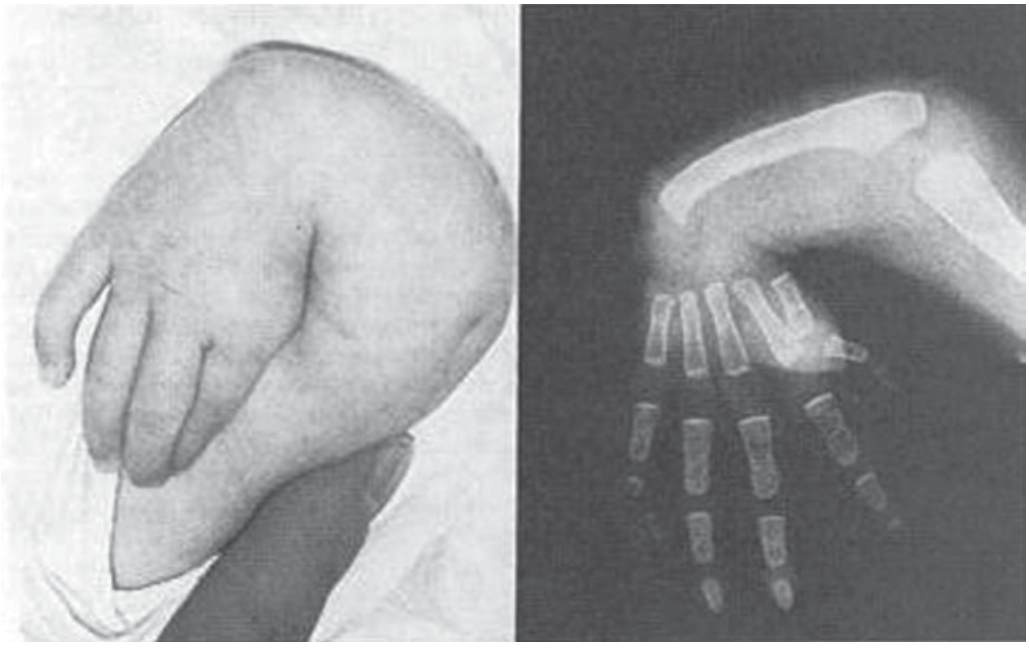

Figure 32–6 Thrombocytopenia with absent radii syndrome. *Left*, A typical upper extremity deformity. *Right*, Radiograph showing complete absence of the radius. *(Adapted from Hoffbrand A, Pettit J: Sandoz Atlas of Clinical Hematology. London, Gower Medical, 1988.)*

of primitive cells to differentiate into the megakaryocyte lineage.[114] This was found not to be secondary to c-*MPL* genetic abnormalities in any of the patients, as no mutation or rearrangement in the c-*MPL* gene, or its promoter, was found by Southern blotting or gene sequencing. Western blot and RNA analyses revealed decreased levels of *MPL* RNA and protein in the platelets of these same patients compared with normal control subjects, but other studies have found normal *MPL* receptor level expression and structure in TAR patients.[115] Abnormalities in thrombopoietin signaling in TAR patients have been suggested.[115]

The molecular cause of TAR remains unknown, as does the link between osteodysgenesis and thrombocytopenia. Recently, however, an intriguing link between these two seemingly disparate abnormalities was uncovered. The homeobox (HOX) transcription factors have long been considered candidate genes for TAR syndrome because of their well-established function in limb development.[116] In support of the possible involvement of the *HOX* genes, two families were recently reported with radial-ulnar synostosis and amegakaryocytic thrombocytopenia (OMIM 605432) caused by a mutation of the *HOXA11* gene.[98] However, the autosomal dominant inheritance pattern, mild forearm deformities of the patients, and persistence of severe thrombocytopenia all distinguished this condition from a typical TAR syndrome.[98] Complete sequencing of the coding regions of *HOXA10*, *HOXA11*, and *HOXD11* failed to detect any abnormalities in ten individuals with TAR syndrome.[117]

The diagnosis of TAR is suspected when the typical skeletal malformations are encountered. Prenatal diagnosis is possible using ultrasonography, skeletal radiography, and fetal blood sampling.[115,118] TAR is distinguished from Fanconi syndrome by the presence of the thumbs and by the lack of genetic instability. There is no specific treatment for TAR except for platelet transfusions when necessary. Steroids, splenectomy, or intravenous IgG treatments are usually ineffective.[113,119] Orthopedic surgery to correct skeletal defects is best postponed during the first few years of life. On rare occasions, thrombocytopenia may first manifest itself in adulthood. Splenectomy has been reported to be useful under such circumstances.[120] In the unusual case in which the disease does not remit, stem cell transplantation may be considered for children who suffer from recurrent significant bleeding episodes.[121]

Bernard–Soulier Syndrome (OMIM 231200)

Bernard–Soulier syndrome (BSS) is characterized by mild to moderate, though occasionally severe, macrothrombocytopenia. Patients with BSS most often have only a mild bleeding diathesis that requires no treatment.[122] Others may have a significant bleeding diathesis, often out of proportion to the thrombocytopenia alone, because of the functional defects displayed by BSS platelets.[119] The functional defect of BSS platelets is due to decreased or absent expression of the von Willebrand factor (vWF) receptor.[123] WF receptor consists of four polypeptide chains: GP1b-a, GP1b-b, GPV, and GPIX. Mutation of the gene encoding GP1b-a (*GP1BA*) is the most common in BSS. Mutant GP1b-b has also been reported.[74,124] Recently, a previously reported A-to-G mutation in nucleotide 1826 of the *GPIX* gene was found in several German patients who had been misdiagnosed with ITP. This mutation results in an Asn-to-Ser substitution. Because this mutation had been described previously, it is now the most commonly identified molecular defect causing BSS in Caucasian subjects.[125]

Why a seemingly isolated defect in the vWF receptor would lead to macrothrombocytopenia remains unclear. Although shortened platelet survival has also been reported in BSS patients,[126,127] many others are reported to have normal platelet survival, suggesting that production defects contribute to the thrombocytopenia in some patients. A candidate mechanism for disordered thrombopoiesis would be dysfunctional internal membrane formation.[128] The role of this abnormality in causing large platelets is uncertain. It is also conceivable that deficiencies or mutations of the GPIb-IX complex may be important in the formation of platelet territories.[129]

The presence of large platelets in decreased numbers may at times suggest a diagnosis of ITP. In patients who bleed out of proportion to their thrombocytopenia, or who do not respond to the usual ITP treatments, platelet function studies will suggest the correct diagnosis. Significant bleeding is usually managed by platelet transfusions, but success with the use of recombinant factor VIIa has also been reported.[130] For particularly difficult cases, with severe recurrent bleeding, hematopoietic stem cell transplantation has also been employed.[131]

X-LINKED DISORDERS

Wiskott–Aldrich Syndrome and X-Linked Thrombocytopenia (OMIM 301000 and 313900)

The Wiskott–Aldrich syndrome is a rare X-linked disorder characterized by microthrombocytopenia, immunodeficiency, and eczema.[132,133] The platelets of WAS patients, and those with related disorders, are reduced in number and size. Typically, platelet counts are in the 5000 to 50,000 μL range, with a volume approximately 50% that of normal platelets (MPV 3.5–5.0 fL). It has been estimated that the combined reduction in platelet volume and number results in an effective platelet mass approximately 1% of that found in normal individuals. Biochemical abnormalities are also present that variably compromise platelet function.[134–137] An abnormality of GPIb, for example, has been observed in some, but not all, patients.[138,139] The protease calpain is reduced in the platelets of WAS patients relative to normal subjects as well, although, interestingly, calpain levels are normal in affected lymphocytes.[140] It has been speculated that decreased platelet calpain leads to inappropriate platelet stimulation and subsequent increased clearance from the circulation.[132] WAS patients will have a rise in their platelet counts after a splenectomy. Nevertheless, whereas platelet survival time is approximately half of normal,[141] this finding has proved insufficient to explain the degree of thrombocytopenia seen in all patients. In this regard, platelet turnover has been estimated to be approximately 25% of normal, and the mass of megakaryocyte cytoplasm has been found to be normal.[142] Therefore, ineffective platelet production also makes an important contribution to the thrombocytopenia observed in WAS patients.[136] The immune defects are due to dysfunctional T lymphocytes. The T cells of WAS patients manifest decreased responsiveness to mitogenic stimuli. Ultrastructural and biochemical defects have been noted in the T cells of WAS patients, including a decrease in the surface microvilli, a decrease in cell surface sialoglycoproteins, and abnormal glycosyltransferases.[133,143]

The gene involved in the pathogenesis of the syndrome has been localized to the short arm of the X chromosome (Xp11.22).[144] The gene, *WAS*, is composed of 12 exons and encodes a protein (WASP) of 502 amino acids.[145] WASP (WAS protein) contains a number of functional domains that are believed to provide a critical link between the cell's cytoskeleton and signal transduction pathways.[146] For example, WASP and several related proteins are involved in the reorganization of the actin cytoskeleton by activating Arp2/3-mediated actin polymerization.[147] This function is controlled by the small GTPase Cdc42, which regulates the autoinhibitory loop formation of WASP. In addition, WASP is involved in cytoplasmic signaling through its interaction with a variety of adaptor molecules. There are src homology 3 (SH3) domains for interacting with GTPases, the Pleckstrin homology domain for membrane phospholipid interactions, Cofilin and Verprolin domains for polarized cytoskeletal elements, and the unique WASP-interacting protein.[148]

How WASP mutations lead to the development of microthrombocytes is still not understood. Megakaryocytes from patients with WAS are capable of forming proplatelet processes and platelets of normal sizes in vitro.[149] Analysis of the X-chromosome inactivation pattern in female heterozygotes (who have no abnormalities) has revealed nonrandom inactivation of WASP in multiple hematopoietic lineages, including $CD34^+$ progenitors, suggesting that WASP

plays a crucial function in hematopoietic cell development.[150] Quite recently, Sabri and colleagues have reported mechanistic studies that might shed light on this phenomenon. Using a murine model, these workers identified a critical role for WASP during murine platelet biogenesis. By electron microscopy, WASP-deficient MKs appeared to have shed platelets ectopically within the bone marrow space. WASP-deficient megakaryocytes (MKs) also displayed defects in response to fibrillar collagen I in vitro, the major matrix component of bone. These included a loss of normal $\alpha_2\beta_1$ integrin-mediated inhibition of proplatelet formation, a marked abrogation of SDF-1-induced chemotactic migration of $CD41^+$ MKs adherent to fibrillar collagen I, and an almost complete lack of actin-rich podosomes, normally induced by interaction between fibrillar collagen I and its receptors GPVI or $\alpha_2\beta_1$ integrin. On the basis of these results, these investigators postulated that WASP plays an important role in platelet biogenesis, at least in mice, and might also be important in explaining the platelet abnormalities characteristic of patients with WAS.[151] In addition to these studies, it has also been reported that gene silencing-induced loss of PIP4Kα impaired demarcation membrane system development, actin fiber assembly, as well as enlargement of megakaryocyte size. On this basis, they suggested that a perturbation of the signaling pathway employing PI-4,5-P(2) might contribute to the abnormal platelets found in Wiskott–Aldrich syndromes.[20]

There are a variety of mutations involving the WASP gene, leading to either absent or mutated protein.[141,142,144,145,152] To a large extent, the phenotypic variation of WAS can be explained by the location and nature of the genetic mutations.[153] Frameshifts, nonsense mutations, and large deletions generally cause classic WAS, whereas single amino acid substitutions, especially of exons 1 to 3, cause the milder X-linked thrombocytopenia. When WASP is completely absent, the disease is more severe likely for the reasons just discussed above. When WASP is present at even low-moderate levels, the disease is frequently milder.[153]

The diagnosis of WAS should be considered in any male child with thrombocytopenia and immunodeficiency.[133] Classic WAS is usually recognized in the first year of life as a result of the affected child's hemorrhagic tendencies, typified by easy bruising, epistaxis, bloody diarrhea, and even intracranial hemorrhage. Intercurrent infections, usually bacterial in origin, are also typical. The classic triad of infections, thrombocytopenia, and eczema is only seen in approximately 25% of patients at diagnosis, perhaps because infections and eczema, unlike the thrombocytopenia, are not present at birth. The latter are usually problematic after the first 6 to 12 months of life.[154] One-third of cases have no family history. In such instances, it has been suggested that confirmatory sequencing of the *WAS* gene be carried out.[42] Beyond the complications of infections and bleeding, there is a significant risk of the development of a malignancy. These are most often lymphoid, and patients with autoimmune manifestations of this disease are at highest risk.[154] Acute myeloid leukemia may also complicate this syndrome, as well as other malignancies that are not hematopoietic in origin.[155] Enlarged lymph nodes and hepatosplenomegaly resulting from lymphoid hyperplasia occur commonly and must be distinguished from the development of a lymphoid malignancy. Fifty percent of the deaths associated with this syndrome are infectious, 25% related to hemorrhage, and 5% related to malignancy.[156] Life expectancy is usually less than 10 years.

The thrombocytopenia of WAS has been reported to respond to anti-CD20 monoclonal antibody treatment, though relapse rates were as high as 80%. For that reason, multiple treatment courses would likely be required.[157] Such treatments will not prevent the development of leukemia or other marrow failure syndromes. Accordingly, as with many disorders affecting stem cells, hematopoietic stem cell transplantation, either in the form of an HLA-matched marrow or cord blood donor is probably the most effective treatment for WAS.[146,158–161] Corticosteroids are not indicated, because they do not ameliorate the thrombocytopenia and only contribute to the propensity for infection. Some recent studies suggest that patients who exhibit significant bleeding may benefit from splenectomy.[158,162–164] Median survival times in 39 untransplanted, splenectomized patients have been reported to be 25 years, but many patients are now living into their third and fourth decades, thanks primarily to advances in support therapy, in particular antibiotics and intravenous gamma globulin.[158,162]

Wiskott–Aldrich Syndrome Variants and Other X-Linked Recessive Thrombocytopenias

Girls have occasionally been noted to have microthrombocytes, with or without other components of WAS.[165] In one such patient, a spontaneous mutation in one *WAS* allele, coupled with skewed X inactivation among hematopoietic cells, was shown to be responsible.[166] However, in other families more than one female has been affected, and no *WAS* gene mutations could be found.[167] A mutation in a gene that encodes a WASP interacting protein might conceivably cause a similar disease phenotype.

A number of families with an isolated X-linked thrombocytopenia, or with a WAS-like condition consisting of variable immune deficiencies and eczema, have been described.[168,169] Family studies of patients with WAS-like disorders have suggested both autosomal recessive and autosomal dominant modes of inheritance.[165,167] The thrombocytopenia usually is mild in these families, and most cases have been discovered incidentally. Marrow megakaryocytes are normal or increased.[149,170,171] As noted earlier, in those few patients in whom thrombocytopenia was severe and bleeding was a significant clinical issue, splenectomy was found to be useful. Because it is now felt that WAS and, aside from the rare exceptions noted earlier, most of the X-linked isolated thrombocytopenias are caused by *WAS* mutations, sequencing of the gene should prove a reliable molecular diagnostic tool. At institutions where such molecular diagnostics are not available, a diminished lymphocyte mitogenic response to periodate may be useful as a diagnostic test, because WAS variants as well as classic WAS have such defects in lymphocyte function.[172] This fact could also prove useful for distinguishing variant WAS from other congenital thrombocytopenias.

GATA1 Mutation: A Recently Recognized X-Linked Thrombocytopenia (OMIM 305371)

A thrombocytopenic disorder accompanied by mild to moderate dyserythropoiesis and an X-linked pattern of inheritance was recently described in five separate families.[173–177] This disorder was distinguishable from WAS by the fact that the platelets were of normal to large size, and none of the affected individuals developed eczema, immunodeficiency, hematologic malignancies, or aplastic anemia over time. The degree of thrombocytopenia was moderate to severe (10,000–40,000/L) and platelet function defects were detectable.[174] The associated bleeding diathesis was often severe. In contrast, the anemia was of variable severity. The bone marrow of these individuals was typically hypercellular, with dysplastic erythropoiesis and megakaryopoiesis.[176]

Mutations in the *GATA1* gene, which encodes a transcription factor required for normal megakaryocyte and erythroid development, has been found in each of the five families. The mutations are clustered in the highly conserved N-zinc finger domain. They result in single amino acid substitutions at four positions (Val205Met,[65] Gly208Ser,[68] Arg216Gly,[69] Asp218Gly,[66] and Asp218Tyr[69]). Four of these mutations disrupt the ability of *GATA1* to associate with a known cofactor, *FOG1* (friend of *GATA1*).[178,179] Interestingly, the severity of the thrombocytopenia correlates with the degree to which the *GATA1–FOG1* interaction is impaired.[166,174,176] In contrast, Arg-216Gly results in impaired binding of *GATA1* to palindromic DNA-binding sites.[177] This mutation also causes a moderate globin chain imbalance (thalassemia).[180] *FOG1* gene mutations, which would be expected to yield a similar clinical phenotype, have yet to be described. More disruptive *GATA1* mutations are unlikely to be compatible

with survival of the embryo, because the gene is required for normal hematopoietic cell development.

GATA1 mutations should now be suspected in male children with severe thrombocytopenia, normal to large platelets, and absence of immunodeficiency and eczema. Mild anemia and a hypercellular bone marrow with dyserythropoiesis and megakaryocytopoiesis are supportive of the diagnosis as well. *GATA1* gene sequencing, available only in a specialized reference laboratory, would be required to confirm this diagnosis. Bleeding episodes in these patients can be treated with platelet transfusions, which, for reasons already discussed, should be kept to the minimum necessary to control this problem. If life-threatening thrombocytopenia or anemia intervenes, stem cell transplantation is a potentially curative option. The development of an effective gene therapy, though likely a long way off, would be a very acceptable alternative to hematopoietic stem cell transplant.

ACQUIRED THROMBOCYTOPENIAS DUE TO INEFFECTIVE THROMBOPOIESIS

As is true for the congenital thrombocytopenias, acquired thrombocytopenia can be caused by a failure of either megakaryocytopoiesis or thrombopoiesis. Of these two possibilities, ineffective thrombopoiesis is the more likely cause, as pure megakaryocyte aplasia or hypoplasia is quite rare. Indeed, thrombocytopenia secondary to decreased marrow megakaryocytes is much more likely to be a prodrome of aplastic anemia, or an early myelodysplastic syndrome. Clues to these conditions can be found in the marrow, where often subtle abnormalities of other hematopoietic lineages, such as macrocytosis or dyserythropoiesis, can be observed.[181]

SELECTIVE MEGAKARYOCYTE APLASIA

Acquired selective amegakaryocytic thrombocytopenia is quite rare. It is almost always due to an autoimmune mechanism, either antibody or cell mediated. Autoantibodies reacting with megakaryocytes or their progenitor cells, presumably leading to their destruction, have been described.[182] Antibodies directed to cytokines that regulate megakaryocyte development, in particular thrombopoietin, might also play a role in the biogenesis of such disorders. An unusual case of cyclic amegakaryocytic thrombocytopenia due to an antibody to granulocyte–macrophage colony-stimulating factor (GM-CSF) was documented in one patient. Cases of cell-mediated suppression of megakaryocytopoiesis leading to a complete selective megakaryocyte aplasia have also been described.[183] In these cases, suppression was shown in one case to be due to autoreactive T lymphocytes, whereas a macrophage-derived "factor" was implicated in the other. In the latter case, suppression was shown to be specific for megakaryocytes, because no significant effect on blast-forming units–erythrocyte (BFU-E) or colony-forming units–erythrocyte (CFU-E) derived colony formation by autologous marrow mononuclear cells was reported.

Patients in whom an autoimmune mechanism is operative may respond to treatment with cyclosporine and antithymocyte globulin, achieving durable remissions.[184] Cytotoxic antibodies directed toward the CFU-MK may be treated with corticosteroids, plasmapheresis, intravenous IgG, danazol, cyclosporine, or cyclophosphamide.[185] In a patient in whom an IgG antibody was found to be blocking GM-CSF action, a complete response to cyclophosphamide was observed.[186] Patients with T-cell–mediated inhibition of megakaryocytopoiesis may respond to antithymocyte globulin, cyclosporine, or hematopoietic growth factors.[185] If a particular drug or toxin exposure is believed to be responsible, for example ethanol or a thiazide diuretic, then withdrawal of the offending agent is obviously indicated. If the cause is viral, intravenous IgG or anti-human immunodeficiency virus (HIV) therapies are indicated.[185] Despite the various etiologies of ineffective thrombopoiesis, immunosuppressive therapy was found to be effective in 8 of 30 patients in one series.[187] Therefore, although worth trying, most patients do not respond to this form of therapy, and for these individuals, hematopoietic stem cell transfer remains an option. Treatment with intensive immunosuppressive therapy may not prevent progression to aplastic anemia.[188]

INFECTION

Many infectious diseases are associated with thrombocytopenia, and it is likely that infection is the greatest noniatrogenic cause of ineffective platelet production.[189] Infectious agents associated with decreased platelet counts include mycoplasma,[107] mycobacteria,[190] ehrlichiosis,[191] and malaria.[192] In these disorders, the cause of the thrombocytopenia is believed to be diminished platelet production,[193] although immune-mediated thrombocytopenia has also been described in some patients.[190]

Viral infections are by far the most common infectious agents associated with thrombocytopenia due to ineffective megakaryocyte or platelet production. Thrombocytopenia has been reported in cases of mumps, rubella, measles, varicella, cytomegalovirus, infectious mononucleosis, chickenpox, dengue and other hemorrhagic fevers, hepatitis, and parvovirus infections.[180,194–196] Live measles virus vaccination can also induce thrombocytopenia due to decreased production.[197] The mechanism responsible for viral suppression of platelet counts is not completely clear. It is known that megakaryocytes are capable of being infected by a variety of viruses. Infected cells may appear dysplastic, with inclusion bodies, vacuoles, or degenerating nuclei. Naked megakaryocyte nuclei may be seen in particular after HIV infection.[193] That such cytopathic cells might have trouble producing platelets is not difficult to imagine.

Perhaps the best studied virally induced thrombocytopenia is that associated with HIV infection.[198] Mild to moderate reduction in platelet counts are quite common in patients with this disease. In a large study (738 patients) of HIV-positive patients with hemophilia, the cumulative frequency of thrombocytopenia 6 years after seroconversion was 16% for children and 18% for adults. At 10 years, the frequency increased to 27% in children and 43% in adults.[199] In another study, the frequency of thrombocytopenia was 16% among 103 homosexual men and 37% among 182 intravenous drug users with a new diagnosis of HIV infection.[200] Thrombocytopenia was also reported to be relatively common in HIV-negative homosexual men (3%) and intravenous drug users (9%). It was speculated that this might be due to the high rates of hepatitis in these patient groups.[200] Except for patients who acquire HIV in the background of hemophilia, bleeding secondary to thrombocytopenia is unusual, as the counts are rarely less than 50,000/μL. Thrombocytopenia may precede frank immunodeficiency, but does correlate with viral load and depletion of the CD4 T-cell population.[185,201]

The principal cause of thrombocytopenia appears to vary with the stage of disease. A retrospective study of 85 patients with HIV and thrombocytopenia suggested that in the early stages of infection, platelet destruction is predominant, whereas in patients with full-blown acquired immunodeficiency syndrome, thrombocytopenia is more often due to a production defect.[202,203] Thrombocytopenia due to platelet production abnormalities may be related directly to an HIV infection, to adverse effects of drug therapy, or to secondary malignancy or myelodysplasia. Platelet kinetic studies have shown that patients infected with HIV have a moderate reduction in platelet survival, but all have decreased platelet production regardless of the degree of thrombocytopenia.[202,204] On the basis of the finding of HIV mRNA and p24 antigen in megakaryocytic cytoplasm, HIV has been shown to infect megakaryocytes directly, as evidenced by finding HIV mRNA and p24 antigen in megakaryocyte cytoplasm.[205–207] The portal of entry might be through megakaryocyte surface CD4,[208,209] but more recent studies suggest that CXCR4, which is expressed on megakaryocytes[210] and is a critical coreceptor for viral uptake, is more likely involved.[211] In these studies, infection with HIV-1 Env-pseudotyped luciferase reporter viruses indicated that X4 Env

(CXCR4-using) pseudotypes infected megakaryocytic cells whereas R5 Env (CCR5-using) pseudotypes did not.

Examination of a bone marrow aspirate and biopsy specimens may be required to assess whether infiltration by granulomatous infection or a malignancy is contributing to, or causing, the thrombocytopenia in an HIV patient (Table 32–3). Assuming no other obvious cause of the thrombocytopenia, and the presence of typical megakaryocytic morphologic abnormalities, antiretroviral therapy is the principal treatment. Zidovudine was the mainstay in the past,[201] but current combination antiretroviral regimens will likely be more effective in increasing platelet counts as well as enhancing CD4 cell counts and reducing HIV viral loads.[197,212,213] For patients with severe and/or symptomatic thrombocytopenia, ITP regimens may well be effective. These include prednisone (1 mg/kg per day) or short courses of dexamethasone.[198] IVIgG may be effective in low weekly doses (0.04 g/kg per week),[214] and anti-D has been used extensively in these patients.[198] Splenectomy is quite effective therapy when the above therapies are either ineffective or contraindicated, and it appears to have no adverse effect on HIV progression.[215]

CHEMOTHERAPY AND IRRADIATION

Chemotherapy and irradiation reliably damage bone marrow in a dose-dependent fashion. Megakaryocytes and their progenitors seem to be particularly sensitive to the effects of these agents. As a result, thrombocytopenia is one of the most frequent adverse effects of total body irradiation[216] and chemotherapy. Allogeneic or autologous marrow transplantation is often complicated by prolonged thrombocytopenia, which may persist long after restoration of neutrophil and red blood cell counts. Transplantation of umbilical cord stem cells is also associated with delayed platelet recovery. In one study of 39 pediatric patients receiving such transplants, the median time to platelet count recovery was 49 days (range, 15–117 days).[217] The explanation for the tardiness of platelet recovery in these instances is not always clear, but ineffective thrombopoiesis has been shown to be important in at least some cases.[218] Various strategies to ameliorate this problem have been tried, including the use of peripheral blood "stem cells," which may lead to a faster rate of platelet recovery when compared with marrow transplantation. More recently, attempts have been made to expand megakaryocyte progenitor cells, either with a recombinant form of thrombopoietin[219] or other cytokines.[220] The clinical utility of this approach, or the simple administration of recombinant thrombopoietin after transplantation, remains uncertain[221] but might eventually prove useful.[222] Accordingly, posttransplantation thrombocytopenia remains a problem.[223]

Isolated thrombocytopenia with decreased megakaryocytes has been reported after chemotherapy for acute myeloid leukemia. Cyclosporine was reported to augment the platelet count in such patients.[224] Recombinant thrombopoietin has not been shown to be useful in this setting and appears to induce marrow changes suggestive of a myeloproliferative disorder, which is reversed when the thrombopoietin is discontinued.[225]

Alkylating agents in general produce more prolonged thrombocytopenia than antimetabolites. It has been claimed that some alkylating agents spare megakaryocytes (eg, cyclophosphamide), but this is a relative phenomenon. Agents such as busulfan, the nitrosoureas, or platinum may cause cumulative damage of the more primitive progenitor cells. Other chemotherapeutic agents, such as the vinca alkaloids, may not decrease the platelet count significantly.

Potential mechanisms for the relative sparing of platelets production by certain chemotherapeutic regimens have been investigated.[226] In one study, for example, potential platelet sparing mechanisms of chemotherapy regimens containing paclitaxel and carboplatin has been explored by examining (a) normal donor and chemotherapy patient-derived erythroid (BFU-E), myeloid (CFU-GM), and megakaryocyte (CFU-MK) progenitor cell proliferation in vitro; (b) P-glycoprotein protein and glutathione *S*-transferase (GST) messenger RNA expression; (c) serum thrombopoietin, stem cell factor, interleukins (IL)-6, IL-11, IL-1b, IL-8, and tumor necrosis factor-α levels in patients treated with paclitaxel and carboplatin; and (d) stromal cell production of thrombopoietin and stem cell factor after paclitaxel and carboplatin exposure. It was found that CFU-MK was more resistant to paclitaxel alone, or in combination with carboplatin, than CFU-GM and BFU-E. Although all progenitors expressed P-glycoprotein protein and GST mRNA, verapamil treatment significantly, and selectively, increased the toxicity of paclitaxel and carboplatin to CFU-MK, suggesting an important role for P-glycoprotein in megakaryocyte drug resistance. Compared with normal controls, serum thrombopoietin levels in patients receiving paclitaxel and carboplatin were significantly elevated 5 hours after infusion and remained elevated at day 7 (287% ± 63% increase; $P < 0.001$). Marrow stroma was shown to be the likely source of this thrombopoietin. It was concluded that P-glycoprotein-mediated efflux of paclitaxel, and perhaps GST-mediated detoxification of carboplatin, results in relative sparing of CFU-MK, which may then respond to locally high levels of stromal cell-derived thrombopoietin. The confluence of these events was hypothesized to bring about the platelet-sparing phenomenon observed in patients treated with this form of combination chemotherapy.

For patients who suffer from severe or prolonged thrombocytopenia, reducing the intensity of the chemotherapy is the most appropriate approach to management. It had been anticipated that the use of recombinant thrombopoietin might significantly ameliorate this problem, but unfortunately this has not yet been demonstrated.[227] The formation of antibodies to a thrombopoietin derivative, with resulting profound thrombocytopenia, has significantly slowed clinical investigations of this cytokine.[228] Administration of the compound intravenously instead of subcutaneously might avoid at least some of this immunogenicity observed.[227] A number of other cytokines have also been reported to raise platelet counts in this setting, including IL-1, IL-3, IL-6, and IL-11, but most are no longer available and their clinical utility was not clearly demonstrated.[229–235] Only IL-11 is currently approved for the treatment of thrombocytopenia following chemotherapy. Newer thrombopoietin mimetic drugs have recently entered clinical trial. It is thought that they will be less immunogenic, and in disorders such as ITP they appear to have activity.[236] Whether they will be of help in patients with impaired thrombopoiesis is undetermined but this will no doubt be evaluated in the near future.

At the present time, supportive therapy with platelet transfusions and drugs such as ε-aminocaproic acid for patients who have become refractory to platelet transfusions remain the mainstays of therapy. Amifostine, a phosphorylated aminothiol agent used primarily in the treatment of myelodysplastic syndromes, has been reported to have cytoprotectant value and to ameliorate the neutropenia and thrombocytopenia in patients being irradiated or receiving various types of chemotherapy in a phase III study.[237] Nevertheless, differences in the degrees of thrombocytopenia and neutropenia were not dramatic, and the investigators suggested that confirmatory studies needed to be carried out.

NUTRITIONAL DEFICIENCIES

Thrombocytopenia of various degrees can be observed in patients with either folate or vitamin B_{12} deficiency.[238–240] In some cases, it

can be severe.[241,242] The mechanism of thrombocytopenia is ineffective platelet production.[11] Megakaryocyte numbers are normal or increased in the marrow, and platelet survival is normal or slightly shortened.[243] Vitamin B_{12} deficiency was reported to cause a case of amegakaryocytic thrombocytopenia.[244] Folate deficiency is frequently associated with ethanol abuse, and the etiology of the thrombocytopenia in patients who abuse ethanol is often complex.

Examination of a peripheral blood smear will typically show macrocytosis and hypersegmented neutrophils in addition to thrombocytopenia. The bone marrow often, but not always, shows megaloblastic changes in the erythroid and myeloid lineages.[245] Megakaryocytes are normal in number. Some may appear large, and in some cells multiple disconnected nuclear lobulations have been described. Often, however, distinctive morphologic abnormalities of the megakaryocytes are not seen. Rapid recovery of the platelet count can be achieved with administration of the appropriate vitamin.

IRON DEFICIENCY

Patients with iron deficiency typically exhibit thrombocytosis, but rare patients may become thrombocytopenic.[246] In some instances, decreased megakaryocytes are seen in the marrow,[247] but in a very recent study of six children with severe iron deficiencies when bone marrow examinations were performed in three patients, all showed increased numbers of megakaryocytes. After treatment with therapeutic doses of oral iron, each of the patients showed rapid increases in their platelet counts. The increased numbers of megakaryocytes and the extremely rapid increase in platelet counts after initiation of iron therapy suggested an essential role for iron in a late stage of thrombopoiesis.[248] Curiously, thrombocytopenia has been caused by iron therapy in a patient with severe iron deficiency. It was suggested, but not addressed experimentally, that the profound anemia caused preferential development of erythroid cells with a consequent decrease in megakaryocytes because they share a common progenitor.[249]

MARROW INFILTRATION

It is not rare for marrow infiltrative diseases of any type to cause ineffective hematopoiesis. Blood cell production disorders are commonly observed when the marrow is involved with metastatic cancer, lymphoma, or leukemia. Table 32–3 categorizes the infiltrative processes associated with thrombocytopenia. Physical replacement of marrow is the cause of the thrombocytopenia in many cases; it is also possible that inhibitory factors produced by the infiltrating cells are toxic to the cells of the megakaryocytic lineage or interfere with normal regulatory mechanisms. The diagnosis of infiltrative disease is made by marrow examination, although diagnostic clues are usually provided by history, physical examination, and a leukoerythroblastic blood smear. The marrow shows decreased megakaryocytes, which may be larger than normal because of a compensatory physiologic response to the thrombocytopenia. The treatment approach is specific to the infiltrative process.

ETHANOL-RELATED DISORDERS

Ethanol abuse is very commonly associated with thrombocytopenia, which may result from several different mechanisms.[240,250–255] These include, most commonly, increased splenic pooling as a result of portal hypertension and ineffective production related to folate deficiency (which may lead to severe thrombocytopenia). Ethanol itself can be directly toxic to the marrow.[253,256,257] In vitro studies have shown that alcohol concentrations achievable in vivo inhibit megakaryocyte maturation but do not inhibit CFU-MK.[253,256] Megakaryocyte numbers usually are normal, but markedly decreased megakaryocytes have been observed.[253] In one such case, labeling with platelet-specific antibodies demonstrated that numerous, small, unidentifiable cells were immature megakaryocytes.[253] Rarely, marrow panhypoplasia has been observed in association with alcohol ingestion.[257] Anemia and macrocytosis accompanied by megaloblastic changes and ringed sideroblasts in the erythroid marrow are typically observed in the marrows of patients who abuse ethanol. The severity of the anemia shows no correlation with the thrombocytopenia. Treatment consists of withdrawal of ethanol and administration of a normal diet. Recovery of the platelet count, often with a rebound thrombocytosis, usually occurs within 2 weeks.

OTHER DRUG-RELATED DISORDERS

A variety of drugs and toxins have been implicated in isolated platelet production defects. Estrogen, for example, has been reported to decrease platelet counts through an unknown mechanism.[258] Thrombocytopenia due to thiazide diuretics has been reported frequently.[259] Although the cause of the thrombocytopenia in most cases is probably increased clearance, decreased marrow megakaryocyte numbers have been noted.[260] Interferons and IL-2 may induce thrombocytopenia.[261,262] The most likely explanation is an inhibition of CFU-MK. Anagrelide is a very useful drug for lowering platelet counts in patients with myeloproliferative disorders and appears to work by reducing megakaryocyte size and ploidy and by disrupting maturation.[263]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal disorder resulting from mutations in the X-linked gene *PIG-A* that encodes for an enzyme required in the initial step of biosynthesis of glycosylphosphatidylinositol anchors (PNH is discussed in Chapter 30).[264] Approximately 25% of patients with PNH have significant marrow aplasia.[265] Thrombocytopenia at diagnosis is a poor prognostic indicator.[74] Because platelet survival is usually normal in cases of PNH,[266] thrombocytopenia is due to decreased or ineffective platelet production. Megakaryocyte progenitors have a decreased proliferative activity and exhibit increased sensitivity to complement.[4,267,268] Treatment with antithymocyte globulin or granulocyte colony-stimulating factor and cyclosporine has ameliorated the thrombocytopenia in some patients,[269,270] whereas marrow transplantation has resulted in long-term remissions in patients with aplasia associated with PNH.[271]

Refractory Thrombocytopenia Due to Myelodysplasia

Myelodysplastic syndromes may present as isolated thrombocytopenias in a very small number of cases (<1%).[272] The diagnosis of myelodysplasia should be considered when there are clonal chromosome abnormalities. Typically, they involve chromosomes 3, 5, 8, or 20, but partial deletions of other chromosomes have also been reported.[273] The usual laboratory findings include macrocytosis of platelets and red blood cells. Small dysplastic megakaryocytes, sometimes present in increased numbers, are the most typical abnormalities observed.[272,274,275] Dysplastic erythroblasts or myeloid cells may also be noted.

The clinical course of patients with this type of disorder is progressive. Additional cytopenias invariably develop so that the patient then has a typical myelodysplastic syndrome. A significant number of cases will evolve into an acute myeloid leukemia.[272] Therapy has not been shown to be beneficial. Some patients with a full-blown myelodysplastic syndrome associated with marked thrombocytopenia and less than 10% blasts have been reported to experience increases in platelet counts after androgen therapy.[276] As noted earlier, amifostine may be beneficial for some patients. It has been reported that some of these patients have been misdiagnosed as having ITP and treated for this disease. Because such therapy is not useful or helpful, it is important to recognize this entity.

Cyclic Thrombocytopenia

Cyclic oscillations in the platelet count have been reported many times in the literature.[186,277–282] The fluctuations in platelet count can be extreme, with thrombocytopenic bleeding being the result.[283] Women are often affected and in such patients the cycling occurs in association with the menstrual cycle. A study of 10 patients with cyclic thrombocytopenia suggested various causes of the thrombocytopenia, with cyclic variations in platelet production being responsible for some cases, including the two male patients in that group.[284] A case with antibodies toxic to megakaryocytes has also been reported.[37] The possibility that fluctuating cytokine levels may contribute to the pathogenesis of the disorder has been raised by several studies, although it is difficult to distinguish cause from effect.[184,285,286] Cyclic thrombocytopenia may rarely be a presenting manifestation of myelodysplasia.[287] Treatment has been variable; responses to low-dose contraceptives and intravenous gamma globulin have been reported.[279,288]

DIAGNOSING THROMBOCYTOPENIA DUE TO IMPAIRED THROMBOPOIESIS

Compiling a thorough patient history is the first step in a complete workup of a thrombocytopenic patient. Many potential causes will be revealed by a good history, including obtaining a family history of thrombocytopenia, recent infection, medication or substance ingestion, or radiation or chemotherapy.

A careful physical examination could also contribute to making a diagnosis. For example, physical findings suggesting any of the inherited disorders described earlier might be discerned, as might findings suggestive of malignancy such as enlarged lymph nodes. Splenomegaly itself is not indicative of a platelet production abnormality, but is often found in patients with lymphoma, or other processes associated with marrow infiltration and damage that might cause impaired thrombopoiesis.

The peripheral blood smear is next examined and this is needed to rule out pseudothrombocytopenia. Moreover, the blood smear provides additional clues to both the pathophysiologic mechanism of the thrombocytopenia and the diagnosis. For example, giant platelets suggest a hereditary or myelodysplastic syndrome; oval macrocytosis and hypersegmented neutrophils suggest a folate or vitamin B_{12} deficiency; and a leukoerythroblastic smear points to an infiltrative process.

Examination of the bone marrow is also required to evaluate megakaryocyte number and morphology. A biopsy is more reliable than an aspirate to determine whether megakaryocytes are decreased in number. However, an aspirate showing abundant megakaryocytes in the presence of thrombocytopenia is sufficient to suggest platelet destruction or ineffective production. Megakaryocytes are not evenly distributed throughout the marrow so examination of many fields is required in order to determine if adequate numbers of cells are present. Megakaryocyte morphology is also useful to observe. The normal compensatory response to thrombocytopenia is enlargement of the cells with increased ploidy. Small, microlobulated or hypolobulated megakaryocytes may be seen in myelodysplastic syndromes. Dysmorphic megakaryocytes may be also observed in viral infections, including human immunodeficiency virus. In the future, flow cytometry[61] may provide a more objective analysis of megakaryocytes.

Ultimately, a diagnosis of ineffective thrombopoiesis is made by exclusion. The marrow examination reveals quantitatively normal megakaryocytes, and the apparent absence of peripheral platelet destruction together with the appropriate clinical circumstances (eg, folate or vitamin B_{12} deficiency) often point to this mechanism. Platelet function tests may be helpful in distinguishing ineffective production from platelet destruction. In destructive processes such as immune thrombocytopenia, function is normal, whereas in ineffective platelet production impaired function is not uncommon, as noted above. In complex cases, platelet survival studies may be necessary to show that consumption or splenic pooling are not significant contributors to the thrombocytopenia; however, survival studies are rarely required for clinical purposes. In the future, flow cytometric estimation of platelet production rate and measurement of thrombopoietin levels may permit a more facile approach to the differential diagnosis of thrombocytopenia.

CHAPTER 33

PATHOBIOLOGY OF THE HUMAN ERYTHROCYTE AND ITS HEMOGLOBINS

Martin H. Steinberg, Edward J. Benz, Jr., Adeboye H. Adewoye, and Benjamin L. Ebert

Anemia, polycythemia, and functional derangements of the human erythrocyte together represent a particularly important group of human disorders. Although sickle cell disease, hemoglobin E (HbE)-associated disorders and the thalassemias are humankind's most common single gene diseases, the relevance of red cell disorders to general medicine extends beyond their individual clinical severities or the number of patients affected. A critical added dimension of erythrocyte disorders is the extraordinarily detailed knowledge available about the basic biochemistry, physiology, and molecular biology of the human red blood cell and its membrane, enzymes, and major component, hemoglobin. Red blood cells are especially abundant, relatively simple, and readily accessible for repeated testing in individual patients. These features have facilitated rapid application of the techniques of cellular and molecular biology to studies of the red blood cell, its component molecules and structures, and syndromes resulting from abnormalities of these entities. Taken as a group, erythrocyte disorders are better understood at the molecular and cellular levels than disorders of any other cell or tissue. It is for this reason that these conditions merit particularly careful scrutiny by students of hematology.

This chapter reviews concepts about normal red blood cell homeostasis that form the essential knowledge base for understanding anemias, polycythemias, and functional erythrocyte disorders. The primary focus and the object for detailed discussion within this chapter is hemoglobin, the major component, both quantitatively and qualitatively, of the erythrocyte. Hemoglobin molecules dominate the pathophysiology of many red blood cell disorders and modulate most of the others, in part because of their sheer quantitative predominance in red blood cell cytoplasm. The other major relevant aspects of human red blood cells—the membrane, the enzymes used for intermediary metabolism, differentiation and development, and the process of destruction—are discussed in detail in the introductory portions of other chapters. This chapter surveys these areas only briefly. Detailed descriptions of the red blood cell membrane can be found in Chapter 46. Red blood cell enzymes and enzymopathies are described in Chapter 45; differentiation and development are described in Chapter 25; regulation of the red blood cell mass by erythropoietin is discussed in Chapter 25; and the necessary aspects of red blood cell destruction are considered in Chapters 33, 47, and 48.

ESSENTIAL FEATURES OF RED BLOOD CELL HOMEOSTASIS

As discussed in Chapter 25, the mature red blood cell is the product of a complex and orderly set of differentiation and maturation steps beginning with the pluripotent stem cell. By incompletely understood mechanisms involving hierarchic networks of cytokines, a portion of these cells becomes committed to differentiate along the erythroid pathway. Commitment to erythropoiesis provokes a progressively increasing sensitivity to the stimulatory actions of the hormone erythropoietin. As differentiation proceeds there is preprogramming of certain genes whose expression at high levels will be required during the maturation phase of erythropoiesis. Genes coding for molecules defining the red blood cell phenotype (eg, globin) are poised for activation at later maturation steps.

Intermediate progenitor cells arising during differentiation have been characterized experimentally, including the burst-forming unit-erythroid (BFU-E) and the colony-forming unit-erythroid (CFU-E) stages. BFU-Es are progenitor cells that in culture produce bursts or clusters of erythroid colonies, are relatively less sensitive to erythropoietin, and are more plastic with respect to important gene expression parameters, such as the synthesis of adult or fetal hemoglobin by their descendants. CFU-Es produce single colonies, exhibit considerably higher sensitivity to erythropoietin, and appear to be more fixed in their potential to express a particular subset of globin genes. As discussed in Chapter 25, CFU-Es appear to give rise to the first morphologically recognizable erythroid cells, the proerythroblasts. At this "primitive" morphologic stage, the program of erythroid cell expression has already been essentially predetermined. The cell is predestined to undergo only a limited additional number of cell divisions, culminating in formation of the enucleate reticulocyte. The terminal maturation stages are morphologically recognizable as erythroblasts exhibiting progressive hemoglobinization of the cytoplasm, condensation and eventual ejection of the nucleus, and remodeling of the plasma membrane. Actual expression of the preprogrammed genes occurs during the 5- to 7-day period of erythroblast maturation.

As discussed in Chapter 25, the actual reconfiguration of chromatin for activation of the genes and activation itself appear to require the concerted and complex interaction of a diverse but limited group of transcription factors. These regulatory proteins recognize a specific array of promoter and enhancer sequences that are embedded as recurrent motifs in and around the appropriate target genes. Even though an enormous amount of information has been gathered about sequences such as the GATA enhancers and their cognate transcription factors (eg, GATA, FOG, ETS), the precise means by which these sequences and factors cause erythroid differentiation remains mysterious. At this time, this information is of limited clinical relevance to anemias or polycythemias. The orderly 14- to 21-day sequence of differentiation and maturation becomes progressively influenced by the levels of erythropoietin available to the progenitor cells, possibly because of increasing density and affinity of erythropoietin receptors on their cell surfaces. Cytokines such as fibroblast growth factor (FGF) can affect erythroid and myeloid development. In the Zebrafish, knockdown of FGF expression alters normal development of erythroid and myeloid elements. Although the exact role of FGF has not been fully elucidated in humans, these observations suggest that FGF-related pathways might play a role in aplastic anemia and pure red cell aplasia. Within 24 hours after enucleation, the reticulocyte traverses the bone marrow–blood barrier membrane and enters the circulation as an immature erythrocyte. These cells retain remnants of nucleated precursors in the form of a relatively small number of polyribosomes actively translating messenger RNA (>90% of which is globin messenger RNA), a cell membrane that retains some molecules and structures reminiscent of its earlier stages of differentiation, and the only complement of enzymes, phospholipids, and cytoskeletal proteins that the cell will possess throughout its remaining life span.

During its first 24 hours in the circulation, the reticulocyte spends considerable amounts of time in the spleen, during which its membrane is "polished." This is a poorly understood remodeling process by which some lipids and proteins, including adhesive molecules such as fibronectin, are removed. The content of polyribosomes and other nucleic acids progressively declines so that stainability with methylene blue, until recently the standard method used for clinical enumeration of reticulocytes, is lost by the end of the first day. At this time, the red blood cell is regarded as a mature erythrocyte, and it circulates largely unchanged for the remainder of its 120-day life span.

Perhaps the most remarkable feature of the human red blood cell is its durability, given that it is an enucleated cell devoid of organelles that appear to be critical for the survival and function of most other cell types. The red blood cell has no mitochondria available for efficient oxidative metabolism, no ribosomes for regeneration of lost or damaged proteins, a very limited metabolic repertoire that largely precludes de-novo synthesis of lipids, and no nucleus to direct regenerative processes, adaptation to circulatory stresses, or cell division to replenish itself. Given these handicaps, the 120-day survival of these cells is even more striking considering the multiple and often exceedingly hostile environments they must traverse. Mechanical stresses of the circulation include high hydrostatic pressure and turbulence and the shear stresses inherent in a microcirculation networked with many capillaries having diameters only one-third to one-half that of the normal red blood cell. Biochemical stresses include osmotic and redox fluxes associated with travel through the collecting system of the kidney; the sluggish vascular beds of the spleen, muscle, and bone; and the rapid changes in ambient oxygen pressures occurring in the lungs. All conspire to damage red blood cells. Their 4-month survival is truly remarkable.

The ability of the red blood cell to persist in the circulation depends on its simple but exquisitely adaptive membrane structures, its pathways of intermediary energy metabolism and redox regulation, and its ability to maintain its largest cytoplasmic component, hemoglobin, in a soluble and nonoxidized state. The membrane and enzymes of the red blood cell appear to be exquisitely crafted to protect the cell from the external ravages of the circulation and the potential internal assaults of the massive amount of iron-rich and potentially oxidizing protein represented by its complement of hemoglobin molecules. For these reasons, a few basic features of these membrane and enzyme systems merit comment before considering the hemoglobin molecule itself.

MAJOR FEATURES OF THE RED BLOOD CELL MEMBRANE

Chapter 45 describes the red blood cell membrane in considerable detail, using it as a model for understanding membrane structure in general. Only a few major aspects of that discussion bear repeating for the purposes of this chapter. The red blood cell membrane and its underlying cytoskeleton have evolved to provide mechanical strength and the necessary pliability and resilience to withstand the mechanical, osmotic, and chemical stresses of the circulation. Because the lipid bilayer membrane essentially has the physical properties of a soap bubble, it would rapidly be emulsified in the circulation. Strength and order are provided to the lipid bilayer by the hexagonal arrays of the highly helical protein spectrin, which forms a latticework underlying the membrane.

The spectrin meshwork is held together by adaptor molecules, such as protein 4.1, adducin, p55, and ankyrin, arrayed at defined points along the highly coiled, rod-like structure of the spectrin oligomers. These protein-protein interactions appear to be critical for holding the latticework together in what has been described as the "horizontal" dimension that permits resistance to shear stress (see Chapter 46). The involvement of intermediate-length actin fibers and the variability of binding affinities by phosphorylation state appear to provide some flexibility and pliability at these points of interaction. Strength in the "vertical" dimension is provided by additional molecules or additional binding functions of the same molecule, whereby the latticework is attached to the lipid bilayer. For the most part, the physiologically important attachments appear to be indirect. Linkage is mediated through the interaction of the adaptor proteins, such as ankyrin and protein 4.1, with the cytoplasmic domains of abundant transmembrane proteins. These proteins traverse and are embedded in the lipid bilayer, providing a firm anchor. The two most critical of these molecules appear to be band 3 (ie, the anion transport channel) and a glycophorin, probably glycophorin C/D. A possible additional stabilizing role for the Rh protein complex has been suggested. The construction of these attachments by multiple "hinge" or coupling molecules appears to provide for the flexibility and distensibility of the red blood cell membrane, a property essential to its ability to flow through small capillaries.

As described in Chapter 46, the complex structure of the membrane is exquisitely sensitive to perturbations impinging on any of its components. In particular, the membrane cytoskeleton and phospholipid structures are each highly susceptible to oxidation, particularly by partially proteolyzed molecules of hemoglobin, which denature to form highly toxic compounds called *hemopyrroles*. This interaction of denatured hemoglobin with the red blood cell membrane is clinically important, as illustrated by its impact on the pathophysiology of sickle cell anemia (see Chapter 42) or of oxidized and precipitated globin inclusion bodies in thalassemia. In this chapter, it is sufficient to note that alterations of proteins of the red blood cell membrane can contribute to shortening the life span of the red blood cell. Damage can result from direct defects in the cytoskeletal proteins themselves or from susceptibility of these proteins to direct oxidation or attack by oxidized or denatured hemoglobin molecules. The reader is referred to the aforementioned chapters for detailed descriptions of the relevant phenomena.

ENZYMES OF RED BLOOD CELL INTERMEDIARY

Metabolism

Mammalian erythrocytes possess a highly specialized but remarkably simplified set of metabolic pathways. As discussed in Chapter 45, there are essentially three relevant sets of pathways. The first two are interconnected by the enzyme glucose-6-phosphate dehydrogenase (G6PD). Glucose entering the red blood cell is metabolized by an anaerobic pathway, the Embden-Meyerhof pathway, which terminates with the enzyme lactic dehydrogenase, forming lactate. Despite its inefficiency (a net of only two adenosine triphosphate [ATP]/glucose molecule), this pathway is the sole source of usable ATP in the cell. Moreover, the pathway generates reduced nicotinamide adenine dinucleotide (NADH), a molecule necessary for driving the reduction of methemoglobin to hemoglobin (see Chapter 45). A shunt within this pathway, the Rapoport-Luebering shunt, generates the compound 2,3-bisphosphoglycerate (bis[phosphoglyceric acid]) (2,3-BPG), an important cofactor that, when bound to hemoglobin, reduces the affinity of hemoglobin for oxygen (see "Hemoglobin Function). The ATP generated is necessary for kinase reactions controlling phosphorylation of membrane and signaling components, for fueling ion pumps and channels, and for maintaining phospholipid levels.

The anaerobic metabolic pathway generates, as one of its intermediates, glucose-6 phosphate, which is the substrate for G6PD. G6PD appears to be the rate-limiting enzyme for a linked pathway called the *oxidative hexose monophosphate shunt*. This pathway involves a cascade of reactions culminating in the reduction of oxidized glutathione to reduced glutathione. Reduced glutathione is used to reverse oxidation of critical structures, including hemoglobin, cytoskeletal proteins, and membrane lipids. Anaerobic glycolysis generates NADH for methemoglobin reduction, 2,3-BPG for modulation of hemoglobin oxygen affinity, and ATP for metabolic energy requirements. Its end product is lactate. The oxidative glycolysis pathway generates nicotinamide adenine dinucleotide phosphate (NADPH)

and reduced glutathione for use as the major erythrocyte antioxidant.

During the past decade, most of the enzymes (or at least the erythroid isoforms of these enzymes) involved in red blood cell intermediary metabolism have been characterized at the molecular level by cloning of their cDNAs or genomic loci, or both. Some of the more relevant information arising from this progress is discussed in Chapter 45. The erythrocyte possesses membrane-based signaling receptors and cytoplasmic signal transduction elements similar, although perhaps less elaborate, than those of nucleated cells. The relevance of these systems to the pathophysiology of red blood cell disorders is just becoming apparent.

RED BLOOD CELL SENESCENCE AND DESTRUCTION

Erythrocytes, despite their impressive adaptations to circulatory stresses, eventually wear out and are destroyed. Red blood cell survival in humans appears to be remarkably uniform under normal circumstances, spanning approximately 120 days from release of the reticulocyte into the circulation to sequestration of the senescent red blood cell in the reticuloendothelial cells of the liver and spleen. The precise signal, or signals, marking red blood cells for destruction remain unknown, as does the underlying pathophysiology within the red blood cell or on its surface. However, several interrelated theories have emerged; these are discussed only briefly because they are mentioned in other chapters.

Red blood cells accumulate surface blemishes during their lives in the circulation. These appear to result in part from the accumulation of small amounts of oxygen damage to membrane structures. The altered regions are sensed by the reticuloendothelial cells during passage of the erythrocytes through the liver and spleen. Removal or pitting of these damaged regions from red blood cell membranes can be documented microscopically; small amounts of normal membrane are also lost during the process.

The biconcave disk shape of the red blood cell, so important to its distensibility, depends on a high ratio of surface area to volume. This requires redundant membrane surface area. The membrane surface area of the normal biconcave disk is approximately 140 μm^2. To enclose a sphere containing a normal red blood cell volume (approximately 90 fL), only approximately 95 μm^2 would be needed. Progressive loss of membrane surface by means of the pitting phenomenon should ultimately cause the aging erythrocyte to assume a more rigid spherical shape. A sphere is inevitably far less distensible and far less capable of passing through small apertures than a disk, especially in the sluggish and torturous circulation of the spleen. This geometric mechanism can lead to the eventual destruction of the red blood cell.

Red blood cells progressively lose some of the critical enzymes needed for intermediary metabolism and antioxidant capacity. G6PD levels, for example, progressively decline during the circulating life span, as do levels of several other enzymes. The decline of certain enzymes can be used as a crude means of estimating the relative age of different red blood cell populations. The biochemical or oxidative mechanism of destruction postulates that aged red blood cells are eventually depleted of critical enzymes needed for maintenance of redox status. Oxidation of critical membrane proteins, lipids, and hemoglobin would then ensue, causing distortion and rigidity of the red blood cell membrane, with accelerated loss as previously described. The end product would be spherocytes incapable of traversing the splenic vascular bed and escaping engulfment by the reticuloendothelial cell.

It has been proposed that an immune-type mechanism can contribute to normal and pathologic red blood cell senescence. This hypothesis is based on the observation that oxidative damage, regardless of cause, promotes a clustering, or *capping*, of oligomers of band 3 on the red blood cell surface. Under normal circumstances, band 3 molecules form monomers, dimers, or tetramers. Higher-order aggregates appear to be recognized by an endogenous isoantibody possessed by all people. Any red blood cell accumulating oxidative damage from wear and tear in the circulation, from depletion of enzymes, or from internal pathologic processes such as denaturation of hemoglobin in certain hemoglobinopathies can accumulate these aggregates. The aggregates would then be bound by antibody and be removed by the reticuloendothelial cells as antigen-antibody complexes, employing the same means used by reticuloendothelial cells to recognize any immune complex. This mechanism could also provide for the pitting or polishing of damaged red blood cell membranes. All three of the proposed mechanisms are interrelated by their inception with oxidative damage.

Other membrane-related changes might influence red cell destruction. Bcl-X_L (also designated BCL2L1), a suppressor of apoptosis, is present in erythrocyte membranes and its antagonization may promote cell death. This may be mediated by calcium accumulation and phosphatidylserine exposure. Cholesterol and fatty acids accumulate on the aging red cell membrane and might be targets for oxidation induced by reactive oxygen species. Red cells are removed from the circulation by splenic macrophages, probably by several mechanisms. SHPS-1, a surface glycoprotein and a member of the immunoglobulin superfamily that interacts with red cell membrane CD47, is abundant in macrophages. Studies using mice expressing a mutant SHPS-1 suggested that this molecule might negatively regulate phagocytosis influencing cell lifespan. Increasing phosphatidal serine exposure and reduced aminophospholipid translocase activity during aging might induced oxidative damage to the cell. It is probable that these mechanisms leading to cell destruction are not mutually exclusive, that no single effect predominates, and these events occur at different times at different sites of red cell damage.

Regardless of the mechanism(s) fostering eventual senescence and destruction of red blood cells, the process itself involves components clinically useful for assessment of anemias associated with accelerated destruction. Chief among these is the generation of indirect or unconjugated bilirubin, the by-product of heme catabolism occurring within the reticuloendothelial cells. In markedly accelerated states of red blood cell destruction, hypertrophy of the liver and spleen can also occur, providing a useful physical indicator of hemolytic anemia. These indirect clinical features, coupled with the reticulocyte count, remain more useful for detecting clinical hemolysis than complicated studies of red blood cell kinetics.

HEMOGLOBIN SYNTHESIS, STRUCTURE, AND FUNCTION

Basic Features

Hemoglobins are the major oxygen-carrying pigments of the body. They are packaged into red blood cells in quantities sufficient to carry enough oxygen from the lungs to the tissues to meet the needs of those cells for oxidative metabolism. These quantities are enormous–almost two pounds of hemoglobin are present in the body of a reasonably sized human at any given time. Because free hemoglobin in the bloodstream is catabolized and excreted renally in a matter of minutes, packaging in erythrocytes is essential to preserve the newly synthesized molecules for the entire 4-month life span of the red blood cell. Otherwise, the caloric and biosynthetic resources needed to replace daily losses of hemoglobin would be prohibitive. The red blood cell's major function is to encase hemoglobin and protect it so it can function as an oxygen transporter for a prolonged period. An additional function of hemoglobin is to modulate vascular tone by its transport of nitric oxide (NO), and, possibly nitrous oxide.

The cellular content of blood influences its viscosity; in particular, the hemodynamics are adversely compromised by the presence of too many circulating erythrocytes, because blood viscosity correlates especially with hematocrit. To provide for adequate oxygen transport (ie, enough hemoglobin molecules) in a number of red blood cells compatible with tolerable viscosity, each cell must enclose a high concentration of hemoglobin (32 to 35 g per 100 mL of cytoplasm). This concentration is close to the solubility limit of hemoglobin in physiologic solutions. It follows that even minor perturbations within these molecules (eg, oxidation) or in the milieu (eg, changes in pH

or ionic strength) can have potentially devastating effects on the solubility of hemoglobin. Because polymerized or precipitated hemoglobins derange intracellular viscosity, trigger proteolytic reactions that lead to oxidative damage of erythrocytes, and compromise oxygen transport, it is not surprising that the fate of the red blood cell is inextricably interwoven with the state of its enormous complement of hemoglobin molecules.

Hemoglobin Structure

The hemoglobin tetramer consists of two pairs of unlike globin polypeptide chains, each associated with a heme group. Normal hemoglobin has two α- and two non-α-globin chains; the interaction of these chains is responsible for the quaternary structure of the hemoglobin molecule and normal oxygen transport. Functionally, the second exon of each globin gene encodes the major component of the heme-binding pocket, and the α and non-α contacts are regulated by the third exon.

The behavior of hemoglobin is determined by its primary structure, the covalent linking of amino acids to form the polypeptide globin. The higher-order structures of hemoglobin depend on the sequence of amino acid residues that make up the globin chain. The α-globin chains contain 141 residues, and the β-globin–like chains are 146 amino acids long (Fig. 33–1). There is considerable homology among these globins, especially among the non–α-globin chains. Whereas the α-globin genes (*HBA2, HBA1*) result from a very ancient gene duplication, the non–α-globin genes (*HBE, HBG2, HBG1, HBD, HBB*) are the result of more recent gene duplications and are more akin to each other than they are to the α-like globin genes. Gene conversion events also ensure the similarity of duplicated genes.

Elements of the secondary structure of globin are shown in Figs. 33–1 and 33–2. Approximately 75% of the globin polypeptide chain forms an α-helix. There are eight helical segments, A through H, separated by short stretches from which the α-helix is absent. These nonhelical segments permit folding of the polypeptide on itself and are often dictated by the presence of prolyl residues, which are generally unable to participate in the formation of α-helices. Although the helical segments of the α- and non–α-globin chains do not exactly correspond, it is possible to align amino acid residues in all globin peptides by their helical and nonhelical residue numbers, as indicated in Fig. 33–1. This permits greater appreciation of the homology among globins. Some of the amino acids of globin are invariant, or conserved, in the sense that they are preserved during phylogeny. These residues occur at portions of the molecule that are critical for its stability and function, such as heme binding residues, hydrophobic amino acids of the interior of the molecule, and certain subunit contacts at the α_1-β_2 interface. The introduction of prolyl residues into α-helical segments by mutation leads to interruption of the α-helix and instability of the resulting hemoglobin molecule.

The poorly understood laws that govern the folding of proteins are responsible for the tertiary structure of globin, shown in Fig. 33–2. This folding pattern places polar residues exteriorly and provides a hydrophobic niche for the heme ring between the E and F helices. Numerous noncovalent bonds are formed between the heme and surrounding amino acid residues of globin. An iron atom in the center of the porphyrin ring forms an important bond with the F8 or proximal histidine and through the linked oxygen with the E7 or distal histidine residue. Oxygenation and deoxygenation of hemoglobin occur at the heme iron. Folding of globin and association of chains into dimers and tetramers was once thought to occur spontaneously. However, it is now clear that these processes are assisted by chaperone proteins, which are described in Chapters 3, 4 and 5.

Two α-globin chains and two non–α-globin chains fit together specifically to form a hemoglobin tetramer with a molecular mass of approximately 64,000 daltons and with the quaternary structure shown in Fig. 33–3. The motion of individual globin chains, as well as the movement of globin chains relative to each other during oxygenation and deoxygenation, gives hemoglobin its unique usefulness as a respiratory protein.

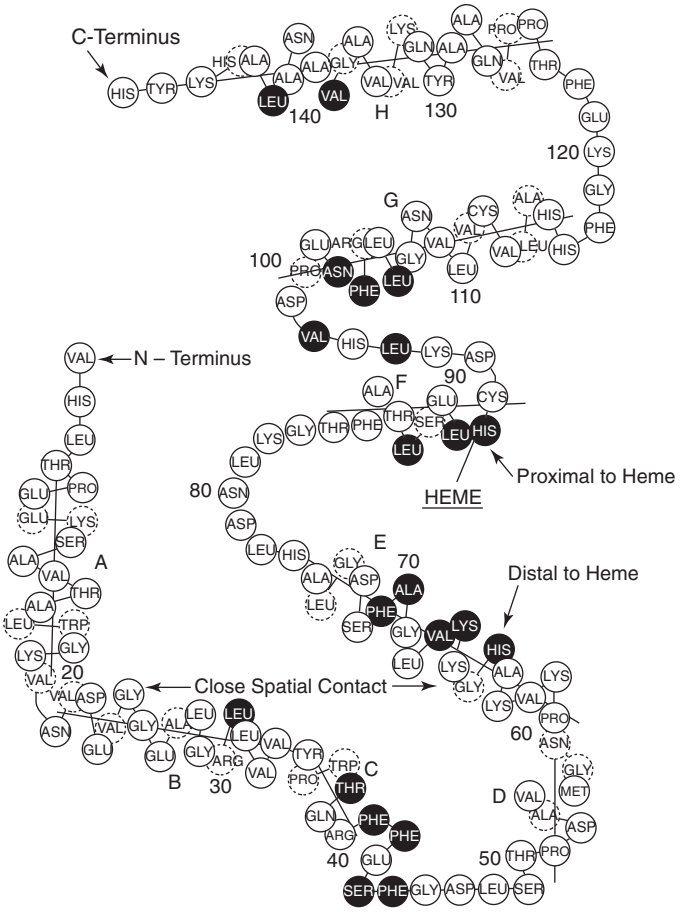

Figure 33–1. The β-globin chain, showing helical and nonhelical segments. The helical segments are labeled A through H, and nonhelical segments are designated NA for residues between the N terminus and the A helix, CD for residues between the C and D helices, and so forth. *(From Huisman THJ, Schroeder WA: New Aspects of the Structure, Function, and Synthesis of Hemoglobin. Boca Raton, FL, CRC Press, 1971.)*

Hemoglobin Function

Evolution has honed the hemoglobin tetramer into a molecule ideally suited for its tasks. Because human hemoglobin must behave differently than that of altitude dwelling species or species inhabiting hypoxic locales, many different variants of the same basic molecular design have evolved. Because of the exigencies of molecular evolution, we find in the genome of all animals, including humans, attempts by nature to propagate a variety of different globin genes. The crystallographic studies of Perutz and coworkers defined the oxygenated and deoxygenated structures of hemoglobin at Ångström-unit resolution and provided an exquisitely detailed picture of how the globin chains and individual amino acid residues respond to the loading and unloading of oxygen. All of these, however, share the properties of highly reversible oxygen binding, and high solubility in cytoplasm. We know more about the function of hemoglobin than about virtually any other protein, and the knowledge of this mechanism provides a beautiful and intellectually satisfying culmination to decades of study by many investigators.

The oxygen dissociation curve of hemoglobin, shown in Fig. 33–4, describes the percent saturation of hemoglobin with oxygen at

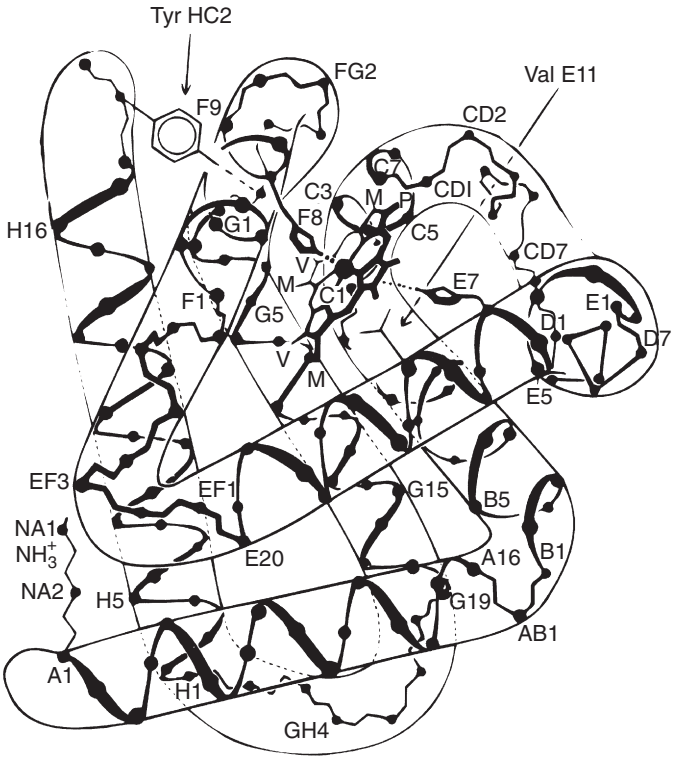

Figure 33–2. Tertiary structure of a globin chain. Globin folds into a tertiary structure such that polar or charged amino acids are located on the exterior of the molecule and the heme ring resides in a hydrophobic niche between the E and F helices. Linked to the heme are the proximal (F8) histidine and the distal (E7) histidine. *(From Perutz MF: Molecular anatomy, physiology, and pathology of hemoglobin. In Stamatoyannopoulos G, Neinhuis AW, Leder P, Majerus PW [eds]: The Molecular Basis of Blood Diseases. Philadelphia, WB Saunders, 1987, p 127.)*

different oxygen tensions. The sigmoidal shape of this curve is a result of interaction among the subunits of hemoglobin. Communication within the tetramer is called heme-heme interaction or cooperativity. This implies that the four heme groups do not undergo simultaneous oxygenation or deoxygenation, but rather that the state of each heme unit with regard to the presence or absence of bound oxygen influences the binding of oxygen to other heme groups. Myoglobin, a heme-containing protein with virtually the same tertiary structure as globin, exists in muscle as a monomer. The oxygen equilibrium curve of myoglobin is a rectangular hyperbola; in physiologic terms, it rapidly becomes fully saturated at low oxygen tensions and remains saturated as the oxygen tension plateaus. The difference in the oxygen equilibrium curves of myoglobin and hemoglobin lies in the tetrameric nature of the hemoglobin molecule and the cooperativity permitted by the association of similar but unlike subunits. Compared with hemoglobin, myoglobin has a very low P_{50} (ie, oxygen partial pressure at which the molecule is one-half saturated). It therefore has an extremely high oxygen affinity and would not be useful for delivering oxygen to tissues. The oxygen in myoglobin is passed on to the mitochondria, where oxidative metabolism occurs. The sigmoidal shape of the oxygen dissociation curve of hemoglobin indicates that the totally deoxygenated hemoglobin tetramer is slow to become oxygenated, but as oxygenation proceeds, the reaction of heme with oxygen accelerates. Perutz has drawn an analogy in which the "appetite" of heme for oxygen grows with the "eating," and conversely, loss of oxygen by heme lowers the oxygen affinity of the remaining heme groups. The Hill coefficient, *n*, which can be calculated from plots of oxygen equilibrium curves, is a description of heme-heme interaction or cooperativity that explains in part the oxygen-binding properties of hemoglobin and myoglobin. The Hill coefficient for myoglobin is 1, indicating no cooperativity; *n* is approximately 3 for the normal human hemoglobin A molecule.

The oxygen affinity of hemoglobin within the erythrocyte does not depend solely on the intrinsic properties of the tetramer. The position of the hemoglobin oxygen dissociation curve, and therefore the P_{50}, can be influenced by a number of heterotropic modifiers,

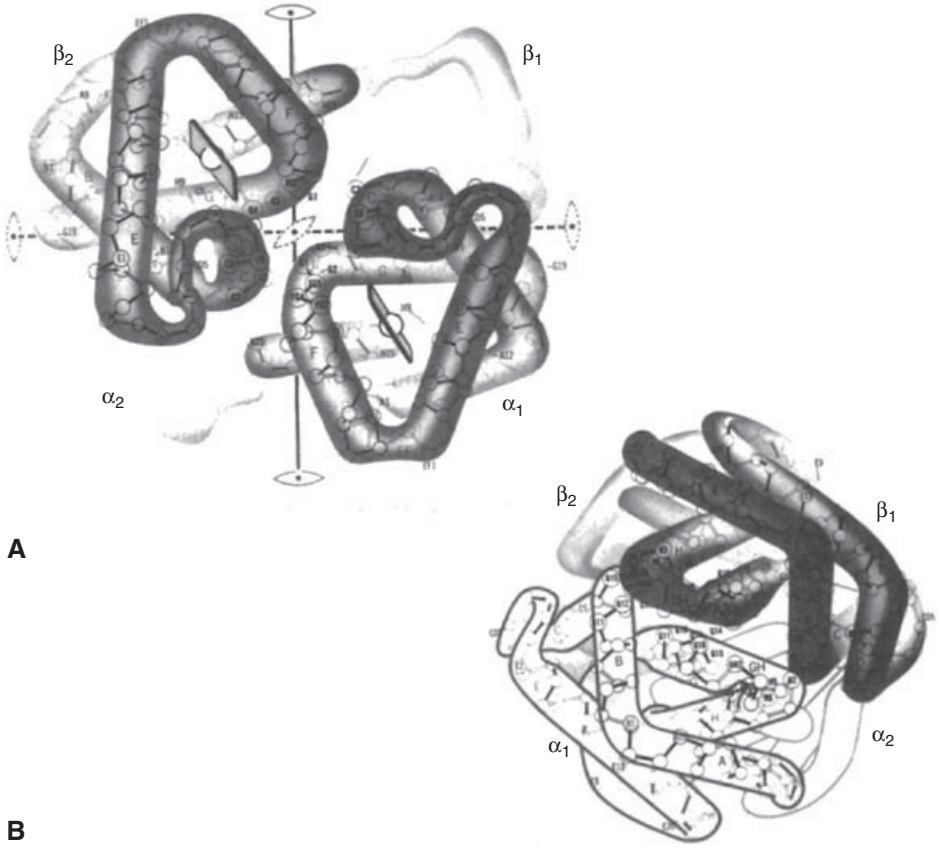

Figure 33–3. Quaternary structure of hemoglobin. The contacts between subunits are shown as circled amino acids. In the front view (A), $\alpha 1$-$\beta 2$ contacts are shown, and in the side view (B), $\alpha 1$-$\beta 1$ contacts are depicted. *(From Dickerson RE, Geis I: Hemoglobin: Structure, Function, and Evolution Pathology. Menlo Park, CA, Benjamin-Cummings, 1983.)*

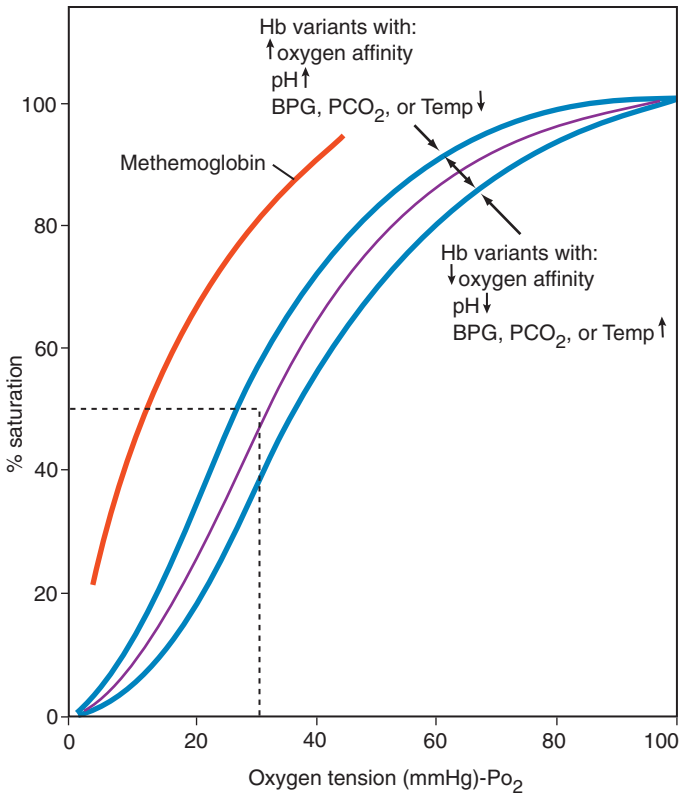

Figure 33–4. Oxygen dissociation curve of hemoglobin. The percent saturation of hemoglobin with oxygen at different oxygen tensions is depicted by the red sigmoidal curve. The P_{50} (ie, oxygen tension at which the hemoglobin molecule is one-half saturated) is approximately 27 mm Hg in normal erythrocytes (dotted lines). Heterotopic modifiers of hemoglobin function can shift the curve leftward by increasing or rightward by decreasing its oxygen affinity. PCO_2, partial pressure of carbon dioxide. *(From Benz EJ Jr: Synthesis, structure, and function of hemoglobin. In Kelly WN, DeVita VT [eds]: Textbook of Internal Medicine, vol 1. Philadelphia, JB Lippincott, 1989, p 236.)*

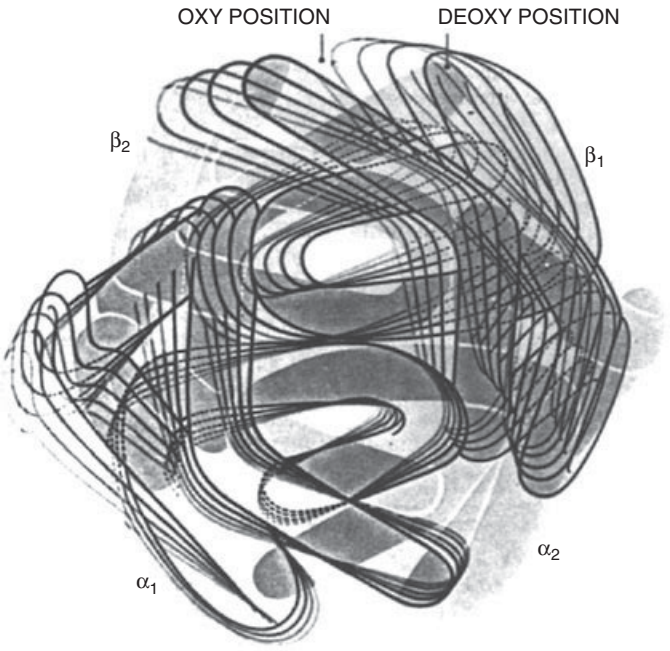

Figure 33–5. Subunit motion in the hemoglobin tetramer. The relative motion of hemoglobin subunits on oxygenation and deoxygenation is shown. The $\alpha_1\beta_1$ dimer (shown in black) is moving relative to the $\alpha_2\beta_2$ dimer (shaded). The oxyhemoglobin tetramer (R state) is more compact than the deoxyhemoglobin configuration (T state). *(From Dickerson RE, Geis I: Hemoglobin: Structure, Function, and Evolution Pathology. Menlo Park, CA, Benjamin-Cummings, 1983.)*

including temperature, pH, and small organic phosphate molecules in the cell. The effects of these modifiers on P_{50} are shown in Fig. 33–4.

Hemoglobin is the prototype of an allosteric protein; its structure and function are influenced by other molecules. The major intracellular modulator of hemoglobin-oxygen affinity in human erythrocytes is 2,3-BPG, an intermediate product of glycolysis that is present within the erythrocyte at concentrations equimolar to hemoglobin. The synthesis of 2,3-BPG is enzymatically regulated, and its levels can change depending on the conditions extant. 2,3-BPG is able to bind stereospecifically within the central cavity of the hemoglobin tetramer. Hemoglobin prepared in the absence of 2,3-BPG has a very high oxygen affinity, but as 2,3-BPG is added to a hemoglobin solution, the oxygen affinity progressively decreases. 2,3-BPG is a polyanion that binds strongly to the deoxygenated form of hemoglobin but poorly to its oxygenated or other liganded forms. Specific amino acids are involved in the binding of 2,3-BPG; these β-chain residues include the N-terminal valines, the H21 histidine (position 143), and the EF6 lysine (position 82). In oxyhemoglobin, the H helices of the β-chains are insufficiently spread to permit firm binding of 2,3-BPG; this, along with other conformational changes, favors the binding of this anion to the deoxygenated rather than the oxygenated form of hemoglobin. The binding of 2,3-BPG stabilizes the T (tense) structure of the deoxygenated form at the expense of the R (relaxed) structure of the oxyhemoglobin tetramer.

Transition from the deoxy (T) to the oxy (R) form of hemoglobin is accompanied by rotation of the αβ dimers along the α_1-β_2 contact region (Fig. 33–5). The T structure is stabilized by salt bridges, which are broken as the molecule switches into the R structure. Some abnormal hemoglobins with an intrinsically high oxygen affinity, or low P_{50}, occur as a result of an amino acid substitution that leads to loss of bonds that stabilize the tetramer in the T conformation. Hydrogen ions, chloride ions, and carbon dioxide all decrease the affinity of hemoglobin for oxygen by strengthening the salt bridges that lock the molecule into its T conformation. The corollary of the lowering of hemoglobin oxygen affinity by protons is the combination of hemoglobin with protons on deoxygenation. This is known as the Bohr effect and is responsible for carbon dioxide transport in blood, another critical function of the hemoglobin molecule. Deoxyhemoglobin binds the hydrogen ion liberated by the reaction of carbon dioxide with water, increasing the concentration of bicarbonate. Within the lungs, hydrogen ions are lost as hemoglobin binds oxygen; therefore, carbon dioxide leaves solution and is excreted from the body through the lungs. Deoxyhemoglobin can also directly bind carbon dioxide; however, this process involves the minority of carbon dioxide exchanged by the red blood cells.

Red blood cells containing high levels of hemoglobin F have high oxygen affinity because it binds 2,3-BPG poorly. Physiologically, this predicts that the hemoglobin of the fetus should be oxygenated at the expense of the maternal hemoglobin A. The high oxygen affinity of hemoglobin F is accounted for by a single change in its primary structure, the presence of a serine residue at helical position H21 in place of the histidine found in the β-globin chain. This weakens the binding of 2,3-BPG and leads to stabilization of the molecule in its R state.

Interactions of hemoglobin with NO have been a recent focus of investigation. NO, generated from L-arginine by nitric oxide synthases, activates soluble guanylate cyclase to produce the second messenger cyclic guanosine monophosphate (cGMP). As a potent vasodilator, NO is an important regulator of vascular tone. The

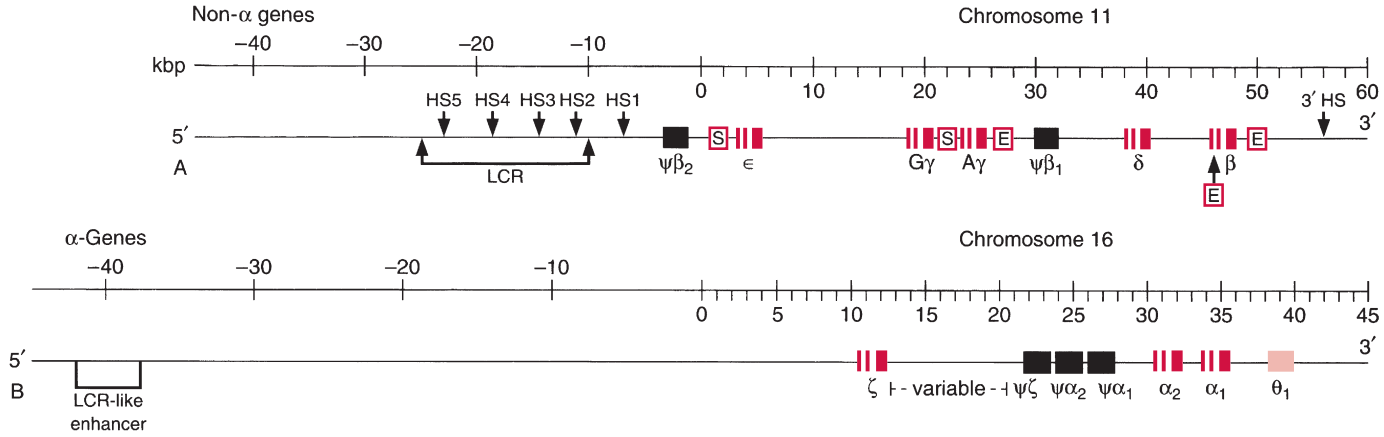

Figure 33–6. Maps of the β-like and α-like globin gene clusters located on chromosome 11 (**A**) and chromosome 16 (**B**). Within each gene cluster are pseudogenes, which are remnants of previously expressed globin genes that have become inactivated as a result of mutation. Active genes are shown in *red boxes* filled with clear introns; inactive or pseudogenes genes are shown in *solid boxes*, and the θ-globin gene is shown as a *pink box*. Although this gene is transcribed, it is not clear whether it is represented in a cellular protein. The distance between the functional ζ-globin and pseudo-ζ-globin gene is variable because of the presence of repeated elements. E, enhancer; HS, DNase hypersensitive site; LCR, locus control region; S, silencer.

reaction of free NO with erythrocytes is diffusion-limited. Normally, the primary NO-hemoglobin adduct is nitrosyl (heme) hemoglobin (HbFe[II]NO). Within the erythrocyte, β93 cysteine is reduced and seems incapable of NO storage and delivery by *S*-nitrosohemoglobin as originally proposed. NO was thought to form *S*-nitrosylhemoglobin in the lungs, where hemoglobin is in its R or oxygenated state, and liberate NO in the microcirculation, where the transition of the R to T conformation induced by deoxygenation released NO from hemoglobin. However, studies suggest that NO binding to heme groups is physiologically a rapidly reversible process. This view supports a model of hemoglobin delivery of NO distinct from its dissociation from the β93 cysteine residues. Small nitrosothiol molecules could also be involved in NO transfer. The thiol groups of hemoglobin can exchange NO with small nitrosothiols derived from free cysteine and glutathione. Accordingly, the thiol groups of hemoglobin could bind and transfer NO or exchange NO with small shuttle molecules, increasing perfusion of hypoxic tissues. It has been suggested that cytoskeletal and other erythrocyte proteins slow NO influx into the cell and, coupled with NO heme binding, preserve NO bioactivity. NO-hemoglobin interactions, whether through *S*-nitrosohemoglobin formation at the β93 cysteine or the formation of nitrosointermediates are likely to be physiologically important. Hemoglobin liberated from the intravascularly hemolyzed red cells rapidly inactivates NO. As the red cell lyses, arginase is also released and destroys the substrate for NO synthases, L-arginine. Together, this leads to a reduction in biologically active NO. With hemolysis as in sickle cell disease or thalassemia, reduced NO bioavailability is associated with disease complications such as pulmonary hypertension, leg ulcers, priapism, and perhaps increased risk of stroke. Lactic dehydrogenase also released from the red cell in hemolytic anemia is an excellent marker of these complications.

In summary, the primary amino acid structure of α- and non–α-globin chains dictates the inevitable quaternary structure in which resides the ability of hemoglobin to serve as a respiratory protein. Cooperativity ensures rapid binding of oxygen in the lungs and unloading in tissues. Similarly, carbon dioxide is transported from tissues to lungs. The function of hemoglobin may be influenced by mutation and by heterotropic effectors such as protons and 2,3-BPG. The molecule itself changes shape as it provides oxygen for metabolism; it is a lung in miniature, breathing as it allows the body to respire.

Globin Gene Clusters

The amounts and types of human hemoglobin produced at any given age are determined primarily by the selective expression of the individual genes encoding each globin chain. The globin genes of humans are located in two clusters (Fig. 33–6): α-like genes in approximately 30 kb of DNA on the short arm of chromosome 16 between band p13.2 and the telomere and β-like genes in approximately 70 kb of DNA on the terminal portion of the short arm of chromosome 11 (p15). Each gene shares certain basic organizational features. Each contains three exons separated by two introns. Both introns of the α-gene are small (100 to 300 bp); non–α-genes have one small and one large (1000 to 1200 bp) intron. The second exon of each globin gene encodes the major components of the heme-binding pocket, and the third encodes the α- and non-α contact points.

Flanking each gene at the 5′ and 3′ ends are groups of conserved nucleotides. In conjunction with protein factors, these influence the promotion of gene transcription, ensure the fidelity of the transcript and its translatability, specify sites for the initiation and termination of translation, and improve the stability of the newly synthesized mRNA (Fig. 33–7). Also encoded within the genes are signals that permit the enzymatic machinery within the nucleus to excise precisely the introns from the mRNA precursor and splice together the exons to form a contiguous "mature" mRNA. The spliced mRNA is transported to the cytoplasm and translated into protein. These conserved signals lie at the junction of the exon and intron and within the introns themselves. They are recognized by small nuclear ribonucleoprotein (RNP) particles, which participate in the formation of a spliceosome, or splicing complex. Their preservation is critical for the splicing process to occur. When mutations occur within splice signal sites, globin synthesis is often impaired. The 5′ end of the mRNA contains a cap structure, and the 3′ end contains a poly(A) tail, as described in Chapter 1.

Conserved nucleotide clusters 5′ to the coding portion of each globin gene in aggregate act as promoters (see Fig. 33–7). Globin promoters are modular. Some modules are located relatively close to the initiation site of mRNA translation, and some are more distally placed. Promoters ultimately form the binding sites for the RNA polymerase complexes that catalyze gene transcription. Mutations within the promoter can affect the level of gene transcription and the amount of globin made. Surrounding and within each gene are other sequence elements that play important roles in its transcriptional

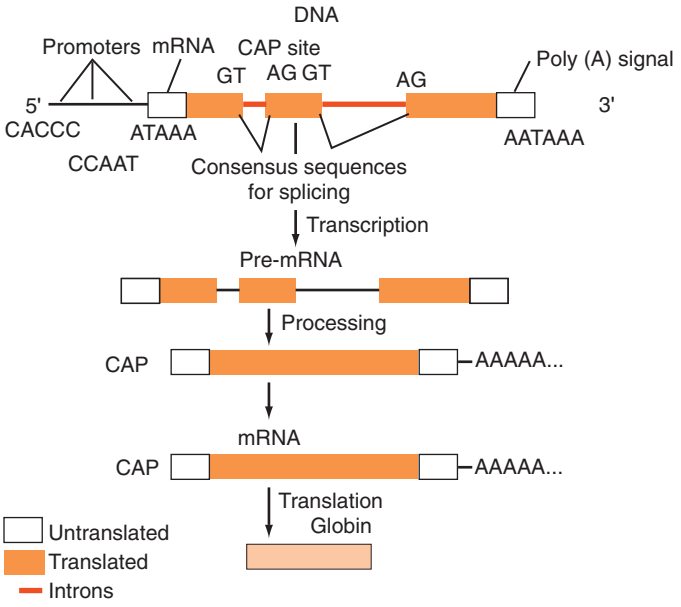

Figure 33–7. Pathway of globin biosynthesis. Transcription of the globin gene results in a large pre-mRNA molecule containing intervening sequences. During intranuclear processing of this molecule, the intervening sequences are excised and the coding sequences ligated to form a contiguous stretch of RNA, which codes for the globin protein. The message is further processed by the addition of a CAP and a poly(A) tail. The mature message is transported from the nucleus to cytoplasm, where it is translated on polyribosomes by the addition of activated amino acids to a growing polypeptide chain. Globin acquires heme and α: non-α dimers are formed and a hemoglobin tetramer is assembled. *(From Steinberg, MH: Hemoglobinopathies and thalassemias. In Stein JH [ed]: Internal Medicine, 4th ed. St. Louis, Mosby-Year Book, 1994, p 852.)*

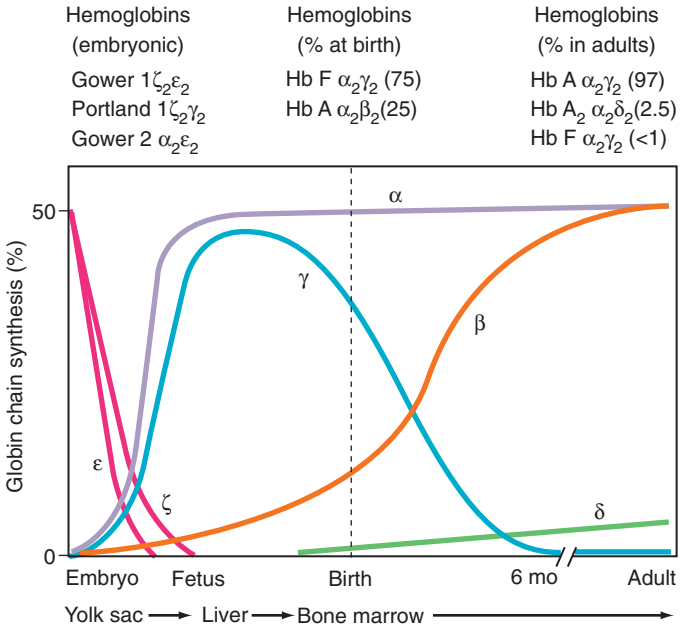

Figure 33–8. Hemoglobin (Hb) switching during embryonic, fetal, and adult development. The ζ and ε genes are transcribed during embryonic development and are soon replaced by the fetal γ- and adult α-globin gene. At birth, fetal hemoglobin (HbF) forms approximately 75% and hemoglobin A forms 25% of the total. Transcription of the γ gene begins to decrease before birth, and by 6 months of age, this gene is expressed only at very low levels. Expression of the δ-globin gene begins near birth. In adults, hemoglobin A makes up approximately 97%, hemoglobin A_2 approximately 2.5%, and HbF less than 1% of the total. *(From Steinberg MH: Hemoglobinopathies and thalassemias. In Stein JH [ed]: Internal Medicine, 4th ed. St. Louis, Mosby-Year Book, 1994, p 852.)*

regulation (see Fig. 33–6). These clusters, called *enhancers* and *silencers* (see Chapter 1) may lie within introns or 5′ and 3′ to the coding sequences; in some instances, they are quite remote from the gene. The higher-order structure of DNA in chromatin may permit close approximation of these remote enhancers to the gene during transcription. Enhancers play important roles in the tissue-specific regulation of globin gene expression. Representative regulatory sequences near the globin genes are shown in Fig. 33–6 (locus control region [LCR], LCR-like enhancer). DNA elements controlling globin genes are described in more detail later.

The α-like and β-like globin genes are ordered in the 5′ to 3′ direction in the same sequence expressed during embryonic, fetal, and adult development (Fig. 33–8). The functional significance of this arrangement is unclear. However, evidence suggests that the ordering of the ε, γ, δ, and β genes could be an important factor influencing the ability of each locus to interact with distant control elements at different developmental stages.

The α-like and β-like gene clusters probably are the result of an ancient duplication of a primordial globin gene that existed early in the history of vertebrates, approximately 500 million years ago. Each gene cluster probably developed from the duplication of ancestral genes and subsequent divergence through eons of evolution. Within the α-like gene cluster, the δ-globin gene is expressed only very early in embryogenesis and participates in the formation of embryonic hemoglobins. A μ, α-like globin gene (*HBM*), that codes for a 141 amino acid α-globin–like chain has been recently detected and is expressed in erythroid cells in a highly regulated fashion however, an associated protein has not been found.

The α-globin genes are duplicated, a characteristic of most globin genes, and their encoded amino acid sequences are identical; therefore, only a single α-globin polypeptide results. Minor differences within the second intervening sequence and the 3′ flanking regions of the α-globin gene permit identification of transcripts from each gene. The 5′ or α_2-gene is expressed more efficiently than the 3′ or α_1-gene, so that abnormalities of this gene are more likely to be clinically apparent. Both clusters contain genes that are actively transcribed, as well as pseudogenes whose defective structures prohibit expression at any time.

The gene 3′ to the α_1-gene is the θ-gene, a somewhat mysterious element of the α-gene cluster. Although θ-gene transcripts are found in fetal tissue and adult erythroid marrow, it is unclear whether this gene's translation product is able to participate in the formation of a functional tetramer. The θ-globin protein has been found in vivo, but deletion of the θ-globin gene does not appear to have any implications for the developing fetus. In vitro, θ-globin mRNA is correctly spliced, and θ-globin cDNA can direct synthesis of a translatable mRNA and a θ-globin protein.

The β-like–globin gene cluster consists of the embryonic ε-gene, transcribed only during the first 6 to 11 weeks of life; the duplicated γ-globin genes that code for the dominant non–α-globin of fetal life; and the δ- and β-globin genes that code for the hemoglobins of the adult. The coding sequences of the two γ-globin genes are identical, except at codon 136, where the 5′ or Gγ-gene codes for glutamic acid; the 3′ or Aγ-gene encodes an alanine residue. These genes are unequally expressed during fetal development. A switch in their relative rates of expression leads to a similar disparity between the amounts of Gγ and Aγ chains in adults. Although the Gγ/Aγ switch is interesting from the standpoint of the control of gene expression, it is of little clinical importance. Hemoglobin F in the fetus and the adult contains a mixture of Gγ and Aγ chains; the functional qualities of these hemoglobins are identical.

The δ- and β-globin genes are probably the result of a duplication event that occurred more than 40 million years ago. The β-globin gene has become the predominant gene, coding for most non–α-

globin chains of the adult. The δ-globin gene has undergone mutation in several critical areas, and its expression is greatly curtailed. Its product, a minor fraction of adult hemoglobin (HbA_2), has become functionally insignificant by virtue of its very low level in the erythrocyte. It is likely that the δ-globin gene is a "pseudogene in evolution." HbA_2 is clinically useful however, for characterizing hemoglobinopathies such as β-thalassemia. In time, its expression may be totally abolished as it acquires an inactivating mutation. The pseudogenes dispersed within both globin gene clusters provide interesting glimpses into the evolutionary history of globin genes. Pseudogenes are inactive remnants of previously expressed genes. As a result of relaxed selection, their mutation rates are higher than those of surrounding active genes.

The expression of the human globin genes is highly regulated. Globin is synthesized in only one tissue—erythroid cells—and only during a narrowly defined stage of erythroid progenitor cell differentiation—the 5 to 7 days that commence with the proerythroblast stage and end when the enucleated reticulocyte loses the last traces of its RNA. Within the confines of these strict tissue-specific and differentiation stage-specific boundaries, the globin genes are extraordinarily active. By the late normoblast and reticulocyte stages, 90% to 95% of all protein synthesis in these cells is globin synthesis.

Individual globin genes are expressed at different levels in developing erythroblasts of the human embryo, fetus, and "adult" (ie, 37 to 38 weeks of gestation and beyond). Different subsets of α- and non–α-genes are expressed and silenced at each developmental stage. Moreover, the overall balance of non–α-globin, α-globin, and heme production is maintained throughout each of these complex switching events. The complex mechanisms ensuring the proper tissue-specific, differentiation stage-specific, and ontologic stage-specific expression are incompletely defined. Much information about relevant DNA control elements and transcription factors is emerging. These topics are discussed after a review of the ontogeny of hemoglobin.

Ontogeny of Hemoglobin

The hemoglobin composition of the erythrocyte depends on when in gestation or postnatal development it is measured. This is a result of sequential activation and inactivation (i.e., switching) among genes within the α- and non–α-globin gene clusters (see Fig. 33–8). What controls these switches in globin gene transcription is not understood. The two early embryonic hemoglobins consist of ζ- and ε-globin chains (Hb Gower-1) and α- and ε-globin chains (Hb Gower-2). The ζ-globin gene is akin to the α-globin genes but is expressed only during early embryogenesis. The ε-embryonic globin chain is a β-like element. The combination of ζ- and γ-globin chains forms hemoglobin Portland. These early hemoglobins are made primarily in yolk-sac erythroblasts and are detectable only during the very earliest stages of embryogenesis except in certain pathologic states, in which they may persist until gestation is complete. The major hemoglobin of intrauterine life is fetal hemoglobin (HbF), which consists of two α- and two γ-globin chains. Expression of the γ-globin gene begins early in embryogenesis, peaks during midgestation, and begins a rapid decline just before birth. By 6 months of age in normal infants, only a remnant of prior γ-globin gene expression remains. The level of HbF in the blood declines rapidly thereafter to less than 1% of the total. Expression of the α-globin gene starts early in the first trimester, peaks quickly, and is sustained for life. Expression of the β-globin gene also commences early in gestation and reaches its zenith within a few months after birth. The combination of α-globin with β-globin chains forms hemoglobin A (HbA) the predominant hemoglobin of postnatal life. Adult cells also contain $Hb\text{-}A_2$. The δ-globin gene, which directs synthesis of the non–α-globin chain of HbA_2, is very inefficiently expressed. Only low levels of HbA_2 are present; defects in the δ-globin gene are of no clinical consequence. In adult blood, HbF is not evenly distributed among erythrocytes and is present in only a very small number of red blood cells, called *F cells*. HbA_2 is present in all red blood cells, albeit at levels less than 3.5% of the total hemoglobin in adult life.

Hemoglobin Biosynthesis and Its Regulation

Throughout development, genes coding for α-globin, non–α-globin, and heme exhibit coordinated expression. Almost equal amounts of each of the moieties that ultimately constitute the hemoglobin tetramer are made. Excess unpaired globin chains and mutant globins are removed from the cell by ATP-dependent proteases, ensuring a balance between accumulation of α- and non–α-globin chains. Balanced chain synthesis and coordination of globin chain production with synthesis of heme are important because hemoglobin tetramers are highly soluble, whereas the components of hemoglobin (ie, unpaired chains, protoporphyrin, and iron) are not. Precipitation of any of these is deleterious to cell survival. Erythroblast proteases are not efficient enough to eliminate the substantial excesses of unpaired chains that accumulate when an α- or non–α-gene is selectively impaired by severe thalassemia mutations. The mechanisms regulating heme production and some of the interactions between heme and globin synthesis are discussed in Chapter 38.

The proper production of the individual globin chains within erythroid tissues at the appropriate states of differentiation and development is predominantly ensured by regulation at the level of transcription. The onset of phenotypic maturation at the proerythroblast stage is marked by the onset of globin mRNA biosynthesis in dramatically increasing quantities. Expression of α- and non–α-globin genes begins at essentially the same time, although some studies suggest a slightly earlier onset for α-globin gene expression. Transcription persists at a high level throughout most of the remainder of erythropoiesis, declines as the nucleus condenses, and is eventually lost in late erythroblasts. Even as the absolute rates of globin gene transcription begin to decrease, however, the relative percentage of total transcriptional activity devoted to globin gene expression continues to increase; this reflects the silencing of transcription of almost every other gene in the erythroblast.

The transcriptional activation of the globin genes is the major event that must be understood to define and manipulate the regulation of hemoglobin biosynthesis and hemoglobin switching. However, posttranscriptional mechanisms contribute to the final distribution of globin and nonglobin mRNAs and to the balance of α- and non–α-globins within the erythroblasts. When compared with many other mRNAs, such as cytokine mRNAs, globin mRNAs are extraordinarily stable. Their half-lives have been estimated at 30 to 50 hours. Most other mRNAs have turnover rates, or half-lives, measured within the range of a few minutes to 5 or 6 hours. The increase in the percentage of total mRNA that is globin mRNA is greatly accentuated because the newly transcribed globin mRNAs accumulate and remain quite stable in the cell, whereas nonglobin mRNAs, which are no longer being produced, are also disappearing at a faster rate. Consequently, the mRNA content of the reticulocytes consists of 90% to 95% globin mRNA.

The transcription rates of the α- and non–α-globin genes are not precisely equal. (This phenomenon has been studied in detail only in adult erythroid cells expressing the α- and β-globin genes.) A slight, but reproducibly detectable, excess of α-globin mRNA is present in erythroblasts. However, β-globin mRNA is translated somewhat more efficiently than α-globin mRNA. These counterbalancing forces result in almost equal syntheses of α- and β-globin polypeptide chains. There is a very slight excess of α-globin production, resulting in a small pool of free α-globin chains.

Alpha hemoglobin-stabilizing protein (AHSP), a small protein present at high concentrations in red cells, binds specifically to the α-globin polypeptide protecting the unstable free α-globin chain by inhibiting heme loss, and oxidant-mediated chain precipitation. It remains unclear whether mutations of this protein can modify the phenotype of β-thalassemia by increasing the imbalance in globin chain synthesis. Some α-globin chain variants, because the

mutations alter AHSP binding, are associated with mild thalassemia-like features.

Newly synthesized β-globin chains are rapidly and completely incorporated into αβ dimers, that spontaneously associate as tetramers. Hemoglobin tetramers are remarkably stable throughout the life span of the circulating red blood cell by virtue of their long half-lives. Only small amounts suffer oxidative or proteolytic damage.

Hemoglobin molecules are exposed for prolonged periods to chemically active compounds in the milieu of the bloodstream. They often become nonenzymatically modified by such processes as glycosylation, acetylation, and sulfation. Glycosylation occurs more extensively during periods of hyperglycemia and leads to elevated levels of the glycosylated form of HbA, HbA_{1c}. This phenomenon is the basis of a useful test for control of the blood sugar in diabetics. Other posttranslational modifications are of little clinical importance, except as already noted for 2,3-BPG, carbon dioxide (CO_2), and NO.

Transcriptional Regulation of Globin Gene Expression

Precise regulation of the globin gene clusters involves a complex interplay between *trans*-acting proteins, such as transcription factors, and *cis*-acting sequences that act as promoters, enhancers, and silencers of gene activity. DNA-binding proteins interact with sequences in regulatory regions of the globin gene cluster and with other proteins through specific protein-protein interactions, forming DNA-protein complexes that regulate gene transcription. Chapter 21 provides background information about the basic features and properties of transcription factors. *Trans*-acting factors mediate the remodeling of chromatin structure, influencing gene expression for the entire globin gene clusters. Mutations in the *cis*-acting sequences or *trans*-acting proteins cause dysregulated expression of globin genes, resulting in thalassemia-like syndromes. Elucidating the full extent of sequences required for appropriate expression of globin genes will inform the development of constructs for gene therapy.

Requisite for the expression of the globin genes is a local chromatin structure that supports transcription. "Open" chromatin, or (EO) euchromatin, generally appears cytogenetically uncondensed and is associated with hyperacetylated histones, unmethylated CpG dinucleotides, and active transcription. ATRX is a protein that has been implicated in the modulation of chromatin structure at the α-globin locus. Mutations in the *ATRX* gene, located on the X chromosome, cause a syndrome of α-thalassemia, severe mental retardation, facial dysmorphism, and urogenital abnormalities. ATRX, a member of the SNF2 family of helicase/ATPases, localizes to pericentromeric heterochromatin during interphase and mitosis and contains a plant homeodomain (PHD)-like domain that is found in chromatin-associated proteins. Cells with a mutated *ATRX* gene have altered patterns of DNA methylation. The ATRX protein therefore exemplifies the connections between DNA methylation, chromatin remodeling, and expression of the α-globin genes.

Chromatin structure can be manipulated pharmacologically through the influence of drugs on methylation and histone acetylation. Cytidine analogs such as 5-azacytidine and its less toxic derivative, decitabine, inactivate DNA methyltransferases, inducing γ-globin gene expression and increasing HbF levels in patients with sickle cell anemia. Histone deacetylase inhibitors such as butyric acid are being studied as agents to increase γ-globin expression.

The regions of the globin gene clusters with essential regulatory sequences and erythroid-specific chromatin remodeling extend far beyond the coding sequences of the globin genes. The key regulatory element for the α-globin gene (HS −40) lies in an erythroid-specific DNase I hypersensitive site 40 kb from the α-globin gene. The LCR is critical for high level expression of the β-globin gene cluster, consisting of five sites that are hypersensitive to DNase I (HS 1–5) (see Chapter 1). Patients with deletion of the HS −40 site exhibit α-thalassemia, and patients with deletions of the β-globin LCR develop β-thalassemia; however, the thalassemia can be a result of changes in chromatin caused by the large deletion. Similarly, transgenic mice bearing deletions of these critical regulatory regions have severely restricted expressions of the respective globin genes.

Mini-chromosome constructs, in which globin genes are attached directly to the LCR in the absence of most intervening DNA sequences, are expressed at rates approaching those of endogenous globin genes in cultured erythroid cells and transgenic mice. Some nonglobin genes are also expressed at very high levels in erythroid cells when attached to these LCR sequences. The LCRs contain binding sites for the major erythroid transcription factors, GATA1 and NFE2, as well as sites for transcription factors found more widely distributed in many cell types. One site in the β-globin LCR is believed to act as an insulating element, which protects expressed genes from gene silencing through the regulation of chromatin structure. The interrelationships among the LCR and individual promoters, enhancers, and silencers during erythroid differentiation and hemoglobin switching remain incompletely understood despite extraordinary experimental scrutiny. The LCR might have its effects by multiple mechanisms that include chromatin looping between the enhancer and promoters, by tracking or scanning along chromatin until a competent promoter is encountered, a combination of the two mechanisms or by binding of facilitator proteins between an enhancer and its cognate gene defining an activation domain. Modification of chromatin histones by acetylation and other mechanisms might determine which genes are activated by the LCR.

The LCR is unquestionably essential for the quantitatively high rates of β-globin gene expression during erythroid differentiation. The role of the LCR in dictating tissue specificity (ie, shutdown of globin gene expression in other tissues) or the sequential activation of silencing of genes during hemoglobin switching is less clear. Studies suggest that tissue specificity and qualitatively proper switching of γ- and β-globin gene expression in transgenic mice could be obtained with DNA constructs lacking the LCR. However, these genes were invariably expressed only 0.5% to 5% as actively as the endogenous globin genes of the host cell. The degree and fidelity of tissue-specific expression also appeared to depend on several factors, such as the site of transgene integration.

Shutdown of the embryonic genes late in the first trimester and, possibly, the decline of γ-gene expression during the perinatal period may also require the participation of active silencing mechanisms. The predominance of β-globin gene expression over γ-gene expression in adult life is not merely the result of preferential stimulation of β-gene expression. Active repression of the γ-genes may also be relevant; these mechanisms, if they exist, may have to be reversed to manipulate hemoglobin switching therapeutically.

The nuclei of erythroid cells contain numerous proteins that have been identified as transcription factors. Many of these are found in a wide variety of tissues. At least two factors, GATA1 and NFE2, are much more restricted in their ranges of expression and have been implicated as particularly important for globin gene expression. Mutations in GATA1 or its required coactivating protein (FOG1, also known as ZFPM1) can cause β-thalassemia and thrombocytopenia in patients.

GATA1 is named on the basis of the DNA sequence motif (T/A) GATA (A/G), the GATA motif that it recognizes and binds. It is a zinc finger class DNA-binding protein (see Chapter 21). GATA1 has been shown to activate promoters containing the cognate DNA sequence motif, even when placed in nonerythroid cells. Activity of GATA1 requires binding to a zinc finger protein cofactor called FOG1 (named for Friend of GATA1, but renamed ZFPM1 for zinc finger protein, multitype 1). NFE2 recognizes the DNA sequence motif (T/C) GCT GA (C/G) TCA (T/C). It is a member of the B-zip class of transcriptional activators. GATA1 and NFE2 were originally identified and cloned on the basis of their interactions with their cognate sequences in the globin genes. Initially, each was thought to be present only in erythroid cells. However, further work has demonstrated that each protein has a wider range of tissue expression. For example, GATA1 is also present in other hematopoietic cell lineages, whereas NFE2 consists of two subunits, one that is widely expressed and one that is expressed in several hematopoietic lineages and the

intestine. Erythroid Kruppel-like factor (EKLF, also called KLF1) may be the most specific of the erythroid transcription factors yet discovered. EKLF interacts specifically with the β-globin gene promoter and may influence the γ-β switch. Mice homozygous for disruption of the EKLF gene have lethal β-thalassemia.

Neither GATA1, NFE2, EKLF, nor FOG1 alone can be the sole determination of tissue specificity of the globin genes; otherwise, globin gene expression should occur at some level in other tissues in which these proteins are present. However, there is no doubt that each of these proteins is indispensable for globin gene expression and erythropoiesis. Gene knock-out studies have shown that absence of each protein results in greatly impaired erythropoiesis. Several other proteins have been identified as binding to various control elements in the globin gene cluster. Some of these appear to be stage-specific selector elements that bind predominantly to the γ- or β-globin gene enhancers and promoters. Others are generic transcription factors. Regulation at these sites is probably hierarchic, depending on the appropriate combination of DNA-binding proteins, the types of proteins that interact with them, and the activation state of the bound proteins through such processes as ribosylation and phosphorylation. It is also possible that the same sequence element may interact with different combinational sets of proteins, with a different resulting effect on transcriptional activity, depending on the stage of differentiation and embryonic, fetal, or adult development.

The precise molecular machinery necessary for regulation of transcription of individual globin genes is beginning to be defined. The globin genes are also subject to regulation by cellular, microenvironmental, and humoral influences affecting the proliferation and differentiation state of primitive erythroid stem cells in yolk sac, fetal liver, or bone marrow. Overwhelming evidence supports the hypothesis that the potential for expression of γ- or β-genes, or both, is determined in primitive erythroid stem cells (ie, BFU-E) long before actual expression of the globin genes is initiated at a later stage of differentiation. The relative percentage of maturing erythroblasts that will ultimately express HbF or HbA, or both, can be altered by factors such as cytotoxic drugs or bone marrow stress that alter the relative percentages of HbF-potent or HbA-potent stem cells undergoing cell cycle events, differentiation, and so forth. Drugs used to manipulate HbF switching seem to work primarily through these cellular mechanisms (see Chapter 25).

Posttranscriptional, Translational, and Posttranslational Mechanisms

Processed globin mRNA is exported from the nucleus to the cytoplasm by a mechanism that is not clearly defined. mRNA translation occurs in the cytoplasm (see Fig. 33–7). The triplet codons or mRNA are recognized by the anticodons of specific tRNAs that bring activated amino acid residues to the nascent polypeptide chains. The process of translation, in which an mRNA template directs the synthesis of protein, is typically divided into three phases: initiation, elongation, and termination (see Chapter 1). Each phase is regulated by a variety of protein factors.

The globin mRNA molecule becomes associated with four to six ribosomes, forming the polyribosome. At least 11 eukaryotic translation initiation factors interact with the polyribosome. They mediate stabilization of a preinitiation complex, binding of the initiator methionine tRNA to ribosomal subunits, binding of mRNA to the preinitiation complex, stabilization of mRNA binding, recognition of the cap site at the 5′ end of mRNA, and release of initiation factors from the preinitiation complex. Several elongation and termination factors have also been defined. Initiation or an early step in the elongation process is the rate-limiting factor.

The first posttranslational step in tetramer formation is the combination of α- and non–α-globin chains to form dimers, an event that appears to depend on the relative charge of each globin subunit. The dimers then form tetrameric hemoglobin. Because of charge differences among non–α-globin chains, there is a hierarchy or affinity of these chains for α-globin chains. The combination of α- and β-globin chains is most favored, followed by a combination of α-, γ-, and δ-globin chains. Certain mutant hemoglobins that have gained or lost a charge may alter this hierarchic arrangement. This may influence the proportion of variant hemoglobin present, especially when the patient also inherits an α-thalassemia syndrome, in which the synthesis of α-globin chains is reduced. The supply of available α-globin chains is then limited, and non–α-globin chains compete with one another to form tetramers with the limiting α-globin chain pool.

Globin chain biosynthesis and heme synthesis are mutually important. Heme plays a role in the regulation of the initiation complex. A deficiency of heme (eg, in iron deficiency) is associated with the accumulation of a repressor of translation initiation factors. Translation of β-globin mRNA appears to be initiated more efficiently than α-globin mRNA, conferring on the associated anemia some of the features of mild α-thalassemia. This phenomenon occurs

Table 33–1. Classification of Hemoglobinopathies and Thalassemias

Structural hemoglobinopathies—mutations altering the amino acid sequence of a globin chain and altering physical or chemical properties of the hemoglobin tetramer in such a way that function is deranged
Abnormal hemoglobin (Hb) polymerization—sickle cell hemoglobin (HbS); hemolysis, vasoocclusion
Abnormal hemoglobin crystallization (eg, HbC)
High oxygen affinity—polycythemia (Hb Zurich)
Low oxygen affinity—cyanosis (Hb Kansas)
Hemoglobins that oxidize or precipitate too readily—unstable hemoglobins (Hb Köln)
M hemoglobins—methemoglobinemia, cyanosis (eg, Hb Milwaukee)
Thalassemia—defective production of globin chains with hypochromia, anemia, hemolysis, altered erythropoiesis
α-Thalassemia
β-Thalassemia
δβ-Thalassemias, γδβ-thalassemias, αβ-thalassemias
"Thalassemic" hemoglobinopathies and dominantly inherited thalassemias—mutations altering the synthesis and structure or function of the hemoglobin gene products (eg, HbE, Hb Terre Haute, Hb Lepore, Hb Constant Spring)
Hereditary persistence of fetal hemoglobin—persistence of high levels of fetal hemoglobin (HbF) into adult life
Pancellular—high HbF levels in all red blood cells
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellular—inherited increases in the percentage of F cells
Acquired hemoglobinopathies
Methemoglobinemia caused by toxic exposures
Sulfhemoglobinemia caused by toxic exposures
Carboxyhemoglobinemia caused by toxic exposures
HbH in erythroleukemias
Acquired elevations in F cells and HbF
Erythroid stress (eg, recovery from bone marrow suppression)
Bone marrow dysplasias
Exposure to agents altering stem cells or gene expression (eg, hydroxyurea, butyric acid)

because heme deficiency depresses the availability of initiating factors for which the less efficient α-mRNA must compete with the more efficient β-mRNA.

NOSOLOGY OF HEMOGLOBINOPATHIES

Inherited abnormalities of the hemoglobin molecules that cause morbidity are called *hemoglobinopathies* and *thalassemias*. Many of these conditions produce diseases (eg, sickle cell anemia, thalassemia, unstable hemoglobins, M hemoglobins) that are especially important to hematologists. A few acquired conditions lead to modifications of hemoglobin (eg, carbon monoxide exposure, producing carboxyhemoglobinemia, nitrite exposure causing methemoglobinemia) that produce clinical abnormalities. These situations are summarized by the term *acquired hemoglobinopathies* or *dyshemoglobinemias*.

Most of the more than 1200 mutations of the globin gene that have been described produce no disease or only trivial clinical effects. The remainder can be classified according to the hematologic and clinical phenotypes that cause reduced solubility with hemolytic anemia (unstable hemoglobins and polymerizing hemoglobins, such as sickle hemoglobin), hemoglobins with altered oxygen affinity, hemoglobins predisposing to methemoglobin formation, and the thalassemias involving abnormal synthesis of one or more globin chains with anemia, hemolysis, and alterations of erythropoiesis. Some mutations, such as that responsible for HbE, can alter the structure and synthesis of the molecule. A classification of hemoglobinopathies and thalassemias is provided in Table 33–1. Individual conditions are discussed in the chapters already cross-referenced in earlier sections of this chapter.

CHAPTER 34

APPROACH TO ANEMIA IN THE ADULT AND CHILD

Peter W. Marks and Bertil Glader

Anemia is among the most common hematologic problems in both adults and children.[1–3] A systematic approach to the patient with anemia can rapidly lead to the appropriate diagnosis of the most common entities with minimal diagnostic testing. It also facilitates the specialized investigation necessary to identify some of the less commonly encountered congenital and acquired anemias.

OVERVIEW OF ERYTHROPOIESIS

Erythropoiesis is an orderly process that leads to the production of mature erythrocytes.[4] Proliferation and differentiation of stem cells in the bone marrow are driven by a variety of factors, most notably erythropoietin. Reticulocytes are ultimately released into the circulation (Fig. 34–1). Within one day, reticulocytes transition into mature red blood cells that circulate for 100 to 120 days, at which time they are removed from the circulation by macrophages in the spleen and other reticuloendothelial tissues.[5] Under normal conditions, the process is regulated such that an equivalent number of erythrocytes are produced to replace those lost through senescence. In the event of anemia (defined by a decline in the circulating red blood cell mass), decreased oxygen delivery to the kidney drives the production of erythropoietin, which then stimulates red blood cell production in the bone marrow (Fig. 34–2).[6] Provided that there is an adequate supply of folate, vitamin B_{12}, iron, and other nutrients, the marrow responds by increasing the production and release of erythrocytes into the circulation.[7]

MECHANISMS OF ANEMIA

In the setting of acute or chronic blood loss, increased red blood cell production occurs in response to erythropoietin, provided that adequate nutrients are present for the formation of new cells.[8] Aside from hemorrhage, anemias can be categorized as either hypoproliferative or hemolytic (hyperproliferative). Hypoproliferative anemias are due to impaired red blood cell production and often result from acquired nutritional deficiencies or systemic diseases. Hemolytic anemias may be either congenital or acquired, the former being more common in children and the latter in adults.[9]

Hypoproliferative Anemias

The inability to produce an adequate number of erythrocytes in response to the appropriate stimulus defines the hypoproliferative anemias. Nutritional deficiencies are the most common causes of hypoproliferative anemia worldwide and affect both adults and children (Table 34–1).[10] It is estimated that 4% of women in the United States between the ages of 20 and 49 years have iron deficiency anemia.[11] Other common causes include the anemia of acute or chronic inflammation[12,13] and the anemia of renal disease (essentially a deficiency in erythropoietin).[12] Hematologic malignancies and solid tumors infiltrating the bone marrow (myelophthisis) may be encountered in adults and, to a lesser extent, in children. Acquired and congenital red blood cell hypoplastic disorders frequently are encountered in children and much less so in adults.[14]

Hemolytic Anemias

The hemolytic anemias are a consequence of the premature destruction of erythrocytes and are due to a broad array of disorders that may be congenital or acquired (see Table 34–1).[15] Congenital causes of hemolytic anemia may lead to severe problems in early childhood (eg, β-thalassemia major, sickle cell anemia), or may remain silent until a stressor is encountered later in life, provoking a crisis (eg, glucose-6-phosphate dehydrogenase deficiency).[16] Alternatively, some hereditary hemolytic anemias may go unrecognized throughout much of childhood and adult life (eg, mild hereditary spherocytosis).[17] Acquired hemolytic anemias due to stem cell disorders (paroxysmal nocturnal hemoglobinuria) occur primarily in adults. Acquired hemolytic disorders resulting from immune dysregulation (autoimmune hemolytic anemia) and those caused by the mechanical destruction of the erythrocyte (microangiopathic hemolytic anemia) occur in both children and adults.[18,19]

NORMAL RED BLOOD CELL VALUES IN THE ADULT AND CHILD

Modern laboratory instruments provide a wealth of diagnostic information for interpretation.[20] Using these data thoughtfully in combination with information from review of the peripheral blood smear can often lead directly to the correct diagnosis without additional diagnostic testing.

It is important to recognize that the normal ranges for hemoglobin, hematocrit, and red blood cell indices are different for infants, children, and adults (Table 34–2).[21] In addition, with the aging process, modest changes in red blood cell mass occur in adults.[22,23] Knowledge of age- and sex-appropriate normal values is important in the evaluation of anemia. For instance, in healthy men, there is a modest decline in hemoglobin with age of about 1 g/dL between the ages of 70 and 88 years, in part due to the decreased production of androgens. Only a minimal decrease in hemoglobin occurs between these ages in healthy women (about 0.2 g/dL).[24] Physician awareness of the expected change in hemoglobin in older men and its relative stability in older women can help avoid unnecessary laboratory investigations in older men and correctly initiate further diagnostic evaluations in older women with mild anemia.

SYSTEMATIC APPROACH TO THE EVALUATION OF ANEMIA

The correct diagnosis of anemia can often be determined by combining a thorough history and physical examination with reviews of the complete blood cell count, reticulocyte count, and peripheral blood smear.

History and Physical Examination

Because anemia can be a primary disorder or secondary to other systemic processes, a careful history and physical examination will provide valuable insight into the potential cause. Fatigue often

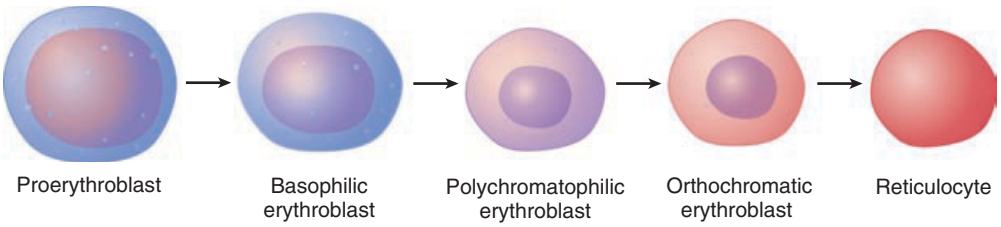

Figure 34–1 Overview of erythropoiesis.

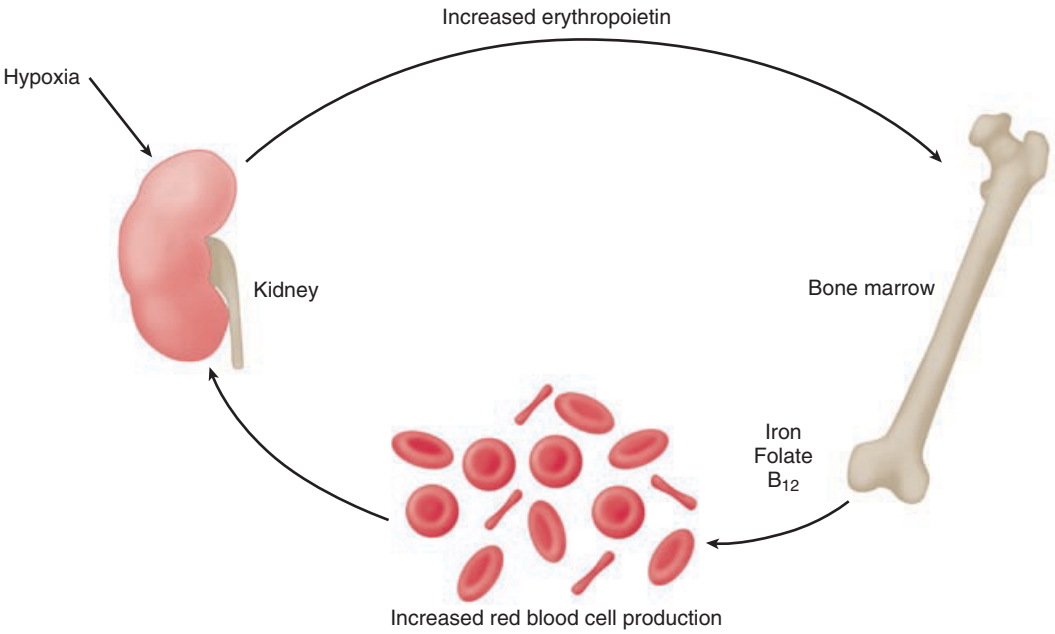

Figure 34–2 Regulation of erythropoiesis.

Table 34–1 Common Causes of Newly Diagnosed Anemia

Iron deficiency
Acute or chronic inflammation
Renal disease
Folate or vitamin B_{12} deficiency
α- or β-thalassemia syndromes
Sickle cell disease
Enzymopathies (G6PD, others)
Hereditary spherocytosis
Autoimmune hemolytic anemia
Myelodysplastic syndromes
Myelophthisic processes
Leukemia
Congenital or acquired red cell aplasia

G6PD, glucose-6-phosphate dehydrogenase.

accompanies anemia, but it is very nonspecific and may be related to systemic illness. Nonetheless, determining the concomitant presence of a systemic inflammatory disorder, infection, or malignancy associated with fatigue may be critical in determining the underlying causes of anemia in both adults and children.[25] Past medical history may also be quite informative. For example, a history of diabetes mellitus can be associated with significantly impaired renal production of erythropoietin even in the setting of only a mildly elevated creatinine level.[26] Because certain medications may be associated with bone marrow depression or, alternatively, the development of autoimmune hemolytic anemia, all pharmacologic agents, prescribed and over-the-counter, including alternative medicines, should be reviewed.[27] Occupational history is occasionally relevant, as in the case of individuals, such as welders, who might have been exposed to lead or other potentially marrow toxic agents.[28,29] Social history can be important. Thus, a history of intravenous drug use might suggest the possibility of virally transmitted diseases, such as HIV, which may be associated with anemia.[30] Dietary history is very important, particularly in the young and the elderly with anemia. The finding of pica in adults (most commonly ice chips or cornstarch) is well known to be associated with iron deficiency anemia.[31] Ingestion of paint chips may suggest the need to investigate the possibility of toxic lead ingestion. Family history of anemia is particularly important in the evaluation of children with anemia. However, it is also relevant in adults because certain congenital anemias, such as hereditary spherocytosis, occasionally first become clinically apparent in adulthood.[32]

The significance of pallor on physical examination is in many ways similar to the historic feature of fatigue: it is a common but nonspecific finding. More specific findings may be found in certain types of anemias. For example, angular cheilitis (cracking at the edges of the lips) and koilonychia (spooning of the nails) may accompany iron deficiency anemia.[33] Splenomegaly may be present in patients with anemia arising from a wide variety of different causes.[34] When present early in life, it is suggestive of a congenital hemolytic anemia, such as thalassemia, sickle cell disease, or hereditary spherocytosis. When found for the first time later in life, splenomegaly may indicate an acquired disorder, such as autoimmune hemolytic anemia, lymphoproliferative disease, or agnogenic myeloid metaplasia. Other physical findings can also sometimes provide insight into the investigation of anemia when combined with historic features and laboratory data. Although anemia itself may lead to the presence of systolic cardiac murmurs, the finding of an increased cardiac murmur in an anemic patient with a prosthetic aortic valve and new microangiopathic change on peripheral smear may indicate that investigation into the possibility of perivalvular leak or prosthetic dysfunction is in order.[35] Finally, because neurologic manifestations can accompany or even predate the anemia associated with vitamin B_{12} deficiency, findings

Table 34–2 Normal Red Blood Cell Values

	Hemoglobin g/dL		Hematocrit (%)		Red Cell Count (10^{12}/L)		MCV (fL)		MCH (pg)		MCHC (g/dL)

such as loss of vibration or position sense in the extremities may be relevant.[36]

Reticulocyte Count

As a marker of red blood cell production, the reticulocyte count provides important information in directing the initial investigation of anemia. Modern flow cytometers accurately determine the reticulocyte count using fluorescent probes that bind to the residual ribonucleic acid present in newly released red blood cells.[37] These measurements are useful, are accurate, and reflect the state of erythropoiesis. However, when significant numbers of nucleated red blood cells or nuclear debris are present in the peripheral blood, this diagnostic accuracy declines, and manual counting methods are generally preferable.

When the reticulocyte count is reported as a percentage, it needs to be adjusted for the total number of red blood cells present. This correction can be made by multiplying the reticulocyte count by the patient's hematocrit divided by an age- and sex-appropriate normal hematocrit. No such correction is necessary when the reticulocyte count is reported as an absolute number or when it is converted to an absolute number by multiplying the percentage by the red blood cell number (in RBC/μL).

In the absence of anemia, the normal absolute reticulocyte count is between 25,000 and 75,000/μL. In the presence of anemia, an absolute reticulocyte count of less than 75,000/μL is indicative of a hypoproliferative process, whereas an absolute reticulocyte count of greater than 100,000/μL is indicative of hemolysis or an appropriate erythropoietic response (Table 34–3). Reticulocyte counts between 75,000 and 100,000/μL require interpretation in the context of other available clinical data including the severity of anemia present.

Table 34–3 Usefulness of the Reticulocyte Count in the Diagnosis of Anemia

Diagnosis	Value
Hypoproliferative anemias	***Absolute reticulocyte count <75,000/μl***
Anemia of chronic disease	
Anemia of renal disease	
Congenital dyserythropoietic anemias	
Effects of drugs or toxins	
Endocrine anemias	
Iron deficiency	
Marrow replacement	
Maturation abnormalities	***Absolute reticulocyte count <75,000/μl***
Vitamin B_{12} deficiency	
Folate deficiency	
Sideroblastic anemia	
Appropriate response to blood loss or nutritional supplementation	***Absolute reticulocyte count >100,000/μl***
Hemolytic anemias	
Hemoglobinopathies	
Immune hemolytic anemias	
Infectious causes of hemolysis	
Membrane abnormalities	
Metabolic abnormalities	
Mechanical hemolysis	

Mean Corpuscular Volume and Red Blood Cell Distribution Width

Automated cell counters provide a wealth of information regarding the size, shape, and hemoglobin content of red blood cells. The two parameters most useful in classifying anemia are the mean corpuscular volume (MCV) and the red blood cell distribution width (RDW). MCV is reported in femtoliters (fL) and reflects average cell size. RDW is a dimensionless quantity (actually the standard deviation of red blood cell volume divided by the mean volume) that reflects the variation in cell size in the population of red blood cells.[38] These

parameters are useful because relatively reproducible changes in the MCV and RDW are associated with certain types of anemia (Table 34–4). Particularly when combined with the reticulocyte count, the MCV and RDW can significantly narrow the differential diagnosis (Table 34–5).

Examination of the Peripheral Blood Smear

Despite the availability of automated cell counters and sophisticated diagnostic testing, review of a well-made peripheral blood smear remains one of the most informative and rewarding diagnostic procedures. It offers the chance to confirm the findings of the automated complete blood cell count, which can be inaccurate in the presence of nucleated red blood cells or rouleaux formation. Review of the blood smear also allows for evaluation of other cell lineages, which might suggest a primary marrow or infiltrative disease. The finding of hypersegmented neutrophils suggests a megaloblastic process, and this morphologic abnormality can be seen in the blood smear before there are significant changes in the hemoglobin or MCV (see box on the Systematic Approach to the Diagnosis of Anemia). Also, only the blood smear reveals the unique morphologic changes occurring with various hemolytic disorders.

There are several commonly encountered findings that can be seen in red blood cells on the peripheral blood smear (Table 34–6, and Fig. 34–3). Microcytic, hypochromic red blood cells are suggestive of iron deficiency anemia or thalassemia (Fig. 34–3F); whereas macrocytic red blood cells with ovalocytes (oval red blood cells) are suggestive of megaloblastic anemias (Fig. 34–3G). Some findings reflect organ dysfunction, such as echinocytes (burr cells) in uremia (Fig. 34–3R), or acanthocytes (spur cells) in severe liver disease (Fig. 34–3S), although acanthocytes may also be seen in rare conditions such as abetalipoproteinemia. Target cells may be seen in cases of liver disease but may also be present in hemoglobinopathies, including sickle cell disease or thalassemia (Fig. 34–3W). The presence of schistocytes or red blood cell fragmentation often reflects systemic disease, such as disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, or the hemolytic uremic syndrome (Fig. 34–3P). Finding spherocytes on a smear is suggestive of autoimmune hemolytic anemia or hereditary spherocytosis (Fig. 34–3H). Occasionally, the clue to the correct diagnosis of a systemic illness comes in the form of the observation of intraerythrocytic inclusions, such as malarial (Figure 34–3O) or babesial forms, and examination of a thick blood smear may be useful for the diagnosis of these disorders when a low parasite burden is suspected.

Table 34–5 Combining the Reticulocyte Count and Red Blood Cell Parameters for Diagnosis

MCV, RDW	Reticulocyte Count <75,000/μL	Reticulocyte Count >100,000/μL
Low, Normal	Anemia of chronic disease	
Normal, Normal	Anemia of chronic disease	
High, Normal	Chemotherapy/antivirals/alcohol Aplastic anemia	Chronic liver disease
Low, High	Iron deficiency anemia	Sickle cell-β-thalassemia
Normal, High	Early iron, folate, vitamin B_{12} deficiency Myelodysplasia	Sickle cell anemia, sickle cell disease
High, High	Folate or vitamin B_{12} deficiency Myelodysplasia	Immune hemolytic anemia Chronic liver disease

MCV, mean corpuscular volume; RDW, red blood cell distribution width.

Systematic Approach to the Diagnosis of Anemia

Integration of historic features and physical findings with thoughtful review of the results of the automated complete blood cell count and of the peripheral smear often serves to narrow down the differential diagnosis significantly. For example, a patient status post-gastric bypass eating a normal diet who presents with gradual onset of fatigue accompanied by the more recent onset of distal paresthesias and a finding of decreased vibration sense, in the setting of anemia with significantly elevated MCV and RDW values and numerous six-lobed polymorphonuclear leukocytes on peripheral blood smear, almost certainly has a vitamin B_{12} deficiency. This is suggested even before the return of specific laboratory testing because of the relatively narrow differential diagnosis for megaloblastic anemia and the fact that neurologic abnormalities are not associated with folate deficiency. For the purposes of diagnostic efficiency, the rewards of correlation of historic features and physical findings with a careful review of the peripheral blood smear cannot be overstated.

Special stains of the peripheral blood smear can be helpful in elucidating the cause of anemia. If there is significant nuclear debris present, the reticulocyte count obtained by automated methods can be inaccurate. In such cases, manual counting after staining with new methylene blue, which stains residual RNA in reticulocytes, permits accurate enumeration. If bite cells are detected on peripheral smear, supravital staining with methyl crystal violet can reveal Heinz bodies. These are aggregates of denatured hemoglobin reflecting an oxidative insult, most commonly due to glucose-6-phosphate dehydrogenase deficiency or, less frequently, to the presence of an unstable hemoglobin (Fig. 34–3H).

Table 34–4 Usefulness of the Mean Corpuscular Value (MCV) and Red Blood Cell Distribution Width (RDW) in the Diagnosis of Anemia

	Low MCV (<80 fL)	Normal MCV (80–99 fL)	High MCV (>100 fL)
Normal RDW	Anemia of chronic disease α- or β-Thalassemia trait Hemoglobin E trait	Acute blood loss Anemia of chronic disease Anemia of renal disease	Aplastic anemia Chronic liver disease Chemotherapy/antivirals/alcohol
Elevated RDW	Iron deficiency Sickle cell-β-thalassemia	Early iron, folate, or vitamin B_{12} deficiency Dimorphic anemia (for example, iron + folate deficiency) Sickle cell anemia Sickle cell disease Chronic liver disease Myelodysplasia	Folate or vitamin B_{12} deficiency Immune hemolytic anemia Cytotoxic chemotherapy Chronic liver disease Myelodysplasia

Table 34–6 Features of the Peripheral Blood Smear

Red Blood Cell Morphology	Definition	Interpretation
Polychromasia	Large, bluish red blood cells lacking normal central pallor on peripheral blood smear; bluish stain is the result of residual ribonucleic acid.	Rapid production and release of red blood cells from marrow; elevated reticulocyte count; most commonly seen in hemolytic anemia.
Basophilic stippling	Many small bluish dots in portion of erythrocytes; comes from staining of clustered polyribosomes in young circulating red blood cells.	Seen in a variety of erythropoietic disorders, including acquired and congenital hemolytic anemias and occasionally in lead poisoning (lead inhibits pyrimidine 5′-nucleotidase, which normally digests the residual RNA).
Pappenheimer bodies	Several grayish, irregularly shaped inclusions in a portion of erythrocytes visible on peripheral smear; composed of aggregates of ribosomes, ferritin, and mitochondria.	Erythropoietic malfunction in congenital anemias such as hemoglobinopathies, particularly with splenic hypofunction or acquired anemias such as megaloblastic anemia.
Heinz bodies	Several grayish, round inclusions visible after supravital staining with methyl crystal violet of the peripheral blood smear, often in the context of bite cells; represent aggregates of denatured hemoglobin.	Indicative of oxidative injury to the erythrocyte, such as occurs in G6PD deficiency, or less commonly of unstable hemoglobins.
Howell-Jolly bodies	Usually one or at most a few purplish inclusions in the erythrocyte visible on the routine peripheral blood smear; represent residual fragments of nuclei containing chromatin.	Associated with states of splenic hypofunction or after splenectomy.
Schistocytes	Red blood cells that are fragmented into a variety of shapes and sizes, including helmet-shaped cells; indicative of shearing of the erythrocyte within the circulation.	Associated with microangiopathic hemolytic anemias, including DIC, TTP/HUS, as well as other mechanical causes of hemolysis, such as prosthetic valves.
Spherocytes	Red blood cells that have lost their central pallor and appear spherical; indicative of loss of cytoskeletal integrity due to internal or external causes.	Associated with hereditary spherocytosis, autoimmune hemolytic anemia; may also be observed in addition to schistocytes in the presence of microangiopathic hemolytic anemia.
Teardrop cells	Pear-shaped erythrocytes visible on peripheral blood smear; indicative of mechanical stress on the red blood cell during release from the bone marrow or passage through the spleen.	Seen in a variety of conditions, including congenital anemias such as thalassemia and acquired disorders such as megaloblastic anemia; may also suggest a more ominous process such as myelophthisis (marrow replacement).
Burr cells (echinocytes)	Red blood cells that have smooth undulations present on the surface circumferentially; pathogenesis unknown.	Indicative of uremia when present on a properly made peripheral blood smear.
Spur cells (acanthocytes)	Red blood cells that have spiny points present on the surface circumferentially; reflective of abnormal lipid composition of red blood cell membrane.	Most commonly indicative of liver disease when present in significant numbers; also seen in abetalipoproteinemia and in red blood cells lacking the Kell blood group antigen.

DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

Bone Marrow Examination

Bone marrow aspiration and biopsy permit evaluation of cellular morphology and marrow architecture, respectively. Special stains, flow cytometry, cytogenetics, fluorescence in situ hybridization (FISH), and molecular testing that can be performed on the marrow also can provide a wealth of diagnostic information.[39] Because of the discomfort involved in the procedure, however, careful consideration should be given to determining the array of tests required, so that repeated marrow aspirates or biopsies need not be performed. If there is any consideration of the possibility of myelodysplasia, leukemia, or lymphoma, an aliquot of anticoagulated aspirate should be set aside at the time of the initial procedure that can be sent, if necessary, for flow cytometry or cytogenetics after review of the aspirate smear.

Diagnostic uncertainty in the setting of hypoproliferative anemia is an indication for bone marrow biopsy. Hematologic disorders such as myelodysplasia, leukemia, lymphoma, or myeloma may be identified. Myelodysplasia in the marrow classically includes megaloblastic change and nuclear budding in maturing erythroblasts, as well as morphologic abnormalities in other lineages, such as hypolobated megakaryocytes and hypogranulation of the myeloid lineage.[40] A variety of infiltrative (myelophthisic) processes may be observed. These include malignancies such as small cell lung, breast, and prostate cancers, which not infrequently can appear in advanced stages with marrow involvement. Alternatively, granulomas may be present, suggesting the possible presence of mycobacterial disease. In children, disseminated neuroblastoma and rhabdomyosarcoma occasionally can appear as a myelophthisic anemia.

Even when properly performed, difficulty obtaining a bone marrow aspirate is commonly observed in certain situations, such as myelofibrosis, erythroblastic leukemia (M6), and hairy cell leukemia.[41] In these cases, touch preps of the bone marrow biopsy may help expedite diagnosis.

DIFFERENCES IN THE EVALUATION OF ANEMIA BETWEEN PEDIATRIC AND ADULT PATIENTS

There are several features that distinguish evaluation of pediatric patients, the most important being that the normal ranges for red blood cell parameters are significantly different in infants and chil-

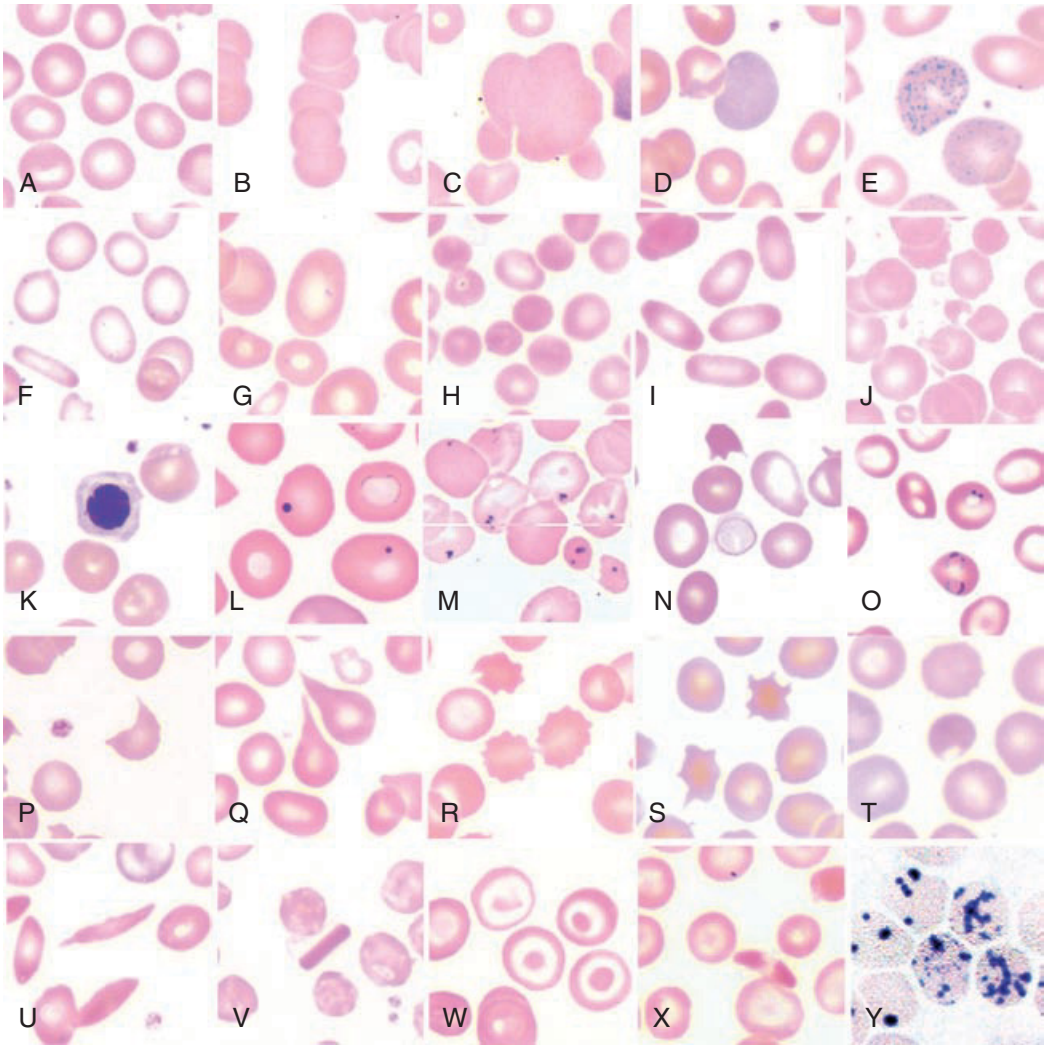

Figure 34–3 Useful peripheral blood and red blood cell features in the evaluation of anemia: A–Y. **A.** Normal red blood cells. Note the central pallor is one-third the diameter of the entire cell. **B.** Rouleaux formation is indicative of increased plasma protein. **C.** Agglutination indicates an antibody-mediated process such as cold agglutinin disease. **D.** Polychromatophilic cell. The gray-blue color is due to RNA and the cell is equivalent to a reticulocyte, which must be identified with a reticulocyte stain. **E.** Basophilic stippling. This also is due to increased RNA due either to a left shift in erythroid cells or to lead toxicity. **F.** Hypochromic microcytic cells typical of iron deficiency anemia. Note the widened central pallor, and the "pencil" cell in lower left. **G**. Macroovalocyte as can be seen in either megaloblastic anemia or MDS. **H.** Microspherocytes typical of hereditary spherocytosis. **I.** Elliptocytes (ovalocytes) from a patient with hereditary elliptocytosis. **J.** Red blood cell fragments from thermal injury (burn patient). **K.** Nucleated red blood cell. **L.** Howell-Jolly bodies indicative of splenic dysfunction or absence. **M.** Pappenheimer bodies from patient with sideroblastic anemia. **N.** Cabot ring, as can be seen in megaloblastic anemia or MDS. **O**. Malarial parasites (*Plasmodium falciparum*). **P.** Schistocyte typical of a microangiopathic hemolytic anemia. **Q.** Tear-drop form indicates marrow fibrosis and extramedullary hematopoiesis. **R.** Echinocyte (Burr cell) with rounded edges. **S.** Acanthocyte (spur cell) with more irregular pointed ends. This was from a patient with neuroacanthocytosis. They can also be seen in patients with liver disease and lipid abnormalities. **T.** "Bite" cell from a patient with G6PD deficiency. **U.** Sickle cell, from a patient with HbSS disease. **V.** Hemoglobin C crystal. **W**. Target cells. **X.** Hemoglobin SC. Note red blood cell in center has condensed hemoglobin at each pole. **Y.** Heinz body preparation (supravital stain) from a patient with G6PD deficiency. Note cells to right have increased precipitated hemoglobin. G6PD, glucose-6-phosphate dehydrogenase; HbSS, homozygous sickle cell; MDS, myelodysplasia syndrome.

dren and do not reach adult levels until adolescence. Thus, the determination of whether anemia is present must be based on age-appropriate normal values (see Table 34–2). Upon identification of anemia, the likelihood of certain diagnostic entities is different in infants, children, and adults. In infants and children, anemia often represents a nutritional deficiency or a primary hematologic process, whereas in adults anemia more commonly is an indicator of systemic disease or malignancy.

Approach to Hypoproliferative Anemia in the Adult

Hypoproliferative anemia is reasonably common in adults. Except in the setting of acute blood loss, the new onset of anemia in an adult is more commonly associated with a hypoproliferative process rather than a hemolytic one. A systematic approach integrating historic features with laboratory findings can often lead to a short differential diagnosis list (Fig. 34–4).

Microcytic anemia with an MCV of less than 70 fL is most commonly associated with iron deficiency anemia or thalassemia. MCV values between 70 and 80 fL may be associated with the anemia of chronic disease or endocrine causes such as hyperthyroidism. MCV values above the upper limit of normal suggest the possibility of increased ethanol intake, liver disease, myelodysplastic syndrome, and also megaloblastic anemia due to folate or vitamin B_{12} deficiency. When the MCV is greater than 120 fL, however, this most often is associated with folate or vitamin B_{12} deficiency.

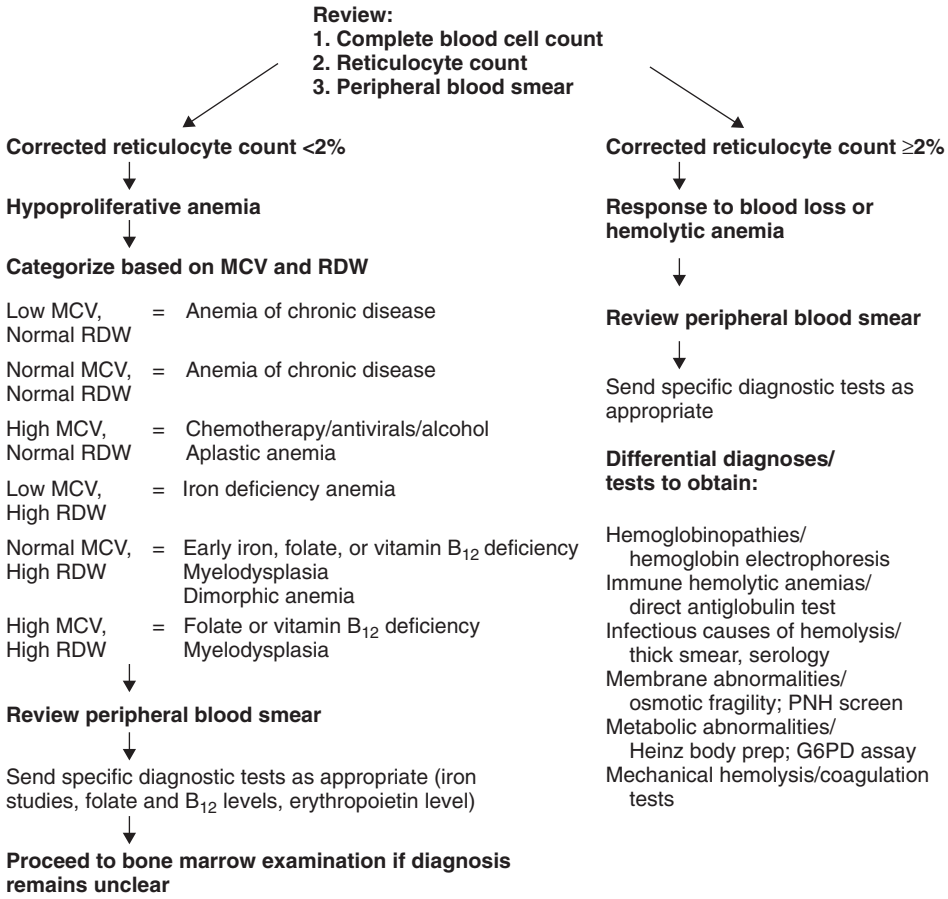

Figure 34–4 Approach to the differential diagnoses of anemia in the adult and child. G6PD, glucose-6-phosphate dehydrogenase; MCV, mean corpuscular volume; PNH, paroxysmal nocturnal hemoglobinuria; RDW, red blood cell distribution width.

The most commonly encountered normocytic hypoproliferative anemia in adults is due to chronic disease, which, when broadly defined, includes anemias due to renal disease and inflammatory causes. Mild or early iron deficiency anemia is also a common cause of normocytic anemia. In such cases, erythropoietin levels may be of value in the diagnostic evaluation, before proceeding to bone marrow examination.[42] Occasionally, a normocytic anemia represents the result of averaging two populations of red blood cells: one microcytic and one macrocytic. Such cases of dimorphic anemia are encountered in combined nutritional deficiencies, such as when iron and folate deficiencies are present. The RDW is usually markedly elevated in such cases, and review of the peripheral blood smear confirms the diversity in red blood cell size.

Approach to Hemolytic Anemia in the Adult

Newly diagnosed hemolytic anemia is less common in adults than hypoproliferative anemia. Because the differential diagnosis is relatively broad, historical factors, such as information regarding the onset of anemia, and physical findings, such as splenomegaly, may help to narrow the diagnostic entities under consideration (see Fig. 34–4). Review of the peripheral blood smear is essential and potentially more useful than bone marrow examination in providing valuable diagnostic information.

Hemolytic anemia in the adult may represent an inherited condition that has gone previously undiagnosed. For example, mild to moderate hereditary spherocytosis or sickle/β^+-thalassemia sometimes may not manifest until adulthood. Alternatively, hemolysis may be due to a new acquired disorder such as autoimmune hemolytic anemia (AIHA) or a microangiopathic process. Autoimmune hemolytic anemia is occasionally associated with lymphoproliferative and rheumatologic disorders, so these potential underlying conditions should routinely be considered when the diagnosis of AIHA is made. Similarly, the cause of a microangiopathic hemolytic anemia is often clear from the clinical setting, although it sometimes is a clue to the diagnosis of an occult malignancy, such as metastatic prostate cancer.

Approach to Hypoproliferative Anemia in the Child

A systematic diagnostic approach, similar to that used in the adult, is most productive in children (see Fig. 34–4). Nutritional anemias due to iron deficiency are a particularly common cause of low hemoglobin in the first 2 years of life. Often the cause of this anemia is excessive intake of cow's milk to the exclusion of other sources of calories, and this information is often obtained from the medical history. Anemia due to iron deficiency often is quite severe, and characteristically has a very low MCV (50–65 fL). Hypoproliferative anemia in childhood also occurs in association with leukemia, and in these cases, other characteristic clinical and laboratory features also are present. Two other causes of hypoproliferative anemia are congenital and acquired red blood cell aplasia. The former, also known as Diamond-Blackfan anemia, is a lifelong disorder manifesting in the first year of life, usually with persistent macrocytosis beyond infancy; it is also associated with a variety of congenital abnormalities. Transient erythroblastopenia of childhood is an acquired immunologic red blood cell aplasia, lasting a few weeks, and occurring in the first 3 years of life in otherwise normal children. The MCV in children with transient erythroblastopenia of childhood is normal for age, thus distinguishing them from children with iron deficiency (low MCV) or Diamond-Blackfan anemia (high MCV).

Approach to Hemolytic Anemia in the Child

Hemolytic anemia in children most commonly reflects an inherited disorder. However, acquired causes of hemolysis also occur, such as autoimmune hemolysis or microangiopathic hemolytic anemia as

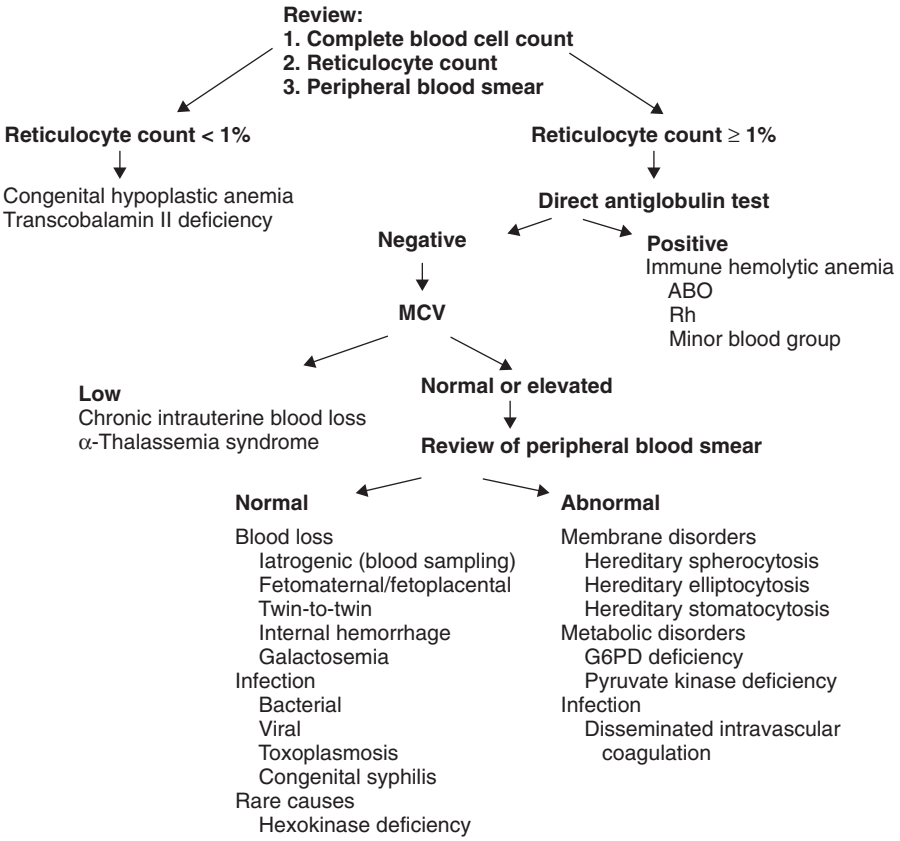

Figure 34–5 Approach to the differential diagnosis of anemia in the newborn. G6PD, glucose-6-phosphate dehydrogenase; MCV, mean corpuscular volume.

seen in the hemolytic uremic syndrome. In newborns, the major clinical finding suggestive of hemolysis often is a marked exaggeration of the normal physiologic hyperbilirubinemia, thus causing significant jaundice that requires specific therapy. Once it is ascertained that a neonate has a hemolytic anemia, the differential diagnosis is limited. The most important consideration is immune-mediated hemolysis, although hemolytic anemias caused by red blood cell membrane and metabolic disorders also occur (Fig. 34–5). Of interest, the anemias caused by sickle cell disease and β-thalassemia are not associated with clinical manifestations in the newborn period. These disorders become significant only after 4 to 6 months of age when β-globin production is established. Review of family history and ethnic background of the parents often is highly informative. Physical findings may include splenomegaly, such as those observed in patients with hereditary spherocytosis. In addition to careful review of the peripheral blood smear, hemoglobin electrophoresis is of utility when a hemoglobinopathy is suspected. In the United States, however, some of this information may be available as a result of newborn hemoglobin screening programs.

CONCLUSION

Anemia may represent a primary hematologic disorder or may represent the manifestation of a systemic process. In the pediatric population, the former tends to be somewhat more common than the latter, and in adults the converse is true. However, in both children and adults, a systematic approach to the evaluation of anemia that includes careful review of historic features, the complete blood cell count, and peripheral smear facilitates an efficient diagnosis and minimizes unnecessary testing.

CHAPTER 35

PATHOLOGY OF IRON METABOLISM

Nancy C. Andrews

INTRODUCTION

Iron is an essential metal for all mammalian cells, serving as a mediator of enzymatic electron exchange (in cytochromes, peroxidases, ribonucleotide reductases, and catalases) and a carrier of oxygen (in hemoglobin and myoglobin). However, its flexible redox state and its interactions with oxygen can also promote cellular damage when the reactivity of iron is not restrained by protein binding. Excess iron potentiates the formation of reactive oxygen species that attack cellular lipids, proteins and nucleic acids. In normal individuals, iron homeostasis is meticulously regulated to avoid deleterious extremes of iron deficiency and iron overload. All known disorders of iron metabolism can be considered abnormalities of iron balance or distribution.

Iron normally enters the body through dietary absorption, at a rate that balances small losses caused by bleeding and exfoliation of skin and mucosal cells. Neither the liver nor the kidney has a mechanism for excretion of iron that is not needed. In fact, no regulated pathway for iron excretion has been identified, making it likely that iron balance is determined primarily by the absorptive capacity of the intestinal epithelium. This is modulated in response to various conditions, as discussed in Regulation of Iron Homeostasis in the Entire Organism. Iron homeostasis is challenged when intake and losses are not matched. Iron deficiency occurs when the dietary iron supply is inadequate, when losses are increased (usually because of bleeding) or when both of these circumstances act to put the body into iron deficit. Iron overload results when iron absorption is constitutively increased because of genetic defects perturbing normal regulation, or when repeated blood transfusions create an iron surfeit.

Normal adult men usually absorb approximately 0.5 to 1 mg of iron on a daily basis. This amount is doubled in menstruating women, and approximately quadrupled during pregnancy, to balance the high iron cost of carrying and delivering an infant. On average, each pregnancy results in maternal iron losses of approximately 680 mg, and an additional 450 mg is used transiently to support increased maternal blood volume, although this latter amount is returned to maternal stores after delivery. Lactation results in a daily iron loss of approximately 0.5 to 1 mg. The iron content of human breast milk is minimally affected when maternal iron stores are depleted. Because normal menstruation is usually inhibited while breast-feeding continues, iron requirements in the lactating mother approximate those of the menstruating woman.

Full-term infants are born with an iron endowment of approximately 350 mg. Over the course of a lifetime this increases to a total of 3 to 5 g in normal individuals. Patients with genetic hemochromatosis can have iron burdens greater than 15 g. Approximately 2.7 g of iron is normally dedicated to the erythron in adults, distributed between bone marrow precursors and circulating erythrocytes. Packed red blood cells contain approximately 1 mg/mL iron. Iron not required by other tissues is stored in hepatocytes and macrophages. In adult men, iron stores gradually increase throughout life. In contrast, iron stores are small in prepubertal children and menstruating women, because of the demands of rapid growth and menstrual blood loss, respectively.

Our understanding of the molecular processes of iron metabolism has advanced considerably over the last decade, as new techniques in genetics and molecular biology have been applied to problems in iron biology. The study of animal models has been particularly valuable, owing to the existence of both spontaneous and induced mutations affecting key genes. Mechanisms of iron transport and regulation are highly conserved among mammalian species, allowing information from experiments in rodents to be extrapolated to humans.

MECHANISMS OF IRON TRANSPORT

General Concepts

Iron cannot freely diffuse across cellular membranes; therefore, transmembrane transfer requires specialized transport mechanisms. Some cells, including intestinal epithelial cells, hepatocytes and macrophages, are equipped both to take in (import) iron and to release (export) it. These cells play roles in the acquisition, storage, and mobilization of iron. Other cells, particularly erythroid precursors, use most or all of the iron they import and do not need to export it. These cells are the major consumers of iron.

Each day, normal adults need 25 mg of iron to support hemoglobin production in maturing erythrocytes. This amount is much greater than the 1 to 2 mg absorbed daily through the intestine. Obviously, iron needed for erythropoiesis must be acquired from supplies already existing in the body. The primary source of plasma iron is the reticuloendothelial macrophage system, which recovers iron from senescent and damaged erythrocytes. In normal individuals, nearly all circulating iron is bound to transferrin (Tf), an abundant plasma protein with the capacity to bind two iron atoms per molecule. Because macrophages both supply iron to erythroid precursors and recover it from effete erythrocytes, much of the body's iron metabolism can be considered to be a closed loop (Fig. 35–1). Other significant sites of iron exchange are the intestine, as discussed earlier, and the liver, whose iron stores can be expanded or mobilized as needed.

Several distinct iron uptake (import) mechanisms have been described in mammals. Intestinal absorptive cells express plasma membrane transporters that carry ferrous (Fe^{2+}) ions directly across the membrane. They may also have mechanisms for transport of intact heme. Erythroid precursors meet their large iron needs by accumulating diferric (Fe_2)-Tf within intracellular vesicles prior to transmembrane transport of the metal into the cytoplasm (the Tf cycle, see The Transferrin Cycle). Some embryonic cells may use an analogous uptake mechanism, involving receptor-mediated endocytosis of iron bound to a lipocalin molecule.[1] Cardiac cells may, under conditions of iron overload, take up iron through co-opted *L*-type calcium channels.[2] Hepatocytes may use all of these strategies. Finally, reticuloendothelial macrophages acquire much of their iron through phagocytosis of aged or damaged erythrocytes, destruction of the phagocytosed cells, and enzymatic degradation of their hemoglobin. Other iron transport mechanisms, including receptor-mediated uptake of the iron-containing ferritin, have also been postulated. Furthermore, it is possible that molecules transporting other transition metals (eg, copper, zinc) can also carry iron across cellular membranes.

Intestinal Iron Absorption

Dietary iron is absorbed in the first segment of the duodenum, just beyond the gastric outlet. The duodenal epithelium is organized into

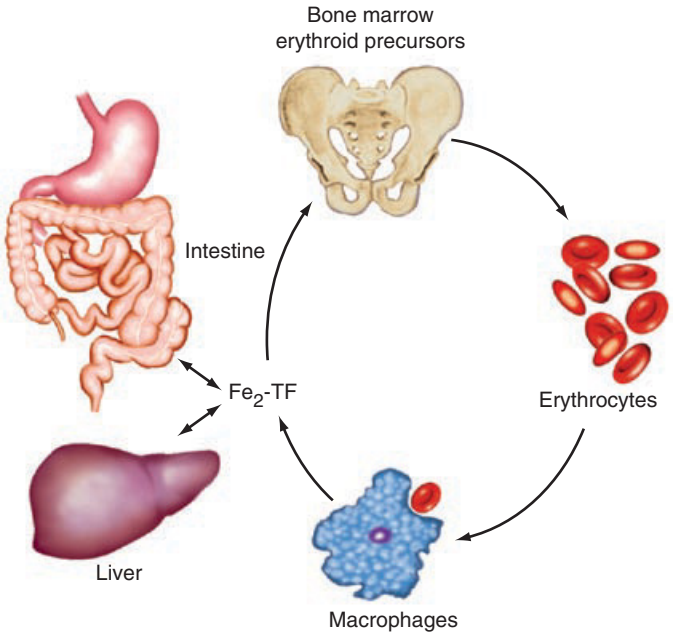

Figure 35–1 The iron cycle. To a first approximation, mammalian iron metabolism can be thought of as a closed loop involving circulating diferric transferrin, the erythroid bone marrow, circulating erythrocytes, and reticuloendothelial macrophages. Most iron in the body can be found in this cycle. However, a small amount is absorbed and lost through the intestinal mucosa. Additionally, iron in excess of tissue needs is stored in the liver. For simplicity, other sites of iron use are not shown here. The most important of these is muscle, where iron is incorporated into myoglobin. Iron homeostasis is markedly affected by pregnancy, when the developing fetus draws iron out of this system in the mother. Fe_2-TF, diferric transferrin.

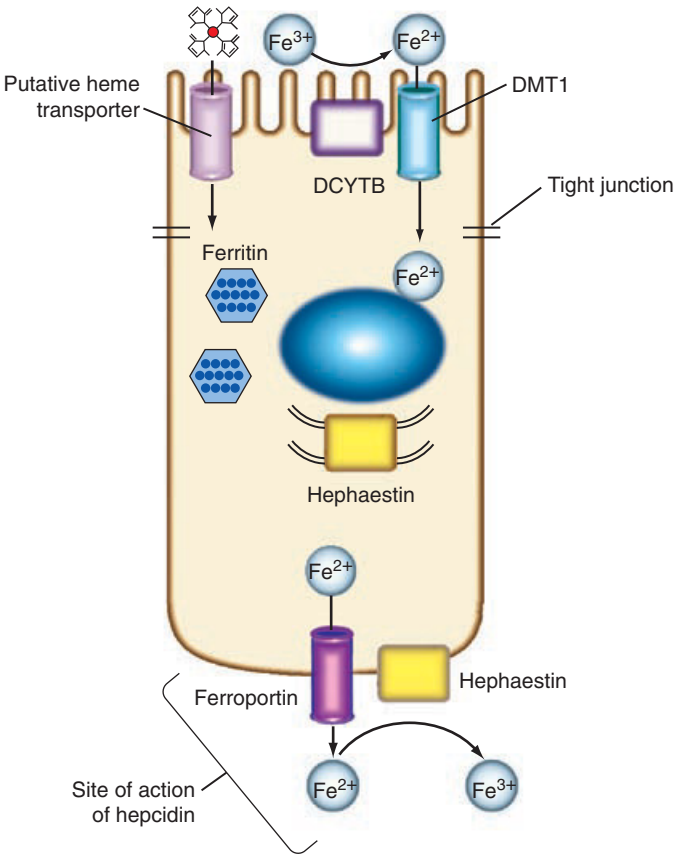

Figure 35–2 Intestinal nonheme iron transport. This diagram summarizes our current understanding of iron transport through enterocytes in the duodenal epithelium. The apical brush border of the cell, facing the gut lumen, is shown at the top, and the basolateral surface on the bottom. The mechanism of heme iron uptake has not yet been worked out, but a transmembrane heme transporter has been postulated to exist. Dietary nonheme iron is primarily in the ferric (Fe^{3+}) form. Fe^{3+} must be reduced to the Fe^{2+} form, probably by the ferrireductase DCYTB. The reduced iron is a substrate for the transporter DMT1, which is located in the apical membrane. Iron entering the cell is partitioned between storage (ferritin) and export across the basolateral membrane. Ferroportin serves as the basolateral transporter, most likely requiring Fe^{2+} as its substrate. Hephaestin, a ferroxidase, appears to aid ferroportin, although some investigators have reported that it localizes to a perinuclear compartment rather than the basolateral surface. For that reason, it is shown in both sites in this diagram. Regardless, iron must be oxidized to the Fe^{3+} form to bind transferrin (Tf). Hepcidin regulates basolateral iron export by binding to ferroportin to trigger its internalization and lysosomal degradation.

fingerlike villi, lined by absorptive cells. The apical brush border of this epithelium is bathed in gastric acid, which solubilizes iron in food and provides a low pH environment necessary for the function of membrane transporters. Most nonheme dietary iron is in the ferric (Fe^{3+}) form. It can be reduced to ferrous (Fe^{2+}) iron by a cytochrome b-like ferrireductase, DCYTB[3]. Expression of DCYTB is induced by iron deficiency. Fe^{2+} ions are carried across the apical membrane by divalent metal transporter 1 (DMT1, also called NRAMP2, DCT1, SLC11A2), an integral membrane protein that bears no resemblance to other classes of membrane transporters.[4,5,6] DMT1 is not specific for iron—it also transports divalent forms of manganese, cobalt, copper, zinc, and lead.[4] Metal transport is dependent on cotransport of protons in the same inward direction. Animals lacking DMT1 activity have profound iron deficiency, indicating that it is a major carrier for nonheme iron entering through the brush border.[7] However, human patients with mutations in DMT1 have been reported to have hepatic iron overload and iron-deficient erythropoiesis.[8] The increased hepatic iron may be attributable to multiple transfusions or to increased heme iron absorption through an alternative pathway.

Within intestinal epithelial cells, some of the imported iron is incorporated into ferritin and other storage forms. A fraction of the iron taken up from the intestinal lumen passes through the cell, and is exported across the basolateral membrane to enter the body. Ferroportin (also called IREG1, MTP1, SLC40A1), a metal ion transporter that bears no structural homology to DMT1, serves as the basolateral iron exporter.[9] Like DMT1, ferroportin is an integral membrane protein that transports ferrous ions. It may work in conjunction with a multicopper oxidase protein, hephaestin, which is believed to oxidize Fe^{2+} to Fe^{3+} to allow it to bind to plasma Tf.[10] Our current understanding of enterocyte nonheme iron transport is depicted in Fig. 35–2.

The mechanisms controlling the rate of iron flux through this enterocyte transport system determine overall iron absorption. It is important to consider that only some of the dietary iron taken up by enterocytes transits both the apical and basolateral membranes to enter into the plasma. Iron that is retained within enterocytes is lost from the body when those cells senesce and are sloughed into the gut lumen. Thus, absorption can be regulated simply by controlling how much iron is retained and how much is exported to the plasma. As discussed in Regulation of Iron Homeostasis in the Entire Organism, the peptide hormone hepcidin modulates iron absorption in this way.

Uptake of heme iron occurs through a distinct pathway, but the details have not been worked out. A membrane transporter that was recently postulated to be a heme importer was subsequently shown to be a folate transporter instead. Heme iron absorption is important, because 10% to 15% of iron in nonvegetarian Western diets is in this form. It is more efficient than absorption of inorganic iron, and

it appears to be less sensitive to the regulatory mechanisms that govern nonheme iron absorption.

Iron absorption is affected by the presence of other substances in the intestinal lumen. It is enhanced by dietary meat proteins and ascorbate, but inhibited by phytates, tannins, phosphates, antacids, and competing metals (eg, zinc). Although milk components generally inhibit iron absorption, extraction of iron from human breast milk is highly efficient, allowing young infants to acquire a very large proportion of the limited iron present in that fluid.

The Transferrin Cycle

In normal individuals, almost all iron in the circulation is carried by Tf, which is present at concentrations of 2 to 3 g/L. Tf binds iron with extremely high affinity to prevent precipitation of Fe^{3+} ions, which are almost insoluble in aqueous fluids. It prevents the iron from reacting with other molecules and allows it to be delivered to the tissues in a safe, non-toxic form. Tf molecules carrying one or two iron atoms bind to specific cell surface Tf receptors (Tfrs), which have a preference for the diferric form. Mature, differentiated cells express few, if any Tfrs. In contrast, they are highly expressed on the surfaces of cells with exceptional need for iron, including erythroid precursors, tumor cells, and activated lymphocytes. Erythroid precursors have the greatest demand for iron, to support the large scale production of hemoglobin. They express as many as 800,000 Tfr molecules per cell at the time that they are taking up maximal amounts of iron. Tfrs are cleared from the cells as they complete maturation, and few if any are found on circulating, fully differentiated erythrocytes. Tumor cells and activated lymphocytes presumably express Tfrs to optimize iron uptake to support rapid proliferation. Serum or soluble Tfr (sTfr) is a proteolytic cleavage product of Tfr that contains the entire extracellular portion of the molecule. It is found in the circulation in proportion to the erythroid cell mass.[11] Measurement of elevated sTfr concentration is useful in the diagnosis of iron deficiency, although sTfr levels also increase in conditions associated with ineffective erythropoiesis.[12]

When iron-loaded Tf binds to Tfr, portions of the cell membrane bearing the Tf-Tfr complex invaginate into the cytoplasm and bud off as intracellular vesicles. The vesicular pH drops to approximately 5.5, leading to conformational changes in the Tf-Tfr complex and liberation of the bound iron. Released iron is reduced to the ferrous form by the ferrireductase Steap3 protein[13] and transported across the endosomal membrane into the cytoplasm by DMT1, taking advantage of the acidic milieu within the endosome for the same type of proton-dependent transport process as occurs at the apical membrane of the intestine.[14] Different isoforms of the DMT1 protein appear to be used for intestinal iron uptake and endosomal iron transport, but they are highly similar and are encoded by the same gene.[15] Concurrently, apoprotein (apo)-Tf and Tfr proteins return to the cell surface to participate in further cycles of iron delivery. This process is summarized in Fig. 35–3.

Within the cytoplasm, iron is sequestered by proteins and small molecules, and shuttled to sites of use and storage. Most stored iron is present in ferritin, a polymeric protein basket that can hold up to 4500 atoms of iron (see Cellular Iron Storage below). There is less ferritin in erythroid precursors, because most iron is destined for the mitochondria where it is incorporated into heme.

Considering the fact that cells can take iron up directly, why should they need the complicated Tf cycle? There are at least two likely answers. First, tight binding of iron to Tf is advantageous while iron is in the circulation, but it complicates the matter of bringing iron into cells. The pH-dependent release of iron, occurring in a controlled intracellular environment, solves the problem of liberating the iron. Second, receptor-mediated endocytosis of diferric Tf serves to concentrate iron, achieving high local concentrations in the vicinity of DMT1. It thus allows more efficient iron uptake by cells with substantial needs without exposing other cells to unnecessary iron. Studies of animals lacking either Tf[16] or Tfr[17] indicate that erythroid precursors are highly dependent on the Tf cycle, but most other cell types assimilate iron efficiently without it.

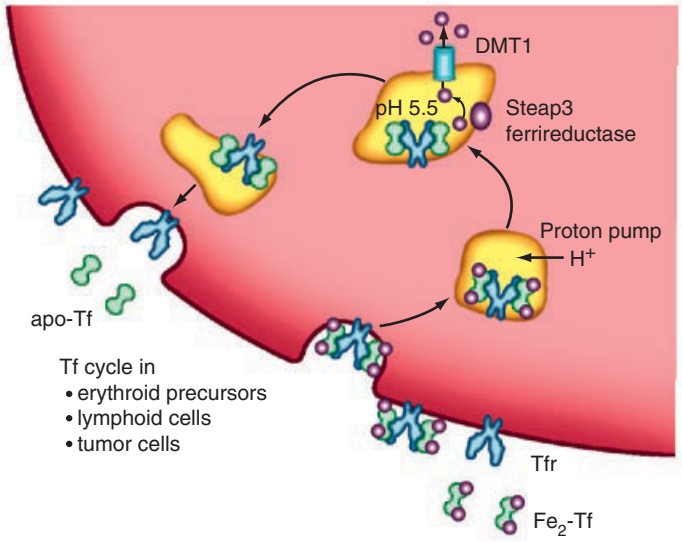

Figure 35–3 The transferrin cycle. Erythroid precursors, lymphoid cells, tumor cells and perhaps others rely on the transferrin (Tf) cycle to augment cellular iron uptake. Diferric-Tf (Fe_2-Tf) binds to a specific cell surface receptor, Tfr, to initiate receptor-mediated endocytosis. Within the cell the Tf-containing endosomes are acidified through the action of a proton pump, resulting in dissociation of iron from the proteins. The iron is reduced by Steap3, a ferrireductase located in the endosomal membrane. The reduced iron exits the endosome through DMT1 to enter the cytoplasm. The Tf-Tfr protein complex recycles to the cell surface where the ambient pH leads to dissociation of Tf and availability of both protein components for further cycles of iron delivery. Tfr, transferrin receptor.

Iron Transport in Other Cells

Hepatocytes serve as a major storage depot for body iron in excess of immediate needs. They express Tfr but also express high levels of a related molecule designated transferrin receptor 2 (Tfr2).[18] Like Tfr, Tfr2 can bind and internalize Tf, although it does so much less efficiently, and Tf-mediated iron uptake is probably not its primary physiological role. Importantly, Tfr2 forms a molecular complex with HFE, the protein mutated in patients with classical hemochromatosis,[19] and mutations in the gene encoding Tfr2 also cause hemochromatosis. Over the past few years the molecular basis of hemochromatosis has been worked out in detail (see Chapter 36).

Hepatocytes are also capable of taking up non-Tf-bound iron directly when the plasma iron concentration exceeds the binding capacity of Tf. This is an abnormal situation, because there is normally enough Tf in the plasma to bind approximately three times more iron than is present (ie, plasma Tf is normally approximately 30% saturated with iron). But patients with genetic or transfusional iron overload disorders can have fully saturated Tf, and excess iron is rapidly removed from circulation by the liver. The molecular details of hepatic non-Tf-bound iron uptake are not yet understood, but this process appears to involve a transport mechanism distinct from DMT1.

Hepatocyte iron stores act as a reserve that can be mobilized when the plasma iron supply becomes insufficient for erythropoiesis and other needs. Ferroportin, the iron exporter thought to function in basolateral intestinal iron transport, may also mediate iron export from hepatocytes, but this has not yet been established experimentally. To date, no other transmembrane iron exporters have been identified in mammals.

As discussed earlier, reticuloendothelial macrophages recycle iron from phagocytosed red blood cells. After they lyse the cells, iron is

recovered from degraded hemoglobin through the action of heme oxygenase, an enzyme that catalyzes the degradation of heme. Macrophages may also acquire smaller amounts of iron through other pathways, including the Tf cycle. Similar to intestinal cells and hepatocytes, reticuloendothelial macrophages store some iron and release some directly into the circulation. Macrophage iron export also involves ferroportin, which it is expressed at high levels in iron recycling macrophages.[9]

Two distinct clinical presentations have been reported in patients with mutations in the gene encoding ferroportin.[20,21] Some patients develop an autosomal dominant iron overload disorder that is indistinguishable from hereditary hemochromatosis. These patients carry mutations that prevent the normal regulation of ferroportin's activity (see Chapter 36). More often, however, patients carrying ferroportin mutations present with hyperferritinemia, iron accumulation in tissue macrophages, and few (if any) complications of iron overload.

Macrophage iron export also requires ceruloplasmin, a copper-containing ferroxidase circulating in plasma. When the gene encoding ceruloplasmin was disrupted in mice, macrophages failed to release their iron at a normal rate, leading to hypoferremia in the presence of normal iron stores.[22] The abnormality was promptly corrected by administering exogenous ceruloplasmin. A similar phenomenon was noted in aceruloplasminemic human subjects.[23] Ceruloplasmin probably acts by catalyzing the oxidation of ferrous iron to the ferric form, which is a prerequisite for iron binding by apo-Tf. This function is analogous to that proposed for hephaestin, a highly related intestinal protein.

The capacity for macrophage iron storage is regulated in response to the iron needs of the body, through the action of the peptide hormone hepcidin (see Regulation of Iron Homeostasis in the Entire Organism). The concentration of plasma iron (and hence the Tf saturation) is predominantly determined by two factors—macrophage iron release (allowing iron to enter the plasma) and erythroid iron use (extracting iron from the plasma). Intestinal iron absorption and hepatocyte iron mobilization both contribute to the amount of plasma iron too, but to a lesser extent. When erythropoiesis occurs at a steady rate, Tf saturation is determined primarily by the amount of iron entering the plasma, that is, the amount of iron exported from macrophages, enterocytes and hepatocytes. When erythroid demand increases, plasma iron concentrations decrease unless release from stores is accelerated. Serum Tf saturation is calculated as the ratio of serum iron to total iron-binding capacity (TIBC; binding sites for iron available on plasma Tf) expressed in the same units. In clinical practice, Tf saturation is a useful indicator of how much iron is available for erythropoiesis.

Serum ferritin concentration, also used for clinical evaluation of iron status, reflects the amount of storage iron in the body. The origin of serum ferritin is not known, but it appears to be derived primarily from hepatocytes and reticuloendothelial macrophages. It differs from the ferritin used to store iron within cells—it is glycosylated (suggesting that it is actively secreted) and iron-poor. Serum ferritin is not a very accurate indicator of iron stores, however, because levels are increased when there is inflammation or tissue damage and in rare, congenital hyperferritinemia disorders. Nonetheless, a low serum ferritin value invariably indicates depleted iron stores. The ratio of sTfr to the log of the serum ferritin concentration has been touted as an index to distinguish pure iron deficiency anemia from the anemia of chronic disease. When this ratio is greater than 1.5, iron deficiency is usually present, with or without inflammation.[24]

The Iron-Copper Connection

It has long been known that copper deficiency is associated with abnormalities in iron metabolism and iron deficiency anemia. It is now clear that this is caused, at least in part, by the importance of the copper-containing ferroxidases ceruloplasmin and hephaestin. Both molecules are glycoproteins containing six to seven copper atoms. Ceruloplasmin has been shown to act as an oxidase for a variety of substrates. Hephaestin functions similarly. As discussed earlier, there is evidence that each of these molecules is required for the optimal mobilization of iron from cells to plasma.

Cellular Iron Storage

Intracellular storage iron is mostly found in ferritin, a large polymer composed of two types of polypeptide subunits (L and H ferritins), each approximately 20 kilodaltons in size. The H ferritin polypeptide has an enzymatic ferroxidase activity that is lacking in the L polypeptide. Each ferritin multimer is made up of 24 of these subunits, with changeable proportions of L and H chains. The L to H ratio varies among different cell types, but it is not known how it is determined. The interior of the ferritin molecule contains mineralized iron in a solid form. Ferritin prevents iron from reacting with other cellular constituents and allows for controlled iron release in response to increased cellular needs. Hemosiderin is a conglomerate composed of partially degraded ferritin, remnants of organelles and other proteins associated in an amorphous particle. The iron in hemosiderin is difficult to mobilize, and the conglomerate probably serves little purpose other than to keep iron from causing harm. Both ferritin and hemosiderin are abundant in iron-overloaded tissues.

As discussed earlier, the liver serves as the major depot for iron in excess of immediate needs. Hepatocytes and macrophages have a very large capacity for accumulating and holding iron, although this capacity is ultimately exceeded in iron overload disorders. The liver is an early site of iron accumulation in iron overload, owing to the fact that hepatocytes avidly take up non–Tf-bound iron from the plasma. Although other tissues (myocardium, pancreas) also accumulate excess iron, liver damage is often the first major clinical complication in adult-onset hemochromatosis. In contrast, juvenile hemochromatosis and transfusional (secondary) iron overload frequently present with relatively insignificant liver damage but prominent cardiomyopathy and endocrinopathies. The heart and endocrine tissues seem to be more susceptible to damage when iron loading occurs rapidly, particularly in young patients who develop significant iron overload before puberty.

Regulation of Cellular Iron Balance

Iron balance is regulated at many levels. The most fundamental level is iron-regulated expression of intracellular proteins of iron metabolism. There is evidence for transcriptional regulation in response to cellular or organismal iron status, but the mechanisms responsible for this effect have not been elucidated in mammals. Regulation at the level of translation is better understood. Several mRNA molecules encoding proteins of iron metabolism contain similar RNA stem-loop structures in their non-coding segments. These RNA stem-loop structures are iron responsive elements (IREs), which are specifically recognized and bound by iron regulatory proteins (IRPs).[25]

IRPs bind to IREs when iron is scarce, and dissociate from IREs when iron is plentiful. There are two known IRPs, IRP1 and IRP2. IRP1 has two distinct activities—in addition to binding to IREs, it can function as a cytoplasmic aconitase enzyme. The IRP1 polypeptide incorporates an iron-containing functional group, termed an iron-sulfur cluster. When present, the iron-sulfur cluster is important for aconitase activity, but it precludes binding to IREs. When it is absent, IRP1 no longer functions as an aconitase, but it gains the ability to bind to IREs. IRP2 is a similar protein, but it is regulated differently—it is stable under low iron conditions but rapidly degraded when iron is abundant. IRP2 has no aconitase activity.

IRPs are known to mediate translational effects in two distinct ways, depending on the location of the IRE stem-loop structure in the mRNA. When the IRE is located within the 5′ untranslated region of an mRNA (as in the mRNAs encoding L- and H-ferritin, ferroportin, and the heme biosynthetic enzyme aminolevulinic acid synthase), IRP binding is known[26] or expected to disrupt translational initiation by preventing assembly of initiation factors at the initiator

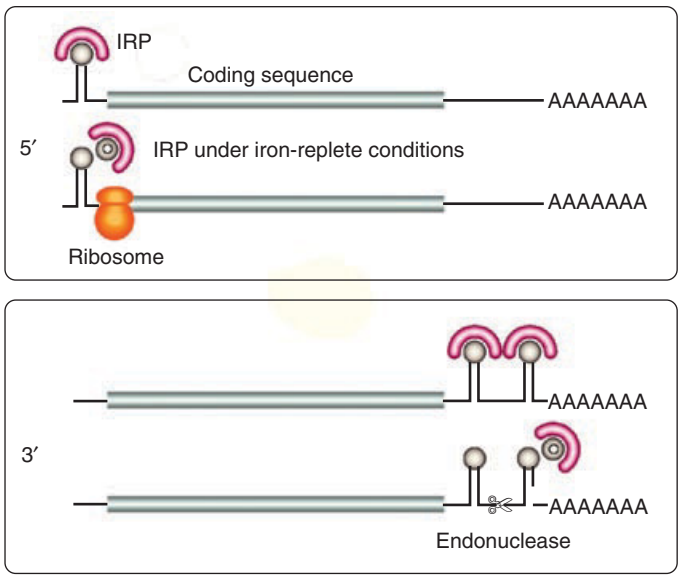

Figure 35–4 Regulation of gene expression by iron regulatory proteins (IRPs). Translation is regulated by iron through at least two distinct activities of iron responsive elements (IREs) and IRPs. When IREs are located in the 5′ untranslated regions of mRNAs (eg, ferritin mRNAs) binding of IRPs blocks the initiation of translation, thereby preventing protein expression (*top panel*). This blockade is relieved in the presence of iron, as described in the text. In contrast, the IREs located in the 3′ untranslated region of the mRNA encoding transferrin receptor (Tfr) are involved in regulating message stability. IRP binding prevents degradation by cellular endonucleases, resulting in increased protein expression in the absence of iron. Under iron replete circumstances the IRPs do not bind, and the mRNA is unstable (*bottom panel*). IREs located in the 3′ untranslated region of other mRNAs are believed to act through a similar mechanism, though this has not been validated experimentally.

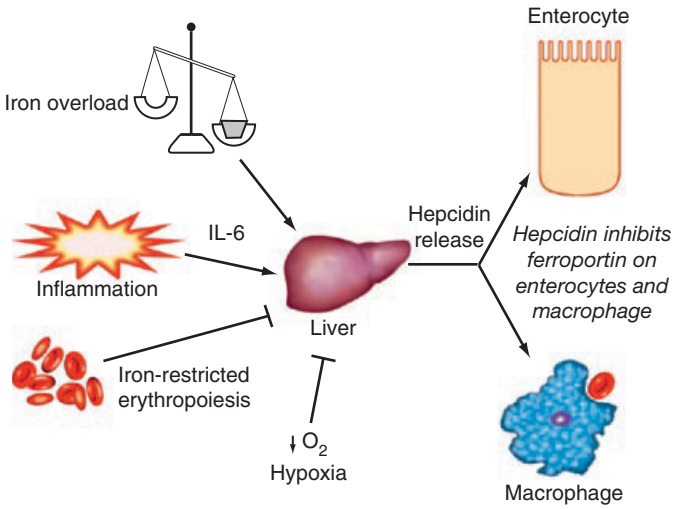

Figure 35–5 Regulation of hepcidin expression. At least four circumstances modulate hepcidin expression by the liver. Expression is increased in response to iron overload and inflammation. Interleukin-6 (IL-6), and possibly other inflammatory cytokines, induces hepcidin transcription in inflammation. Hepcidin expression is decreased in response to iron-restricted erythropoiesis and hypoxia, but the molecular details of those regulatory pathways have not yet been elucidated. In the effector arm of these multiple pathways, hepcidin produced by the liver has two actions: It blocks intestinal iron transport and inhibits export of iron from macrophages. Both can be explained by its regulatory interaction with ferroportin. O_2, oxygen.

methionine codon. In contrast, when IREs are found within the 3′ untranslated region of mRNAs (such as the mRNAs encoding Tfr and DMT1) IRP binding is known[27] or expected to confer stability to messages that would otherwise undergo rapid endonucleolytic digestion. Thus, in contrast to the effect mediated by 5′ IREs, 3′ IREs increase translation in the absence of iron. The current model is that binding of IRPs to IREs controls and coordinates translation of iron-related mRNAs in two ways—it inhibits production of proteins involved in iron storage (and probably iron export) and it promotes production of proteins necessary for iron uptake. These activities should contribute to the maintenance of intracellular iron homeostasis in response to iron levels. This is summarized in Fig. 35–4.

Regulation of Iron Homeostasis in the Entire Organism

Just as individual cells must have mechanisms for coordinated regulation of iron transport and iron storage to maintain adequate amounts to meet their needs but avoid iron overload, so must whole tissues. Regulation involves control of cellular iron uptake, retention and export. Recently, new insights have emerged that are leading to a comprehensive understanding of regulation at each of these steps.

In the absence of medical intervention, iron can only enter the body through the intestine. Dietary iron absorption is enhanced in response to insufficient iron stores, increased erythropoietic demand or hypoxia. It is diminished in response to iron surfeit and inflammation. Based on these observations, four different "regulators" have been defined functionally, although they are incompletely understood at a molecular level. The *stores regulator* modulates absorption several fold, increasing it in iron deficiency and decreasing it in iron overload. The *erythroid regulator* is more potent—it can increase iron absorption 6- to 10-fold when erythropoiesis becomes iron-restricted. Iron-restricted erythropoiesis can result either from iron deficiency (linking the stores and erythroid regulators) or from accelerated production of erythroid precursors, outstripping the capacity of Tf to supply adequate iron for hemoglobin synthesis. The *hypoxia regulator* appears to be distinct from the erythroid regulator, although it has overlapping function. It mediates an increase in iron absorption in response to hypoxia, to allow for production of hemoproteins that bind and carry oxygen. Finally, there is compelling evidence that an *inflammatory regulator* also exists, which acts to decrease iron absorption in response to inflammation associated with a wide variety of medical conditions. The inflammatory regulator comes into play in the anemia of chronic disease, as discussed in Chapter 37.

It is now clear that all of these regulators act through a common, humoral effector that coordinates intestinal iron absorption and macrophage iron recycling. Hepcidin (also called HAMP) is a 25 amino acid peptide that has intrinsic antimicrobial activity, similar to defensins, but also plays a major role in iron metabolism. It is produced in the liver, cleaved from a larger precursor molecule and secreted into the plasma. The amino-terminal portion of the preprotein has no known function, although there have been several studies attempting unsuccessfully to relate serum levels of this remnant to iron homeostasis. Hepcidin itself is rapidly cleared by the kidneys, allowing for dynamic regulation at the level of its production. Over the past few years, the biologic activity of hepcidin has been elucidated. Circulating hepcidin attaches to ferroportin expressed on enterocytes and macrophages, causing ferroportin to be internalized into the cell and degraded in lysosomes.[28]

Expression of hepcidin is modulated in response to all of the regulators described earlier (Fig. 35–5). Hepcidin is induced in response to iron overload and inflammation. It is turned off in response to iron deficiency, ineffective erythropoiesis and hypoxia. Although it has become clear that much or all regulation of hepcidin expression takes place at the level of transcription, the signals that turn on and turn off hepcidin production are incompletely understood. Two cellular signaling pathways have clearly been shown to regulate hepcidin transcription. In the setting of inflammation, the inflammatory cytokine interleukin-6 (IL-6) binds to hepatocyte IL-6 receptors, triggering a JAK/STAT3 signaling cascade that leads to binding of activated

STAT3 to a distinct element in the hepcidin promoter.[29] This explains, at least in part, the induction of hepcidin in inflammation. A second signaling pathway appears to be essential for basal hepcidin expression and possibly also regulation. Bone morphogenetic proteins (BMPs) bind to cell surface BMP receptors to activate a signaling cascade involving regulatory SMAD proteins (SMADs 1, 5, and 8) and a unique, required co-SMAD (SMAD4). It was recently shown through two complementary approaches that BMP signaling induces hepcidin expression.[30,31] Hemojuvelin, a molecule that is mutated in severe, early onset hemochromatosis (see Chapter 36) acts as a BMP coreceptor in promoting hepcidin expression. As it is already clear that other proteins mutated in patients with hemochromatosis (HFE, Tfr2) are also involved in the regulation of hepcidin expression, it is likely that they, too, participate in signaling cascades regulating hepcidin transcription.

Elucidation of the molecular events controlling hepcidin gene expression will give insight into other components of the four regulators of intestinal iron absorption. Studies have begun to dissect the other promoter elements involved in controlling hepcidin mRNA expression.[32]

CONCLUSIONS

Many details of iron transport and homeostasis have been elucidated over the past decade, but much remains to be learned. Identification and characterization of the genes and proteins involved has given insight into human iron overload disorders and the anemia of chronic disease, as discussed in other chapters. At the same time, cloning of iron overload disease genes has expanded our knowledge of basic iron biology.

CHAPTER 36

DISORDERS OF IRON METABOLISM: IRON DEFICIENCY AND IRON OVERLOAD

Gary M. Brittenham

Iron is an essential nutrient required by every human cell. Both decreases and increases in body iron are often clinically important. If too little iron is available (iron deficiency), limitations on the synthesis of physiologically active iron-containing compounds can have deleterious consequences. If too much iron accumulates (iron overload) and exceeds the body's capacity for safe transport and storage, iron toxicity may produce widespread organ damage and death.

Remarkable progress in our understanding of the molecular mechanisms underlying iron homeostasis is described in Chapter 35. This chapter focuses on the clinical applications of these advances and improvements in the diagnosis and management of both iron deficiency and iron overload.

LABORATORY EVALUATION OF IRON STATUS

The major routes of iron movement are shown in Fig. 36–1. The continuum of changes in iron stores and distribution in the presence of increased or decreased body iron content is illustrated in Fig. 36–2, along with characteristic values for clinically available indicators of iron status. The general usefulness of these measures is considered in this section, and their specific applications in the diagnosis of iron deficiency and iron overload are described in Iron deficiency laboratory evaluation and in Iron overload: laboratory evaluation.

Body iron supply and stores can be evaluated by both direct and indirect means, but no single indicator or combination of indicators is ideal for evaluation of iron status in all clinical circumstances. As body iron content decreases from the iron-replete normal to the amounts found in iron-deficiency anemia or as it increases to the magnitudes found in the various forms of iron overload, each available measure reflects in a different manner the continuum of changes shown in Fig. 36–2. In addition, each indicator may be affected by coexisting conditions, such as infection, inflammation, ineffective erythropoiesis, hypoxemia, liver disease, malignancy, and malnutrition. Recognizing that these coexisting conditions act principally through a common pathway that modulates the expression of hepcidin (see Chapter 35 and box on Control of Iron Homeostasis by Hepcidin and Ferroportin) greatly assists in the interpretation of the patterns of changes found in specific clinical conditions.

Direct Measures

The direct measures of body iron status yield quantitative, specific, and sensitive determinations of body or tissue iron stores. Quantitative phlebotomy provides a direct measure of total mobilizable storage iron.[1] Quantitative phlebotomy is inapplicable to most anemic disorders but occasionally is useful in the diagnostic evaluation of some forms of iron overload (e.g., in patients with hereditary hemochromatosis who do not undergo liver biopsy). Bone marrow aspiration and biopsy can provide information about (a) macrophage storage iron, by semiquantitative grading of marrow hemosiderin stained with Prussian blue or, if needed, by chemical measurement of nonheme iron; (b) iron supply to erythroid precursors, by determining the proportion and morphology of marrow sideroblasts (i.e., normoblasts with visible aggregates of iron in the cytoplasm); and (c) general morphologic features of hematopoiesis. Bone marrow aspiration and biopsy are useful in studies of iron deficiency[2] but of limited applicability in the evaluation of iron overload because no information about the extent of parenchymal iron deposition is provided. In the evaluation of iron overload, liver biopsy is the best direct test for assessing iron deposition, permitting quantitative measurement of the nonheme iron concentration and histochemical examination of the pattern of iron accumulation in hepatocytes and Kupffer cells.[1,3–5]

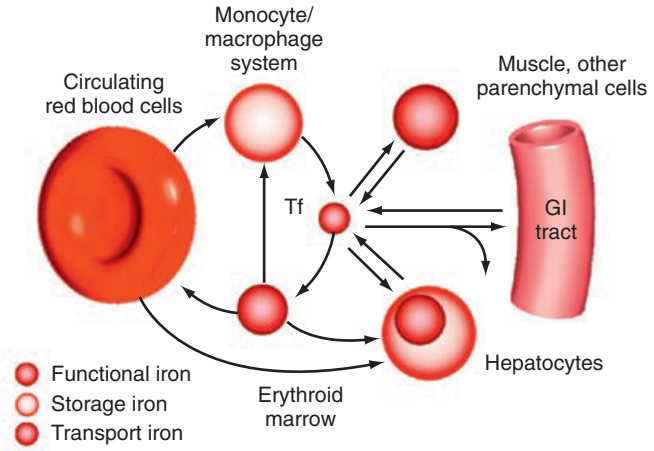
Direct methods for assessing iron status have the disadvantages of being invasive procedures, with their attendant discomfort, lack of acceptability to patients, and, in the case of liver biopsy, risk. A variety of noninvasive means of measuring tissue iron stores have been developed and applied in clinical studies,[6,7] including determination of hepatic magnetic susceptibility, computed tomography, and magnetic resonance imaging.[8–12] When available as appropriately calibrated and validated techniques, these new noninvasive methods are helpful in the diagnosis and management of iron overload[13] but lack the accuracy required for measurements to detect iron deficiency.

Indirect Measures

Indirect measures of body iron status have the advantages of ease and convenience, but all are subject to extraneous influences and lack specificity, sensitivity, or both. When used to estimate body iron stores, all of the available indirect measures are influenced not only by total body iron stores but also by the effects of acute or chronic changes in plasma hepcidin (see box on Control of Iron Homeostasis by Hepcidin and Ferroportin). Assays for urinary and plasma hepcidin are under development[14,15] and likely will be helpful in the clinical evaluation of patients with disorders of iron metabolism.

Measurement of plasma ferritin provides the most useful indirect estimate of body iron stores. Ferritin is secreted into the plasma in small amounts, but its physiologic role is obscure.[16,17] Whereas intracellular ferritin is produced by the smooth endoplasmic reticulum, plasma ferritin is synthesized by the rough endoplasmic reticulum and glycosylated by the Golgi apparatus. Under normal circumstances, the amount of plasma ferritin synthesized and secreted seems to be proportional to the amount of cellular ferritin produced in the internal iron storage pathway so that the plasma ferritin concentration is related to the magnitude of body iron stores. The small amounts of ferritin secreted into the circulation can be measured by immunoassay and have a logarithmic relationship to body iron stores in healthy persons. In the absence of complicating factors that alter plasma hepcidin, plasma ferritin concentrations decrease with depletion of storage iron and increase with storage iron accumulation. A maximum glycosylated plasma ferritin concentration of approximately 4000 mg/L has been postulated, perhaps representing an upper physiologic limit of the rate of synthesis.[18] Higher concentrations are believed to be due to release of intracellular ferritin from damaged cells.

Measurement of plasma transferrin receptor concentration provides a useful new means of detecting tissue iron deficiency.[19–21] The soluble transferrin receptor is a truncated form (relative molecular mass [M_r] 85,000) of the tissue transferrin receptor that consists of the amino (N)-terminal cytoplasmic domain that probably has been proteolytically released from the cell membrane. Immunoassays that



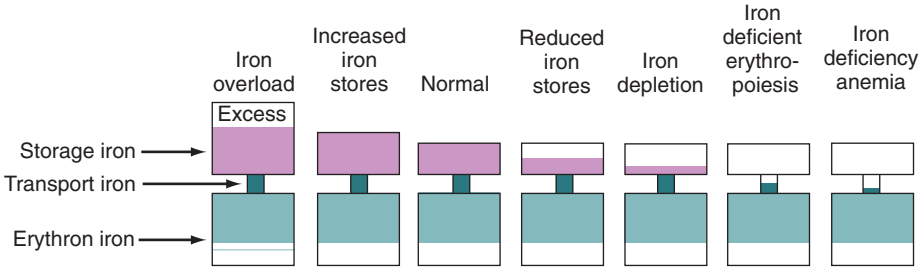


Figure 36–1 Body iron supply and storage. Schematic representation of the routes of iron movement. The major pathway of internal iron exchange is a unidirectional flow from plasma transferrin (Tf) to the erythron to the macrophage and back to plasma transferrin. Storage iron in the macrophages of the liver, bone marrow, and spleen is derived almost entirely from phagocytosis of senescent erythrocytes or defective developing red cells. The macrophage takes up little iron from plasma transferrin, whereas the hepatocyte may either donate iron to or receive iron from plasma transferrin. Other pathways of iron movement involve approximately equal exchanges for iron absorption and losses, for transfer between the plasma and extravascular transferrin compartments, and for movement between extravascular transferrin and parenchymal tissues. Increases in hepcidin decrease macrophage release of iron derived from senescent red blood cells, diminish delivery of iron from duodenal enterocytes absorbing dietary iron, and inhibit release of iron stored in hepatocytes. *(Modified from Finch CA, Huebers H: Perspectives in iron metabolism. N Engl J Med 306:1520, 1982.[230])*

Control of Iron Homeostasis by Hepcidin and Ferroportin

Hepcidin functions as the chief controller of body iron supply and storage by interacting with ferroportin, a transmembrane protein that is the only known iron exporter in humans (see Chapter 35). Hepcidin binds to ferroportin, inducing its internalization and degradation, thereby inhibiting iron efflux from the principal sources of plasma iron: macrophages, duodenal enterocytes, and hepatocytes (see Fig. 36–1). Under physiologic conditions, hepatic hepcidin production coordinates body iron supply with iron need. If body iron stores expand, hepcidin production increases. Increments in plasma hepcidin reduce the amount of ferroportin in cell membranes, causing a prompt fall in plasma iron concentration by decreasing macrophage release of iron derived from senescent red blood cells, diminishing delivery of iron from enterocytes absorbing dietary iron, and inhibiting release of iron stored in hepatocytes. Conversely, if body iron stores contract, hepcidin production decreases. Decrements in plasma hepcidin concentration increase the amount of ferroportin, producing a rise in plasma iron concentration as a consequence of enhanced delivery from macrophages, increased dietary iron absorption from enterocytes, and mobilization of storage iron from hepatocytes. In addition to these effects of body iron stores, hepcidin production is stimulated by inflammation and inhibited by increased erythropoiesis. Depending on clinical circumstances, the effects of inflammation or increased erythropoiesis on hepatic hepcidin synthesis may predominate over the effects of body iron stores.

	Iron overload	Increased iron stores	Normal	Reduced iron stores	Iron depletion	Iron deficient erythropoiesis	Iron deficiency anemia
Marrow iron stores	4+	3-4+	2-3+	1+	0-Trace	0	0
Transferrin IBC (µg/dl)	<300	<300	330±30	330-360	360	390	410
Plasma ferritin (µg/L)	>250	>250	100±60	<25	<20	10	<10
Plasma transferrin receptor	5.5	5.5	5.5±1.5	5.5	5.5	10	14

Erythrocytes	Normal	Normal	Normal	Normal	Normal	Normal	Microcytic hypochromic

Figure 36–2 Continuum of changes in iron stores and distribution in the presence of increased or decreased body iron content. Abnormalities indicating the onset of specific stages of negative iron balance are enclosed in boxes. In iron overload, excess storage iron may increase from the normal range of 1 g or less to as much as 40 to 50 g. Marrow iron stores are increased as shown only in disorders of iron overload with reticuloendothelial iron loading, such as transfusional iron overload. Marrow iron stores may be normal or even absent in hereditary hemochromatosis. *(Adapted from Herbert V: Anemias. In Paige DM [ed.]: Clinical Nutrition. St. Louis, CV Mosby, 1988, p 593,[231] with permission.)*

can detect the soluble truncated form of the transferrin receptor in human plasma are clinically available.[22] A majority of plasma transferrin receptors are derived from the erythroid marrow, and their concentration is determined primarily by erythroid marrow activity. Decreased levels of circulating soluble transferrin receptor are found in patients with erythroid hypoplasia (aplastic anemia, chronic renal failure), whereas increased levels are present in patients with erythroid hyperplasia (thalassemia major, sickle cell anemia, anemia with ineffective erythropoiesis, chronic hemolytic anemia). Iron deficiency also increases soluble transferrin receptor concentrations. The plasma transferrin receptor concentration reflects the total body mass of tissue receptor; thus, in the absence of other conditions causing erythroid hyperplasia, an increase in plasma transferrin receptor concentration provides a sensitive, quantitative measure of tissue iron deficiency.[19] In particular, measurement of plasma transferrin receptor concentration may help differentiate between the anemia of iron deficiency and the anemia associated with chronic inflammatory disorders. Although the plasma ferritin concentration may be disproportionately elevated in relation to iron stores in patients with inflammation or liver disease, the plasma transferrin receptor concentration seems to be unaffected by these disorders and appears to provide a more reliable laboratory indicator of iron deficiency.[20]

The erythrocyte zinc protoporphyrin level provides an indicator of iron supply to erythroid precursors.[20,23] In heme biosynthesis, the final reaction is chelation of a ferrous ion by protoporphyrin IX. If no iron is available, zinc is chelated instead to form zinc protoporphyrin. Because zinc protoporphyrin formed during development persists throughout the lifespan of the red cell, the blood concentration changes only as new cells are formed and old cells are destroyed, providing a retrospective view of iron supply over the preceding several weeks. An elevated erythrocyte zinc protoporphyrin concentration (sometimes measured as the zinc protoporphyrin-to-heme ratio) lacks specificity because concentrations increase not only with absent iron stores in iron deficiency but also with other conditions that increase plasma hepcidin and restrict iron availability, such as infection, inflammation, and malignancy. Levels also are increased in many sideroblastic anemias and especially with chronic lead poisoning.[20,24] The test is useful for detecting lead poisoning but is of no value in detecting iron overload.

Measurements of the proportion of hypochromic circulating red cells and the hemoglobin content of reticulocytes are possible with some hematology analyzers[25,26] and offer new means of detecting restriction of iron supply for erythropoiesis. The proportion of hypochromic red cells provides information similar to that derived from the erythrocyte zinc protoporphyrin level and becomes abnormal only after weeks of iron-restricted erythropoiesis. Measurements of the mean cellular hemoglobin content of reticulocytes or the reticulocyte hemoglobin equivalent permit earlier detection of iron-restricted erythropoiesis[25] but are unable to distinguish between the absent iron stores of iron deficiency and decreased iron availability due to increases in plasma hepcidin associated with infection, inflammation, and malignancy.

Measurement of urinary iron excretion with chelating agents, usually either deferoxamine or diethylenetriamine pentaacetic acid, offers another means of assessing body iron stores.[7,27] This test is not helpful for detecting iron deficiency because of the overlap between values in persons with normal and those with decreased iron stores; it is used primarily for the evaluation of iron overload. The usefulness of the measurement of chelated iron in the urine is limited by a lack of correlation between chelatable iron excretion and the results of quantitative phlebotomy with parenchymal iron overload and by the susceptibility of the effects of increases in plasma hepcidin associated with inflammatory states.

Examination of peripheral blood by measurements of hemoglobin concentration, hematocrit, red cell indices, red cell volume distribution, and reticulocyte count and by inspection of erythrocyte morphology reveals abnormalities only after depletion of iron stores restricts the availability of iron for erythropoiesis. The changes are not specific for iron deficiency and may be found in other conditions with defective hemoglobin synthesis, such as thalassemia, infection, inflammation, liver disease, and malignancy. Iron overload does not produce any diagnostic abnormalities in the peripheral blood.

IRON DEFICIENCY

Iron deficiency denotes a deficit in total body iron resulting from a sustained increase in iron requirements over iron supply. The continuum of decreased body iron is shown in Fig. 36–2. Three successive stages of iron lack can be distinguished. A decrement in storage iron without a decline in the level of functional iron compounds is termed *iron depletion* (see Fig. 36–2). After iron stores are exhausted, lack of iron limits the production of hemoglobin and other metabolically active compounds that require iron as a constituent or cofactor. *Iron-deficient erythropoiesis* (see Fig. 36–2) develops, although the effect on hemoglobin production may be insufficient to be detected by the standards used to differentiate normal from anemic states. Further diminution in the body iron produces frank *iron-deficiency anemia* (see Fig. 36–2).

Epidemiology

Iron deficiency is the most common cause of anemia in the United States and worldwide.[28–30] In the United States, adequacy of bioavailable iron in the diet, together with food fortification and the widespread use of iron supplements, has reduced the overall prevalence and severity of iron deficiency, but iron nutrition remains a problem in some subpopulations, especially toddlers, adolescent girls, women of childbearing age, and some minority groups.[28,31,32] Without iron supplementation, most women will become iron deficient during pregnancy. Globally, 30% to 70% of the populations in developing countries are iron deficient, with the highest prevalence among persons who have diets low in bioavailable iron, or who suffer from chronic gastrointestinal blood loss as a result of helminthic infection, or both.[28–30,33]

Etiology and Pathogenesis

The foremost task in the evaluation of patients with iron deficiency is identifying and treating the underlying cause of the imbalance between iron requirements and supply that is responsible for the lack of iron (Table 36–1). Overall, the *iron requirement* for an individual includes not only the iron needed to replenish physiologic losses and meet the demands of growth and pregnancy but also any additional amounts needed to replace pathologic losses. Physiologic iron losses generally are restricted to the small amounts of iron contained in the urine, bile, and sweat; shedding of iron-containing cells from the intestine, urinary tract, and skin; occult gastrointestinal blood loss;

Table 36–1 Causes of Iron Deficiency

Increased Iron Requirements
Blood loss

Impaired iron transport

and, in women, uterine losses during menstruation and pregnancy.[34–36] In normal men, the daily basal iron loss is slightly less than 1.0 mg/day. In normal menstruating women, the daily basal iron loss is approximately 1.5 mg/day. The median total iron loss with pregnancy is approximately 500 mg, or almost 2 mg/day over the 280 days of gestation. Genetic factors may influence the risk of iron deficiency, but the mechanisms responsible have not been identified.[35,36]

The most common pathologic cause of increased iron requirements leading to iron deficiency is blood loss. In men and postmenopausal women, iron deficiency almost inevitably signifies gastrointestinal blood loss.[20,37] Within the gastrointestinal tract, any hemorrhagic lesion may result in blood loss, and the responsible lesion may be asymptomatic. Iron deficiency often is the first sign of an occult gastrointestinal malignancy[38,39] or other unrecognized conditions such as coeliac disease,[40] or autoimmune, atrophic, or *Helicobacter pylori* gastritis.[41,42] Chronic ingestion of drugs such as alcohol, salicylates, steroids, and nonsteroidal antiinflammatory drugs may cause or contribute to blood loss. Worldwide, the most frequent cause of gastrointestinal blood loss is hookworm infection, but other helminthic infections, such as *Schistosoma mansoni* and S*chistosoma japonicum,* and severe *Trichuris trichiura* infection also may be responsible.

In women of childbearing age, genitourinary blood loss with menstruation adds to iron requirements.[43] Menstrual losses tend to decrease with use of oral contraceptives but increase with use of intrauterine devices. Other, less frequent causes of genitourinary bleeding should be considered, including chronic hemoglobinuria and hemosiderinuria resulting from paroxysmal nocturnal hemoglobinuria[44] or from chronic intravascular hemolysis.

Uncommonly, respiratory tract blood loss resulting from chronic recurrent hemoptysis of any cause produces iron deficiency. In two rare conditions, Goodpasture syndrome and idiopathic pulmonary siderosis, hemoptysis and intrapulmonary bleeding may be inapparent but lead to sequestration of iron in pulmonary macrophages.[45] Although still within the body, the sequestered iron is "lost" from systemic use, and severe iron-deficiency anemia may develop. Recurrent blood donation may lead to iron deficiency, particularly in menstruating women.[46]

In infants, children, and adolescents, the need for iron for growth may exceed the supply available from diet and stores.[47] Premature infants, who have a lower birth weight and a more rapid postnatal rate of growth, are at high risk for iron deficiency unless given iron supplements.[48] With rapid growth during the first year of life, the body weights of term infants normally triple, and iron requirements are at high levels. Iron requirements decline as growth slows during the second year of life and into childhood but rise again with the adolescent growth spurt.[49]

Without supplemental iron, pregnancy entails the net loss of the equivalent of 1200 to 1500 mL of blood. After delivery, resumption of menstruation usually is delayed for months. If the infant is breastfed, lactation necessitates an intake of approximately 0.5 to 1.0 mg of iron daily.

In some instances, an insufficient supply of iron may contribute to the development of iron deficiency. In infants or in women who have experienced heavy menstrual losses or multiple pregnancies, the risk of iron deficiency may be further increased by diets with insufficient amounts of bioavailable iron, such as those with little or no heme iron and with small amounts of enhancers or large amounts of inhibitors of nonheme iron absorption.[37] For older children, men, and postmenopausal women, the restricted availability of dietary iron is almost never the sole explanation for iron deficiency, and other causes, especially blood loss, must be considered.[20,37]

Impaired absorption of iron in itself infrequently produces iron deficiency. Intestinal malabsorption of iron may occur as a manifestation of more generalized syndromes.[50] Atrophic gastritis and the attendant achlorhydria may impair iron absorption.[42] In persons of all ages and both genders, but particularly in pregnant women and children, pica, the compulsive chewing or ingestion of food or nonfood substances, may contribute to iron deficiency if the material consumed inhibits iron absorption.[51] Iron deficiency frequently complicates gastric surgery, such as partial or total gastric resection or gastroenterostomy for bypass of the duodenum.[52]

Increased iron requirements and an inadequate supply of iron often work in concert to produce iron deficiency. Infants fed cow's milk receive a diet that not only contains small amounts of iron of low bioavailability but also increases iron losses by causing gastrointestinal bleeding.[47] Menstruating women, who have some of the highest iron requirements, may consume diets that have a low content of iron and contain inhibitors of iron absorption, such as calcium.[43] Patients with ulcer disease and increased gastrointestinal blood loss may habitually take antacids, which diminish dietary iron absorption.

Clinical Presentation

Patients with iron deficiency may present with (a) no signs or symptoms, coming to medical attention only because of abnormalities noted on laboratory tests; (b) features of the underlying disorder responsible for the development of iron deficiency; (c) manifestations common to all anemias; or (d) one or more of the few signs and symptoms considered highly specific for iron deficiency, namely, pagophagia, koilonychia, and blue sclerae. In addition, a high prevalence of iron deficiency with or without anemia has been reported among patients with the restless legs syndrome (Ekbom syndrome), a neurologic disorder characterized by a distressing need or urge to move the legs (akathisia).[53,54]

An uncomplicated depletion of storage iron generally is not associated with signs or symptoms, although patients without iron reserves will not respond as rapidly to an increased need for iron resulting from blood loss, growth, or pregnancy. Greater deficits in body iron, which restrict the synthesis of functional iron compounds and cause anemia, either may be asymptomatic or may produce a variety of clinical manifestations. Iron-deficiency anemia produces the signs and symptoms common to all anemias: pallor, palpitations, tinnitus, headache, irritability, weakness, dizziness, easy fatigability, and other vague and nonspecific complaints. The prominence of these signs depends on the degree and rate of development of the anemia. Because iron deficiency often is of insidious onset and prolonged duration, adaptive circulatory and respiratory responses may minimize these manifestations, permitting a surprising tolerance of low hemoglobin concentrations. With greater severity, anemia becomes increasingly debilitating as work capacity and tolerance of physical exertion are restricted and eventually can produce cardiorespiratory failure and even death.

Iron deficiency may produce clinical manifestations independent of anemia. The abnormalities seem to result from depletion of functional iron compounds in nonerythroid tissues, resulting in impaired proliferation, growth, and function. Epithelial tissues have high iron requirements due to rapid rates of growth and turnover and thus are affected in many patients with chronic iron deficiency. Glossitis, angular stomatitis, postcricoid esophageal web or stricture (which may become malignant), and gastric atrophy may develop. The combination of glossitis, a sore or burning mouth, dysphagia, and iron deficiency is called the Plummer-Vinson or Paterson-Kelly syndrome.[55] The prevalence of these abnormalities seems to vary geographically, which suggests that environmental or genetic factors are involved.

Determining whether gastric atrophy is the cause or the consequence of iron deficiency may be difficult,[42] particularly in older patients. In some patients, pernicious anemia and iron deficiency coexist. Changes in the lingual or buccal mucosa have been suggested as factors causing or contributing to the pica that develops in many patients with iron deficiency.[51] Pagophagia, a variant of pica in which ice is the substance obsessively consumed, is a behavioral abnormality that is considered to be a highly specific symptom of iron deficiency, resolving within a few days to 2 weeks after beginning iron therapy.[56] Other types of pica involving a variety of nonfoods, such as clay, starch, paper, and dirt, or an assortment of foods may occur in iron

Iron Deficiency and Coexisting Disorders

Detection of iron deficiency in the presence of chronic infectious, inflammatory, or malignant disorders is more problematic than in the absence of such disorders. Even if iron lack contributes to the anemia of chronic disease, the transferrin concentration (or total iron-binding capacity) will be decreased and the plasma ferritin concentration will be increased. Because the serum transferrin receptor concentration is not affected by inflammation, its measurement usually can determine whether iron stores are absent.[20,22,65] If uncertainty remains, bone marrow examination is definitive. If iron deficiency is present, iron stores are absent; if the anemia of chronic disease alone is responsible, iron stores are present and typically increased.

deficiency but are not as clearly linked to a lack of iron or as frequently responsive to iron therapy. In *koilonychia*, the fingernails are thin, friable, and brittle, and the distal half of the nail is a concave or "spoon" shape resulting from impaired nail bed epithelial growth. This condition is considered virtually pathognomonic of iron deficiency but occurs in a small minority of patients.[57] Blue sclerae, a condition in which the sclerae have a definite or striking bluish hue, were recognized in 1908 by Osler as being associated with iron deficiency[58] and have been reported to be a highly specific and sensitive indicator of iron deficiency.[59] The bluish tinge is believed to result from thinning of the sclera, which makes the choroid visible. This thinning has been postulated to result from impairment of collagen synthesis by iron deficiency. Iron deficiency has been postulated to have other nonhematologic consequences associated with impaired immunity and resistance to infection,[60] diminished exercise tolerance and work performance,[61] and a variety of behavioral and neuropsychological abnormalities.[62]

Laboratory Evaluation

A characteristic sequence of changes in the clinically useful indications of iron status occurs as body iron decreases from the iron-replete normal to the levels found in iron-deficiency anemia. This sequence is illustrated in Fig. 36–2. The patterns shown develop in the absence of complicating factors, such as infection, inflammation, liver disease, malignancy, or other disorders (see box on Iron Deficiency and Coexisting Disorders). Initially, as a result of any of the causes listed in Table 36–1, iron requirements exceed the available supply of iron. Iron is mobilized from body stores, and iron absorption is increased. If the amounts of iron available from body reserves and absorption are inadequate, depletion of storage iron follows. At this stage, bone marrow examination shows absent, or nearly absent, hemosiderin iron. The serum ferritin level falls while the total iron-binding capacity rises. Exhaustion of iron reserves then results in an inadequate supply of iron to the developing erythroid cell, and iron-deficient erythropoiesis commences. Plasma transferrin receptor concentrations increase as the total body mass of tissue receptor expands. The plasma ferritin level decreases to less than 12 mg/L (see box on Plasma Ferritin Concentrations), reflecting the absence of storage iron, and the total iron-binding capacity continues to rise. The plasma iron level declines, and, in combination with the increase in total iron-binding capacity, transferrin saturation falls to less than 16% (see box on Plasma Iron and Transferrin Saturation). Marrow examination shows, in addition to the absence of hemosiderin iron, a decrease in the proportion of sideroblasts because too little iron is available to support siderotic granule formation. The erythrocyte zinc protoporphyrin level progressively increases with reduction of the amount of iron available for heme formation. Measurement of reticulocyte cellular indices, such as the reticulocyte hemoglobin content or the reticulocyte hemoglobin equivalent, seems to provide an nearly means of detecting iron-restricted erythropoiesis,[25] both in uncomplicated iron deficiency and in the "functional" lack of iron in patients receiving recombinant erythropoietin.[63,64]

As hemoglobin production becomes restricted, frank iron-deficiency anemia develops. The normocytic, normochromic red cells previously formed under iron-replete circumstances gradually are replaced by a microcytic hypochromic population. Both the time needed to replace the normal population and the extent of the disparity between erythroid needs and available iron supply determine the rate and degree of change in erythrocyte morphology and red cell indices, such as mean corpuscular volume, mean corpuscular hemoglobin, and measures of the distribution of red cell volumes such as red cell volume distribution width. Chronic, long-standing iron-deficiency anemia may produce severe microcytosis and hypochromia, with very pale, distorted red cells and dramatic reductions in the mean corpuscular volume and mean corpuscular hemoglobin (Fig. 36–3). In contrast, some patients with mild iron-deficiency anemia may have erythrocyte morphology and indices indistinguishable from values found in normal, iron-replete individuals.

Plasma Ferritin Concentrations

Decreased plasma ferritin concentrations are of great value in the detection of iron deficiency. Plasma ferritin concentrations decline with storage iron depletion; a plasma ferritin concentration less than 12 mg/L is virtually diagnostic of absence of iron stores. The only known conditions that may lower the plasma ferritin concentration independently of a decrease in iron stores are hypothyroidism and ascorbate deficiency,[66] but these conditions only rarely cause problems in clinical interpretation. Increased plasma ferritin concentrations may indicate increased iron stores, but a number of disorders may raise the plasma ferritin level independently of the body iron store. Plasma ferritin is an acute-phase reactant, with increased ferritin synthesis a nonspecific response that is part of the general pattern of the systemic effects of inflammation. Thus, fever, acute infections, rheumatoid arthritis, and other chronic inflammatory disorders elevate the plasma ferritin concentration. Both acute and chronic damage to the liver, as well as to other ferritin-rich tissues, may increase plasma ferritin concentration through an inflammatory process or by releasing tissue ferritins from damaged parenchymal cells; these tissue ferritins are not glycosylated. Plasma ferritin concentrations in individuals of Asian or Pacific Island ancestry have been found to be higher than in other populations,[67] but the basis for this difference is unknown.

Plasma Iron Concentration and Transferrin Saturation

Plasma iron concentration and transferrin saturation, which equals the ratio of plasma iron to total iron-binding capacity, provide a measure of current iron supply to tissues. After storage iron is depleted, the serum iron concentration falls; a transferrin saturation less than 16% often is used as the criterion for iron-deficient erythropoiesis. In contrast, plasma iron concentration and transferrin saturation are not reliably elevated with increased iron stores within macrophages, as occurs initially with transfusional iron overload, although the transferrin saturation may increase with parenchymal iron loading. Interpretation of the transferrin saturation is complicated by substantial circadian fluctuations in plasma iron concentration as day-to-day variations of 30% or greater. Furthermore, plasma iron concentration is decreased by infection, inflammation, malignancy, and ascorbate deficiency but increased by iron ingestion, aplastic and sideroblastic anemias, ineffective erythropoiesis, and liver disease.

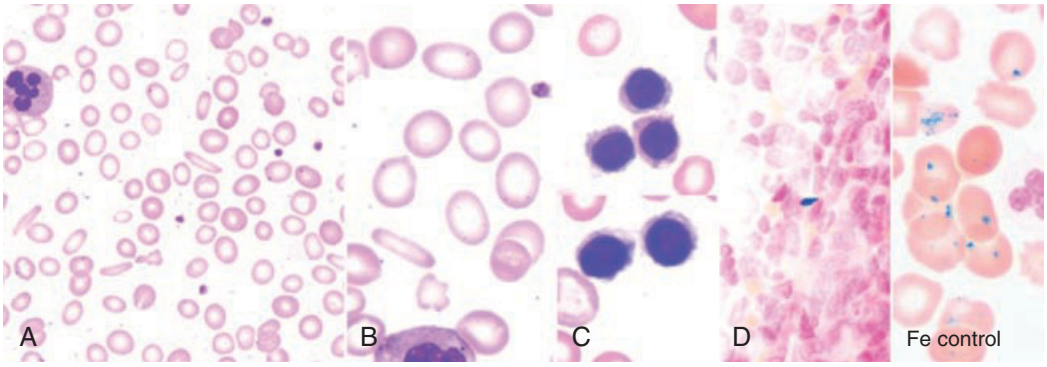

Figure 36–3 Iron-deficiency anemia. Peripheral blood smear (**A, B**), bone marrow aspirate (**C**), and Prussian blue stain of bone marrow aspirate (**D**) with control from a 16-year-old girl with hemoglobin 6.7 g/dL, hematocrit 22.6%, and mean corpuscular volume 59.2 fL. Peripheral smear shows hypochromic microcytic red blood cells (**A**), with widening of the central pallor and "pencil" cells (**B**). Polychromatophilic erythroid precursors in the aspirated specimen have scanty cytoplasm that is irregular and vacuolated (**C**). The Prussian blue–stained aspirate shows no iron stores in multiple spicules (**D**). Care must be taken not to overinterpret positive staining debris on top of cells (center). Lack of staining on the bone marrow biopsy sample can be misleading because the decalcification process is known to "leach-out" iron. An appropriate control should be similar to the patient material. Peripheral blood smears made from a patient with increased iron-containing Pappenheimer bodies and fixed with 100% methanol can serve as an easily accessible control.

Table 36–2 Differential Diagnosis of Microcytic Hypochromic Anemia

Decreased Body Iron Stores
Iron-deficiency anemia
Normal or Increased Body Iron Stores
Impaired iron metabolism

Thalassemia
Other microcytic hemoglobinopathies
Disorders of heme synthesis: sideroblastic anemias
Hereditary
Acquired

Therapeutic Trial of Iron

The diagnosis of iron deficiency often is confirmed by the outcome of a therapeutic trial of iron. A specific orderly response to, and only to, treatment with iron constitutes the final definitive proof that a lack of iron is the cause of an anemia. The unequivocal diagnostic response consists of (a) a reticulocytosis, which begins approximately 3 to 5 days after adequate iron therapy is instituted, reaches a maximum on days 8 to 10, and then declines; and (b) a significant increase in hemoglobin concentration, which should begin shortly after the reticulocyte peak, is invariably present by 3 weeks after iron therapy is begun, and persists until the hemoglobin concentration is restored to normal. The result of a therapeutic trial of iron must be evaluated for possible confounding factors, such as poor compliance with iron therapy, malabsorption of therapeutic iron, continuing blood loss, and the effects of coexisting conditions, especially infectious, inflammatory, or malignant disorders. The therapeutic trial merely aids in establishing the presence of iron deficiency. The search for underlying causes must continue despite a positive response to iron therapy.

Nonetheless, laboratory evaluation of uncomplicated iron deficiency in otherwise healthy persons usually is not difficult, and the characteristic patterns of indicators of body iron status shown in Fig. 36–2 typically are diagnostic. The diagnostic point is that early or mild iron deficiency must be considered in the workup of normocytic as well as microcytic anemia.

Differential Diagnosis

Iron deficiency is the only microcytic hypochromic disorder in which mobilizable iron stores are absent; in all other disorders, storage iron is normal or increased (Table 36–2). Early or mild iron deficient anemia may be normocytic. In these cases, the hematocrit usually is greater than 30, but the serum iron and iron saturation levels usually are low. Difficulties in the evaluation of microcytic hypochromic disorders usually arise when direct assessment of marrow iron is unavailable and the diagnosis depends on indirect indicators of iron status (see boxes on Iron Deficiency and Coexisting Disorders and on Therapeutic Trial of Iron). Of the indirect indicators, the plasma ferritin level is most useful if the concentration is less than 12 mg/L, because in the absence of hypothyroidism or ascorbate deficiency, such a low ferritin level is highly specific for iron deficiency. In contrast, a plasma ferritin concentration within the normal range does not necessarily indicate the presence of storage iron, because ferritin concentrations may be increased independently of iron status by infectious, inflammatory, or malignant disorders, liver disease, and other conditions. Measurement of the plasma transferrin receptor concentration may be useful in differentiating the anemia of iron deficiency from the anemia associated with chronic inflammatory disorders. The ratio of serum transferrin receptor to serum ferritin concentration may provide an even better means of identifying iron deficiency.[19]

Specific entities to be considered in the differential diagnosis of hypochromic microcytic disorders are listed in Table 36–2; in all of these disorders, body iron stores are normal or increased. The anemia of chronic disease (see Chapter 37) is the most common cause of anemia in hospitalized patients and generally is mild to moderate, typically developing over several weeks in patients with chronic infectious, inflammatory, or malignant disorders.[68] Microcytic hypochromic anemias resulting from disorders of heme synthesis (sideroblastic anemias, congenital and acquired) and disorders of globin synthesis (thalassemias, microcytic hemoglobinopathies) are discussed in Chapters 38 and 41, respectively. Other rare congenital or acquired defects with microcytic hypochromic anemias are atransferrinemia[69] (or hypotransferrinemia; see Table 36–4) and a variety of other uncommon disorders.[69–78]

Oral Iron Therapy

Oral iron therapy should begin with a ferrous iron salt, taken separately from meals in three or four divided doses and supplying a daily total of 150 to 200 mg of elemental iron in adults or 3 mg of iron per kilogram of body weight in children. Simple ferrous preparations are the best absorbed and least expensive. Ferrous sulfate is the most widely used, either as tablets containing 60 to 70 mg of iron for adults or as a liquid preparation for children. Administration between meals maximizes absorption. In patients with a hemoglobin concentration less than 10 g/dL, this regimen initially will provide approximately 40 to 60 mg of iron daily for erythropoiesis, permitting red cell production to increase to two to four times normal and the hemoglobin concentration to rise by approximately 0.2 g/dL/day. An increase in the hemoglobin concentration of at least 2 g/dL after 3 weeks of therapy generally is used as the criterion for an adequate therapeutic response. For milder anemia, a single daily dose of approximately 60 mg of iron per day may be adequate. After the anemia has been fully corrected, oral iron should be continued to replace storage iron, either empirically for an additional 4 to 6 months or until the plasma ferritin concentration exceeds approximately 50 μg/L.

Parenteral Iron Therapy

Four parenteral iron preparations are approved for use in the United States: higher- and lower-molecular-weight iron dextran, sodium ferric gluconate complex, and iron sucrose.[82] Each has been widely used, often in hemodialysis patients receiving recombinant human erythropoietin, but prospective, randomized controlled comparisons among the four agents are lacking. Immediate life-threatening anaphylactic reactions constitute the most serious risk associated with use of either intramuscular or intravenous iron preparations and may have a fatal outcome. Delayed but severe serum sickness-like reactions may develop, with fever, urticaria, adenopathy, myalgias, and arthralgias. Data from the U.S. Food and Drug Administration from 2001 to 2003 found that the absolute rates of reported *life-threatening* adverse drug events were 11.3, 3.3, 0.9, and 0.6 per million for higher- and lower-molecular-weight iron dextran, sodium ferric gluconate complex, and iron sucrose, respectively.[84]

Therapy

The goal of therapy for iron-deficiency anemia is to supply sufficient iron to repair the hemoglobin deficit and replenish storage iron. Oral iron is the treatment of choice for almost all patients because of its effectiveness, safety, and economy and should always be given preference over parenteral iron for initial treatment (see box on Oral Iron Therapy).[20,37] The risk of local and systemic adverse reactions restricts the use of parenteral iron to the small number of patients who are unable to absorb or tolerate adequate amounts of oral iron. Rarely, red cell transfusions are needed to prevent cardiac or cerebral ischemia in patients with severe anemia or to support patients whose chronic rate of iron loss exceeds the rate of replacement possible with parenteral therapy.[79]

Most patients are able to tolerate oral iron therapy without difficulty, but 10% to 20% may have symptoms attributable to iron.[20,37] The most common side effects are gastrointestinal. The development of either diarrhea or constipation usually can be treated symptomatically, because alterations in bowel habits do not appear to be related to the dose of iron and seldom necessitate a change in the oral regimen. Upper gastrointestinal tract symptoms do seem to be dose related, reflecting the concentration of ferrous iron in the stomach and duodenum. These side effects occur within approximately 1 hour of iron ingestion and may be mild, with nausea and epigastric discomfort, or severe, with abdominal pain and vomiting. Often, upper gastrointestinal side effects can be managed by administering the iron with or immediately after meals. If symptoms persist, reductions in the amount of iron in each dose may be helpful, either by changing to tablets that contain smaller amounts of iron or by using a liquid preparation of ferrous sulfate. Decreasing the amount of iron in each dose usually is effective in controlling side effects, but if symptoms persist, a reduction in frequency to a single daily dose may be helpful. After a time at lower doses, patients subsequently may be able to tolerate more iron. With persistence and patience, an acceptable oral iron regimen can be devised for virtually all patients. Costly iron preparations with other additives, polysaccharide–iron complexes, or enteric coatings or in sustained-release forms do not appear to offer any advantages that cannot be achieved by simply reducing the dose of plain ferrous salts.[80] Administering iron with food and decreasing the dose will diminish the amount of iron absorbed daily and thereby prolong the period of treatment, but haste in the correction of iron deficiency is rarely needed.

Parenteral iron therapy (see box on Parenteral Iron Therapy), with the risk of adverse reactions, should be reserved for the exceptional patient who (a) remains intolerant of oral iron despite repeated modifications in dosage regimen, (b) malabsorbs iron, or (c) has iron needs that cannot be met by oral therapy because of either chronic uncontrollable bleeding or other sources of blood loss, such as hemodialysis, or a coexisting chronic inflammatory state.[20,81,82] A screening test for iron malabsorption is the administration to the fasting patient of 100 mg of elemental iron as ferrous sulfate in a liquid preparation, followed by measurements of plasma iron concentrations 1 and then 2 hours later. In an iron-deficient patient with an initial plasma iron concentration less than 50 mg/dL, an increase in plasma iron concentration of 200 to 300 mg/dL is expected. An increase in plasma iron concentration less than 100 mg/dL suggests malabsorption and is an indication for a small-bowel biopsy.[83]

Prognosis

The prognosis for iron deficiency itself is excellent, and the response to either oral or parenteral iron also is excellent. Frequently, both clinical and subjective indications of constitutional improvement are seen within the first few days of treatment, with the patient reporting an enhanced sense of well-being and increased vigor and appetite. Pica may resolve, and soreness and burning of the mouth abate. Mild reticulocytosis begins within 3 to 5 days, is maximal by days 8 to 10, and then declines. The hemoglobin concentration begins to increase after the first week and usually returns to normal within 6 weeks. Complete recovery from microcytosis may take up to 4 months. With oral iron dosage totaling 200 mg/day or less, the plasma ferritin concentration remains less than 12 mg/dL until the anemia is corrected and then gradually rises as storage iron is replaced over the next several months. Although epithelial abnormalities begin to improve promptly with treatment, resolution of glossitis and koilonychia may take several months. The overall prognosis depends on the underlying disorder responsible for the iron deficiency.

Failure to obtain a complete and characteristic response to iron therapy necessitates a review of findings and reevaluation of the patient. A common problem is an incorrect diagnosis, with the anemia of chronic disease mistaken for the anemia of iron deficiency. Coexisting conditions, such as other nutritional deficiencies, hepatic or renal disease, or infectious, inflammatory, or malignant disorders, may impede recovery. Occult blood loss may be responsible for an incomplete response. With oral iron therapy, the adequacy of the form and dose of iron used should be reconsidered, compliance with the treatment regimen reviewed, and, finally, the possibility of malabsorption considered.

IRON OVERLOAD

Iron overload denotes an excess in total body iron resulting from an iron supply that exceeds iron requirements. Because requirements are limited and humans lack a physiologic means of excreting excess iron, any sustained increase in intake eventually may result in accumulation of iron. The continuum of increased body iron is shown in Fig. 36–2. Whatever the source and the sites of excess iron deposition, when the accumulation overwhelms the cellular capacity for safe storage, potentially lethal tissue damage is the result. The toxic manifestations of iron overload vary with the precise pathogenic defect responsible but are dependent on the amount of excess iron, rate of iron accumulation, cellular pattern of deposition, and presence of complicating factors such as hepatitis or drug or alcohol use.

Epidemiology

The most common form of iron overload in the United States is a genetically determined disorder, the homozygous state for hereditary hemochromatosis, which occurs in approximately 0.26% of the total population, or approximately 1:385 persons.[85] In the United States, other forms of iron overload are less frequent but affect thousands of patients with iron-loading or chronically transfused anemias, such as thalassemia major, sickle cell disease, and acquired refractory anemias. Globally, hereditary hemochromatosis is the most common genetic disorder in populations of northern European ancestry.[86–89] Thalassemia major and other iron-loading anemias are important public health problems in countries bordering the Mediterranean and in an area extending from southwest Asia and the Indian subcontinent to southeast Asia.[90] Dietary iron overload resulting from intake of iron in brewed beverages is a common problem affecting many populations in sub-Saharan Africa and may have a genetic component.[91,92] Other inherited types of systemic iron overload, the various forms of perinatal iron overload,[93] and the syndromes associated with focal sequestration of iron are uncommon or rare disorders.

Genetic Aspects

The varieties of iron overload known to be genetically determined are listed in Table 36–3, and their cardinal features are summarized in Table 36–4 (see Chapter 35 for a description of the genes involved). By far, the most common form of inherited iron overload is hereditary hemochromatosis, a disorder of autosomal recessive inheritance. In populations within Europe or of European ancestry, 64% to 100% of cases clinically diagnosed as hemochromatosis are due to mutations in the *HFE* gene and are classified as HFE-associated hemochromatosis.[94] The great majority of affected persons are homozygous for the mutation designated C282Y (i.e., C282Y/C282Y) or are "compound" heterozygotes for the C282Y mutation and either the mutation identified as H63D (C282Y/H63D) or, in a smaller proportion of cases, S65C (C282Y/S65C). In most of the other patients, the disorder is classified as non–HFE-associated hemochromatosis.[95,96] A subset of these patients have a disorder of autosomal recessive inheritance associated with mutations in the gene for transferrin receptor 2 (see Chapter 35)[97]; the genetic basis for the remaining patients is unknown.

Juvenile hemochromatosis is a rare disorder of autosomal recessive inheritance that produces a pattern of iron loading like that seen in hereditary hemochromatosis but becomes clinically manifest much earlier, in the second decade of life.[98] Most cases seem to be due to mutations in the gene *HJV* at chromosome 1q21, but a severe form is caused by mutations in *HAMP*, the gene for hepcidin.[99]

Autosomal dominant forms of hemochromatosis have been found to be caused by mutations in the gene for ferroportin.[95,100] Homozygous or compound heterozygous mutations in divalent metal transporter 1 (*DMT1*, *SCL11A2*) have been found to be associated with severe microcytic anemia and hepatic iron overload; three patients have been identified.[70,75,101] Mutations in the genes for transferrin[69] and ceruloplasmin[102] produce rare autosomal recessive disorders with distinctive syndromes of iron overload. Many of the genetically determined forms of iron overload are rare, but their characterization has made fundamental contributions to the understanding of the control of iron metabolism (see Chapter 35).

Several of the acquired forms of iron overload involve disorders with a genetic origin or component. The genetically determined iron-loading anemias include the inherited sideroblastic anemias (see Chapter 38), some of the hereditary disorders of globin synthesis (see Chapter 41), and some chronic hemolytic anemias (see Chapters 44, 45, and 46). Similarly, some forms of chronic liver disease and porphyria cutanea tarda are inherited disorders. African dietary iron overload[103] and, possibly, susceptibility to iron accumulation with prolonged medicinal iron ingestion may have genetic components.[104] Many of the disorders necessitating chronic red cell transfusion are hereditary, including thalassemia major (see Chapter 41), sickle cell disease (see Chapters 42 and 43), and other chronic refractory anemias. Although the precise etiology of many of these conditions are unknown, subsets of the disorders leading to perinatal iron overload[93] or focal sequestration of iron[105] have an established genetic basis.

Table 36–3 Causes of Iron Overload

Hereditary Iron Overload
Hereditary hemochromatosis
HFE-associated (type 1)
Non–HFE-associated:
Transferrin receptor 2–associated (type 3)
Juvenile hemochromatosis (type 2)
Hemojuvelin-associated (type 2A)
Hepcidin-associated (type 2B)
Autosomal dominant hemochromatosis
Ferroportin-associated (type 4)
DMT1-associated hemochromatosis
Atransferrinemia
Aceruloplasminemia
Acquired Iron Overload
Iron-loading anemias (refractory anemias with hypercellular erythroid marrow)
Chronic liver disease
Porphyria cutanea tarda
Insulin resistance–associated hepatic iron overload
African dietary iron overload[a]
Medicinal iron ingestion[a]
Parenteral iron overload
Transfusional iron overload
Inadvertent iron overload from therapeutic injections
Perinatal Iron Overload
Neonatal hemochromatosis
Trichohepatoenteric syndrome
Cerebrohepatorenal syndrome
GRACILE[b] (Fellman) syndrome
Focal Sequestration of Iron
Idiopathic pulmonary hemosiderosis
Renal hemosiderosis
Associated with neurologic abnormalities
Pantothenate kinase–associated neurodegeneration (formerly called Hallervorden-Spatz syndrome)
Neuroferritinopathy
Friedreich ataxia

[a]May have a genetic component.
[b]GRACILE, growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death.

Table 36–4 Hereditary Iron Overload Disorders

Disorder	Gene, Chromosome Location	Inheritance	Plasma Transferrin Saturation	Plasma Ferritin	Iron Deposition Sites	Clinical Manifestations
Hereditary hemochromatosis, HFE-associated	*HFE*, 6p21	Autosomal recessive	Early increase; >45%	Later increase after third decade	Parenchymal iron overload affecting liver, heart, pancreas, other organs	Liver and heart disease, diabetes, gonadal failure, arthritis, skin pigmentation
Hereditary hemochromatosis, TfR2-associated	*TFR2*, 7q22	Autosomal recessive	Early increase; >45%	Later increase after third decade	Parenchymal iron overload affecting liver, heart, pancreas, other organs	Liver and heart disease, diabetes, gonadal failure, arthritis, skin pigmentation
Juvenile hemochromatosis, hemojuvelin-associated	*HJV*, 1q21	Autosomal recessive	Early increase; >45%	Increased by second decade	Parenchymal iron overload affecting liver, heart, pancreas, other organs	As for hereditary hemochromatosis, but liver involvement less prominent
Juvenile hemochromatosis, hepcidin-associated	*HAMP*, 19q13	Autosomal recessive	Early increase; >45%	Increased by second decade	Parenchymal iron overload affecting liver, heart, pancreas, other organs	As for hereditary hemochromatosis, but liver involvement less prominent
Hemochromatosis, ferroportin-associated	*SLC11A3*, 2q32	Autosomal dominant	Remains normal or low	Early increase	Some mutations show selective reticuloendothelial; others also show parenchymal (liver, heart, pancreas)	None with only reticuloendothelial iron; others as for HFE-associated hemochromatosis
DMT1-associated hemochromatosis	*SCL11A2*, 12q13	Autosomal recessive	Early increase; >45%	Normal to moderately elevated	Hepatic iron overload, predominantly parenchymal	Severe microcytic anemia, liver dysfunction
Atransferrinemia	*TF*, 3q21	Autosomal recessive	No plasma transferrin	Increased	Parenchymal iron overload affecting liver, heart, pancreas; no iron in bone marrow or spleen	Transfusion-dependent iron deficiency anemia, growth retardation, poor survival
Aceruloplasminemia	*CP*, 3q23-q24	Autosomal recessive	Decreased	Increased	Marked iron accumulation in basal ganglia, liver, pancreas	Diabetes, progressive neurologic disease, retinal degeneration

Etiology and Pathogenesis

Iron overload is caused by conditions that alter or bypass the normal control of body iron content by adjustment of intestinal iron absorption (see Table 36–3). Genetic characterization of patients with disorders listed in Table 36–3 and studies of animal models of disorders of iron homeostasis (see Chapter 35) are helping to decipher the intricate regulatory pathways involved.[89,96,100,106–108] A major advance has been the recognition that the known forms of hereditary iron overload (see Table 36–3) have a common pathogenic origin in genetically determined abnormalities in the interaction of hepcidin and ferroportin[109] (see box on Common Pathogenic Origin of Hereditary Iron Overload: The Interaction of Hepcidin and Ferroportin).

The exact mechanisms whereby iron produces cellular injury are not established, but lipid peroxidation of membrane lipids of subcellular organelles, iron-induced lysosomal disruption, or both may be involved.[113] Whatever the precise mechanisms responsible for the harmful effects of iron, the pattern of the organs affected, the timing of the onset of toxic manifestations, and the severity of tissue damage are known to be influenced by a variety of factors in both hereditary and acquired varieties of systemic iron overload. Within the systemic circulation, these factors include (a) the specific underlying genetic or acquired abnormality, (b) the magnitude of iron excess, (c) the rate of iron loading, (d) the distribution of iron load between more innocuous storage deposits in reticuloendothelial macrophages and potentially injurious accumulations in parenchymal cells of the liver, pancreas, heart, and other organs, and (e) the extent of internal redistribution of iron between macrophage and parenchymal sites. Twin studies suggest that still unidentified genes have substantial effects on iron accumulation and toxicity.[114] In other forms of iron overload, another level of complexity is introduced because the central nervous system, the testes, and the fetus are functionally separate from the systemic circulation and cannot acquire iron directly from plasma transferrin.[115] Instead, iron must be taken up from the systemic circulation by barrier cells and then exported across the blood–brain and blood–cerebrospinal fluid barriers into the brain

interstitial and cerebrospinal fluids, across the blood–testis barrier, and across the placenta to the fetus. As a consequence, disorders affecting the proteins responsible for iron supply to these compartments have distinctive manifestations.

Hereditary Iron Overload

Within the systemic circulation, the specific patterns of iron deposition and damage found in the hereditary disorders of iron overload can be characterized by reference to the pathways of internal iron exchange shown in Fig. 36–1 and the classification of disorders given in Table 36–4. For the specific defects in the interaction between hepcidin and ferroportin responsible for each form of iron overload, see the box on Common Pathogenic Origin of Hereditary Iron Overload: The Interaction of Hepcidin and Ferroportin.

In *hereditary HFE-associated hemochromatosis*, an autosomal recessive disorder, the underlying genetic defect in the regulation of hepcidin production results in an inappropriately elevated iron absorption at any level of body iron, with a chronic progressive increase in body iron stores accompanied by enhanced release of iron from reticuloendothelial macrophages. The means whereby mutations in *HFE* produce these effects are unknown but involve an impaired increase in production of hepcidin in response to iron loading (see Chapter 35). Patients seem unable to effectively upregulate hepcidin expression as iron stores increase.[116] Of importance, intestinal iron absorption, although inappropriately high in hereditary HFE-associated hemochromatosis, still is regulated by body iron levels.[117] As the body iron level rises as a consequence of increased absorption, circulating transferrin becomes fully saturated. The excess iron is deposited predominantly within the parenchymal cells of the liver (Fig. 36–4), but subsequently the iron accumulates in the pancreas, heart, and other organs. By the time symptoms of organ damage develop, usually in the fourth or fifth decade of life, body iron stores typically have increased from the normal range of 1 g or less to 15 to 20 g or more.[118] Further increments in body iron stores may be fatal, although some patients are able to tolerate a total iron accumulation of as much as 40 to 50 g.

Patients with autosomal recessive *hereditary non–HFE-associated hemochromatosis* due to mutations in the gene for transferrin receptor 2 seem to be clinically similar to those with the HFE-associated form.[107,109] This clinical resemblance and observations in vitro suggest that these two proteins are involved in a common pathway regulating hepcidin synthesis.[119]

Patients with autosomal recessive *juvenile hemochromatosis* have the same pattern of tissue iron deposition found in hereditary HFE-associated hemochromatosis but develop severe iron overload much earlier, with hypogonadism and cardiac disease manifesting in the second decade of life.[120] The rate of iron accumulation is increased substantially and is estimated to be three to four times greater than that in HFE-associated disease. The gene responsible for most cases of juvenile hemochromatosis has been identified as *HJV* with the protein product hemojuvelin.[121,122] A subgroup of patients with juvenile hemochromatosis with null mutations in the hepcidin gene has been identified.[99] The consequent loss of all hepcidin-mediated regulation of intestinal iron absorption may explain the great acceleration in the rate of iron loading in this form of juvenile hemochromatosis. Interestingly, digenic inheritance of mutations in both the *HFE* genes (C282Y/H63D heterozygote) and the transferrin receptor 2 genes (Q317X homozygote) results in a phenotype like that of juvenile hemochromatosis.[123]

Patients with *autosomal dominant hemochromatosis* resulting from mutations in the ferroportin gene share the characteristic of reticuloendothelial iron overload, in contrast to the relative sparing of reticuloendothelial macrophages seen in patients with hereditary HFE-associated hemochromatosis.[95] Some mutations (i.e., those resulting in ferroportins that are unable to reach the cell surface to interact with hepcidin) produce an exclusively reticuloendothelial pattern of iron overload that is devoid of clinical manifestations and apparently does not require treatment.[100,124] Other mutations (i.e., those resulting in ferroportins that reach the cell surface but do not respond to hepcidin) are implicated not only in reticuloendothelial iron deposition but also in parenchymal iron loading associated with hepatic fibrosis, diabetes, impotence, arthritis, and arrhythmias. Affected patients may have a reduced tolerance for phlebotomy and become anemic with therapy, despite persistently elevated serum ferritin concentrations.[125,126] Another form of autosomal dominant iron overload reported in a single family has been attributed to a mutation in the gene for the iron responsive element of the H-subunit of ferritin.[127]

The three patients reported with *DMT1-associated hemochromatosis* have in common a severe microcytic anemia with high transferrin saturation, marked hepatic iron deposition, but normal to moderately elevated serum ferritin concentration.[70,75,101]

Congenital *atransferrinemia* (hypotransferrinemia) is a rare disorder of autosomal recessive inheritance in which plasma transferrin is nearly absent; only 10 cases have been reported.[69,128] Hepcidin levels are extremely low[107] and iron absorption is increased, but the absorbed

Common Pathogenic Origin of Hereditary Iron Overload: Interaction of Hepcidin and Ferroportin

The known forms of hereditary iron overload (Table 36–3) all involve defects in the interaction of hepcidin and ferroportin. Hepatic hepcidin production is inappropriately low in the autosomal recessive disorders HFE-associated and transferrin receptor 2–associated hereditary hemochromatosis and hemojuvelin- and hepcidin-associated juvenile hemochromatosis.[107] In autosomal dominant ferroportin disease, mutations produce ferroportins that either are unable to reach the cell surface to interact with hepcidin or reach the cell surface but do not respond to hepcidin.[100,110] In DMT1-associated hemochromatosis, urinary hepcidin is low.[75] In atransferrinemia, hepcidin levels are extremely low.[107,111] In aceruloplasminemia, the lack of ceruloplasmin prevents stable expression of ferroportin on the cell surface, leading to its internalization and degradation.[112] In each form, the resultant homeostatic dysregulation leads to excessive intestinal iron absorption and body iron excess. The rate, distribution, and harmful effects of tissue iron loading depend on the specific abnormality in the interaction between hepcidin and ferroportin produced by each mutation.

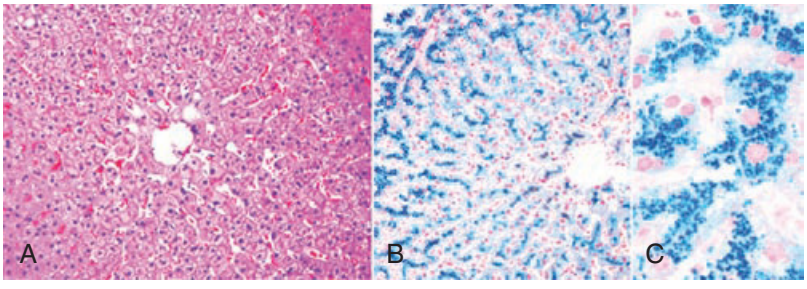

Figure 36–4 Hemochromatosis. Liver biopsy sample from a 46-year-old man with homozygous hemochromatosis. Hematoxylin and eosin stain of the liver (**A**) shows intact hepatic architecture. Iron stain (**B,C**) shows marked diffuse iron deposits in the hepatocytes throughout the lobules. A normal liver would show essentially no iron in the hepatocytes.

iron circulates as non-transferrin-bound plasma iron and, lacking a physiologic means of entry into erythroid precursors, cannot be used for erythropoiesis. Patients have a severe hypochromic microcytic anemia and die without transferrin infusion or blood transfusions. The circulating non-transferrin-bound plasma iron is progressively deposited in the liver, pancreas, heart, and other parenchymal tissues, but deposits are scant or absent in the bone marrow and spleen.[69,128] The distribution of iron deposits with atransferrinemia suggests the importance of non-transferrin-bound plasma iron as a mediator of iron accumulation by parenchymal tissues in hereditary and acquired forms of iron overload.[129]

Hereditary *aceruloplasminemia* (hypoceruloplasminemia) is a rare disorder of iron metabolism inherited as an autosomal recessive trait, resulting from absence or severe deficiency of ceruloplasmin occurring as a consequence of mutations in the ceruloplasmin gene.[102] Ceruloplasmin has an essential role in iron metabolism as a multicopper ferroxidase[102] catalyzing the oxidation of ferrous to ferric iron, a prerequisite for iron binding by apotransferrin (see Chapter 35). A glycosylphosphatidylinositol-anchored form of ceruloplasmin is expressed in the central nervous system and is required for iron efflux.[115,130] It appears to help protect the brain against iron-mediated oxidant damage. The lack of ceruloplasmin prevents stable expression of ferroportin on the cell surface, leading to its internalization and degradation[112] and intracellular accumulation of iron. Patients with ceruloplasminemia typically present in the fourth or fifth decade of life with a triad of diabetes mellitus, progressive neurologic disease (dementia, dysarthria, and dystonia), and retinal degeneration.[102] Marked iron accumulations are evident in the liver, pancreas, and brain, with smaller amounts of excess iron found in the spleen, heart, kidney, thyroid, and retina. Despite a degree and distribution of hepatic iron deposition comparable with those found in hereditary HFE-associated hemochromatosis, liver injury or fibrosis is not seen. The serum iron concentration is low, the serum total iron-binding capacity is normal, the serum ferritin concentration is moderately elevated, and a mild normochromic normocytic anemia usually is present.[102] Phlebotomy does not mobilize hepatic iron, but iron chelation with deferoxamine is effective and can ameliorate neurologic symptoms.[112,131]

Acquired Iron Overload

Iron-loading anemias may be associated with excessive absorption of dietary iron that can produce severe iron overload. The postulated *erythroid regulator*[132] can increase iron absorption dramatically when accelerated erythropoiesis exceeds the ability of transferrin to provide sufficient iron for hemoglobin production (see Chapter 35). The iron-loading anemias are characterized by the combination of erythroid hyperplasia with marked ineffective erythropoiesis.[133,134] These refractory disorders include thalassemia major and intermedia, hemoglobin E/β-thalassemia, congenital dyserythropoietic anemia, pyruvate kinase deficiency, a variety of sideroblastic anemias, and other anemias associated with blocks in the incorporation of iron into hemoglobin. The rate of iron loading is related not to the severity of the anemia but rather to the extent of ineffective erythropoiesis, and patients with nearly normal hemoglobin concentrations may develop massive iron overload. Any red cell transfusions will add to the iron burden.[135] Clinical manifestations include liver disease, diabetes mellitus, endocrine disorders, and cardiac dysfunction. Diminished hepcidin production as a result of ineffective erythropoiesis is believed to be responsible for increased iron absorption.[135,136]

Chronic liver disease with increased absorption of dietary iron may produce mild iron overload in some patients,[137,138] including individuals with alcoholic cirrhosis or portacaval shunts. Patients with alcoholic liver disease are more commonly iron deficient as a result of repeated episodes of gastrointestinal blood loss, but storage iron is increased in a minority of patients. The *HFE* gene is not responsible. The cause(s) of the increased absorption is not established with certainty, but alcohol metabolism–mediated oxidative stress downregulates hepcidin transcription, leading to increased intestinal iron absorption.[139–141] Alcohol-induced folate and sideroblastic abnormalities with ineffective erythropoiesis and hyperferremia also may contribute. Patients with chronic hepatitis C have been reported to have decreased hepatic hepcidin expression.[142] Storage iron usually is increased modestly, to only 2 to 4 g, but in patients with alcoholic cirrhosis, the higher the liver iron, the shorter the survival.[143] The pattern of iron distribution is seen predominantly in Kupffer cells rather than in parenchymal cells.

Porphyria cutanea tarda (see Chapter 38), the most common type of human porphyria, is caused by iron-dependent oxidation of uroporphyrinogen to uroporphomethene, a competitive inhibitor of uroporphyrinogen decarboxylase.[144] In this disorder, the liver produces excessive amounts of photosensitizing porphyrins, which circulate in the skin.[145] Mild hepatic iron overload is found in most patients, and iron depletion by phlebotomy produces clinical and biochemical remission of the disease.[146] *HFE* mutations are common in patients of European origin and seem to contribute to the pathogenesis of both the familial and sporadic forms of the disorder.[147] The mechanism for iron loading in patients without mutations in *HFE* is unknown.

Insulin resistance–associated hepatic iron overload (also known as "dysmetabolic hepatosiderosis") is a syndrome of iron overload in which the combination of an increased serum ferritin level with a normal transferrin saturation is found in association with glucose or lipid metabolic abnormalities.[148,149] The iron overload typically is mild or moderate, and there is no evidence of familial transmission. On histologic examination, a mixed pattern of iron deposits in hepatocytes and sinusoidal cells is seen that is distinct from that of HFE-associated hemochromatosis.[150] The clinical value of phlebotomy in removing the modest iron excess in these patients is under study.[151,152]

African dietary iron overload occurs in sub-Saharan Africa in association with greatly increased dietary iron intake from a traditional fermented beverage with high iron content; however, a genetic component not linked to *HFE* also may be involved.[92,103,153] Iron burdens of magnitudes comparable to those found in hereditary hemochromatosis may accumulate, and liver disease with cirrhosis and hepatoma, pancreatic disease with diabetes mellitus, endocrine disorders, and cardiac dysfunction may develop.[91] On histologic examination, iron deposits are prominent in both macrophages and hepatic parenchymal cells,[91] in contrast with the predominantly parenchymal iron loading found in HFE-associated hemochromatosis. A ferroportin mutation (Q248H), unique to African populations, has been identified but does not seem to account for the condition.[92,103]

Medicinal iron ingestion can add to the body iron burden of patients with iron-loading disorders, especially iron-loading anemias.[104] In persons without abnormalities affecting iron homeostasis, the extent to which orally administered iron can increase the body iron stores is uncertain. Although case reports have described iron accumulation in patients who have taken medicinal iron for long periods, the potential involvement of an unrecognized iron-loading mutation in these patients cannot be excluded.

Parenteral iron overload usually is the result of repeated red cell transfusions in patients with chronic anemia, but occasionally it is unintentionally produced by repeated injections of iron dextran or other parenteral iron preparations in patients with anemias unresponsive to iron therapy, such as patients undergoing chronic hemodialysis.[154]

Transfusional iron overload progressively develops in patients with chronic refractory anemia who require red cell support.[155] In patients with severe congenital anemias such as thalassemia major (Cooley's anemia) or Blackfan-Diamond syndrome, transfusional iron loading begins in infancy.[156,157] Severe iron loading may develop in transfusion-dependent anemias that appear later in life, namely, aplastic anemia, pure red cell aplasia, hypoplastic or myelodysplastic disorders, and the anemia of chronic renal failure. Patients with sickle cell anemia or sickle cell/β-thalassemia also are at risk for iron overload if chronically given transfusions for prevention of recurrent complications such as stroke, severe infections and incapacitating painful crises.[158] If ineffective erythropoiesis and erythroid hyperplasia com-

plicate the underlying anemia, increased absorption may contribute to the iron burden. The greater the extent of ineffective erythropoiesis, the greater the suppression of hepcidin synthesis and the greater the magnitude of the increase in iron absorption.[135,159,160] An adequate transfusion regimen will help suppress erythropoiesis and contribute to iron loading, resulting in relatively higher hepcidin levels, which in turn will decrease dietary iron absorption.

Perinatal iron overload develops in some rare or uncommon metabolic disorders of the newborn, presumably as the result of disturbances in the regulation of fetal or maternal–fetal iron balance and in some instances as a result of severe intrauterine liver disease producing severe hypotransferrinemia.[93] *Neonatal* (or *perinatal*) *hemochromatosis* is a diverse collection of disorders associated with severe congenital hepatic disease and deposits of iron in the liver and pancreas, heart, and other extrahepatic sites, with evidence of autosomal recessive inheritance in some cases and an alloimmune etiology in others.[161,162] The *trichohepatoenteric syndrome* is an apparently distinct disorder with hepatic hemosiderosis, facial dysmorphism, hair abnormality, failure to thrive and intractable diarrhea.[163,164] The *cerebrohepatorenal syndrome* (or Zellweger syndrome) is a fatal disorder of peroxisomal biogenesis with an autosomal recessive mode of inheritance, characterized by abnormal facies, hypotonia, and polycystic kidneys. Parenchymal iron deposits are found in the liver, spleen, kidney, and lungs.[165,166] *GRACILE* (*g*rowth *r*etardation, *a*minoaciduria, *c*holestasis, *i*ron overload, *l*actic acidosis, and *e*arly death) *syndrome* is a recessively inherited lethal disease characterized by fetal growth retardation, lactic acidosis, aminoaciduria, cholestasis, and abnormalities in iron metabolism.[167] A mutation in *BCS1L*, a gene that encodes a mitochondrial protein that functions as a chaperone in the assembly of complex III (cytochrome bc1 complex) of the mitochondrial respiratory chain, is responsible,[168] but the mechanism of the effects on iron metabolism has not been identified.

Focal sequestration of iron in other rare disorders produces various patterns of localized iron deposition. In *idiopathic pulmonary hemosiderosis*, repeated episodes of alveolar hemorrhage are followed by uptake and sequestration of iron in pulmonary macrophages.[169] The excess iron is not available for use elsewhere, and iron stores in the liver and bone marrow may be decreased or absent.[45,170] In conditions with chronic hemoglobinuria, *renal hemosiderosis* may develop and, in some cases, can cause or contribute to renal failure.[171] Finally, remarkable progress is being made in elucidating the bases for disorders with specific patterns of brain iron deposition in association with neurologic abnormalities,[105,115] including *Friedreich ataxia*,[172] *pantothenate kinase-associated neurodegeneration*[173] (formerly called Hallervorden-Spatz syndrome), and *neuroferritinopathy*.[174]

Clinical Presentation

Clinical manifestations of iron toxicity generally develop only in patients with forms of systemic parenchymal iron overload in which the magnitude of iron accumulation is sufficient to produce tissue and organ damage. Individuals at risk include homozygotes for the types of hereditary and juvenile hemochromatosis listed in Table 36–3, some forms of ferroportin-associated hemochromatosis, aceruloplasminemia, and patients with iron-loading anemias, African dietary iron overload, transfusional iron overload, and, apparently, insulin resistance-associated hepatic iron overload. Patients with forms of iron overload restricted to reticuloendothelial tissue do not seem to develop clinical complications.[124] Specific patterns of neurologic signs and symptoms occur in patients with aceruloplasminemia,[102] pantothenate kinase-associated neurodegeneration,[173] Friedreich ataxia,[172] and neuroferritinopathy that reflect the brain distribution of the excess iron.[174]

In patients with systemic parenchymal iron loading, similar clinical features eventually develop with sufficient iron accumulation to produce organ dysfunction and damage. At earlier stages, with lower body iron burdens, no distinctive signs or symptoms may be present, and patients may come to attention only because of abnormal laboratory test results. Symptomatic patients may present with any of the characteristic manifestations of parenchymal iron deposition: liver disease, diabetes mellitus, gonadal insufficiency and other endocrine disorders, cardiac dysfunction, arthropathy, and increased skin pigmentation. The rate of iron deposition also seems to influence the pattern of organ dysfunction that develops. For example, the mean body iron burdens as determined by phlebotomy were almost identical in a group of patients homozygous for juvenile hemochromatosis and a comparison group of patients with hereditary hemochromatosis (all homozygous for the C282Y mutation in *HFE*).[120] In the patients with juvenile hemochromatosis, the iron load had accumulated by a mean age of 23.3 ± 6.2 years, and the major manifestations were hypogonadism in 96%, reduced glucose tolerance in 58%, and cardiomyopathy in 35%. In the patients with hereditary HFE-associated hemochromatosis, the nearly identical mean body iron burden had accumulated significantly later, by a mean age of 44.8 ± 10.7 years, and the corresponding prevalences for these complications were significantly lower: hypogonadism was present in only 18%, reduced glucose tolerance in 27%, and cardiomyopathy in 7%. The prevalences of cirrhosis (42% vs 52%) and arthropathy (27% vs 12%) did not differ significantly between the two groups.[120]

Characteristic manifestations of iron toxicity are found in specific organ systems. Liver disease is the most common complication of systemic iron overload.[137,138] In all varieties of systemic parenchymal iron overload, the development and severity of liver damage are closely correlated with the magnitude of hepatic iron deposition. On an intriguing note, the sole exception seems to be aceruloplasminemia, in which liver damage and fibrosis do not develop despite hepatic iron accumulations of the magnitudes found in hereditary hemochromatosis.[175] Otherwise, whether derived from increased absorption of dietary iron or from transfused red cells, progressive parenchymal iron accumulation eventually produces hepatomegaly, functional abnormalities, fibrosis, and, finally, cirrhosis. Hepatocellular carcinoma seems to be the ultimate complication of cirrhosis in iron overload. The development of cirrhosis increases the risk of hepatoma by more than 200-fold.[176]

Diabetes mellitus is another common complication of all forms of systemic parenchymal iron overload[151,177,178] (including aceruloplasminemia[102,175]). The risk may be greater in patients with a family history of diabetes. Virtually all of the secondary manifestations of diabetes may develop, including retinopathy, nephropathy, neuropathy, and vascular disease.

Gonadal insufficiency and other endocrine abnormalities occur.[151,178,179] Hypogonadism may result from primary testicular failure or may be hypogonadotropic in origin. Abnormalities in pituitary and end-organ functions may develop; hypothyroidism, hypoparathyroidism, and adrenal insufficiency are infrequent complications. During the second decade of life, both growth and sexual maturation usually are retarded in untreated patients with transfusional iron overload.

Iron-induced cardiac disease, occurring as a cardiomyopathy with heart failure, arrhythmias, or both, may be a fatal complication of all varieties of systemic parenchymal iron overload. Heart disease is the most frequent cause of death in patients with transfusional iron overload.[177,180] Severe cardiac disease in particular may be the presenting manifestation in young patients with juvenile hemochromatosis.[120]

Increased skin pigmentation, with a bronze hue in some patients and a slate-gray coloration in others, often accompanies iron overload, although the change in pigment may be too slight to be readily evident clinically. Massive iron overload sometimes produces "reverse freckling," with small pigment-free areas scattered over a conspicuous slate-gray discoloration of the skin. Chondrocalcinosis and other forms of arthropathy are common complications of hereditary hemochromatosis and may occur in other forms of systemic parenchymal iron overload.[151,181–183] An increased susceptibility to infectious disease may be found in patients with transfusional and other forms of iron overload. Clinical reports suggest that an increased availability of iron may be related pathogenetically to infections with certain organisms, including *Vibrio vulnificus*, *Listeria monocytogenes*, *Yersinia enteroco-*

litica, Escherichia coli, Candida species, and *Mycobacterium tuberculosis*.[184–188]

Laboratory Evaluation

The typical sequences of changes in clinically useful indicators of iron status, as body iron increases from the iron-replete normal to the amounts found in hereditary hemochromatosis and transfusional iron overload, are shown in Fig. 36–2. Characteristic changes in laboratory measures of iron status in the disorders of hereditary iron overload are listed in Table 36–4.

Population-based screening for iron overload has been widely discussed.[189–192] However, after review of the available evidence,[193] the U.S. Preventive Services Task Force presently recommends against routine genetic screening for hereditary HFE-associated hemochromatosis in the general population.[194] Uncertainty about the penetrance of the most common form of iron overload has been a major consideration.[88] Large studies have suggested that the penetrance of hereditary HFE-associated hemochromatosis is low.[195–197] One of the studies concluded that a "best estimate is that less than 1% of homozygotes develop frank clinical hemochromatosis."[195] These interpretations, based on cross-section surveys that did not include thorough evaluation of hepatic function with liver biopsy, have been challenged,[87,198] but large-scale population-based screening seems unlikely to be adopted in the near term.

In contrast, screening for iron overload is clearly indicated for patients with any of the symptoms and signs associated with iron overload, including chronic liver disease, cardiomyopathy, diabetes, endocrine disorders, arthropathy, increased skin pigmentation, and porphyria cutanea tarda.[94,151] Screening can use phenotypical methods, genotypical methods, or both. Phenotypical screening can provide biochemical evidence of iron overload in patients with hereditary or juvenile hemochromatosis but will not identify all persons genetically at risk for iron loading.[195] In populations of northern European ancestry, genotypical screening for the C282Y and H63D mutations in *HFE* can identify most persons at risk for developing hereditary hemochromatosis but gives no information about the presence or magnitude of iron overload. Genotyping the spouse of a C282Y homozygote provides the best guide for assessing children for *HFE* mutations. Despite these advantages, testing solely for the C282Y and H63D mutations of *HFE* will not identify other mutations associated with iron loading. In populations not of northern European ancestry, many persons at risk will not be identified.[199,200] In most clinical circumstances, a combination of phenotypical and genotypical methods is the best strategy for screening.

In individuals of northern European ancestry, measurement of the serum transferrin saturation usually is the best method for initial phenotypical screening for systemic parenchymal iron overload. A persistent value of 45% or greater often is recommended as a threshold value for further investigation. In the absence of complicating factors, elevated concentrations of serum ferritin provide biochemical evidence of iron overload. Genetic testing then should be considered in persons with abnormal transferrin saturation, serum ferritin concentration, or both. If a persistently elevated transferrin saturation is found in a person who is homozygous for the C282Y mutation (i.e., C282Y/C282Y), the diagnosis of hereditary hemochromatosis can be considered established. In most such patients, liver biopsy is no longer needed to confirm the diagnosis. Liver biopsy is indicated for prognostic purposes to detect cirrhosis if the serum ferritin concentration is greater than 1000 μg/L and may be contemplated in the presence of hepatomegaly or abnormalities on liver function testing, or in patients older than 40 years.[151,178,201,202] Bone marrow examination is of limited usefulness in the evaluation of patients for hereditary or juvenile hemochromatosis because no information about the extent of parenchymal iron deposition is provided.

Heterozygotes for the C282Y mutation (C282Y/wild-type) have serum transferrin saturations and serum ferritin concentrations that are similar to those of wild-type homozygotes, and clinically meaningful iron overload does not develop.[35,196] In heterozygotes for the C282Y and H63D mutations (C282Y/H63D), mild–to-moderate iron overload may develop, but the penetrance of this genotype is even less than that of C282Y/C282Y homozygotes.[196,203,204] Heterozygotes for H63D (i.e., H63D/wild-type) may have elevated transferrin saturations,[203] but iron overload does not develop. Homozygotes for H63D (i.e., H63D/H63D) also may have elevated transferrin saturations but have little risk of iron overload.[203] Less common mutations of the *HFE* gene have been identified. In S65C heterozygotes with either C282Y (i.e., S65C/C282Y) or H63D (i.e., S65C/H63D), mild iron overload may develop.[205,206]

Persons with phenotypical evidence of iron overload who are neither C282Y/C282Y homozygotes nor C282Y/H63D heterozygotes can be considered for further genetic testing for less common *HFE* mutations and for non-*HFE* mutations associated with iron loading, for noninvasive assessment of the liver iron concentration,[6,7] or for diagnostic liver biopsy.

Liver biopsy can establish a definitive diagnosis of hereditary and juvenile hemochromatosis regardless of genotype and can demonstrate the reticuloendothelial pattern of iron loading found with ferroportin mutations and the characteristic histologic appearance of insulin resistance-associated hepatic iron overload (see box on Testing for Iron Overload).[150,151,178,201] A quantitative determination of the nonheme iron concentration in the liver sample should be made, the pattern of iron deposition examined histochemically, and the extent of tissue injury assessed histopathologically. In patients found to have an increased body iron concentration, additional clinical and laboratory studies should seek evidence of complications of iron overload. Further investigation may include liver function testing, testing for diabetes mellitus, evaluation of hormonal function, cardiac examination, joint and bone x-ray examination, and, especially if cirrhosis is present, screening for hepatocellular carcinoma.[151,178,201] Liver biopsy with quantitative determination of iron stores remains the reference method for assessing the extent of iron overload in patients with transfusional iron overload.[1,6,7,13]

Patients with autosomal dominant forms of iron overload generally display an early increase in the plasma ferritin concentration that precedes a rise in the transferrin saturation.[204] A mild hypochromic anemia may be present, especially among young women. Liver biopsy demonstrates predominantly reticuloendothelial iron overload; a lesser degree of parenchymal iron deposition is found in some but

Testing For Iron Overload

A direct measure of body iron avoids the uncertainties inherent in the interpretation of indirect indicators of iron status. Liver biopsy is the definitive direct test for assessing iron deposition and tissue damage in iron overload, permitting measurement of the nonheme iron concentration, histochemical determination of the cellular distribution of iron between hepatocytes and Kupffer cells, and pathologic examination of the extent of tissue injury. When available as appropriately calibrated and validated techniques, new noninvasive methods using hepatic magnetic susceptibility and magnetic resonance imaging[9–12,207,208] may replace liver biopsy when only determination of the liver iron concentration is needed. Magnetic resonance imaging studies of the heart are particularly useful in patients at risk for cardiac iron deposition.[180,208,209] In patients with hereditary hemochromatosis undergoing therapeutic venesection, quantitative phlebotomy provides an accurate retrospective determination of the amount of storage iron that can be mobilized for hemoglobin formation. When liver biopsy is contraindicated in a patient, quantitative phlebotomy occasionally is useful in establishing the diagnosis of hereditary hemochromatosis. Bone marrow aspiration and biopsy provide no information about the extent of parenchymal iron loading and are of limited value in the evaluation of iron overload. Iron overload produces no specific abnormalities in the peripheral blood.

not all patients.[110,204] Atransferrinemia or hypotransferrinemia is readily demonstrable by measurement of the plasma transferrin concentration.[69,128] Similarly, aceruloplasminemia or hypoceruloplasminemia can be diagnosed by measurement of the plasma ceruloplasmin concentration.[102,210] At diagnosis, the plasma ferritin concentration is increased, often to 1000 to 2000 μg/L, but the transferrin saturation is decreased. A mild normochromic, normocytic anemia usually is present. Liver biopsy shows iron accumulation in hepatocytes and Kupffer cells. Magnetic resonance imaging examination shows low-intensity signals on T1- and T2-weighted studies of the basal ganglia.

For detection and diagnosis of iron-loading anemias, measurement of the plasma transferrin receptor and examination of the bone marrow may be helpful in demonstrating ineffective erythropoiesis in combination with the erythroid hyperplasia characteristic of these disorders.

Differential Diagnosis

Detection and diagnosis of iron overload are most problematic in the hereditary forms of iron overload (see Table 36–3). The combination of phenotypical and genotypical screening described in the preceding section should lead to a definitive diagnosis in most patients. Practice guidelines for the detection, diagnosis,[211] and management of hereditary hemochromatosis have been published.[151,178,193,194,201,211] Aceruloplasminemia is a rare disorder, but distinguishing this form of iron overload from hereditary hemochromatosis is important in guiding effective therapy that can prevent or arrest neurologic damage.[140,151,210]

In patients with iron-loading anemias who are not transfusion dependent, the severity of anemia provides no indication of the risk of iron loading from increased dietary iron absorption. Patients with only minor degrees of anemia may accumulate major iron loads.[133,136,212] In the diagnostic evaluation of these patients, examination of the peripheral blood may show changes indicative of the underlying hematologic disorders. Either morphologic techniques or measurement of the plasma transferrin receptor concentration can be used to estimate the extent of ineffective erythropoiesis and of erythroid marrow hyperplasia and may be useful in assessing the risk of iron loading.[213] The differential diagnosis directed at the remaining causes of iron overload listed in Table 36–3 poses few problems. Porphyria cutanea tarda is discussed more fully in Chapter 38 and is readily diagnosed by the measurement of urinary porphyrins. The source of iron overload in patients with parenteral iron loading is evident, whether from transfusion or from repeated injections of therapeutic iron. The various causes of perinatal iron overload are clearly distinguished by clinical and pathologic findings. The diagnosis of idiopathic pulmonary hemosiderosis should be considered whenever iron-deficiency anemia develops with coexisting pulmonary abnormalities. Previously, the demonstration of iron deposits in the brain of patients with Friedreich ataxia, pantothenate kinase-associated neurodegeneration (formerly called Hallervorden-Spatz syndrome), and neuroferritinopathy was possible only at autopsy, but magnetic resonance imaging now provides a means for detecting localized brain iron deposits during life.[214]

Patients with hyperferritinemia but no clinical manifestations or elevated transferrin saturations may have mutations in the ferroportin gene (Table 36–4) or in the gene for the iron responsive element in L-ferritin messenger RNA.[100,215–217] The latter mutations are responsible for hereditary hyperferritinemia with cataract, a newly recognized disorder of autosomal dominant inheritance in which affected family members present with early-onset bilateral nuclear cataracts and moderately elevated plasma ferritin concentrations due to increased concentrations of L-ferritin. Serum iron concentration and transferrin saturation are normal or low, body iron level as evaluated by phlebotomy is not increased, and no hematologic or biochemical abnormalities are evident in affected persons.[216] Molecular studies have identified mutations in the iron responsive element of the L-ferritin messenger RNA as responsible. The only sign of the mutation seems to be an accumulation of L-type ferritin in the lens, resulting in cataract formation.[218]

Therapy

The goal of therapy for iron overload is reduction and maintenance of body iron at normal or near-normal levels. If possible, phlebotomy is the treatment of choice for hereditary hemochromatosis,[151,178] iron-loading anemia if the hemoglobin concentration is high enough to permit venesection,[134] porphyria cutanea tarda,[146] and African dietary iron overload.[91] Once the diagnosis of iron overload is established, phlebotomy therapy should begin promptly because any delay extends exposure to potentially toxic iron accumulations.

For most patients, phlebotomy should remove 500 mL of blood, containing 200 to 250 mg of iron, once weekly, until storage iron is depleted. The regimen should be individualized. For patients with iron-loading anemia, smaller amounts of blood will need to be withdrawn weekly, whereas for heavily iron-loaded patients with hereditary hemochromatosis, an even more vigorous program of twice-weekly phlebotomy can be used. The hematocrit or hemoglobin concentration should be measured before each phlebotomy procedure. After an initial fall in the hemoglobin concentration as erythropoiesis accelerates to keep pace with venesection, the hemoglobin will remain at approximately 90% of its initial value. The progress of iron removal can be followed by periodic measurements of plasma ferritin and iron concentrations and transferrin saturation. The plasma ferritin concentration declines progressively as iron is removed, but the plasma iron concentration and transferrin saturation remain elevated until iron stores near depletion. In a patient with porphyria cutanea tarda, a few weeks of phlebotomy will suffice, whereas in a patient with hereditary hemochromatosis and an initial body iron burden of 25 g, removal of the iron burden may require 2 years or more of phlebotomy.

Occasionally, plasma iron concentration falls and hemoglobin regeneration is temporarily delayed despite incomplete removal of excess iron, as indicated by continued elevation of the plasma ferritin concentration. A brief halt in the phlebotomy regimen, which presumably allows mobilization of the remaining iron, usually is all that is needed before resumption of weekly venesection. Eventually, when iron stores are exhausted, the ferritin will decline to less than 12 mg/L, the plasma iron concentration and transferrin saturation will be decreased, and the hemoglobin concentration will fall to less than 10 g/dL for 2 weeks without further phlebotomy. After complete removal of the iron load, lifelong maintenance therapy is needed, usually necessitating phlebotomy of 500 mL every 3 to 4 months or, in some patients, even less frequently. Maintenance phlebotomy should preserve a plasma ferritin concentration less than 50 mg/L. Although well-controlled studies are lacking, phlebotomy generally is not recommended for patients with the modest iron overload that sometimes develops with chronic liver disease; removal of the iron load in these cases seems to have no clinical benefit. In aceruloplasminemia, phlebotomy cannot remove the excess iron,[219] but iron chelation therapy with deferoxamine can provide effective treatment.[131,220]

For patients with transfusion-dependent refractory anemias, most patients with iron-loading anemias, and rare patients with hereditary hemochromatosis in whom phlebotomy is impossible, treatment with an iron chelator is the only means of preventing or removing toxic accumulations of iron (see box on Timing of Chelation Therapy). In patients with hereditary hemochromatosis and cardiac failure, a combination of phlebotomy and chelation therapy has been recommended. In the United States, two iron-chelating agents are available: deferoxamine, given parenterally, and deferasirox, administered orally.

For the past 3 decades, deferoxamine, a hexadentate bacterial siderophore purified from *Streptomyces pilosus*, has been regarded as the drug of choice for treatment of transfusional iron overload. It is a generally safe and efficacious means of controlling body iron that can prolong survival and prevent or ameliorate organ dysfunc-

Timing of Chelation Therapy

In patients who are transfusion dependent from early infancy (i.e., those with thalassemia major or other congenital refractory anemias), chelation therapy is best started after 10 to 20 transfusions, usually at approximately 3 years of age. In older patients with acquired refractory anemias who become transfusion dependent, it seems advisable to begin chelation early, after transfusion of 10 to 20 units of blood. In patients with iron-loading anemias and those with sickle cell disease who are chronically transfused for prevention of complications, early therapy also seems prudent, beginning when the hepatic iron concentration or the serum ferritin concentration increases to about two or three times the upper limit of normal. In each of these disorders, delay in beginning chelation therapy only exposes the patient to greater risk of iron toxicity.

tion.[207,221–223] Unfortunately, deferoxamine given orally is poorly absorbed. To be effective, the drug must be administered by prolonged subcutaneous or intravenous infusion with a small portable syringe pump, ideally each day, making compliance a demanding task. In patients with modest iron loads and no evidence of iron toxicity, slow subcutaneous infusion of deferoxamine for 9 to 12 hours daily usually provides adequate therapy.[223] In severely iron-loaded patients and in patients with evidence of iron toxicity, particularly those with cardiac complications, chronic slow intravenous infusions given through an indwelling central venous catheter may permit more rapid reduction of the body iron burden.[224] Deferoxamine is a generally safe and nontoxic drug for iron-loaded patients, but systemic complications have been reported, including allergic anaphylactoid reactions, infectious complications, visual abnormalities, auditory dysfunction, and growth retardation. The risk of many of these complications may be minimized by adjusting the deferoxamine dose to the magnitude of the body iron load.[223] Adequate deferoxamine therapy should produce a progressive decrease in the body storage iron of almost any patient with iron overload. If no decline is observed, blood and deferoxamine use, compliance, ascorbate status, and other features of the therapeutic regimen should be thoroughly reassessed.

Deferasirox, a synthetic orally active tridentate iron chelator, was approved for use by the U.S. Food and Drug Administration in 2005 for treatment of transfusional iron overload in adults and children older than 2 years.[225] Deferasirox has a long plasma half-life, making possible once-daily dosing. Extensive systematic clinical trials in patients with thalassemia major,[226] sickle cell disease,[227] and other transfusion-dependent anemias have provided evidence that the effectiveness of deferasirox in the management of iron overload is comparable to that of deferoxamine.[228] The most common adverse events have been rash, gastrointestinal disturbances, and abnormalities in renal function. Additional clinical studies examining the long-term safety and efficacy of deferasirox are in progress, but the initial experience suggests that this orally active iron-chelating agent is a well-tolerated, once-daily treatment for control of transfusional iron overload.

Prognosis

The prognosis in patients with iron overload is influenced by many factors, including the magnitude, rate, and route of iron loading; distribution of iron deposition between macrophage and parenchymal sites; amount and duration of exposure to circulating nontransferrin-bound iron; ascorbate status; and coexisting disorders, especially alcoholism. The magnitude of iron accumulation seems to be a critical determinant of the risk of cirrhosis of the liver and, in turn, of hepatocellular carcinoma, now the two major causes of death in hereditary hemochromatosis.[118] The development of cirrhosis increases the risk of hepatocellular carcinoma more than 200-fold.[118] Hepatomas, the ultimate cause of death in 20% to 30% of patients with hemochromatosis, occur almost exclusively in patients with hepatic cirrhosis.[229] If the disease is diagnosed before tissue injury occurs, phlebotomy therapy to remove the excess iron can prevent all of the complications of hemochromatosis, including cirrhosis, and return the patient's life expectancy to normal.[118] Even if organ damage is present, phlebotomy prevents further progression, and amelioration of some features of the disease is possible. Skin pigmentation diminishes; hepatic function may improve while fibrosis is arrested or sometimes regresses;[87] and cardiac abnormalities, including even cardiac failure, may resolve. Diabetes and other endocrine abnormalities usually are ameliorated only slightly, if at all, although reversal of hypogonadism has occurred. Arthropathy usually does not subside and may even continue to progress despite phlebotomy.

In patients with iron overload who cannot be treated by phlebotomy, chelation therapy is effective in reducing the body iron burden and improving the prognosis. Chronic infusion of parenteral deferoxamine decreases the hepatic iron concentration, improves hepatic function, promotes growth and sexual maturation, and helps protect against cardiac disease and early death. Early experience suggests that orally administered deferasirox may be similarly effective in many patients. In all forms of iron overload, the most effective means of preventing complications is prevention of iron accumulation, either by early identification and phlebotomy treatment of homozygotes for hereditary hemochromatosis or by early institution of chelation therapy in patients with iron-loading or transfusion-dependent anemias.

CHAPTER 37

ANEMIA OF CHRONIC DISEASES

Lawrence B. Gardner and Edward J. Benz, Jr.

Anemia is commonly associated with many diverse systemic inflammatory conditions, including infection, rheumatologic disorders, and cancer. The cause of the anemia of chronic disease (ACD) is multifactorial and includes a mildly decreased life span of erythrocytes coupled with deregulated iron absorption and transport, a direct inhibition of hematopoiesis, and a relative deficiency of erythropoietin. Research over the past decade has delineated the important role of inflammatory cytokines in each of these causes and the emerging role of the iron regulator hepcidin in the pathogenesis of ACD. Clinical trials have led to effective treatment options for patients with ACD.

DESCRIPTION AND EPIDEMIOLOGY

ACD is an anemia of underproduction that usually is normocytic, normochromic, and relatively mild, with a hemoglobin level greater than 10 g/L.[1] However, the anemia can be severe, and the mean corpuscular volume may be reduced, sometimes dramatically, in approximately 30% of patients. ACD is one of the most common causes of anemia. Over a 2-month period of observation, 52% of hospitalized patients with anemia who were not iron deficient, hemolyzing, or suffering from a hematologic malignancy met the laboratory criteria for ACD.[2] Although anemia is extremely common in cancer patients undergoing chemotherapy, up to 30% of patients with a variety of nonhematologic cancers have anemia before treatment. The presence of anemia may correlate with survival.[3] ACD has been diagnosed in up to 27% of outpatients with rheumatoid arthritis.[4] Although most hospitalized patients with ACD have active infection, an inflammatory condition, or a malignancy, other reported precipitating illnesses include alcoholic liver disease, congestive heart failure, thrombosis, chronic pulmonary disease, diabetes, trauma, and a variety of other medical conditions.[2,5] Because of the lack of standard for the diagnosis of ACD (as discussed in Diagnosis), such epidemiologic studies may be suspect. However, it is intriguing that some of the diverse diseases that have not been thought to be inflammatory in nature, such as congestive heart failure, have been associated with many of the cytokine abnormalities found to play a causative role in ACD.[6]

ETIOLOGY AND PATHOGENESIS

ACD is marked by low serum levels of iron. However, in contrast to iron-deficiency anemia, total iron stores are normal or elevated, and these findings appear to parallel disease activity.[7] Because of the well-established serum markers in ACD, initial theories on the etiology of ACD emphasized the role of iron. Subsequent models focused on a direct suppression of hematopoiesis and a relative deficiency of erythropoietin. With the observations that hepcidin levels are elevated in ACD and that hepcidin plays an important role in iron utilization (see Biology and Molecular Aspects), models of ACD again are focusing on the role of iron metabolism. Interestingly, evidence also suggests that hepcidin has a direct effect on erythroid progenitor proliferation and survival.[8,9] It is clear that the pathogenesis of ACD is multifactorial and complex (Table 37–1).

Although a variety of studies demonstrate that red cell survival in ACD is only mildly decreased, even a small decrease in erythrocyte half-life may have an impact on hemoglobin concentrations when erythropoiesis is concomitantly suppressed, as has been demonstrated in ACD (see Biology and Molecular Aspects). Rats given endotoxin have a reduced erythrocyte half-life,[10] and a mildly shortened erythrocyte half-life has been observed in patients with rheumatoid arthritis and ACD.

It has long been established that iron metabolism is deregulated in ACD. Early studies in a variety of animal models demonstrated that radiolabeled iron absorption and half-life were diminished with concomitant systemic inflammation.[10,11] Other studies using trace quantities of labeled iron showed no direct impairment of iron incorporation into red blood cells, suggesting that inflammation impairs iron release from storage sites, decreasing plasma iron concentrations and decreasing iron available for hemoglobin synthesis. Sterile inflammation in a dog model impairs only the reuse of iron from senescent red cells, further suggesting that inflammation leads to a defect in iron release from tissues to the plasma transferrin pool.[12] Studies in patients with rheumatoid arthritis and a diagnosis of ACD also demonstrate decreased iron turnover in comparison to normal or iron-deficient control subjects.[13]

Abnormal iron turnover in ACD may occur via several mechanisms. Decreased transferrin receptors in the serum[14] and on erythroblasts[15] have been found in patients with ACD. Other investigators have suggested that increased release of lactoferrin from neutrophils[16] or increased synthesis of apoferritin[17] leads to a pool of iron trapped in storage form, unavailable for hemoglobin synthesis. More recently, hepcidin, originally characterized as a small, circulating antimicrobial, has been implicated in ACD. Hepcidin binds, internalizes, and degrades the iron export channel ferroportin, thus blocking iron release from macrophages, hepatocytes, and the duodenum and leading to a decrease in available iron.[9,18,19] Overexpression of hepcidin leads to a fatal anemia in mice, with a decrease in iron absorption and an increase in reticuloendothelial stores of iron.[20] Hepcidin is increased in inflammatory conditions in mice (see Biology and Molecular Aspects later)[21] and is elevated in a variety of diseases associated with ACD. Together, these data suggest that hepcidin is a major mediator for many of the iron changes seen in ACD.

In addition to a decrease in an important hemoglobin precursor (i.e., iron), a direct inhibition of hematopoiesis and a relative deficiency of erythropoietin are found in ACD. Inhibition of hematopoiesis found in ACD is thought to be caused by soluble factors present in the perturbed bone marrow microenvironment (see Biology and Molecular Aspects later). Studies have shown that removal of bone marrow–adherent cells (mostly macrophages and monocytes) from patients with ACD leads to increased erythroid colony formation. This process can be reversed by coculture of ACD-adherent cells but not by adherent cells from control marrow.[22] In a study of patients with rheumatoid arthritis with ACD, the numbers of erythroid progenitors in control and in anemic patients were similar (not accounting for the difference in anemia between the two groups). Serum from patients with rheumatoid arthritis with anemia produced decreased burst-forming unit-erythroid (BFU-E) proliferation, whereas serum from nonanemic arthritic patients did not.[23] Peripheral blood mononuclear cells from patients with rheumatoid arthritis also suppress BFU-E growth.[24]

Most of the supporting data for direct inhibition in hematopoiesis are derived from in vitro studies. Data from more clinically relevant studies have clearly documented a *relative* deficiency of erythropoietin in many chronic diseases associated with anemia. Although serum

Relative deficiency of erythropoietin

erythropoietin levels may be increased, they are not as elevated as they should be for the degree of anemia present. In a study of 81 patients with solid tumors who exhibited laboratory data compatible with ACD and who did not have marrow involvement by tumor, erythropoietin levels were higher than in control subjects without anemia, but they were only half the values typical of subjects with similar hematocrits caused by iron deficiency. The normal inverse relationship between hemoglobin and erythropoietin levels also was not seen.[25] In 41 anemic patients with rheumatoid arthritis, 14 of whom had plentiful iron on bone marrow aspirate, serum erythropoietin levels for all rheumatoid patients were lower than for those with simple iron-deficiency anemia and comparable hemoglobin levels.[26] Serum erythropoietin levels have been shown to be inappropriately low in human immunodeficiency virus (HIV)-positive patients with normochromic normocytic anemia[27] and in lung transplant recipients.[28]

Patients with diabetes with anemia, normal renal function, and lower-than-expected erythropoietin levels have been reported. This condition is hypothesized to be caused by diabetic neuropathy,[29] although there also may be a direct role of insulin on stem cells.[30] Up to 40% of patients with chronic liver disease are anemic. Although this anemia is clearly multifactorial, some studies have found a blunted erythropoietin response to anemia in patients with cirrhosis.[31] However, at least one study of veterans with anemia and alcoholic liver disease found a serum erythropoietin level appropriate for the degree of anemia.[32] Of note, the observation that hepcidin synthesis may be altered in liver disease may provide further insight into ACD in this setting.[33]

BIOLOGY AND MOLECULAR ASPECTS

The role of inflammatory cytokines in many of the underlying diseases associated with ACD has suggested a mechanistic link for much of the pathophysiology of anemia, including decreased erythrocyte survival, decreased access to available iron through upregulation of hepcidin and other mechanisms, direct inhibition of hematopoietic progenitor growth, and inadequate erythropoietin response to anemia.

Increased serum levels of cytokines, particularly interleukin (IL)-1, IL-6, IL-10, tumor necrosis factor (TNF), interferon (IFN)-α, and IFN-β, have been observed in many inflammatory diseases, including acquired immunodeficiency syndrome (AIDS), hepatitis C, tuberculosis, bacterial and fungal infection, rheumatoid arthritis, inflammatory bowel diseases, and both solid and hematologic malignancies.[34–36] Erythrocytes infected with various strains of malaria or with peptides of *Plasmodium falciparum* stimulate macrophages to secrete TNF. Elevated levels of several cytokines have been found in patients with malarial infections.[37] TNF-α synthesis is increased in mucosal T cells in patients with Crohn disease[38] and in blood mononuclear cells from patients with rheumatoid arthritis.[39] High levels of inflammatory cytokines may be concentrated in the bone marrow milieu. Bone marrow of patients with rheumatoid arthritis has increased levels of IL-6 and TNF-α.[40] Bone marrow stromal cells in patients with giant cell arteritis may produce less stem cell factor and granulocyte-macrophage colony-stimulating factor than do controls.[39]

The fact that cytokines are thought to play such an important role in many of the diseases associated with anemia and that levels of many of these cytokines often correlate with the degree of anemia suggests an association between inflammatory cytokines and anemia. Indeed, serum TNF-α levels correlate with both disease activity and the degree of anemia in rheumatoid arthritis.[41] Trials of cytokine antagonists in inflammatory diseases have shown them to improve anemia.[42,43] Many molecular mechanisms by which cytokines directly or indirectly affect hematopoiesis have been described.

Cytokine-Induced Decreases in Red Cell Survival

Several studies suggest a role for decreased erythrocyte survival in the pathogenesis of ACD. Early in vivo and in vitro experiments suggested that fever itself can induce rheologic changes in erythrocytes within a few days, leading to increased destruction and up to 15% decline in red cell mass.[44] Later studies suggested that cytokines, the cause of fever in many of the diseases associated with ACD, also may alter red cell kinetics. For example, rats receiving chronic intraperitoneal injections of IL-1 and TNF showed a twofold decline in ^{59}Fe radioactivity, suggesting decreased erythrocyte survival. This effect has been postulated to involve cytokine-induced macrophage and reticuloendothelial system activation.[10]

Cytokine-Induced Abnormalities in Iron Metabolism

Many of the cytokines implicated in ACD appear to have effects on iron metabolism. Nude mice inoculated with Chinese hamster ovary cells that had been engineered to secrete TNF-α show an almost 60% decline in serum iron levels after 3 weeks while maintaining normal bone marrow stores of iron.[45] Rats injected with IL-1 or TNF experienced a 40% drop in serum iron levels; TNF also caused a significant decrease in iron incorporation into erythrocytes.[10] These findings are consistent with the observation that iron reuse is defective in ACD.[12] TNF has been shown to increase radiolabeled iron uptake by peritoneal macrophages without an increase in iron release,[46,47] suggesting that macrophage sequestration of iron is cytokine induced. In clinical trials, IL-10 led to anemia in patients with Crohn disease and to an increase in ferritin levels, decreasing iron availability to red blood cell precursors.[35]

Molecular evidence suggests a direct cytokine effect on iron metabolism. Even though IL-1β has no effect on ferritin transcription, it increases the synthesis of ferritin in human hepatoma cells by an increase in mRNA translation.[48,49] Increased translation depends on a 5′ untranslated region, distinct from the well-known iron responsive element but similar to a 38-nucleotide consensus sequence found in other IL-sensitive acute-phase reactants.[49] The increase in ferritin synthesis occurs without increased cellular transferrin receptor transcription or expression and involves no new iron influx.[48] IL-1 could lead directly to the creation of an intracellular iron pool that is not available for hemoglobin synthesis. IL-10 also appears to increase ferritin translation.[35]

More recent data demonstrate that inflammatory cytokines upregulate hepcidin, which, as previously noted, may mediate many of the iron changes seen in ACD. IL-1α, IL-1β, and other inflammatory cytokines have been demonstrated to upregulate hepcidin,[50,51] but the best described inducer, and perhaps the only direct inducer, of hepcidin is IL-6.[52] The transcription factors STAT3[53] and SMAD4,[54] both of which are upregulated by IL-6 and other inflammatory cytokines, have been found to activate the hepcidin promoter and induce hepcidin mRNA. In humans injected with lipopolysaccharide, IL-6 increases dramatically after 3 hours, followed by an increase in urinary hepcidin by 6 hours.[55] Direct administration of IL-6 to humans also leads to increased urinary hepcidin and decreased serum iron.[19] In patients with ACD, increased pro-hepcidin serum concentrations are associated with decreased expression of ferroportin in circulating monocytes along with increased ferritin accumulation in these cells.[56]

Cytokines Leading to Direct Inhibition of Hematopoiesis

Although data demonstrate that cytokines, including IL-1, IFN, and TNF, can have a direct inhibitory effect on hematopoiesis, almost all

of the evidence supporting such a role for cytokines is derived from in vitro experiments, and the clinical relevance is unclear. The role of IL-6 in the direct inhibition of hematopoiesis is controversial. Exogenous IL-6 given to monkeys causes a dose-dependent, mild, short-lived anemia within 4 weeks.[57] Some studies have shown that IL-6 has direct inhibitory effects on stem cells.[58] However, other studies have demonstrated that IL-6, which is elevated in rheumatoid arthritis, has no direct effect on bone marrow hematopoiesis.[59] Juvenile-onset chronic arthritis is associated with increased IL-6 levels and anemia, but this anemia is one of iron deficiency.[60] IL-6 has been shown to cause bleeding in the rat intestinal wall.[40] As discussed, several cytokines, including IL-6, can upregulate hepcidin. In vitro studies have demonstrated that colony-forming unit-erythroid (CFU-E) formation is diminished at low erythropoietin conditions when hepcidin was added. Some evidence suggests that this effect may be due to proapoptotic functions of hepcidin.[8]

There is much better evidence for the role of IFN in the direct inhibition of erythropoiesis. IFN-γ can inhibit highly purified CFU-E from mice spleens in a dose-dependent manner.[61–63] Marrow stromal cells retrovirally engineered to secrete IFN-γ inhibit hematopoiesis in long-term bone marrow cultures by blocking cell cycle progression and inducing apoptosis in CD34 cells to a much greater degree than exogenous IFN.[64] IFN inhibition can be reversed by exogenous addition of murine IFN-γ receptors.[61] Inhibition by IFN-γ can be reversed in a dose-dependent manner by erythropoietin, a phenomenon also seen in ACD,[61,65,66] and partial reversal can be achieved by stem cell factor.[67] The concentration of IFN-γ required to suppress BFU-E was less than that needed to suppress CFU-E, suggesting the suppression occurs at the earlier stages of erythroid development.[63] Like IFN-γ, IFN-β appears to act directly on CFU-E, and inhibition does not require accessory T cells or adherent bone marrow cells.[61,68] Inhibition by IFN-α appears to work indirectly. Inhibition by IFN-α or IFN-β is not reversed by erythropoietin.[68]

TNF serum levels correlate with the degree of anemia in ACD. Erythroid growth is increased in the bone marrow of control and chronically anemic patients by monoclonal antibodies against TNF.[41] Transplantation of a Chinese hamster ovary cell line transfected with the human TNF gene led to anemia in nude mice within 3 weeks, with a significant decrease in BFU-E and CFU-E.[45] Exogenous TNF decreases erythroid colony formation.[41] For example, the inhibition of BFU-E growth sustained by normal bone marrow cultured in the presence of peripheral blood mononuclear cells of patients with rheumatoid arthritis can be reversed by antibodies to TNF-α.[24] However, evidence indicates that the effect of TNF on hematopoiesis is indirect, mediated by the local release of other cytokines, including IFN from accessory cells.[66] The inhibitory effect of TNF on CFU-E was completely abated by neutralizing antibodies against IFN-β but not by antibodies to IFN-γ or IL-1.[34] The effects of IL-1 also appear to be indirect. Growth of purified CFU-E is inhibited by recombinant IL-1 only in the presence of adherent T lymphocytes. The inhibition can be reversed by antibodies to IFN-γ, suggesting that IL-1 leads to lymphocyte secretion of IFN.[68]

Cytokines Leading to Decreased Erythropoietin Secretion

Cytokines have been implicated in the blunted, inappropriately low erythropoietin levels seen in ACD. In the erythropoietin-producing human hepatoma cell line HepG2 grown in diffusion-limited oxygen conditions, IL-1α, IL-1β, and TNF-α significantly lowered erythropoietin production. IL-1β also inhibited erythropoietin production in perfused rat kidneys. These effects were not accompanied by alterations in α-fetoprotein, showing that the effect was specific and not secondary to a generalized inhibitory growth effect.[69] Using another hepatoma cell line, Hep3B, hypoxia-driven erythropoietin production was inhibited with IL-1α, IL-1β, and TNF-α (with IL-1β being the most potent inhibitor) in a dose-dependent, additive manner.[58] Other soluble factors, in addition to cytokines, may play a role in directly inhibiting erythropoiesis in ACD. Animal models have suggested that vascular endothelial growth factor, which is commonly elevated in cancer, wounds, and ischemia, may act as a negative regulator of erythropoietin synthesis,[70] thus suggesting a potential link between diverse systemic illnesses and erythropoietin deficiency.

Perhaps one of the strongest arguments for a role of erythropoietin in causing ACD is that exogenous erythropoietin can at least partially reverse ACD. However, supraphysiologic levels of erythropoietin may simply overcome a direct inhibition of erythropoiesis (see Treatment later). Inhibition by IFN-γ can be reversed by erythropoietin.[65] Moreover, the capacity of monocytes from patients with inflammatory bowel disease to secrete TNF predicts therapeutic response to exogenous erythropoietin.[71]

DIAGNOSIS

Because ACD is a multifactorial disease and is seen in many clinical settings, an unequivocal diagnosis often is difficult. Many chronic illnesses are associated with other factors leading to anemia, including iron and nutritional deficiency, bleeding, hemolysis, renal failure with absolute erythropoietin deficiency, and marrow fibrosis or infiltration. Up to 70% of the anemia associated with rheumatoid arthritis may be multifactorial.[72] From 25% to 70% of patients with rheumatoid arthritis whose iron study results are consistent with ACD also are iron deficient.[73,74] Of 184 patients admitted to intensive care units, most anemic patients were found to have erythropoietin levels and iron study results consistent with ACD; however, 13% also had iron, folate, or B_{12} deficiency.[75] The role of frequent phlebotomy in hospitalized patients should be fully appreciated[76] (see box on Diagnosis of Anemia of Chronic Diseases).

ACD often is not diagnosed, although it plays an important role in anemia. For example, the anemia of renal failure traditionally has not been thought of as an ACD but rather as an anemia of absolute erythropoietin deficiency. However, efficient dialysis leads to an improved response to erythropoietin,[77,78] which suggests that other factors, perhaps including cytokines, play a role. Anemic hemodialysis patients may have occult infections of nonfunctioning arteriovenous grafts with markers of inflammation and erythropoietin resistance; removal of these grafts may correct the anemia.[79] Fifty percent of adults with chronic idiopathic neutropenia have an anemia consistent with ACD.[80] Remarkably, multiply traumatized patients have increased inflammatory cytokines and inappropriately low erythropoietin levels consistent with ACD.[5] In patients with congestive heart failure, TNF is elevated, cytokines levels are proportional

Diagnosis of Anemia of Chronic Diseases

The diagnosis of ACD is primarily one of exclusion and often is difficult. Various laboratory tests have been suggested as helpful, but few have proven value in the general population. However, because ACD occurs in too large a variety of acute and chronic illnesses. The best way to diagnose ACD, at least provisionally, is to document an anemia of underproduction (i.e., low reticulocyte index) with low serum iron and transferrin levels and elevated serum ferritin level in the setting of a systemic, usually inflammatory, illness. A thorough search may be necessary to document the precise underlying illness.

Other causes of anemia, such as hemolysis, nutritional deficiency, or sequestration, should be ruled out, and a component of iron deficiency should be strongly considered in a patient with systemic inflammation and a low or "normal" serum ferritin concentration. These other causes of anemia often accompany ACD. Bone marrow examination usually is not helpful but may be necessary to rule out malignancy (including a myelodysplastic syndrome), infection, or iron deficiency.

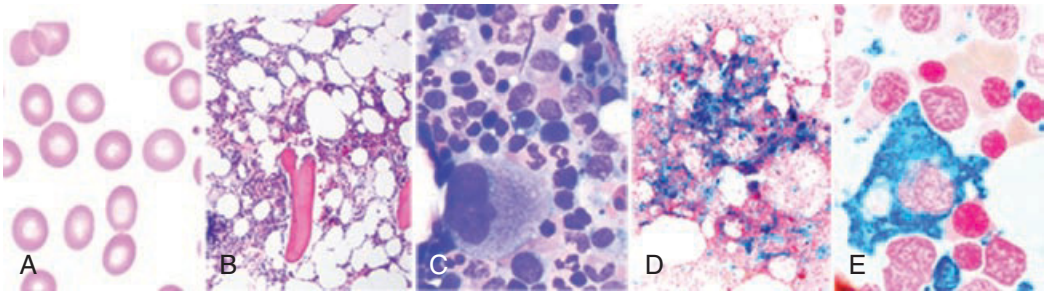

Figure 37–1 Anemia of chronic disease. **A**, Peripheral blood typically exhibits a normochromic, normocytic anemia. **B, C,** Bone marrow examination is sometimes performed to rule out other causes of anemia. Typically the marrow is morphologically normal. **D, E,** Prussian blue iron stain shows increased iron stores with increased histiocytic iron but decreased sideroblastic iron.

to the severity of anemia, and erythropoietin level is not elevated in proportion to the degree of anemia,[6,81,82] all consistent with ACD playing a role in the anemia commonly found in patients with heart failure.

The clinical setting in which the anemia is found helps with the diagnosis; however, in 30% of cases, no chronic illness can be identified. Acute illnesses can lead to anemia.[2] Some authorities argue that a normocytic, normochromic anemia may occur in otherwise healthy people; normal elderly people can have mild anemia.[83] One major problem with prevalence studies is that ACD is primarily a diagnosis of exclusion. This often necessitate evaluation of the bone marrow to ensure adequate iron stores, rule out infiltration by tumor, fibrosis, or infections, and exclude a myelodysplastic syndrome (Fig. 37–1). It should be noted, however, in a study of mostly older patients with an idiopathic mild anemia (10 ± 0.6 g/dL), a bone marrow aspirate with biopsy was found to add little to an extensive negative serologic workup and physical examination.[77]

The diagnosis of ACD usually is made on the basis of elevated marrow iron stores (usually assessed by serum ferritin) and low serum iron level, transferrin level, and total iron-binding capacity. Because ACD is a hypoproliferative and sometimes microcytic anemia, the differential diagnosis often includes iron deficiency. A low serum ferritin level associated with anemia suggests iron deficiency. A normal or elevated ferritin level is more difficult to interpret because ferritin is an acute-phase reactant. Some investigators argue that a ferritin level higher than 50 ng/mL excludes any component of iron deficiency, even in inflammatory states.[84] Nomograms correcting ferritin for the degree of inflammation present have been published.[85] Other researchers have shown that, in acute inflammation, serum ferritin levels greater than 3500 ng/mL can exist with absent bone marrow iron stores tested by aspirate.[86] Most investigators maintain that serum iron studies cannot predictably rule out iron deficiency.[87]

The concentrations of erythroblast and serum transferrin receptors are elevated in iron-deficiency anemia. Several studies have shown that the numbers of transferrin receptors on erythroblasts are lower in rheumatoid arthritis patients with ACD than in patients with iron-deficiency anemia,[15] and some may be decreased even below those without inflammatory conditions.[88] Although erythroblast transferrin studies are primarily a research tool, several studies have shown that the levels of serum transferrin receptors in rheumatoid arthritis and ACD are normal or slighter higher than normal, although generally lower than those with iron-deficiency anemia.[89,90] Patients with rheumatoid arthritis and elevated concentrations of serum transferrin receptors have responded to iron therapy.[90]

Several algorithms have been generated to diagnose or exclude ACD. In 120 anemic patients with inflammatory, infectious, or malignant diseases in whom bone marrow aspirates were obtained for assessment of iron stores, the serum ferritin level was significantly lower in patients who were iron deficient but still was elevated (63.7 vs 212 ng/mL). The combination of a serum ferritin level less than 70 ng/mL and a red cell ferritin level of 4 ng or less per erythrocyte had specificity of 0.97 and positive predictive value of 0.82, although these values were not validated in a prospective study.[74] A three-step algorithm has been derived for patients with rheumatoid arthritis and serologic evidence of ACD. Male patients with hemoglobin levels less than 11.0 g/dL and serum ferritin concentration less than 40 μg/L have iron deficiency, and those with a mean corpuscular volume greater than 85 fL or an iron saturation level greater than 7% have ACD. This formula led to a correct diagnosis in 89% of patients, but this finding was not independently validated.[73] Combining assessment of serum ferritin and plasma transferrin receptor concentration with the erythrocyte sedimentation rate has been suggested as an algorithm for differentiating iron deficiency and ACD in elderly women.[91] However, the specificity for any individual test and even for complex algorithms is relatively poor. Although hepcidin currently is measured in the urine, studies have demonstrated that urinary hepcidin levels mirror hepatic hepcidin mRNA concentrations in patients with a variety of inflammatory diseases.[92] The finding that hepcidin levels are elevated in ACD and parallel both IL-6 and ferritin levels[93] may make the assessment of hepcidin levels helpful in diagnosing ACD, although the sensitivity, specificity, and clinical utility of this assay in a wide patient population is unknown (see Summary and Future Directions later). Therefore, the diagnosis of ACD remains a clinical one.

TREATMENT

The anemia associated with chronic illness usually is mild. Correction often is unnecessary, especially if as many contributing factors as possible can be reversed. There may be a teleologic reason for ACD; the fever associated with infections has been shown to inhibit bacterial growth, and decreased iron concentrations (as seen in ACD) act synergistically with pyrexia to inhibit bacterial growth.[94] The attempt by hosts to withhold iron from invaders, called *nutritional immunity,* has been postulated to be an adaptive factor of ACD.[95] However, ACD can be severe, and almost by definition patients with ACD have comorbidities. Optimizing any reversible process, including hemoglobin and oxygen content and delivery, may have a dramatic beneficial effect. Unfortunately, few randomized, well-controlled, blinded studies are available to support anecdotal observations (see box on Treatment of Anemia of Chronic Diseases).

Optimal treatment of ACD is correction of the underlying disease process, if one can be clearly documented. ACD mirrors laboratory[59,72] and clinical[7] correlates of disease activity and duration of disease in rheumatoid arthritis. HIV patients receiving highly active antiretroviral therapy have a mean increase in hemoglobin concentration of more than 3 g/L compared with a decrease in hemoglobin concentration in patients not receiving these medications.[96] Treatment of underlying inflammatory diseases using cytokine antagonists has often led to improvements in anemia.[42,43] Definitive treatment of chronic diseases usually is difficult. Iron chelators such as deferoxamine have been shown in some animal studies to have mild effects on ACD, perhaps by decreasing free radicals and inflammation, but other studies have not duplicated this finding.[97,98]

Treatment of Anemia of Chronic Diseases

Treating ACD often is unnecessary if the patient is asymptomatic. However, the anemia may be severe, and quality of life may be greatly improved with treatment, even in patients who believed they felt well with their anemia. A trial of therapy may be indicated.

The first priority should be to correct any reversible contributors to the anemia (e.g., iron deficiency, absolute erythropoietin deficiency). Because the extent of ACD mirrors the activity of the underlying disease, all efforts should be made to treat the underlying disease. Although transfusion is the fastest way to reverse ACD, many studies have shown responses to erythropoietin. High doses of erythropoietin may be necessary. A starting dose of 20,000 to 40,000 units given subcutaneously each week can be initiated. If a hemoglobin response is seen, the dose can be decreased and the duration prolonged to titrate the hemoglobin to an asymptomatic level. Not only does this minimize expense and the number of injections needed, but it also may minimize any potential detriments of high hematocrits and/or high levels of exogenous erythropoietin. This response may take 4 to 8 weeks and should be monitored with objective symptomatic improvements (e.g., exercise tolerance). Although oral iron may not be absorbed or may be poorly tolerated and intravenous iron may be inconvenient and potentially dangerous, iron administration should be considered in poor responders, even in individuals with normal iron stores.

If the anemia is symptomatic or severe, treatment of the anemia itself may be indicated. Transfusion therapy may be the most common form of treatment of symptomatic ACD. Unfortunately, red blood cell transfusions are costly, have the potential detriments of infection, alloimmunization, and graft-versus-host disease, and are a limited resource. Serum levels of erythropoietin, although often elevated in ACD, are not elevated appropriately for the degree of anemia. Moreover, inhibition of hematopoiesis by cytokines is reversed in model systems by erythropoietin.[65] These observations have led to several successful trials of recombinant erythropoietin in the treatment of ACD. This strategy may be more cost effective than transfusion but erythropoietin must also be used cautiously . A relatively small, multicenter, placebo-controlled trial monitored the effects of erythropoietin in patients with rheumatoid arthritis and laboratory data consistent with ACD. The results showed a dose-dependent response to 50 to 150 U/kg of erythropoietin three times each week; 11 of 17 patients had a response rate of almost six hematocrit points.[99] Anemic patients with AIDS who were treated with recombinant erythropoietin had a significantly decreased transfusion requirement, especially if their endogenous erythropoietin level was less than 500 IU/L; however, all of these patients were also receiving zidovudine, a potential bone marrow suppressant.[100] Recombinant erythropoietin raised the hemoglobin level in patients with a variety of nonhematologic malignancies, including squamous cell cancer, breast cancer, and colon cancer.[101–104] Large trials enrolling patients undergoing chemotherapy have suggested that once-weekly injections of recombinant erythropoietin are as effective as thrice-weekly injections.[105] Injections of long-lasting erythropoietin analogues have been effective in treating the anemia that occurs with chemotherapy administration[106] and in animal models of ACD[107] and can be used to decrease the frequency of administration.

Responses by patients with ACD to erythropoietin range from 40% to 80% and can take up to 4 weeks.[98,99,108] Studies suggest that if no effect is seen by 3 months, further treatment likely will not be effective.[109] The response of ACD to erythropoietin is predicted by a low pretreatment erythropoietin level.[101,104] Although baseline duration of malignant disease, previous and current cancer treatment, bone marrow involvement, and type of tumor (hematologic vs solid tumor) were found to be negative predictors of response to erythropoietin treatment, only the absolute hemoglobin value, serum erythropoietin level, and ferritin level were found to be independent predictors in a multivariate analysis of 80 patients with chronic anemia of cancer.[109] Median survival of patients who responded was 12.6 months, compared with 4.3 months for nonresponders. This finding does not necessarily causally link correction of anemia to survival, because ability to respond, like baseline hematocrits, may be a marker for improved survival.[3] If after 2 weeks the serum erythropoietin level is higher than 100 mU/mL and the hemoglobin concentration has not increased by at least 0.5 g/dL or if after 2 weeks of treatment the serum ferritin level is higher than 400 ng/mL, a response is very unlikely.[109]

Functional iron deficiency is one possible reason for a failed response to erythropoietin.[110] It may be caused by a baseline iron deficiency, depletion of iron stores during hematopoiesis, or inability to mobilize stored iron; the latter is a hallmark of ACD. Intravenous iron decreased erythropoietin requirements, even compared with oral iron, in several cohorts, including hemodialysis patients[111] and those with inflammatory bowel disease.[112] Intravenous iron improves erythropoietin responses and is a cost-effective measure in dialysis patients, even in those with elevated ferritin levels.[113]

Although erythropoietin administration often leads to an increased hemoglobin concentration, this does not a priori ensure an improvement in morbidity, mortality, or quality of life. Reversal of anemia with erythropoietin in randomized and nonrandomized, open-label studies has been correlated with improvements in functional status, pain, nausea, anxiety, level of activity, and fatigue in large cohorts of patients receiving chemotherapy and smaller studies of cancer patients not undergoing chemotherapy.[102,104,105,114] However, these studies have limitations.[115] A thorough examination of the literature led to the suggestion that in cancer patients receiving chemotherapy, the hemoglobin level should be maintained at 12 g/L, and further rigorous studies on the impact on quality of life are necessary.[115] Many studies have shown that pretreatment anemia is a poor prognostic factor for a wide variety of patients with solid tumors undergoing chemotherapy and irradiation, it is unclear whether correction of this anemia can improve survival.[3]

Most studies and consensus statements on the efficacy of correcting anemia have derived from cancer patients receiving chemotherapy. However, the acute anemia and symptoms associated with myelosuppressive chemotherapy have limited similarities to ACD. Small and preliminary studies of cancer patients with ACD who were not receiving cytotoxic therapy suggest that performance and quality of life may improve with increased hemoglobin concentrations.[104] In a large study of critically ill patients, no change in a variety of outcomes were observed when patients were transfused when the hemoglobin level was 10 g/L, as opposed to a control group in whom the transfusion trigger was a hemoglobin level of 7 g/L.[116] Although administration of erythropoietin to critically ill patients decreased the number of transfusions, no change in clinical outcome was observed.[117] Moreover, increasing the hematocrit to 42% in a large number of hemodialysis patients with cardiac disease led to an increased number of deaths, and the number of cardiac events was increased in patients with chronic renal disease treated with erythropoietin with a goal of complete normalization of hemoglobin (12.0–15.0 g/dL) as opposed to partial normalization (10.5–11.5 g/dL).[118,119] Although low pretreatment hemoglobin levels have been demonstrated repeatedly to be a predictor of good response to chemotherapy and radiation,[120] two studies have demonstrated that patients with breast cancer or head and neck cancer treated with erythropoietin have increased disease progression and worse survival than placebo-treated patients.[121,122] This finding may reflect a direct antiapoptotic effect of erythropoietin on tumors.[123] Not all studies have demonstrated increased risks associated with aggressive erythropoietin treatment in patients with kidney disease or cancer.[124,125] However, based on these studies and interim analyses of several additional studies, in early 2007 the United States Food and Drug Administration warned that erythropoietin should be given only in the lowest possible doses necessary to avoid blood transfusions.

In summary, although treatment of ACD often increases the hemoglobin level and may improve quality of life and function, data from formal, well-controlled studies are pending, especially for patients not receiving cytotoxic chemotherapy. In particular, high doses of erythropoietin and/or high hemoglobin levels may be associated with increased risk for cardiac events, thromboses, and tumor progression.

SUMMARY AND FUTURE DIRECTIONS

Anemia is common in many chronic inflammatory, infectious, and malignant conditions, and often it is multifactorial. Anemia is exacerbated by inflammatory cytokines, which are thought to be the most important causative factors in ACD. ACD is difficult to diagnose but usually can be strongly suspected based on clinical findings, elimination of other causes of anemia, low serum iron and transferrin levels, and elevated ferritin level.

Cytokines such as IFN and TNF have wide-ranging effects, including both direct and indirect inhibition of hematopoiesis. Direct inhibition of hematopoiesis is mediated by both a relative decrease in erythropoietin as well as a decrease in iron available for hemoglobin synthesis. Many of the abnormalities of iron metabolism in ACD are caused by cytokine-induced increases in hepcidin. An understanding of the role of hepcidin in ACD may lead to improvements in both the diagnosis and treatment of ACD. Additional studies are required to delineate better the role of cytokine antagonists in treating ACD and its underlying causes. Controlled studies, clearly revealing the impact of correction of anemia on quality of life, medical outcomes, and survival of patients with ACD, particularly in those not undergoing chemotherapy, could provide insight into the role of hypoxia on tumors and other disease.

CHAPTER 38

HEME BIOSYNTHESIS AND ITS DISORDERS: Porphyrias and Sideroblastic Anemias

James S. Wiley and Michael R. Moore

The porphyrias and the sideroblastic anemias are metabolic disorders that involve defects in heme biosynthesis. Most forms of porphyria are inherited in a Mendelian autosomal dominant pattern, but some types are recessive and others are acquired through exposure to porphyrinogenic drugs and chemicals. A linked group of diseases, the porphyrinurias, are not porphyrias but have in common alterations of heme biosynthesis. Porphyrins are tetrapyrroles, which are ubiquitous in nature and exhibit characteristic red fluorescence on exposure to ultraviolet light. The iron-porphyrin complex, called *heme*, is central to all biologic oxidation reactions. In plants, the porphyrin molecule is combined with magnesium to form chlorophyll. Porphyrin biosynthesis is one of the most essential biochemical processes in most life forms.

In humans, mutations affecting the first enzyme of the heme biosynthetic pathway produce sideroblastic anemia. Inborn errors that occur at subsequent sites in this pathway usually result in metabolic disorders known as the *porphyrias* (Fig. 38–1). Historical analysis of the potential presence of acute porphyria in the British Royal family has been published,[1–3] as well as a study of the family of Vincent van Gogh.[4]

HEME BIOSYNTHESIS

Biosynthetic Pathways

Heme biosynthesis is an essential pathway and occurs in all metabolically active cells that contain mitochondria. It is most active in erythropoietic tissue, where it is required for hemoglobin synthesis, and in hepatic tissue, where the heme forms the basis of various heme-containing enzymes such as the cytochromes P450, catalase, cytochrome oxidase, and tryptophan pyrrolase. The synthetic pathway starts with the condensation of glycine and succinyl CoA to form 5-aminolevulinate (ALA) under the control of the mitochondrial enzyme ALA synthase (ALAS). This enzyme requires pyridoxal phosphate as a cofactor. A series of enzymes then controls the conversion of ALA first to the monopyrrole porphobilinogen (PBG) and then to the various porphyrins. Iron is inserted into protoporphyrin by the enzyme ferrochelatase to form heme (see Fig. 38–1). During the past 10 years, cDNA clones have been obtained for all of the enzymes of heme biosynthesis, and the structures of the corresponding genes have been determined. These advances are certain to improve understanding of the pathogenesis of the porphyrias and methods for identification of carriers. The enzymes of the biosynthetic pathway have all been mapped to specific chromosomes (Table 38–1). Heme synthesis and its disorders have been the subject of reviews[5–9] and included in a volume covering the history and biological diversity of the tetrapyrroles.[10]

Control of Heme Biosynthesis

The overproduction of porphyrins and their precursors in the different porphyrias is mainly hepatic or erythropoietic in origin. In the acute porphyrias and in porphyria cutanea tarda, the liver is the main source of overproduction; in congenital porphyria, the marrow is the main source; and in erythropoietic protoporphyria, porphyrins are overproduced by the liver and marrow.

Control of hepatic heme biosynthesis is regulated by the rate of the initial enzymatic step, ALAS (now designated ALAS1) which is under negative-feedback control by heme. This occurs by more than one mechanism. Heme represses transcription of the *ALAS1* gene and increases the rate of degradation of the mRNA (Fig. 38–2A). At the posttranslational level, heme blocks the translocation of pre-ALAS1 into the mitochondrion.[11] In the mitochondrion, the molecular mass of ALAS is smaller than that of the cytosolic pre-ALAS[11] because of the removal of the mitochondrial targeting sequence.

The erythroid bone marrow is the major heme-forming tissue in the body, producing 85% of the daily heme requirement. Heme synthesis in erythroid cells varies from that in hepatocytes; it is linked to tissue differentiation, and the half-life of the same end product of the two is quite different. Heme complexed with globin is preserved in circulating red blood cells for approximately 120 days, whereas heme produced in liver for cytochromes and enzymes, such as catalase, is subject to much more rapid turnover, measurable in hours. Regulation in the liver is exquisitely sensitive to fluctuations in intracellular heme levels[12] and responds rapidly to the requirements for synthesis as described in Fig. 38–2A. However, heme synthesis in the bone marrow shows a more leisurely response. This fundamental difference is explained by the finding of two different tissue-specific isoenzymes and two different cDNAs for human liver or "housekeeping" ALAS (ALAS1) and an erythroid ALAS (eALAS or ALAS2), which is expressed exclusively in erythroid cells.[13] The gene for ALAS2 has been mapped to the X chromosome and that for the hepatic enzyme to chromosome 3.[13] The *ALAS2* gene has 11 exons; exons 5 to 11 encode the catalytic domain of the enzyme and include a lysine residue that forms a Schiff base with the pyridoxal phosphate cofactor. Exon 1 contributes to the 5′-untranslated region whose structure allows iron to regulate ALAS2 mRNA translation, whereas exons 1 and 2 contribute the sequence that targets the enzyme to the mitochondria and is cleaved after import. Succinyl CoA synthetase associates specifically with ALAS2 within the mitochondrion, which helps promote the first step of heme synthesis.[14]

Enzyme levels of ubiquitous and erythroid isoenzymes of ALAS are controlled by different mechanisms. Ubiquitous ALAS1 levels in liver are regulated by negative feedback by heme that inhibits gene transcription and import of pre-ALAS1 (see Fig. 38–2A). More recently ALAS-1 has been shown to be upregulated by PPAR γ–coactivator 1α which regulates mitochondrial biogenesis and oxidative metabolism. Transcription of this coactivator 1α is controlled by glucose availability. Coactivator 1α production increases when glucose levels are low leading to increased levels of ALAS-1 and heme. These conditions are conducive to an acute attack of porphyria. However the relative contribution of heme and PGC-1α in regulating ALAS-1 expression remains to be resolved.[15,16] In contrast, heme does not affect transcription of the *ALAS2* gene, which is under the control of erythroid-specific promoters such as GATA1, a globin transcription factor. Whether heme inhibits import of pre-ALAS2 into the mitochondrial matrix remains to be unequivocally established. Heme may possibly also prevent the accumulation of intracellular iron by controlling the acquisition of iron from transferrin (Fig. 38–2B). In addition to transport of iron from plasma to the cytosol by the transferrin receptor, a second transport step is required for mitochondrial uptake of iron. This step is fulfilled mitoferrin (mfrn), a 333 residue polypeptide recently cloned from zebrafish.[17] Levels of intracellular iron regulate the translation of ALAS2 mRNA. A specific

repressor protein interacts with an iron-responsive element in the 5′ untranslated region of the ALAS2 mRNA and prevents translation, and this repression is relieved by high iron levels.[12] Iron uptake by erythroid cells has a positive effect on the enzymatic step catalyzed by ALAS2 (see Fig. 38–2B). This effect ensures that protoporphyrin synthesis is coupled to iron availability.

A second rate-limiting step in the overall heme synthetic pathway lies at the level of porphobilinogen deaminase (PBGD), which has a low endogenous activity and is inhibited by protoporphyrinogen and coproporphyrinogen. There are also two forms of PBGD. The PBGD gene *(HMBS)* encodes two enzymes; the 10-kb-long gene with 15 exons has two overlapping transcription units. The upstream promoter works in all cell types and produces a protein with a molecular mass of 42 to 44 kd, whereas the downstream promoter is only active in erythroid cells and by differential splicing produces a smaller protein with a mass of 40 to 42 kd.[18]

Erythroid porphobilinogen deaminase (ePBGD) is stimulated by erythropoiesis in vitro and may play a regulatory role in heme biosynthesis during differentiation. Studies of the erythroid promoter for ePBGD have found that two major erythroid transcription factors, GATA1 and NFE2, may bind to sequences in the PBGD promoter.[19]

HMBS, the human PBGD gene, has attracted extensive investigation because of the practical importance of detecting carriers of the gene for acute intermittent porphyria.[20] Studies of the genetic locus of PBGD on chromosome 11 show great molecular heterogeneity,[21] as is also found in the parents of a homozygous case of acute intermittent porphyria.[22] This heterogeneity results in several phenotypic subtypes of the enzyme at the protein level. Most are cross-reacting immunologic material (CRIM)-negative subtypes, but some are CRIM-positive types.[23] There is a high interspecies conservation of structure of the enzyme. Most human mutations have been described on exons 10 and 12,[24] which is consistent with alteration of the binding sites for the dipyrromethane cofactor for the enzyme.[25] The three-domain structure of porphobilinogen deaminase has been defined by x-ray crystallography. The active site is located between domains 1 and 2. The dipyrromethane cofactor linked to cysteine protrudes from domain 3 into the mouth of the cleft. Flexible segments between domains 1 and 2 are thought to have a role in a hinge mechanism, facilitating conformational changes. Biochemical and x-ray crystallographic studies have shown that the enzyme from *Escherichia coli, Euglena gracilis,* rats, and humans has 12 conserved arginine residues in the cleft between the three protein domains. This structure fits well with the need to bind six PBG molecules each with two carboxyl groupings.

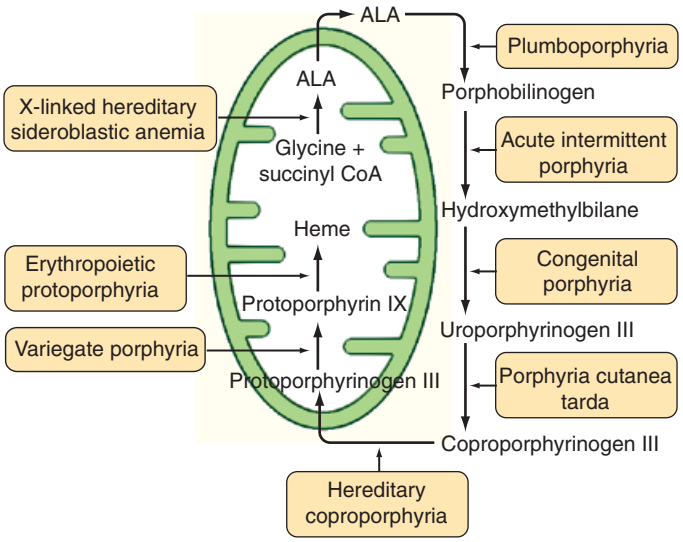

Figure 38–1 Pathway of heme biosynthesis in mammalian cells. The first step in the pathway is catalyzed by aminolevulinate synthase (ALAS) and occurs within the mitochondrion using pyridoxal 5′-phosphate as a cofactor. 5-Aminolevulinate (ALA) then leaves the mitochondrion and is converted by ALA dehydratase to give a monopyrrole, porphobilinogen. Four molecules of this compound are converted by porphobilinogen deaminase to a linear tetrapyrrole, hydroxymethylbilane. This molecule is then cyclized by uroporphyrinogen III synthase to uroporphyrinogen III, which is decarboxylated to coproporphyrinogen III. This molecule enters the mitochondrion and is oxidized in succession by coproporphyrinogen III oxidase and protoporphyrinogen III oxidase. The product is protoporphyrin IX, a substrate for ferrochelatase, which catalyzes the insertion of Fe^{2+} to form heme. The defective steps associated with specific porphyrias and X-linked hereditary sideroblastic anemias are shown.

PORPHYRIAS

Biologic and Molecular Aspects

The porphyrias are classified as acute or nonacute (cutaneous) according to their clinical and biochemical features (Table 38–2).

Table 38–1 Porphyrias: Clinical Involvement, Enzymatic Etiology, and Chromosomal Location

Porphyria (Synonym)	Acute Attack, Skin and Organ Involvement	Enzyme of Heme Biosynthesis Affected	Chromosome Location
—	—	Hepatic aminolevulinate synthase-1 (ALAS1)	3p21
X-linked sideroblastic anemia	Bone marrow	Erythroid ALA synthase (ALAS2)	Xp11.21
ALA dehydratase deficiency porphyria (plumboporphyria)	Acute liver	ALA dehydratase (porphobilinogen synthase)	9q34
Acute intermittent porphyria (intermittent acute porphyria)	Acute liver	Porphobilinogen deaminase (hydroxymethylbilane synthase)	11q24.1–q24.2
Congenital erythropoietic porphyria (Günther disease)	Skin, red cells, bone marrow	Uroporphyrinogen III synthase	10q25.2–q26.3
Porphyria cutanea tarda (symptomatic porphyria, cutaneous hepatic porphyria)	Skin, liver	Uroporphyrinogen decarboxylase	1p34
Hereditary coproporphyria	Acute skin, liver	Coproporphyrinogen oxidase	3q12
Variegate porphyria (porphyria variegata)	Acute skin, liver	Protoporphyrinogen oxidase	1q21–q23
Erythropoietic protoporphyria (erythrohepatic protoporphyria)	Skin red cells, liver	Ferrochelatase (heme synthase)	18q21.3

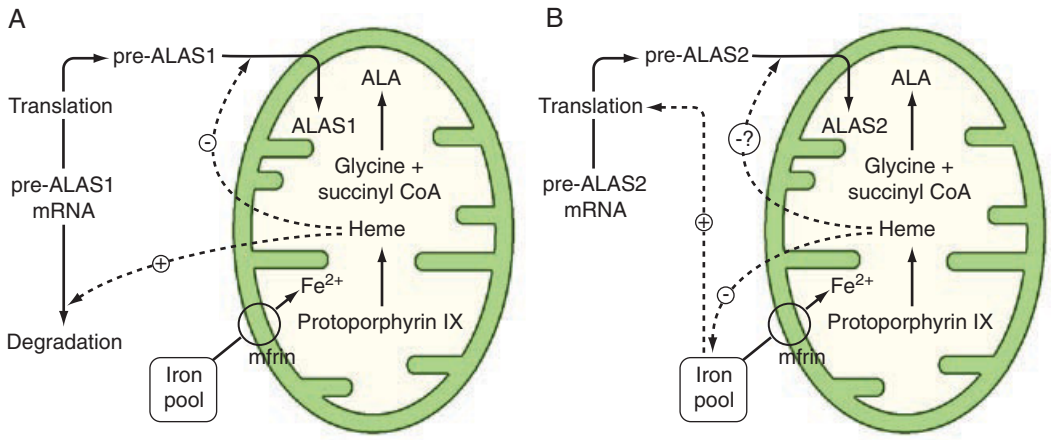

Figure 38–2 A, Control of heme synthesis in hepatic and other tissues. The rate of heme synthesis depends on the first and rate-limiting enzymatic step catalyzed by aminolevulinate synthase-1 (ALAS1). Heme represses transcription of the *ALAS1* gene, increases the rate of degradation of its mRNA, and blocks the translocation of the ALAS1 isoenzyme into the mitochondrion. **B,** Control of heme synthesis in erythroblasts. Cytosolic iron enhances the translation of mRNA of the pre-ALAS2 by inhibiting the interaction of a repressor protein with an iron-responsive element in the mRNA. The product of the last step, heme inhibits the uptake of iron from transferrin into the cytosol. Heme also may inhibit translocation of ALAS2 into the mitochondrion. The overall result is that the rate of heme synthesis is tightly linked to the availability of iron for the ferrochelatase reaction. Mfrn-mitoferrin transports Fe^{2+} into the mitochondrial matrix.

Table 38–2 Classification of Porphyrias

Classification	Disease	Biochemistry	Clinical Features
Acute porphyria	Acute intermittent porphyria	Increased ALA and PBG	Acute attack
	Variegate porphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	Hereditary coproporphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
Nonacute porphyria	Porphyria cutanea tarda	Increased porphyrin	Photosensitivity
	Erythropoietic protoporphyria	Increased porphyrin	Photosensitivity
	Congenital porphyria	Increased porphyrin	Photosensitivity
Porphyrinurias	Lead, alcohol, iron-deficiency anemia, liver disease	Various biochemical manifestations	Various clinical presentations

ALA, 5-aminolevulinate; PBG, porphobilinogen.

Each of the different types of porphyria is linked to a reduced activity or deficiency of a specific enzyme in the heme biosynthetic pathway (see Fig. 38–1). The enzyme deficiency impairs the production of the end product heme, and there is overproduction and increased excretion of the heme precursors formed by the steps before the enzyme defect. There is also a compensatory increase in activity of the initial and rate-controlling enzyme ALAS. In the acute porphyrias, there is overproduction of all the porphyrins and porphyrin precursors (eg, ALA, PBG) formed proximal to the enzyme defect. The increased excretion of porphyrin precursors in the acute porphyrias is caused by decreased activity of PBGD in these conditions. The decrease can be caused by genetic mutation of the enzyme (in acute intermittent porphyria) or by inhibition of PBGD by protoporphyrinogen and coproporphyrinogen in variegate porphyria and hereditary coproporphyria, respectively.[26]

In the nonacute porphyrias, there is overproduction of all porphyrins formed before the enzyme defect but no overproduction of porphyrin precursors. The cause of this lack of overproduction of porphyrin precursors in the nonacute porphyrias is unclear, but it may result from a compensatory increase in the activity of the enzyme PBGD in addition to increased activity of ALAS and to site-specific heme synthesis.[29] The pattern of overproduction and excretion of porphyrins and porphyrin precursors in the various porphyrias is shown in Table 38–3. A consequence is that each of the different porphyrias is characterized by a different excretion pattern. Quantitative studies of the different porphyrins and precursors in the urine and feces usually identify the particular type of porphyria. The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of the bile (see box on Measurement of Porphyrins and Precursors).

Measurement of Porphyrins and Precursors

Diverse techniques such as high-pressure liquid chromatography,[27] extraction, and various forms of fluorometry are used to measure porphyrins and precursors. A recent addition has been fluorescence emission scanning to differentiate variegate porphyria, erythropoietic protoporphyria, and other photocutaneous porphyrias.[28] The International Federation for Clinical Chemistry presents diagnostic information on the Internet (www.ifcc.org).

The clinical manifestations of an acute attack of porphyria can be explained by dysfunction of the central, peripheral, and autonomic nervous systems. The mechanism by which altered heme synthesis results in dysfunction is unknown.

Perhaps the most likely hypothesis is that the clinical manifestations of acute porphyria arise as a result of heme deficiency within the nerve cells, although this does not exclude the possibility that ALA may also act as a pharmacologic agent in these diseases, compounding the effects of heme deficiency.[30] ALA has a prooxidant

Table 38–3 Changes in Porphyrins and Their Precursors in the Porphyrias, Porphyrinurias, and Hereditary Sideroblastic Anemia

Porphyrias and Other Conditions	ALA	PBG	Urine Uroporphyrin	Urine Coproporphyrin	Feces Coproporphyrin	Feces Protoporphyrin	Erythrocyte Protoporphyrin
ACUTE PORPHYRIAS							
Acute intermittent porphyria	Raised, very high in attack	Raised, very high in attack	Usually raised*	Sometimes raised	Sometimes raised	Sometimes raised	Normal
Variegate porphyria	Raised in attack	Raised in attack	Usually raised in attack	Usually raised in attack	Raised	Raised	Normal
Hereditary coproporphyria	Raised in attack	Raised in attack	Sometimes raised in attack	Usually raised, always in attack	Raised	Usually normal	Normal
NONACUTE PORPHYRIAS

* PBG may cyclize to uroporphyrin nonenzymatically. ALA, 5-aminolevulinic acid; PBG, porphobilinogen.

effect on rat brain tissues and generates free radical species during its autooxidation.[30,31] The concept of autooxidation or oxidative stress is supported by the hypothesis that manganese excess could contribute to induction of superoxide dismutase[32] and increased indicators of such stress in lead exposure.[33] There is evidence that ALA enters cells by a pathway common to it and γ-aminobutyric acid (GABA).[34]

Genetic Aspects

The enzymatic links and genetic loci in each of the hereditary porphyrias are shown in Table 38–1. Nearly all are inherited as autosomal dominant traits. Few carriers of the abnormal gene show clinical signs of the disease, but most can be identified by intensive biochemical investigation. The rare congenital porphyria shows autosomal recessive inheritance. The mutations producing each of the acute porphyrias are heterogeneous at the molecular level and include complete or partial gene deletions, alterations of splicing or stability of mRNA, and missense mutations. An exception is variegate porphyria in South Africa, in which the founder effect ensures a predominance of the Arg59Tryp mutation.[35,36] Homozygotic or compound heterozygotic inheritance has been found in a number of the porphyrias, as has concurrent inheritance of more than one defect. This may present as two types of porphyria in one family[37] or as two types in one patient.[38] Examples of this "concurrent" porphyria are the Chester porphyria (ie, acute intermittent porphyria and variegate porphyria)[37] and dual porphyria (ie, variegate porphyria and porphyria cutanea tarda).[39]

The prevalence of the different forms varies widely. For example, in northern Europe and North America, approximately 1 of 10,000 individuals carries the gene for acute intermittent porphyria, although only about 10% of the affected persons will present with clinical features. It has been suggested that spontaneous mutation accounts for 3% of acute intermittent porphyria cases.[40] Variegate porphyria occurs in 1 of 400 white South Africans. There is a reduction in gene frequency in variegate porphyria from generation to generation that suggests that the allele associated with it is selectively deleterious.[41] The same is probably true of the other porphyrias. The pedigree of Chester porphyria is shown in Fig. 38–3.

Acute Intermittent Porphyria

Clinical and Laboratory Manifestations

Acute intermittent porphyria is the most severe of the acute porphyrias. During an attack, patients display abdominal and neuropsychiatric or neurovisceral disturbances. Onset occurs in puberty; female patients exhibit a fourfold greater incidence of attacks than males. Attacks occur mainly in young adults and become less frequent after menopause. It is uncommon to see attacks in children.[42] Crises may vary in duration from several days to months. They are most commonly followed by complete remission, although deaths are still reported, especially with acute intermittent porphyria[43] (see box on Precipitating Factors in Acute Porphyria).

Gastrointestinal symptoms occur in 95% of cases; most patients present with acute colicky central abdominal pain. Examination reveals tenderness but little rigidity, and patients may also experience limb pain or generalized muscular aches. Severe vomiting may occur, and constipation is usual. Hyponatremia occurs in severe attacks.

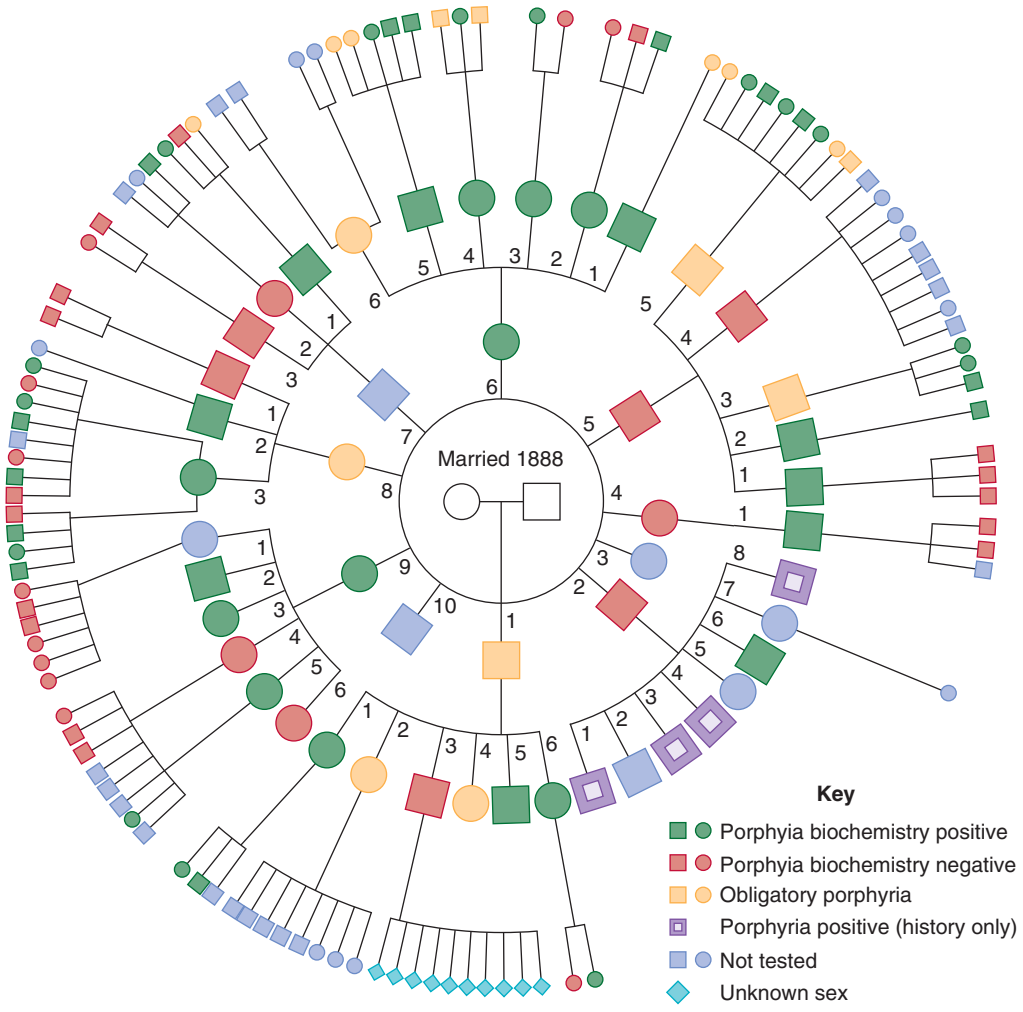

Figure 38–3 The Chester family pedigree. The propositus, Peter Dobson, was a salmon fisherman from a close-knit community living on the bank of the River Dee, which runs through the city of Chester, U.K. Most of the 330 descendants of his marriage in 1888 still live in the city. Many suffered disabling illnesses and psychiatric upsets, which often went unrecognized as porphyria. The family called their illness *Dobson's complaint*. *(Courtesy Giles R. Youngs.)*

Precipitating Factors in Acute Porphyria

Most patients who have inherited acute porphyria enjoy normal health and go through life without any knowledge of their disorder or ever experiencing an acute attack. All porphyrics, however, are at risk of developing an attack if exposed to various precipitating factors. Drugs are the most common precipitating agents. Other factors that may trigger attacks include alcohol ingestion, reduced caloric intake (from fasting or dieting), and infection. Smoking can cause more frequent attacks.

Hormonal status is also important. Attacks are more common in females, and rarely, they occur before puberty or after menopause. Pregnancy and oral contraceptives may also precipitate attacks. Some women experience regular attacks, commencing in the week before the onset of menstruation. These may require luteinizing hormone–releasing hormone (LHRH) antagonists for control (see Table 38–4).

Drugs for Porphyria

Before prescribing any medication to a porphyric patient, advice must be sought from an appropriate specialist. Full drug lists are available on the Internet (www.drugs-porphyria.org). It should be borne in mind that such lists are far from encyclopedic, that new drugs are constantly being introduced to the pharmacopoeia, and that any form of combined preparation must be viewed with suspicion, because little is known about metabolic interactions in these diseases.[48] More details of such use and side effects of drugs can be sought from the literature.[49]

Table 38–4 PRECIPITATING FACTORS IN ACUTE PORPHYRIA

Drugs	Other Stimuli
Alcohol	Fasting or dieting
Barbiturates	Hormones, stress
Angiotensin-converting enzyme (ACE) inhibitors	Smoking
Anticonvulsants	
Antidepressants	
Calcium channel blockers	
Cephalosporins	
Ergot derivatives	
Erythromycin	
Steroids or anabolic steroids	
Contraceptives, hormone replacement therapy	
Sulfonamides	
Sulfonylureas	

Figure 38–4 Bilateral wrist drop caused by peripheral neuropathy in a patient with acute intermittent porphyria.

Figure 38–5 Cutaneous lesions and scarring in a patient with variegate porphyria.

Motor neuropathy complicates two thirds of porphyric attacks and may be the presenting feature. Motor involvement is most common, but paresthesias may also occur. Paralysis usually starts peripherally and then spreads proximally; however, in some patients, shoulder girdle involvement may be the first manifestation. The neuropathy may progress rapidly, resulting in respiratory insufficiency. Weakness, usually symmetric, involves proximal and distal limb muscles more often than those of the trunk. Upper limbs and proximal muscles are often affected. Involvement of the wrists, ankles, and small muscles of the hand may lead to a permanent deformity (Fig. 38–4), and trunk muscle weakness can lead to respiratory embarrassment. Death is usually caused by respiratory paralysis. Progressive weakening of the voice may suggest this; treatment requires tracheotomy and intermittent positive pressure ventilation. Paresthesias, numbness, and objective evidence of sensory impairment may occur with loss of pinprick sensation, which is most marked around the shoulder and hip areas; generalized tonic-clonic seizures occasionally occur.

Severe anxiety, depression, and frank psychosis are the main psychiatric manifestations of porphyric attacks. These psychiatric manifestations may result in a patient being misdiagnosed as suffering from a primary psychiatric disorder. Agitation, mania, depression, hallucinations, and schizophrenic-like behavior may occur. Psychiatric manifestations may persist between attacks.[44] Quality of life is severely affected in those suffering from repeated attacks of acute porphyria.[45]

The cardiovascular system is involved in approximately 70% of attacks. Sinus tachycardia (to 160 beats/min) and hypertension can occur; these elevations usually revert to normal after an attack. There is evidence that hypertension may occasionally be permanent, even in latent cases of acute intermittent porphyria (see box on Differential Diagnosis of Acute Intermittent Porphyria).

Differential Diagnosis of Acute Intermittent Porphyria

Attacks of acute porphyria must be distinguished from other causes of acute abdominal pain or peripheral neuropathy sometimes associated with psychosis. Heavy metal poisoning (ie, lead or arsenic) and Guillain-Barré syndrome must be considered, as well as paroxysmal nocturnal hemoglobinuria with its characteristic early morning hemoglobinuria and abdominal pain.

During an attack, all patients excrete a massive excess of the porphyrin precursors, 5-aminolevulinic acid (ALA) and porphobilinogen (PBG), in their urine. Urine, when first voided, is clear and darkens on exposure to light as the hexa-hydroporphyrins, the porphyrinogens, are oxidized to porphyrins.

A rapid screening test during an acute attack is to mix equal volumes of urine and Ehrlich's aldehyde reagent and observe for the pink color of porphobilinogen. The differential diagnosis of porphyrias uses qualitative and quantitative measurement of porphyrins and precursors, with subsequent use of enzymatic assay and identification of familial genetic alterations.[50]

Other Acute Porphyrias

Hereditary Coproporphyria

Hereditary coproporphyria (HC) combines the clinical features of acute porphyria with photosensitive skin manifestations. It results from mutations in the gene encoding coproporphyrinogen oxidase, whose activity is decreased,[46,47] leading to overproduction of coproporphyrin.

The porphyrin precursors ALA and PBG and the more water-soluble porphyrins (with multiple carboxyl groups) are excreted mainly in the urine. Other porphyrins are mainly excreted in the feces by way of bile.

Variegate Porphyria

Variegate porphyria is similar to hereditary coproporphyria, except that there are more severe skin lesions, sometimes with scarring (Fig. 38–5). Protoporphyrinogen oxidase is the affected enzyme, and protoporphyrin is the major circulating porphyrin. Conventionally, variegate porphyria is most readily diagnosed by measurement of fecal porphyrin concentrations. However, it has been reported[51] that biliary porphyrin levels may provide a better discriminator from normal patients in the asymptomatic phase. As in erythropoietic protoporphyria, there is a tendency toward cholelithiasis. The mechanism by which gallstones form is not certain, but some studies have suggested that porphyrins are cholestatic.[52] In hereditary coproporphyria and variegate porphyria, the pathway intermediates produced in excess, coproporphyrinogen and protoporphyrinogen, respectively, are inhibitors of the secondary rate-controlling enzyme PBGD.[26,53] Numerous mutations in the protoporphyrinogen oxidase gene have been described leading to 50% reduction in enzyme activity. In a few cases homozygosity or compound heterozygosity has been described.[54,55]

ALA-Dehydratase Deficiency Porphyria

In this porphyria (also known as plumboporphyria), the ALA dehydratase activity is depressed, as occurs in lead poisoning. The clinical

Management of Acute Porphyria

Treatment of Acute Attack

A carbohydrate intake of 1500 to 2000 kcal/24 hours should be maintained throughout the attack to reduce porphyrin synthesis; give this orally or, for more severe attacks, through a fine-bore Teflon nasogastric tube. If this cannot be tolerated, intravenous dextrose (eg, 20% solution, 2 L/day) should be given. If early in the attack (2 to 4 days from onset), give intravenous hematin as heme arginate (Normosang, Leiras) at 2 to 4 mg/kg over 30 minutes once or twice each day to further reduce the overproduction of porphyrin and precursors.[63,64] Hematin (Panhematin, Abbott) in similar doses may also be used, although it should be reconstituted in human albumin solution to avoid phlebitis and mild transient prolongation of coagulation times. No renal complications have occurred with the standard recommended dosages, and even patients with renal insufficiency tolerate hematin well, although the dosage should be reduced slightly. The action of heme therapy may be extended by heme oxygenase blockers such as tin protoporphyrin.[63]

Prophylaxis

Many drugs are contraindicated, and the patient must be warned to avoid precipitating factors. Alcohol should be restricted and smoking discouraged. Dieting (<800 kcal/day) must be avoided. Pregnancy should also be avoided if the disease is active. If a patient requires an anesthetic, nitrous oxide, ether, and cyclopropane are safe, and suxamethonium appears to be a safe muscle relaxant. The opiates and belladonna derivatives can be used for premedication and propofol for maintenance of anesthesia. Infection can precipitate an attack and should therefore be sought and treated. Blood relatives of patients should be screened to see if they carry the gene.

Luteinizing hormone-releasing hormone (LHRH) antagonists that suppress ovulation are a valuable form of prophylaxis in menstrually related attacks.[65] Estrogens and progestogens such as those in the contraceptive pill must be avoided in acute porphyria. The same applies to most steroids and receptor antagonists such as mifepristone.[66]

Management of Nonacute Porphyria

Patients should avoid exposure to sunlight and use sun block and physical barriers such as cotton gloves.

Porphyria Cutanea Tarda

The clinical features are reversed by removing any precipitating agent such as alcohol, halogenated hydrocarbons, and drugs. The patient should be screened for hepatic neoplasm and hepatitic viral infection. The mainstay of treatment is to remove liver iron by venesection of 500 mL of blood weekly until clinical remission occurs or until the hemoglobin level falls below 12 g/dL. Chloroquine, at low doses of 125 mg twice per week for several months, has also been helpful because it enhances urinary clearance of porphyrin. When venesection is difficult, desferrioxamine can be used to reduce liver iron stores. It is of value to screen the patient and first-degree relatives for hereditary hemochromatosis.

Erythropoietic Protoporphyria

Oral β-carotene offers effective protection in EPP against solar sensitivity. It does so by quenching the radical formation that is a feature of the skin damage. Yellowing of the skin (ie, carotenemia) is one side effect. Interruption of the enterohepatic protoporphyrin circulation by bile salt sequestering agents such as cholestyramine reduces plasma protoporphyrin levels and may retard the development of the liver disease. Liver transplantation has been reported to be an effective measure in preventing the progression of this disease,[67] and sequential liver and bone marrow transplantation has been described in one patient.[68]

Congenital Porphyria

Erythropoiesis should be reduced by means of erythrocyte hypertransfusion and by hematin or heme arginate infusion.[69] Bone marrow transplantation has given encouraging biochemical and clinical results but insufficient numbers of patients have been treated to be certain of the future prospects of this therapy.[70] Splenectomy and chloroquine therapy (125 mg twice weekly) have an ameliorating effect, as does hypertransfusion, but life expectancy is usually severely shortened.

picture resembles acute intermittent porphyria, but very few cases have been described, and the disease only manifests in homozygous cases when there is a precipitating factor.[56,57]

Concurrent Porphyrias

The concurrent porphyrias are a rare group of conditions in which there is concurrent inheritance of two different defects within the heme biosynthetic pathway. There is good precedent for more than one defect within the pathway. Previous descriptions[39–42] have shown the presence of concurrent porphyria within a family, and toxicologically, there is good evidence that exposure to poisons such as lead can induce multiple changes within the pathway.[58] Chester porphyria, for example, combines the clinical features of acute and cutaneous porphyria. PBGD and protoporphyrinogen oxidase activity are reduced, leading to overproduction of PBG and protoporphyrinogen.[37] In another patient, dual genetic defects involving 5-aminolevulinate dehydratase and coproporphyrinogen oxidase have been described.[659,60]

Nonacute or Cutaneous Porphyrias

In all cutaneous porphyrias, porphyrins (which are photosensitizing) are deposited in the upper layers of the skin, and they are responsible for the characteristic skin lesions.[61] In the development of these lesions, reactive oxygen species and other radicals are formed and probably induce oxidative membrane damage, particularly to mast cells, which enables complement activation as one part of the inflammatory reaction[62] (see box on Management of Acute Porphyria).

Porphyria Cutanea Tarda or Cutaneous Hepatic Porphyria

Biologic and Molecular Aspects

Porphyria cutanea tarda (PCT) exists in inherited and acquired forms. An inherited, more severe form of this disease, hepatoerythropoietic porphyria (HEP), has been described.[71,72] Mutations in the uroporphyrinogen decarboxylase are found in around one-third of patients with PCT. In inherited and acquired forms, there is diminution in the activity of hepatic uroporphyrinogen decarboxylase, which converts uroporphyrinogen to coproporphyrinogen by the stepwise decarboxylation of the acetyl groups to methyl groups. Most carriers of mutant uroporphyrinogen decarboxylase are not clinically evident unless precipitating factors are present. Iron alone or chlorinated hydrocarbons can diminish activity of uroporphyrinogen decarboxylase, and this effect is greatly potentiated when both are given

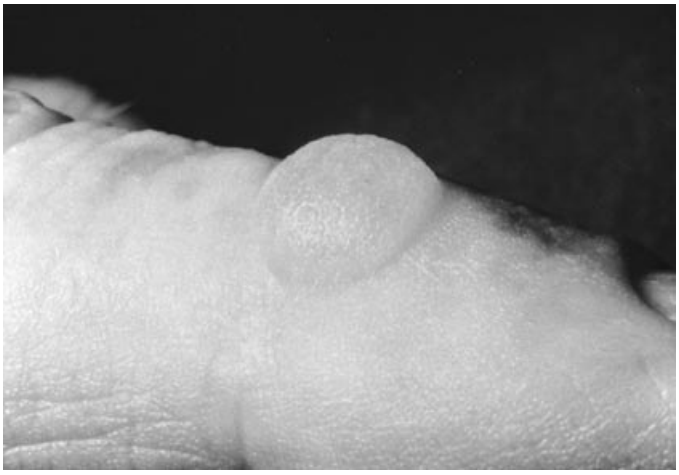

Figure 38–6 A bullous skin lesion of porphyria cutanea tarda.

together.[72,73] A genetic mouse model has been developed for familial PCT, and a zebrafish model is available for HEP, which should enhance our understanding of these diseases.[74,75]

Patients may have clinical and biochemical evidence of liver disease. Hepatic siderosis invariably occurs, and iron is one of the causative agents in acquired PCT. An association of PCT with hereditary hemochromatosis has been documented, with about 20% of PCT patients being homozygous for the Cys282Tyr mutation in the *HFE* gene, a defect that characterizes hereditary hemochromatosis.[76–78] These results strongly implicate the *HFE* gene as a genetic susceptibility factor in acquired PCT. An apparent association has emerged between HIV infection, hepatitis C infection, and PCT.[79] The etiologic role of viral infection in PCT is not yet clear. It is possible that therapy for HIV with zidovudine precipitates the disease, but it is more likely that the association is merely coincidental or that the viral infection unmasks the preexisting uroporphyrinogen decarboxylase defect.[80]

Genetics

Whereas familial PCT is inherited in an autosomal dominant mode, HEP is inherited in an autosomal recessive pattern.[72] As in the other genetic lesions in the porphyrias, there is heterogeneity in the mutations causing PCT and HEP phenotypes.[81,82] In the inherited form, more than 40 different mutations (mainly missense) have been identified in uroporphyrinogen decarboxylase, many of which lie near the dimer interface resulting in an unstable protein and reduced enzyme activity.[83] In different population groups, it is difficult to find the relative numbers of acquired and familial disease. In one analysis in Hungary, 77.5% of patients were found to suffer from the acquired form, and of the patients with the familial disease, females were affected more than males, suggesting that inheritance may predispose patients to estrogen-precipitated disease.[84]

Clinical Features

The most striking clinical feature of both forms of PCT is a bullous dermatosis on light-exposed areas. This starts as erythema and progresses to vesicles that become confluent to form bullae (Fig. 38–6), which may hemorrhage and leave scars; pruritus is often troublesome. Milia are common and may precede or follow vesicle formation. Increased fragility of the skin is important and, in less severe cases, may be the only clinical sign. In severe cases, photomutilation can result, usually because of infection of slowly healing lesions.

The thickening and scarring with calcification has been described as pseudoscleroderma. Hyperpigmentation is common, and women often complain of hirsutism. Neurologic change is not observed.

Pseudoporphyria and Renal Dialysis

The term *pseudoporphyria* has been used to describe a bullous dermatosis associated with a number of dermatologic conditions that bear some resemblance to porphyria.[85] This photosensitivity is often induced by drugs such as the tetracyclines, naproxen, furosemide, voriconazole, oxaprozin, and many others. In these conditions, there is no alteration in porphyrin metabolism or excretion. It is therefore incorrect to name any of them porphyria; the term pseudoporphyria should not be applied to them, but only to conditions in which alterations of porphyrin metabolism can be found such as the bullous dermatosis of hemodialysis.[86]

Patients with renal failure can present with many biochemical features of porphyria before hemodialysis. These abnormalities normalize after dialysis, especially when electrolyte abnormalities such as zinc deficiency are also corrected.[86] In a considerable proportion of patients with chronic renal failure, skin changes resembling porphyria cutanea tarda (PCT) develop some months to years after the onset of maintenance hemodialysis. In a minor proportion, genuine PCT can be diagnosed.[87] In such cases, there are elevated total porphyrin levels in plasma and in urine if the patient is not anuric. These patients present a therapeutic dilemma because they are normally anemic and unsuitable for phlebotomy therapy.

Patients may have clinical and biochemical evidence of chronic liver disease, sometimes with cirrhosis. There is an association with hepatocellular carcinoma. Hepatomegaly is particularly common when alcohol intake is excessive.

Precipitating Factors

Many patients with PCT have multiple precipitating factors, including mutations of the *HFE* gene, hepatitis C infection, or exposure to estrogen.[76,77] Excessive alcohol intake is an important precipitating agent, perhaps because of increased hepatic iron deposition in alcoholics. However, certain halogenated hydrocarbons are sometimes implicated. PCT may also develop in people treated with hemodialysis for kidney failure. An outbreak of cutaneous hepatic porphyria in southeast Turkey in 1956 was traced to seed wheat dressed with the fungicide hexachlorobenzene. A neoplastic subgroup has been identified in which PCT is associated with benign or malignant liver tumors.

Differential Diagnosis

Other causes of bullous or vesicular skin lesions should be excluded, such as a drug reaction (see box on Pseudoporphyria and Renal Dialysis) or chronic renal failure. The distinction between PCT, variegate porphyria, and hereditary coproporphyria rests on biochemical testing of urine and feces, with the highest levels of urinary uroporphyrin found during attacks of PCT (see Table 38–3).

Erythropoietic Protoporphyria

Biologic and Molecular Aspects

Although not described until 1961, this form of erythropoietic porphyria (EPP), also known as erythrohepatic protoporphyria, is much more common than congenital porphyria. Ferrochelatase activity is reduced in peripheral blood, liver, bone marrow, and skin, and protoporphyrin is synthesized in excess.[88] The erythroid progenitor cells (ie, burst-forming units-erythroid [BFU-E]) in EPP patients show intense fluorescence when viewed under 405 nm light. The gene

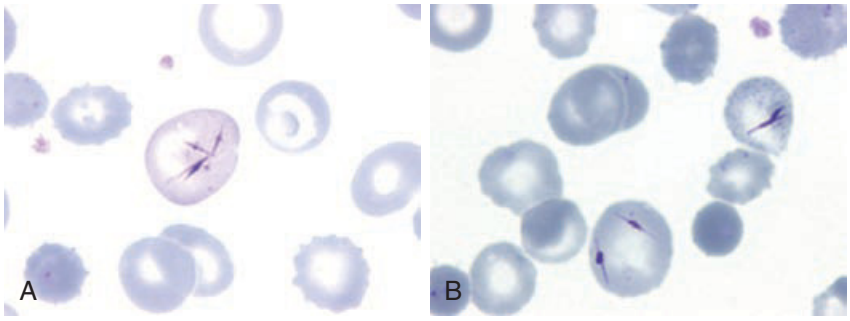

Figure 38–7 Needle like inclusions of porphyrin in the circulating red cells of a patient with congenital porphyria after splenectomy *(Merino A, To-Figueras J, Herrero C: Atypical red cell inclusions in congenital erythropoietic porphyria. Br J Haematol 132:124, 2006.)*

mutation in EPP shows heterogeneity as in other porphyrias.[89] The last enzyme of the biosynthetic pathway, ferrochelatase, is important because its endogenous activity is relatively low, and it could act as a control point in the pathway. Ferrochelatase ligates iron bound to three cysteine residues in an iron-sulfur cluster,[90] the mutation of which leads to decreased enzyme activity.[91] A multiple-enzyme complex spanning the mitochondrial membrane would allow for channeling of substrate from the cytoplasm to the mitochondrial matrix.[92] Immunologic studies on human protoporphyria show that immunologically reactive ferrochelatase is present, but that enzyme activity in three subjects was on average only 17% of normal.[93]

Genetics

EPP is inherited as an autosomal dominant disorder with incomplete penetrance, although recessive inheritance has been described.[94,95] Haplotype segregation analysis has shown intronic nucleotide polymorphisms in the ferrochelatase gene (FECH) that produces aberrant splicing of mRNA to a form that degrades more rapidly resulting in enzyme deficiency.[96] Although these disease associated polymorphisms are common,[97] there is heterogeneity of the molecular defect, including aberrant splicing and loss of function of the mitoferrin protein.[14,88,89,98]

Clinical Features

The clinical features are mainly cutaneous on exposure to sunlight and can occur at any age, including infancy and childhood.[94] They include pruritic urticarial swelling and redness of the skin on exposure to sunlight. The most distressing symptom is an unbearable burning sensation on the affected parts. Remarkably, such features are ameliorated during pregnancy, which has been linked to lowered protoporphyrin levels.[99] Hepatic involvement, which occurs in later life, involves deposition of hepatotoxic protoporphyrin in the liver and can lead to fatal liver failure from an active chronic hepatitis with cirrhosis.[100] Such protoporphyrin deposition may also cause cholelithiasis; the gallstones contain high concentrations of protoporphyrin. The liver disease of EPP seems to correlate with erythrocyte protoporphyrin concentrations.[101] Mild microcytic anemia has been reported,[102,103] as well as mitochondrial iron accumulation and ring sideroblasts, in about 30% of patients.[104] Late onset of EPP has been reported in patients with myelodysplastic syndrome or overlap myelodysplasia/myeloproliferation. In one patient EPP has been acquired as a result of expansion of hemopoietic cells containing only one allele of the FECH gene. Inactivation of one allele by deletion involving chromosome 18 thus appears to be sufficient for overproduction of protoporphyrin.[104,105]

Differential Diagnosis

EPP should be distinguished from other causes of a photosensitive rash. The distinction can be made by demonstrating fluorescence in a proportion of red cells (ie, fluorocytes) in the peripheral blood and confirmed by measurement of greatly increased erythrocyte and fecal protoporphyrin. Patients with EPP have a relatively high incidence of ring sideroblasts in the marrow.[104] This can lead to diagnostic difficulty because some patients with idiopathic sideroblastic anemia have increased levels of erythrocyte protoporphyrin.[107–110] However, EPP can be distinguished by the autosomal dominant inheritance pattern, dermal photosensitivity, normal or low serum levels of iron, and levels of protoporphyrin in red blood cells and feces.

Congenital Porphyria (Gunther Disease)

Biologic and Molecular Aspects

Congenital porphyria, or Günther disease, although extremely rare, was the first porphyria to be described in 1874.[111] Unlike the other porphyrias, it is inherited in a Mendelian autosomal recessive pattern causing reduced activity of uroporphyrinogen III synthase. The onset of solar photosensitivity results from gross overproduction of porphyrins, caused by deficiency of uroporphyrinogen III synthase. Like other porphyrias, the defective enzyme results mainly from point mutations at multiple sites within the gene.[112] Other enzymes are largely normal, although there is an increase in ALAS activity.[113] Excess porphyrins, particularly uroporphyrin-1, accumulate in the normoblasts of the bone marrow and are excreted in the urine and feces. They are also deposited in bones and in the teeth, resulting in a pink-brown discoloration that fluoresces bright red in light of wavelengths around 400 nm. Dental restoration has been used to correct the esthetic appearance of the teeth. There are frequently profound changes in bone structure in patients with congenital porphyria. This has been linked to vitamin D deficiency because of light avoidance.[114] However, bone changes can be seen when vitamin D levels are adequate, and it is reasonable to speculate that the porphyrins deposited in bone are cytotoxic because similar bone changes are features of homozygous variegate porphyria and hepatoerythropoietic porphyria.[115]

Clinical Features

Typically, the onset of congenital porphyria is from birth, but occasionally, late-onset cases have been reported.[116] The skin reaction is severe and can be devastating, and the teeth become brownish pink because of their high porphyrin content. Severe cutaneous photosensitivity is manifested by blistering of light-exposed areas and fragility of the epidermis. Skin thickening occurs, and there is extensive scarring and hypertrichosis. The recurrent damage associated with scarring on the hand may produce a claw-shaped deformity and loss of digits. Dystrophic nails may curl up and drop off. Lenticular scarring may lead to blindness. Hemolytic anemia often occurs and is associated with increased erythrocyte fragility and splenomegaly. Dyserythropoiesis may contribute to the anemia.[117] One patient who underwent splenectomy at five years of age has been described with needle-like inclusions of porphyrin in the circulating red cells (Fig. 38–7).[118]

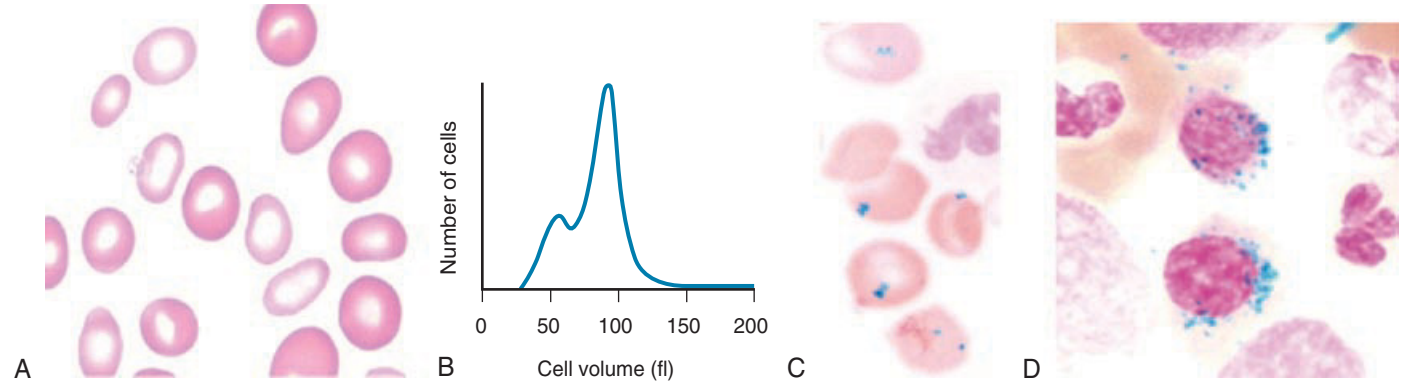

Figure 38–8 A, Peripheral blood smear from a patient with hereditary sideroblastic anemia shows a population of hypochromic and microcytic erythrocytes. **B,** Erythrocyte volume distribution curve of a patient with hereditary sideroblastic anemia. A dimorphic size distribution is evident. **C,** Peripheral blood showing Pappenheimer bodies (Prussian blue stain). **D,** The bone marrow smear stained with Prussian blue shows ring sideroblasts.

Differential Diagnosis

The most characteristic feature of congenital porphyria is the excess production of series 1 porphyrins rather than series 3 isomer produced in the other porphyrias. Red blood cells fluoresce in ultraviolet light, as do the brown-stained teeth, because of high porphyrin content (see box on Pseudoporphyria and Renal Dialysis).

SIDEROBLASTIC ANEMIAS

Sideroblastic anemias are a heterogeneous group of disorders characterized by anemia of varying severity and diagnosed by finding ring sideroblasts in the bone marrow aspirate. The peripheral blood shows hypochromic red cells, which are microcytic in the hereditary forms (Fig. 38–8A) but are often macrocytic in the acquired forms of the disease. The red blood cell parameters from automated cell counting may show bimodal volume distribution curves or widened range of cell sizes (see Fig. 38–8B); however, this dimorphic size distribution is not always present. Tiny inclusions may be visible in the red blood cells; these can be confirmed as iron-containing Pappenheimer bodies by Prussian blue staining of the blood smear (see Fig 38–8C). The diagnostic test is bone marrow examination together with Prussian blue staining of the bone marrow smears.

The presence of ring sideroblasts (see Fig. 38–8D) is defined as erythroblasts containing iron-positive (siderotic) granules arranged in a perinuclear collar distribution around one-third or more of the nucleus. Electron microscopic examination has shown that these siderotic granules are mitochondria containing amorphous deposits of ferric phosphate and ferric hydroxide. Iron is also bound to mitochondrial ferritin, a molecular form of ferritin that can be distinguished from cytoplasmic ferritin and that accumulates in large amounts in the erythroblasts of subjects with impaired heme synthesis.[119,120]

Iron overload is a common clinical feature of refractory sideroblastic anemia and, in severe cases, may lead to complications that characterize secondary hemosiderosis (eg, diabetes, cardiac failure). Marrow examination shows prominent erythroid hyperplasia, which is a sign of the ineffective erythropoiesis and is responsible for increased iron absorption. The sideroblastic anemias have diverse causes but have in common an impaired biosynthesis of heme in the erythroid cells of the marrow. Most sideroblastic anemias are acquired as a clonal disorder of erythropoiesis, with various degrees of myelodysplastic features (Table 38–5). The inherited forms are uncommon and occur predominantly in males with an X-linked pattern of inheritance. A number of drugs have been associated with reversible sideroblastic anemia, and ring sideroblasts may be found in patients who abuse alcohol (see Table 38–5). The first descriptions of ring sideroblasts in association with chronic refractory anemias appeared in the late 1950s,[121,122] after an earlier description of familial X-linked hypochromic microcytic anemia.[123]

Table 38–5 Classification of Sideroblastic Anemias

Hereditary
X-linked *
Autosomal dominant or recessive
Acquired
Idiopathic acquired* (refractory anemia with ring sideroblasts)
Associated with previous chemotherapy, irradiation, or in "transitional" myelodysplastic or myeloproliferative diseases
Drugs
Alcohol
Isoniazid
Chloramphenicol
Other drugs
Rare causes
Erythropoietic protoporphyria
Pearson syndrome
Copper deficiency or zinc overload
Thiamine-responsive megaloblastic anemia
Hypothermia

*Trial of pyridoxine indicated.

Hereditary Sideroblastic Anemia

Biologic and Molecular Aspects

Erythroid cells from patients with X-linked forms of hereditary sideroblastic anemia generally exhibit low activity of ALAS.[8,124] A defect in this enzyme is firmly established in patients whose anemia responds to pyridoxine therapy, because pyridoxal phosphate is an essential cofactor for ALAS. However, even affected female patients with moderate anemia unresponsive to pyridoxine have been documented to have low levels of ALAS in bone marrow lysates. In some male patients with X-linked pyridoxine-responsive sideroblastic anemia, the low ALAS activity in bone marrow increased to levels above the normal range when the patient took pyridoxine supplements and

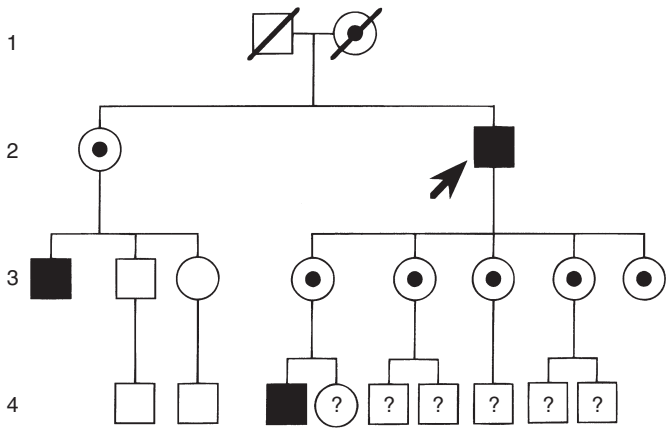

Figure 38–9 Pedigree of a family with pyridoxine-responsive sideroblastic anemia showing X-linked recessive inheritance. Affected *(filled box)*, carrier *(filled circle within open circle)*, and unknown status *(question mark within circle or box)* are indicated. *Diagonal lines* indicate deceased members. This pedigree[125] has been abbreviated to show only the affected branches of the family. The *arrow* indicates the proband.

recovered from the anemia.[125] There are several possible explanations for this enhancement of ALAS activity by dietary pyridoxine supplements. The most likely is that pyridoxine (or its phosphate) may stabilize the ALAS during folding of the mutant enzyme after its synthesis.[124] The gene for the ALAS2 isoenzyme has been localized to the X chromosome, and this gene is known to be the site of most mutations giving rise to X-linked pyridoxine-responsive sideroblastic anemia.[9,126] Approximately three dozen different mutations have been identified in individuals or families with hereditary sideroblastic anemia, and nearly all have resulted from single base alterations in DNA. A frequent mutation affects arginine at residue 452 of ALAS-2, which occurs in a quarter of all pedigrees but does not affect enzyme activity measured in vitro.[127] All known mutations lie between exons 5 and 11 of *ALAS2*, the region that codes for the catalytic domain, with most lying within exon 9, which contains the lysine at which binding of pyridoxal 5′-phosphate occurs.[7] A mutation, Asp190Val, has been described in a pyridoxine-refractory patient and appears to affect the proteolytic processing of the ALAS2 during or after import into the mitochondrion.[128] The variety of different mutations in the erythroid *ALAS2* gene responsible for X-linked sideroblastic anemia and their pyridoxine responsiveness have been reviewed recently.[9]

An inherited deficiency of flavin monooxygenase has been suggested as a rare cause of sideroblastic anemia.[129]

Genetic Aspects

In most families with hereditary sideroblastic anemia, males are affected with an X-linked pattern of inheritance (Fig. 38–9). However female carriers, although usually normal, can develop erythrocyte dimorphism or varying degrees of anemia. The assignment of the gene for erythroid *ALAS2* to the X chromosome[126] and the many mutations documented in erythroid *ALAS2* provide the genetic basis for this X-linked disease. In several families, coinheritance of other X-linked traits (eg, glucose-6-phosphate dehydrogenase [G6PD] deficiency, ataxia with sideroblastic anemia) has been described.[130,131] In X-linked sideroblastic anemia with ataxia, a mutation has been described in the *ABCb7* gene, which leads to a limitation of competent heme synthesis from protoporphyrin and iron, possibly through diminished availability of Fe^{2+} iron,[132,133] There are well-documented families in which the sideroblastic anemia was inherited as an autosomal dominant trait, as well as rare cases that are autosomal recessive.[134] Sporadic and familial cases have been described that affect only females, which has been shown to represent skewed X-chromosome inactivation ("unfortunate skewing") affecting the normal allele for the *ALAS2* gene.[135] The absence of affected male members in these pedigrees suggests that the *ALAS2* defects identified are lethal in hemizygous males.

Clinical and Laboratory Evaluation

Typically, the anemia manifests in infancy or childhood, but the milder forms of anemia may not be found until midlife. Even elderly patients have been diagnosed with this anemia.[136] Some cases may be discovered only during family surveys, which should always be undertaken when hereditary sideroblastic anemia is diagnosed. Still other patients may present with features of iron overload, such as diabetes or cardiac failure. Iron overload occurs commonly even with mild anemia and may occasionally be seen with female carriers. Enlargement of the liver and spleen may occur with mild abnormalities of liver function tests.

Anemia is extremely variable, but even when little or no anemia is present, the mean corpuscular volume (MCV) is low, and the red cell volume distribution width may be increased. When anemia is severe, the MCV may be as low as 50 fL (μ^3). The blood smear shows a population of cells with hypochromic, microcytic morphology (see Fig. 38–8), which contrasts with the other normochromic, normocytic cells (ie, dimorphism). Anisocytosis, poikilocytosis, elongated cells, and siderocytes may also be seen. The characteristic erythrocyte dimorphism is most prominent in patients with milder anemia, in female carriers, and in patients in whom pyridoxine has corrected the anemia but not restored the MCV to normal. In some pedigrees with only affected females macrocytosis may be present which contrasts with the typical microcytosis of male hemizygotes.[110,135] Leukocyte values are normal, whereas the platelet count is normal or increased.

Serum iron concentration is increased, and transferrin shows an increased percentage of saturation with iron. Serum ferritin levels are invariably increased. Ineffective erythropoiesis can be confirmed by ferrokinetic measurements showing that plasma iron clearance is rapid, with subnormal retention of the iron isotope in erythrocytes after 10 to 14 days. Other features of ineffective erythropoiesis may be variably present: a mild increase in bilirubin concentration, decrease in haptoglobin levels, mild increase in lactate dehydrogenase levels, and normal or slight increase in reticulocyte numbers. The magnitude of iron overload correlates poorly with the degree of anemia in patients who are not transfused. The degree of ineffective erythropoiesis is a better predictor of the amount of iron overload. When ferrokinetics are unavailable, the extent of erythroid hyperplasia relative to normal acts as a rough measure of the magnitude of ineffective erythropoiesis. Several studies have shown that the relative increase in erythroid activity multiplied by the patient's age shows a good correlation with the degree of iron overload as measured by plasma ferritin.[137,138] The iron overload does not result from mutations in the *HFE* gene[139] (see box on Therapy for Hereditary Sideroblastic Anemia).

Differential Diagnosis

Hereditary sideroblastic anemia should be distinguished from idiopathic hemochromatosis, because both have biochemical evidence of iron overload and a similar tissue pattern of iron deposition. Careful hematologic assessment of patient and family members should make the distinction, because the hemoglobin level and MCV are normal in idiopathic hemochromatosis.

Acquired Idiopathic Sideroblastic Anemia

Acquired sideroblastic anemia may be idiopathic or occur after chemotherapy or irradiation (see Table 38–5). The clonal nature of hemopoiesis in this condition was first suggested by Dacie and col-

Therapy for Hereditary Sideroblastic Anemia

A trial of pyridoxine (100 to 200 mg/day taken orally) is indicated for 3 months for all patients with hereditary sideroblastic anemia. Response is variable and ranges from complete correction of hemoglobin levels to no effect. Even when pyridoxine completely corrects the anemia (Fig. 38–10), the increase in MCV may not reach normal values, and a population of hypochromic, microcytic cells remains.

About 25% to 50% of patients with hereditary sideroblastic anemia show a full or partial response to pyridoxine, and this vitamin should be continued on a lifelong basis in the responders. A lower maintenance dose should be determined for each responding patient by progressive dose reduction, because long-term therapy with pyridoxine at 100 to 200 mg/day has been associated with peripheral neuropathy.[140] The adult nutritional requirement for pyridoxine is 1 to 2 mg/day; some patients have been maintained on as little as 4 mg/day as a supplement.[125] Folic acid supplements should also be administered because the erythroid hyperplasia increases demand for this vitamin.

There is one report of successful allogeneic peripheral blood stem cell transplantation in a 19-year-old man with transfusion-dependent hereditary sideroblastic anemia.[141] Transfusions are the mainstay of treatment for severe anemia unresponsive to pyridoxine. Regular administration of packed red cells using white blood cell filters are given to relieve symptoms and permit normal childhood development. Iron overload and secondary hemosiderosis rapidly progress after transfusions begin; chelation therapy with desferrioxamine or oral deferasirox should be initiated from the onset.

Iron removal may be of great benefit for patients who have mild or moderate anemia and evidence of iron overload.[137,138] These patients can often tolerate intermittent phlebotomy, which is preferable to chelation therapy for iron removal, and should be continued to reduce ferritin levels to less than 300 ng/mL. All patients with iron overload should avoid ingestion of ascorbic acid supplements, which enhance iron absorption and increase the tissue toxicity of elemental iron. Alcohol should also be avoided. Splenectomy is contraindicated in this disease.

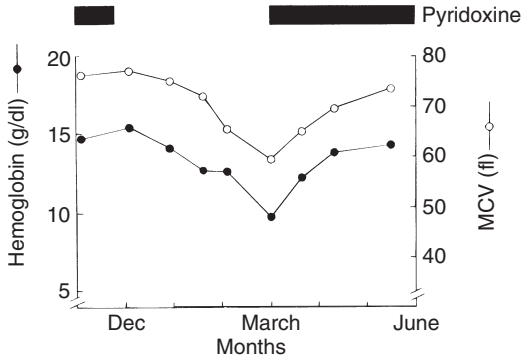

Figure 38–10 Response of the hemoglobin concentration and mean corpuscular volume (MCV) to withdrawal and reinstitution of pyridoxine in a patient with responsive hereditary sideroblastic anemia.

leagues.[122] Nearly all cases show evidence of dyserythropoiesis in the marrow, and there may also be dysplastic changes in the myeloid precursors or megakaryocytes, or both. Acquired idiopathic sideroblastic anemia falls within the diagnostic category of refractory anemia with ring sideroblasts as defined by the French-American-British group.[142] Acquired sideroblastic anemia has also been a rare finding in myeloproliferative disorders such as idiopathic myelofibrosis or essential thrombocythemia. Distinguishing between idiopathic myelofibrosis and myelodysplasia is sometimes difficult, and there is increasing recognition for an overlap or transitional entity, myelodysplasia/myeloproliferative disease, unclassifiable.[143,144] Thus many patients with refractory anemia with ring sideroblasts and thrombocytosis have a point mutation in the Janus Kinase 2 gene (changing valine-617 to phenylalanine), which is a feature usually associated with the myeloproliferative disorders.[145] This latter group have a clinical phenotype which includes normal MCV, marrow fibrosis, and splenomegaly (See Chapters—37 and 67).[145]

Biologic and Molecular Aspects

Clonal hematopoiesis has been demonstrated in acquired idiopathic sideroblastic anemia and in the related myelodysplastic syndromes. Specific evidence was first provided by finding a single G6PD isoenzyme in erythrocytes, granulocytes, platelets, and B lymphocytes in a woman who was heterozygous for G6PD and carried two isoenzymes in her skin and T lymphocytes.[146] This technique is applicable only to the few women who have G6PD heterozygosity, but restriction fragment length polymorphism analysis can be applied to most women using probes directed at other X-chromosome genes such as that for phosphoglycerate kinase or to an X-linked, variable-copy-number tandem repeat sequence (see Chapter 1).[147] The results show uniform monoclonality of hematopoiesis in acquired sideroblastic anemia with or without associated myelodysplastic features. Initial reports of low levels of ALAS in bone marrow of acquired idiopathic sideroblastic anemia have not been confirmed, and the cause of the defective heme synthesis in the abnormal clone is unclear. Some indirect evidence exists for a primary mitochondrial lesion, perhaps in the mitochondrial respiratory chain, which impairs the reduction of Fe^{3+} because Fe^{2+} is essential for heme synthesis.[148–150]

Etiology

Clonal chromosomal changes are found in bone marrow cells in approximately 60% of patients with acquired sideroblastic anemia. Characteristic changes are monosomy 7; trisomy 8; deletions involving chromosomes 5, 7, 11, or 20; and a number of balanced translocations.[151] When sideroblastic anemia is acquired after chemotherapy or irradiation, chromosomal changes are usually found and tend to be multiple.[151] Among these changes, the loss of an entire chromosome (5 or 7, or both), deletion of a long arm [del(5), del(7), or del(13)], and an unbalanced translocation are typical.[152,153] When karyotype shows loss of material from chromosomes 5 or 7, or both, a detailed occupational history may show exposure to potentially mutagenic chemical agents in a proportion of patients.[154] However, the development of visible chromosomal changes is probably a late event in acquired sideroblastic anemia and may be preceded by the expansion of a clone of genetically unstable stem cells. This concept is in accord with the view that multiple genetic events underlie the pathogenesis of other myelodysplastic syndromes and acute myeloid leukemia[146,155](see box on Clinical and Laboratory Evaluation of Sideroblastic Anemia).

Differential Diagnosis

Ring sideroblasts are not limited to acquired sideroblastic anemia; they also occur in other myelodysplastic conditions, such as refractory anemia with excess blasts, in which the blast count is higher than 5%.[156] Careful examination of peripheral blood and bone marrow can distinguish acquired idiopathic sideroblastic anemia from these related myelodysplastic conditions. Family surveys are very useful in distinguishing acquired from hereditary forms of sideroblastic anemia, because the latter may present in late adult life.

Clinical and Laboratory Evaluation of Sideroblastic Anemia

Typically, sideroblastic anemia develops insidiously in a middle-aged or elderly patient with normal or increased MCV and a blood smear showing a population of hypochromic red cells. Hepatosplenomegaly may be present. Leukocyte and platelet counts are usually normal, but some patients have thrombocytosis that occasionally exceeds 1000×10^9/L.[157] If leukopenia or thrombocytopenia is present, a careful search should be made for myelodysplastic features, which lead to the more descriptive term of *refractory cytopenia* for the condition.[158,159] An iron stain of the bone marrow aspirate shows ring sideroblasts, which should total more than 15% of all erythroblasts to make the diagnosis of acquired sideroblastic anemia.[142,159–161] Iron cannot be assessed in the marrow trephine biopsy core because it may leach out during decalcification.

The bone marrow also shows erythroid hyperplasia. Although mild dyserythropoiesis (eg, multinuclearity, nuclear budding) and megaloblastoid changes are present, myelopoiesis and megakaryopoiesis are usually normal. When changes are confined to dyserythropoiesis, the condition has been called *pure sideroblastic anemia*.[159,162] However, dysplasia of myelopoietic and megakaryopoietic elements may be present (ie, trilineage dysplasia) with the following features: Pelger-Huët–like anomaly, hypersegmentation or hypogranularity of neutrophils, micromegakaryocytes, large mononuclear megakaryocytes, and megakaryocytes with multiple small nuclei (see Chapter 67).[159] Dysmegakaryopoiesis is more easily detected in trephine biopsies than in marrow smears, although the trephine may also show unsuspected islands of myeloblasts characteristic of myelodysplasia.[163] The overall blast count in marrow smears is, by definition, less than 5%, and the peripheral blood monocyte count is less than 1.0×10^9/L. Cytogenetic analysis of marrow aspirates provides important information, because a normal karyotype predicts long survival in any type of acquired sideroblastic anemia.[164]

Prognosis

Acquired idiopathic sideroblastic anemia and the related entity of refractory anemia have the most favorable outlook among the myelodysplastic syndromes, with a median survival of 42 to 76 months and 3% to 12% incidence of leukemic progression in different series.[151,165,166] The prognosis can be correlated with three factors. First is the severity of the anemia, because repeated transfusions markedly increase iron overload and invariably lead to the organ dysfunction characteristic of secondary hemosiderosis (eg, heart and liver failure, diabetes). The second factor is whether neutropenia and thrombocytopenia are associated with the anemia. These cytopenias form the basis of a simple prognostic scoring system in which two or more of the following place the patient in a poor prognostic category: hemoglobin level less than 10 g/dL, neutrophil count less than 2.5×10^9/L, platelet count less than 100×10^9/L, and blasts more than 5% of the total.[165,166] Thirdly, karyotypic analysis of marrow aspirates provides valuable information, because a normal karyotype carries a more favorable prognosis. Conversely, monosomy 7 or a partial loss of the long arm of chromosome 7 as a single defect imparts a high probability of transformation to acute myeloid leukemia. Multiple chromosomal abnormalities and del(20q) are also associated with an increased risk of progression to leukemia; in contrast, trisomy 8 has no adverse prognostic significance.[151] Evolution of acquired idiopathic sideroblastic anemia to other myelodysplastic conditions, such as refractory anemia with excess blasts, has been described[167] (see box on Therapy for Acquired Sideroblastic Anemia).

Therapy for Acquired Sideroblastic Anemia

Transfusions are indicated for relief of symptomatic anemia. A trial of pyridoxine at 100 to 200 mg/day for 3 months is worthwhile in patients who have anemia but who do not display neutropenia or thrombocytopenia. However, few patients with acquired idiopathic sideroblastic anemia respond to this vitamin. If any response is achieved, maintenance therapy with pyridoxine at lower dosage is indicated. Cyclosporin (5 to 6 mg/kg/day) has been reported to benefit the anemia of the closely related myelodysplastic condition of refractory anemia, although the response appeared limited to those with hypoplastic bone marrows.[168]

SIDEROBLASTIC ANEMIA AND PORPHYRINURIA CAUSED BY DRUGS

Alcohol

Ring sideroblasts may be found in the bone marrow of malnourished anemic alcoholics, usually in the presence of associated folate deficiency.[169–171] In contrast, binge drinking or chronic alcohol ingestion in subjects with good nutrition is not associated with sideroblastic abnormality. Sideroblastic change is never the sole cause for the anemia of alcoholism. Alcohol has a direct toxic effect on hematopoiesis.[172] An increased or high-normal MCV and vacuolation of red blood cell precursors is often seen in addition to the ring sideroblast abnormality. Red blood cells show dimorphic morphology; evidence in the marrow of folate deficiency is present in half of cases.[172] Transferrin saturation and marrow iron stores tend to be increased but may be low if gastrointestinal bleeding is present. The ring sideroblasts gradually disappear over 4 to 12 days when alcohol is withdrawn[171]; during this period, there may be a rebound erythroid hyperplasia, reticulocytosis, and thrombocytosis. Folic acid should be given for the associated megaloblastic changes after blood is taken for vitamin B_{12} and folate assays.

Alcohol consumption lowers the plasma concentration of pyridoxal phosphate, a cofactor for ALAS, needed in the first step in heme synthesis.[173] Conversion of ethanol to acetaldehyde is necessary for this effect, and acetaldehyde acts by accelerating the degradation of intracellular pyridoxal phosphate in the liver, lowering plasma levels of this coenzyme.[174]

Chronic alcoholics have an altered heme metabolism with increased urinary excretion of coproporphyrin, mainly isomer 3, but normal urinary excretion of uroporphyrin, ALA, and porphobilinogen. Acute and chronic ethanol ingestion markedly depresses the activity of ALA dehydratase in peripheral blood. Ethanol administration to normal subjects results in increased activity of leukocyte ALAS and erythrocyte PBGD, the two rate-controlling enzymes of the pathway. The activities of each of the other four enzymes are depressed. Ferrochelatase, the enzyme that inserts iron into protoporphyrin to form heme, shows the most marked depression, and in alcoholism there is prolonged depression of uroporphyrinogen decarboxylase, which provides a rationale for the role of ethanol in the etiology of porphyria cutanea tarda.[175,176] As above, ethanol is a major precipitating factor in acute porphyria.[177]

Isoniazid

Administration of the antituberculous drug isoniazid occasionally has been associated with development of a sideroblastic anemia after 1 to 10 months of therapy. The anemia is hypochromic and microcytic, with a dimorphic blood smear and ring sideroblasts in the marrow. This complication is thought to occur only in slow acetylators of isoniazid, allowing this drug to react nonenzymatically with pyridoxal and to form a hydrazone that is rapidly excreted in the urine. The

anemia can be fully reversed by coadministration of pyridoxine (25 to 50 mg/day) with isoniazid or by withdrawing isoniazid.[178]

Chloramphenicol

Chloramphenicol is an antibiotic that produces a reversible suppression of erythropoiesis after several days of therapy (plasma levels of 10–15 μg/mL). This effect is predictable and separate from the rare idiosyncratic side effect of aplastic anemia in approximately 1 of 20,000 exposed persons. Nearly all patients given chloramphenicol (>2 g/day) develop vacuolation of the erythroid precursors and ring sideroblasts. These effects are thought to arise from suppression of mitochondrial respiration. Chloramphenicol inhibits mitochondrial protein synthesis and reduces cytochrome $a + a_3$ and b levels.[179] Serum iron concentrations are increased, and reticulocyte numbers are subnormal; these changes revert on stopping the antibiotic.

Other Drugs

A reversible acquired sideroblastic anemia has been described with penicillamine therapy and with the use of triethylene tetramine hydrochloride, a copper-chelating agent used in the treatment of Wilson disease.[180] Acquired sideroblastic anemia has also been precipitated by progesterone given to a patient on two separate occasions 15 years apart, and this anemia promptly reversed on withdrawal of the drug.[181]

Presentations Associated with Sideroblastic Anemia or Porphyrinuria

Mitochondrial Myopathy and Sideroblastic Anemia (Pearson Syndrome)

Pearson syndrome is a rare entity that manifests in early infancy with anemia and exocrine pancreatic dysfunction. The anemia is normocytic or macrocytic, reticulocyte counts are low, and variable degrees of neutropenia and thrombocytopenia are present. The bone marrow shows a striking vacuolation and ring sideroblasts.[182] Although usually fatal, milder forms of the anemia are consistent with survival into adult life. The syndrome, which is related to the Kearns-Sayre syndrome, is thought to result from deletions, mutations, or duplications of mitochondrial DNA, variably affecting multiple tissues of the body.[183,184] A missense mutation of mitochondrial DNA (in the PUS1 gene coding for pseudouridine synthase) has been associated with mitochondrial myopathy and sideroblastic anemia.[185]

Copper Deficiency or Zinc Overload

The copper content of a Western diet averages 0.9 to 1.6 mg each day, which is only a few times greater than the amount needed to maintain homeostasis of this essential element.[186] Copper deficiency has been described in malnourished premature infants,[187] in patients receiving long-term parenteral or enteral hyperalimentation,[188] after gastrectomy,[189] with copper-chelating agents,[180] or on an idiopathic basis.[190] The syndrome of copper deficiency consists of sideroblastic anemia with hypochromic cells in the blood smear, accompanied by ring sideroblasts and vacuolated erythroid and myeloid precursors in the marrow, and of neutropenia with an absence of late myeloid forms in the marrow. In some reports, patients present with neurologic symptoms such as paresthesias, weakness, or ataxia; and demyelination is seen on the magnetic resonance image of the brain.[190] In infants, additional features may be seen, such as osteoporosis and long bone changes, depigmentation of skin and hair, and central nervous system abnormalities. The platelet counts remain normal. Serum copper and ceruloplasmin levels are low, whereas serum iron and transferrin saturation levels are normal. The serum zinc concentration may be increased.[190] Prompt reversal of the hematologic changes follows therapy with 2 to 5 mg per day of copper sulfate taken orally or 100 to 500 μg per day of copper supplement to the intravenous alimentation formula.

Large quantities of ingested zinc interfere with copper absorption and produce the neutropenia and sideroblastic anemia characteristic of copper deficiency.[191] Zinc sulfate is freely available from health food stores, and as little as 450 mg per day for 2 years is sufficient for this effect. Sideroblastic anemia has also been ascribed to zinc toxicity arising from the ingestion of coins over a period of many years.[192] Serum zinc levels are high, whereas serum copper and ceruloplasmin levels are low. Zinc must be discontinued for 9 to 12 weeks for full reversal of the anemia and neutropenia.

Iron-Deficiency Anemia

In iron-deficiency anemia, there is an accumulation of protoporphyrin in erythrocytes that rarely reaches the level found in EPP. The zinc complex of protoporphyrin is produced, because ferrochelatase uses Zn^{2+} during iron-deficient erythropoiesis.[193] Erythrocyte protoporphyrin may be raised before changes appear in peripheral blood and may be helpful in diagnosing iron deficiency when serum iron and ferritin levels are rising as a result of patients having started iron therapy. In iron-deficient erythropoiesis, erythroid ALAS activity is reduced below normal.[194]

Hypothermia

Thrombocytopenia, erythroid hypoplasia, and ring sideroblasts have been described in patients with hypothermia associated with neurologic disease.[195] These changes reverse slowly as body temperature returns to normal.

Thiamine-Responsive Megaloblastic Anemia

A triad of megaloblastic anemia with ring sideroblasts, diabetes mellitus, and progressive neural deafness has been described as a rare autosomal recessive disorder.[196] The anemia responds to high doses of thiamine and is thought to result from a defect in the cell-membrane transporter for thiamine.[197]

Other Conditions

In hereditary tyrosinemia, excess urinary ALA is excreted because ALA dehydratase is inhibited by succinyl acetone. Like acute porphyria and lead poisoning, this disease is associated with neurobehavioral disturbance (see box on Lead Poisoning). In liver disease, there may be increased urinary excretion of coproporphyrin, predominantly isomer I.[10] In the Dubin-Johnson syndrome, the ratio of coproporphyrin isomer I to isomer 3 is markedly increased in the urine (>80%), possibly as a result of deficiency of hepatic uroporphyrinogen III cosynthase and increased activity of PBGD. In Rotor syndrome, total urinary excretion of coproporphyrin is markedly increased and consists predominantly of coproporphyrin isomer I. In the unconjugated hyperbilirubinemia of Gilbert syndrome, depressed activity of protoporphyrinogen oxidase and increased activity of ALAS has been found in peripheral leukocytes.[198]

Environmental Intolerances

It has been hypothesized that several otherwise-unexplained chemical-associated illnesses, such as multiple chemical sensitivity (MCS) syndrome, may represent mild chronic cases of porphyria or other acquired abnormalities in heme synthesis. However, evidence for this concept is lacking.[200,201]

Lead Poisoning

It has been known for some time that patients suffering from lead poisoning have an accumulation of protoporphyrin in erythrocytes and increased urinary excretion of ALA and coproporphyrin.[199] There are sex-related differences in the porphyrin synthetic response to lead, with females showing a more profound coproporphyrinuria than men.[200] The elevated protoporphyrin chelated by zinc is retained in the erythrocyte, which may explain the absence of photosensitivity. This accumulation of porphyrins and precursors is caused by the inhibition by lead of the heme biosynthetic enzymes: ALA dehydratase, coproporphyrinogen oxidase, and ferrochelatase. An increase in the activity of the rate-controlling enzyme ALAS results.

Many of the clinical manifestations of lead poisoning may be the result of altered heme biosynthesis.[58] A mild to moderate anemia that can be hypochromic and microcytic occurs in a minority of patients, whereas basophilic stippling is prominent due to inhibition of pyrimidine 5′- nucleotidase in the maturing reticulocyte. Ring sideroblasts have not been reported. The abdominal pain, constipation, and peripheral neuropathy that occur in lead poisoning are also seen in acute attacks of hepatic porphyria. Neuropathy, seen in lead poisoning, may also be the result of disorders of heme biosynthesis, as in the porphyrias.[199] Alterations in porphyrin metabolism have provided a useful means of detecting and assessing the severity of lead exposure and poisoning. The diminution in activity of erythrocyte ALA dehydratase and elevated erythrocyte protoporphyrin levels are the most sensitive measures.

CHAPTER 39

MEGALOBLASTIC ANEMIAS

Aśok C. Antony

GENERAL CONCEPTS

The term *megaloblastic anemia* is used to describe a group of disorders characterized by a distinct morphologic pattern in hematopoietic cells. A common biochemical feature is a defect in DNA synthesis, with lesser alterations in RNA and protein synthesis, leading to a state of unbalanced cell growth and impaired cell division. Most megaloblastic cells are not resting but vainly engaged in attempting to double their DNA, with frequent arrests in the S phase and lesser degrees of arrest in other phases of the cell cycle. An increased percentage of these cells have DNA values between 2*N* (*N* = amount of DNA in the haploid genome) and 4*N* because of delayed cell division. This increased DNA content in megaloblastic cells is morphologically expressed as larger than normal "immature" nuclei with fine particulate chromatin, whereas the relatively unimpaired RNA and protein synthesis results in large cells with greater "mature" cytoplasm and cell volume. The net result of megaloblastosis is a cell whose nuclear maturation is arrested (immature) while its cytoplasmic maturation proceeds normally independently of the nuclear events. The microscopic appearance of this nuclear–cytoplasmic asynchrony (or dissociation) is morphologically described as megaloblastic. Each cell lineage has a limited but unique repertoire of expression of defective DNA synthesis. This is significantly influenced by the normal patterns of maturation of the affected cell line. Additional variables that affect RNA and protein synthesis can lead to the attenuation or modification of megaloblastic expression (see Masked Megaloblastosis).

Megaloblastic hematopoiesis commonly manifests as anemia, but this feature is only a manifestation of a more global defect in DNA synthesis that affects all proliferating cells. The peripheral blood picture is characteristic and reflective of megaloblastic hematopoiesis within the bone marrow. The diagnosis is therefore usually straightforward, but because any condition that specifically perturbs DNA synthesis may lead to megaloblastosis, determination of the precise cause is necessary before institution of therapy. Inappropriate therapy can lead to disastrous consequences for the patient. The biochemical basis for megaloblastosis needs to be understood within the context of evaluation of potential and real variables affecting DNA, RNA, and protein synthesis in a given patient. The most common causes of megaloblastosis are true cellular deficiencies of vitamin B_{12} (cobalamin) or folate, vitamins that are essential for DNA synthesis. The pathophysiology of cellular deficiency is most readily discerned by the clinician who approaches megaloblastosis with a clear understanding of the physiology of these vitamins. A detailed discussion of cobalamin and folate therefore follows.

COBALAMIN

The term *cobalamin* refers to a family of compounds with the structure shown in Fig. 39–1; cobalamin itself lacks a ligand in the cobalt beta-position. Vitamin B_{12} is called *cyanocobalamin* because when it was originally isolated from the liver, this position was occupied by a cyano group (an artifact generated in vitro). Details of the chemistry, nomenclature, and in vivo substitutions of cobalamin are shown in Figs. 39–1 to 39–3, and excellent reviews are available on the history, chemistry, and biology of cobalamin.[1,2] Cobalamin is synthesized and used by some microorganisms (eg, bacteria, fungi). Some strains produce cobalamin in excess of their requirements, making them excellent and cheap commercial sources for cobalamin used in therapy. Cobalamin analogs with cobalamin-like or anticobalamin-like effects are produced by microbes through purely chemical interactions of cobalamin in nature or as by-products of cobalamin metabolism in vivo.[2]

Nutrition

Cobalamin is only produced in nature by cobalamin-producing microorganisms, and humans receive cobalamin solely from the diet.[3] Although cobalamin is produced by bacteria in the large bowel of humans, this is at a site that is too distal for physiologic cobalamin absorption. Herbivores obtain their dietary quota of cobalamin from plants contaminated with cobalamin-producing bacteria that grow in the roots and nodules of legumes. Exogenous contamination of plants by feces (eg, manure used in fertilization) may also be a source of cobalamin, so in theory organically grown leafy vegetables may have higher cobalamin than those exposed to nonorganic (chemical) fertilizers. Moreover, insecticides could render such vegetables free of minute insects that could otherwise be inadvertently consumed and be a contributory source of cobalamin.[4] Lower animals receive their cobalamin by eating insects and other animals and by coprophagy, and the ingested cobalamin is then used for cobalamin-dependent reactions in muscular and parenchymal tissues that are then consumed by higher animals.

Animal protein is the major dietary source of cobalamin for nonvegetarians. Meats from parenchymal organs are richest in cobalamin (>10 μg cobalamin per 100 g wet weight); fish and animal muscle, milk products, and egg yolks have 1 to 10 μg per 100 g of wet weight. An average nonvegetarian Western diet contains 5 to 7 μg of cobalamin per day, which adequately sustains normal cobalamin equilibrium. A vegetarian diet supplies between 0.25 and 0.5 μg cobalamin daily, so most vegetarians do not receive adequate dietary cobalamin and are at risk for cobalamin deficiency.[5] The recommended daily allowance is 2.4 μg for men and nonpregnant women, 2.6 μg for pregnant women, 2.8 μg for lactating women, and 1.5 to 2 μg for children 9 to 18 years old.[4]

Although food cobalamin is stable at high-temperature cooking processes, it can readily be converted to inactive cobalamin analogs by ascorbic acid. Cobalamin is exceptionally well stored in tissues in its coenzyme forms. Of the total-body content of 2 to 5 mg in adults, approximately 1 mg is in the liver. There is an obligatory loss of 0.1% per day (1.3 μg) regardless of total-body cobalamin content. It takes approximately 3 to 4 years to deplete cobalamin stores when dietary cobalamin is abruptly malabsorbed, but it may take longer to develop nutritional cobalamin deficiency, because of an efficient enterohepatic circulation, which accounts for the turnover of 5 to 10 μg/day of cobalamin.[1]

Absorption

Cobalamin in food is usually in coenzyme form (5′-deoxyadenosyl cobalamin [adenosylcobalamin] and methylcobalamin), nonspecifically

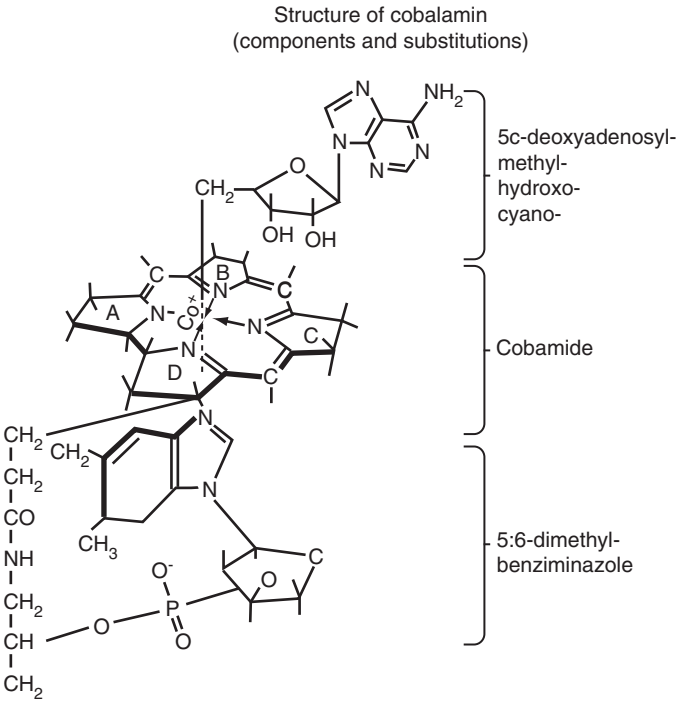

Figure 39–1 Cobalamin chemistry and nomenclature. Vitamin B_{12} (ie, cyanocobalamin) is a complex molecule consisting of two major portions. A planar group consisting of four reduced pyrrole rings (ie, the corrin nucleus) is attached at right angles to an unusual nucleotide. Three of the four reduced pyrrole rings (designated A to D) are connected to one another by methylene carbon bridges; the alpha-carbons of rings A and D are, however, directly linked. The pyrrole rings are linked to a central cobalt atom. One coordinate position of cobalt (above the plane of the corrin nucleus) occupied by CN in cyanocobalamin can be occupied by various anionic group ligands (–R) in vitro and in vivo. Substitution at this position forms the basis for the specificity of the molecule as a coenzyme in vivo. The second coordination position of the central cobalt atom (below the plane of the corrin nucleus and almost perpendicular to it) is a linkage with the glyoxalinium nitrogen atom of the imidazole ring of the nucleotide. The nucleotide consists of a base, 5,6-dimethylbenziminazole, attached to ribose phosphate by alpha-glycoside linkages. The ribose is phosphorylated at C3; the nucleotide is connected to ring D of the corrin nucleus through an ester linkage. Compounds containing a corrin nucleus are given the generic name *corrinoid*. The addition of cobalt to the corrin nucleus containing standard side chains gives rise to cobyrinic acid. Additional substitutions in terminal carboxyl groups or modified carboxyl groups (designated *a* to *g*) give rise to various compounds such as cobamic acid, cobinic acid, cobinamide, and cobamide. Cobamide is found in vitamin B_{12}, whose systematic name is therefore alpha-(5,6-dimethylbenziminazolyl)cobamide cyanide (Adapted from Chanarin I: The Megaloblastic Anemias. Oxford, UK, Blackwell Scientific Publications, 1979.)

bound to proteins (see Fig. 39–2). In the stomach, peptic digestion at low pH is a prerequisite for cobalamin release from food protein.[1] This is of clinical significance in the 70- to 80-year-old population among whom hypochlorhydria is frequently present (in 25% to 50%) leading to inadequate release of protein-bound cobalamin by proteolysis with pepsin (because pepsin requires a low pH for optimum activity); these individuals can therefore develop cobalamin deficiency, resulting in what is known as food-cobalamin malabsorption. Although they can absorb crystalline cobalamin well, such individuals exhibit abnormalities in absorption when crystalline cobalamin is bound to proteins before ingestion (in the research setting).[2]

Once released by proteolysis, cobalamin preferentially binds a high-affinity, 150-kd, cobalamin-binding protein called R protein (also called haptocorrin) from gastric juice and saliva that has higher affinity for cobalamin than the gastric intrinsic factor (IF). The cobalamin–R protein (holo-R protein) complex, along with excess unbound (apo)-R protein and IF, passes through into the second part of the duodenum where pancreatic proteases degrade holo-R and apo-R proteins (but not IF). This results in the transfer of cobalamin to IF, a 45-kd glycoprotein with high-affinity binding ($K_a = 1.5 \times 10^{10}\ M^{-1}$), 1 : 1 molar stoichiometry, stability, and resistance to proteolysis over a pH range of 3 to 9.[1] Failure to degrade holo-R proteins by pancreatic protease precludes the involvement of IF in cobalamin absorption, because ileal IF–cobalamin receptors are specific for IF-bound cobalamin and not for R-bound cobalamin.[1] Although R proteins bind cobalamin and most cobalamin analogs with comparably high affinity, IF only binds cobalamin.

IF is produced in parietal (oxyntic) cells in the fundus and cardia of the stomach,[1] and released by membrane-associated vesicular transport.[1] IF has two binding sites: one for cobalamin and another for the ileal IF–cobalamin receptor. IF is produced in far greater excess than is actually required for absorption[1] and the IF in 2 to 4 mL of normal gastric juice is all that is necessary to reverse cobalamin deficiency in adults who lack IF. In the absence of IF, less than 2% of ingested cobalamin is absorbed, whereas in its presence approximately 70% is absorbed.

IF is secreted in response to food in the stomach in a manner analogous to secretion of acid (ie, by vagal and hormonal stimulation); IF release can be inhibited by long-term intake of H_2 blockers. Addition of proton pump inhibitors can reduce the absorption of protein-bound cobalamin, which can eventually lead to food-cobalamin malabsorption.[2] IF binds biliary cobalamin and newly ingested cobalamin following its transfer from R protein.[1,2] Because biliary cobalamin analogs are not transferred from R protein to IF, this appears to be an efficient method for fecal excretion of cobalamin analogs while allowing for reabsorption of biliary cobalamin. The stable IF–cobalamin complex passes through the jejunum to the ileum, where specific membrane-associated IF–cobalamin receptors for IF–cobalamin are located on the microvilli of the mucosal cells of the ileum.[1]

The functional IF–cobalamin receptors are composed of a complex of two proteins collectively known as cubam—composed of cubulin (encoded by the *CUBN* gene)[6] and amnionless (encoded by the *AMN* gene)[7]—that are essential to complete transport of the IF–cobalamin complex from the intestinal lumen into the enterocyte. Dysfunction of cubam is the basis for Imerslund–Gräsbeck syndrome. These IF–cobalamin receptors (cubam) require Ca^{2+} for binding at pH above 5.4; they do not bind free IF, cobalamin, or R-cobalamin and are therefore highly specific for IF–cobalamin ($K_a = 10^9\ M^{-1}$). The human ileum contains enough IF–cobalamin receptors to bind up to 1 mg of IF-bound cobalamin; this is the rate-limiting factor in cobalamin absorption.[1] Parenthetically, cubam is also responsible for the reabsorption of several vitamin carrier proteins (ranging from the transcobalamin–B_{12} complex, vitamin D–binding protein, retinol-binding protein) and a laundry list of other carrier proteins (albumin, myoglobin, hemoglobin, lactoferrin, transferrin), hormones (insulin, parathyroid) enzymes, drugs, and toxins (aminoglycosides).[8]

The events following the binding of the IF–cobalamin complex to IF–cobalamin receptors on enterocytes have not been fully delineated. Although transport into the cells requires energy, some studies suggest that the IF–cobalamin complex is first internalized by endocytosis and then released from cobalamin by lysosomal digestion, whereas others suggest that only cobalamin, but not IF, is internalized.[1] Transcobalamin II (TC II) is secreted unidirectionally across the basolateral surface and cobalamin apparently binds TC II within or at the basal surface of the ileal enterocyte.[1] Cobalamin bound to IF is transcytosed from the apical to the basal direction, and during transcytosis, a transfer to TC II is accomplished.[2] After a delay of 3 to 5 hours, cobalamin appears in the portal blood largely (>90%) bound to TC II. Although some cobalamin in the enterocyte is converted to adenosylcobalamin, most is destined for the portal blood and reaches peak levels in approximately 8 hours.[1]

Cobalamin in large doses can also passively diffuse through buccal, gastric, and jejunal mucosa so that less than 1% of a large dose of

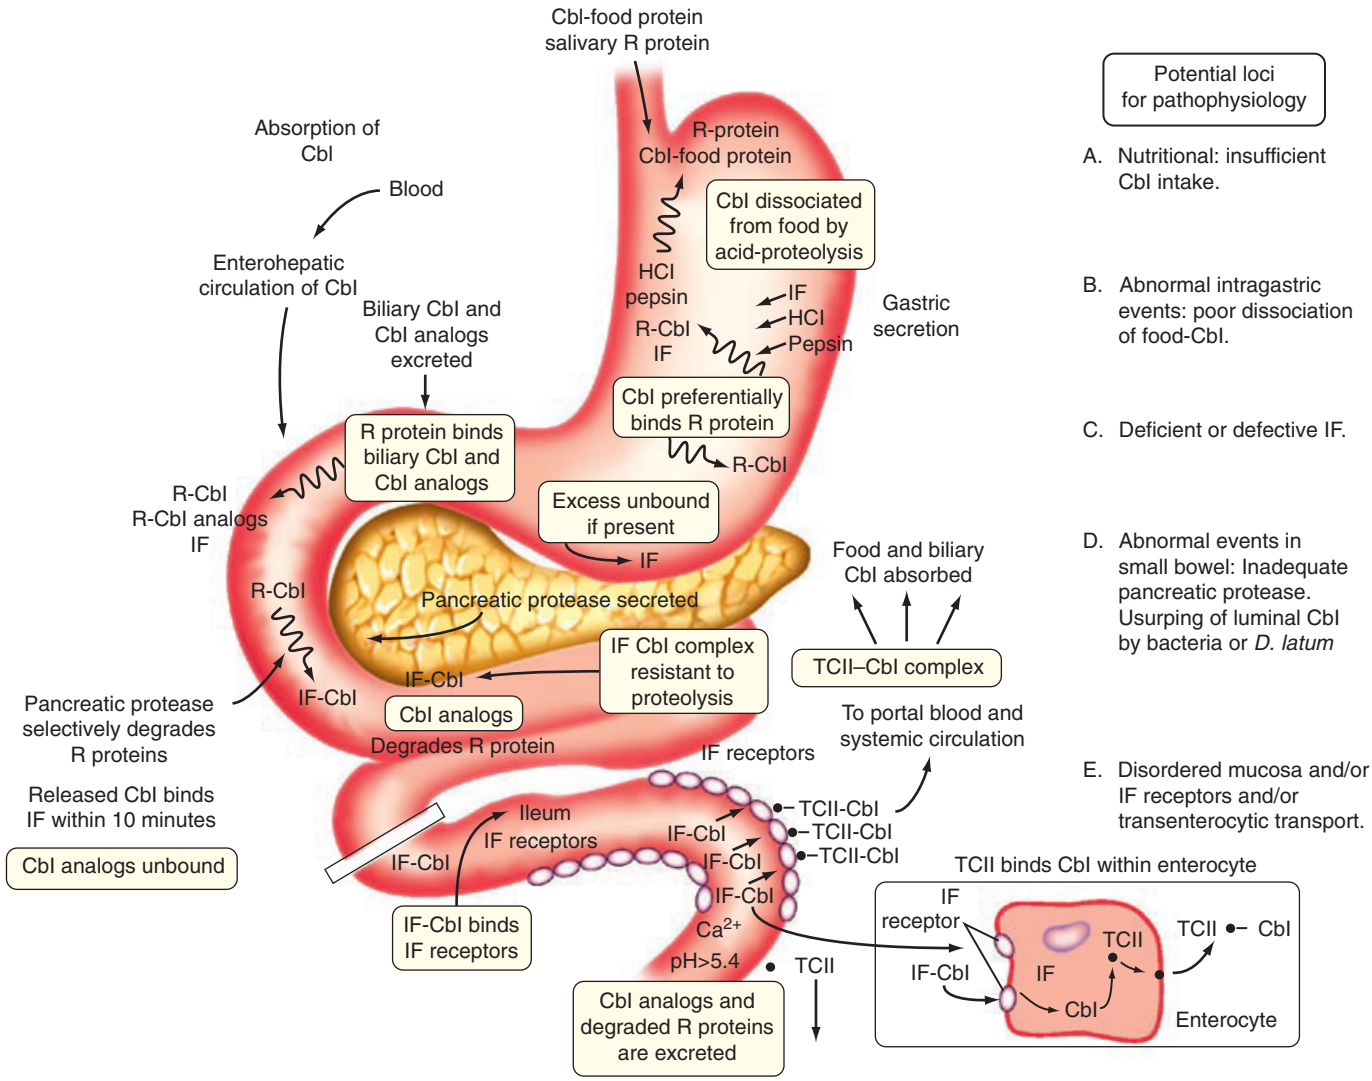

Figure 39–2 Components and mechanism of cobalamin absorption. Cbl, cobalamin; HCl, hydrochloric acid; IF, intrinsic factor; R, protein ligand; TCII, transcobalamin II.

oral cobalamin appears in the circulation within minutes. This property is used to advantage in some individuals with cobalamin malabsorption in lieu of parenteral replacement (discussed later).[1]

Transport

More than 90% of recently absorbed or injected cobalamin is bound to TC II, which is a specific transport protein for delivery of cobalamin to tissues. TC II, a 38-kd polypeptide synthesized in many tissues, binds cobalamin with 1:1 molar stoichiometry and high affinity ($K_a = 1 \times 10^{11}\ M^{-1}$).[2] Unlike IF, it can also bind a variety of cobalamin analogs (as R protein does). However, it does not belong to the R protein family and is immunologically distinct from two other plasma cobalamin-binding R proteins, TC I and TC III. The TC II–cobalamin complex is cleared so rapidly from the circulation (half-life of 6–9 minutes)[1] that 98% of TC II in plasma is unsaturated. TC II–cobalamin is rapidly bound to specific surface receptors for TC II present on several cells.[1] High-affinity TC II–cobalamin binding to TC II receptors is specific only for holo- and apo-TC II ($K_a = \sim 5 \times 10^{10}\ M^{-1}$). Because some cobalamin analogs can bind TC II with high affinity, these also have the same potential for cellular uptake as cobalamin.[1] Once bound to TC II receptors, the TC II–cobalamin complex is internalized by receptor-mediated endocytosis.[1] At the low pH extant in lysosomes, TC II dissociates from cobalamin; it is then degraded and the cobalamin is reduced and converted to coenzyme forms (see Fig. 39–3). The importance of the transport function of TC II is underscored by the fact that TC II deficiency leads to life-threatening cellular cobalamin deficiency.[1]

Cobalamin is not found free in plasma. Binding to TC II accounts for 10% to 30% of the total serum cobalamin, and most of the remaining cobalamin is bound to another R protein, TC I. TC I is not a transport protein and cobalamin-bound TC I has a slow clearance rate (half-life of 9–12 days). Despite the fact that TC I binds approximately 75% of the circulating cobalamin (present predominantly as methylcobalamin) in fasting plasma, approximately one-half of the total TC I is in apo-form.

Neither the origin nor the physiologic importance of TC I in blood has been defined. Hereditary deficiency of TC I is apparently of no clinical consequence.[1] TC I may be a plasma-storage form of cobalamin, because it accounts for less than 0.5% of total cellular cobalamin uptake. TC I and TC III are found in secondary granules of mature polymorphonuclear leukocytes (PMNs).[2] TC III appears to have a transport function, because it is cleared from plasma within 3 minutes exclusively by hepatic asialoglycoprotein receptors, a mechanism common to a variety of asialoglycoproteins whose terminal beta-galactosyl end groups are intact. Conversely, desialation of TC I results in hepatic clearance identical to that of TC III,[1] which because of its rapid clearance is predominantly unsaturated. Functionally, TC III binds a wide spectrum of cobalamin analogs that are

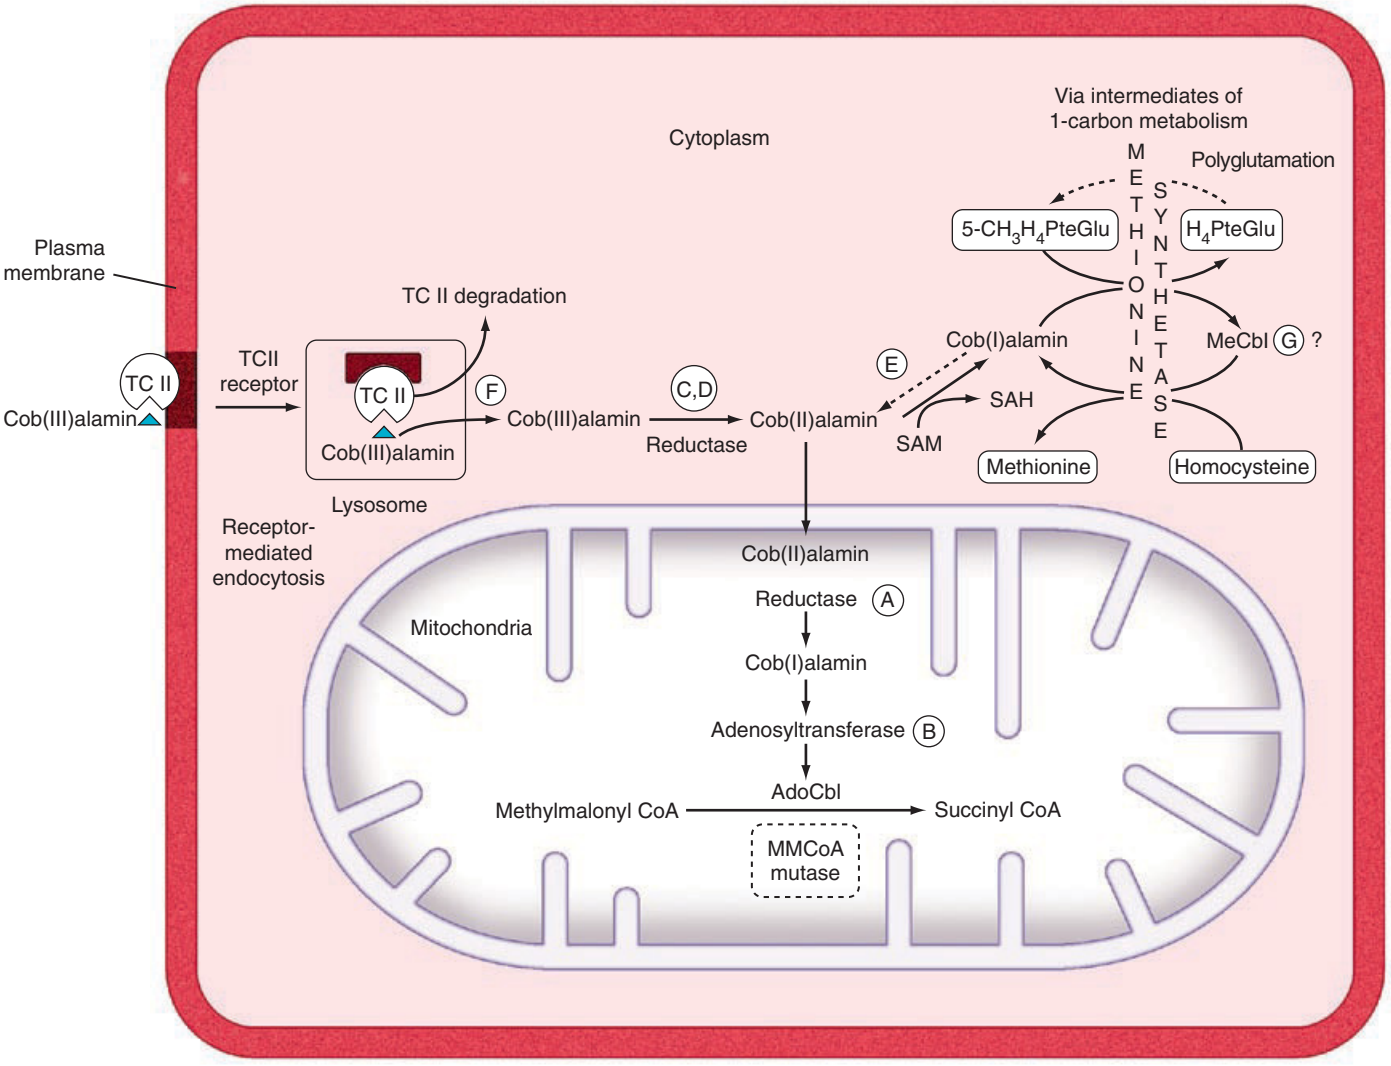

Figure 39–3 Cellular uptake and intracellular reactions involving cobalamin. A large family of natural and synthetic cobalamins can be generated when the cyanide (CN) moiety (upper axial ligand in cyanocobalamin) is replaced. On exposure to light, CN is gradually lost from cyanocobalamin, with the production of hydroxocobalamin. In vivo substitutions include the replacement of hydroxocobalamin or cyanocobalamin by a 5′-deoxyadenosyl group attached by a covalent bond, giving rise to adenosylcobalamin (AdoCbl). Methylcobalamin (MeCbl) is the main form in plasma. In vivo, 5-methyltetrahydrofolate readily donates its methyl group to cob(I)alamin in a reaction involving methionine synthase to form methylcobalamin. The loci for defects in cobalamin mutants *cblA* through *cblG* are indicated.

rapidly cleared by the liver into bile for fecal excretion. In contrast, between 0.5 and 9 μg of cobalamin taken up by hepatic TC II receptors is secreted into the bile, of which approximately 75% is reabsorbed, analogous to food cobalamin.[1]

Cellular Processing

After TC II receptor-mediated endocytosis (see Fig. 39–3) into lysosomes, the release of cobalamin by lysosomal degradation of TC II is an obligatory process for further intracellular metabolism.[1] After transport across the lysosome into the cytoplasm by a specific transport system,[2] more than 95% of intracellular cobalamin is bound to two intracellular enzymes, methylmalonyl-CoA mutase and methionine synthase.[1] Cob(III)alamin, the most "oxidized" form of cobalamin, must be converted to cob(II)alamin and cob(I)alamin by two sequential reductase steps (see Fig. 39–3).

In mitochondria, cob(I)alamin is subsequently converted to its coenzyme form adenosylcobalamin, which acts as a coenzyme in the intramolecular exchange of a hydrogen atom attached to one carbon atom with a group attached to an adjacent carbon atom. Methylmalonyl-CoA mutase in the presence of adenosylcobalamin converts methylmalonyl-CoA to succinyl-CoA, thereby converting the products of propionate metabolism (ie, methylmalonyl-CoA) into easily metabolized products. In the cytoplasm, cobalamin, as methylcobalamin, functions as a coenzyme for the reaction involving methionine synthase, which catalyzes the transfer of methyl groups from methylcobalamin to homocysteine to form methionine.[2] In this process methylcobalamin is converted to cob(I)alamin. The methyl group of 5-methyl-tetrahydrofolate (5-methyl-H_4PteGlu) is donated to cob(I)alamin, regenerating methylcobalamin, and 5-methyl-H_4PteGlu is converted to tetrahydrofolate (H_4PteGlu). Thus, folates and cobalamin are required together for normal one-carbon metabolism. After methionine is formed, it can get adenylated to *S*-adenosyl-methionine that can, in turn, donate its methyl group in a critical series of biologic methylation reactions involving more than 80 proteins, phospholipids, neurotransmitters, RNA and DNA. Methionine synthase also catalyzes the conversion of *S*-adenosyl-methionine to *S*-adenosyl-homocysteine, during which process the methyl group of *S*-adenosyl-methionine may also be used for remethylation of cob(I)alamin. Spontaneous oxidation of cob(I)alamin to the catalytically inactive cob(II)alamin form requires reduction back to

cob(I)alamin before it can accept a methyl group because the cobalt atom in methylcobalamin has a 1+ valence. There is a redox regulator known as *methionine synthase reductase* that restores enzyme activity in the presence of *S*-adenosyl-methionine and NADPH.[9] This enzyme is clinically significant in that mothers with a polymorphism in methionine synthase reductase (A66G) and the common *MTHFR* (C677G) polymorphism are at increased risk of producing offspring with Down syndrome.[10] The physiologic importance of the key cofactor roles of the two forms of cobalamin, adenosylcobalamin and methylcobalamin, in methylmalonyl-CoA mutase and methionine synthase, respectively, is that the products and by-products of these enzymatic reactions are critical for DNA, RNA, and protein biosynthesis (discussed later).

Methionine synthase is a modular protein with four distinct and separate regions for binding homocysteine, 5-methyl-tetrahydrofolate (5-methyl-H_4PteGlu), the cobalamin prosthetic group, and *S*-adenosyl-methionine.[2] This explains how this enzyme plays a central role in catalyzing the transfer of a methyl group from bound methylcobalamin to homocysteine, yielding enzyme-bound cob(I)alamin and methionine, after which the free cofactor, cob(I)alamin, is remethylated by the methyl group from 5-methyl-H_4PteGlu, thereby completing the cycle (see Fig. 39–3).

Renal conservation of cobalamin is poorly understood. A 550-kd membrane protein called *megalin*, which interacts with cubulin and is found in renal proximal epithelial cells, functions as a multiligand receptor for a variety of macromolecules.[11] Megalin also specifically binds to and mediates the endocytosis of TC II–cobalamin complexes in kidney proximal tubules.[2]

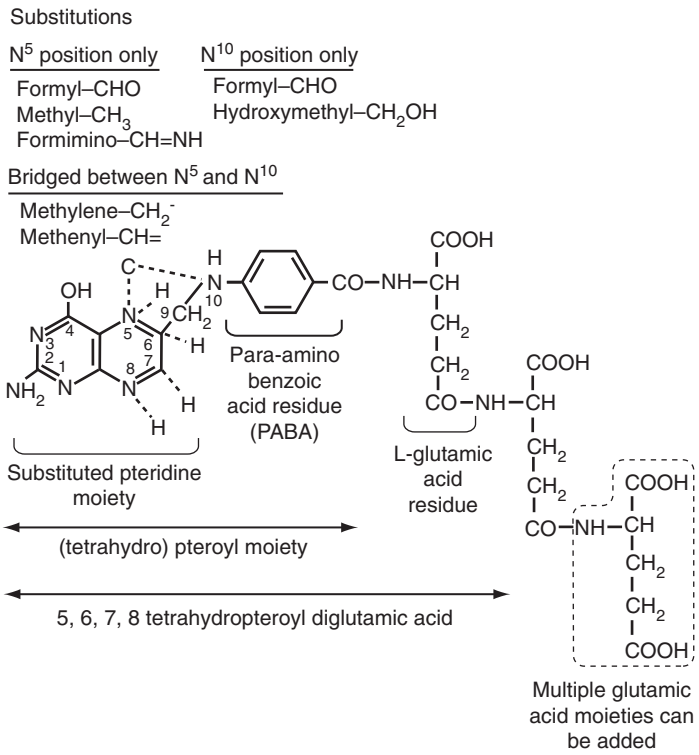

Figure 39–4 Folate chemistry and nomenclature. Folic acid (pteroylmonoglutamate [PteGlu]) is the commercially available parent compound for more than 100 compounds collectively referred to as *folates*. PteGlu consists of three basic components: a pteridine derivative, a *p*-aminobenzoic residue, and an L-glutamic acid residue. Before PteGlu can play a role as a coenzyme, it must first be reduced at positions 7 and 8 to dihydrofolic acid (H_2PteGlu) and then to 5,6,7,8-tetrahydrofolic acid (H_4PteGlu), and one to six additional glutamic acid residues must then be added by means of gamma-peptide bonds to the L-glutamate moiety (for which the subscripted *n* in PteGlu$_n$ denotes polyglutamation). Folate coenzymes donate or accept one-carbon units in numerous reactions in amino acid and nucleotide metabolism. The various substitutions in H_4PteGlu$_n$ occur at position 5 or 10, or both; position 5 can be substituted by methyl (CH_3), formyl (CHO), or formimino (CHNH), and position 10 can be substituted by formyl or hydroxymethyl (CH_2OH). Positions 5 and 10 can be bridged by methylene (–CH_2–) or methenyl (–CH=).

FOLATES

Nutrition

Folates, which are widely distributed in nature in reduced and polyglutamated forms, are synthesized by microorganisms and plants; Fig. 39–4 shows the chemistry and nomenclature, and Hoffbrand and Weir[12] provide an engaging review of the rich history of folic acid. Leafy vegetables (eg, spinach, lettuce, broccoli), beans, fruits (eg, bananas, melons, lemons), yeast, mushrooms, and animal protein (eg, liver, kidney) are rich sources of folate.[1] Folates are highly susceptible to breakdown during cooking for >15 minutes, so cultural and ethnic cooking practices that often involve prolonged boiling of lentils or beans in spices for over 30 minutes in large volumes of water,[2] or frying foods in an open pan, can result in loss of 50 to 95% of folate. In many cultures, it is also not common to eat fresh raw or stir-fried vegetables or salads that are rich in folate. Oxidation of food folate by nitrites (used in curing meats) reduces its bioavailability.[2] The recommended daily allowance of folate is as follows: adult men and nonpregnant women, 400 µg; pregnant women, 600 µg; lactating women, 500 µg; children aged 9 to 18 years, between 300 and 400 µg.[4] A balanced Western diet contains adequate amounts of folate, but the net dietary intake of folate in many developing countries is often insufficient to sustain folate balance.[1,2,13,14]

Absorption

Dietary folates, which are in the form of pteroyl*poly*glutamates (PteGlu$_n$), are absorbed less efficiently than pteroyl*mono*glutamate (PteGlu; folic acid). Although folates in some foods (eg, cabbage, lettuce, orange) are not well absorbed,[1] most other dietary folates are nutritionally available (ie, bioavailable). Pteroylpolyglutamates must be hydrolyzed to pteroylmonoglutamate derivatives before absorption by pteroylpolyglutamate hydrolase, an enzyme present in the brush border membranes of small intestinal cells.[1] This enzyme has maximal exopeptidase activity at pH 5.5 in the presence of zinc, with equal affinity for PteGlu$_n$ of different glutamate chain lengths. Luminal pteroylglutamate interacts with brush border membrane-associated reduced-folate carriers (RFCs), which exhibit rapid equilibrium binding (<5 minutes), pH dependency (pH 5 optimal), high affinity (K_d approximately 0.08 mM), and transport of reduced folates within seconds.[15,16] *RFC* gene expression (encoding a 58-kd protein) is developmentally regulated, showing higher maximum capacity for 5-methyl-H_4PteGlu influx in mature (absorptive) rather than proliferative crypt cells.[2] RFC can be upregulated in response to dietary folate deficiency in mice, which would presumably allow maximizing the transport of folate under conditions of dietary folate deficiency.[17] The simultaneous upregulation in the activity of pteroylpolyglutamate hydrolase[18] and cell surface folate receptors[17,19] allows folate-deficient luminal cells to maximize their own uptake and maintain cellular integrity under folate-deficient states. However, the key experimental studies designed to distinguish transenterocytic folate transport from the transport of folate that is only destined for the enterocyte remain to be conducted to clarify the functional basis for upregulation of these two folate transporters.

Considerable gaps still exist in our knowledge of the structure and functional interrelationships of the human intestinal folate transport carrier proteins, the precise mechanism of passage of folate within the enterocyte, and interaction with lysosomal pteroylpolyglutamate hydrolases. This 75-kd enzyme is maximally active at pH 4.5 and cleaves terminal and internal gamma-glutamate linkages with greatest affinity for PteGlu$_n$ with longer glutamate chains.[1] The basolateral

membrane also possesses a carrier-mediated system that apparently transports folate more efficiently than across brush borders, suggesting adaptation for eventual transport into portal blood.[1]

Ingested human milk, which contains specific folate-binding proteins (FBP), probably regulates the nutritional bioavailability of ingested folate in neonates.[2] Although the precise mechanism is obscure, it could involve interaction with megalin, which can bind and mediate the cellular uptake of soluble milk FBPs containing bound folate into the enterocytes.[20]

Passive diffusion of folic acid (aka pteroylglutamate, PteGlu) is probably the primary mechanism of intestinal mucosal folate absorption at high pharmacologic concentrations.[1] The small intestine has a large capacity to absorb folate, with peak folate levels in plasma achieved 1 to 2 hours after oral administration. Whereas therapeutically administered PteGlu enters the portal blood unchanged, food $PteGlu_n$ is hydrolyzed before transport into the enterocyte, where it is reduced to H_4PteGlu (tetrahydrofolate) and methylated to 5-methyl-H_4PteGlu before release into plasma.

Plasma Transport and Enterohepatic Circulation

The normal serum folate level is maintained by dietary folate and a substantial enterohepatic circulation that amounts to approximately 90 μg/day of folate.[1] Folates are rapidly cleared from plasma (up to 95% in 3 minutes) by tissues, including the liver, by an RFC-related species.[15] Biliary drainage results in a dramatic fall in serum folate (to approximately 30% of basal levels in 6 hours), and abrupt interruption of dietary folate leads to a fall in serum folate levels in approximately 3 weeks. In the plasma, one-third of the folate is free, and two-thirds is nonspecifically and loosely bound to serum proteins. A small amount of folate is specifically bound to high-affinity, intrinsically soluble hydrophilic 40-kd FBPs; the physiologic significance of this interaction is not clear.[21] In contrast to cobalamin uptake, there is no specific *serum* transport protein that enhances cellular folate uptake.

Cellular Folate Uptake

Folate transport involves translocation of the ligand into cells from the extracellular compartment (ie, cellular uptake mechanisms) or across cellular barriers from one compartment to another (ie, transcellular mechanisms).[2,21] Two distinct components are involved in cellular folate transport. The RFC is a low-affinity, high-capacity system that mediates the uptake of physiologic and other reduced folates into a variety of cells.[15] Folate transport into cells is also mediated by 44-kd membrane-associated FBPs or folate receptors (FRs) (these terms are synonymous) that bind physiologic folates (ie, serum 5-methyl-H_4PteGlu) with high affinity in the nanomolar range (ie, the range needed for binding serum folates).[21]

The pathways for entry of folates and antifolates are likely to be distinct in different cells depending on the relative efficiency of FR- and RFC-mediated mechanisms, as well as the intracellular and extracellular concentration of folates and antifolates. There are probably other determinants in some malignant human cells; for example, despite high FR expression, the RFC was the preferential carrier of antifolates in some cells.[2]

Transcellular folate transport systems are operative in placental[22] and renal tubular cells.[2] Although choroid plexus contains a significant amount of FR, their role in folate transport across the blood–brain barrier and blood–cerebrospinal fluid barrier is still unclear.[21] A third pathway for folate transport by passive diffusion[21] is also integrally involved (in concert with FR) in transplacental folate transport (discussed later).[22]

Folate Receptors

FRs mediate the cellular uptake of the physiologic folate, 5-methyl-H_4PteGlu, in several malignant and normal cells.[21,23] Of the three human FR isoforms, FR-alpha and FR-beta are attached to the cell surface through a glycosyl-phosphatidylinositol membrane anchor, whereas the third (FR-gamma) is constitutively secreted.[2]

FR transfers folate intracellularly by endocytosis by means of clathrin-coated pits[2] or by caveolae.[2] In the latter model (which is controversial),[2,21] folate is dissociated from the FR at acid pH generated within caveolae by a proton pump and is transported through a putative folate transporter into the cytoplasm, whereas apo-FRs recycle back to the surface to bind more folate (Fig. 39–5). More recent studies on this issue have been reviewed.[24] FR-alpha are expressed in most normal and many malignant epithelial tissues.[2] The expression of FR-beta in normal tissues is restricted to the placenta and hematopoietic cells.[2,25]

The FR- and RFC-mediated folate transport systems do not communicate with one another (ie, there is no cross-talk), and both RFC and FR are efficient in the transport of methotrexate and function independently of one another.[2] When enough FRs are expressed, they can mediate the uptake of methotrexate and 5-methyl-H_4PteGlu with comparable rates to cells expressing only the RFC, so FRs have physiologic and pharmacologic importance.

There is an inverse relationship between cell proliferation and FRs,[2,26] but the underlying mechanism of this relationship is still unclear. FRs are upregulated in response to extracellular and intracellular folate concentrations in some cells[2] through transcriptional, translational, or posttranslational mechanisms. Posttranslational downregulation of FRs (ie, FBPs) in rat kidney during folate deficiency occurs through preferential proteolysis of apo-FR by a kidney metalloprotease called *meprin*, but the precise triggering mechanism is unclear.[27] In human cervical cancer, translational upregulation of FR-alpha in folate deficiency is mediated by homocysteine, which increases interaction between an 18-base *cis*-element in the 5′-untranslated region of FR-alpha mRNA and a heterogeneous nuclear ribonucleoprotein E1 *trans*-factor.[28,29] On replenishment of folate and reduction in intracellular homocysteine, there is reversal of this interaction leading to downregulation. This is an example of linkage between perturbed folate metabolism and coordinated upregulation of FRs.[29] Perturbation of plasma membrane metalloprotease,[2] cholesterol,[2] and sphingolipids[2] can also modulate the expression of FRs in various tissues through poorly understood mechanisms.

The functional role of FRs, which are expressed in several normal tissues,[2] has been demonstrated in the placenta, proximal renal tubular cells, and hematopoietic progenitor cells. Because FR-α are overexpressed in some malignancies (eg, most cervical[26] and ovarian cancers[2]), they are potential targets for exploitation as Trojan horses for the delivery of folate-tethered liposomes bearing various cargos (ie, chemotherapy, imaging reagents, genes, or other agents).[2,30,31] Induction of FR-beta expression in AML with retinoic acid is another possible therapeutic strategy under investigation.[2,32]

Reduced-Folate Carriers

The second mechanism for folate uptake is a carrier-mediated, pH- and energy-dependent process that transports reduced folates equally efficiently at higher than physiologic concentrations.[15] The RFC gene[33,34] encodes a 58-kd polypeptide and resembles the mammalian glucose transporter (GLUT1), which is a member of the 12-transmembrane domain-spanning membrane transporter family. The acquisition of methotrexate transport deficiency in some cells results from inactivating mutations of RFC gene alleles,[2] and acquired transport resistance in relapsed acute lymphocytic leukemia is also associated with decreased RFC expression.[2]

Cellular Retention and Excretion

Polyglutamation of folate is the major factor for intracellular retention (see Fig. 39–5).[2] As a corollary, human malignant cells with reduced folylpolyglutamate synthase are resistant to antifolates, which

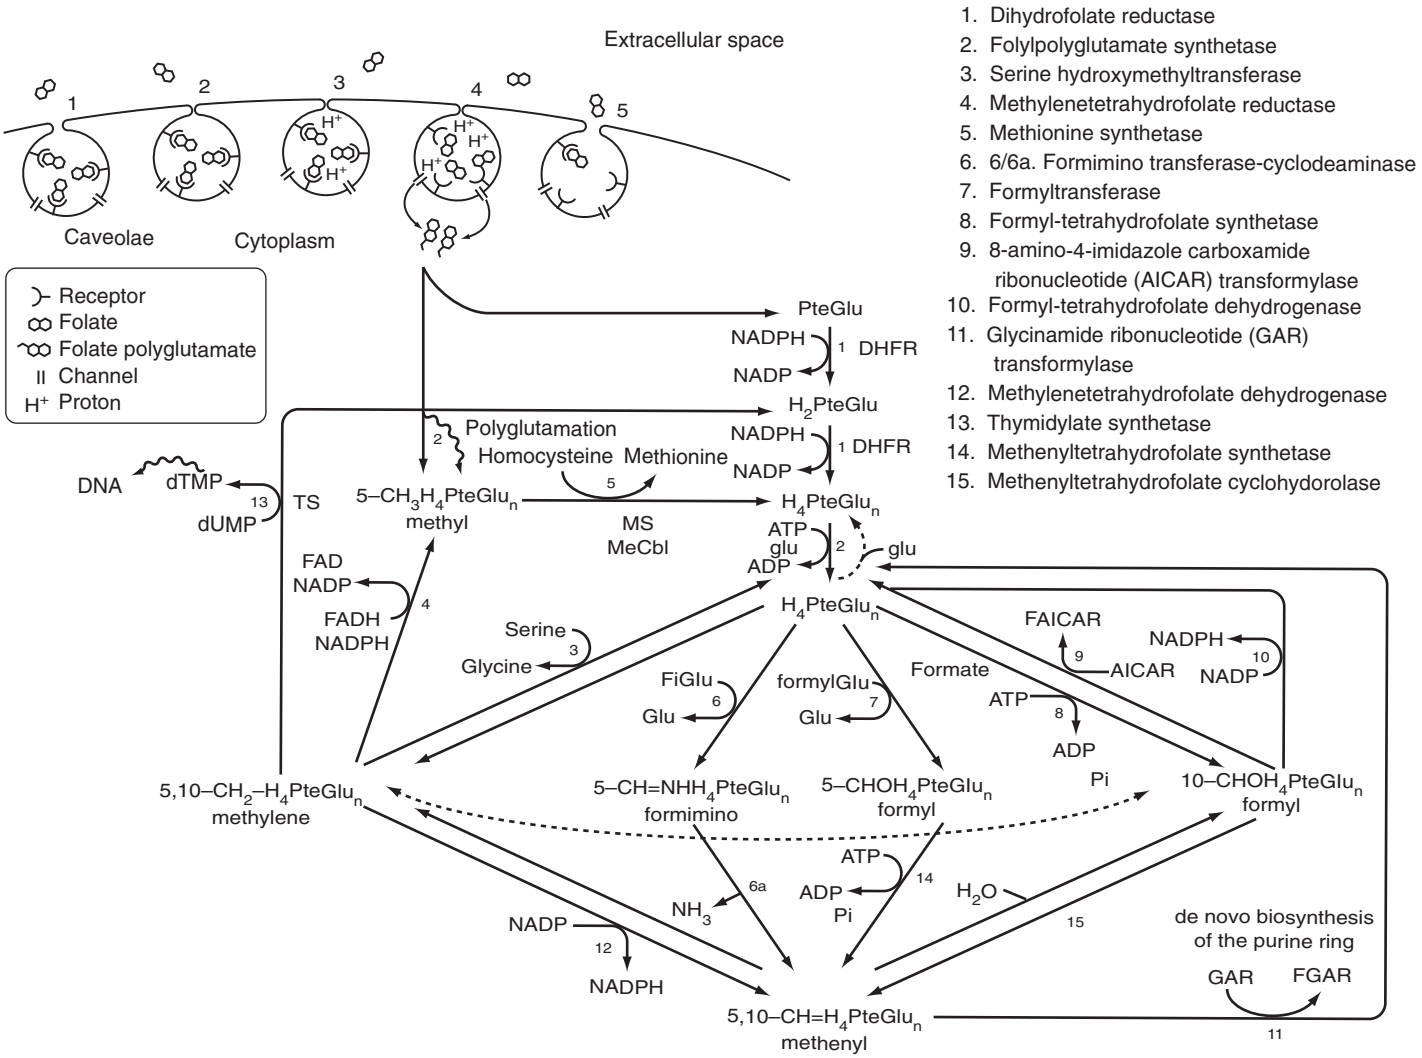

Figure 39–5 Folate receptor (FR)-coupled folate uptake and intracellular one-carbon metabolism involving folates. See text for details. The contribution of the reduced-folate carrier (RFC)-mediated transport and passive diffusion of folate into cells is not shown. (Adapted from Shane B, Stokstad EL: Vitamin B_{12}–folate interrelationships. Annu Rev Nutr 5:115, 1985, and from Rothberg KG, Ying Y, Kolhouse JF, et al: The glycophospholipid-linked FR internalizes folate without entering the clathrin-coated pit endocytic pathway. J Cell Biol 110:637, 1990.)

cannot be (polyglutamated and) retained intracellularly.[2] In human erythrocytes (RBCs), folate is accumulated at earlier stages within the marrow by FRs[1]; on maturation, more than 90% of $PteGlu_n$ molecules interact with hemoglobin, which, because of its high capacity, assists in intracellular folate retention.[1]

Folate turnover and catabolism can be accelerated by the activity of heavy-chain ferritin,[35] which limits the amount of newly imported (unbound) folate monoglutamates before they are polyglutamylated and can function as cofactors with intracellular enzymes; indeed, increased ferritin expression can deplete cellular folate concentrations in cells cultured with folate-rich medium.[35] However, approximately 50% of intracellular folates appear protected, possibly because of sequestration in mitochondria.

After glomerular filtration, luminal folate binds FR in the brush border membranes of proximal renal tubular cells[2] and is internalized rapidly by FR-mediated endocytosis; in the low pH of endocytotic vesicles, there is dissociation of folates and slow transport across basolateral membranes into the blood, with recycling of apo-FR back to the luminal brush border membrane.[1] Both megalin and cubulin cooperate to mediate the uptake of several other ligands via receptor-mediated endocytosis including reabsorption of filtered folate bound to soluble FBPs via kidney proximal tubules.[20]

INTRACELLULAR METABOLISM AND COBALAMIN–FOLATE RELATIONSHIPS

Pteroylpolyglutamates are the natural substrates for the various enzymes involved in one-carbon metabolism (Figs. 39–5 and 39–6). Pteroyl*mono*glutamates must be *poly*glutamated by folylpolyglutamate synthase before they participate in one-carbon metabolism.[1] Tetrahydropteroylglutamate ($H_4PteGlu$) is the preferred physiologic substrate for folylpolyglutamate synthase, and the polyglutamyl form ($H_4PteGlu_n$) plays a central role in one-carbon metabolism.[1] Factors that limit the supply of $H_4PteGlu$ or regulate folylpolyglutamate synthase influence polyglutamation and cellular retention of folates. $H_4PteGlu_n$ can be converted to formate as 10-formyl-$H_4PteGlu_n$ (used in de novo biosynthesis of purines) and formaldehyde as 5,10-methylene-$H_4PteGlu_n$ (for synthesis of thymidylate). Moreover, 5,10-methylene-$H_4PteGlu_n$ and 10-formyl-$H_4PteGlu_n$ can be interconverted by intermediates (see Fig. 39–5).

To understand the functions of folate coenzymes (see Figs. 39–5 and 39–6), it is important to recognize at the outset that 5,10-methylene-$H_4PteGlu_n$ can be used in the *thymidylate cycle* by thymidylate synthase for thymidine and DNA synthesis or in the *methylation cycle* after its conversion to 5-methyl-$H_4PteGlu_n$, which by means of

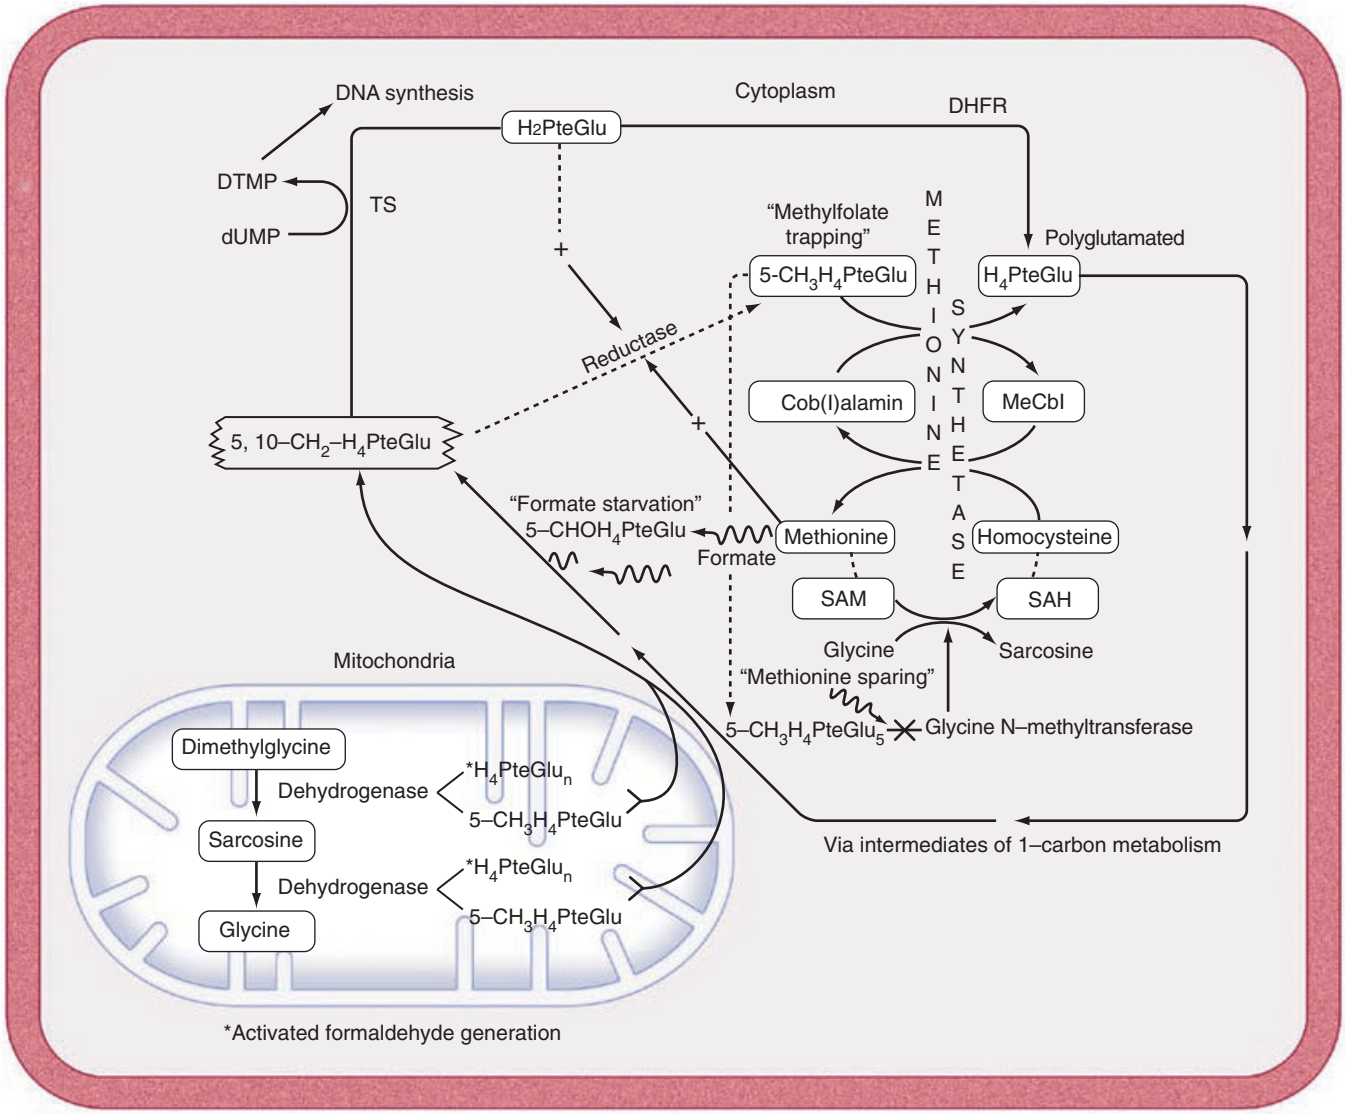

Figure 39–6 Major pathways involving cobalamin–folate interrelationships. Intramitochondrial dehydrogenases that preferentially bind $H_4PteGlu_5$ provide activated formaldehyde (by means of dimethylglycine to sarcosine to glycine). The activated formaldehyde nonenzymatically reacts with the enzyme-bound tetrahydrofolate pentaglutamate ($H_4PteGlu_5$) to form 5,10-methylene-$H_4PteGlu_n$ for methionine synthase and thymidylate synthase. Another cytosolic dehydrogenase (glycine *N*-methyltransferase) that synthesizes sarcosine in the presence of *S*-adenosyl-methionine from glycine (with conversion of *S*-adenosyl-methionine to *S*-adenosyl-homocysteine) is activated on phosphorylation but is allosterically inhibited (trapped and polyglutamated) by 5-methyl-$H_4PteGlu_5$ in cobalamin deficiency. This effect of 5-methyl-$H_4PteGlu_5$ may lead to methionine-sparing, and the methionine could inhibit the formation of more 5-methyl-$H_4PteGlu_5$ from 5,10-methylene-$H_4PteGlu_n$ and channel the latter for DNA synthesis.[2]

methionine synthase leads to the formation of methionine and $H_4PteGlu_n$.

Pteroylmonoglutamate (PteGlu, folic acid) is not a biologically active form of folate; when given therapeutically, it requires reduction to $H_4PteGlu$ by dihydrofolate reductase (a 20-kd enzyme) in a two-step reaction (pteroylglutamate [PteGlu] to *dihydro*pteroylglutamate [$H_2PteGlu$] to *tetrahydro*pteroylglutamate [$H_4PteGlu$]). The major form of folate transported into the cell by FR and RFC is 5-methyl-$H_4PteGlu$ (see Fig. 39–5). Evidence suggests that folate-mediated one-carbon metabolism is compartmentalized among intracellular organelles, leading to substrate channeling along folate coenzymes.[2,36] For example, some of the enzymes distal to $H_4PteGlu_n$ are multifunctional, allowing sequential channeling of folate coenzyme forms (eg, $H_4PteGlu_n$ to 5-formino-$H_4PteGlu_n$ to 5,10-methenyl-$H_4PteGlu_n$). Thymidylate synthase catalyzes the transfer of the formaldehyde from 5,10-methylene-$H_4PteGlu_n$ to the 5 position of deoxyuridylate; in this process 5,10-methylene-$H_4PteGlu_n$ is also reduced to dihydrofolate, which inhibits 5,10-methylene-$H_4PteGlu_n$ reductase. Because methionine, the product of the methionine synthase reaction, also inhibits this enzyme, this illustrates that modulation of 5,10-methylene-$H_4PteGlu_n$ reductase by levels of dihydrofolate and methionine can determine the degree of channeling of 5,10-methylene-$H_4PteGlu_n$ into the methylation and thymidylate cycle (Figs. 39–5 and 39–6).

Folate metabolism and folate-dependent enzymes are compartmentalized in the mitochondrial matrix and cytoplasm (with each compartment containing near equal concentrations of folate cofactors),[37] and there are homologs of the major cytosolic enzymes (see Fig. 39–5) within mitochondria. Folate monoglutamates are transported from the cytoplasm into the mitochondria by a reduced-folate carrier that is specific for mitochondria,[38] within which they are converted to polyglutamylated forms. Most of the one-carbon units, in the form of formate, are derived from mitochondria and are used for the synthesis of formate, glycine, and f-met-tRNA. A new model[36] suggests a smooth unidirectional flow of one-carbon units from the mitochondria to the cytosol. In the mitochondria, 5,10-methylene-$H_4PteGlu$ is first generated primarily from the conversion of serine

to glycine (with other contributions from the catabolism of glycine and choline) followed by sequential transfer of one-carbon units to 10-formyl-H_4PteGlu and then on to formate, which then leaves the mitochondria. In the cytosol, formate is coupled to H_4PteGlu to form 10-formyl-H_4PteGlu, which constitutes the major pool of cytosolic folate and the primary source of one-carbon units for the synthesis of thymidylate, methionine, and purines.

The mechanism whereby cobalamin deficiency produces its megaloblastic effects is not precisely known. It is generally agreed that cobalamin deficiency causes a functional intracellular deficiency of 5,10-methylene-H_4PteGlu$_n$ (see Figs. 39–5 and 39–6). The methyl-folate trap hypothesis was originally formulated in an attempt to explain why cobalamin deficiency resulted in a functional folate deficiency. Under normal conditions, 5-methyl-H_4PteGlu is converted by the cobalamin-dependent methionine synthase to H_4PteGlu, which is subsequently polyglutamated and then used in one-carbon metabolism. With cobalamin deficiency, methionine synthase is inactive, leading to buildup of 5-methyl-H_4PteGlu, which is a particularly poor substrate for folate polyglutamate synthase. With no alternative metabolic pathway but this cobalamin-dependent reaction, the "trapped" 5-methyl-H_4PteGlu leaks out of the cell, leading to a progressive deficiency of polyglutamated folate intracellularly. The formate starvation hypothesis centers on the relatively greater merit of formate (in the form of 10-formyl-H_4PteGlu$_n$) and the precursor of formate, methionine, which is also decreased when methionine synthase is inhibited by cobalamin deficiency.[1] When methionine is in excess intracellularly, its methyl group is oxidized to formate, which can be used to generate 5-formyl- and 10-formyl-H_4PteGlu$_n$ (Fig. 39–5, reactions 7 and 8). There are articles that support either hypothesis.[2]

CONSEQUENCES OF PERTURBED ONE-CARBON METABOLISM

Thymidylate and DNA Synthesis

In cobalamin or folate deficiency, a net decrease in 5,10-methylene-H_4PteGlu$_n$ interrupts the reaction mediated by thymidylate synthase, which converts deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). Although there is a salvage pathway using thymidine kinase that normally accounts for 5% to 10% of thymidine synthesis, this pathway cannot meet the remaining 90% demand for dTMP generation. (Salvage pathways for purine synthesis can be activated to compensate for diminished generation of purines through folate coenzyme-mediated reactions.) The resulting thymidine deficiency causes a marked increase in the dUMP/dTMP ratio. Because of the decrease in dTMP (and eventually dTTP), dUMP and therefore deoxyuridine triphosphate (dUTP) increase. Because DNA polymerase cannot distinguish between dUTP and dTTP, the elevated dUTP level promotes misincorporation of uridine residues into DNA.[2] An editorial enzyme, DNA uracil glycosylase, recognizes this faulty misincorporation. It excises dUTP, but the inadequate supply of dTTP leads to failure to repair the break in this DNA strand. Repeated DNA strand breaks lead to significant fragmentation of DNA, with consequent leakage of DNA fragments out of the cell.[2] The foregoing considerations form the basis for the dU suppression test that is occasionally employed as a research tool clinically to differentiate cobalamin from folate deficiency and when inborn errors of cobalamin or folate metabolism are suspected.[1]

Chromosome and Cell Cycle Defects

Defective DNA synthesis is reflected by numerous chromosomal abnormalities. There is excessive chromosomal elongation with despiralization associated with random breaks and exaggerated centromere constriction, expression of folate-sensitive fragile sites in hematopoietic cells, and reduced biosynthesis, acetylation, and methylation of arginine-rich histone.[1,2] All this leads to perturbation of the cell cycle, with an increased proportion of cells in the prophase of the mitotic cycle and G_2. In an in vitro model of folate-deficient erythroblastosis, apoptosis of erythroblasts in the late stages of differentiation apparently led to decreased erythrocyte production and anemia.[2]

MORPHOLOGIC EXPRESSION OF MEGALOBLASTOSIS

There is widening disparity in nuclear–cytoplasmic asynchrony as a cobalamin- or folate-deficient cell divides, until the more mature generations of daughter cells die in the marrow or are arrested (as megaloblastic cells) at various stages in the cell cycle.[1] The plethora of bone marrow morphologic changes may lead the untrained observer to the diagnosis of acute leukemia.[2] All proliferating cells exhibit megaloblastosis, including epithelial cells lining the gastrointestinal tract (buccal mucosa, tongue, small intestine), cervix, vagina, and uterus.[1] However, megaloblastic changes are most striking in the blood and bone marrow (see Fig. 39–7). Ineffective hematopoiesis extends into the long bones, and the bone marrow aspirate (which is better than the biopsy for observing megaloblastosis) exhibits trilineal hypercellularity, especially in the erythroid series. The appearance of exuberant cell proliferation with numerous mitotic figures is misleading because these cells are actually very slowly proliferating.

Erythroid hyperplasia reduces the myeloid-to-erythroid ratio from 3:1 to 1:1. Proerythroblasts are not as obviously abnormal as later forms; they may simply be larger (promegaloblasts). Megaloblastic changes are most strikingly displayed in intermediate and orthochromatic stages, which are larger than their normoblastic counterparts. In contrast to the normally dense chromatin of comparable normoblasts, megaloblastic erythroid precursors have an open, finely stippled, reticular, sievelike pattern. The orthochromatic megaloblast, with its hemoglobinized cytoplasm, continues to retain its large sievelike immature nucleus, in sharp contrast to the clumped chromatin of orthochromatic normoblasts. The nucleus is often eccentrically placed in these large oval or oblong cells and lobulation or indentation of nuclei with bizarre karyorrhexis is often seen. In cells destined for the circulation as macroovalocytes, the nucleus may occasionally not be completely extruded. Of the potential progeny of proerythroblasts that develop into later megaloblastic forms, 80% to 90% die in the bone marrow. Marrow macrophages effectively scavenge dead or partially disintegrated megaloblasts. This is the basis for ineffective erythropoiesis (intramedullary hemolysis).

Morphology in Megaloblastosis from Cobalamin and Folate Deficiency is the Same

Peripheral Smear

- Increased mean corpuscular volume (MCV) with macroovalocytes (up to 14 μm), which is variously associated with anisocytosis and poikilocytosis
- Nuclear hypersegmentation of polymorphonuclear neutrophils (PMNs) (one PMN with six lobes or 5% with five lobes)
- Thrombocytopenia (mild to moderate)
- Leukoerythroblastic morphology (from extramedullary hematopoiesis)

Bone Marrow Aspirate

- General increase in cellularity of all three major hematopoietic elements
- Abnormal erythropoiesis-orthochromatic megaloblasts
- Abnormal leukopoiesis-giant metamyelocytes and "band" forms (pathognomonic), hypersegmented PMNs
- Abnormal megakaryocytopoiesis-pseudohyperdiploidy

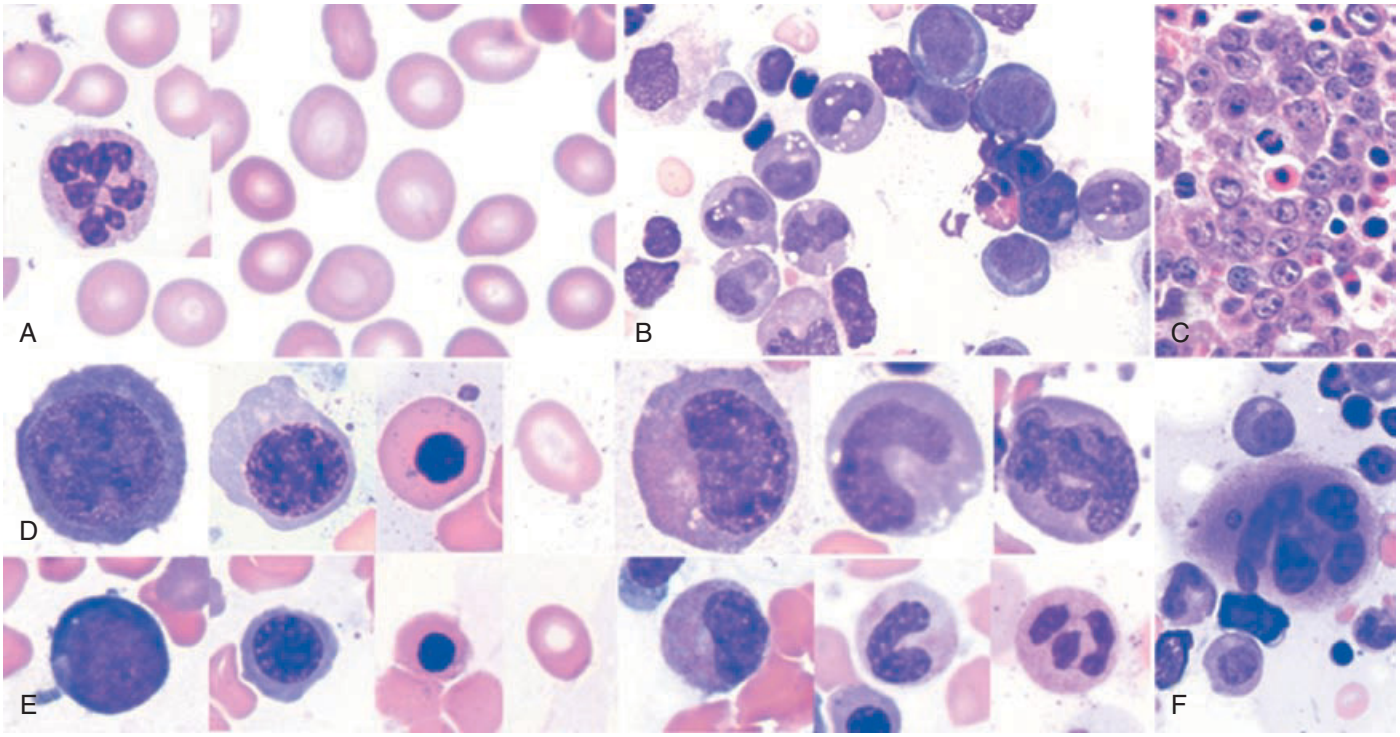

Figure 39–7 Megaloblastic anemia: peripheral blood (**A**), bone marrow aspirate (**B**), and biopsy **C**. The peripheral smear (**A**) exhibits macroovalocytosis, and hypersegmented polys (inset). The bone marrow aspirate (**B**) shows megaloblastic changes in both granulopoiesis and erythropoiesis. The biopsy (**C**) is hypercellular and shows sheets of immature erythroid precursors with a high mitotic rate. These can mimic acute erythroleukemia or even metastatic tumor cells. Details from the cells in the aspirate (**D**) compared with normal hematopoiesis at same magnification (**E**). Note the giant metamyelocyte and band form. In megaloblastic anemia, megakaryocytes also have nuclear atypica including abnormal nuclear segmentation (**F**).

Leukopoiesis is also abnormal. There is an absolute increase in these cells, which are large and have similar sievelike chromatin. Spectacular giant (20–30 μm) metamyelocytes and "band" forms that are often seen are pathognomonic for megaloblastosis. There may be bizarre nucleoli with small cytoplasmic vacuoles. It is probable that giant metamyelocytes cannot easily traverse marrow sinuses, and their maturation into circulating hypersegmented polymorphonuclear neutrophils (PMNs) is unlikely. Granulation of the cytoplasm remains unaffected.

Megakaryocytes may be normal or increased in numbers and may exhibit additional complexities in megaloblastic expression. The process of complex hypersegmentation (ie, pseudohyperdiploidy) is associated with liberation of fragments of cytoplasm and giant platelets into the circulation. The net output of platelets is invariably decreased in severe megaloblastosis and abnormal but reversible platelet dysfunction has been documented.[2]

In early cobalamin or folate deficiency, normoblasts may dominate the marrow, with only a few megaloblasts seen. Complete transformation to megaloblastic hematopoiesis is observed in florid cases and is reflected by various degrees of pancytopenia.

The earliest manifestation of megaloblastosis is an increase in mean corpuscular volume (MCV) with macroovalocytes (up to 14 μm). Because these cells have adequate hemoglobin, the central pallor, which normally occupies approximately one-third of the cell, is decreased. In severe anemia, poikilocytosis and anisocytosis are evident. Cells containing remnants of DNA (ie, Howell–Jolly bodies), arginine-rich histone, and nonhemoglobin iron (ie, Cabot rings) may be observed. Extramedullary megaloblastic hematopoiesis may also result in a leukoerythroblastic picture.

Ineffective use of iron results in an increased percentage of saturation of transferrin and increased iron stores. If there is associated iron deficiency, the MCV may be normal, and only iron therapy can unmask the megaloblastic manifestations in the peripheral blood. In thalassemia, the entire erythrocyte morphology normally expected in megaloblastosis is masked[1]; however, megaloblastic leukopoiesis is still observed. Significant intramedullary hemolysis (ineffective erythropoiesis) involving more than 90% of megaloblastic precursors is reflected by a lowered absolute reticulocyte count, increased bilirubin (up to 2 mg/dL), decreased haptoglobin, and increased lactate dehydrogenase (often above 1000 units/mL). There is also a modest decrease in the circulating RBC life span.

Nuclear hypersegmentation of DNA in PMNs strongly suggests megaloblastosis when associated with macroovalocytosis. Normally, less than 5% of PMNs have more than five lobes, and no cells have more than six lobes in the peripheral blood. If megaloblastosis is suspected (greater than 5% PMNs with more than five lobes or a single PMN with more than six lobes), a formal lobe count per PMN (ie, lobe index) above 3.5 may be obtained.

Megaloblastosis in rapidly proliferating cells of the gastrointestinal tract leads to a variable degree of morphologic changes and atrophy of the epithelial cells of the luminal lining. This leads to functional defects, which include a failure in secretion of IF and malabsorption of cobalamin and folate in certain subsets of patients. A vicious cycle whereby megaloblastosis begets more megaloblastosis is established that can be interrupted only by specific therapy with cobalamin or folate. This fact must be recognized when interpreting diagnostic tests involving cobalamin absorption (Table 39–3). Similar hematopoietic changes have been induced in a folate-deficient mouse model.[2]

NEUROLOGIC DYSFUNCTION WITH COBALAMIN DEFICIENCY

Because megaloblastosis due to folate or cobalamin deficiency leads to a functional folate coenzyme deficiency, the morphologic mani-

Clues for Distinguishing Cobalamin and Folate Deficiencies

Although the megaloblastic manifestations of cobalamin and folate deficiencies are clinically indistinguishable, certain distinct patterns in mode of presentation provide clues to the type and cause of deficiency. In general, the cause of folate deficiency can be found in the patient's recent past (within 6 months), primarily discerned from the history and physical examination. In contrast, the cause of cobalamin deficiency can remain obscure until specific tests to define the cause (eg, Schilling test) are carried out. In the past, by the time anemia was symptomatic, more than 80% of patients had neurologic manifestations, and in 50%, this led to some incapacity. Perhaps as a result of widespread use of multivitamins containing folic acid among patients and even in the food given livestock in the West, the hematologic expression of cobalamin deficiency is often substantially attenuated, leading to pure neurologic presentations. Studies highlight the apparent inverse correlation between hematologic and neurologic presentations such that in a third of patients with cobalamin deficiency, the earliest signs are often purely neurologic, and symptoms related to paresthesias and diminished proprioception cause the patient to see the physician. On the basis of the multiple potential causes, the warning that "what the mind does not know, the eyes do not see" is a caveat that cannot be taken lightly; failure to recognize cobalamin deficiency as the cause of neurologic disease and treatment of cobalamin deficiency with folate or misdiagnosis of megaloblastosis as erythroleukemia represent significant extremes of deviation from the dictum *primum non nocere.* Areas of overlap in the symptoms of cobalamin or folate deficiency are related to megaloblastosis (ie, common cardiopulmonary and some gastrointestinal manifestations). Although pure folate deficiency in the alcoholic with thiamine deficiency (ie, Wernicke encephalopathy) and peripheral neuropathy is almost indistinguishable from and may mimic cobalamin deficiency, the remainder of the neurologic manifestations are uniquely characteristic of cobalamin deficiency. Folate deficiency in adults has not been unequivocally shown to give rise to neurologic findings. Coexistence of folate deficiency with neurologic disease should prompt investigations to rule out cobalamin and other nutrient deficiencies arising from dietary insufficiency or malabsorption.

festations of both deficiencies are understandably indistinguishable. However, only cobalamin deficiency results in a patchy demyelination process, which is expressed clinically as cerebral abnormalities and subacute combined degeneration of the spinal cord.[1] The precise role of cobalamin in maintaining the integrity of the central nervous system has not been completely defined. Reviews have presented balanced views on various arguments.[2]

The demyelinating process involves patchy swelling of the myelin sheath followed by its breakdown (demyelination), leading to axonal degeneration. Microscopic foci coalesce with one another, giving the surface of the spinal cord (on cross-section) a spongy appearance; later there is secondary Wallerian degeneration of long tracts. Patchy demyelination usually begins in the dorsal columns in the thoracic segments of the spinal cord and then spreads *contiguously* to involve corticospinal tracts. These lesions spread throughout the length of the cord and ultimately involve spinothalamic and spinocerebellar tracts. There is also degeneration of the dorsal root ganglia, celiac ganglia, and Meissner and Auerbach plexus. Although demyelination may also extend to the white matter of the brain, it is unclear whether the peripheral neuropathy is caused by a distinct lesion or results from spinal cord disease; the clinical manifestations may be extremely varied.[1,2]

OTHER EFFECTS OF COBALAMIN AND FOLATE DEFICIENCY

Cobalamin deficiency more often than folate deficiency can also result in sterility from the effects on the gonads. An unexplained finding is generalized melanin pigmentation that is reversible by specific nutrient replenishment. Defective bactericidal activity and increased susceptibility to *Mycobacterium tuberculosis* occurs in cobalamin deficiency for poorly understood reasons.[1] The associations of folate deficiency with increased susceptibility to carcinogenesis, neural tube defects (NTDs), and hyperhomocysteinemia are discussed later in this chapter.

BIOCHEMICAL INDICATORS OF EVOLVING DEFICIENCY

Early clinically evaluable manifestations of negative cobalamin balance are increased serum methylmalonic acid (MMA) and total homocysteine levels.[2] This occurs when the total cobalamin in serum is still normal. Continued negative cobalamin balance leads to an absolute decrease in serum cobalamin level. Likewise, metabolic evidence for folate deficiency (ie, increased homocysteine level) is often found when serum folates are still in the low normal range. Metabolite tests reflective of decreased intracellular nutrient availability are also reflected by biochemical evidence of abnormal thymidylate synthesis (impaired conversion of dUMP to dTMP), morphologic expression of perturbed DNA in PMNs (lobe index), macroovalocytosis, and anemia. The biochemical basis for selective nutrient deficiency in various tissues (eg, cervical[2] or hematopoietic but not gastrointestinal cells[1]) is still unclear.

BIOCHEMICAL EVALUATION OF COBALAMIN AND FOLATE DEFICIENCIES

Total Serum Homocysteine and Methylmalonic Acid Levels

Cellular nutrient *deficiency* of cobalamin or folate is reflected by decreased intracellular concentrations. *Defective use* of cobalamin or folate because of intracellular cobalamin- or folate-dependent enzyme deficiency may allow normal intracellular coenzyme levels. Deficient coenzyme and enzyme levels are both reflected by perturbation of the major cobalamin- or folate-dependent enzyme-catalyzed reactions. The activity of methionine synthase is reduced, leading to substrate (homocysteine) buildup and to elevated serum levels of homocysteine, which can be measured by a sensitive assay.[2] In a classic series of studies, 77 of 78 patients with clinically confirmed cobalamin deficiency had elevated values of homocysteine, correlating with clinical parameters of cobalamin deficiency.[2] In this patient group, 74 of the 78 also had increased serum methylmalonic acid (MMA) levels, indicating reduced activity of the second cobalamin-dependent enzyme, methylmalonyl-CoA mutase, which converts methylmalonyl-CoA to succinyl-CoA. Similarly, 18 of 19 patients with folate deficiency had elevated levels of homocysteine due to reduced activity of the methionine synthase-catalyzed reaction.[2]

Both homocysteine and MMA levels are elevated in patients with dehydration and renal failure; propionic acid derived from anaerobic fecal bacterial metabolism can also contribute substantially to methylmalonate production.[4] In this setting, the gut flora contribution to MMA can be reduced by treatment with metronidazole.

Total homocysteine concentration, which comprises the sum of all homocysteine species in the plasma and serum, including free and

Total Serum Homocysteine and Methylmalonic Acid Levels in Cobalamin and Folate Deficiencies

The combined use of homocysteine and methylmalonic acid (MMA) levels can differentiate cobalamin from folate deficiency, because most patients with folate deficiency have normal MMA levels, and the remainder have only mild elevations.[2] These two tests are useful diagnostically. The abnormally high levels of metabolites return to normal only when the patient receives replacement with the appropriate (deficient) vitamin. A positive response to cobalamin, documented by falling levels of homocysteine and MMA, is evidence of cobalamin deficiency. Conversely, therapy with folate results in a decrease in the isolated homocysteine level if folate deficiency is present.[2] Indeed, because of several non–vitamin deficiency-related variables (such as age, mild renal dysfunction) that can falsely elevate serum homocysteine and MMA levels, proof of vitamin deficiency requires clear-cut demonstration of a reduction in metabolite levels after specific vitamin supplementation.[2,40]

If the serum cobalamin test is broadly used as a screening test, by virtue of the way *normalcy* is defined, 2.5% of nondeficient individuals will have low levels. Because many millions of individuals probably have serum cobalamin tests done every year, several thousand are found to have "low" cobalamin levels, which reflects our definition of the lower limit of normal for this test.[2]

The serum cobalamin concentration is less than 300 pg/mL in 99% of patients with clinical hematologic or neurologic manifestations of cobalamin deficiency.[2] Conversely, a cobalamin level of more than 300 pg/mL predicts folate deficiency or some other hematologic disease (Table 39–2). However, if the serum folate levels are borderline or normal and the patient has megaloblastic anemia with cobalamin levels more than 300 pg/mL, metabolite tests or a therapeutic trial may be necessary to rule out underlying folate deficiency.

How often do patients with cobalamin deficiency have normal cobalamin levels? Among 173 unambiguously cobalamin-deficient patients,[2] approximately 5% had normal cobalamin levels and up to 10% of adults with true cobalamin deficiency have cobalamin values in the low normal (200–300 pg/mL) range. Although traditionally such patients would have been regarded as not having cobalamin deficiency, they should be tested with the more sensitive metabolite tests (MMA and homocysteine), (Table 39–2). Studies have again highlighted the need to be vigilant for clinical and biochemical evidence of cobalamin deficiency in the elderly at "normal" cobalamin concentrations.[2] A study of 548 surviving members of the original Framingham Study revealed a prevalence of cobalamin deficiency of approximately 12%.[2] Nevertheless, approximately 90% of older patients with serum cobalamin levels less than 150 pmol/L show evidence of true tissue cobalamin deficiency.[2]

protein-bound forms, can be measured in the plasma or serum.[2,39] In general, plasma levels are slightly lower. The normal value for serum homocysteine is 5.1 to 13.9 μM and serum MMA is 73 to 271 nM, and in general, the higher the values, the more severe the clinical abnormalities.[2] However, there is a fairly wide range of "normalcy" in homocysteine values because of age-, creatinine-, gender-, diet-, and race-dependent variables.[39] Homocysteine is a continuous (progressive) risk factor for occlusive vascular disease (ie, higher levels predict higher risk) that is modifiable and likely causal; therefore, the lower the level, the better. Basal levels of MMA are usually less than 500 nM, and in renal failure, it rarely increases by more than 1000 nM.[2] If unseparated blood stands at room temperature, homocysteine levels will *increase* over 4 to 24 hours, but frozen serum (from measurements of serum folate or cobalamin) can be used for serum MMA and homocysteine determinations (See box on left and Table 39–2).

Among 1160 elderly participants in the original Framingham Heart Study cohort, almost one-third had high plasma homocysteine levels that inversely correlated most with plasma folate levels and, to a lesser extent, with cobalamin and vitamin B_6 (ie, pyridoxine; pyridoxal-5′-phosphate is the active form).[2] Most cases of high homocysteine levels in the elderly can probably be attributed to low vitamin status.

Table 39–1 Serum Cobalamin: False-Positive and False-Negative Test Results

Falsely Low Serum Cobalamin in the Absence of True Cobalamin Deficiency
Folate deficiency (one-third of patients)
Multiple myeloma
Transcobalamin I (TC I) deficiency
Megadose vitamin C therapy
Patient's serum contains other radioisotopes (^{99m}Tc or ^{67}Ga and other radiopharmaceuticals used in organ scanning)
Falsely Raised Cobalamin Levels in the Presence of a True Deficiency*
Cobalamin binders (TC I and II) increased (eg, myeloproliferative states, hepatomas, and fibrolamellar hepatic tumors)
TC II-producing macrophages are activated (eg, autoimmune diseases, monoblastic leukemias and lymphomas)
Release of cobalamin from hepatocytes (eg, active liver disease)

*Although a low serum cobalamin is not synonymous with cobalamin deficiency, 5% of patients with true cobalamin deficiency have low-normal cobalamin levels, a potentially serious problem because the patient's underlying cobalamin deficiency will progress if uncorrected.

Serum Cobalamin Levels

Serum cobalamin levels previously measured by microbiologic assay using the cobalamin-dependent organism *Lactobacillus leichmannii* have been replaced by a simpler assay method that relies on the competitive inhibition by serum cobalamin of the binding of CN-[^{57}Co]cobalamin (cyanocobalamin) to IF. Earlier, the use of R protein (which measures cobalamin analogs in addition to cobalamin) led to misleadingly higher serum cobalamin values that masked the presence of true cobalamin deficiency.[1,2] For the most part, serum cobalamin is an established biochemical indicator of cobalamin deficiency. However, a report of neuropsychiatric disorders attributed to cobalamin deficiency in some patients, despite the absence of anemia and normal or minimally depressed cobalamin levels, underscores the caution with which clinicians should proceed when interpreting this test.[2] A low serum cobalamin is not synonymous with cobalamin deficiency and several associated diseases and conditions can falsely raise or lower cobalamin levels (Table 39–1). Studies have also identified patients with true cobalamin deficiency who have cobalamin levels in the low normal range (see discussion in box on left).

Serum Folate Levels

Microbiologic assays of folate using *Lactobacillus casei* suffer from the same limitations as microbiological assays for cobalamin,[1] and these have been supplanted, primarily for convenience, by various radioisotope dilution or other biochemical assays. However, the clinical validity of these modifications has in many cases not been adequately documented.[1] There is also significant discrepancy in folate levels when a variety of kits are used on the same sample, raising questions about the reliability of these assays for clinical use, especially compared with microbiologic assays.[2]

Diagnosing Folate Deficiency

When combined with a clinical picture of megaloblastic anemia and additional results of low cobalamin levels, the serum folate concentration is the cheapest and most useful initial biochemical test to diagnose folate deficiency (Table 39–2).[2] The serum folate level is highly sensitive to folate intake, and a single hospital meal may normalize it in a patient with true folate deficiency. Rapidly developing nutritional folate deficiency first leads to a decline in the serum folate level below normal (less than 2 ng/mL) in approximately 3 weeks; it is a sensitive indicator of negative folate balance.[1] However, isolated reduction of serum folate in the absence of megaloblastosis (ie, false-positive result) occurs in one-third of hospitalized patients with anorexia, after acute alcohol consumption, during normal pregnancy, and in patients on anticonvulsants[2]; unfortunately, these are the very groups at high risk for folate deficiency and the people who exhibit low serum folate levels when they become folate deficient.[1] Conversely, in 25% to 50% of cases (predominantly alcoholics) with folate-deficient megaloblastosis, the serum folate levels may be low normal or borderline (2–4 ng/mL by radioisotope dilution assay).[2] The serum folate level alone should never dictate therapy. It is important to consider the clinical picture, peripheral smear, and bone marrow morphology and to rule out underlying cobalamin deficiency.

When negative folate balance continues, hepatic folate stores are depleted in approximately 4 months.[1] This leads to tissue folate deficiency, which was clinically correlated with a decrease in RBC folate (less than 150 ng/mL) by a microbiologic assay in the 1960s.[1] Thus, a reduction in serum and RBC folate in the setting of megaloblastic anemia was consistent with the diagnosis of folate deficiency using the older microbiologic RBC folate assays.[1] However, current RBC folate tests have major limitations in sensitivity and specificity and are notoriously unreliable in alcoholics and in pregnancy; furthermore, a reduction of RBC folate also occurs in approximately 60% of patients with cobalamin deficiency. By contrast, the serum folate level is falsely low less often (<10%) with cobalamin deficiency.

Other compelling evidence argues against the use of RBC folate in the diagnosis of folate deficiency. The original microbiologic assays for RBC folates have been replaced by radioassays currently used for measurement of *serum* folate levels. However, unlike the serum folate (which is entirely 5-methyl-tetrahydrofolate), RBC folates are a heterogeneous mixture of different coenzyme forms with various polyglutamate chain lengths that have different affinity for the FBP used in the radioassay kit for folates; whether this can affect net measurement of RBC folate content has not been experimentally clarified. Moreover, apart from a lack of clinical validation of the use of *radio*assays for measuring RBC folates (ie, they have not been adequately validated against actual patients with normal and deficient folate status), the assays themselves have had a long history of being unreliable.[2] A quality assurance study from Australia involving 134 laboratories identified nine operator-controllable factors that could also lead to poor RBC folate results.[2] An analysis of its clinical value led to the conclusion that RBC folate tests added little useful information to that provided by serum folate levels.[2] Together, these clinically relevant issues have considerably dampened the enthusiasm for use of RBC folate tests and have led several experts in the United States to entirely avoid their use pending a resolution of these multiple problems (see Table 39–2).[2] Parenthetically, it should be noted that the large clinical trials that rely on measurement of RBC folates use a single commercial kit for their studies that allows for direct comparison of RBC folate values among study subjects; however, this is not the real-world situation, where a variety of RBC folate kits are available and where there has been proven inaccuracy among several of them. This is the reason why the measurement of serum folate is preferred over RBC folates as the initial test for evaluation of folate deficiency.

Summary of the Clinical Usefulness of Tests for Cobalamin and Folate Deficiencies

The greater sensitivity of MMA and homocysteine test results (than of cobalamin) are best illustrated in patients with pernicious anemia who do not receive cobalamin for some time; the levels of MMA and homocysteine progressively increase much earlier than the drop in cobalamin levels.[2] Overlooking true cobalamin deficiency is highly unlikely when the two metabolites are measured, because one or both metabolites was increased in 99.8% of more than 400 patients with proven cobalamin deficiency.[2] These serum tests (MMA and homocysteine) are the gold standard for the diagnosis of cobalamin deficiency.

On the basis of the lower costs of serum cobalamin and folate compared with serum MMA and total serum homocysteine levels, it is recommended (see Table 39–2) to first use the cheaper tests that can assist in the diagnosis of the most obvious cases of cobalamin and folate deficiency.[2] Clinicians should also restrict the use of serum MMA and homocysteine to patients with borderline cobalamin and folate levels; to patients with existing conditions associated with difficulties in the interpretation of test results; to situations in which cobalamin and folate levels are low, when a high MMA level is useful in confirming cobalamin deficiency (rather than attributing the condition to folate deficiency alone); and to patients with clearly low serum levels but for whom there is an alternative explanation for the findings that caused an unusual serum cobalamin level to be obtained (eg, a diabetic or alcoholic with peripheral neuropathy, an alcoholic with a high MCV and a low serum cobalamin without anemia). In these cases, serum levels of metabolites can assist in the diagnosis of vitamin deficiency.

Diagnostic algorithms consistently stress the value of clinical data to improve the pretest probability of serum cobalamin and serum folate tests.[2] Without detailed clinical information, the combined test results for serum cobalamin, folate, and metabolites (homocysteine and MMA) are not sufficiently unambiguous to diagnose and distinguish cobalamin deficiency from combined cobalamin-plus-folate deficiency. In combined cobalamin-plus-folate deficiency, both vitamins would be needed to restore baseline values particularly of homocysteine.[2] In the context of diagnosing a subclinical deficiency of cobalamin (or folate) based on increased serum levels of MMA or homocysteine, or both, despite normal serum cobalamin (or folate) levels, positive attribution can be confidently made only after the demonstrated reversal of laboratory values after treatment with cobalamin or folate, or both.[2] This is similar in principle to that used to confirm clinically significant nutrient deficiency.[2,40,41]

Other Tests

The use of low holo-transcobalamin II (holo-TCII) levels to diagnose cobalamin deficiency is still under evaluation to identify its proper niche within the diagnostic algorithm for cobalamin deficiency.[42] Although holo-TCII is an early marker of cobalamin homeostasis,[43] it cannot be used as a marker to diagnose cobalamin malabsorption or as a surrogate for the Schilling test,[44] neither can it be used to displace the use of metabolite measurements to define the cause of cobalamin deficiency in routine clinical use. There is insufficient clinical data to support the routine use of a urinary MMA test.[2]

Table 39–2 Approach to the Diagnosis of Cobalamin and Folate Deficiencies

Megaloblastic Anemia or Neurologic–Psychiatric Manifestations Consistent with Cobalamin Deficiency Plus Test Results for Serum Cobalamin and Serum Folate

Cobalamin[†] (pg/mL)	*Folate[‡] (ng/mL)*	*Provisional Diagnosis*	*Proceed with Metabolites?*
>300	>4	Cobalamin or folate deficiency is unlikely	No
<200	>4	Consistent with cobalamin deficiency	No
200–300	>4	Rule out cobalamin deficiency	Yes
>300	<2	Consistent with folate deficiency	No
<200	<2	Consistent with (1) combined cobalamin plus folate deficiency or (2) isolated folate deficiency	Yes
>300	2–4	Consistent with (1) folate deficiency or (2) an anemia unrelated to vitamin deficiency	Yes

Test Results for Metabolites: Serum Methylmalonic Acid and Total Homocysteine[§]

Methylmalonic Acid (Normal = 70–270 nM)	*Total Homocysteine (Normal = 5–14 μM)*	*Diagnosis*
Increased	Increased	Cobalamin deficiency is confirmed; folate deficiency still possible
Normal	Increased	Folate deficiency is likely; <5% may have cobalamin deficiency
Normal	Normal	Cobalamin and folate deficiency is excluded

[†]Serum cobalamin levels: abnormally low, <200 pg/mL; clinically relevant low-normal range, 200–300 pg/mL.
[‡]Serum folate levels: abnormally low, <2 ng/mL; clinically relevant low-normal range, 2–4 ng/mL.
[§]Any frozen-over sample from a serum folate or cobalamin determination can be subjected to metabolite tests.

PATHOGENESIS OF COBALAMIN DEFICIENCY

Nutritional Cobalamin Deficiency Because of Insufficient Intake

Vegetarian diets can be classified as lacto-vegetarian, ovo-vegetarian, lacto-ovo-vegetarian, or vegan, respectively, if they include dairy products, eggs, dairy products and eggs, or no animal products at all.[5] Vegan diets contain a very low cobalamin content, warranting routine cobalamin supplementation. Studies over the past five decades have consistently demonstrated that asymptomatic lacto-ovo-vegetarians and lacto-vegetarians[5] also have low cobalamin levels when compared with nonvegetarians, but it was difficult to characterize this as a cobalamin-deficient state (implying disease). However, new evidence[45] suggests that such individuals have increased blood total homocysteine and MMA levels consistent with biochemical evidence for cobalamin deficiency. Ultimate proof of deficiency must be based on complete normalization of abnormal test results after specific vitamin replacement.[40] Nevertheless, all of the earlier studies using cobalamin levels as an indicator of cobalamin status raise the likelihood (confirmed recently)[45] that those "normal" asymptomatic subjects would have been found to be cobalamin deficient had more sophisticated metabolite tests been employed.[5] Because one-half or more of those with metabolically defined mild, preclinical cobalamin deficiency[2] have abnormalities in electroencephalographic, evoked potential, and electrophysiologic markers of cognitive ability, this strongly supports a causal relationship between subtle neurologic problems associated with otherwise "asymptomatic" cobalamin deficiency.

There are two closely related groups whose diets are quite similar and who exhibit clinical and biochemical evidence of dietary cobalamin deficiency: voluntary vegetarians who base their dietary preferences on religious or philosophical grounds (many among the Indian population) and poverty-imposed near-vegetarians who live in developing countries worldwide. The latter are nonvegetarians who consume meat infrequently (because it is more expensive than plant protein) and when consumed, the serving portions of meat are also meager. These poverty-imposed near-vegetarians have a cobalamin status that is only marginally better than lacto-ovo-vegetarians.[5] Thus, as many as 700 to 800 million Indians who are life-long vegetarians or near-vegetarians could have low cobalamin status in addition to the untold millions of poor in two parts of the developing world subjected to poverty-imposed near-vegetarianism. Thus worldwide, the commonest cause of cobalamin deficiency among all ages is likely to be nutritional insufficiency. But in the West, where regular consumption of cobalamin-rich foods such as meat is common, food-cobalamin malabsorption especially among the elderly is probably the commonest cause of cobalamin deficiency [Inadequate Dissociation of Cobalamin From Food Protein (Food-Cobalamin Malabsorption)].

Infants born of cobalamin-depleted vegetarian mothers are at risk for cobalamin deficiency, especially if they receive prolonged breastfeeding. An "infantile tremor syndrome" is found exclusively among breast-fed infants of mothers who come from extremely low socioeconomic conditions in developing countries.[5] Within a background of apparently adequate general nutrition, these infants exhibit apathy, megaloblastic anemia, skin pigmentation, involuntary movements, and developmental regression that is rapidly corrected by cobalamin. Similar cases have been described in the West. Whereas the fetus depends on the mother for cobalamin,[1,2] the longer the mother has been vegetarian, the greater the likelihood she will have low maternal serum and breast milk cobalamin concentrations that closely correlate with cobalamin insufficiency in the infant.[46]

A longitudinal cohort study has documented that infants fed a macrobiotic (vegan-like with occasional servings of fish) diet[2] must be rapidly replenished with supplemental cobalamin before switching to a cobalamin-rich diet. Otherwise, up to 20% continue to have low cobalamin status.[2] This can lead to impaired psychomotor functioning well into youth and later adolescence with compromise in faculties related to reasoning, abstract thinking, and learning ability.[47]

Reports on nutritional macrocytic anemia identified cobalamin deficiency as the basis for anemia in up to 50% of cases of Indian children 6 months to 12 years old,[5] and 20% of anemic children 3 months to 3 years old in an urban Indian slum had cobalamin deficiency by serum levels.[2] It is likely that metabolite testing would have picked up many more asymptomatic cobalamin-deficient children. Parallel results come from studies on Guatemalan women.[2] Further evaluation of Guatemalan children indicates that they too continue to have low cobalamin status through dietary insufficiency alone or combined with as yet uncharacterized gastrointestinal cobalamin malabsorption.[48] The risk of a lower cognitive and neuromotor performance is real among children with low cobalamin status.[2,22] Reasoning, short-term memory, and perception were poorer than in the adequate-cobalamin group.[2,22] Guatemalan children represent the category of poverty-imposed near-vegetarianism that is prevalent throughout the developing world. Therefore cobalamin deficiency in children fed vegetarian diets, as with poverty-imposed near-vegetarianism, has very significant worldwide health implications. The fact that there is clear-cut biochemical evidence of perturbed cobalamin metabolism in vegetarians[45] and that hyperhomocysteinemia is a risk factor for several diseases (discussed later) suggests that vegetarians should be routinely taking inexpensive (generic) cobalamin supplements.[5]

Poverty afflicts approximately one-third of the Indian subcontinent,[2] and a World Bank report[2] on the crisis of malnutrition in India highlighted the fact that one-half of all children younger than 4 years are malnourished, 30% of all newborns are underweight, and 60% of all women are anemic. Any discussion of vegetarianism and cobalamin deficiency in developing countries immediately raises the question of whether folate deficiency—which consistently accompanies poverty and malnutrition—has become an uncommon cause of megaloblastic anemia. Although some studies suggest this is the case,[2] there remain nagging questions as to whether such patients had combined cobalamin-plus-folate deficiency.[2,40] This remains unresolved because testing using metabolites before and after cobalamin replacement has not been carried out in these populations.[5]

INTRAGASTRIC EVENTS LEADING TO COBALAMIN MALABSORPTION

Inadequate Dissociation of Cobalamin From Food Protein (Food-Cobalamin Malabsorption)

Dietary cobalamin is bioavailable only after proteolytic digestion of food by gastric acid and pepsin. Failure to release cobalamin from food protein can present as cobalamin deficiency even though gastric analysis reveals the presence of IF.[2] Some older patients (over 50 years of age) with atrophic gastritis or partial gastrectomy with hypochlorhydria have low serum cobalamin levels and normal absorption of crystalline cobalamin. Although they have poor absorption of CN-[^{57}Co]cobalamin that is incorporated into food as a "food cobalamin" absorption test,[2] this test is not standardized for general clinical use.

Among a cohort of patients (median age 76 years) with food-cobalamin malabsorption (who had normal stage I Schilling tests),[49] the clinical spectrum included neurologic or psychologic impairment with mild sensory polyneuropathy (nearly among one-half), with confusion or impaired mental functioning and physical asthenia (among one-fifth). There were mild hematologic changes (in one-third). Although there was improvement in hematologic changes among two-thirds, only one-third had improved peripheral neuropathy.

Congenital Intrinsic Factor Deficiency

Congenital IF deficiency, transmitted as an autosomal recessive trait and expressed in homozygotes by the age of 2 years, is characterized by a pure IF deficiency without other gastric abnormalities. Only approximately 40 cases have been described; affected children present with irritability, vomiting, diarrhea, and loss of weight with megaloblastic anemia. Except for the absence of IF in gastric juice, gastric histology and function are normal.[1] Mutations in the gastric IF are the basis for hereditary intrinsic factor deficiency (less than 100 cases reported).[50]

Loss or Atrophy of Gastric Oxyntic Mucosa

IF deficiency arising from atrophy of gastric parietal (oxyntic) mucosal cells must be associated with parallel insufficient HCl secretion and can be caused by total or partial gastrectomy; autoimmune destruction as observed in adult addisonian pernicious anemia or, rarely, in a similar disease in children (juvenile pernicious anemia); and destruction of gastric mucosa by caustic (lye) ingestion.

Total gastrectomy that results in removal of IF-producing cells invariably leads to cobalamin deficiency in approximately 5 years (range 2–10 years). This condition is often associated with iron deficiency (dimorphic anemia),[1] warranting routine cobalamin and iron replacement prophylactically.

Cobalamin deficiency is observed in only 10% to 20% of patients 8 years after partial gastrectomy, although 30% have cobalamin malabsorption[1]; up to 6% of these cobalamin-deficient patients will develop frank clinical manifestations of cobalamin deficiency with megaloblastic anemia. The cause is multifactorial, and contributing factors include decreased IF secretion, hypochlorhydria (from atrophy of residual oxyntic mucosal cells), intestinal bacterial overgrowth of cobalamin-consuming organisms, associated nutritional folate deficiency in 20%, and iron deficiency in approximately 50%. The degree of cobalamin deficiency depends on the size of the remaining gastric remnant. It is more common in Bilroth II than in Bilroth I surgery, in subtotal than in partial gastrectomy, and in gastric rather than duodenal peptic ulcer disease. Morbidly obese patients treated surgically with gastric bypass also have more food-cobalamin malabsorption than patients treated with vertical banded gastroplasty.[2]

Absent Intrinsic Factor Secretion and Pernicious Anemia

The most common cause of cobalamin malabsorption is pernicious anemia, a disease of unknown origin in which the fundamental defect is atrophy of the gastric (parietal cell) oxyntic mucosa eventually leading to the absence of IF and HCl secretion. Because cobalamin is only absorbed by binding to IF and uptake by ileal IF–cobalamin receptors, the net consequence is severe cobalamin malabsorption leading to cobalamin deficiency.

The annual incidence of pernicious anemia is approximately 25 new cases per 100,000 persons older than 40 years. Although the average age of onset is approximately 60 years, it is increasingly encountered in persons 5 to 10 years younger.[1] Pernicious anemia is not a respecter of age, race, or ethnic origin. The predisposition to developing pernicious anemia may have a genetic basis but neither the mode of inheritance nor the initiating event or primary mechanism is precisely understood. There is a positive family history for approximately 30% of patients, among whom the risk of familial pernicious anemia is 20 times as high as in the general population; approximately 20% of siblings of patients are projected to develop pernicious anemia by the age of 90 years. Pernicious anemia developing concordantly in identical twins has been documented.

There is a significant association of pernicious anemia with other autoimmune diseases[1] (ie, the polyglandular autoimmune syndrome characterized by multiple endocrine hypofunction with antibodies to endogenous endocrine glands). Pernicious anemia is associated with Graves disease (30%), Hashimoto thyroiditis (11%), vitiligo (8%), Addison disease, idiopathic hypoparathyroidism, primary ovarian failure, myasthenia gravis, insulin-dependent diabetes, and adult hypogammaglobulinemia.[1,2] Autoimmune gastritis (leading to

chronic atrophic gastritis) associated with pernicious anemia involves the fundus and body of the stomach. The histologic appearance of the gastric mucosa (infiltration with plasma cells and lymphocytes) is also strongly reminiscent of autoimmune-type lesions. There is also a high incidence of anti–parietal cell IgG antibodies in the serum of 90% of patients with pernicious anemia. The major antigen to which antibodies from patients with autoimmune gastritis and pernicious anemia are directed is the acid-producing enzyme H^+/K^+ ATPase (a 92-kd protein, the target of proton pump inhibitors), found on the membrane of parietal cells.[2] The precise interplay of the various mechanisms for anti–parietal cell IgG-mediated dysfunction of parietal cells remains to be shown in vivo. Anti-IF antibodies are found in the serum of approximately 60% of patients with pernicious anemia and in the gastric juice of 75%; approximately 90% of patients with pernicious anemia have anti-IF antibodies in serum or gastric juice.[1] Similar IF antibodies are quite rare in the general population. Thus, anti-IF antibodies are highly specific and confirmatory for pernicious anemia, but their absence does not rule out the condition. The assay for anti-IF blocking antibodies depends on the displacement of CN-[^{57}Co]cobalamin binding to IF in vitro. This can be significantly affected by prior injection of cobalamin (as given with a Schilling test) or by radioactive isotopes from other diagnostic tests.

There are two types of IF antibodies. Type I antibodies are directed to the cobalamin-binding site on IF and are usually of IgG subclass in the serum. In gastric secretions, they may be both IgG and secretory IgA subclasses. Type II IF antibodies bind to the IF–cobalamin complex and prevent binding to ileal IF–cobalamin receptors. Type II antibodies, usually not seen in the absence of type I antibodies, are found in approximately 35% of patients with pernicious anemia, although studies using a technique that detects both antibodies indicates a higher prevalence than previously documented.[2] Because of their functional properties, these intraluminal anti-IF antibodies may hasten development of pernicious anemia and interfere with tests for cobalamin absorption.[1]

The corticosteroid responsiveness in some patients with pernicious anemia (ie, regeneration of atrophic gastric mucosa and increased IF secretion antedating a decrease in anti-IF antibodies) also implicates an autoimmune pathogenesis of pernicious anemia.[1] The clustering of parietal cell dysfunction among first-degree relatives of patients with pernicious anemia (in inbred populations), the fact that some individuals (96% of African American women with pernicious anemia) have high titers of blocking anti-IF antibodies but lack anti–parietal cell antibodies,[1] and the fact that neither antibody may be detected in patients with pernicious anemia and acquired agammaglobulinemia all suggest that the pathogenesis of pernicious anemia is heterogeneous.

Juvenile pernicious anemia manifests in the second decade with severe cobalamin deficiency in conjunction with many of the associated endocrinopathies and autoantibodies observed in adults.[1] Why these patients present so much earlier with an apparently identical disease is unknown. Taken together, these facts suggest that although there is a genetic predisposition to pernicious anemia, the full expression of the disease, which appears to have an autoimmune basis, may be modified by acquired environmental influences.

Undiagnosed pernicious anemia is common among the free-living elderly (over 60 years)[2] who have only minimal clinical manifestations of cobalamin deficiency (ie, 1.9% of the survey population had unrecognized and untreated pernicious anemia). The prevalence was 2.7% in women and 1.4% in men, but 4.3% of the African American women and 4.0% of the white women had pernicious anemia. If these findings can be extrapolated, approximately 800,000 elderly people in the United States may have undiagnosed pernicious anemia.

In the absence of a Schilling test (which is currently not available in the United States), one-half of those with pernicious anemia can be diagnosed using serum anti-IF antibodies. The other half with pernicious anemia and negative antibodies and those with suspected food-cobalamin malabsorption (with no other obvious causes of malabsorption) are clinically indistinguishable. Fortunately, both these types of individuals can be successfully treated with oral cobalamin (over 1000 μg/day) in the long term (discussed later in Therapy).

Abnormal Intrinsic Factor Molecules

In three siblings, a defective IF molecule was identified by age 2 years that was identical to IF in all but one respect: it was markedly susceptible to acid and proteolytic enzyme (pepsin or trypsin) digestion, resulting in defective cobalamin absorption by ileal IF–cobalamin receptors and megaloblastic anemia.[1] In another case, an abnormal IF molecule having a 60-fold lower binding affinity for ileal IF–cobalamin receptors resulted in lower (but not absent) cobalamin absorption, probably accounting for the delayed clinical presentation with cobalamin deficiency at the age of 13 years.[1]

ABNORMAL EVENTS IN THE SMALL BOWEL LUMEN: IMPAIRED TRANSFER OF COBALAMIN FROM R PROTEIN TO INTRINSIC FACTOR

Insufficient Pancreatic Protease

Because approximately 30% of patients with severe pancreatic insufficiency fail to degrade R proteins, there is no transfer of food cobalamin to IF and consequent cobalamin malabsorption (R-cobalamin does not bind ileal IF–cobalamin receptors). R proteins are highly susceptible to proteolysis by even small quantities of pancreatic protease released in response to food. In partial insufficiency, there is abnormal absorption of CN-[^{57}Co]cobalamin on an empty stomach but normal absorption when the CN-[^{57}Co]cobalamin is given with food. Administration of pancreatic extract normalizes cobalamin malabsorption in those with complete pancreatic insufficiency.[1]

Inactivation of Pancreatic Protease

Pancreatic protease can be inactivated by massive gastric hypersecretion arising from a gastrinoma in Zollinger–Ellison syndrome.[1] The continued low pH of the luminal contents reaching the ileum may also perturb interaction of the IF–cobalamin complex with IF–cobalamin receptors (which requires a pH above 5.4).

Usurpation of Luminal Cobalamin

The near-sterile condition of the small bowel is maintained by a combination of the mechanical cleansing action of peristalsis and the chemical action of gastric acid. Disorders conducive to relative stasis, impaired motility, and hypogammaglobulinemia are predisposing factors favoring colonization by bacteria. Many of these bacteria take up free cobalamin, whereas the uptake of IF-bound cobalamin is markedly diminished. However, if colonization extends proximally to the locus at which IF and cobalamin interact, significant cobalamin may be usurped before it can bind to IF.[1] This cobalamin malabsorption can be corrected to some extent by a 7- to 10-day course of antibiotic therapy; definitive surgical correction may be indicated if the patient has significant symptoms (weight loss and diarrhea) that are only partially relieved by antibiotics. The malabsorption of food cobalamin in patients with atrophic gastritis has also been normalized with antibiotics, thereby incriminating bacterial usurpation of food cobalamin at a very proximal level.[2]

Approximately 3% of individuals infested with the fish tapeworm *Diphyllobothrium latum* develop frank cobalamin deficiency. In the life cycle of this parasite, tapeworm eggs passed in human feces embryonate in cool freshwater; the ciliated embryos are then swallowed by cyclops, which are the first intermediate host. After burrowing into the body cavity of the cyclops, they mature into the procercoid larval stage. The hapless cyclops (now infected with pro-

cercoids) are then swallowed by freshwater fish (eg, pike, perch, trout, and salmon found in lakes in Russia, Japan, Switzerland, Germany, and North America), and procercoids then migrate into the fish's flesh (ie, second plerocercoid larval stage). Humans become infected when they eat partially cooked or raw fish containing plerocercoids that develop into adult worms in approximately 6 weeks, growing to a length of 10 m, with up to 4000 proglottids[1]; when these worms lay eggs, the life cycle is repeated. In a given patient, the degree of cobalamin deficiency is probably related to the number and extent to which worms lodge proximal to ileal IF–cobalamin receptors. They are commonly found in the jejunum; poised in this strategic location, they avidly usurp cobalamin for growth.[1] After ova have been identified in the stools, expulsion of the worms by praziquantel (10–20 mg/kg as a single dose taken orally) and cobalamin replenishment is invariably curative.

DISORDERS OF ILEAL INTRINSIC FACTOR-COBALAMIN RECEPTORS OR MUCOSA

Absence of Intrinsic Factor–Cobalamin Receptors

The distal ileum has the greatest density of IF–cobalamin receptors, and removal of only 1 to 2 feet of terminal ileum by resection or bypass can reduce ileal IF–cobalamin receptor numbers or interaction with IF–cobalamin, respectively, to result in cobalamin malabsorption.[1,2] Ileal bypass or diseased ileal architecture may lead to reduction in transenterocytic transport of cobalamin, which is treatable with parenteral cobalamin replacement.

Defective Intrinsic Factor–Cobalamin Receptors or Post-Intrinsic Factor–Cobalamin Receptor Defects

Imerslund–Gräsbeck syndrome is a term used collectively for a heterogeneous group of congenital disorders in children involving selective cobalamin malabsorption that cannot be corrected by the administration of IF and that lead to megaloblastic anemias and low serum cobalamin associated with mild, persistent, benign, proteinuria (in 90% of cases). There have only been approximately 250 cases described worldwide. There is recessive inheritance, early onset (between 3 and 10 years), pallor, fatigue, anorexia, and failure to thrive, associated with frequent infections and bruising (from pancytopenia). In addition, there have also been variable neurologic symptoms such as cognitive problems, peripheral neuropathy, and dementia among these patients. These children have normal IF. It has now been shown that biallelic mutations in either the cubulin (*CUBN*) or amnionless (*AMN*) genes—whose gene products combine tightly to form the functional IF–cobalamin receptor[51] (now also called cubam)—are the cause of Imerslund–Gräsbeck syndrome. Because cubam also participates in the renal tubular absorption of several other proteins, this is the basis for proteinuria found in Imerslund–Gräsbeck syndrome. Interestingly, in Finland, all cases of Imerslund–Gräsbeck syndrome were found to be due to mutations in cubulin, whereas in Norway, the cases involved mutations in amnionless.[52] Because the radiocobalamin (Schilling) test is not available in many countries and without this test hereditary IF deficiency is indistinguishable from Imerslund–Gräsbeck syndrome, the only way to distinguish between these is through the analysis of mutational status of *CUBN* and *AMN* genes.[53]

Drug-Induced Defects

H_2 antagonists, but not proton pump inhibitors, inhibit IF secretion.[2] However, malabsorption of food-cobalamin from long-term omeprazole has been reported.[2] Biguanides (ie, metformin) appear to decrease IF and acid secretion in healthy volunteers; they also inhibit transenterocytic transport of cobalamin in 7%.[1] The latter is presumed to be caused by the displacement of calcium, which is required for the normal interaction of IF–cobalamin with the IF–cobalamin receptor. Because many diabetics take metformin, this could lead to a significant problem; fortunately, increased intake of calcium (1.2 g/day) can reverse the cobalamin malabsorption.[54] Other drugs (eg, Slow-K, cholestyramine, colchicine, neomycin) probably also impair transepithelial transport of cobalamin[1]; these drugs can interfere with the Schilling test.

DISORDERS OF PLASMA COBALAMIN TRANSPORT

Absence of Transcobalamin I and Transcobalamin III

Congenital R-protein deficiency is not associated with cellular cobalamin deficiency. However, because approximately 80% of serum cobalamin is bound to TC I, the serum cobalamin levels are invariably low with normal MMA and homocysteine levels. Two of six patients in one study developed a biochemically uncharacterized neurologic syndrome, which led to speculation that TC III deficiency might result in the inability to clear cobalamin analogs that may have a pathogenic role in the neurologic dysfunction.[1]

Deficiency of Transcobalamin II

Megaloblastic anemia in infancy associated with normal cobalamin levels is the characteristic clinical presentation when TC II is absent or markedly deficient. The impairment in intestinal absorption of cobalamin in such patients is also caused by the absence of TC II, which plays an important role in binding cobalamin within the enterocyte before its entry into the circulation. In all, approximately 30 patients have been described.[2] They can be successfully treated by daily or biweekly injections of 1 mg of cobalamin, which ensures passive cobalamin delivery into cells.

Defective Transcobalamin II

Defective TC II can be diagnosed when the amount of TC II measured by radioimmunoassay is normal but there is a qualitative abnormality based on its inability to bind cobalamin.[1] Conversely, in another patient with normal amounts of TC II by radioimmunoassay, the TC II was functionally active in binding cobalamin but unable to facilitate the uptake of cobalamin into cells.[1]

Clinical correlations of various polymorphisms among proteins involved in cobalamin metabolism are still under scrutiny to define if there are populations who are more susceptible to cobalamin deficiency and who may benefit from cobalamin supplementation. In most instances, these polymorphisms result in minor elevations in homocysteine that are clinically insignificant.[55]

DISORDERS OF INTRACELLULAR COBALAMIN USE

Congenital Metabolic Defects of Cobalamin Metabolism: Cobalamin Mutants A–F

The combination of megaloblastic anemia with increased levels of homocysteine or MMA, or both, in serum and urine despite normal cobalamin and folate levels should suggest an inborn error of cobalamin metabolism.[2,50] The inherited defects of cobalamin use (see Fig. 39–3) are heterogeneous and are empirically defined as cobalamin mutations A to G (*cblA* to *cblG*) through the use of complementation studies involving in vitro fusion of cultured mutant fibroblasts obtained from skin biopsies. Mutants involving the synthesis of adenosylcobalamin within the mitochondria involve defects in the reduction of cob(II)alamin to cob(I)alamin (*cblA*) and of cob(I)alamin to

adenosylcobalamin by adenosylcobalamin transferase (*cblB*). These defects result in an accumulation of excess MMA. The clinical picture in infancy is dominated by acidosis and ketosis associated with lethargy, failure to thrive, vomiting, dehydration, respiratory distress, hepatomegaly, and coma. Biochemical evidence of methylmalonic acidemia, ketonemia, and ketonuria without megaloblastosis is found. Because some of these defects are incomplete, treatment with large doses of cobalamin may alleviate the defect.[2,50] Defects involving conversion of cob(III)alamin to cob(II)alamin (*cblC*, *cblD*) present with combined evidence of reduced activity of methylmalonyl-CoA mutase and methionine synthase (ie, with increased homocysteine and MMA in blood and urine).[2,50] These patients have prominent neuropsychiatric problems with mental retardation, microcephaly, psychosis, delirium, and retinopathy with megaloblastosis. The *cblC* mutants have hemolytic uremic syndrome as an integral manifestation of the spectrum of this disorder.[2] Although the disorder usually manifests in infancy, some patients manifest problems in later childhood. Hydroxocobalamin [cob(III)alamin] appears to be more effective than cyanocobalamin in these patients. *cblE* (distinguished by the lack of increase in MMA) is thought to be a defect arising from the inability to maintain cobalamin bound to methionine synthase in its reduced state.[1] The *cblF* mutation is caused by an inability of cobalamin to be transported from the lysosome into the cytoplasm.[2] *cblG* patients have defects in methionine synthase activity.[2] Among patients with mutant *cblG* defects, one patient presenting at the age of 21 years with a multiple sclerosis-like syndrome was initially undiagnosed simply because the serum cobalamin level and studies of cobalamin absorption were normal.[2] This suggests that adults presenting with cerebral, myelopathic, or neuropathic disturbances (occasionally masquerading as multiple sclerosis) should be screened for such defects in specialized laboratories. The retardation of myelination in a small series of infants with congenital disorders of cobalamin metabolism[56] and dramatic reversal with cobalamin on cranial MRI indicates the possibility of reversibility with early diagnosis and treatment with cobalamin.

Functional Cobalamin Deficiency after Nitrous Oxide Exposure

Nitrous oxide (N_2O) inactivates coenzyme forms of cobalamin by oxidizing the fully reduced cob(I)alamin to cob(III)alamin; this results in a state of functional intracellular cobalamin deficiency. This syndrome was first identified in patients with tetanus given N_2O for up to 6 days.[1] Subsequently, persons exposed to N_2O for open heart surgery and through chronic (surreptitious, accidental, or occupational) exposure have been recognized as being at a high risk for developing megaloblastosis and cobalamin-deficient neuromyelopathy.[1] Although megaloblastosis develops within 24 hours and lasts less than 1 week after a single exposure, the neurologic syndrome is usually seen with chronic intermittent exposure. However, severe neurologic deficits have been reported after prolonged intraoperative exposure to N_2O in patients with unsuspected cobalamin deficiency.[2] The integrity of the methionine synthase-catalyzed reaction can be tested by measuring the serum homocysteine concentration, even after 75 minutes of exposure during surgery.[2] Reduced enzyme activity explains the metabolic block, which can be bypassed by 5-formyl-tetrahydrofolate (ie, leucovorin). No screening is routinely carried out for elderly patients who are placed under anesthesia with N_2O, despite the fact that subclinical cobalamin deficiency exists among 15% to 20% of them in some series, and despite the recognition that those with frank cobalamin deficiency can suffer adversely with postoperative cognitive and other neurologic dysfunction following exposure to N_2O.[2,57] Whether individuals with subclinical cobalamin deficiency are indeed at risk for postoperative cognitive dysfunction remains to be defined.

CLINICAL EVALUATION OF COBALAMIN ABSORPTION

The Schilling Test

With rare exceptions, adults with cobalamin deficiency have cobalamin malabsorption (from pernicious anemia, food-cobalamin malabsorption, infestation with *D. latum*, bacterial overgrowth, or ileal malabsorption) or, in vegetarians, dietary cobalamin insufficiency. All of these conditions can be treated similarly with monthly parenteral cobalamin or daily oral cobalamin (discussed later in this chapter in Therapy). Because information on the cause and locus of cobalamin deficiency does not appear to alter or direct therapy with cobalamin, does the identification of the locus of cobalamin malabsorption make any difference to the outcome in adults? (That is, should a Schilling test be done at all?) Two compelling arguments in favor of the Schilling test are that the test results can suggest additional diagnostic tests (eg, intestinal biopsy, examination of stool for malabsorption, *D. latum* infestation) and specific therapy (eg, gluten-free diet, folate, antibiotics, antihelminthics) and that it can identify the potential for reversibility and thereby dictate the duration of cobalamin replacement.

Etiopathophysiologic Classification of Cobalamin Deficiency

I. Nutritional cobalamin deficiency (ie, insufficient cobalamin intake)
   A. Vegetarians, poverty-imposed near-vegetarians, breast-fed infants of mothers with pernicious anemia
II. Abnormal intragastric events (ie, inadequate proteolysis of food cobalamin)
   A. Atrophic gastritis, partial gastritis with hypochlorhydria, proton-pump inhibitors, H_2 blockers
III. Loss or atrophy of gastric oxyntic mucosa (ie, deficient intrinsic factor [IF] molecules)
   A. Total or partial gastrectomy, pernicious anemia, caustic destruction (lye)
IV. Abnormal events in small bowel lumen
   A. Inadequate pancreatic protease (eg, R-cobalamin not degraded, cobalamin not transferred to IF)
      1. Insufficient pancreatic protease (ie, pancreatic insufficiency)
      2. Inactivation of pancreatic protease (ie, Zollinger–Ellison syndrome)
   B. Usurping of luminal cobalamin (ie, inadequate cobalamin binding to IF)
      1. By bacteria, during stasis syndromes (eg, blind loops, pouches of diverticulosis, strictures, fistulas, anastomosis), impaired bowel motility (eg, scleroderma), hypogammaglobulinemia
      2. By *Diphyllobothrium latum* (fish tapeworm)
V. Disorders of ileal mucosa/IF–cobalamin receptors (ie, IF–cobalamin not bound to IF–cobalamin receptors)
   A. Diminished or absent IF–cobalamin receptors (eg, ileal bypass, resection, fistula)
   B. Abnormal mucosal architecture/function (eg, tropical or nontropical sprue, Crohn disease, tuberculosis ileitis, infiltration by lymphomas, amyloidosis)
   C. IF-/post-IF–cobalamin receptor defects (eg, Imerslund–Gräsbeck syndrome, transcobalamin II [TC II] deficiency)
   D. Drug effects (eg, slow K, metformin, cholestyramine, colchicine, neomycin)
VI. Disorders of plasma cobalamin transport (ie, TC II–cobalamin not delivered to TC II receptors)
   A. Congenital TC II deficiency, defective binding of TC II–cobalamin to TC II receptors (rare)
VII. Metabolic disorders (ie, cobalamin not used by cells)
   A. Inborn enzyme errors (rare)
   B. Acquired disorders (eg, cobalamin functionally inactivated by irreversible oxidation, N_2O inhalation)

Nevertheless, given the current lack of availability of the Schilling test, the default option is to give cobalamin replacement at a dose of 2000 μg/day (orally) for adult cobalamin deficiency from any cause. (If there are clinical or metabolic abnormalities arising from long-standing cobalamin deficiency, the patient would be best served by initial parenteral therapy with cobalamin to rapidly replenish stores.) The same approach may not be appropriate in the case of children with congenital cobalamin deficiency where it is important to know the basis for cobalamin deficiency, and how best to aggressively reverse congenital metabolic defects of cobalamin metabolism, as well as which type of cobalamin preparation should be used. Such children should be referred to specialized centers for further evaluation.[50]

A promising alternative to the Schilling test that is currently under investigation involves oral administration of ^{14}C-cobalamin and measurement of absorbed ^{14}C-cobalamin in a capillary-sized blood sample by accelerator mass spectrometry.[58] This method can measure attomole (10^{-18} mol) amounts of ^{14}C-cobalamin in milligram or microliter amounts without need of a flushing dose or collection of urine and with negligible exposure of subjects to radioactivity (equivalent of 1.1 millirem, which is comparable to the solar radiation dose sustained by passengers during a 2-hour commercial airline flight). Although the principles of the Schilling test would still be applicable to any new cobalamin absorption test, this method using accelerator mass spectrometry still requires additional clinical validation.

The Schilling Test

If cobalamin absorption is intact, CN-[^{57}Co]cobalamin administered orally will first bind R-protein in the stomach. In the duodenum, the R-protein of the R-CN-[^{57}Co]cobalamin complex is degraded by pancreatic protease, resulting in rapid transfer of released CN-[^{57}Co]cobalamin to the patient's own intrinsic factor (IF). The CN-[^{57}Co]cobalamin–IF complex travels to the ileum, where it interacts with specific IF–cobalamin receptors. After it is taken up by the enterocyte, CN-[^{57}Co]cobalamin is transported into the portal blood while bound to transcobalamin II (TC II). If the blood contains an excess of cobalamin (eg, from a flushing injection of exogenously administered cobalamin), more than 8% of the CN-[^{57}Co]cobalamin will be excreted in the urine within 24 hours (ie, a normal stage I test). If there is a decrease in endogenous IF, as in pernicious anemia, less than 8% will ultimately be excreted; however, if IF is given exogenously with the CN-[^{57}Co]cobalamin, the abnormality will be corrected (ie, a corrected stage II test). When CN-[^{57}Co]cobalamin is usurped by bacterial overgrowth, resulting in decreased absorption of CN-[^{57}Co]cobalamin plus IF, prior therapy with antibiotics for 7 to 10 days can correct cobalamin malabsorption (ie, a corrected stage III test)[1]; however, antibiotics cannot correct cobalamin malabsorption caused by fish tapeworm infestation or defects involving net deficiency of IF–cobalamin receptors, such as ileal resection, fistulas, or diseases of the ileal mucosa, including TC II deficiency (Table 39–3 and Fig. 39–2). The most common cause of an abnormal Schilling test[1] is incomplete collection of urine. Patients with renal impairment also excrete less than normal amounts of radioactive cobalamin. A significant titer of IF antibodies of the blocking type in gastric juice can lead to an abnormal stage II Schilling test. False normal values in the presence of true cobalamin deficiency can arise from contamination of urine with stool containing unabsorbed CN-[^{57}Co]cobalamin and the presence of another isotope used in diagnostic tests (such as ^{99m}Tc, ^{67}Ga, ^{123}NaI, ^{131}I-MIBG, and ^{201}thallous chloride); delaying the Schilling test by 4 months will avoid interference with radiopharmaceuticals.[2] The flushing dose of unlabeled cobalamin administered during the Schilling test invalidates further testing of serum cobalamin and initiates a hematologic response in cobalamin-deficient patients. Because cobalamin or folate deficiency causes megaloblastosis of intestinal cells, the stage I Schilling test (with CN-[^{57}cobalamin] alone) may be abnormal in folate deficiency, or a patient with IF deficiency (eg, pernicious anemia) may be diagnosed as having an abnormal stage II test result because of an intestinal disorder.[1] This phenomenon occurs often enough (25% to 75% of cases) to warrant a repeat stage II Schilling test in patients diagnosed as having cobalamin malabsorption (from an intestinal cause) after 2 months of cobalamin replacement; only patients with pernicious anemia show correction in the stage II test (see Table 39–3).

Gastric Analysis

Gastric analysis for achlorhydria in adults is valuable only in the single situation in which the presence of gastric acidity in response to maximal stimulation (eg, Histalog) helps exclude the diagnosis of pernicious anemia. In children, however, gastric analysis for IF and acid can differentiate between congenital IF deficiency (acid present), juvenile pernicious anemia (acid and IF absent), and Imerslund–Gräsbeck syndrome (acid and IF present).

PATHOGENESIS OF FOLATE DEFICIENCY

Folate deficiency is usually recognized in the course of certain clinical presentations that predispose to negative folate balance and subsequent deficiency. It is instructive, therefore, to conceptualize cellular folate deficiency as arising from etiologic categories of *decreased supply*

Table 39–3 Results of Schilling Tests

	Material Administered				
Condition	*CN-[^{57}Co]Cbl Plus H_2O (Stage I Test)*	*CN-[^{57}Co]Cbl Plus IF (Stage II Test)*	*CN-[^{57}Co]Cbl After 7–10 Days of Antibiotics (Stage III Test)*	*CN-[^{57}Co]Cbl Plus Pancreatic Extract*	*CN-[^{57}Co]Cbl Food-Cbl Absorption Test (Research Tool)*
Normal	N				
Lack of IF	Low	N			
Usurping of Cbl by bacteria	Low	Low	N		
Pancreatic insufficiency	Low	Low	Low	N	
Lack/bypass of ileal IF-Cbl receptors or defective transenterocytic Cbl transport	Low	Low	Low	Low	
Inadequate dissociation of food Cbl	N				Low

Cbl, cobalamin; IF, intrinsic factor; Low, results indicate less than normal absorption; N, results indicate normal absorption.

Table 39–4 Similarities of Clinical Manifestations and Megaloblastic Sequelae of Folate and Cobalamin Deficiency*

System	Manifestations
Hematologic	Pancytopenia with megaloblastic marrow
Cardiopulmonary	Congestive heart failure
Gastrointestinal	Beefy-red tongue and added stigmata of broad-spectrum malabsorption in folate deficiency†
Dermatologic	Melanin pigmentation and premature graying
Genital	Cervical or uterine dysplasia
Reproductive	Infertility or sterility
Psychiatric	Depressed affect and cognitive dysfunction
Neuropsychiatric‡	Unique to cobalamin deficiency with cerebral, myelopathic, or peripheral neuropathic disturbances, including optic and autonomic nerve dysfunction

*However, the neurologic spectrum of dysfunction in cobalamin deficiency is distinct. Inadequate hemoglobinization (from inadequate iron stores or globin synthesis) can mask the expected erythroid megaloblastic morphology in the bone marrow and peripheral smear, and only specific therapy (ie, iron) can unmask classic megaloblastic manifestations (ie, masked megaloblastosis). Megaloblastic leukopoiesis is unchanged.

†If folate deficiency is uncorrected for 2 to 3 years, cobalamin deficiency will supervene.

‡Dorsal tract involvement is earliest manifestation in more than 70% of patients with cobalamin deficiency. Neuropsychiatric manifestations are not associated with megaloblastosis in up to 30% of patients.

(ie, reduced intake, absorption, transport, or use), or *increased requirement* (ie, metabolic consumption, destruction, or excretion). However, in the same patient more than one mechanism may result in net folate deficiency. The precise contribution of one mechanism over the other is often not obvious. And specific tests to define each mechanism are not routinely available for clinical use. Thus, the clinical context is especially important for interpreting test results for folate supply and function. Manifestations of folate deficiency may be hematologic (pancytopenia with megaloblastic marrow), cardiopulmonary, gastrointestinal (megaloblastosis with or without malabsorption), dermatologic (skin pigmentation), genital (megaloblastosis of cervical epithelium), infertility (sterility), and psychiatric (Table 39–4). These manifestations are discussed within the context of the history and physical examination (see Clinical Presentations and Evaluation for Floate and Cobalamin Deficiency). Cases of neuropathy in adults attributed to folate deficiency are rarely encountered; when they are, the possibility of alcoholism with thiamine deficiency must be considered. In any case, every patient with neuropathy, myelopathy, or psychiatric manifestations associated with megaloblastosis must be investigated in detail to rule out cobalamin deficiency. It must be remembered that gastrointestinal megaloblastosis begets further folate malabsorption, which propagates a vicious cycle of folate deficiency in the short term and cobalamin deficiency in the long term. With the exception of drug-induced defects or inborn errors of folate metabolism that result in decreased use of intracellular folates, all causes, irrespective of mechanism, result in reduced net delivery of folates to normal proliferating cells. In pursuing the causes of folate deficiency in a given patient, efforts should be directed toward obtaining positive evidence for all possible conditions predisposing to negative folate balance and deficiency.

NUTRITIONAL CAUSES OF FOLATE DEFICIENCY

The body stores of folate are adequate for approximately 4 months only.[1] Folate stores are probably depleted much earlier in individuals who are chronically in negative folate balance or who have additional conditions that can "tip" them into true folate deficiency. The incidence of folate deficiency in the setting of general malnutrition in developing countries is very high and is invariably a problem of multiple vitamin deficiencies when associated with protein-calorie malnutrition.[2] Decreased availability of folate-rich foods (in winter, after natural disasters, or the wet season in central Africa), poverty, various cultural or ethnic diets (consisting of maize, rice or well-cooked beans and vegetables), and cooking techniques that destroy food folate, coupled with the anorexia that accompanies chronic illnesses, are just a few of the reasons for rapid development of folate deficiency.[1,2]

The rapidly proliferating tissues in children have an absolute requirement for exogenously supplied folate. Although human or cow's milk is barely adequate to maintain folate balance in breast-fed infants, superimposition of associated illnesses that lead to anorexia or folate malabsorption readily shifts them into negative folate balance. Infants fed powdered milk formulas, goat's milk (which contains only 6 μg/L folate), or milk that has been boiled (approximately 50% of folate may be destroyed) are at high risk in this regard, as are those on restricted formulas for phenylketonuria and maple syrup urine disease. In Western countries food faddism, alcoholism, and slimming diets usually lead to decreased folate intake in young to middle-aged individuals.[1] Although beer has a higher folate content than other alcoholic beverages, alcoholism may lead to neglect of healthy dietary practices in favor of the high calories and "high" of alcohol. The edentulous, infirm, or neglected elderly who are too ill to prepare their meals, as well as psychiatric patients, are particularly at risk for nutritional folate deficiency.[1]

Etiopathophysiologic Classification of Folate Deficiency

I. Nutritional causes
  A. Decreased dietary intake
    1. Poverty and famine
    2. Institutionalized individuals (eg, psychiatric, nursing homes), chronic debilitating disease
    3. Prolonged feeding of infants with goat's milk, special slimming diets or food fads (ie, folate-rich foods not consumed), cultural or ethnic cooking techniques (ie, food folate destroyed)
  B. Decreased diet and increased requirements
    1. Physiologic (eg, pregnancy and lactation, prematurity, hyperemesis gravidarum, infancy)
    2. Pathologic (eg, intrinsic hematologic diseases involving hemolysis with compensatory erythropoiesis, abnormal hematopoiesis, or bone marrow infiltration with malignant disease and dermatologic disease such as psoriasis)

II. Folate malabsorption
  A. With normal intestinal mucosa
    1. Some drugs (controversial)
    2. Congenital folate malabsorption (rare)
  B. With mucosal abnormalities (eg, tropical and nontropical sprue, regional enteritis)

III. Defective cellular folate uptake
  A. Familial aplastic anemia (rare)
  B. Acute cerebral folate deficiency

IV. Inadequate cellular use
  A. Folate antagonists (eg, methotrexate)
  B. Hereditary enzyme deficiencies involving folate

V. Drugs
  A. Multiple effects on folate metabolism (eg, alcohol, sulfasalazine, triamterene, pyrimethamine, trimethoprim-sulfamethoxazole, diphenylhydantoin, barbiturates)

VI. Acute folate deficiency
  A. Intensive care unit setting
  B. Uncertain origin

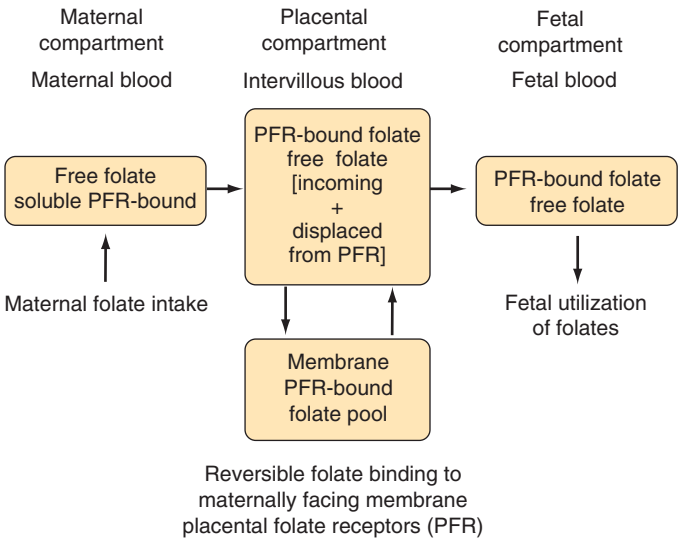

Figure 39–8 Diagrammatic representation of maternal-to-fetal transplacental folate transport involving placental folate receptors (PFRs). (Adapted from Henderson GI, Perez T, Schenker S, et al: Maternal-to-fetal transfer of 5-methyltetrahydrofolate by the perfused human placental cotyledon: Evidence for a concentrative role by placental folate receptors in fetal folate delivery. J Lab Clin Med 126:184, 1995.)

PREGNANCY AND INFANCY

Except for malnutrition in children, pregnancy with poor folate intake is the most common cause of megaloblastic anemia in the world. Pregnancy and lactation are associated with significantly higher folate requirements (over 400 µg/day) for growth of the fetus, placenta, breast, and other maternal tissues[59]; studies have identified increased catabolism of folate during pregnancy as another cause of deficiency.[2] This demand for folate must be met by adequate dietary intake. The placenta has a large number of folate receptors (FRs)[2,23] that facilitate binding and transport of folates to the developing fetus.[22] Preferential delivery of folate to the fetus can cause or aggravate folate deficiency in the mother.[1] This is observed clinically when a mother with severe folate deficiency gives birth to a baby who has normal folate stores. Folate deficiency in the pregnant mother can nevertheless lead to decreased placental weight and premature, low-birth-weight infants.[1] In this context, it is significant that (folate-responsive) hyperhomocysteinemia is recognized as a risk factor for women with unexplained recurrent early pregnancy loss[2] as well as in placental abruption or infarction[2]; thus, the very significant protective role of folates for the fetus.[22]

Placental FRs have a major role in transplacental folate transport (Fig. 39–8).[2,22] Net maternal-to-fetal folate transfer is a process consisting of two steps. First is the concentrative component in which circulating 5-methyl-tetrahydrofolate (5-methyl-H_4PteGlu) is bound to (ie, captured by) placental FR on the maternally facing chorionic surface. Although kinetics favor binding, a dynamic state exists wherein a gradual release of 5-methyl-H_4PteGlu from this pool adds to incoming circulating folates to generate an intervillous blood level approximately three times that in the maternal blood. In the second step, folates are transferred to the fetal circulation along a downhill concentration gradient. It turns out that the prodigious, reversible, high-affinity binding of maternal folates by placental FRs[2,22] is the key modulator of transplacental folate transport. Once captured, placental FR-bound folates are predestined for transplacental folate transport, because incoming (dietary) folates displace placental FR-bound folates, which then passively diffuse down a concentration gradient to the fetus.[2,22] This elegant cycle ensures continued unidirectional transplacental folate transport (Fig. 39–8).

Before the advent of routine folate supplementation during pregnancy, the incidence of megaloblastic marrows in the United States, Canada, and the United Kingdom during late pregnancy was approximately 25%, but in southern India, it was approximately 55%.[1] Folate deficiency is eight times as high in twin pregnancies. Multiparity (multiple frequent pregnancies with a prolonged state of negative folate balance) and hyperemesis gravidarum commonly lead to folate deficiency. Because the anemia of pregnancy is most frequently caused by iron deficiency, combined iron and folate deficiency (dimorphic anemia) is the more frequent clinical presentation. Increased use of folates in newborns leads to a drop in folate levels by approximately 6 weeks. This drop is exaggerated in premature infants, who because of feeding difficulties, infection, or hemolytic disease often develop pure folate deficiency.[1]

Recent studies of low socioeconomic status groups from North India[13,14] have estimated that the daily intake of folic acid range between 75 and 167 µg, which is far lower than the 400 µg necessary to prevent birth defects. Experimental studies to define the influence of gestational folate deficiency on the fetus (conducted on dams) using controlled dietary folate restriction—which was similar in principle to the extant diet of women in North India[13,14]—have identified adverse effects on reproductive performance, implantation, fetal growth, and other defects in murine fetal development; these defects included increased cell loss and subtle architectural anomalies that were traced in some tissues to megaloblastosis and in some cells apoptosis and severe dysplasia.[19] The folate-deficient murine fetuses exhibited an impressive net loss of cortical cells (by ~20%) in various regions of the brain, as well as a major alteration in white matter,[19] findings consistent with decreased progenitor cell proliferation and increased apoptosis in fetal mouse brain.[60] Because cobalamin deficiency leads to a functional intracellular folate deficiency and apoptosis, these findings of a loss of brain cell mass in folate deficiency in utero can explain the profound anatomic abnormalities noted on magnetic resonance imaging of the brains of infants and children with cobalamin deficiency.[2,61] Longitudinal follow-up identified that gestational folate deficiency also resulted in behavioral changes—an anxiety phenotype—during adulthood in these mice,[62] thereby supporting the fetal origins of disease hypothesis; the extent to which these important findings are relevant to humans remain to be determined.

FOLATE-RESPONSIVE NEURAL TUBE DEFECTS AND NEUROCRISTOPATHIES

NTDs are the most common major congenital malformation of the central nervous system. They arise from disturbances in neurulation that involve incomplete closure of neural tissues leading to major midline defects. The neural tube, which begins as a tiny ribbon of tissue, normally folds inward to form a tube by the 28th day after conception. Thus, NTDs originate in the first month of pregnancy (before many women know they are pregnant). Embryonic neural tube and neural crest cells have critical bursts of proliferative activity (with occasional doubling times as fast as 5 hours!), so it is not surprising that cellular folate deficiency has profoundly adverse effects on cells of the neural tube and neural crest that are responsible for midline closure during embryogenesis.[63] It is critical for a woman to have enough folic acid in her system before conception (periconceptionally) to ensure availability for the embryo.

The delivery of an optimum physiologic amount of folic acid to developing neural tube and neural crest cells appears to be the critical determinant to prevent NTD.[22,63] Genetic susceptibility, as occurs with the thermolabile *MTHFR* polymorphism, can explain only a small proportion (<15%) of the incidence.[2,64] A recent review[65] concluded that definitive conclusions about the precise role of specific folate pathway gene variants (polymorphisms) in causing spina bifida cannot be made at this time. However, a transgenic mouse model with a targeted inactivation of the murine FR-alpha gene resulted in homozygous mice that had NTDs and died by the 10th gestation day; these embryos could be rescued by very large doses of folinic acid.[2] Studies using mouse embryos cultured in vitro have demon-

Figure 39–9 Folate-responsive neural tube defects: anencephaly with complete rachischisis (*top panel*); open infected meningomyelocele (*bottom left*); and iniencephaly with cleft lip (*bottom right*). (Courtesy of Prof Molly Paul, Anatomy Department Museum, Christian Medical College and Brown Memorial Hospital, Ludhiana, Punjab, India.)

strated that alterations in FR by perturbing the coding sequences or a critical regulatory *cis*-element can play a role in NTDs.[66] So whether defects in regulatory proteins involved in translation of FR can lead to reduced expression of FR and NTD is now under investigation. In parallel with experimental studies involving exposure of pregnant rats to anti-FR antisera[67] which induced NTD, blocking autoantibodies against FR have been detected in women with a pregnancy that was complicated by a NTD[68] and orofacial clefts.[69] In addition to induction of NTD, knockout of FR and knock-down of FR have given rise to neurocristopathies that have now provided more support to the observational clinical studies which suggested that many of these—including cleft lip/palate,[2] conotruncal heart defects,[2] urinary tract defects[2] and limb reduction defects,[2] and omphalocele[70]—may be prevented by periconceptional folate supplements.[2,22]

Anencephaly and spina bifida, the commonest NTDs, are important factors in fetal mortality (Fig. 39–9). Worldwide, the risk in the general population ranges from less than 1 to 9 cases per 1000 births; for example, a recent population-based study in the least developed area in India identified that the incidence of NTDs was up to 8.21 per 1000 live births, which is among the highest worldwide.[71] By contrast, with less than 1 case per 1000 each year in the United States, approximately 4000 fetuses are affected, and at least one-third are lost through spontaneous or elective abortions when an affected fetus is detected; 100% of fetuses with anencephaly are stillborn or die shortly after birth. An association between folate and NTDs was conclusively established by a randomized, controlled study that investigated mothers with a history of delivery of a child with an NTD; these women have a 10-fold higher risk of having a second and subsequent baby with an NTD. This study showed that periconceptional folate supplementation (4000 μg/day) reduced NTD recurrence by 72%.[2] Periconceptional folate supplementation (800 μg/day) was then shown to dramatically reduce the first-time occurrence of NTD,[2] a result confirmed by a large study (with over 100,000 subjects in each arm) in which periconceptional folates (400 μg/day) also led to a dramatic prevention of NTDs in China.[2] There is some (nonrandomized) evidence that periconceptional folate deficiency also leads to oral clefts, conotruncal heart defects, and urinary tract abnormalities and limb reduction defects.[2] Conversely, the use of folic acid antagonists (trimethoprim, triamterene, carbamazepine, phenytoin, phenobarbital, and primidone) during pregnancy increases the risk of these birth defects by twofold.[72] Collectively, these studies confirm that folic acid has multiple salutatory effects during human development and that major abnormalities can be prevented by periconceptional folate supplementation.[59]

Can a young woman get enough folic acid by eating a "balanced Western diet"? The answer found in a controlled study[2] was a definitive no. Only those who received folic acid supplements or had folate-fortified foods improved their folate status (this is explained by the lower bioavailability of folate in foods). Because 50% of pregnancies in the United States are unplanned and compliance with taking

folic and supplements to preventing NTD is only at approximately 50%, this led to a consensus that fortification of food with folic acid in the United States was the best way to improve overall folate status in women at risk for NTD occurrence. By January 1998, fortification of foods (ie, rice, flour, pasta, macaroni, breads, and cake at 140 μg of folic acid per 100 g of food) was part of American Law. This level was chosen to ensure that women of childbearing age would have an increase in folic acid intake of 100 μg a day, which is approximately 25% of the recommended daily intake.

Assessment of folate status in the Framingham Offspring Cohort before and after fortification has indicated that food fortification with folate does not give the expected 100 μg a day; instead the estimate is between 1.5 and 3 times more than originally estimated.[2] As a consequence, after fortification the prevalence of folate deficiency (based on a plasma folate level less than <3 ng/mL) has been reduced in the United States from approximately 20% to 1%.[2] Independent studies have confirmed a near doubling of serum folate after fortification—from 12 to 20 ng/mL in a managed care setting.[73] This is suspected to be caused by manufacturers' overages (ie, addition by the manufacturer of a greater amount than specified) in folate fortification.

Although typical intakes of folic acid from fortified foods are more than twice the level originally predicted,[74] there remain questions about the effectiveness of the folic acid fortification program for women in the 15- to 35-year age group in preventing NTDs. Because of an incomplete knowledge base among some women,[2,75] and the tendency to consume low-carbohydrate foods (which are the very foods that are fortified), there is continued concern that this group is still not getting adequate amounts of dietary folate. This is the basis for recommendations to continue to educate women in the childbearing age to take folate supplements at 400 μg/day (beyond what they are already receiving through food folate fortification).

What impact has folic acid fortification of the US food supply had on the occurrence of NTDs? The birth prevalence of NTDs reported on birth certificates has decreased by 19%,[76] but the use of birth certificate data[77] might have led to underreporting. In Ontario, Canada, the prevalence of open NTDs also has declined from 1.13 per 1000 pregnancies before fortification to 0.58 per 1000 pregnancies thereafter.[78] Another recent study from Canada has identified that the prevalence of NTDs decreased from 1.58 per 1000 births before fortification to 0.86 per 1000 births during the full fortification period (a 46% reduction), with the decrease greatest in areas in which the baseline rate was high.[79]

Despite recommendations to increase folic acid to prevent NTDs, there has been no detectable impact in the trends of incidence of NTD worldwide.[80] This has led to calls to redouble efforts to quickly integrate food fortification with fuller implementation of recommendations on supplements. Even in the USA, it has been the position of some authorities that the majority of women in the childbearing age are not receiving the optimum amount of folate (400 μg folic acid per day). This has led to calls to increase the current fortification levels (140 μg/100 g of flour) to levels such as those used in Chile using 220 μg/100 g of flour[81]; however, this has been resisted with cogent arguments by others.[82] Moreover, based on a recent analysis of high quality studies from Canada that has a similar fortification program as the USA, it appears that the food fortification program is achieving near maximal outcomes, in that it appears to be preventing approximately 50% of NTDs.[79,83]

The potential masking of the hematologic manifestations of cobalamin deficiency by food fortification with folic acid remains a valid concern.[84] Those at greatest risk for receiving too much folate are the elderly with biochemical evidence of cobalamin deficiency.[2] This concern is amplified by a recent study that identified an increase in cognitive impairment among those with low cobalamin status who have high serum folate levels.[85] Another group who could potentially be inadvertently affected are children who consume large amounts of folate-fortified cereal and thereby exceed their recommended daily allowance of folate (ie, greater than 300 μg/day); the long-term consequence of persistently higher-than-normal folate levels is an unknown entity.

Among cultures in which most pregnancies are well planned, supplementation in the form of folic acid tablets is considered best.[2] Moreover, in places where food production and distribution is generally local, centralized fortification does not reach the masses, as is the case in developing countries such as India, where approximately 80% live in villages and small towns. There is no formal program in most developing countries for prevention of NTDs. In these settings, the methods employed to educate the educated minority need to be different from those used to educate the less educated. However, there is no information on which is the best method to reach these groups of women from the behavioral research standpoint.

INTRINSIC HEMATOLOGIC DISEASE

Because folate is necessary for hematopoiesis, folate requirements are increased when there is significant compensatory erythropoiesis in response to peripheral RBC destruction, abnormal hematopoiesis, or infiltration by abnormal cells in the marrow. The recognition that folate deficiency developing in hemolytic disorders can lead to an acute aplastic crisis has led to routine prophylactic administration of folate. An unexpected increase in transfusional requirement or a fall in platelets should also suggest folate deficiency.[1] The case of a patient with sickle cell disease on long-term folate who developed cobalamin malabsorption and presented with neuropsychiatric dysfunction is a valuable reminder that those on folate prophylaxis need periodic follow-up for signs and symptoms of supervening cobalamin deficiency.[86]

Folate Malabsorption With Normal Intestinal Mucosa

The enzyme folylpolygamma-glutamate carboxypeptidase that is expressed by the *GCP2* gene (also called *FOLH1*) is responsible for breakdown of polyglutamated folates to monoglutamated forms before absorption. The extent of [poly]glutamylation of folate in natural food folates is not the limiting factor in the extent of absorption of food folates,[87] and there appears to be little effect of an earlier described polymorphism[88] in the catalytic region of GCPII (resulting in 50% enzyme activity) on intestinal absorption of dietary folates.[89]

Congenital Folate Malabsorption

Patients with this disorder (usually the progeny of consanguineous marriages) present in the first 3 months with failure to thrive; diarrhea; sore mouth; megaloblastic anemia with low levels of serum, RBC, and cerebrospinal fluid folates; normal cobalamin levels; progressive mental retardation; seizures; cerebral calcification; athetosis; and ataxia. They do not respond to oral folate or 5-formyl-H_4PteGlu (5 mg) because of specific intestinal folate malabsorption as well as defective folate transport into the central nervous system.[1] Parenteral therapy in high concentrations is necessary to ensure passive folate transport. To establish the diagnosis, it is necessary to document that the patient has normal gastrointestinal absorption of other nutrients, intact pancreatic function, and normal mucosa on small intestinal biopsy. The differential diagnosis includes congenital IF deficiency, Imerslund–Gräsbeck syndrome, TC II deficiency, and inborn errors of cobalamin metabolism.

Folate Malabsorption With Intestinal Mucosal Abnormalities

Tropical Sprue

Residents of, and visitors to, endemic areas in the tropics can acquire a disorder of unknown cause characterized by small intestinal malabsorption.[1] Generalized, nonspecific small bowel malabsorption leads

to a wide spectrum of clinical manifestations arising from defective absorption of fat, carbohydrate, albumin, calcium, folate, and in later stages, cobalamin.[1] The endemic nature of this disorder in the tropics (and in certain households)[1] and the beneficial response to antibiotics all suggest an infectious origin. However, the dramatic response to folate, which is curative in the first year in approximately 60% of cases (this cure is cited to be almost diagnostic of the disease), has not been explained.[1] It is unlikely that pure folate deficiency is the primary cause, because nutritional folate deficiency does not result in tropical sprue; the clinical response to antibiotics suggests a close interplay between a pathogenic infectious agent, endogenous flora, and the folate status of the enterocyte.

There is some degree of villous atrophy and loss of intestinal functional surface. Although less severe than in nontropical sprue, it is more extensive, involving the entire small intestine. There is abrupt onset of explosive, intermittent, or continuous diarrhea, abdominal distention, and pain associated with anorexia, vomiting, and extreme fatigue. Stools are fluid or semisolid and frequently contain mucus and blood. This stage is followed weeks to months later by nutrient deficiency. Later, as steatorrhea continues, megaloblastosis dominates the clinical picture. In the short term, malabsorption leads to folate deficiency, but later in the chronic (longer than 3-year) phase of the disease, cobalamin malabsorption contributes additional clinical manifestations of cobalamin neuropathy.[1]

Coexisting iron deficiency (common in these areas) leads to a dimorphic blood picture; pellagra and beri-beri may also coexist in these patients. Treatment of the chronic phase with folate can cure the hematologic manifestations but exacerbate cobalamin-deficient neurologic disease. In South India, among 64 patients with megaloblastic anemia from tropical sprue, 21% were caused by cobalamin deficiency, 33% by folate deficiency alone, and 44% by combined cobalamin and folate deficiency.[1] After investigations for associated iron, cobalamin, and folate deficiencies, therapy with folate and a broad-spectrum antibiotic (eg, tetracycline) is indicated together with symptomatic treatment of diarrhea, vomiting, fluid, mineral and electrolyte imbalance, and associated additional nutritional deficiencies.[1]

Nontropical Sprue

Nontropical sprue (ie, celiac disease, gluten-induced enteropathy) is the most common cause of intestinal malabsorption in temperate zones. It results from a possibly inherited sensitivity to gluten (a glutamine-rich protein found in wheat, barley, rye and other grains) and a related substance, gliadin.[1] The precise mechanism for induction of sensitivity is not known. The intestinal lesion (ie, villous atrophy with hypertrophied crypts and lymphocytic and plasma cell infiltrate of the lamina propria) is more florid than that seen in tropical sprue but occurs to a greater extent in the proximal small intestine with relative ileal sparing; as a result, cobalamin malabsorption is less common. The consequences of malabsorption are otherwise the same. Patients present between the ages of 30 and 50 years with intermittent or persistent diarrhea (abrupt in 20%), weight loss, abdominal distention with discomfort, glossitis, and megaloblastic anemia. Diagnosis is established by demonstration of sensitive and specific serum antiendomysial antibodies IgA type or antitissue transglutaminase antibodies, malabsorption, and jejunal biopsy. The symptoms are exacerbated after a challenge with gluten, and institution of a gluten-free diet not only is curative but also decreases the risk of subsequent malignancy (small intestinal lymphoma or gastrointestinal carcinoma, especially esophageal). Iron deficiency is prominent, especially in children. The megaloblastosis responds well to folate therapy.[1]

Regional Enteritis and Other Small Intestinal Disorders

The distal small intestine is involved in 80% of individuals with Crohn disease, but folate is efficiently absorbed in other more proximal areas. Only with extensive involvement or fistulas do these patients develop folate deficiency. Even in this case, the blood picture is more that of an iron deficiency or anemia of chronic disease. Frank, pure megaloblastic anemia occurs rarely enough in this setting to suggest another cause for folate or cobalamin malabsorption. HIV infection results in an enteropathy, in the absence of opportunistic infection, which leads to the malabsorption of folates.[2]

INFANTILE ACUTE CEREBRAL FOLATE DEFICIENCY SYNDROME

Infantile-onset cerebral folate deficiency[90] that develops 4 to 6 months after birth is characterized by marked irritability, slow head growth, psychomotor retardation, cerebellar ataxia, pyramidal tract signs in the legs, dyskinesias (such as choreoathetosis and ballismus), and in some cases, seizures. Untreated, central visual disturbances can become manifest and lead to optic atrophy and blindness by the third year. Because there is a low level of 5-methyl-H_4PteGlu$_n$ in the cerebrospinal fluid, with normal folate levels in the serum and erythrocytes, a blood-to-CSF folate transport defect was suspected. Further analysis has demonstrated that a high number of children (25 of 28) had high-affinity blocking FR-autoantibodies that could react against membrane-bound FR that are normally present on the choroid plexus. Oral folinic acid normalized 5-methyl-H_4PteGlu$_n$ levels in the cerebrospinal fluid and led to clinical improvement. It is therefore speculated that anti-FR antibodies prevented the transfer of folate from the plasma to the cerebrospinal fluid via the choroid plexus, thereby depriving the developing brain of folate. Although plausible, this hypothesis has not been rigorously proven experimentally. Nevertheless, this experiment of nature may point to a situation where normal physiology involving the blood-to-CSF folate transport has gone awry.

INBORN ERRORS OF FOLATE METABOLISM

Knowledge of the intracellular metabolic pathways involving folates can help predict the net effect of deficiency of a single enzyme (see Fig. 39–5). Substrate buildup or product deficiency leads to the clinical manifestations. The precise biochemical defects can be proved by specific enzyme assays of the patient's fibroblasts. Deficiency of 5,10-methylene-tetrahydrofolate reductase (MTHFR) is the most frequent of these rare disorders and manifests with excess homocysteine in the serum and urine and with hypomethioninemia. The disease is recognized in infancy because of developmental delay or mental retardation, with motor abnormalities and disturbance in gait. It has, however, occasionally remained undiagnosed until the teenage years. Serum folate levels are normal or low, but the cobalamin concentration is normal. There is no megaloblastosis, TC II levels are normal, and there is often a poor response to folic acid (PteGlu). Despite a variety of treatments administered, no consistent pattern of response has emerged (which likely reflects significant genetic heterogeneity within this disorder).[2,50] Excellent reviews of these and other inborn errors of folate metabolism are available.[2,50] Thermolabile MTHFR is discussed later in Hyperhomocysteinemia and Folate and Carcinogenesis.

ACUTE FOLATE DEFICIENCY

The cause of acute folate deficiency in some patients in intensive care units is not known. Clinically the presentation is acute megaloblastic arrest of hematopoiesis with thrombocytopenia. These patients are often acutely ill and in subclinical negative folate balance. The combination of additional insults (decreased intake, total parenteral nutrition containing ethanol, dialysis, surgery, sepsis, drugs) appears to provoke frank folate deficiency. The serum folate is often normal in the face of megaloblastosis in the bone marrow without obvious peripheral blood abnormalities. The dU suppression test[2] has docu-

mented intracellular folate deficiency, but there are no data on MMA and homocysteine levels in this condition. Empirical therapy with 5-formyl-H_4PteGlu (leucovorin) is recommended. Exposure to N_2O should also be considered in the differential diagnosis.[2]

MEGALOBLASTIC ANEMIA NOT CAUSED BY FOLATE OR COBALAMIN DEFICIENCY

Several chemotherapeutic agents (eg, antimetabolites, alkylating agents) kill malignant cells primarily by interfering with DNA synthesis; megaloblastosis is therefore an expected side effect. Hereditary orotic aciduria usually manifests in the first year of life because of a deficiency or absence of enzymes that convert orotic acid to uridine monophosphate via orotidine monophosphate. The net cellular deficiency of uridine monophosphate leads to perturbed synthesis of DNA as well as RNA.[1] Thiamine-responsive megaloblastic anemia is an early-onset, autosomal recessive disorder defined by the occurrence of megaloblastic anemia, diabetes mellitus, and sensorineural deafness (ie, the DIDMOAD syndrome: *d*iabetes *i*nsipidus, *d*iabetes mellitus, *m*egaloblastosis, *o*ptic *a*trophy, and sensorineural *d*eafness) that responds to various degrees to thiamine treatment; it is caused by a single gene disorder involving the thiamine transporter.[2]

CLINICAL PRESENTATIONS AND EVALUATION FOR FOLATE AND COBALAMIN DEFICIENCY

Clinical presentations and evaluations for folate and cobalamin deficiency are shown in Table 39–4.

INTERVIEW

The patient's general demeanor and answers to questions may reveal a blunted affect with evidence of depression, irritability, forgetfulness, and sleep deprivation (common in pure folate deficiency). Alternatively, cobalamin deficiency may present with paranoid ideation (mimicking paranoid schizophrenia), dementia, cognitive dysfunction, delusions, or lack of energy manifested by slowed responses. Hallucinations or even obtundation may preclude obtaining an adequate history. The family may indicate the progressive evolution of a marked personality change and may be able to help trace the evolution of symptoms and deviations from the time when the patient was last well. Intermittent therapy with multivitamins, liver pills, or injections (often given by a well-meaning family member or unregistered practitioner) is a common quick fix in many cultures. The family is a good source for details on the patient's dietary habits (food faddism, vegetarianism, alcohol intake) and family history of medical problems (blood diseases, gluten sensitivity, autoimmune diseases).

A medical history of epilepsy or alcoholism with seizure disorder (anticonvulsant therapy) is important. Rarely, patients with autoimmune hemolytic anemias may be lost to follow-up and return with acute aplastic crises when they run out of folate. A surgical history of total or partial gastrectomy, anastomosis, fistula, or bowel resection can reveal the potential for perturbation of physiologic absorption (loss of IF, bypassing or loss of absorptive surface, blind loop syndromes). Surreptitious or accidental inhalation of N_2O in an occupational setting (dental or anesthesiology professionals) and deliberate inhalation of N_2O (cartridges attached to whipped-cream dispensers or visits to "houses of laughter," where N_2O can be inhaled for a small fee) can be revealed only on direct questioning. Visits to tropical countries and the development of intermittent episodic diarrhea may give a clue to tropical sprue; prolonged (over 3 years) chronic gastrointestinal symptoms followed by insidious development of neurologic problems predicts a combined (folate followed by cobalamin) deficiency.

Systemic review of symptoms may range from none (ie, incidental increased MCV or PMN hypersegmentation) to severe (ie, unstable angina from severe anemia). With slow development of anemia, the patient often does not develop cardiopulmonary symptoms until there is a 50% reduction in hemoglobin concentration, which leads to dyspnea on exertion, palpitation, and generalized fatigue or lethargy. Only when the hemoglobin concentration is below 5 g/dL does the patient develop dyspnea at rest and angina on modest exertion or even at rest. Congestive heart failure is heralded by pedal edema, nocturia, orthopnea, and tender hepatomegaly.

Upper gastrointestinal symptoms with anorexia associated with intrinsic gastrointestinal disease or anemia with heart failure must be distinguished from symptoms due to glossitis. The latter may lead to inability to wear dentures, tolerate hot drinks or spicy foods because of burning, and even odynophagia, which may further compromise food intake (seen in cobalamin and folate deficiencies). The patient may volunteer that glossitis is relieved by multivitamin ingestion. Weight loss in cobalamin deficiency is not as severe as in folate deficiency arising from intrinsic gastrointestinal disease. Episodic or chronic diarrhea with steatorrhea is commonly caused by tropical sprue, although it may be brought on by gluten-containing foods. Although these symptoms may be accompanied by abdominal pain, pain in the absence of diarrhea could be caused by tabetic crisis (vomiting, abdominal rigidity, absence of leukocytosis, or fever) accompanying spinothalamic involvement in cobalamin-deficient myelopathy.

The patient with pernicious anemia may have two or three semisolid bowel movements per day; although this may be construed as a normal pattern, it may represent a change since the last time the patient was well. Constipation may be related to obstipation arising from the involvement of Meissner and Auerbach plexus within the gastrointestinal tract. Similarly, incipient loss of bladder or bowel control due to cobalamin myelopathy may present with urgency or nocturia.

In contrast to musculoskeletal symptoms (arthralgia or frank arthritis) of autoimmune diseases, nocturnal cramps or pain in upper and lower extremities may indicate spinothalamic tract involvement. Hypoparathyroidism or systemic lupus erythematosus, alone or associated with pernicious anemia, leads to significant overlap of cerebral, musculoskeletal, and neurologic presentations.

Review of skin symptoms may elicit a history of increased diffuse or blotchy generalized brownish skin pigmentation, especially of nail beds and skin creases. This is common in cobalamin and folate deficiency; associated vitiligo suggests autoimmune disease.

Although symptoms related to neurologic dysfunction may be volunteered, a complete detailed questionnaire should be formulated during the interview. Questions should be directed to perversions in taste or smell, decreased visual acuity, changes in color vision, and eye pain (neuritis), tinnitus, or headache. Dizziness with orthostatic hypotension and "blacking out" may be related to severe anemia.

Miscellaneous Megaloblastic Anemias Not Caused By Cobalamin or Folate Deficiency

I. Congenital disorders of DNA synthesis
   A. Orotic aciduria
   B. Lesch–Nyhan syndrome
   C. Congenital dyserythropoietic anemia
II. Acquired disorders of DNA synthesis
   A. Deficiency (ie, thiamine-responsive megaloblastic anemia [DIDMOAD syndrome])
   B. Malignancy (ie, erythroleukemia)
      1. Refractory sideroblastic anemias
      2. All antineoplastic drugs that inhibit DNA synthesis (and antinucleosides used against HIV and other viruses)
   C. Toxic sources, including alcohol

Drugs That Perturb Folate Metabolism

Ethanol in amounts of more than 80 g/day is toxic to hematopoietic precursors and can directly lead to megaloblastosis with abnormal vacuolization of normoblasts and to sideroblastic anemias. These toxic changes seen in severe alcoholics are usually associated with significantly higher alcohol consumption and revert to normal with alcohol withdrawal. Patients who have one nutritious meal each day tend to stave off the eventual development of folate deficiency. Alcohol consumption leads to a relatively rapid (2- to 4-day) fall in serum folate levels. This is a result of the combined effects of increased urinary folate excretion[2]; interruption of the enterohepatic circulation (resulting from an effect on hepatic pteroylpolyglutamate synthesis and reduced release of tissue folates into plasma and bile); formation of acetaldehyde–H_4PteGlu adducts (5,10-(CH_3-CH)-H_4PteGlu$_n$); increased catabolism of folate by ethanol to acetaldehyde/xanthine oxidase-generated superoxide[2]; malabsorption of folate by inhibition of jejunal folate pteroylpolyglutamate hydrolase[2]; perturbation of methionine synthase activity[2]; and increased urinary excretion of formate, which is normally metabolized by folate-requiring enzymes.[1] The relative degree to which each of these mechanisms contributes to folate deficiency remains to be determined. Excess alcohol consumption is probably the most common cause of folate deficiency in the United States.[1]

Trimethoprim and *pyrimethamine* bind to bacterial and parasitic dihydrofolate reductase with much greater affinity than to human dihydrofolate reductase, but patients with underlying folate deficiency appear to be more susceptible to the effects of these drugs. The ensuing megaloblastosis can be reversed by 5-formyl-H_4PteGlu.

Methotrexate binds to human dihydrofolate reductase ($K_i = 7 \times 10^{-10}$ M) and leads to trapping of folate as a metabolically inert form (dihydrofolate, H_2PteGlu). This leads to a true depletion of H_4PteGlu$_n$ within hours and consequently to functional deficiency of 5,10-methylene-H_4PteGlu$_n$ and reduced thymidylate synthesis. Although megaloblastosis can develop rapidly, the toxic effects of methotrexate can be avoided by rescue with 5-formyl-H_4PteGlu (ie, leucovorin). However, the effects of repletion on tumor with 5,10-methylene-H_4PteGlu$_n$ presents a problem. Folate receptors take up methotrexate at lower doses, but reduced-folate carrier-mediated and passive diffusion appear to be the main routes of cellular uptake at high doses. Once in the cell, methotrexate is polyglutamated, which determines its cytotoxicity. The maintenance of a gradient between the extracellular and intracellular compartment appears to determine polyglutamation and efficiency of cytotoxicity.

Sulfasalazine produces megaloblastosis in up to two-thirds of patients taking full doses (over 2 g/day) by decreasing absorption of folates (ie, decreasing conversion of H_4PteGlu$_n$ to H_4PteGlu) and induction of Heinz body hemolytic anemia (ie, increased requirements).

It is still not clear whether cases in which megaloblastic anemia develops while patients are receiving *oral contraceptives* represent a cause-and-effect relationship. Oral contraceptives may increase folate catabolism (ie, metabolic consumption) or may weakly interfere with DNA synthesis. It is significant that the megaloblastosis of cervical epithelium often reverses with folate therapy alone.

Reduction of serum folate levels by *anticonvulsants* during prolonged therapy probably results from the combined action on reduced absorption and through induction of microsomal liver enzymes.[2] It is unclear how folates provoke a return of seizures in some patients receiving anticonvulsants, but this effect may be mediated by glutamate (or related) receptors.[2] Despite this potential risk, consensus guidelines have stressed the importance of ensuring that pregnant women[2] and children[91–94] with epilepsy be prescribed folates together with anticonvulsants.

Although *antineoplastics* and *antiretroviral antinucleosides* such as azidothymidine lead to megaloblastosis, the temporal sequence and investigations to rule out cobalamin or folate deficiency should easily lead to a correct causal assignment.

Vertigo or difficulty in walking in the dark (loss of proprioception and position sense), difficulty in ambulation (which may feel like "walking on cotton wool"), stiffness of extremities (corticospinal tracts), or ataxia (spinocerebellar tracts) may be indicative of a serious cobalamin myelopathy. Early symptoms are symmetrical tingling ("pins and needles"), extending from the tips of the toes to a glove and stocking distribution in later stages. "Burning feet" syndrome, or more commonly, complaints of difficulty in performing simple tasks such as buttoning clothes, may also be a presenting symptom. When loss of bladder and bowel control brings the patient to the physician, advanced neurologic dysfunction is invariably present.

Other genitourinary symptoms such as recurrent cystitis from bladder dysfunction, impotence (ie, cobalamin neuropathy), or a recent Pap smear indicative of cervical dysplasia rarely may be presenting symptoms. Multiple pregnancies with short intervals between delivery and conception predispose to a high risk for overt folate deficiency (cobalamin deficiency is more often associated with infertility).

PHYSICAL EXAMINATION

Physical examination may reveal different features in well-nourished patients (cobalamin-deficient vegetarians or pernicious anemia patients) and poorly nourished (folate-deficient) individuals. The latter show evidence of significant weight loss or other stigmata of multiple deficiencies due to "broad-spectrum" malabsorption. Associated deficiency of vitamins A, D, and K and protein-calorie malnutrition may give rise to angular cheilosis, bleeding mucous membranes, dermatitis, osteomalacia, and chronic infections. Various degrees of pallor with lemon-tint icterus (ie, a combination of pallor and icterus best observed in fair-skinned individuals) are common features of megaloblastosis.

When anemia is severe, the patient may have a low-grade fever. The skin may reveal a diffuse, brownish pigmentation or abnormal blotchy tanning. Special emphasis should be given to pigmentation of skin creases and nail beds. (Mucous membrane pigmentation is not observed, in contrast to Addison disease.) Premature graying is observed in light- and dark-haired individuals.

A blunted masklike facies is extremely common in folate deficiency. Alternatively, there may be evidence of classic hyperthyroid or hypothyroid facies (associated with pernicious anemia). Special attention should be given to the eyes and eyebrows for signs of thyroid dysfunction.

Examination of the mouth may reveal glossitis with a smooth (depapillated), beefy red tongue with occasional ulceration of the lateral surface. The neck may reveal thyromegaly (diffuse or with nodules) if there is associated disease. Increased jugular venous distention should alert the examiner to cardiovascular failure, with its attendant gallop, cardiomegaly (with or without pericardial effusions), pulmonary basal crepitations, and pleural effusion, tender hepatomegaly, and pedal edema. Nontender hepatomegaly, but more often mild splenomegaly, may rarely be caused by extramedullary hematopoiesis in severe anemia, but a midepigastrium mass raises the ominous possibility of gastric carcinoma, which is three times as likely in patients with pernicious anemia.

An inverse correlation has been identified between the extent of anemia and neurologic dysfunction. Patients with normal complete

blood count values often have neurologic signs and symptoms. In prolonged cobalamin deficiency, the neurologic examination reveals clear-cut evidence of involvement of posterior and pyramidal, spinocerebellar, and spinothalamic tracts. Among the earliest signs of posterior column dysfunction are loss of position sense in the index toes (before great toe involvement), which is elicited by passive movement, and loss of the ability to discern vibration of a high-pitched (256 Hz) tuning fork (a very early elicitable, objective sign), which invariably precedes by many months the loss of ability to sense the vibration of a lower-pitched (128 Hz) tuning fork. Usually, the patient loses vibration sense to 256 Hz from toe to hip before the loss of 128 Hz vibration sense even begins. Because of the slow coalescence of contiguous spinal cord lesions, a constellation of elicitable signs may be obtained. Upper motor neuron disease is indicated by weakness and progressive spasticity with increased muscle tone, exaggerated deep tendon reflexes with clonus, extensor plantar response, and incoordinate or scissor gait, which may progress to spastic paraplegia. The involvement of peripheral nerves may markedly modify these signs to include flaccidity and the absence of deep tendon reflexes. A positive Romberg sign is not uncommon and a positive Lhermitte sign may be elicited. Loss of sphincter and bowel control, altered cranial nerve dysfunction with altered taste, smell, and visual acuity or color perception, and optic neuritis (unexplained predominance in males) may be other physical signs indicating cobalamin deficiency. Inability to carry out serial subtraction of 7 from 100 is a valuable test to document reduced cerebral function (the electroencephalogram often reveals slow wave frequency) in pernicious anemia.

INSIGHTS INTO THE CHANGING SPECTRUM OF COBALAMIN DEFICIENCY

The biochemical and clinical spectrum of presentations of cobalamin deficiency has changed dramatically compared with earlier descriptions. For instance, earlier in developing countries, most cases with nutritional cobalamin deficiency presented in the second and third decades with pancytopenia, mild hepatosplenomegaly, fever, and thrombocytopenic bleeding, all of which are in keeping with the concept of ineffective hematopoiesis of megaloblastosis.[2] Implicit in the earlier literature was the dictum that the neurologic and psychiatric syndrome uniquely associated with cobalamin deficiency usually developed in approximately 80% by the time anemia was symptomatic, and in approximately 50% of patients, this led to some incapacity. However, from southern Africa among 144 consecutive adults (who were not vegetarian, pregnant, or lactating) with megaloblastic anemia[2] and similar presentations of megaloblastosis as reported from India, there was a high incidence of neurologic disease among patients with mild to moderate anemia due to cobalamin deficiency (in 86%). (How many of these subjects had nutritional cobalamin deficiency from poverty-imposed near-vegetarianism is unclear.) This report nevertheless reversed previous presumptions that the primary cause of megaloblastic anemia in this population in developing countries is invariably folate deficiency.

That such classic hematologic presentations are infrequently observed in the West was initially recognized when anemia and macrocytosis were not invariably associated with cobalamin deficiency.[2] When the clinical spectrum and diagnosis of cobalamin deficiency was reevaluated among a cohort of unselected consecutive patients in New York and Colorado who fulfilled criteria for unambiguous cobalamin deficiency, normal values in hematocrit, mean cell volume, and LDH were found in more than one-third of the patients, and approximately 80% had normal white blood cells and platelets and serum bilirubin levels.[2] Strikingly, 33% of the patients' blood smears were not identified as diagnostic when evaluated by laboratory personnel, compared with 94% when evaluated by the investigators themselves. This fact is important because most physicians in general practice rely heavily on laboratory personnel to identify an abnormal blood smear. Equally striking was the important finding that neuropsychiatric abnormalities were observed in nearly one-third of patients often in the absence of anemia, macrocytosis, or both.[2] These data formed the basis for reevaluating the diagnostic sensitivity and specificity of serum homocysteine and MMA in clear-cut cobalamin deficiency (406 patients) or folate deficiency (119 patients).[2] In patients with cobalamin deficiency, serum MMA levels were elevated in 98.4% and serum homocysteine in 95.9%; both metabolites were normal in only one patient (0.2%). For patients with folate deficiency, the serum homocysteine was increased in 91% and MMA was elevated in 12.2%, but in all but one this was attributed to renal insufficiency or dehydration, conditions that are known to falsely raise concentrations of this metabolite. These data allowed for the conclusion that normal levels of MMA and homocysteine rule out clinically significant cobalamin deficiency with virtually 100% certainty.[2]

The changing pattern of neurologic presentations also deserves special mention. From a classic review of 153 episodes of cobalamin deficiency involving the nervous system, the following facts emerged[2]: First and foremost, in over a quarter of these patients, there was no reduction in the hematocrit level despite neurologic disease, and only a minority of patients had combined hematologic and neurologic disease. The inclusion of anemic and nonanemic patients who were cobalamin-deficient led to the dramatic conclusion that the higher the hematocrit, the more severe is the neurologic disorder. (This has its experimental correlates in monkeys and fruit bats, which have severe neurologic disease in the absence of anemia![1,2]) Profoundly anemic patients frequently had no neurologic deficits, and the level of cobalamin had no correlation with the existence or severity of neurologic disease. Although simultaneous consumption of folate may have negated the development of potential hematologic abnormalities in cobalamin deficiency, this could not be documented. Among patients studied, 65% had mild, approximately 25% had moderate, and approximately 10% had severe neurologic deficits. Paresthesias or ataxia were most commonly the first symptoms and diminished vibratory sensation and proprioception in the lower extremities were the most common objective early signs. Although multiple neurologic syndromes were often seen in the same patient, the spectrum of objective signs could include loss of fine or coarse touch, decreased or increased deep tendon reflexes with spasticity or muscle weakness, urinary or fecal incontinence, orthostatic hypotension, amaurosis, dementia, psychosis, or mood disturbances.[2] Overall, although the neurologic deficits were mild in most cases, the severity was judged relative to the duration of symptoms before diagnosis; not unexpectedly, those with a shorter duration of symptoms responded most to appropriate replacement. The demonstration of cognitive improvement in 11 of 18 geriatric subjects with low cobalamin and quantitative cognitive dysfunction treated with cobalamin, and the observation that there is a limited window of opportunity for effective intervention, also highlights the importance of early diagnosis for this population.[2]

Although the basis for these changes in clinical presentation is speculative, it may reflect heightened awareness of cobalamin deficiency, better diagnostic tools, or supplementary folates taken by humans and given to livestock (which corrects megaloblastosis but aggravates neuropsychiatric disease). As a result of food fortification with folic acid, hyperhomocysteinemia in the United States is most frequently caused by cobalamin deficiency.[2,95]

Among the elderly population, it is estimated that 40% to 50% of cases with subclinical cobalamin deficiency (diagnosed by elevations in both metabolites) are caused by food-cobalamin malabsorption, with only a minority having pernicious anemia; the cause among the remaining 50% to 60% cases of subclinical cobalamin deficiency is not known. These individuals would respond to daily replacement with 1000 μg of cobalamin orally.[96] In developing countries, because of widespread vegetarianism or poverty-imposed near-vegetarianism, the predominant cause is probably dietary deficiency of cobalamin,[5] but an additional gastrointestinal basis for cobalamin malabsorption is also suspected.[48] Classical presentations of cobalamin deficiency are still not uncommon in developing countries, where cobalamin deficiency may be accompanied by folate and iron deficiency.

DIAGNOSTIC ISSUES RELATED TO INFORMATION FROM THE PERIPHERAL SMEAR AND BONE MARROW ASPIRATE

Although not specific for megaloblastic anemia, macroovalocytes are the hallmark of megaloblastosis (Table 39–5). This distinction is important because only 55% of 109 patients with MCV values greater than 105 fl had vitamin deficiency (this percentage may be lower or higher depending on the population under study). In almost one-half of all cases, macrocytosis per se is not associated with megaloblastosis (see Table 39–5) and additional tests are necessary for a complete diagnosis.

The frequency of hypersegmented PMNs (5% with 5 lobes or 1% with six-lobed PMNs) in patients with megaloblastic hematopoiesis is 98%. The sensitivity decreases to only 78% in alcoholics although the specificity of this finding is approximately 95%. With a combination of hypersegmented PMNs and macroovalocytosis, the specificity is 96% to 98%, and the positive predictive value of folate or cobalamin deficiency is approximately 94%.[2] Hypersegmentation of PMNs is insufficiently sensitive, when compared with metabolite levels, to be used as a clinical tool in the diagnosis of mild cobalamin deficiency.[2]

MASKED MEGALOBLASTOSIS

The term *masked megaloblastosis* is reserved for conditions in which true cobalamin or folate deficiency with anemia is not accompanied by classic findings of megaloblastosis in the peripheral blood and bone marrow. This occurs when there is a coexisting condition that neutralizes the tendency to generate megaloblastic cells (usually involving reduction in RBC hemoglobinization, as in iron deficiency or thalassemia). Among the 123 episodes of folate deficiency in 119 patients, the MCV was normal in 25%.[2] A wide RBC distribution width (RDW) on the Coulter counter readout in the presence of a "normal" mean corpuscular hemoglobin (MCH) or MCV may reflect megaloblastic anemia[2] or dimorphic (macroovalocytes plus microcytic hypochromic RBCs) anemia. Because megaloblastic white blood cells and precursors are unaffected by deficient hemoglobinization, these pathognomonic findings (giant myelocytes and metamyelocytes, and hypersegmented PMNs) remain; the latter may persist for up to 2 weeks after replacement with cobalamin or folate.[1] The recognition of masked megaloblastosis should initiate investigations to rule out iron deficiency, anemia of chronic disease, or hemoglobinopathies. Appropriate replacement with cobalamin or folate elicits a maximal therapeutic benefit only when iron deficiency is corrected. Conversely, if combined iron and cobalamin deficiency (total gastrectomy) or iron and folate deficiency (pregnancy) is treated with iron alone, megaloblastosis will be unmasked.

APPROACH TO DIAGNOSIS AND THERAPY OF MEGALOBLASTOSIS

In general, there are three stages in approaching a patient: *recognizing* that megaloblastic anemia is present; *distinguishing* whether folate or cobalamin or combined folate and cobalamin deficiencies have led to the anemia; and diagnosing the *underlying disease* and *mechanism* causing the deficiency. Establishing that the patient does have megaloblastosis is, in theory, straightforward. This is easily done by first evaluating the complete blood count, the mean corpuscular volume and the peripheral smear, followed by a bone marrow aspiration. Clues to whether cobalamin or folate deficiency is responsible for megaloblastosis can be obtained by serum cobalamin and serum folate levels; additional testing of serum MMA and serum homocysteine can define the true nature of the deficiency.[2,97] However, this ideal and orderly workup is not always feasible in clinical practice, because the patient may present for the first time with or without associated neurologic disease, be referred after a variable workup has already been initiated for possible megaloblastosis, present with symptoms primarily attributed to a disease predisposing to cobalamin or folate deficiency (in which case anemia or neurologic dysfunction may only be a minor symptom), present with isolated neurologic disease in the absence of anemia, or be referred after empirical therapy has been given for presumed cobalamin or folate deficiency. The immediate question therefore pertains to the overall status of the patient.

If the patient is decompensated or decompensation is imminent, obtain serum folate and cobalamin levels and bone marrow aspiration to confirm megaloblastosis and proceed with transfusion of 1 unit of packed RBCs *slowly*, with vigorous diuretic therapy to obviate further congestive heart failure from fluid overload. The serum potassium

Diagnostic Bone Marrow Aspiration

Is bone marrow aspiration always necessary to diagnose cobalamin- or folate-deficient megaloblastosis? With the addition of highly sensitive serum tests for the specific diagnosis of cobalamin and folate deficiency, the need for a bone marrow test is often dictated by the urgency to diagnose megaloblastosis (with results available in an hour). For example, in the case of florid hematologic disease with or without neurologic disease suggestive of cobalamin or folate deficiency, bone marrow aspiration carried out as soon as possible is invaluable in assisting the rapid diagnosis of megaloblastosis. However, in the outpatient setting, when the patient has a characteristic peripheral smear, or for a patient with a primary neuropsychiatric presentation, a case can be made to initiate the sequence of diagnostic tests without bone marrow aspiration by proceeding with measurement of serum levels of vitamins or metabolites (see Table 39–2). In pregnant patients with pancytopenia with macroovalocytes, hypersegmented polymorphonuclear neutrophils, and reticulocytopenia with a history of noncompliance with prenatal supplements (and no neurologic findings suggestive of cobalamin deficiency), bone marrow aspiration may not be necessary to initiate therapy for a strong presumptive diagnosis of folate deficiency. If there is no evidence of response within 10 days, bone marrow aspiration is indicated.

Table 39–5 Clinical Conditions Not to Be Confused With Megaloblastosis

Macrocytosis* Without Megaloblastosis†
Reticulocytosis
Liver disease
Aplastic anemia
Myelodysplastic syndromes (especially 5q⁻)
Multiple myeloma
Hypoxemia
Smokers
Spurious Increases in Mean Corpuscular Volume Without Macroovalocytosis‡
Cold agglutinin disease
Marked hyperglycemia
Leukocytosis
Older individuals

*The central pallor that normally occupies about one-third of the normal red blood cell is decreased in macroovalocytes. This contrasts with the finding of thin macrocytes, in which the central pallor is increased.

†Although megaloblastosis implies that a bone marrow test has been performed, with the addition of highly sensitive tests for the specific diagnosis of cobalamin and folate deficiency, the need for a bone marrow test is often dictated by the urgency to make the diagnosis.

‡When the Coulter counter readings of a high MCV are not confirmed by looking at the peripheral smear.

level must be carefully monitored. Cobalamin and folate should be administered simultaneously in full doses. Tests for cobalamin absorption can be deferred until the patient is more stable. Transfusion does not apparently alter serum folate or cobalamin levels but can alter red cell folate levels.[2]

If the patient is moderately symptomatic (but not in heart failure), the strong likelihood of a dramatic response (in the sense of well-being and relief of sore tongue) within 2 to 3 days before hematologic improvement argues against immediate blood transfusion.[2] Therefore, proceed with appropriate diagnostic workup as for the well-compensated patient.

If the patient is well compensated, and in the outpatient setting, the physician has time to develop an orderly sequence of diagnostic tests. First, check the peripheral smear and rule out other macrocytic anemias (thin macrocytes with a normoblastic marrow in contrast to macroovalocytes). Draw blood for cobalamin and folate levels (*before* the patient's first hospital meal) to sort out whether the problem is caused by a deficiency of folate or cobalamin, or both, or some other deficiency (see Table 39–2). Assuming that there is no urgency to make the diagnosis, the physician can elect to wait for the results of these tests before proceeding with the next test in the diagnostic workup. If making the diagnosis is urgent, a cost-effective test is the bone marrow aspirate; results indicating megaloblastosis (or not) can be available within an hour. If bone marrow aspiration is performed, samples are sent for special stains and flow cytometry (megaloblastic erythropoiesis can resemble erythroleukemia) and cytogenetic analysis (myelodysplastic syndromes can exhibit some megaloblastic changes in the erythroid series but megaloblastic granulopoiesis is not seen). If the marrow is not obviously megaloblastic but the iron stain reveals absent stores, review the morphology again with special emphasis on granulocytic precursors and promegaloblasts, and look for more subtle megaloblastic changes.

If the patient refuses bone marrow aspiration and serum cobalamin and folate levels are equivocal (ie, in the low normal range), a strong case can be made to test for serum homocysteine and MMA. Serum MMA and homocysteine are ordered together (the same sample remaining from the serum sent for cobalamin and folate may be used if they were frozen away). Integrating the results for serum MMA and homocysteine levels (which will be available after a week or more) with those for serum cobalamin and folate levels can help distinguish cobalamin and folate deficiencies (see Table 39–2). A normal MMA and homocysteine level eliminates cobalamin deficiency with 100% confidence, and normal homocysteine levels suggest that megaloblastic anemia is not caused by folate deficiency. These tests are particularly useful if the patient has pure neurologic disease or if there are associated conditions such as iron deficiency or thalassemia that can mask megaloblastosis. Administration of folate or cobalamin will reduce elevated serum homocysteine and MMA levels to basal values by 1 week, so there is only a narrow window to clinch the diagnosis using metabolite tests.[2] In the rare situation when a defect in cobalamin or folate metabolism is suspected, early consultation with experts who have published in this area is advised.[50]

A reticulocyte count is useful to follow the patient's response to appropriate replacement therapy. Additional supporting studies documenting increased serum lactate dehydrogenase, haptoglobin, and bilirubin (evidence for intramedullary hemolysis) may be performed. Later, studies to define the mechanism for cobalamin malabsorption can be carried out.

When the megaloblastic state is established, try to determine the underlying mechanism of cobalamin or folate deficiency. The cause of folate deficiency is usually sorted out by this time from the history, physical examination, and the clinical setting. If pure folate deficiency has been prolonged, expect associated cobalamin deficiency to ensue (special emphasis should be given to identifying subtle manifestations of neurologic disease). If cobalamin deficiency is suspected, test for serum anti-IF antibodies (highly specific for pernicious anemia). After this, proceed with the Schilling test (see Table 39–3) to differentiate pernicious anemia from other causes of cobalamin deficiency. (The Schilling test can initiate a reticulocytosis by the second or third day in patients with pure cobalamin deficiency and may also demonstrate a partial response in cases of pure folate deficiency.) Additional tests for associated autoimmune diseases should be made (if indicated) by this time. If serum IF antibodies are negative, gastric analysis for Histalog-fast achlorhydria need not be performed, except in children, for whom it is necessary to differentiate congenital IF deficiency from juvenile pernicious anemia and Imerslund–Gräsbeck syndrome. In adults, a strong presumptive diagnosis of pernicious anemia can usually be made with the Schilling test (see Table 39–3).

THERAPY

Routinely, treatment with full doses of parenteral cobalamin (1 mg/day) and oral folate (folic acid) (1–5 mg) before knowledge of the type of vitamin deficiency is established should only be reserved for the severely ill patient. An appropriate regimen for conditions in which cobalamin replenishment can correct cellular cobalamin deficiency (but not correct the underlying problem that led to the deficiency, such as pernicious anemia) is 1 mg of intramuscular cyanocobalamin per day (week 1), 1 mg twice weekly (week 2), 1 mg/week for 4 weeks, and then 1 mg/mo for life (approximately 15%, or 150 μg, is retained 48 hours after each 1-mg cobalamin injection).

Modified Therapeutic Trials

The traditional therapeutic trial using physiologic doses of vitamins (100 μg of folate or 1 μg of cobalamin given daily while monitoring the reticulocyte response)[1] has given way to a modified therapeutic trial. Rather than making the diagnosis of a deficiency, the intention is often to confirm the clinical suspicion that the patient does not have deficiency.[2] This can be demonstrated by lack of response to full replacement doses of both vitamins (1 mg of folic acid orally for 10 days and 1 mg of cobalamin intramuscularly for 10 days). Clinical scenarios in which such trials may be applicable (after drawing blood for serum cobalamin and folate) are as follows:

1. There is a clinical suspicion that the underlying disease is not caused by a vitamin deficiency, but this idea is not supported by results of clinical, morphologic, and biochemical evaluations. Such conditions include anemia with a megaloblastic bone marrow that may be secondary to chemotherapy, myelodysplastic syndromes, or acute myeloid leukemia; when time is of the essence in making the diagnosis; when the levels of cobalamin are likely to be falsely abnormal because of these diseases; or when there is underlying dehydration or renal dysfunction that predictably gives falsely high levels of metabolites.
2. In other situations (ie, pregnancy, acquired immunodeficiency syndrome [AIDS], or alcoholism) with a multifactorial basis for anemia, the response or lack thereof to full doses can eliminate cobalamin or folate deficiency and thereby narrow the (often extensive) differential diagnosis.
3. In instances when severe anemia with megaloblastosis is clinically obvious and so serious that the physician cannot wait for the results of specific tests for deficiency. Full doses of both vitamins are administered, and if there is a response manifested by brisk reticulocytosis by days 5 to 7, retrospective assignment of the deficiency is based on the results of blood samples drawn before beginning the trial.

In all therapeutic trials, if there is no evidence of response within 10 days, bone marrow aspiration is indicated to identify another primary hematologic disease.

Because the doses of cobalamin are much greater than that required physiologically, any theoretical advantage of OH-cobalamin over cyanocobalamin (greater binding to cobalamin-binding proteins, greater serum levels, and less renal excretion) is of little significance in general clinical practice. A randomized study has demonstrated equivalence between 2 mg cobalamin tablets daily and traditional parenteral treatment for those with relatively replete cobalamin stores.[2] For patients who refuse monthly parenteral therapy or prefer daily oral therapy or in those with disorders of hemostasis, cobalamin (1–2 mg/day as tablets) can be recommended for patients with cobalamin malabsorption (where cobalamin is passively absorbed at high doses).[1,2] This is applicable for patients with pernicious anemia and patients with the inability to absorb food cobalamin. It is important to emphasize that the physician must ensure that the patient's depleted cobalamin stores are rapidly repleted by parenteral cobalamin *before* switching to oral cobalamin in the long term and that the patient is compliant and demonstrates adequate cobalamin levels and resolution of hematologic and neurologic abnormalities on follow-up. For nutritional cobalamin deficiency (eg, vegetarians) when the entire circuitry in cobalamin absorption is intact, oral cobalamin of 5 to 10 μg (found in conventional multivitamin tablets in the United States) taken for a lifetime of vegetarianism will suffice, but only after initially replenishing exhausted cobalamin stores with higher doses. However, if there is malabsorption of food-bound cobalamin, higher doses of cobalamin (greater than 1000 μg/day) are required for elderly patients.[96]

Oral folate (folic acid) at doses of 1 to 5 mg per day results in adequate absorption (even where intestinal malabsorption of physiologic food folate is present). Therapy should be continued until complete hematologic recovery is documented. If the underlying cause leading to folate deficiency is not corrected, folate may be continued. Folinic acid (ie, 5-formyl-H_4PteGlu [leucovorin]) should be reserved *only* for rescue protocols involving antifolates (methotrexate or trimethoprim-sulfamethoxazole) or for 5-fluorouracil modulation protocols, in the rare acute folate deficiency syndrome or after N_2O toxicity. It is too expensive for conventional repletion in folate-deficient states.

RESPONSE TO REPLENISHMENT

The response of the patient to appropriate replacement is reversion of megaloblastic hematopoiesis to normal hematopoiesis (probably initiated at the stem cell level) within the first 12 hours; by 48 hours normal hematopoiesis is reestablished, and the only evidence for a prior megaloblastic state may be the persistence of a few giant metamyelocytes. Because megaloblastosis caused by cobalamin or folate deficiency can be reversed in 24 hours by administration of folate (ie, a nutritious hospital meal), delay of a diagnostic bone marrow aspirate is to be avoided for this reason. Clinically, the first 36 to 48 hours are often highlighted by the awakening of an occasional semistuporous individual whose "chief complaint" is amazement at the remarkably improved sense of well-being experienced, with increased alertness and appetite and reduced soreness of the tongue. The ongoing normoblastic hematopoiesis is evidenced by decreases in plasma iron and potassium (1–2 mEq/dL drop in 48 hours), MMA, homocysteine, and phosphate excretion. The patient must be given supplemental potassium if borderline or low potassium levels are found *before* therapy is initiated to obviate potentially fatal arrhythmias. The elevated serum MMA and homocysteine levels will return to normal by the end of the first week.

Accelerated turnover of normal DNA in erythroid precursors is associated with an increase in serum urate, which usually peaks by the fourth day, and with increased cellular phosphate uptake for nucleotide synthesis. This may precipitate an attack of gout if the patient has a "gouty predisposition." The reticulocyte count increases by the second to third day and peaks by the fifth to eighth day (the peak reticulocyte count is directly proportional to the degree of preexisting anemia). This is followed by a rise in RBC count, hemoglobin, and hematocrit by the end of the first week, which normalizes in approximately 2 months, regardless of the initial degree of anemia. By the end of the third week, the RBC count should be above 3×10^6 mm^3; if it is not, additional causes of underlying iron deficiency, hemoglobinopathy, chronic disease, or hypothyroidism should be considered (Table 39–6).

Table 39–6 Causes of Megaloblastosis Not Responding to Therapy with Cobalamin or Folate

Wrong Diagnosis
Combined folate and cobalamin deficiencies being treated with only one vitamin
Associated iron deficiency
Associated hemoglobinopathy (eg, sickle cell disease, thalassemia)
Associated anemia of chronic disease
Associated hypothyroidism

Hypersegmented PMNs continue to remain in the blood for 10 to 14 days; however, the number of normal PMNs and platelets rises and normalizes within the first week. During this process, there may be a transient left shift to include myeloid precursors. The reduced intramedullary hemolysis (as a result of normalized hematopoiesis) leads to a gradual reduction in the serum bilirubin by the end of the first week, and LDH levels will drop concomitantly.

In response to cobalamin, progression of neurologic damage and dysfunction is inhibited. In general, the degree of functional recovery (reversal of neurologic damage) is inversely related to the extent of disease and duration of signs and symptoms. As a rough estimate, signs and symptoms that have been present for less than 3 months are usually completely reversible; with longer duration, there is invariable residual neurologic dysfunction. The reversibility of neurologic damage is slow (a maximal response may take 6 months). Substantial increments (in recovery) are unlikely to be gained after the first 12 months of appropriate therapy, which indicates irreversibility at this point. However, most neurologic abnormalities have improved in up to 90% of patients, with documented subacute combined degeneration.

FOLLOW-UP

Patients with neurologic dysfunction from cobalamin deficiency have traditionally been given more frequent doses of cobalamin (biweekly rather than monthly therapy for the first 6 months), despite the lack of evidence that this form of therapy is more beneficial. This approach, nevertheless, serves a purpose in that improvement in neurologic status can be carefully documented. Once maximal responses have been established, most patients can be treated with life-long cobalamin with a dose that is appropriate for the underlying cause of cobalamin deficiency. Follow-up outpatient visits every 6 months should be instituted to ensure adequate maintenance of hematopoiesis, as well as early diagnosis of other diseases commonly associated with the cobalamin- or folate-deficient state. Follow-up of 95 patients with pernicious anemia indicates that individuals older than 60 years are prone to developing iron deficiency that arises from poor iron absorption from achlorhydria.[2] All patients with pernicious anemia, especially the elderly, should be screened for iron deficiency at the beginning and during follow-up.

Although patients with pernicious anemia have a twofold increase in proximal femur and vertebral fractures and a threefold increase in distal forearm fractures, it is unclear whether this is reduced by therapy with cobalamin. Because cobalamin stimulates proliferation of bone marrow stromal osteoprogenitors and osteoblastic cells, the suppressed activity of osteoblasts may contribute to osteoporosis and fractures in patients with pernicious anemia.[2]

Studies of a cohort of 5072 patients with pernicious anemia registered in Denmark (1977–1989) revealed that in addition to the well-established increased risk for stomach cancer, there was also a

twofold increase in the relative risk for cancer of the buccal cavity and pharynx; however, previously reported elevated risks for other digestive tract cancers were not confirmed. Because of the excess risk of gastric cancer and carcinoid tumors in patients with pernicious anemia,[2] the value of endoscopic surveillance was studied prospectively; in 56 patients, two patients each with early gastric cancer and gastric carcinoids were identified. Gastric carcinoids associated with pernicious anemia are clinically indolent tumors, particularly when they are smaller than 2 cm.[2] This information can be used to formulate general guidelines for more frequent surveillance of a patient with pernicious anemia who has larger gastric carcinoids.

ROUTINE SUPPLEMENTATION OF COBALAMIN AND FOLATE

Routine *periconceptional* supplementation of folate for normal women[2] and in higher doses for women at risk for delivery of babies with NTDs[2] provides effective prophylaxis against the development of NTDs. Supplementation with folate throughout pregnancy also helps to prevent premature delivery of low-birth-weight infants,[1] and routine supplementation for premature infants and lactating mothers is also recommended. There remains a great discrepancy between increasing knowledge of the value of folic acid for birth defect prevention (which is directly related to educational status of women), and actual intake of folic acid supplements[98]; currently, it is estimated that less than one-third of reproductive aged American women take folic acid supplements daily. Because only half of US obstetricians regularly discuss folic acid with their patients,[99] apart from food fortification (which is intended to provide only one-quarter of the recommended dietary allowance of folate), other innovative methods have been investigated. A recent randomized controlled trial has demonstrated that very brief physician advice combined with a booster phone call and starter bottle of folic acid tablets can markedly increase women's regular intake of folic acid (increase by 68% vs 20% in the control group).[100]

In addition to hematologic diseases leading to increased folate requirements (eg, autoimmune hemolytic anemia, beta-thalassemia), folic acid supplements appear to reduce the toxicity of methotrexate in psoriasis.[2] A recent review[101] concluded that despite the paucity of studies, it appears that folate supplementation is appropriate for all patients receiving methotrexate for psoriasis to reduce hepatotoxicity and gastrointestinal intolerance without impairing the efficacy of methotrexate.

Whether folic acid administered to patients with rheumatoid arthritis reduces the efficacy of methotrexate has been raised, but analysis of the data reveals that these conclusions are far from definitive and none of the studies have been without flaws.[102] It is also not clear whether folate fortification in the USA has negated the need for additional folic acid supplements for patients receiving methotrexate. Supplementation with folic acid protects against the development of colorectal neoplasia in high-risk patients with ulcerative colitis.[2]

Between 15% of Austrian children (average age approximately 13 years)[91] and up to 40% of Spanish children[92] who are on long-term antiepileptic drug therapy (carbamazepine, phenytoin, phenobarbital, and valproate) have hyperhomocysteinemia that is easily reversed by 1 mg folic acid per day.[93] Because hyperhomocysteinemia can be induced within a year of initiation of carbamazepine or valproate in adolescents, and homocysteine is directly neurotoxic leading to DNA damage and hypersensitivity to excitotoxicity,[94] this underscores the importance of prophylactic therapy of all children receiving antiepileptic drugs with folic acid.

Whether cobalamin should be added to food that is fortified with folate is still under consideration; it has been demonstrated that cobalamin added to breakfast cereals can reduce plasma homocysteine concentrations.[103] This could serve two needs: (a) there would be less chance that fortified food folate would mask the neurologic signs of underlying cobalamin deficiency in vulnerable populations (those with undiagnosed clinical or subclinical cobalamin deficiency); and (b) the cobalamin that is present in fortified food will supply those populations who subsist on low cobalamin stores with adequate cobalamin; this latter need is the far greater worldwide, where several hundred million in the developing world do not obtain adequate dietary cobalamin as a result of vegetarianism or poverty-imposed near-vegetarianism.[5] The role of topical cobalamin in atopic dermatitis (presumed through a scavenger role of nitric oxide by cobalamin) requires confirmation.[104] Table 39–7 summarizes conditions that warrant routine folate or cobalamin supplementation.

Table 39–7 Indications for Prophylaxis with Cobalamin or Folate

Prophylaxis with Cobalamin
Infants of mothers with pernicious anemia*
Infants on specialized diets*
Vegetarians and poverty-imposed near-vegetarians*
Total gastrectomy†
Prophylaxis with Folic Acid‡
All women contemplating pregnancy (at least 400 μg/day)§
Pregnancy and lactation, premature infants
Mothers at risk for delivery of infants with neural tube defects††
Hemolytic anemias/hyperproliferative hematologic states
Patients with rheumatoid arthritis or psoriasis on therapy with methotrexate¶

*For vegetarians, prophylaxis with cobalamin (5- to 10-μg tablet/day) orally should suffice. In food-cobalamin malabsorption from an inability to cleave food cobalamin by acid and pepsin, replacement therapy should be with daily tablets of more than 100 μg taken orally. In these and other conditions involving any abnormality of cobalamin absorption, cobalamin tablets of 1000 μg/day should be administered orally to ensure that cobalamin transport by passive diffusion across the intestine is sufficient to meet daily needs.

†Consider late development of cobalamin deficiency and iron malabsorption (prophylaxis with oral cobalamin and iron).

‡Ensure that the patient does not have a cobalamin deficiency before initiating long-term folate prophylaxis.

§For prevention of first occurrence of neural tube defects.

††Previous delivery of a child with neural tube defects (eg, anencephaly, spina bifida, meningocele) imparts a 10-fold greater risk for subsequent delivery of infant with neural tube defects.

††Folic acid (4 mg/day) is administered periconceptionally and throughout the first trimester.

¶To reduce toxicity of the antifolate.

HYPERHOMOCYSTEINEMIA

Normally in cells, homocysteine is metabolized by a methylation and a transsulfuration pathway.[105] In the methylation pathway, homocysteine is methylated to methionine in a reaction involving the cobalamin-dependent enzyme (methionine synthase) and 5-methyltetrahydrofolate (5-methyl-H_4PteGlu), which donates its methyl group to homocysteine (see Figs. 39–3, 39–5, and 39–6). Cellular 5-methyl-H_4PteGlu is generated by the enzyme 5,10-methylene-tetrahydrofolate reductase (MTHFR). The critical nature of the function of this MTHFR (to provide 5-methyl-H_4PteGlu to drive the methylation cycle) is highlighted by evidence that in some adults with hyperhomocysteinemia, a polymorphism within its folate-binding pocket (involving a C-to-T substitution at nucleotide 677, which converts an alanine to valine) results in a dysfunctional thermolabile MTHFR.[106] This leads to a pathologic buildup of homocysteine, which exits from cells into the circulation where it predisposes the patient to premature occlusive vascular disease. In the transsulfuration pathway, cystathionine beta-synthase catalyzes the condensation of homocysteine with serine in the presence of pyridoxyl phosphate (vitamin B_6) to form cystathionine, which is further cleaved by a vitamin B_6-dependent gamma-cystathionase to form cysteine and alpha-ketobutyrate. The cysteine can be used for synthesis of the antioxidant glutathione, a key component that defends against oxidative stress within cells. A limiting reagent in the synthesis of glutathione is cysteine, and approximately 50% of the cysteine in the liver is generated from the transsulfuration pathway. There is a metabolic

link between homocysteine metabolism and the redox pool of glutathione, and there appears to be reciprocal oxidative sensitivity between methionine synthase activity and cystathionine beta-synthase. Oxidative stress inactivates methionine synthase, whereas homocysteine flux is increased through the transsulfuration pathway, which generates more cysteine and glutathione; conversely, antioxidants can generate the opposite effect.[107] Based on these considerations, the level of plasma homocysteine depends on genetically regulated levels of essential enzymes and the intake of folic acid, vitamin B_6 (pyridoxine), and cobalamin, as well as other conditions (renal dysfunction, increased age, nitrous oxide, and antifolates).

Chronic hyperhomocysteinemia is established as a major risk factor in occlusive vascular diseases.[2] These include myocardial infarctions from coronary atherosclerosis,[2] extracranial carotid artery stenosis,[2] and stroke,[2] vascular disease in end-stage renal failure,[2] thromboangiitis obliterans, aortic atherosclerosis,[2] venous thromboembolism,[2] placental abruption or infarction, and recurrent stillbirths.[2] An increment of 5 μmol/L of homocysteine elevates coronary artery disease risk by as much as cholesterol increases of 20 mg/dL.[2] Hyperhomocysteinemia is also associated with increased incidence of bone fracture,[108] dementia and Alzheimer disease,[109] a higher prevalence of chronic heart failure in adults without prior myocardial infarction,[110] and left ventricular mass and wall thickness only among women.[111]

The strong correlation between homocysteine and occlusive vascular disease has been identified primarily through retrospective studies.[112] Although daily oral cobalamin (2500 μg/day), folic acid (400 μg/day), and vitamin B_6 (2 mg/day) can lower elevated homocysteine and MMA levels in elderly persons with hyperhomocysteinemia,[95] prospective studies intended to test the hypothesis that reduction of homocysteine levels results in beneficial vascular outcomes in patients with a prior stroke or venous thromboembolism have been disappointing.[113–115] A recent meta-analysis concluded that folic acid supplementation has not been shown to reduce risk of cardiovascular diseases or all-cause mortality among participants with a prior history of vascular disease.[116] These results cannot however ignore or discount the substantial body of evidence that homocysteine is a factor that promotes oxidant stress, inflammation, cell proliferation, thrombosis, and endothelial dysfunction.[117] It should also be noted that all the current studies related to prevention of disease by homocysteine-lowering maneuvers relate to *secondary* prevention, and it may well be that primary prevention is the more worthwhile target. Hovering over these large negative clinical trials is the fact of a lack of statistical power (to demonstrate the 10%–20% improvement in clinical outcome that might be expected from homocysteine-lowering treatment) arising from mandatory fortification of food by folate.[118]

A notable study among 365 individuals in the NHLBI Family Heart Study[2] raises issues of a gene–environment interaction. Among subjects with lower plasma folate concentrations (less than 15.4 nmol/L), those with the homozygous thermolabile *MTHFR* genotype had fasting homocysteine levels that were 24% greater than those with the normal genotype. Because a difference between genotypes was not seen among individuals with folate levels higher than 15.4 nmol/L, this suggested that a gene–environment interaction might increase the risk by elevating homocysteine, especially when folate intake is low. A similar issue may be relevant to other polymorphisms involving folate and cobalamin metabolism.

How does hyperhomocysteinemia contribute to atherogenesis? There are several plausible mechanisms, among which platelet activation, hypercoagulability, altering expressivity of multiple genes,[2] increased smooth muscle cell proliferation,[2] induction of endothelial cytotoxicity or dysfunction, stimulation of low-density lipoprotein oxidation and apoptosis in various cell types,[2] have all been suggested.[117] In addition, direct molecular targeting by homocysteine of various proteins can occur through the ability of homocysteine to form stable disulfide bonds with target protein cysteine residues even in the presence of other thiols. This is because of the greater stability of a protein–cysteine–S–S–homocysteine mixed disulfide bond than a protein–cysteine–S–S–cysteine disulfide bond based on higher sulfhydryl pK_a's (because the pK_a of the sulfhydryl of homocysteine is 10.0, whereas that of cysteine is 8.3, this results in greater disulfide bond stability for homocysteine in comparison to cysteine).[119] The current thinking is that such homocysteinylation of a target protein can somehow impair its function (eg, fibronectin, metalloproteases, annexin II), but in other cases homocysteinylation can also result in a gain of function in the target protein. Thus, identification of the entire spectrum of target proteins may begin to explain the myriad of effects of homocysteine.

Recent animal models further support the concept that homocysteine causes atherosclerosis and is not merely associated with the disease.[120] However, whether *smaller* concentrations of homocysteine in the human body (intracellularly or in the blood) such as found in folate or cobalamin or vitamin B_6 deficiency can lead to the same plethora of adverse effects (as noted with animal models) remains to be resolved.

Hyperhomocysteinemia is also linked to osteoporotic fractures; indeed, there is a higher incidence of fractures in those with pernicious anemia, and a lower bone mineral density in those with low cobalamin status.[121] A recent randomized double-blind trial among Japanese patients following stroke who were treated with folate and cobalamin had a five times lower risk for hip fracture over a follow-up period of 2 years compared with a placebo group.[122] Although there are inherent problems with this study,[123] it remains to be demonstrated if other populations with high fracture risk and mechanistic studies at a more fundamental level can unravel a causal relationship between homocysteine and bone.

Several clinical trials[124,125] that have employed a variety of vitamin (cobalamin, vitamin B_6, folate) cocktails to successfully reduce plasma homocysteine levels to normal also found no detectable effects on (improvement in) cognitive function. However, because these trials included too few participants, the duration of treatment was too short, and cognitive-function scores in controls remained intact throughout the trial, they lack the statistical power to refute the "homocysteine hypothesis of dementia."[126]

RENAL FAILURE AND COBALAMIN REPLENISHMENT

When coupled with a predisposition to chronic disease anemia, the demonstration of a borderline or low cobalamin level arising from increased cobalamin clearance during high-flux hemodialysis is a matter of some concern,[2] especially because MMA and homocysteine levels are elevated in patients with renal dysfunction and because elevated homocysteine represents an independent risk factor for vascular events in patients on peritoneal dialysis and hemodialysis.[2] Should such individuals be treated during hemodialysis with cobalamin, pyridoxine, and folate? Administration of supraphysiologic-dose folic acid (15 mg/day), B_6 (100 mg/day), and cobalamin (1 mg/day) can lead to a significant reduction in homocysteine without toxicity, and one-third may correct to normal values.[2] Large trials are under way to define whether lowering the elevated homocysteine found in patients with chronic kidney disease can result in reduced cardiovascular disease.[127]

FOLATE AND CARCINOGENESIS

There appears to be gathering evidence that low folate status can predispose to carcinogenesis. The epidemiologic evidence linking low folate status and cancer, the "soft" evidence from intervention studies, and evidence from animal and in vitro studies, and possible mechanisms have been critically assessed.[128] The mechanisms could involve alterations in methylation of DNA, instability of DNA through strand breaks, or misincorporation of uracil into DNA. Methylation of cytosines (as 5-methyl-deoxycytidine) in DNA can involve the coding region of genes (where it could be the initiator of mutations in tumor suppressor genes) or within cytosines of CpG islands within promoters (where methylation can lead to silencing of tumor suppressor genes, or hypomethylation can lead to activation of protoon-

cogenes). Studies suggest that methylation silences gene expression through the acetylation of histone, which is involved in transcriptional repression.[2] Conversely, hypomethylation of DNA relieves the repression, leading to activation of genes. Of significance, such epigenetic changes (hypomethylation) have been observed experimentally in the white blood cells of humans and in carcinogenesis, when adenomas progress to colon cancer. Equally important, there appears to be a field defect involving normal rectal mucosa adjacent to adenomas also. The high frequency of the thermolabile MTHFR in the general population has allowed further study of risk related to carcinogenesis as related to altered folate flux. MTHFR is involved in the unidirectional generation of 5-methyl-H_4PteGlu.[129] When it is thermolabile, there is a preferential rerouting of the one-carbon group through the 5,10-methylene-H_4PteGlu pathway to generate more thymidylate for DNA synthesis (as verified in erythrocytes) provided folate status is normal (see Fig. 39–5). As a consequence, some studies suggest that those who are homozygous for MTHFR have one-half of the risk for colon cancer (provided they have adequate amounts of folate, which optimizes the rerouting). This suggests that preferential flux of folate through the thymidylate synthesis pathway at the expense of the methylation pathway protects DNA. But in individuals with homozygous thermolabile MTHFR who have low folate status, 5,10-methylene-H_4PteGlu fails to stabilize the flavin adenine nucleotide cofactor within the binding pocket of the MTHFR leading to its reduced enzyme activity.[2] The folate deficiency predisposes to hypomethylation of DNA, which can lead to a procarcinogenic risk.[129] This (among other possibilities) can explain the conflicting data on thermolabile MTHFR and risk for cancer.[128]

Overall it appears that there may be a reduction in risk in those with highest dietary intake of folate and indeed small intervention studies have demonstrated some improvement or reversal in surrogate end-point markers. However, it has also been observed in animals that folate supplementation may increase colorectal cancer risk and accelerate progression after neoplastic foci are established. Hence the need for caution and for careful monitoring of populations in the long term in populations that have food fortification programs. However, the jury is still out on the issue of folates and colorectal cancer risk.

Although there is a wealth of animal data and some human studies[130] on a role of folate in DNA hypermethylation of CpG islands resulting in transcriptional silencing of tumor suppressor genes or global hypomethylation, there is insufficient information to conclude that physiologic folate deficiency induces significant enough changes in genomic DNA hypomethylation and/or site and gene-specific aberrant DNA methylation in the colorectal mucosa. Moreover, because of a variety of animal models employed, extrapolation to the human condition must be made with caution. Thus, despite a plethora of experimental evidence that folate deficiency or excess can influence the transformation of normal cells to cancer, and several retrospective and a few prospective epidemiologic studies linking folate deficiency with cancer risk, there is still insufficient data in humans to make conclusions on the role of diet and cancer.

CONCLUSIONS

In this age of spiraling costs for health care delivery and the ongoing debate on ways to reduce these costs, few instances in internal medicine yield more satisfying dividends than diagnosing and treating cobalamin and folate deficiency. These conditions are devastating when undiagnosed, misdiagnosed, or when cobalamin deficiency is treated with folate alone. Recognition of changes in the clinical presentation of cobalamin deficiency and availability of sensitive and specific tests should reduce uncertainty in diagnosis. The studies on folate supplementation during pregnancy that identified new folate-responsive NTDs and neurocristopathies are a paradigm for identification of hitherto unrecognized roles for other nutrients in human development. The significant impact of supplemental folates in relieving human suffering consonant with reducing costs for intensive- and long-term care of infants with prematurity or NTDs is a major achievement and outstanding example of cost-effective preventive medicine. As a result of parallel research in the veterinary sciences, folate supplements have also profited the meat industry. Decisions on the optimum amount of folates needed for fortification of food to prevent this devastating complication in newborns must also respect the dictum of *primum non nocere* for the millions of elderly people with cobalamin deficiency, who could be adversely affected from folate supplementation alone. However, consideration of any adverse effects on these cobalamin-deficient individuals also needs to be tempered by the projected beneficial effects in correction of hyperhomocysteinemia and occlusive vascular disease in many more subjects. Resolution of this very complex debate will establish yet another paradigm for fortification of foods with nutrients that can be beneficial for some but harmful for other population groups.

Dedication

This chapter is dedicated to the memory of Professor Victor Herbert (1927–2002), whose sustained investigations on clinically relevant issues related to vitamin B_{12}, folate, and one-carbon metabolism earned him respect, admiration, and the status as one of the giants in this field.[131]

CHAPTER 40

LABORATORY DIAGNOSIS OF HEMOGLOBINOPATHIES AND THALASSEMIAS

David H. K. Chui and Martin H. Steinberg

INTRODUCTION

Hemoglobin is a tetramer of two pairs of dissimilar globin chains, each containing an identical heme group. Normal adult hemoglobin (Hb A; $\alpha_2\beta_2$) is made of two α- and two β-globin chains. A minor adult hemoglobin (Hb A_2; $\alpha_2\delta_2$) has two α- and two δ-globin chains. Fetal hemoglobin (Hb F; $\alpha_2\gamma_2$) is made of two α- and two γ-globin chains. The α-globin gene cluster, 5′-ζ_2-α_2-α_1-3′, is located on chromosome 16pter-p13.3. The β-globin gene cluster, 5′-ε-$^{G}\gamma$-$^{A}\gamma$-δ-β-3′, is located on chromosome 11p15.5.[1]

More than 1300 natural mutations have been found in the α (>400 mutations), β (>700), δ (>70), and γ (>100) globin genes. These can be reviewed through the World Wide Web (globin.cse.psu.edu). Additional novel globin gene mutations are still being discovered.

More than 900 of the globin gene mutations result in changes of the amino acid composition of the corresponding globin chains, resulting in variant hemoglobins. Most of these mutations are clinically insignificant; however, a small number cause some of the most common hereditary diseases in humans, such as Hb S (*HBB* codon 6 GAG → GTG or Glu6Val), which causes sickle cell disease; Hb C (*HBB* codon 6 GAG→AAG or Glu6Lys), which in combination with Hb S causes a sickling disorder; and Hb E (*HBB* codon 26 GAG→AAG or Glu26Lys), which is a major contributor to severe β-thalassemia syndromes.[2–4]

Almost 400 globin gene mutations can cause either α or β thalassemia. These mutations downregulate or abolish either the transcription of the corresponding globin genes or the translation of the globin mRNA. There are about 50 mutations such as Hb E, Hb Lepore caused by a δ–β fusion globin chain, or Hb Constant Spring (*HBA2* codon 142 TAA→CAA or Term142Gln), which can result in both a variant hemoglobin and a thalassemia phenotype.

Other globin gene mutations can cause hemoglobins with either increased or decreased oxygen affinity (nearly 100 mutations); produce unstable hemoglobins and hemolysis (more than 100 mutations); or allow hemoglobin to be oxidized, causing methemoglobins and cyanosis (9 mutations).

DIAGNOSIS

Collectively, hemoglobin mutations form the most common human single gene disorders. Their detection and correct diagnosis are clinically important. There are several indications for investigation of hemoglobinopathy and thalassemia:

1. Clinical suspicion of sickle cell disease or thalassemia syndromes
2. Hemoglobinopathy and/or thalassemia carrier screening in couples from high-risk populations, for genetic counseling and reproductive decisions
3. Confirmation and follow-up of an abnormal neonatal hemoglobin screening result
4. Investigation of the family members of an individual known to have a hemoglobinopathy or thalassemia
5. Preoperative screening for Hb S and other relevant mutations in high-risk populations
6. Laboratory evidence of hemoglobinopathy and/or thalassemia such as
   a. unexplained or familial polycythemia, hemolytic anemia, or cyanosis
   b. positive Hb S solubility test
   c. hemoglobin variant detected during Hb A_{1C} determination
   d. microcytosis, not due to iron deficiency or chronic disease
   e. abnormal erythrocyte morphology of unknown cause
7. Follow-up studies on patients with severe hemoglobinopathies and/or thalassemia to determine their therapeutic response (eg, Hb F level)

Correct diagnosis of these hereditary hemoglobin disorders and their carrier state is important for several reasons:

1. Planning for appropriate medical treatment program, such as transfusion and iron chelation therapy in β-thalassemia major
2. Instituting appropriate preventive health care measures, such as penicillin prophylaxis and pneumococci vaccination in infants diagnosed to have sickle cell disease, or avoidance of oxidant drugs and prompt treatment of infections and fever in children diagnosed to have Hb H disease
3. Predicting prognosis of affected infants, thus helping parents and families to cope with future disease burdens
4. Preventing an incorrect diagnosis that might lead to invasive investigations such as endoscopy to look for gastrointestinal bleeding, and potentially harmful treatment such as long-term iron therapy for people who have thalassemia trait
5. Detecting carriers of globin gene mutations, which is essential for proper genetic counseling and future reproductive decisions.
6. Determining parental mutations for use in prenatal diagnosis, when appropriate and requested
7. Elucidating complex cases and family studies

Initial Workup

Sickle cell disease and α- and β-thalassemias are the three major and severe hemoglobin disorders. Originating in subtropical and tropical regions of the world where malaria was and might still be endemic, these diseases are now found throughout the world, caused by voluntary and forced population migrations and genetic admixture with indigenous populations over the past two and more centuries. Furthermore, sporadic globin gene mutations are encountered in all populations, including northern Europeans. Thus, an individual's ethnicity is helpful but should not be the sole criterion to determine if a search for a hemoglobin disorder is indicated.[5]

A positive family history such as anemia, erythrocytosis, painful sickle cell crises, hydrops fetalis, or repeated transfusions should alert the physician to the possibility of hereditary hemoglobin disorders. However, for most globin gene mutations like those causing sickle cell disease and β-thalassemia, heterozygous carriers are clinically well. Therefore, the lack of a relevant family history does not in any way exclude the possibility that globin gene mutation(s) might be present.

Consideration of age, gender, ethnicity, reproductive plans, and concomitant medical conditions is also important for the workup of

Hemoglobin Bart Hydrops Fetalis Syndrome

A 22-year-old woman of Asian ethnic background was seen by her physician at the 9th week of her first pregnancy. Blood was sent for blood counts and hemoglobin electrophoresis. The laboratory reported the following: "Hb 12.0 g/dL; MCV 68 fL; Hb A_2 2.6%; Hb F <2%; No abnormal hemoglobin detected."

At a later date, she was sent for consultation at the genetic clinic, because her maternal serum triple screening for α-fetoprotein, estriol, and β-human chorionic gonadotropin was positive for possible neural tube defect or Down syndrome. At the 21st week of pregnancy, an amniocentesis was done. At the same time, the blood sample of her husband was sent for testing. The laboratory reported: "Hb 13.1 g/dL; MCV 62 fL; Hb E 22%; Hb H inclusion bodies positive; Consistent with Hb E trait and α-thalassemia trait; Suggest molecular studies to confirm."

At the 25th week of pregnancy, blood samples from the couple were sent for DNA-based globin genotyping. Both were found to be carrier of deletion of two α-globin genes in *cis* of the Southeast Asian type ($--^{SEA}/\alpha\ \alpha$).

At the 27th week of pregnancy, the cultured amniocytes were sent for DNA analysis. The fetus was diagnosed to have inherited both parental α-thalassemia deletion ($--^{SEA}/--^{SEA}$). Counseling was provided to the couple at the 30th week. Delivery of a stillborn infant with the Hb Bart hydrops fetalis syndrome occurred at the 34th week.

α-Thalassemia deletion of two α-globin genes in *cis* of the Southeast Asian type is prevalent in southern China and Southeast Asia. Up to 14% of the general population are heterozygous carriers of this deletion in parts of Thailand, for example. This deletion causes almost all hydrops fetalis due to α-thalassemia in southeast Asia, and also contributes to most cases of Hb H disease.[15,16]

Heterozygotes for this deletion are clinically well, have near-normal Hb level, significant microcytosis, and no abnormal hemoglobin. The correct diagnosis, which is necessary for family counseling and prenatal diagnosis, can only be confirmed by relatively simple DNA-based gap-PCR procedures. Affected homozygous stillborn has been variously misdiagnosed to have congenital heart disease or unusual genetic syndrome. Incorrect assessment of the reproductive risk of the at-risk couple can result in recurrence of the same devastating syndrome in subsequent pregnancies, and medical and psychological ordeals for the affected parents. This syndrome is encountered in increasing numbers in North America and ought to be recognized by both clinical and laboratory physicians.[16]

Hb S/Hb S-South End Mimicking Hb S/β^+-Thalassemia

A 28-year-old woman from Uganda presented with a history of monthly "painful crises" that required on average hospital admission five or six times a year. She also had avascular necrosis of the right femoral head. Her hemoglobin levels varied between 8 and 10 g/dL, MCV was 79 fL, and reticulocyte count 10%. Her serum ferritin was 210 ng/mL. Hemoglobin analysis by cation HPLC was interpreted to show Hb A 36.8%, Hb S 52.7%; Hb A_2 4.4%; and Hb F 5.4%. Based on these results, she was diagnosed to have Hb S/β^+-thalassemia. Her physician was puzzled by her severe symptoms in view of her having more than 35% Hb A.

She was referred for molecular diagnosis. Her β-globin genes were amplified and sequenced. There was homozygosity for the Hb S mutation in codon 6 (GAG→GTG or Glu6Val). In addition, there was heterozygosity for a single-nucleotide mutation in codon 132 (AAA→AAC or Lys132Asn). These results indicate that one of her β-globin gene alleles had the Hb S mutation. The other β-globin gene allele had two mutations, the Hb S in codon 6 plus another mutation in codon 132. The variant hemoglobin made up of the abnormal β-globin chain with amino acid substitutions in both residues 6 and 132 eluted on HPLC like Hb A, and was named Hb S–South End (Fig. 40–4).[53]

The variant hemoglobin with Lys132Asn alone has been previously described as Hb Yamagata and has a low oxygen affinity. It is surmised that Hb S–South End might have similarly low oxygen affinity, and that in combination with Hb S will impart a relatively severe clinical phenotype as exhibited in this patient.

The patient was also a heterozygous carrier of the single α-globin gene of the rightward type ($-\alpha^{3.7}/\alpha\ \alpha$) that might account for her borderline low MCV.

There are nine known sickle hemoglobin variants, each of which has Hb S mutation plus another mutation in the same β-globin gene.[53] Some of these can bring about sickling symptoms even in heterozygotes, such as Hb S-Antilles (Glu6Val, Val23Ile), Hb Jamaica Plain (Glu6Val, Leu68Phe), and Hb S-Oman (Glu6Val, Glu121Lys). Furthermore, the electrophoretic mobility or HPLC retention time of these variant hemoglobins can mimic that of either Hb A (eg, Hb S-South End), Hb S (eg, Hb Jamaica Plain), or Hb C (eg, Hb S-Oman). There was a 1½-year-old child initially thought to have sickle cell trait based on hemoglobin analysis results who developed a life-threatening splenic sequestration syndrome during her first airplane flight. Subsequently DNA-based diagnostics were carried out. The Hb S fraction eluted from HPLC was actually Hb Jamaica Plain, which can cause sickling symptoms in heterozygotes.[54]

There are other variant hemoglobins of clinical importance that mimic Hb A on HPLC or electrophoresis. There was another child initially diagnosed to have sickle cell trait on the basis of hemoglobin analysis results who developed sickle cell disease complications. Further investigation revealed that she was compound heterozygous for Hb S and Hb Quebec–Chori (*HBB* Thr87Ile).[36,55] Hb Quebec–Chori behaves like Hb A on electrophoresis and HPLC, and in combination with Hb S can cause sickle cell disease. Mixture of Hb Quebec–Chori with Hb S has the same delay time of polymerization as pure sickle hemoglobin. The isoleucine at codon 87 could stabilize a lateral contact between Hb S polymer strands and accelerate sickle hemoglobin polymerization.

Hb C (*HBB* Glu6Lys) and Hb O-Arab (*HBB* Glu121Lys) cannot be separated by HPLC or alkaline electrophoresis but can be resolved by IEF or citrate agar electrophoresis. The distinction between these two variant hemoglobins is clinically important because although Hb O-Arab is much less common than Hb C, when coinherited with Hb S, Hb O-Arab can facilitate the polymerization of Hb S and is associated with more severe disease than Hb SC disease.[56]

Hb Malay (*HBB* Asn19Ser) and Hb Volga (*HBB* Ala27Asp) both behave like Hb A on HPLC or electrophoresis. Hb Malay is common in parts of Southeast Asia, and causes a β-thalassemia phenotype because of the creation of a cryptic RNA splice site. Patients with β-thalassemia intermedia due to compound heterozygosity for Hb Malay and a β^+- or β^0-thalassemia mutation may be misdiagnosed as having β-thalassemia trait.[57] Hb Volga is an unstable variant hemoglobin and causes hemolytic anemia. A person who is heterozygous for Hb Volga and has hemolysis would appear to have only Hb A.[58]

Variant hemoglobins have abnormal HPLC eluting profile or electrophoretic mobility largely because of different surface charge caused by amino acid substitution. As illustrated by this case report and other examples, there are variant hemoglobins of clinical importance that cannot be identified by hemoglobin analytical techniques used in clinical laboratories. These observations illustrate the importance of correlation between clinical and laboratory findings to ensure that correct diagnosis is made. DNA-based globin genotyping is the only way to provide correct and definitive diagnosis.

Hb E/β^0-Thalassemia with Concomitant α-Thalassemia

A baby boy of Asian ancestry presented to pediatric clinic because of growth retardation. Both parents were healthy, and the full term pregnancy was uneventful. Neonatal hemoglobin screening showed Hb FE. At 9 months, he was seen by a pediatrician for failure to thrive. His Hb was 7.4 g/dL. Iron supplements were prescribed.

At 14 months, hemoglobin investigation revealed Hb F 48% and Hb E 52%, consistent with the diagnosis of Hb E/β^0-thalassemia. By 20 months, he was pale, mildly icteric, and noted to have frontal bossing. Both his weight and height were far below the 5th percentile. Marked splenomegaly was present. Blood counts are shown in the table.

He was transfused, subsequently underwent splenectomy, and later started on a regular transfusion program. He gradually improved substantially, and regained appropriate developmental milestones.[7]

Results of hematologic studies and DNA-based diagnostics of both parents and their infant son are summarized as follows:

	Father	*Mother*	*Infant son*
Age	29 years old	23 years old	$1^1/_2$ year old
Hb (g/dL)	11.6	13.0	4.7
MCV (fL)	51	74	61
Reticulocyte (%)	1.5	1.0	15
Hb A (%)	—	65	—
Hb E + A_2 (%)	95	34	52
Hb F (%)	4	<1	48
β-Globin genotype	Compound heterozygous for Hb E, and codon 17 AAG→TAG or Lys17Term β^0-thalassemia mutation.	Heterozygous for Hb E	Identical β-globin genotype as father's
α-Globin genotype	$(- - ^{SEA}/\alpha\alpha)$	(αα/αα)	(αα/αα)

Coinheritance of a single α-globin gene deletion has been reported to ameliorate the severity of β-thalassemia major or intermedia, likely due to lesser imbalance of the β/α-globin chain synthesis.[59] This beneficial effect, however, does not always hold true. In this family, the coinheritance of deletion of two α-globin genes $(- - ^{SEA})$ in the father might account for his relatively mild phenotype, in contrast to his son who was severely affected.[7] But there could be other yet unknown genetic modifiers that are responsible for the phenotypic dichotomy found between the father and son.[50,60] It should also be pointed out that unlike the father in this family, many patients with Hb E/β-thalassemia have Hb E varying from 40% to 70% and Hb F varying from 30% to 60%.

Hb S/β^0-Thalassemia

A 25-year-old African American man had been relatively well except for occasional painful episodes in his extremities. His Hb was 10.7 g/dL and MCV 71 fL. At age 23 following a febrile illness, he had one occurrence of splenic sequestration from which he recovered without the need for transfusion. He had a 32-year-old sister with identical hematologic findings, who also was well, and had two uneventful pregnancies.

DNA-based diagnostics revealed that both the proband and his mother were heterozygous for β^0-thalassemia due to a 1.4 kb deletion from nt −486 to nt +909 relative to the β-globin gene mRNA cap site that removes the promoter region as well as the 5′-coding regions of the β-globin gene and ends in IVSII.[61] The proband also inherited Hb S from his father.

	Father	*Mother*	*Son (age 25 years)*
Hb A (%)	50	90	Absent
Hb S (%)	44	Absent	84
Hb A_2 (%)	3.4	8.8	4.9
Hb F (%)	0.1	2.2	16.2
β-Globin genotype	Heterozygous for Hb S	Heterozygous for 1.4 kb deletion β^0-thalassemia	Compound heterozygous for both parental mutations
α-Globin genotype	(αα/αα)	(αα/αα)	(αα/αα)

The sum of this patient's Hb F and Hb A_2 adds up to more than 20%, which may be sufficiently high to interfere with intracellular Hb S polymerization and thereby lead to a relatively mild phenotype, unlike most other patients with Hb S/β^0-thalassemia.

Point mutations in the γ-globin gene promoter region known to cause hereditary persistence of fetal hemoglobin were looked for in the proband, and none was found. In addition, he did not have the T→C polymorphism at nt −158 5′ to the $^G\gamma$-globin gene, the so-called *XmnI* polymorphism associated with elevated Hb F in some patients with sickle cell disease. The proband had another sister who inherited the same β^0-thalassemia deletion, but not Hb S mutation. Her Hb A_2 was 8.4% and Hb F 3.4%, similar to her mother.

It is now known that carriers of several relatively small deletions removing β-globin gene promoter regions have much higher Hb A_2 and/or Hb F levels than carriers of most other β-thalassemia mutations due to point mutations. The absence of the β-globin gene promoter sequences may conceivably increase the likelihood that transcription factors bind the remaining δ and/or γ-globin gene promoters, thus enhancing gene transcription and expression.[62]

The differential diagnosis of patients found to have only Hb S, no Hb A, slightly elevated Hb A_2 and microcytosis includes homozygosity for Hb S and concomitant inheritance of α-thalassemia. Approximately 30% of African Americans are carriers of α-thalassemia due to either heterozygosity or homozygosity for single α-globin gene deletion that can account for the microcytosis. Therefore, α-globin genotyping ought to be included in the diagnostic schema for these patients.

hemoglobin disorders. In particular, when a pregnant woman is referred for hemoglobin studies, it is imperative to make the correct diagnosis in a timely manner, and to perform a diagnostic evaluation of her partner at the same time.

Some individuals might have inherited two or more globin gene mutations. For example, a person harboring β-thalassemia mutations affecting both β-globin genes on chromosome 11 may also have inherited an α-thalassemia deletion involving two α-globin genes in *cis* on one chromosome 16.[6,7] Correct deciphering of these complex genotypes often can be done only by DNA-based diagnostics.

Physical findings, such as splenomegaly, and clinical history can be very helpful when correlated with laboratory results in pointing to the appropriate diagnosis. In some cases, the possibility of nonpaternity or de novo mutation can be confounding factors in arriving at the correct diagnosis.[8,9]

Table 40–1 Mean Cell Volume (MCV) during Development

Age	Mean Cell Volume (fL)
At birth	110–128
1 week	107–129
1 month	98–112
2 months	87–113
3 months	80–96
1 year	70–84
4 years	73–86
10 years	75–90
15 years	77–92
Adult	80–96

Data from Segal GB, Palis J: Hematology of the newborn. In Beutler E, Lichtman MA, Coller BS, et al (eds.): Williams Hematology, 6th ed. New York, McGraw-Hill, 2001, p 77; and from Hord JD, Lukens J: Anemias unique to infants and young children. In Lee GR, Foerster J, Lukens JN, et al (eds.): Wintrobe's Clinical Hematology, 10th ed. Baltimore, Williams & Wilkins, 1999, p 1518.

Hematologic Parameters

Hemoglobin level and erythrocyte indices are readily available through automated electronic cell counters. Mean corpuscular volume (MCV) is a highly reliable measurement. One potential source of error is that erythrocytes tend to swell after being stored for 2 to 3 days in vitro, and thus have a higher MCV. MCV varies considerably during infancy and adolescence years (Table 40–1). Low MCV, that is, microcytosis, is usually indicative of iron deficiency, thalassemia, or anemia of chronic disease. MCV can be within normal range in heterozygous carriers of α^+-thalassemia or the Hb E mutation.[10]

Iron deficiency usually is characterized by low serum ferritin, low serum iron, high total iron-binding capacity (transferrin), and low serum transferrin saturation. People who have inherited either an α- or a β-thalassemia trait usually have normal iron stores. However, the presence of iron deficiency does not necessarily preclude the person also having inherited thalassemia mutations, or vice versa. In chronic inflammatory disorders, high serum ferritin and low transferrin saturation might be accompanied by mild microcytosis.

The MCV of poorly deformable sickle erythrocytes may be overestimated by cell counters that measure the electrical resistance of cells passing through a small orifice (Coulter principle). Analyzers using light scattering (Mie principle) are more accurate for this determination.[11] This latter method can determine the distribution of red cell density that may be useful for evaluating treatments and clinical course of sickle cell anemia.

Mean corpuscular hemoglobin (MCH) is a calculated value derived from other direct cell counter measurements. This test result remains relatively stable even in blood samples that have been kept at room temperature for 2 to 3 days, and some advocate the use of this parameter instead of MCV.[12]

Red cell distribution width (RDW) index is often normal in thalassemia trait and high in iron deficiency. Several "discriminant functions" using blood counts and erythrocyte indices have been proposed to distinguish iron deficiency from thalassemia trait. These cannot be recommended for reliable diagnostic purposes.

Reticulocyte count reflects erythrocyte production, and when persistently elevated is suggestive of hemolysis. Reticulocytes can be enumerated rapidly by automated blood cell analyzers. However, it should be noted that these instruments are unable to discern reticulocytes from erythrocytes containing Heinz bodies, and therefore yield spuriously high reticulocyte counts in hemolytic anemia caused by unstable variant hemoglobins.[13,14]

Peripheral blood smear morphology can provide clues to the diagnosis of hemoglobin disorders, as in sickle cell disease and thalassemia. In Hb C and Hb SC disease, there is microcytosis, target cells, irregularly contracted cells, and intracellular Hb C crystals. The presence of "bite cells" and irregularly contracted erythrocytes is suggestive of a hemolytic disorder.

In α-thalassemia, there is an excess of β-globin chains. These form β_4 tetramers (Hb H) that precipitate within red blood cells. The formation of these precipitates, Hb H inclusion bodies, is enhanced under the influence of oxidants such as brilliant cresyl blue, and these inclusion bodies can be visualized by light microscopy. When carried out and examined by experienced laboratory personnel, this is a specific screening test for α-thalassemia. But it is time consuming and its accuracy is highly observer-dependent.[15] In Hb H disease, there are many erythrocytes with these inclusion bodies. However, concomitant inheritance of Hb H disease and heterozygosity for β-hemoglobinopathies such as β-thalassemia or Hb E would lead to markedly decreased amount of Hb H and inclusion bodies, and may confound the correct diagnosis of the underlying Hb H disease.[15]

In general, heterozygous carriers of β-thalassemia mutations have microcytosis and elevated Hb A_2 levels. In α-thalassemia carriers, there is microcytosis but Hb A_2 level is normal. A person who is heterozygous for both α- and β-thalassemia mutations has microcytosis and elevated Hb A_2 level, often indistinguishable from a person with β-thalassemia trait alone.[16] For genetic counseling and assessment of potential reproductive risks, DNA-based diagnostics are necessary to determine the correct α- and β-globin genotypes.[17]

HEMOGLOBIN ANALYSIS

High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) has become the standard analytical procedure for the initial evaluation of hemoglobin variants and thalassemia in clinical laboratories. It is rapid, automated, capable of resolving most of the common and many uncommon variants, and provides reliable quantitative measurements of hemoglobin fractions like Hb A_2 and Hb F.[18,19] In cation-exchange HPLC, hemolysate is injected into a chromatography column containing a negatively charged resin onto which the positively charged hemoglobins are adsorbed. Hemoglobins are eluted by passing through a carefully calibrated developing solution containing an increasing concentration of cations (Fig. 40–1).[20] The rate of hemoglobin elution, or the retention time, corresponds to the affinity of each hemoglobin for the column matrix, and is continuously monitored by an optical detector. The chromatogram is stored in and analyzed by a microcomputer.

One caveat with HPLC analysis is that Hb A_2 level measurement is often high in the presence of Hb S. Recent improvement in HPLC and also capillary electrophoresis have largely rectified this problem.[21,22] Furthermore, Hb E and Hb Lepore have similar retention time as Hb A_2, and these hemoglobins cannot be positively separated. Hb C and Hb O^{Arab} also cannot be definitively distinguished by cation-HPLC (Fig. 40–2).

Isoelectric Focusing

In isoelectric focusing (IEF), an electric current is passed through a supporting medium such as a precast agarose or polyacrylamide gel containing carrier ampholytes. These ampholytes migrate through the medium to form a stable pH gradient ranging from pH 6.0 at the anode to pH 8.0 at the cathode. Hemolysate is applied to the gel at the cathode end, and hemoglobin fractions migrate through the pH gradient until they are "focused" into a sharp, distinct band at the pH equal to the isoelectric point (pI) at which the hemoglobin is neutrally charged.[23–25] It has better resolving power than many other electrophoretic techniques as it can distinguish variant hemoglobins on the basis of their minute differences in pI. However, Hb

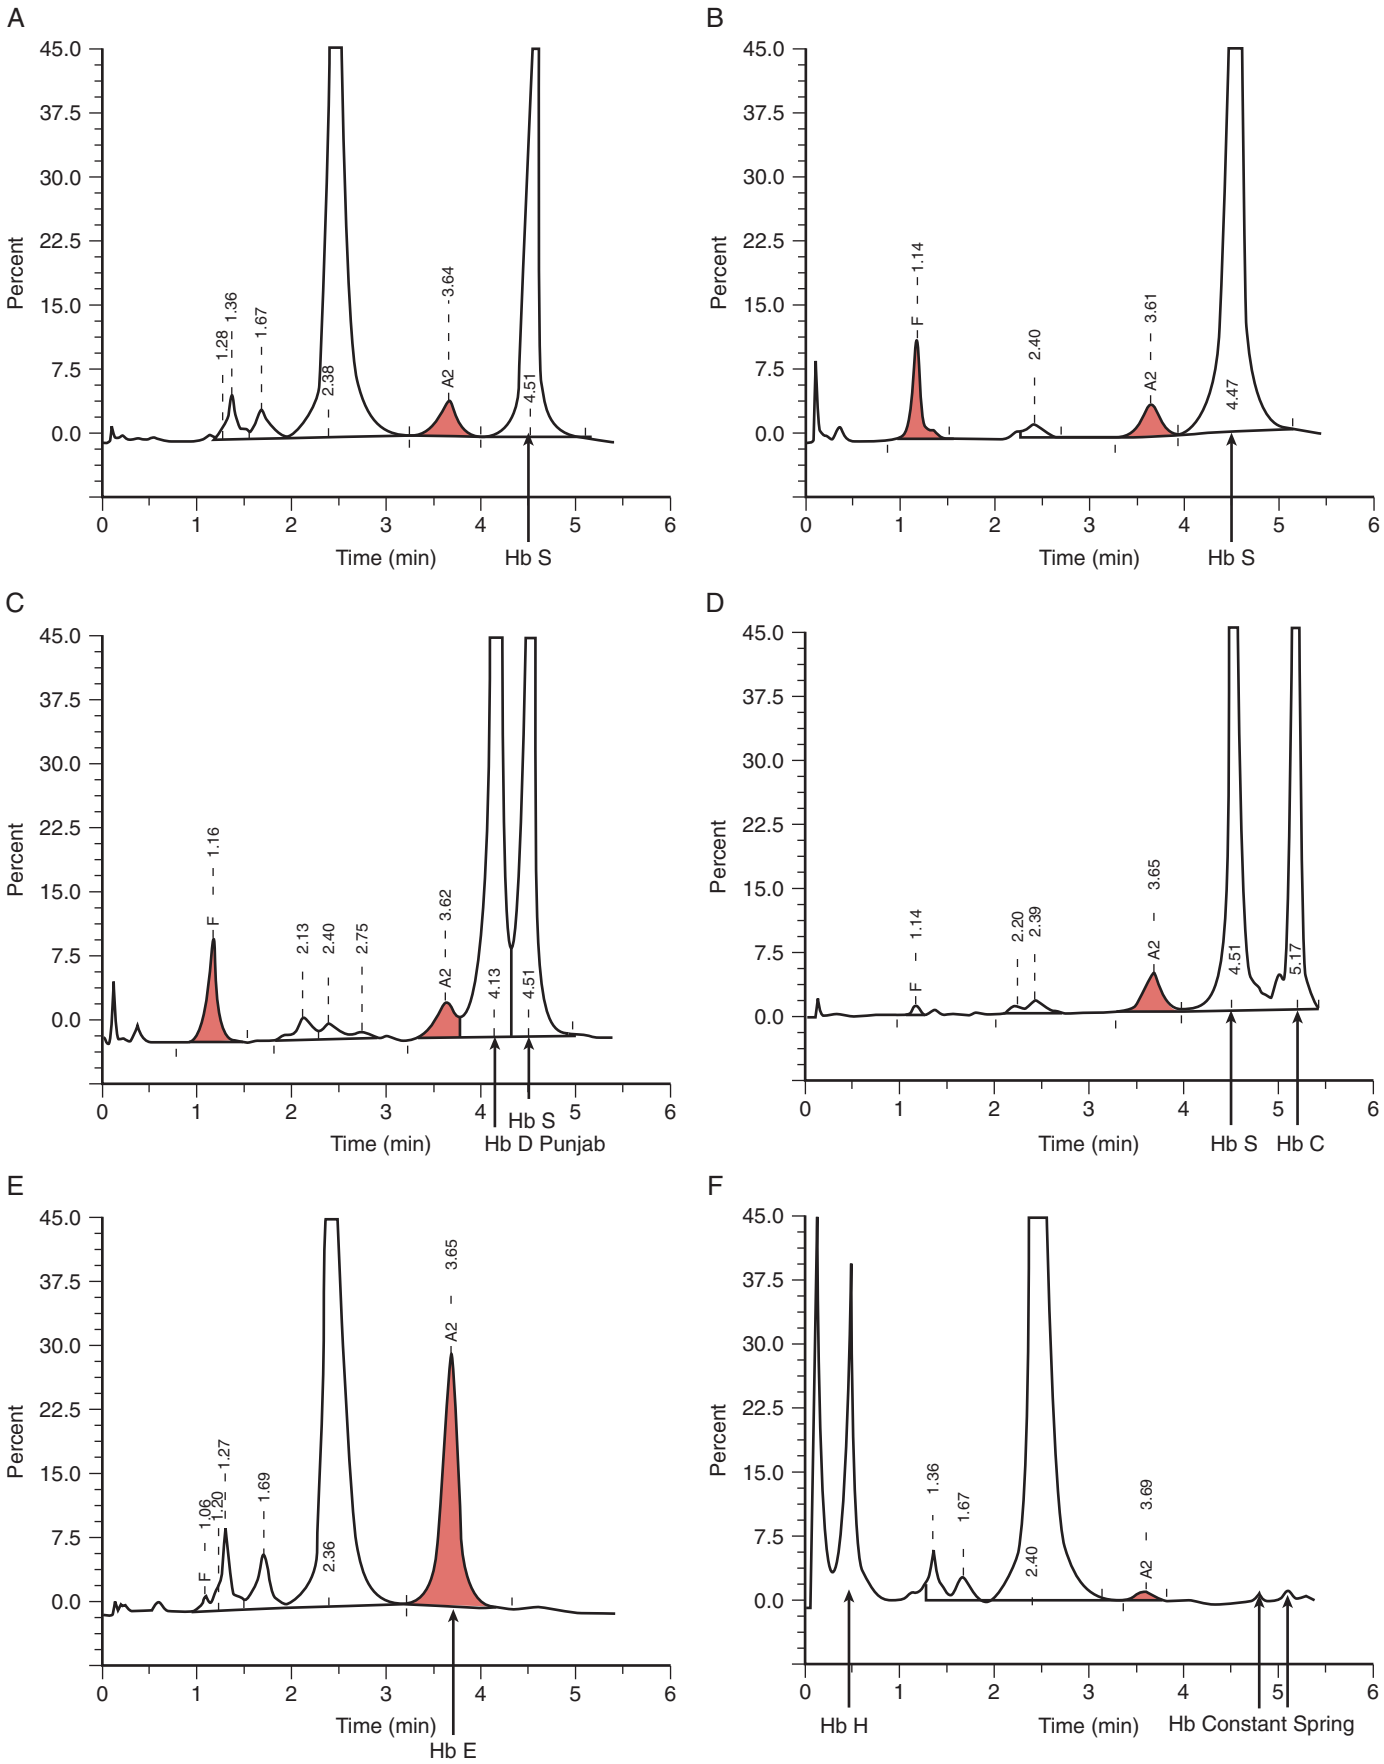

Figure 40–1 Representative tracings from the output of the Biorad Variant II high-performance liquid chromatography analysis of selected hemoglobin variants using the β-thalassemia short program. **A**, Sickle cell trait. **B**, Sickle cell anemia. **C**, Compound heterozygote for Hb D Punjab and Hb S. **D**, Hb SC disease. **E**, Hb E trait. **F**, Hb H disease with Hb Constant Spring. Notice the clear separation of HbA_2 from Hb C (**D**) but the failure to distinguish HbA_2 from Hb E (**E**). Associated with each hemoglobin peak is the elution time from the chromatography column. Hb F and Hb A_2 peaks are shaded. Other peaks represent hemoglobin fractions that have been modified by glycosylation and other posttranslational events. *(Courtesy of Andrew G. McFarlane.)*

O^{Arab} is not well separated from Hb E, nor Hb D^{Punjab} from Hb $G^{Philadelphia}$.

IEF has several drawbacks: A constant temperature at 59°F during the procedure is essential to maintain the pH gradient for proper hemoglobin separation; minor modified hemoglobin bands are often visible because of its high resolving power and these may complicate interpretation; this technique is not amenable to quantifying hemoglobin fractions.

Hemoglobin Electrophoresis

Although a standard in the past, hemoglobin electrophoresis has been supplanted by more rapid, sensitive, and quantitative methods of hemoglobin separation. Cellulose acetate electrophoresis at pH 8.2 to 8.6 can be used to resolve common variants like Hb S and Hb C, but it cannot be used to distinguish between Hb S and Hbs D^{Punjab} and $G^{Philadelphia}$. Similarly, Hb A_2 is not readily separated from Hbs C, E, and O^{Arab}. Quantitative measurements of Hb A_2 and Hb F fractions based on densitometric readings are inaccurate.

Citrate agar electrophoresis at pH 6.0 to 6.2 provides better resolution for different hemoglobin variants.[26–28] Hbs C, C^{Harlem}, E, and O^{Arab} have different migrating mobilities in this acidic medium (Fig. 40–2). It can be used to distinguish Hb S from Hbs D^{Punjab} or $G^{Philadelphia}$, but it cannot separate Hb D^{Punjab} from Hb $G^{Philadelphia}$, or Hb A from Hb A_2. This electrophoretic technique is still used in some laboratories as an aid to variant hemoglobin identification, but it cannot be used for quantitative measurements.

Capillary Electrophoresis

Capillary electrophoresis is carried out by hemoglobin migrating through pH gradients established in fine capillary tubes known as capillary isoelectric focusing or in a capillary filled with an alkaline salt buffer known as capillary zone electrophoresis. This technique is rapid, uses minute amounts of test sample, and potentially has a good resolving power.[29,30] A system designed for use in clinical laboratories to analyze hemoglobin is now available. It provides quantitative measurements and automated data analysis. In particular, it can separate Hb E from Hb A_2 and can also determine Hb A_2 level accurately even in the presence of Hb S (Fig. 40–3).[31] But it cannot resolve Hb C from Hb A_2. These systems can serve as an automated clinical laboratory procedure for hemoglobin analysis, and also for newborn hemoglobin screening programs.

Immunologic Detection

Murine monoclonal antibodies against human normal and variant hemoglobins are available and can be used for identification and/or quantitation of hemoglobins, such as Hb F measurement by radial immunodiffusion, or Hb F-containing erythrocytes (F-cells) by flow cytometry.[32,33] An enzyme-linked immunosorbent assay (ELISA) to detect embryonic ζ-globin chains in adults has been found to be useful to detect carriers of a common Southeast Asian α-thalassemia deletion.[34,35]

Mass Spectrometry

This analytical technology and its proper interpretation are available only in highly specialized laboratories and are not presently used for clinical diagnosis. In mass spectrometry, molecules are converted to gaseous ions, often by electrospray ionization or matrix-assisted laser desorption/ionization. As an accelerating voltage is applied, these particles are separated according to their mass-to-charge ratio. The determination of molecular weight is exquisitely accurate and thus can be reliably used to decipher variant hemoglobins.[36,37] Mass spectrometry can be used to identify highly unstable hemoglobins that may manifest clinically as hemolytic anemia or thalassemia. These variant hemoglobins in trace amounts might not be detected by diagnostic techniques used in most clinical laboratories. In addition, mass spectrometry can provide information on posttranslational modifications, such as oxidation and glycation.

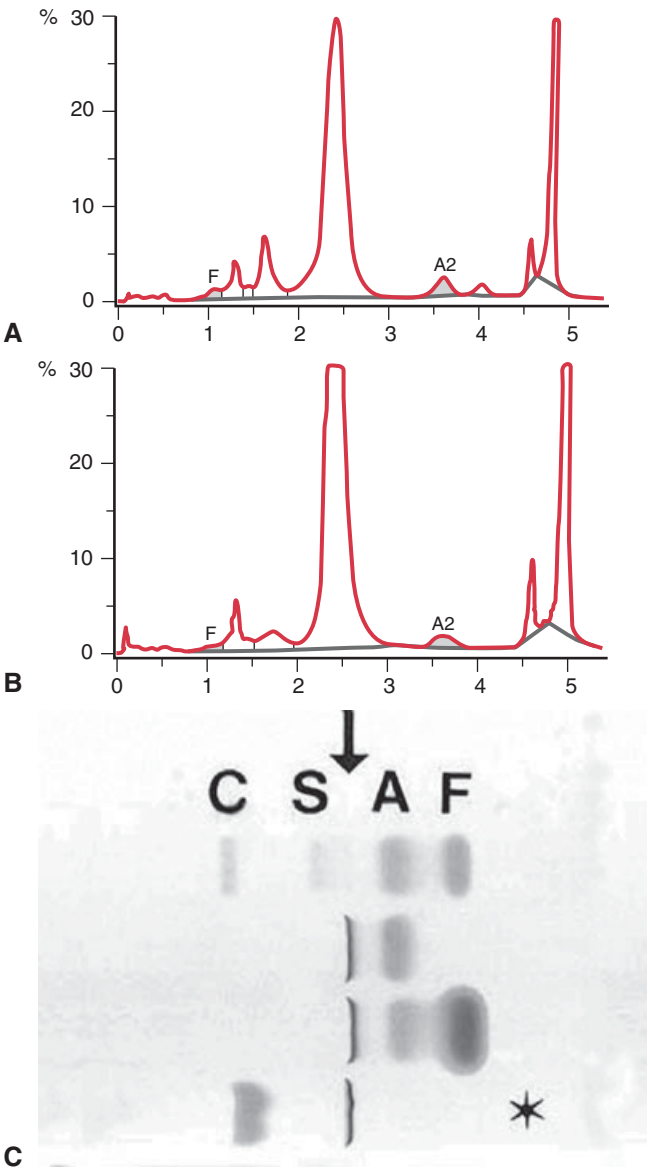

Figure 40–2 **A**, Cation-HPLC chromatogram of Hb O-Arab trait. **B**, Cation-HPLC chromatogram of Hb C trait. Note that Hbs O-Arab and C cannot be distinguished by cation-HPLC. **C**, Citrate agar electrophoresis. *Top lane:* Hbs C, S A, and F. *Second lane:* Adult with Hb O-Arab trait. *Third lane:* Newborn with Hb O-Arab trait. *Bottom lane:* Adult compound heterozygote with Hbs C and O-Arab. Arrow denotes position of Hb O-Arab. Note that Hbs C, S, O-Arab, A, and F can be separated by this technique.

ADDITIONAL TESTS FOR HEMOGLOBIN CHARACTERIZATION

The Hb S Solubility Test

When reduced with sodium dithionite, Hb S is insoluble and precipitates in high-molarity phosphate buffer at neutral pH. This forms the basis for the simple Hb S solubility test.[38] It is also positive in

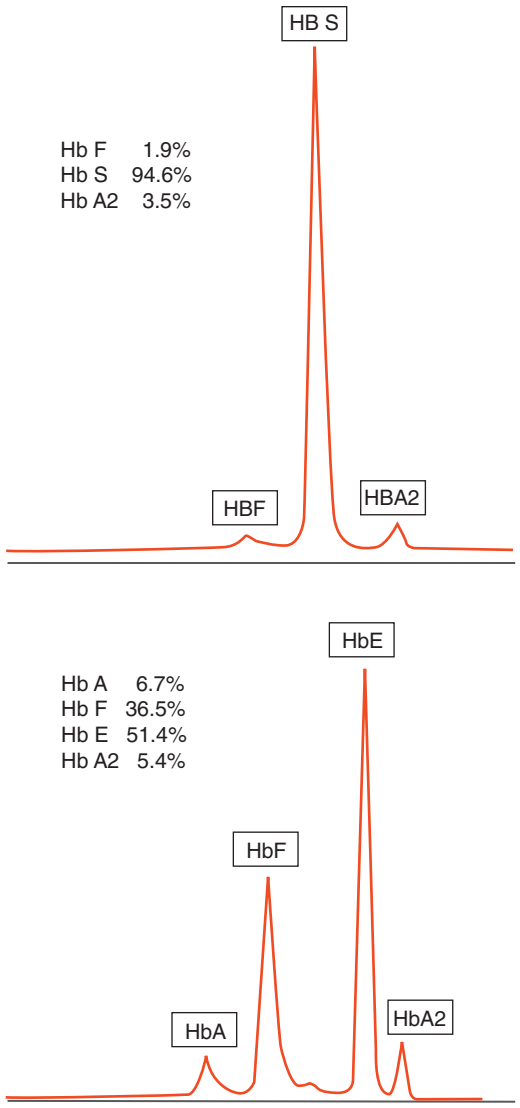

Figure 40–3 Tracings from capillary electrophoresis of hemolysate from homozygous sickle cell anemia (upper figure), and Hb E/IVSI-5 G→C β^+-thalassemia (lower figure). *(Courtesy of Andrew G. McFarlane.)*

other variants that have the Hb S mutation plus an additional amino acid substitution, such as Hb S-Antilles, C-Ziquinchor, C-Harlem, S-Providence, S-Oman, and S-Travis.

The Hb S solubility test has very limited applicability: (a) as a screening test for Hb S in patients preparing for emergency surgery under general anesthesia; and (b) as a confirmatory test when Hb S is detected by either electrophoresis, IEF, HPLC, or capillary electrophoresis to distinguish Hb S from other variants with similar migrating mobility as Hb S.

This solubility test cannot distinguish between sickle cell trait, sickle cell disease, or Hb S/β-thalassemia. The test is negative when the concentration of Hb S is less than 15%, and thus is not suitable for testing blood samples from infants or patients who have been transfused. More important, the test cannot detect hemoglobin variants such as Hbs C, D^{Punjab}, and O^{Arab}. These variant hemoglobins in combination with Hb S can cause a sickling disorder. Thus, Hb S solubility tests should not be used for assessment of potential reproductive risk, for genetic counseling or as a primary diagnostic test.

Hemoglobin Functional Investigations

1. Determination of the P_{50} or oxyhemoglobin dissociation curve is necessary to document variant hemoglobins with either high or low oxygen affinity, including those that might have similar electrophoretic mobility as Hb A.
2. Detection of hemoglobin instability by exposure to heat or isopropyl alcohol, and also by Heinz body detection.
3. Identification of methemoglobins is done by studying their unique absorption spectrum.
4. α- and β-globin chain synthetic studies can be helpful to determine whether a patient might have either α- or β-thalassemia mutation but are rarely used clinically.

Iron Studies

Serum ferritin, or serum iron, total iron-binding capacity, and transferrin saturation determinations are helpful to determine if an individual is iron deficient. Most patients with thalassemia trait are not iron deficient, but there are some who have both thalassemia trait and iron deficiency. Measurement of free erythrocyte protoporphyrin or zinc protoporphyrin are other adjunctive tests that are useful to detect iron deficiency or erythrocyte heme synthetic abnormalities.

DNA-Based Globin Gene Analysis

DNA-based mutational analysis is the only method to provide specific genotyping on hemoglobinopathies and thalassemias, and is essential for family counseling and reproductive decision making. Recent advances in molecular genetics and diagnostic innovations have made it possible to carry out these tests rapidly and efficiently. Increasingly, this technology is now accepted and incorporated into the clinical laboratory diagnostic repertoire for both hereditary and acquired disorders.

Gap-PCR (polymerase chain reaction) tests are now often employed to diagnose common deletions, either singly or in mutliplex form for several deletions.[39,40] Southern blot analysis is still used to detect large or novel deletions. For small deletions/insertions, PCR-based heteroduplex analysis is a reliable and simple test.[41]

To detect single-nucleotide mutations, dot blotting or reverse dot blotting with allele-specific oligonucleotide probes are used.[42] To detect several commonly found mutations in a specific population, one can resort to multiplex PCR using allele-specific primers, or multiplex amplification refractory mutational analysis.[43] Other diagnostic alternatives such as minisequencing, denaturing HPLC, or array testing using allele-specific arrayed primer extension have been proposed to be applicable in different locales and laboratories.[44–46]

For the uncommon mutations, nucleotide sequencing of the PCR-amplified globin gene is necessary. This can now be readily carried out for α-, β-, δ-, and γ-globin genes (Fig. 40–4). Other methods are single-strand conformation polymorphism, denaturing gradient gel electrophoresis, and restriction endonuclease analysis of mutations. Except for the common variant hemoglobins, such as Hbs S, C, and E, variant hemoglobin detection based on hemoglobin analysis is primarily a screening test, and ought to be confirmed definitively by DNA-based diagnostics if clinically indicated.

DNA-based mutational analysis is used for prenatal diagnosis on fetal DNA extracted from either primary chorionic villi samples, amniocytes, or their respective cultured cells. Recent reports of success in analyzing fetal DNA in maternal circulation provide a potential method for noninvasive prenatal diagnosis in the future.[47,48]

Interpretation of Laboratory Results

No single hemoglobin analytical procedure available in clinical laboratories can distinguish definitively all common and clinically

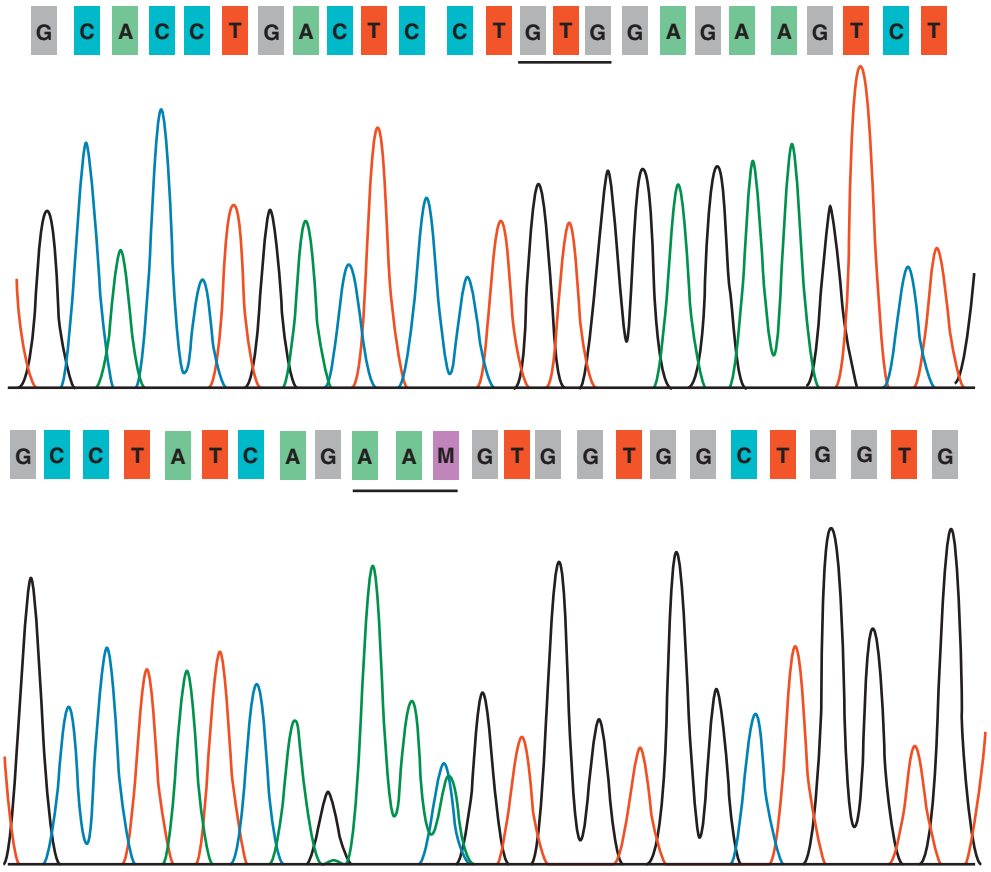

Figure 40–4 β-Globin genes were amplified by PCR and sequenced. The upper figure shows sequences from codons 2 to 9, with homozygosity for GTG instead of GAG in codon 6. The lower figure shows sequences from codons 129 to 136, with heterozygosity in codon 132 AAA→AAC. *(Courtesy of Dr. Hong-Yuan Luo.)*

important variant hemoglobins such as Hb S, C, D^{Punjab}, E, and O^{Arab}. Currently, cation HPLC is the method of choice (Fig. 40–1). It is advisable to have a different diagnostic method, such as IEF or citrate agar electrophoresis, available for confirmation.

Most variant hemoglobins do not cause disease. As the worlds' populations mix, coinheritance of mutations for hemoglobinopathies and thalassemias which alone are innocuous may lead to severe disease.[49] Therefore, careful clinical–laboratory correlation is required to determine if additional investigations are needed to precisely characterize globin gene mutations.

Heterozygotes for β-globin gene mutations usually have one major variant hemoglobin fraction ($\alpha_2\beta^{Variant}_2$), which is often slightly less in amount to the normal Hb A ($\alpha_2\beta_2$). However, heterozygotes for α-globin gene mutations usually have one major variant hemoglobin fraction ($\alpha^{Variant}_2\beta_2$) of approximately 20% of the normal Hb A ($\alpha_2\beta_2$) plus a minor variant hemoglobin made up of two mutant α-globin chains and two normal δ-globin chains forming a variant Hb A_2 fraction ($\alpha^{Variant}_2\delta_2$), in addition to the normal Hb A_2 ($\alpha_2\delta_2$).

Quantitation of Hb A_2 is vitally important, as an elevated value is a diagnostic criterion for β-thalassemia carriers. Care should be exercised to be aware of δ-globin mutations that may cause variant Hb A_2 with a different migration mobility from normal Hb A_2 or δ-thalassemia. Their disregard might lead to an erroneous conclusion that the individual under study is not a β-thalassemia carrier.

Quantitation of Hb F is important for the diagnosis of thalassemia syndromes and hereditary persistence of fetal hemoglobin. It is also often used as a marker for treatment response in sickle cell disease and thalassemias. Hb F can be reliably measured by HPLC or CE, or can be determined by immunologic methods using specific anti-γ-globin chain antibodies.

The accumulation of different hemoglobin in vivo depends on the expression of individual globin genes, the stability of the globin produced, and on the posttranslational assembly of hemoglobin dimers. As an illustration, the Hb A : Hb S ratio in uncomplicated sickle cell trait is 60 : 40. In an individual with sickle cell trait and α-thalassemia, this ratio is 70 : 30 to 75 : 25 because normal β-globin chain has a greater affinity for the limited amounts of α-globin chain than does the sickle β-globin chain. The Hb A : Hb S ratio in a person who has coinherited Hb S and β^+-thalassemia can vary between 30 : 70 and 10 : 90 depending on the nature of the β^+-thalassemia mutation that affects the amount of β^A-globin produced (Table 40–2).

Also as illustrated in Table 40–2, there are considerable overlaps in hematologic findings in sickle cell anemia, Hb S/β^0-thalassemia, and also sickle cell anemia with concurrent α-thalassemia. In all three conditions, the major hemoglobin present is Hb S, with variable amounts of Hb F, and Hb A is absent. Molecular or family studies often are needed to distinguish among these possibilities. Transfusion can provide yet another confounding factor in arriving at the correct diagnosis.

There are genetic modifiers that play critical roles in determining the phenotypic expression of hemoglobin disorders.[50–52] The highly variable clinical manifestations of sickle cell disease and of Hb E/β-thalassemia are but two examples. As these genetic modifiers are characterized, they will have to be included into the future laboratory diagnostic repertoire as they become clinically relevant for predicting prognosis and planning for therapeutic strategies.

There are more than 1300 natural globin gene mutations. In today's multicultural societies in North America and elsewhere, there can be a vast number of different globin genotypes. In some countries, high carrier frequencies of β- and α-thalassemias and variant hemoglobins are present. The common hemoglobin disorders such as homozygous sickle cell anemia can be diagnosed in most clinical laboratories. More complicated and unusual cases should be studied in a reference laboratory capable of carrying out more sophisticated investigations including DNA-based procedures and having both clinical and laboratory expertise in order to provide the best possible diagnostic and consultative advice to the physicians and genetic counselors caring for these patients and their families.

Table 40–2 Hematologic and Hemoglobin Findings in Hemoglobin S, Hemoglobin C, and Hemoglobin E Syndromes

Diagnosis	α-Globin Genotype	Hb (g/dL)	MCV (fL)	Reticulocytes (%)	Variant Hemoglobin (%)	Hb A (%)	Hb A_2 (%)	Hb F (%)
Sickle cell syndromes								
β^A/β^S (sickle cell trait)	αα/αα	13–15	80–90	Normal	Hb S 40	60	2.5	<1

These laboratory results represent ranges in general for adults, and adapted from data from several recent book chapters.[2–4] Individual patient's values might vary and be significantly different from figures in this table. Blood counts and hemoglobin fractions show developmental changes so that a patient's age must be considered in their interpretation.

Considerable overlap of hematologic values and hemoglobin fractions in sickle cell anemia with α thalassemia and Hb S/β^0-thalassemia make family and molecular studies imperative for genetic counseling.

Older methods of measuring Hb A_2, such as hemoglobin electrophoresis, were unable to separate this minor hemoglobin fraction from Hb C and Hb E. Newer techniques like HPLC or CE are able to do this. Whether or not concurrent α-thalassemia changes Hb A_2 in Hb C or Hb E heterozygous carriers is not known.

One caveat with HPLC analysis was that Hb A_2 levels were spuriously elevated in the presence of Hb S.[21] Newer design for HPLC or capillary electrophoresis now allow accurate measurement of Hb A_2 when Hb S is present.[22,31]

CHAPTER 41

THALASSEMIA SYNDROMES

Patricia J. Giardina and Bernard G. Forget

The thalassemia syndromes are a heterogeneous group of inherited anemias characterized by defects in the synthesis of one or more of the globin chain subunits of the hemoglobin tetramer. The clinical syndromes associated with thalassemia arise from the combined consequences of inadequate hemoglobin production and imbalanced accumulation of globin subunits. The former causes hypochromia and microcytosis; the latter leads to ineffective erythropoiesis and hemolytic anemia. Clinical manifestations are diverse, ranging from asymptomatic hypochromia and microcytosis to profound anemia, which can be fatal in utero or in early childhood if untreated. This heterogeneity arises from the variable severities of the primary biosynthetic defects and coinherited modifying factors, such as increased synthesis of fetal globin subunits or diminished or increased synthesis of α-globin subunits. Palliative treatment of the severe forms by blood transfusion is eventually compromised by the concomitant problems of iron overload, alloimmunization, and blood-borne infections.

As a group, the thalassemias represent the most common single genetic disorder known. In many parts of the world, they constitute major public health problems. Laboratory analysis of these disorders has been one of the most productive and enlightening endeavors of biomedical research. Study of the molecular defects underlying the thalassemia syndromes has led to fundamental advances in our understanding of eukaryotic gene structure and function. For each of these reasons, a thorough understanding of thalassemia and its related disorders is essential to the hematologist. This chapter reviews the major features of these syndromes. Readers wanting more detailed information than can be included here are referred to more comprehensive monographs elsewhere.[1,2]

The classification, genetic basis, and pathophysiology of the thalassemia syndromes are based on a thorough understanding of the human hemoglobins, their biosynthesis, their encoding globin gene families, and their roles as soluble oxygen-carrying molecules. Therefore, the readers of this chapter should first familiarize themselves with the material presented in Chapter 33. The material presented in this chapter is also substantially clarified by prior reading of Chapters 35 and 36, because the principles underlying the pathophysiology of and therapy for thalassemia draw heavily on knowledge of iron metabolism.

DEFINITIONS AND NOMENCLATURE

The term *thalassemia* is derived from a Greek term that roughly means "the sea" (Mediterranean) in the blood.[1] It was first applied to the anemias frequently encountered in people from the Italian and Greek coasts and nearby islands.[3–5] The term is now used to refer to inherited defects in globin-chain biosynthesis. Individual syndromes are named according to the globin chain whose synthesis is adversely affected. Thus, α-globin chains are absent or reduced in patients with α-thalassemia, β-globin chains in patients with β-thalassemia, δ-globin and β-globin chains in patients δβ-thalassemia, and so forth. In some contexts, it is also useful to subclassify the syndromes according to whether synthesis of the affected globin chain is totally absent (eg, β^0-thalassemia) or only partially reduced (eg, β^+-thalassemia).

The most common forms of thalassemia arise from total absence of structurally normal globin chains or a partial reduction in their synthesis. In contrast to the "structural" hemoglobinopathies (eg, sickle cell anemia), which are characterized by the production of normal amounts of mutant globin chains having deranged physical or chemical properties, thalassemias are quantitative disorders: the primary lesion lies in the amount of globin produced. However, some rare forms of thalassemia are characterized by the production of structurally abnormal globin chains in reduced amounts. These thalassemic hemoglobinopathies share features of thalassemia as well as those of structural hemoglobinopathies.[6]

Some mutations alter the patterns of fetal to adult hemoglobin switching. These conditions, called *hereditary persistence of fetal hemoglobin*, are not generally associated with clinical symptoms; nonetheless, they merit consideration in this chapter. Their importance lies in their role as modulating factors when coinherited with other hemoglobinopathies, in their usefulness as models for investigating the molecular basis for globin gene regulation during human development and as paradigms for rational therapy for the major β-chain hemoglobinopathies, namely, sickle cell anemia and β-thalassemia.

ETIOLOGY, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

The thalassemias are inherited as pathologic alleles of one or more of the globin genes located on chromosomes 11 and 16 (see Chapter 33). These lesions range from total deletion or rearrangement of the loci to point mutations that impair transcription, processing, or translation of globin mRNA. The precise nature of the defects is summarized in a later section.

Thalassemias have been encountered in virtually every ethnic group and geographic location. They are most common in the Mediterranean basin and tropical or subtropical regions of Asia and Africa. The "thalassemia belt" extends along the shores of the Mediterranean and throughout the Arabian peninsula, Turkey, Iran, India, and southeastern Asia, especially Thailand, Cambodia, and southern China.[7–10] The prevalence of thalassemia in these regions is in the range of 2.5% to 15%. Like sickle cell anemia, thalassemia is most common in those areas historically afflicted with endemic malaria. Malaria seems to have conferred selective survival advantage to thalassemia heterozygotes, in which infection with the malarial parasite is believed to result in milder disease and less impact on reproductive fitness.[1,2,11] Therefore, the gene frequency for thalassemia has become fixed and high in populations exposed to malaria over many centuries.

PATHOPHYSIOLOGY: GENERAL PRINCIPLES

The pathophysiology and molecular genetics of individual forms of thalassemia are closely intertwined. Therefore, detailed consideration of these syndromes is best deferred to their individual subsections. This section considers only mechanisms common to the pathogenesis of all of these syndromes.[1–5,12]

The primary lesion in all forms of thalassemia is reduced or absent production of one or more globin chains. For all practical purposes, the major impact on clinical well-being occurs only when these lesions affect the α- or β-globin chains necessary for the synthesis of hemoglobin (Hb A; $\alpha_2\beta_2$). (Severe impairment of γ-, ε-, or ζ-globin

production is presumably lethal in utero.) One consequence of reduced globin-chain production is immediately apparent: reduced production of functioning hemoglobin tetramers. As a result, hypochromia and microcytosis are characteristic of virtually all patients with thalassemia. In the milder forms of the disease, this phenomenon may be barely detectable.

The second consequence of impaired globin biosynthesis is unbalanced synthesis of the individual α- and β-subunits. Hemoglobin tetramers are highly soluble and have reversible oxygen-carrying properties exquisitely adapted for oxygen transport and delivery under physiologic conditions. Free or "unpaired" α-, β-, and γ-globin chains are either highly insoluble or form homotetramers (Hb H and Hb Bart) that are incapable of releasing oxygen normally and are relatively unstable and precipitate as the cell ages. For poorly understood reasons, no compensatory regulatory mechanism exists whereby impaired synthesis of one globin subunit leads to a compensatory downward adjustment in the production of the other (partner) globin chain of the hemoglobin tetramer. Thus, useless excess α-globin chains continue to accumulate and precipitate in β-thalassemia, whereas excess β-globin chains form Hb H in α-thalassemia. During uterine development, excess γ-globin chains form Hb Bart in α-thalassemic individuals.

The abnormal solubility or oxygen-carrying properties of these chains lead to a variety of physiologic derangements. Indeed, in the severe forms of thalassemia, it is the behavior of the unpaired globin chains accumulating in relative excess that dominates the pathophysiology of the syndrome, rather than the mere underproduction of functioning hemoglobin tetramers. The precise complications of this pathophysiologic phenomenon are diverse and depend on the amount and the identity of the globin chain accumulating in excess. For the moment, the fundamental principle that must be appreciated is that thalassemias cause symptoms by underproduction of hemoglobin and by accumulation of unpaired globin subunits. The unpaired subunits are usually the major sources of morbidity and mortality.

The predominant circulating hemoglobin at the moment of birth is fetal hemoglobin (Hb $F^{\alpha_2\gamma_2}$) (see Chapter 32). Although the switch from γ- to β-globin biosynthesis begins before birth, the composition of hemoglobin in the peripheral blood changes much later because of the long life span of normal circulating red blood cells. Hb F is thus slowly replaced by adult hemoglobin (Hb A), so that infants do not depend heavily on normal amounts and function of Hb A until they are between 4 and 6 months old. The pathophysiologic consequences of these considerations are that α-chain hemoglobinopathies tend to be symptomatic in utero and at birth, whereas individuals with β-chain abnormalities are asymptomatic until 4 to 6 months of age. These differences in the onset of phenotypic expression arise because α-chains are needed to form Hb F and Hb A, whereas β-chains are required only for Hb A.

β-THALASSEMIA SYNDROMES

Nomenclature

Many different mutations cause β-thalassemia and its related disorders, such as δβ-thalassemia and the silent carrier state. They are inherited in a multitude of genetic combinations responsible for a heterogeneous group of clinical syndromes. β-Thalassemia major, also known as Cooley's anemia or homozygous β-thalassemia, is a clinically severe disorder that results from the inheritance of two β-thalassemia alleles, one on each copy of chromosome 11. As a consequence of diminished Hb A synthesis, the circulating red blood cells are very hypochromic and abnormally shaped; they contain markedly reduced amounts of hemoglobin. Accumulation of free α-globin chains leads to the deposition of precipitated aggregates of these chains to the detriment of the erythrocyte and its precursor cells in the bone marrow. The anemia of thalassemia major is so severe that long-term blood transfusions are usually required.

The term β-*thalassemia intermedia* is applied to a less severe clinical phenotype in which significant anemia occurs but chronic transfusion therapy is not absolutely required. It usually results from the inheritance of two β-thalassemia mutations, one mild and one severe; the inheritance of two mild mutations; or, occasionally, the inheritance of complex combinations, such as a single β-thalassemia defect and an excess of normal α-globin genes, or two β-thalassemia mutations coinherited with heterozygous α-thalassemia (in this last form, known as αβ-thalassemia, the α-thalassemia allele reduces the burden of unpaired α-chains).[13–15] Simple heterozygosity for certain forms of β-thalassemic hemoglobinopathies can also be associated with a thalassemia intermedia phenotype, sometimes called dominant β-thalassemia.[16,17]

Thalassemia minor, also known as β-thalassemia trait or heterozygous β-thalassemia, is caused by the presence of a single β-thalassemia mutation and a normal β-globin gene on the other chromosome. It is characterized by profound microcytosis with hypochromia but mild or minimal anemia.

β-Thalassemia is also called by several other names, including Cooley's anemia, Mediterranean anemia, von Jaksch anemia,[1] target cell anemia, erythroblastic anemia, and familial microcytosis.

Molecular Pathology

Forms of β-thalassemia arise from mutations that affect every step in the pathway of globin gene expression: transcription, processing of the mRNA precursor, translation of mature mRNA, and post-translational integrity of the β-polypeptide chain (Fig. 41–1 and Table 41–1).[18–20] Large deletions removing two or more non-α-genes are found in rare cases, as are smaller partial or total deletions of the β-gene alone (see Fig. 41–1). Most types of β-thalassemia are caused by point mutations affecting one or a few bases. (The original literature for this section is extensive; it is summarized in various publications and databases.[18–25] Of the more than ~200 mutations causing β-thalassemia, approximately 15 account for the vast majority of affected patients, with the remainder responsible for the disorder in only relatively few patients. It has been determined that five or six mutations usually account for more than 90% of the cases of β-thalassemia in a given ethnic group or geographic area (see Table 41–1).[22]

Table 41–1 Common β-Thalassemia Mutations in Different Racial Groups

Racial Group	Description
Mediterranean	IVS-1, position 110 (G → A) Codon 39, nonsense (CAG → TAG) IVS-1, position 1 (G → A) IVS-2, position 745 (C → G) IVS-1, position 6 (T → C) IVS-2, position 1 (G → A)
Black	–34 (A → G) –88, (C → T) Poly(A), (AATAAA → AACAAA)
Southeast Asian	Codons 41/42, frameshift (–CTTT) IVS-2, position 654 (C → T) –28 (A → T)
Asian Indian	IVS-1, position 5 (G → C) 619-bp deletion Codons 8/9, frameshift (++G) Codons 41/42, frameshift (–CTTT) IVS-1, position 1 (G → T)

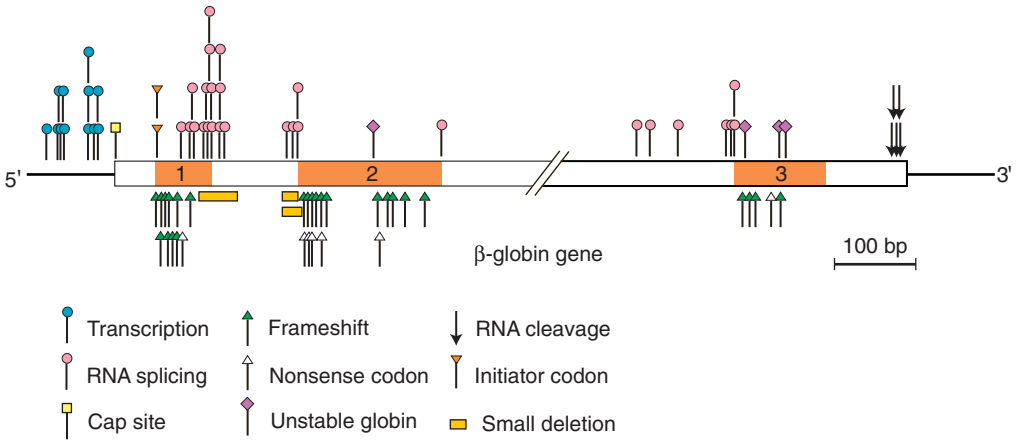

Figure 41–1 Model of the human β-globin gene showing sites and types of various mutations causing β-thalassemia. *(Adapted from Kazazian HH Jr: The thalassemia syndromes: Molecular basis and prenatal diagnosis in 1990. Semin Hematol 27:209, 1990.)*

Transcription

Several mutations alter the promoter region upstream of the β-globin mRNA-encoding sequence, impairing mRNA synthesis, whereas mutations that derange the sequence used as the signal for the addition of the poly-(A) tail of the mRNA (polyadenylation signal; see Chapter 33)[21] have been shown to result in abnormal cleavage and polyadenylation of the nascent mRNA precursor, with resulting reduced accumulation of mature mRNA.[19–21]

Processing

Many forms of β-thalassemia are caused by mutations that impair splicing of the mRNA precursor into mature mRNA in the nucleus or that prevent translation of the mRNA in the cytoplasm. The molecular pathology of splicing mutations is complex (see Fig. 41–1). Some base substitutions ablate the donor (GT) or acceptor (AG) dinucleotides (see Chapter 33), which are absolutely required at the intron–exon boundaries for normal splicing, and thereby completely block production of mature functional messenger RNA. Thus, no β-globin can be synthesized (β^0-thalassemia). Other mutations alter the consensus sequences that surround the GT- and AG-invariant dinucleotides and decrease the efficiency of normal splicing signals by 70% to 95%, resulting in β^+-thalassemia; some consensus mutations even abolish splicing completely, causing β^0-thalassemia. A third type of splicing aberration results from mutations that are not in the immediate vicinity of a normal splice site. These alter regions within the gene, called *cryptic splice sites*, which resemble consensus splicing sites but do not normally sustain splicing (Fig. 41–2). The mutations activate the site by supplying a critical GT or AG nucleotide or by creating a sufficiently strong consensus signal to stimulate splicing at that site 60% to 100% of the time. The activated cryptic sites generate an abnormally spliced, untranslatable mRNA species. Only 10% to 40% of the mRNA precursors are thus spliced at the normal sites, which causes β^+-thalassemia of variable severity. The mutation responsible for the most common form of β-thalassemia among Greeks and Cypriots (see Fig. 41–2) activates a cryptic splice site near the 3′ end of the first intron (position 110).[26,27] The determinants that dictate the degree to which each mutation alters splice site use remain largely unknown.

Translation

Mutations that abolish translation occur at several locations along the mature mRNA and are very common causes of β^0-thalassmia (see Fig. 41–1 and Table 41–1). The most common form of β^0-thalassemia in Sardinians results from a base substitution in the gene that changes the codon encoding the 39th amino acid of the β-globin chain from CAG, which encodes glutamine to TAG, whose equivalent (UAG)

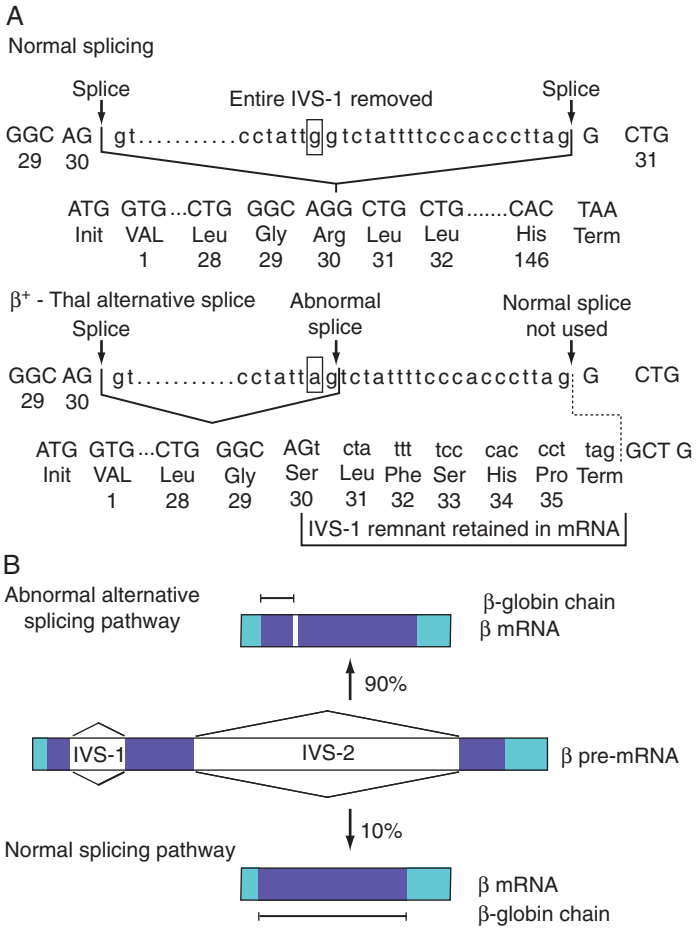

Figure 41–2 β^+-Thalassemia arising from alternative mRNA splicing due to a mutation activating a cryptic splicing site. **A**, The G→A mutation is shown enclosed in squares, located near the 3′ end of intron 1 (IVS-1); it creates a sequence motif closely mimicking a pre-mRNA acceptor splice site. The product of the alternative splicing event is also shown. Note that use of the activated cryptic site generates a mature mRNA that contains an in-frame termination codon and therefore does not encode a functional β-globin chain. *(From Benz EJ Jr: The hemoglobinopathies. In Kelly WN, DeVita VT [eds.]: Textbook of Internal Medicine. Philadelphia, JB Lippincott, 1988, p 1423.)* **B**, Diagram of the means by which use of the cryptic splice site 90% of the time results in only 10% of the mRNA precursor molecules to be spliced normally into translatable mature mRNA, thus causing β^+-thalassemia. *(Adapted from Bunn HF, Forget BG: Hemoglobin: Molecular, Genetic and Clinical Aspects. Philadelphia, WB Saunders, 1986.)*

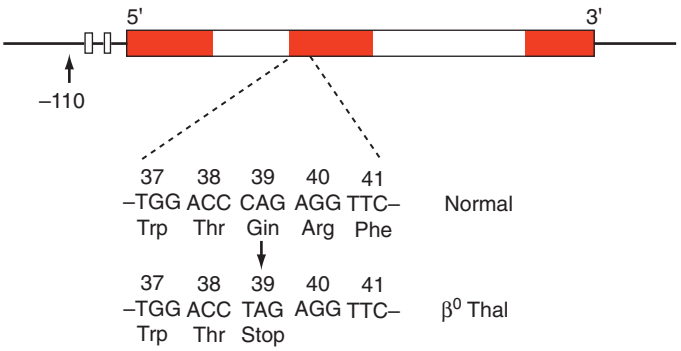

Figure 41–3 β⁰-Thalassemia arising from a mutation changing an amino acid codon to a termination codon (nonsense mutation). *(Adapted from Takeshita K, Forget BG, Scarpa A, Benz EJ Jr: Intranuclear defects in b-globin mRNA accumulation due to a premature translation termination codon. Blood 64:13, 1984.)*

in mRNA specifies termination of translation (Fig. 41–3).[28,29] A premature termination codon totally abrogates the ability of the mRNA to be translated into normal β-globin. Premature translation termination also results indirectly from frameshift mutations (ie, small insertions or deletions of a few bases, other than multiples of 3, that alter the phase or frame in which the nucleotide sequence is read during translation).[29] An in-phase premature termination codon is usually encountered within the next 50 bases downstream from a frameshift.

Other Sites

Rare mutations that affect gene function by intriguing mechanisms have been described. An extremely large deletion of the β-globin gene cluster has been described that removes the ε-, γ-, and δ-genes.[30] The patient has a severe β-thalassemia phenotype, but the β-globin gene and 500 bases of adjacent 5′ and 3′ DNA have an entirely normal nucleotide sequence. The β-gene functions normally in surrogate cells. The important aspect of this deletion is that it removes the critical locus control region[18,31] (see Chapter 33) located thousands of bases upstream from the beginning of the globin gene cluster at the 5′ end of the ε-globin gene; loss of this region severely impairs β-gene expression. A number of additional deletions involving the locus control region and various portions of the β-gene cluster, but sparing the β-gene itself, have the same phenotype.[1,2,19–21] In other cases of β-thalassemia, the β-gene and adjacent DNA are structurally normal, and the basis of abnormal gene expression is unknown.[22]

Relationship between Specific Mutations and Clinical Severity

The relationship between an individual mutation and the clinical severity of the β-thalassemia phenotype associated with that particular mutation is complex.[22] For example, the A to G mutation at position –34 of the β-gene promoter commonly encountered in black patients is associated with a different clinical severity than that found in Chinese patients inheriting the same mutation.[32] Clearly, the genetic "context" of the mutation is different in the two populations. The mutant β-globin gene in the two different racial groups probably arose in different chromosome backgrounds that have different potentials for γ-gene expression, as discussed in the following paragraph.

Multiple forms, or haplotypes, of normal non-α-globin gene clusters exist in various human populations. These are defined by the patterns of restriction fragment length polymorphisms[28] detected when DNA is digested with restriction endonucleases and analyzed by Southern gene blotting for the fragments bearing the non-α-globin genes. Haplotypes differ according to whether each restriction site is present or absent along the gene cluster. More than 12 haplotypes have been defined by examination of several restriction sites located along the cluster that are present or absent in a polymorphic manner in normal individuals.[28] The clinical variability encountered in two different groups bearing identical primary mutations correlates best with the haplotype or chromosome background on which the mutation is inherited. The differences in physiologically important functions among haplotypes that modulate severity remain unknown, but a possible explanation lies in the variable abilities of the γ-globin genes on different chromosomes to respond to severe erythroid stress by increased expression during postnatal life. The β-globin genes carried on some haplotypes differ in the degree to which they can respond in this manner.[33] Because Hb F synthesis reduces the severity of β-chain hemoglobinopathies,[1] the level of γ-gene expression from a given chromosome can play an important modulating role.

Pathophysiology

The biochemical hallmark of β-thalassemia is reduced biosynthesis of the β-globin subunit of Hb A ($\alpha_2\beta_2$). In β-thalassemia heterozygotes, β-globin synthesis is about half-normal (β/α synthetic ratio 0.5–0.7). In homozygotes for β⁰-thalassemia, who account for approximately one-third of patients, β-globin synthesis is absent. β-Globin synthesis is reduced to 5% to 30% of normal levels in β⁺-thalassemia homozygotes or β⁺/β⁰-thalassemia compound heterozygotes, who together account for approximately two-thirds of cases.[1]

Because the synthesis of Hb A ($\alpha_2\beta_2$) is markedly reduced or absent, the red blood cells are hypochromic and microcytic. γ-Chain synthesis is partially reactivated, so that the hemoglobin of the patient contains a relatively large proportion of Hb F.[1] However, these γ-chains are quantitatively insufficient to replace β-chain production.

In heterozygotes (β-thalassemia trait), relatively little α-globin accumulation occurs. Output from the single normal β-globin gene supports substantial Hb A formation, thus preventing harmful accumulation of excess α-globin chains. Thus, one encounters hypochromia with microcytosis but relatively little evidence of anemia, hemolysis, or ineffective erythropoiesis.

Individuals inheriting two β-thalassemic alleles experience a more profound deficit of β-chain production. Little or no Hb A is produced; more importantly, the imbalance of α- and β-globin production is far more severe (Fig. 41–4). The limited capacity of red blood cells to proteolyze the excess α-globin chains, a capacity that probably exerts a protective effect in heterozygous β-thalassemia, is overwhelmed in homozygotes. Free α-globin accumulates, and unpaired α-chains aggregate and precipitate to form inclusion bodies, which cause oxidative membrane damage within the red blood cell[34] and destruction of immature developing erythroblasts within the bone marrow (ineffective erythropoiesis).[35] Consequently, relatively few of the erythroid precursors undergoing erythroid maturation in the bone marrow survive long enough to be released into the bloodstream as erythrocytes. The occasional erythrocytes that are formed during erythropoiesis bear a burden of inclusion bodies. The reticuloendothelial cells in the spleen, liver, and bone marrow remove these abnormal cells prematurely, producing a hemolytic anemia.

Defective β-globin synthesis exerts at least three distinct yet interrelated effects on the generation of oxygen-carrying capacity for the peripheral blood (see Fig. 41–4): (a) ineffective erythropoiesis, which impairs production of new red blood cells; (b) hemolytic anemia, which shortens the survival of the few red blood cells produced; and (c) hypochromia with microcytosis, which reduces the oxygen-carrying capacity of those few red blood cells that do survive. In the most severe forms of the disorder, these three factors conspire to produce a catastrophic anemia, complicated by the effects of exuberant hemolysis.

The profound deficit in the oxygen-carrying capacity of the blood stimulates production of high levels of erythropoietin in an attempt to promote compensatory erythroid hyperplasia. Unfortunately, the

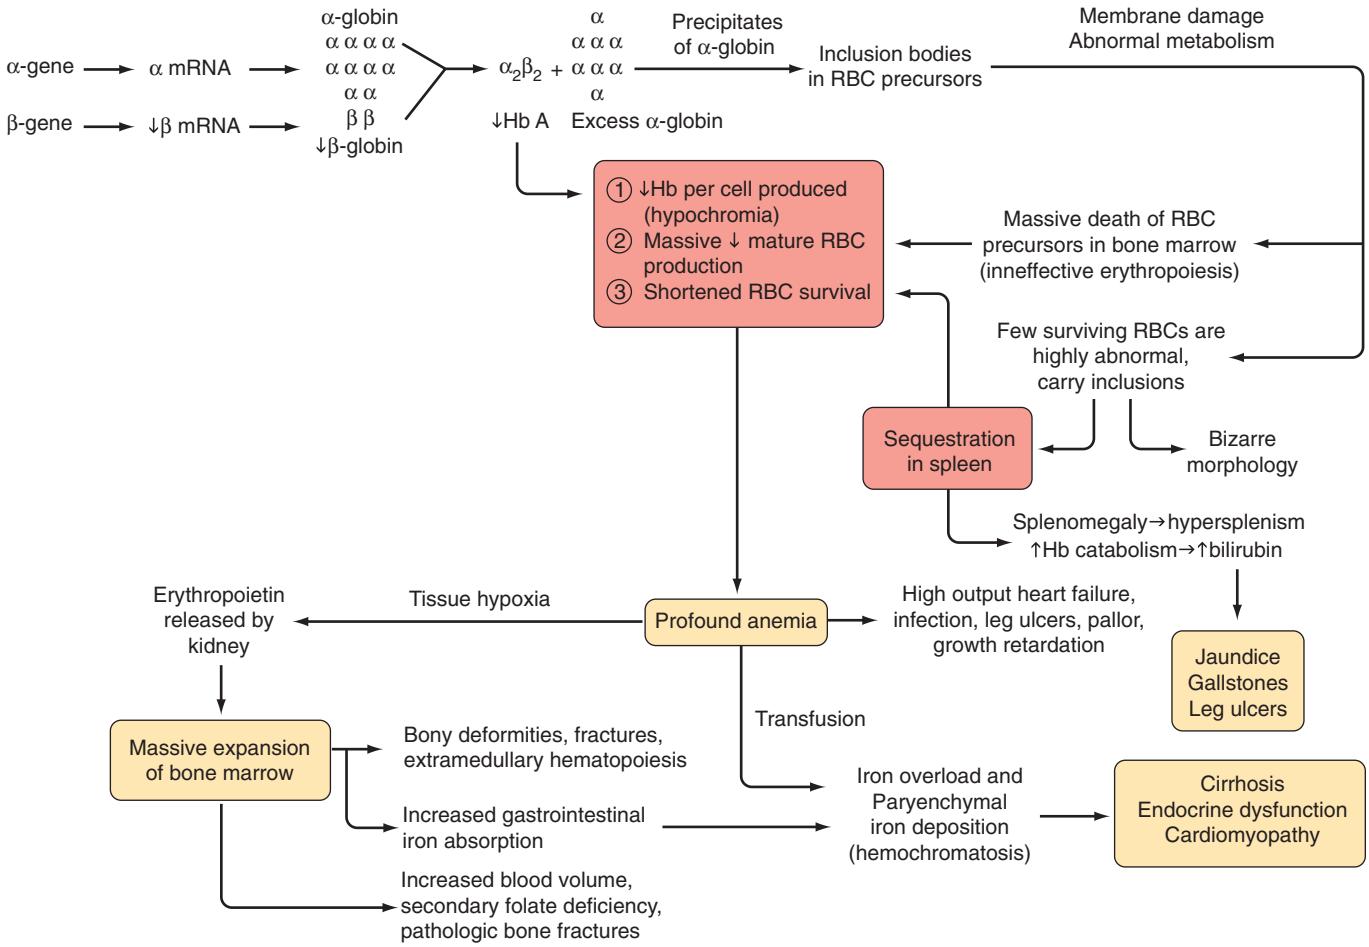

Figure 41–4 Pathophysiology of severe forms of β-thalassemia. The diagram outlines the pathogenesis of clinical abnormalities resulting from the primary defect in β-globin chain synthesis. RBCs, red blood cells.

ability of the marrow to respond positively is markedly impaired by ineffective erythropoiesis. Massive bone marrow expansion does occur, but very few erythrocytes are actually supplied to the circulation. The marrow becomes packed with immature erythroid precursors, which die from their burden of precipitated α-globin chains before they reach the reticulocyte stage. Profound anemia persists, driving erythroid hyperplasia to still higher levels. In some cases, erythropoiesis is so exuberant that masses of extramedullary erythropoietic tissue form in the chest, abdomen, or pelvis.

As described in the following section, massive bone marrow expansion exerts numerous adverse effects on the growth, development, and function of critical organ systems and creates the characteristic facies caused by maxillary marrow hyperplasia and frontal bossing (Fig. 41–5). Hemolytic anemia results in massive splenomegaly and high-output congestive heart failure. In untreated cases, death occurs during the first two decades of life. Treatment with red blood cell transfusions sufficient to maintain hemoglobin levels above 9.0 to 10.0 g/dL improves oxygen delivery, suppresses the excessive ineffective erythropoiesis, and prolongs life. Unfortunately, as discussed in more detail later, complications of chronic transfusion therapy, including iron overload, usually proved to be fatal before 30 years of age. The addition of iron chelation therapy to regular transfusion therapy now prolongs survival and improves the quality of life.

Clinical Manifestations

Clinical Findings at Diagnosis

Protected by prenatal Hb F production, the infant with β-thalassemia major is born free of significant anemia. Nevertheless, deficient β-

chain synthesis can be demonstrated at birth. Clinical manifestations usually emerge during the second 6 months of life as the consequences of defective β-globin synthesis on overall hemoglobin production become more pronounced. The diagnosis is almost always evident by 2 years of age.[36] Pallor, irritability, growth retardation, abdominal swelling due to enlargement of the liver and spleen, and jaundice are the usual presenting features.[37] Facial and skeletal changes caused by bone marrow expansion develop later.

Clinical Findings in Untreated or Undertreated Patients

Untreated patients die in late infancy or early childhood as a consequence of severe anemia. In a retrospective review from Italy, the average survival of children with untreated thalassemia major was less than 4 years; approximately 80% died in the first 5 years of life.[38] Patients who receive transfusions sporadically may live somewhat longer than untransfused patients, but their quality of life is extremely poor as a result of both the chronic anemia and the ineffective erythropoiesis. The low hemoglobin level and massive organomegaly are usually disabling, and the changes in the facial bones are disfiguring. After 10 to 20 years of weakness, stunted growth, and impaired activity, the undertransfused patients usually succumb to congestive heart failure.

This disastrous symptom constellation, so prevalent in the past, is now rare in North America and most industrialized countries. Nonetheless, the clinical manifestations and complications of untreated or undertreated β-thalassemia major illustrate the principles of the pathophysiology. Furthermore, these descriptions accurately characterize the disease that is still prevalent in many parts of the world.

Initial Laboratory Findings

The anemia of thalassemia major is characterized by severe hypochromia and microcytosis. The hemoglobin level decreases progressively during the first months of life. When the child becomes symptomatic, the hemoglobin level may be as low as 3 to 4 g/dL. Red blood cell morphology is strikingly abnormal, with many microcytes, bizarre poikilocytes, teardrop cells, and target cells (Fig. 41–6). A characteristic finding is the presence of extraordinarily hypochromic, often wrinkled and folded cells (leptocytes) containing irregular inclusion bodies of precipitated α-globin chains.

Nucleated red blood cells are frequently present. The reticulocyte count is 2% to 8% lower than would be expected in view of the extreme erythroid hyperplasia and hemolysis. The low count reflects the severity of intramedullary erythroblast destruction. The white blood cell count is elevated. A moderate polymorphonuclear leukocytosis and normal platelet count are typical unless hypersplenism has developed. The bone marrow exhibits marked hypercellularity caused by erythroid hyperplasia. The red blood cell precursors show defective hemoglobinization and reduced amounts of cytoplasm.

The osmotic fragility is strikingly abnormal. The red blood cells are so markedly resistant to hemolysis in hypotonic sodium chloride solution that some are not entirely hemolyzed even in distilled water. Before transfusion therapy is initiated, the serum iron and transferrin saturation are already increased as a result of increased iron absorption.[39]

The hemoglobin profile reveals predominantly Hb F. In patients with homozygous β^0-thalassemia, no Hb A is found throughout life. Hb A may be undetectable in the newborn with β^+-thalassemia and is present in reduced amounts in later life. The levels of Hb A_2 in thalassemia major are variable, probably because of increased numbers of F cells that have a decreased Hb A_2 content.[1] Other biochemical abnormalities of the red blood cell in cases of thalassemia major include a postnatal persistence of the i antigen and a decrease of red blood cell carbonic anhydrase; these findings are probably also caused by the elevated levels of circulating F cells.

The intraerythrocytic inclusions in the peripheral blood cells of patients with thalassemia, first described by Fessas,[40] are especially prominent after splenectomy. These inclusions, best seen by staining with methyl violet or by phase microscopy, are aggregates of precipitated, denatured α-chains.[41] They are also found in large numbers within erythroid precursors in the bone marrow.

The serum is icteric; unconjugated bilirubin levels are in the range of 2.0 to 4.0 mg/dL at the time of diagnosis but may rise substantially as the anemia worsens in the absence of transfusion. Red blood cell

Clinical Heterogeneity of Thalassemia

The severity of β-thalassemia is remarkable for its variability in different patients. Two siblings inheriting identical thalassemia mutations sometimes exhibit markedly different degrees of anemia and erythroid hyperplasia. Many factors contribute to this clinical heterogeneity. Individual alleles vary with respect to severity of the biosynthetic lesion. Other modifying factors ameliorate the burden of unpaired α-globin. High levels of Hb F expression persist to widely various degrees in β-thalassemia. As γ-globin can substitute for β-globin, simultaneously generating more functional hemoglobins and reducing the α-globin inclusion burden, this is a powerful modulating factor. Theoretically, patients may also vary in their ability to solubilize unpaired globin chains by proteolysis. Occasional heterozygous patients have had more severe anemia than expected, possibly because of defects in these proteolytic systems, or because of the type of thalassemic mutation. Inheritance of more than the usual complement of α-globin genes may also increase with severity of β-thalassemia because of additional production of unpaired α-globin chains. All these factors emphasize the essential role of α-globin inclusions in the pathophysiology of β-thalassemia.

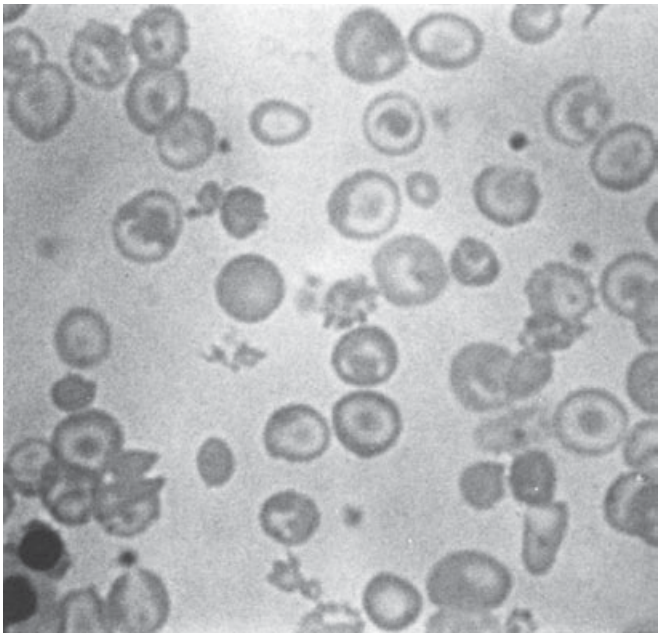

Figure 41–6 Morphologic appearance of the peripheral blood film in a case of severe β-thalassemia. Note the many bizarre cells, the hypochromia, nucleated red blood cells, target cells, and leptocytes. *(From Pearson HA, Benz EJ Jr: Thalassemia syndromes. In Miller DR, Baehner RL, McMillan CW [eds.]: Smith's Blood Diseases of Infancy and Childhood, 5th ed. St. Louis, CV Mosby, 1984, p 439.)*

survival in cases of thalassemia major is variable but usually markedly decreased. The ^{51}Cr half-life ranges between 6.5 and 19.5 days, compared with the normal half-life of 25 to 35 days.[35] Increased plasma iron turnover and poor use of radiolabeled iron indicate ineffective erythropoiesis.[35] Serum aspartate aminotransferase levels are frequently increased at diagnosis because of hemolysis. Alanine aminotransferase levels are usually normal prior to transfusion therapy but may rise subsequently because of iron-induced hepatic damage or viral hepatitis. Lactate dehydrogenase levels are markedly elevated as a consequence of ineffective erythropoiesis. Haptoglobin and hemopexin are reduced or absent.[42]

Later Laboratory Findings

Serum zinc levels may fall to abnormally low levels. A relationship between this finding and growth failure has been postulated but not established.[43,44] Low levels of plasma and leukocyte ascorbic acid are common in thalassemic patients because of increased metabolism of the vitamin to oxalic acid in the presence of iron overload.[45,46] Biochemical evidence of folic acid deficiency may occur as a result of excessive consumption secondary to increased requirements.[47,48] The serum levels of α-tocopherol are often reduced to less than 0.5 mg/dL, and increased red blood cell membrane lipid peroxidation has been described.[49–51]

Coagulation abnormalities consistent with liver disease (ie, lowered levels of factors II, V, VII, IX, and X) may occur in older patients with hepatitis or iron-induced hepatic injury.[52] Only rarely are the abnormalities sufficient to require specific therapy. However, the combination of mild thrombocytopenia due to hypersplenism and low coagulation factors and platelet dysfunction due to liver disease may cause or aggravate bleeding.[53]

Numerous laboratory abnormalities reflect the accumulation of excessive iron and the consequences of iron-induced organ damage, and they are described in the following sections.

Treatment

The advent of modern therapy has had a major impact on the clinical and laboratory features of thalassemia major. Transfusion and chelation therapy, described subsequently in detail, have ameliorated many of the most striking manifestations of the disease. Bone marrow transplantation has allowed for the cure of a select few. However, these therapies have created their own complications, and therefore this section addresses the treatment of the complications of thalassemia and its therapy. Current clinical management and associated clinical manifestations and complications have been reviewed in a number of publications.[54–59]

Transfusion Therapy

Transfusion therapy for thalassemia was once used sparingly administered as a palliative measure when patients became symptomatic. These periodic transfusion regimens were unsatisfactory even for those limited purposes, symptoms of anemia and the cosmetic and other consequences of overgrowth of erythropoietic tissue rendered life unpleasant and uncomfortable for patients. Consequently, several centers initiated transfusion programs in which patients received regular transfusions to keep their hemoglobin levels high enough to ameliorate these symptoms[60,61] but the median survival of patients transfused to maintain hemoglobin levels of 7 to 8 g/dL in the USA in the 1960s was only 17 years of age.[61,62] These "hypertransfusion" programs were designed initially to maintain hemoglobin levels above 8 g/dL. In the more modern application of hypertransfusion therapy, hemoglobin levels are usually maintained above 9 to 10.5 g/dL.

The clinical benefits of hypertransfusion programs are dramatic. The growth of younger children follows normal percentiles for height and weight.[63] Erythropoiesis is partially but substantially suppressed, as evidenced by decreased numbers of reticulocytes and normoblasts, and transferrin receptor levels.[64,65] Hypertransfusion reduces or prevents the enlargement of the liver and spleen. Abnormal facies and bone fractures occur less frequently. The overall sense of well-being allows normal age-appropriate activities.[66,67]

A more vigorous transfusion program (supertransfusion) aimed at keeping hemoglobin levels above 12.0 g/dL has been recommended.[68] This approach rests on the assumption that the benefits of further suppression of erythropoiesis and gastrointestinal iron absorption will offset the increased need for red blood cells. However, several, though not all, studies have demonstrated that transfusion requirements (and therefore the rates of transfusional iron loading) increase as the hemoglobin level is raised (Fig. 41–7).[63,69,70] As a result, the consistent maintenance of hemoglobin levels above 11 or 12 g/dL is generally reserved for patients with poor tolerance of lower hemoglobin levels due to cardiac disease or other reasons.

Alternative approaches to conventional transfusion therapy have been proposed in an effort to reduce the rate of transfusion iron loading. These approaches have generally relied on the concept that younger red blood cells (neocytes) will circulate longer in the recipient than older red blood cells. Preclinical experiments based on the difference in density between younger and older red blood cells established the validity of this approach.[71,72] However, in prospective

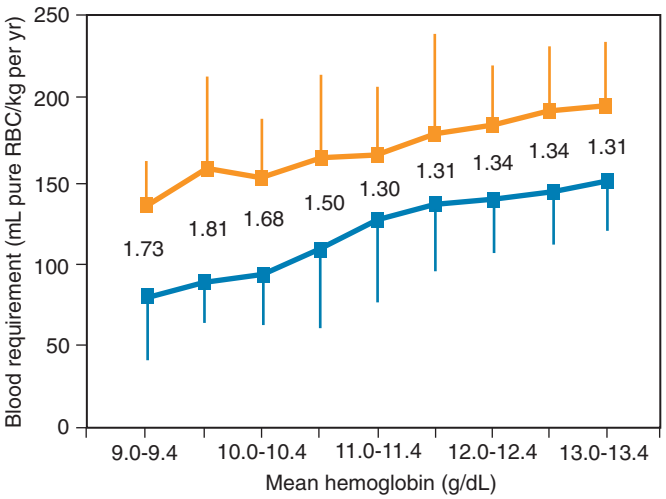

Figure 41–7 Relationship between transfusion requirements and mean hemoglobin level maintained by patients with thalassemia major. *(Adapted from Rebulla P, Modell B: Transfusion requirements and effects in patients with thalassaemia major. Lancet 337:277, 1991.)*

Guidelines for Transfusion Therapy

Although some of the details of a transfusion program for patients with thalassemia major vary from center to center, the following guidelines are important for achieving the benefits while controlling the risks of a transfusion program. The rationales for these guidelines are discussed in the text.

1. Obtain a complete red blood cell antigen profile before the first transfusion.
2. Administer 10 to 15 mL/kg of red blood cells every 2 to 4 weeks to maintain the pretransfusion hemoglobin level above 9 to 10.5 g/dL.
3. Use leukoreduced washed red blood cells that have been stored for less than 7 to 10 days.
4. Avoid the use of first-degree relatives as blood donors.
5. For patients who come to a new center after receiving transfusions elsewhere, contact the previous blood bank for information about alloantibodies.

clinical trials, blood requirements were reduced only by 13% to 20%.[73–75] This reduction in iron loading did not outweigh the disadvantages of neocyte transfusions that included increased cost, wastage of 50% of the donor red blood cells, and increased donor exposures. The use of automated exchange transfusion has been proposed as another approach to reducing iron loading in patients with thalassemia.[76] With this method, red blood cells are removed from the patient at the same time that new donor red blood cells are transfused. This approach has been applied successfully to transfusion therapy for sickle cell disease. However, the goal of transfusion therapy in sickle cell disease is the replacement of Hb S-containing red blood cells with Hb A-containing red blood cells, irrespective of the total hemoglobin level. In contrast, the goal of transfusion therapy in patients with thalassemia is to maintain a specific total hemoglobin level. Despite these different goals, studies of automated exchange transfusion in patients with thalassemia have demonstrated a reduction in net red blood cell requirements of 30% to 50%, either by reducing the amount of blood administered at the usual transfusion interval or by prolonging the interval between transfusions.[76,77] The benefits of this approach are probably due to the removal of previously transfused red blood cells from the patients and replacement with younger, recently donated red blood cells, reducing the overall age of the circulating red blood cell population. Further clinical trials of automated exchange transfusion in thalassemia are currently underway.

The decision to initiate transfusion therapy should take into account the overall clinical condition of the patient as well as the hemoglobin level. Patients with severe and persistent anemia (hemoglobin level of less than 6–7 g/dL) will usually also have failure to thrive, decreased activity level, and irritability. For these patients, transfusion therapy should begin after confirmation of the diagnosis of thalassemia and after demonstration that acute factors such as a febrile illness or folic acid deficiency are not confounding the assessment of the severity of anemia. For patients with higher hemoglobin levels, the decision to begin transfusion depends on the careful assessment of the child's clinical findings. For example, some children with thalassemia will have early and pronounced facial bone deformities caused by bone marrow expansion despite a hemoglobin level of 8 g/dL or higher. For such children, the benefits of transfusion therapy may outweigh the risks. In contrast, some patients with thalassemia have little or no clinical difficulty despite a persistent hemoglobin level of 7 to 8 g/dL, and the benefits of transfusion therapy may be small. Determination of genotype may provide some guidance by distinguishing patients with more severe defects in β-globin production from those with less severe defects, but the overlap between genotype and phenotype in thalassemia still requires reliance on clinical assessment.

Deciding to Begin Transfusion Therapy in Patients with Thalassemia

The decision to initiate regular red blood cell transfusions is one of the most important—and sometimes most difficult—steps in the management of thalassemia. Regular red blood cell transfusions not only distinguish thalassemia major from thalassemia intermedia but also commit the patient to long-term chelation therapy to control the transfusional iron loading. The decision should include consideration of both clinical and laboratory findings. Children who are growing poorly and developing disfiguring bone changes will benefit from regular transfusions even if their hemoglobin levels are 8 to 9 g/dL. On the other hand, children who are asymptomatic at hemoglobin levels of 7 to 8 g/dL may have little to gain from transfusions. Hemoglobin levels below 7 g/dL are usually associated with problems related to both the anemia and the compensatory erythropoiesis. When the hemoglobin level is consistently less than 7 g/dL, there is usually little to be gained from delaying transfusion.

Before the first blood transfusion is given to a child with thalassemia major, a complete red blood cell antigen profile should be obtained. This information is valuable for identifying minor blood group incompatibility if alloimmunization develops later and also helps to distinguish alloantibodies from autoantibodies. The value of extended matching of donor red blood cells has not been established in cases of thalassemia, but experience with sickle cell disease suggests that matching for the full Rh system as well as the Kell antigen may reduce the rate of alloimmunization.

In practice, the goal of maintaining the hemoglobin level above 9 to 10.5 g/dL is usually achieved by administration of approximately 15 mL/kg/month or 1 to 2 units of donor red blood cells every 2 to 5 weeks. Patients with heart disease may need smaller aliquots of red blood cells at more frequent intervals to prevent problems related to volume overload. In general, patients can receive whole units of donor red blood cells. However, fractional units may be appropriate for small patients and for older patients with heart disease. At present, the blood product of choice for patients with thalassemia is filtered red blood cells. Although some centers use filtered washed red cell transfusions, others reserve washed red blood cells to prevent febrile reactions despite filtration of the blood product. Frozen-thawed red blood cells are primarily useful for patients with multiple antibodies who require donor red blood cells with rare phenotypes that must be collected and stored well in advance of the actual transfusion.

With the use of current additive solutions, the duration of storage of donor red blood cells has only a small effect on the 24-hour recovery and the survival of the red blood cells in each transfused unit. However, for patients with thalassemia major who undergo transfusion every 2 to 5 weeks, these small differences may have a significant impact on the annual consumption of blood. Consequently, the use of donor red blood cells that have been stored for less than 7 to 10 days strikes a reasonable balance between the potential reduction in transfusion iron loading and the efficient use of the blood bank inventory. The use of volunteer blood donors remains the standard for patients with thalassemia. Although some families of children with thalassemia prefer directed donations, this approach has not reduced the rate of transfusion-transmitted infections among blood recipients in general and has not been shown to reduce the rate of alloimmunization in thalassemia. If directed donations are used, close relatives should be avoided, because stem cell transplantation may be a later therapeutic option.

Other complications of transfusion therapy include those that are annoying as well as those that can be life threatening. Febrile reactions occur less commonly than in the past as a result of the use of leukoreduced donor red blood cells. If such reactions occur despite the use of filtered blood products, additional measures include pretransfusion therapy with acetaminophen and the use of washed or frozen-thawed red blood cells. Urticarial and other allergic reactions can usually be managed with antihistamine therapy or, when persistent, pretransfusion administration of corticosteroids.

Red blood cell alloimmunization occurs in 3% to 23% of patients with thalassemia major.[70,78–80] If blood donors and recipients come from different ethnic backgrounds with different red blood cell antigen profiles, as in some North American thalassemia centers, the risk of alloimmunization is increased.[81] New alloantibodies may be clinically silent, associated with increasing transfusion requirements, or accompanied by signs of active hemolysis such as increasing jaundice and dark urine. As noted earlier, the use of extended antigen matching may help prevent alloimmunization. Initiation of transfusion therapy before the age of 3 years may also be associated with a lower risk of this complication.[70,80,82] Patients with a history of alloantibodies require particular attention when receiving a transfusion at a new hospital because the serologic studies may fail to detect a clinically significant antibody that is present in low amounts. A review of the blood bank records from the previous institutions is essential in choosing the appropriate red blood cell product.

Autoantibodies also occur in patients with thalassemia major, usually, but not always, after the development of an alloantibody.[83] A subset of patients with autoantibodies has a clinically important autoimmune hemolytic anemia that leads to the premature destruc-

tion of donor cells as well as destruction of the patient's own red blood cells. Transfusion requirements are markedly increased, and further transfusion therapy may be impossible for some patients. Treatment with corticosteroids, other immunosuppressive therapy, or intravenous gamma globulin may improve red blood cell survival in some cases.

A syndrome of posttransfusion hypertension, convulsions, and cerebral hemorrhage has also been reported.[84] The mechanism underlying this complication is uncertain but is possibly related to large changes in hemoglobin level at the time of transfusion. These reactions are uncommon in conventional transfusion programs.

The potential impact of transfusion-transmitted infections on patients with thalassemia major is demonstrated by the high prevalence of human immunodeficiency virus infection in certain thalassemia centers during the 1980s and the nearly universal problem with hepatitis C infection in patients who began transfusion therapy before the 1990s. A 1987 study found that 17% of patients with thalassemia major in one center in New York City were positive for human immunodeficiency virus antibody.[85] The prevalence of hepatitis C infection among patients with thalassemia major is 12% to 91%, with a higher rate among older patients.[86,87] Improvements in donor screening and testing have markedly reduced the risk of transmission by transfusion of known viruses,[88] but patients with thalassemia, because of the frequency of their transfusions, remain at risk not only for viruses that are transmitted infrequently but also for new agents such as Hepatitis A, Babesiosis, and West Nile virus.[89] Hepatitis B vaccine, if not administered as part of the routine childhood immunization program, should be given to patients with thalassemia before transfusion therapy begins.[90] Hepatitis A vaccine should also be administered when age appropriate. The cytomegalovirus status of patients who are potential candidates for stem cell transplantation should be ascertained prior to transfusion and every attempt should be made to provide them with cytomegalovirus-negative blood products. Current studies of pathogen-inactivated red blood cell products hold forth the promise of a means for preventing transfusion-transmitted infections even when the donor's infection escapes detection or when new agents enter the blood supply.[91,92]

Progressive iron overload is the life-threatening complication of transfusion therapy that accounts for the most important long-term morbidity and mortality in patients with thalassemia major.

Chelation Therapy

The clinical effects of iron overload in patients with thalassemia major depend on the amount and the duration of excessive iron accumulation. Transfusion hemosiderosis is the major cause of late morbidity and mortality in patients with thalassemia major. Establishment of therapeutic strategies to achieve iron balance should lead to improved survival. Various strategies to reduce the rate of transfusion iron loading have included modifying the pretransfusion hemoglobin level, adjusting the intervals between transfusions and splenectomy as well as with methods to enhance the rate of iron removal through chelation therapy. Historically efforts were focused on identifying methods to enhance parenteral iron chelation, by adjusting the frequency of daily use, the hours of administration and the route of parenteral administration. These have optimized the use of iron chelation with deferoxamine (Desferal). More recently, efforts are focused on addressing the safety and efficacy of new oral iron chelators, deferasrox (Exjade) and deferiprone (L1), and new ways to assess iron excess.

Each unit of packed red blood cells contains approximately 200 to 250 mg of iron. Based on usual blood requirements in patients with thalassemia major, the rate of transfusional iron accumulation is approximately 0.30 to 0.60 mg/kg/day. The massive ineffective erythropoiesis associated with the intermedia and major thalassemias leads to excessive gastrointestinal iron absorption that adds to the transfusional iron burden, although absorption is reduced when a hemoglobin level above 9 g/dL is maintained.[93,94] Humans have no physiologic mechanism to induce significant excretion of excess iron.

Benefits of Iron Chelation Therapy

More than 30 years of experience using iron chelation therapy with deferoxamine in thalassemia major patients have demonstrated that

1. Liver iron concentrations can be maintained at normal or mildly elevated levels.
2. Hepatic fibrosis is slowed or prevented.
3. The risk of iron-induced cardiac disease, including heart failure and serious arrhythmias, is markedly decreased.
4. Normal growth and sexual development are common although not universal.
5. Long-term survival is substantially improved.

These benefits are directly related to compliance and generally require the prolonged administration of deferoxamine at least five times per week.

6. Long-term safety and efficacy studies of oral iron chelators, deferiprone and deferasirox, are on-going.

Phlebotomy, the most efficient method of removing iron in other situations, is precluded in severely anemic patients with thalassemia owing to transfusion dependence. Phlebotomy may be only applicable in a very few select patients with thalassemia intermedia, and constitutes an important part of the management of patients with thalassemia major who have successfully undergone stem cell transplantation.

A pharmacologic approach using specific iron-chelating agents remains the only strategy for removing excess iron in transfusion-dependent patients.

Several drugs with chelating properties have been synthesized or recovered from microorganisms. Many lack iron specificity or are inefficient; others cause significant toxicity. To chelate iron, the chelating agent must complex with all of the iron atom's six available coordination sites. Three general classes of iron chelators occur or have been synthesized: hexadentate (deferoxamine), bidentate (deferiprone), and tridentate (deferasirox). Only one hexadentate molecule is necessary to bind one atom of iron whereas three molecules of a bidentate iron chelator bind one iron atom and two molecules of a tridentate chelator are required to bind one atom of iron.

Chelatable iron is thought to be derived from the intracellular "labile iron pool"[95,96] and from non-transferrin-bound plasma iron.[97,98]

Deferoxamine

Deferoxamine mesylate (Desferal, DFO) is a naturally occurring hexadentate siderophore isolated from cultures of *Streptomyces pilosus* introduced in 1960. Deferoxamine has a high molecular weight of approximately 600, is poorly absorbed by the gastrointestinal tract, and is rapidly removed from the plasma. It has a relatively short half-life of 8 to 10 minutes, which necessitates intravenous or subcutaneous parenteral administration. It is a hexadentate iron chelator that binds iron in a 1-to-1 complex. It is highly specific for iron and is associated with relatively low toxicity.[99] Deferoxamine enters cells, chelates iron and appears in the serum and bile as the iron chelate product, ferroxamine.[100] Deferoxamine chelates iron released by the reticuloendothelial systems following the catabolism of senescent red blood cells and is excreted in the urine.[101] Unbound deferoxamine is absorbed by the hepatic parenchymal cells and chelates iron from the intracellular pool which is excreted in bile. Approximately one-half to two-thirds of the iron excreted in response to deferoxamine is in the stool, with the remainder in the urine.[102] These proportions vary from patient to patient and at different levels of iron overload, dose of deferoxamine, and endogenous erythropoietic activity.[103]

Iron excretion after the administration of deferoxamine is proportional to body iron stores. To achieve negative iron balance, the chelating agent must cause the daily excretion of 0.3 to 0.6 mg/kg of iron. In the 1960s, deferoxamine was initially administered by daily intramuscular injections of 0.5 g, which led to reduced rates of hepatic iron accumulation and hepatic fibrosis in patients with thalassemia.[104,105] However, intramuscular injections proved to be too painful and were insufficient to achieve negative iron balance. In the mid 1970s it was demonstrated that iron excretion with deferoxamine was markedly enhanced and negative iron balance was attained by continuous, prolonged 24-hour intravenous or 8- to 12-hour subcutaneous infusions administered via a lightweight battery-operated or balloon-driven pump.[106,107] In addition, maintaining normal ascorbic acid levels optimizes iron excretion because it increases tissue iron turnover in the plasma.

Continuous, slow deferoxamine infusions allows for a longer exposure of the drug to the relatively small nontransferrin iron or labile iron pool that is in equilibrium with a nearly nonchelatable iron pool.[108]

A pump infuses an aqueous solution of DFO through a small 27-gauge butterfly needle placed under the skin of the abdomen, thigh, or extremities. Most patients use the pump during sleep.[109] Bolus subcutaneous injections of deferoxamine used twice daily induce levels of urinary iron excretion comparable with subcutaneous infusions and may prove helpful as a respite from overnight infusions in some patients not adherent to prolonged infusions.[110,111] In patients who are poorly compliant with subcutaneous therapy, administration of DFO in normal or higher doses can be accomplished intravenously by means of a deep line indwelling catheter, an externalized venous catheter or a subcutaneous port. Continuous intravenous administration of DFO is particularly useful for rapidly lowering the total iron burden and is used for reversal of cardiac morbidity, for example, cardiac arrhythmias or left-ventricular dysfunction. Complications of indwelling catheters including infection and thrombosis rates have been reported at 1.2 and 0.5 per 1000 catheter days respectively in patients treated over 1 to 5 years.

Prolonged infusions of deferoxamine achieve negative iron balance in most transfusion-dependent patients older than 4 or 5 years of age.[62,112–116] This approach to chelation therapy involves daily 8- to 12-hour subcutaneous infusions of 20 to 60 mg/kg of deferoxamine that should result in 20 to 50 mg/day of iron loss in the urine and stool.[62]

The optimal age for beginning parenteral or oral iron chelation therapy in patients with thalassemia has not been established with certainty. The surprisingly high liver iron concentrations that have been found in some patients with thalassemia within the first 2 to 3 years of transfusion therapy, occasionally accompanied by histologic finding of fibrosis, provided the rationale for the early initiation of deferoxamine iron chelation.[117,118] On the other hand, iron excretion in response to deferoxamine is relatively low during the first few years of iron accumulation and the pharmacokinetics and clearance of iron chelators in children is being further evaluated. Regular deferoxamine chelation therapy begun after the age of 3 to 5 years seems capable of removing previously stored iron and preventing iron-induced liver disease.[62] Data show that deferoxamine started by the age of 3 or 4 forestalls significant iron overload. However, it also promotes elimination of excess iron in patients if started after significant transfusional iron burden has already developed.[119–129] Moreover, deferoxamine may adversely affect bone development and growth in some young patients and the effect newer oral chelators on growth has yet to be addressed.[130–132] Some investigators have recommended the annual assessment of liver iron concentration as a guide for determining the appropriate time to begin iron chelation therapy[118] or a test infusion of DFO to determine if mobilizable iron is present.[133] Others have based this decision on the number of transfusions administered to the patient, that is, approximately 20 to 25 units of blood. Still others wait until the patient is 3 to 5 years old, when significant iron excretion can be accomplished and patient cooperation is better.[62,132]

Assessment of Iron Stores

Because excess transfusional iron cannot be actively excreted it is deposited in the macrophages of the reticuloendothelial system (RES). When the RES is overwhelmed, iron spills over into parenchymal tissue, generating free radical damage with cellular membrane lipid peroxidation and leading to end organ dysfunction, especially of the liver, endocrine system, and myocardium.

The best strategy for monitoring iron accumulation in patients with thalassemia remains controversial. Before chelation therapy is begun, careful recording of transfusion volumes provides an accurate assessment of iron loading. Each milliliter of red blood cells contains approximately 1.1 mg of iron. Therefore, each unit of blood contains approximately 200 mg of iron. The total transfusional iron intake can be calculated from the transfusion record and should be as useful in determining the need to begin chelation therapy as indirect or direct measures of body iron stores, if not more useful. Chelation therapy is initiated after approximately 20 to 25 units of blood have been transfused. However, once chelation therapy has been initiated, iron is going out as well as coming in. Under these circumstances, regular assessment of iron stores is needed to determine the severity of iron overload and to achieve an optimal treatment program.

Measurement of liver iron concentration by biopsy provides a direct assessment of tissue iron loading and reflects total body iron stores. Recent experiences with hepatic resonance imaging suggests that changes in R2 reflects liver iron concentration comparable to that on liver biopsy. Levels between 3 and 7 mg/g dry weight appear to be associated with minimal toxicity. Levels greater than 15 mg/g dry weight are associated with an increased risk of heart disease. Liver biopsy requires a skilled technician, at least 1 mg of tissue at least 2.5 cm in length with 5 portal tracts and has the risk of hemorrhage.

Serum ferritin levels are safe, inexpensive, and readily available and serial measurements are predictive both of critical complications such as iron-induced heart disease and of adverse effects of chelation therapy such as impairment of vision and hearing. However, single ferritin levels may correlate poorly with liver iron concentration, because it is an acute phase reactant, and may be influenced by inflammation, vitamin C deficiency, hepatitis, and other infectious states. Transferrin saturation is not very useful in evaluating the severity of iron overload in patients with thalassemia because the massive ineffective erythropoiesis usually results in a transferrin saturation greater than 60% even in the absence of iron overload.[515]

Noninvasive hepatic magnetic resonance imaging of liver iron by R2 changes correlates with liver iron concentration by biopsy but cannot be used in patients with pacemakers or those who are claustrophobic.

Recent experience with cardiac magnetic resonance imaging suggests that changes in T2* reflect levels of iron in the heart and may predict adverse changes in cardiac function.

Unfortunately, no measure of iron stores has been thoroughly and prospectively studied in patients with thalassemia major or intermedia to establish levels predictive of iron-related complications. Most guidelines are based on retrospective analyses, experience with other diseases, or limited outcome data.

The most common side effect of subcutaneous deferoxamine therapy is inflammation and induration at the site of infusion. Painful lumps may occur despite rotation of infusion sites, appropriate dilution of the drug, and proper placement of the needle. Some investigators have recommended the addition of small amounts of hydrocortisone to the infusion to prevent local reactions. Patients receiving aggressive chelation therapy with lower iron burdens may be more susceptible to toxicity. Neurosensory toxicity of DFO is dose related and inversely correlated with body iron burden. Impairments

of visual and auditory acuity are associated with high doses of deferoxamine relative to the iron load.[134] The ototoxicity is characterized by bilateral high-frequency hearing loss. The retinal toxicity is characterized by the loss of night and color vision, retinal atrophy, and cataract formation.[135] Patients receiving deferoxamine should undergo baseline and annual audiograms and ophthalmologic examinations. Deferoxamine should be discontinued if such abnormalities arise, with cautious reinitiation at lower doses when abnormalities improve or resolve. The risk of visual and auditory side effects can be minimized by adjusting the daily deferoxamine dose to the patients' serum ferritin level.[134] Impaired growth associated with growth plate deformities or metaphyseal rickets-like changes in the long bones and histologic evidence of cartilage dysplasia may occur in young children receiving deferoxamine.[130–132] Regular monitoring with plain radiographs of the extremities and vertebral column allows early detection of this complication and reduction in the dose of deferoxamine or temporary interruption of chelation therapy.

Other, less common complications of deferoxamine include anaphylaxis, hypotension, allergic reactions, acute pulmonary disease, impairment of renal function, and infection.[136–142] Severe allergic reactions are rare and desensitization has been achieved successfully in some patients.[138,139] Acute pulmonary disease and renal failure have occurred in a few patients receiving unusually high doses of deferoxamine by intravenous infusion.[140] The mechanism of this toxicity is unclear. One of the most serious complications of deferoxamine is an increased risk of infection with *Yersinia* and mucomycosis, which uses the deferoxamine iron chelate as a siderophore, whereby enhancing their growth and presenting as colitis, abdominal abscess, or sepsis.[141,142] The safety of deferoxamine during pregnancy has been inferred from case reports rather than formal studies. A summary of these case reports identified 11 women who received deferoxamine beginning in the first trimester and 33 women who used the chelator beginning in the second or third trimester.[142] None of the infants showed evidence of drug-related toxicity.[143]

Regular chelation with deferoxamine has proven remarkably effective in reducing the transfusional iron burden of thalassemia patients. There is increasing evidence that endocrine dysfunction is improved and cardiac disease is delayed or prevented with standard deferoxamine regimens.[144] Cardiac arrhythmias and congestive heart failure have reversed in some patients with standard or aggressive deferoxamine regimens and life expectancy is significantly prolonged.* Intense 24-hour intravenous deferoxamine regimens of more than 15 mg/kg/hour have been reported to reverse early cardiac hemosiderosis whereas even more conventional doses of 50 mg/kg/day have improved left ventricular ejection fractions and prevented death in some patients.[148,149]

Prior to subcutaneous DFO therapy, estimated survival was approximately 16 to 17 years of age, with rare patients surviving into their mid-20s.[62,146,150,151] Since regular subcutaneous deferoxamine regimens have been in use, life expectancy has extended into the fourth decade.[152–154] The increasing widespread use of deferoxamine has steadily increased survival probabilities worldwide.[153,154] However, long-term European studies have demonstrated that improved survivals are clearly related to the degree of compliance with chelation regimens and are associated with lower serum ferritin levels (<1000 mg/mL).[155] Deferoxamine chelation regimens are clearly cumbersome, inconvenient, and costly. More tolerable approaches are required and investigations for alternative oral iron-chelating agents have been ongoing and recently more successful.

Although the prevalence of endocrine disturbances, for example, glucose intolerance and diabetes have reduced since the regular use of subcutaneous deferoxamine,[55,58,144] they persist especially in those who initiated deferoxamine late in their first decade.[124] Growth hormone deficiency, hypothyroidism, hypoparathyroidism, vitamin D deficiency, diabetes, and osteoporosis are still observed and there is little evidence that DFO can reverse established endocrine dysfunctions. The North American Thalassemia Clinical Research Network Registry reported that 96% of thalassemia patients with median age of 20 years were free of hypoparathyroidism, 91% had no thyroid disease, 90% were free of diabetes mellitus, and overall 62% free of any endocrinopathy.[156]

It remains to be determined if starting chelation at a very young age or more easily administered use of oral iron chelation will diminish the endocrine morbidities and further prolong survival associated with iron overload. Direct and indirect measures of iron stores reflect the progress of chelation therapy and help determine appropriate changes in the dose or frequency of chelator use. The serum ferritin level generally declines during regular chelation therapy and may decline rapidly in the first year of treatment in patients with very large iron stores.[112,114] Serum ferritin levels measured over time with use of deferoxamine have predicted the risk of iron-induced heart disease in patients with thalassemia major, and the ratio of the dose of deferoxamine to the ferritin level has identified patients at risk for auditory and visual complications of chelation therapy.[134,147] Although easy to obtain and relatively inexpensive, the serum ferritin level may be increased in the presence of inflammation and may be decreased when iron overload is accompanied by vitamin C deficiency.[157] For these and other reasons, serum ferritin levels frequently correlate poorly with liver iron concentrations, and clinicians and patients may have a false sense of security when the ferritin level is below 2000 μg/L. Some studies using deferoxamine suggest ferritin levels lower than 1000 μg/L are associated with better survival and less cardiac disease as well as hepatic histology and pathology.[155,158,159]

Liver biopsy with biochemical measurement of iron concentration provides a more direct assessment of iron overload, and some investigators recommend such testing yearly. Hepatic iron levels of 15 mg/g dry weight have been associated with a greater risk of iron-induced heart disease.[119] The meaning of lower hepatic iron levels has generally been inferred from experience with primary hemochromatosis.[160] Further studies are needed to determine the clinical usefulness of liver iron concentration in the overall management of thalassemia. Noninvasive techniques for assessing tissue iron offer the possibility of serial measurements without substantial risk to the patient. The noninvasive measurement of iron in the liver, heart, and other target organs are in development. Measurements of liver iron concentration by magnetic susceptometry using a superconducting quantum interference device (SQUID) correlate well with biochemical measurements of tissue iron.[161,162] At present, measurement of tissue iron by SQUID is limited to the liver, and the instruments are available in only two sites in the United States and two sites in Europe. The ability to use magnetic resonance imaging to measure iron stores would dramatically extend the availability of noninvasive tissue iron measurements. Investigators have reported success using proton transverse relaxation rates (R2) with spin-echo imaging, signal intensity ratios, and gradient-echo T2* to assess liver iron concentration.[163–167] The latter two techniques also yield information that appears to reflect cardiac iron loading. Direct comparisons with hepatic tissue samples demonstrate significant correlations ($r = 0.97$ vs 0.95) with biopsy-measured liver iron concentrations in two separate studies.[164,166–170] These noninvasive technologies to measure liver, cardiac, and other tissue iron concentration may prove useful in the future to refine therapeutic strategies. Current needs include the further refinement of magnetic resonance imaging techniques and a better understanding of the relationship between liver iron, iron in other organs (in particular the heart), and clinical complications of iron overload.

A relationship between iron overload and ascorbic acid depletion, first suggested by the epidemiology of scurvy among the Bantu, exists in thalassemia major.[45,157] For thalassemia patients with low levels of ascorbic acid, daily supplementation with 100 to 200 mg of this vitamin increases urinary iron excretion in response to deferoxamine by approximately twofold.[46,108] Ascorbic acid may retard the conversion of ferritin to hemosiderin and therefore allow more iron to remain in the chelatable form.[171,172] However, it can also enhance iron-mediated peroxidation of membrane lipids[173,174] as well as membrane damage in cultured myocardial cells.[175] Cardiac toxicity

*References 55, 61, 119, 120, 123, 125, and 145–147.

manifested as arrhythmias and decreased ventricular contractility has been attributed to vitamin C therapy.[176] Ascorbic acid should be used only while deferoxamine is being administered and only in patients who are ascorbate depleted. Chelation therapy with deferoxamine is expensive and cumbersome because of the need for daily or nightly subcutaneous infusions. Regular infusions require a great deal of dedication and persistence from the patient and family. Noncompliance is common, particularly in the teenage and young adult years, and failure to follow prescribed treatment regimens is the major cause of mortality in patients with thalassemia major.[155] The cost and complexity of deferoxamine administration prevents its availability worldwide, especially in developing countries. The search for a less expensive iron chelator that can be more easily orally administered led to the identification of compounds such as deferiprone and deferasirox.

Deferiprone

One such oral agent is 1,2-dimethyl-3-hydroxypyrid-4-one (L1, deferiprone), a synthetic compound with a low molecular weight of approximately 200. It is an orally active bidentate iron chelator that requires three molecules to bind one iron atom. Deferiprone is absorbed by the gastrointestinal tract, has a plasma half life of approximately 90 minutes (2–3 hours). Chelated iron is excreted predominantly in the urine (90%) and far less in the stool (10%). It was synthesized in the late 1980s and was first tested in uncontrolled clinical trials at the Royal Free Hospital in London, hence the eponym L1.[177,178] Subsequent clinical efficacy studies appeared initially encouraging[179–181] but its long-term efficacy and safety have not been totally established.[180,182–186] Unfortunately, deferiprone was not subjected to Phase III studies wherein its safety and efficacy were directly compared to deferoxamine. Nonetheless, at doses of 75 mg/kg/day, deferiprone administered in three divided doses with meals reduces or maintains iron stores in many regularly transfused patients, for the most part, particularly those with more severe transfusional iron overload.[179,180,182–188] However, some patients continue to accumulate iron during long-term therapy with this dose of deferiprone.[180,184,189] Regimens using higher doses up to 100 mg/kg/day of deferiprone or combination regimens with deferoxamine reduce iron stores or have proved effective in restoring negative iron balance in some of these patients.[190–192] Enhanced urine and stool iron excretion in thalassemia patients using both deferoxamine and deferiprone have suggested an additive effect postulated by the shuttle hypothesis, that is, deferiprone may chelate intracellular labile iron and shuttle it to deferoxamine.[193] Some studies have also suggested that deferiprone alone or in combination with deferoxamine may be more effective than deferoxamine in removing iron from the heart, improving cardiac function, and preventing iron-induced cardiac disease.[170,188,194–197] Schedules for combination therapy vary but have usually included 5 to 7 days of deferiprone and 2 days of subcutaneous deferoxamine weekly.

Side effects of deferiprone include gastrointestinal complaints, mostly nausea and some vomiting that occur in approximately 33% of patients and usually resolve without specific intervention. Arthropathy with arthalgias and some joint effusions occur in approximately 15% of patients. The incidence of joint symptoms varies widely among various studies but may be severe enough to require reduction or interruption of chelation therapy. Abnormal liver function tests may occur gradually or suddenly and in the absence of other causes of hepatic dysfunction. These elevations may return to baseline values with the interruption of deferiprone followed by reinitiation beginning with lower doses and close monitoring of liver function tests. Progressive liver disease attributed to deferiprone has not been reported and concerns about drug-induced hepatic fibrosis have not been substantiated by subsequent studies.[180,183,198,199] However, there is in vitro evidence that deferiprone may potentiate oxidative DNA damage in iron-loaded liver cells that could occur when the concentration of iron is low relative to the iron chelator (Fig. 41–8).[200] Agranulocytosis occurs in 1% of patients and, although rare, remains

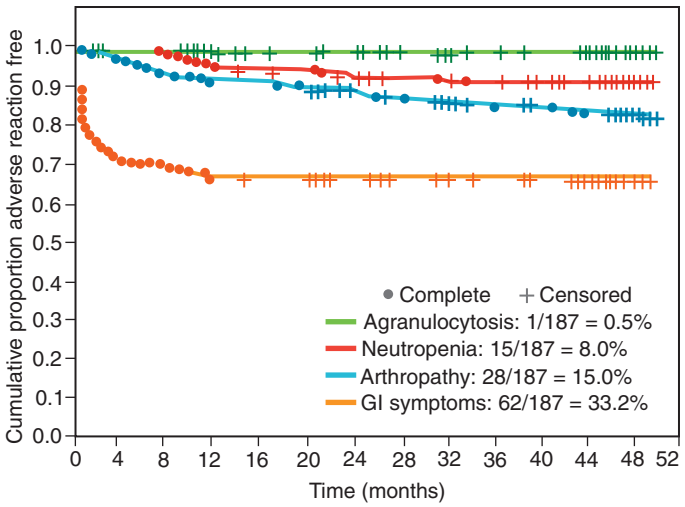

Figure 41–8 Kaplan–Meier curves showing the time to first occurrence of important adverse events in patients treated with deferiprone. The only case of agranulocytosis occurred in the first year, and gastrointestinal complaints were very uncommon after the first year. Neutropenia and joint problems occurred throughout the 4-year study period but were more common in the first year than in each of the subsequent years. *(Adapted from Cohen AR, Galanello R, Piga A, et al: Safety and effectiveness of long-term therapy with the oral iron chelator deferiprone. Blood 102:1583, 2003.)*

the principal concern for patients receiving deferiprone. Milder neutropenia is more common and occurs in approximately 8% of patients. Severely depressed neutrophil counts represents a significant risk of sepsis, hospitalizations, and in some cases administration of G-CSF is required. Some reported deaths have been related to deferiprone-induced agranulocytosis and/or neutropenia. Regular weekly monitoring of blood counts during deferiprone therapy is essential to detect the rare but important deferiprone-induced complications of neutropenia and agranulocytosis.[184–186,201]

Several clinical studies of deferiprone speak to its relative safety and utility demonstrated by a decline in serum ferritin levels in the majority of patients.[170,183–188,194,195,197] Retrospective studies have suggested that deferiprone might be more effective than deferoxamine in chelating cardiac iron. Two multicenter studies have futher supported the theory that combination therapy increases total iron excretion and selectively reduces organ iron burden.[195,197] Longitudinal clinical studies using innovative magnetic resonance imaging technology to measure cardiac (T2*) and liver iron concentration have demonstrated higher estimated liver iron concentration but lower myocardial iron concentration in deferiprone-treated thalassemia patients in comparison to those treated with deferoxamine.[194] In another study, thalassemia patients using deferiprone did not experience any cardiac events nor any cardiac-related deaths in comparison to thalassemia patients on deferoxamine who experienced both cardiac events and some deaths.[195] In another 1-year prospective trial of cardiac iron and function, thalassemia patients treated with deferiprone or deferoxamine had improved myocardial T2* values but more so in the deferiprone-treated group, who also showed a greater improvement in left ventricular ejection fraction. Liver iron concentration fell significantly in the deferoxamine-treated patients but not in the patients receiving deferiprone. A prospective randomized study comparing the combination of deferiprone at 75 mg/kg/day and deferoxamine at 40 to 50 mg/kg/day with deferoxamine alone demonstrated that the combination therapy more rapidly reduced hepatic and cardiac iron stores than deferoxamine alone.[202] Further prospective studies are warranted, especially with the combination of deferiprone with deferoxamine. Deferiprone may play a role in shuttling iron from within intracellular pools and enhance the available iron pool to bind with deferoxamine.[183,203–205] Deferiprone continues to be tested in clinical trials alone and in combination with deferox-

amine to address its impact on cardiac function.[197] The safety profile of deferiprone has been largely defined by single-center studies, multicenter trials, and postmarketing surveillance largely in European and Asian continents. Deferiprone is currently licensed only in Europe as alternative iron chelation therapy for those who are unable to be successfully treated with deferoxamine.

Deferasirox

Deferasirox (ICL670, ExJade) is an orally active iron chelator that was identified by computer technology at Novartis Pharmaceuticals in the 1990s. It is a tridentate compound known as 4-(3,5-bis(2-hydroxyphenyl)-1*H*-1,2,4-triazol-1-yl)-benzoic acid,[206] wherein two molecules of deferasirox are required to bind one atom of iron. It has a high affinity for iron and a much lower affinity for copper and zinc. Deferasirox is orally bioavailable with a low molecular weight of 373 and is absorbed by the gastrointestinal tract. It has a dose-dependent plasma half-life of 12 to 18 hours that allows for once-daily oral administration after fasting on an empty stomach.[207] Deferasirox is given as a suspension in water or apple or orange juice.[208] Iron excretion in response to deferasirox is largely in the stool (90%) and far less in the urine (10%).[208] The pharmacodynamic effects of deferasirox tested in a Phase I clinical iron balance metabolic study measuring stool and urine iron excretion demonstrated increasing iron excretion at doses of 10, 20, and 40 mg/kg/day, which induced a mean net iron excretion (0.119, 0.329, and 0.445 mg Fe/kg/day, respectively) within the clinically relevant range of the rate of transfusion iron loading for most patients. No significant acute side effects occurred other than gastrointestinal disturbances that were generally mild and a diffuse rash in some cases.[208]

Utility and safety of deferasirox have been also shown in short-term toxicity and pharmacokinetic studies.[208,209] Initially, a 1-year Phase II randomized multicenter study of transfusion-dependent thalassemia patients receiving deferasirox at doses of 20 mg/kg in comparison to deferoxamine at 40 mg/kg used subcutaneously 5 nights per week showed that deferasirox induced a 10% greater reduction in liver iron concentration by SQUID measurement than that of deferoxamine.[210] The Phase III worldwide multicenter open-label randomized active comparator control study of deferasirox in comparison to deferoxamine was conducted in 65 sites with 586 regularly transfused patients 2 years or more of age with β-thalassemia. Results indicated that chronic daily use of deferasirox, via a single oral dose of 20 to 30 mg/kg/day, induced decreases in liver iron concentration by biopsy comparable to that achieved with deferoxamine. Patients with liver iron concentrations greater than 7 mg/g dry weight receiving deferasirox at 20 to 30 mg/kg/day had a mean decrease of 5.3 mg/g dry weight that did not differ significantly from a mean decrease of 4.3 mg/g dry weight in patients receiving 35 mg/kg/day or more deferoxamine. Changes in serum ferritin were dose dependent in both treatments paralleling trends in liver iron content.[209] Doses of 5 and 10 mg/kg per day of deferasirox were unlikely to achieve negative iron balance and did not maintain or reduce absolute liver iron concentration and serum ferritin levels increased at these lower doses. The rate of transfusional iron loading may also influence the effectiveness of deferasirox in controlling liver iron concentration, and maintaining a transfusional iron requirement of 0.5 mg/kg/day or less may benefit reduction in liver iron concentration using 20 mg/kg/day of deferasirox.[211] Deferasirox was given Orphan Drug status and was approved by the FDA in 2005 and is commercially available in the United States. Long-term extension clinical studies using deferasirox are in progress.

Deferasirox was generally well tolerated in these clinical trials. Mild gastrointestinal complaints and skin rashes were the most common adverse events. Discontinuation of deferasirox was rarely required but abdominal discomfort occurred in 14% of patients, 12% with diarrhea, 10% nausea, and 9% vomiting. Mild increases in serum creatinine occurred in 38% of patients and a small number exceeded the upper limits of normal; intermittent proteinuria was also observed in 19% of patients. Duplicate serum creatinine level should be assessed prior to initiating therapy. Close monthly monitoring of serum creatinine needs to be maintained because of nephropathy in animal studies and cases of acute renal failure that were reported following postmarketing use of deferasirox. Severe renal complications may occur in patients with preexisting renal disease. Dose reduction, interruption, or discontinuation should be considered for elevations in serum creatinine. Elevations in serum transaminases also occurred in a small number of patients (6%). Recommendations to monitor liver function closely at monthly intervals with interruptions or discontinuations of deferasirox if unexplained or progressive transaminase increases occur. Skin rashes also occurred in 15% of patients usually within the first 2 weeks of treatment. The maculopapular eruptions often resolved spontaneously but severe rashes may require interruption of deferasirox with antihistamine support and possible steroid administration, following which deferasirox may be reintroduced at a lower dose with gradual dose escalation. Minimal (<1%) auditory and ophthalmologic toxicity occurred in the preliminary 1-year safety and efficacy trial. No agranulocytosis was observed in thalassemia subjects during the 1-year primary efficacy trial. Reports of pancytopenia have occurred in postmarketing reports, however, mostly in other patients with preexisting hematologic disorders such as myelodysplastic syndromes that are frequently associated with bone marrow failure. Four-year extension trials of deferasirox are ongoing after licensing by the FDA.

Other approaches to improved chelation therapy have focused on parenteral therapy. The compound HBED, originally developed as a potential oral agent, has been shown in primate studies to be more effective when administered as a subcutaneous injection than deferoxamine administered by subcutaneous infusion.[212] The attachment of deferoxamine to a backbone of starch (S-DFO) extends the circulation time of the chelator, and early studies suggest that this novel form of deferoxamine may reduce the frequency of infusions required to achieve negative iron balance.[213] Another promising oral desferithiocin derivative, Deferitrin (GT56–252), is under study because early phase I safety and efficacy studies have demonstrated tolerability and efficacy.[214]

Specific Complications and Their Management

Skeletal Changes

Skeletal abnormalities (Fig. 41–9) are less common in patients receiving regular red blood cell transfusions but may still occur as a result of partially unchecked ineffective erythropoiesis and expansion of the erythroid marrow.[215] These cause widening of the marrow space and thinning of the cortex, with consequent osteoporosis.[216,217] Changes in the skull and facial bones, including expansion of the frontal bone with prominent frontal bossing, may occur prior to the initiation of transfusion therapy. Radiographs reveal the diploic spaces to be widened. At first, the skull has a granular appearance, but later perpendicular bony trabeculae appear, giving the classic "hair on end" or "crewcut" appearance. Marked overgrowth of the maxilla results in severe malocclusion, jumbling of the upper incisors, and prominence of the molar eminences.[218] These bone changes produce the classic facies. Additional skeletal changes are observed in the metacarpals, metatarsals, and phalanges, where expanded medullary cavities produce a rectangular and then a convex shape (see Fig. 41–9). Irregular fusion of the epiphyses of the proximal humerus results in characteristic shortening of the upper arms.[219,220] Marked osteoporosis and cortical thinning may predispose to pathologic fractures of the extremities and compression fractures of the vertebrae. (Fig. 41–10)

Several abnormalities in the ribs may occur, including notching and osteolytic lesions.[215,221] The ribs become very wide, especially at the points of their attachment to the vertebral column. Marrow masses may extrude from these sites, creating the appearance of paravertebral masses and compressing the spinal cord.[222] Although bone deformities and extramedullary hematopoiesis is uncommon in properly transfused patients with β-thalassemia major, it is not

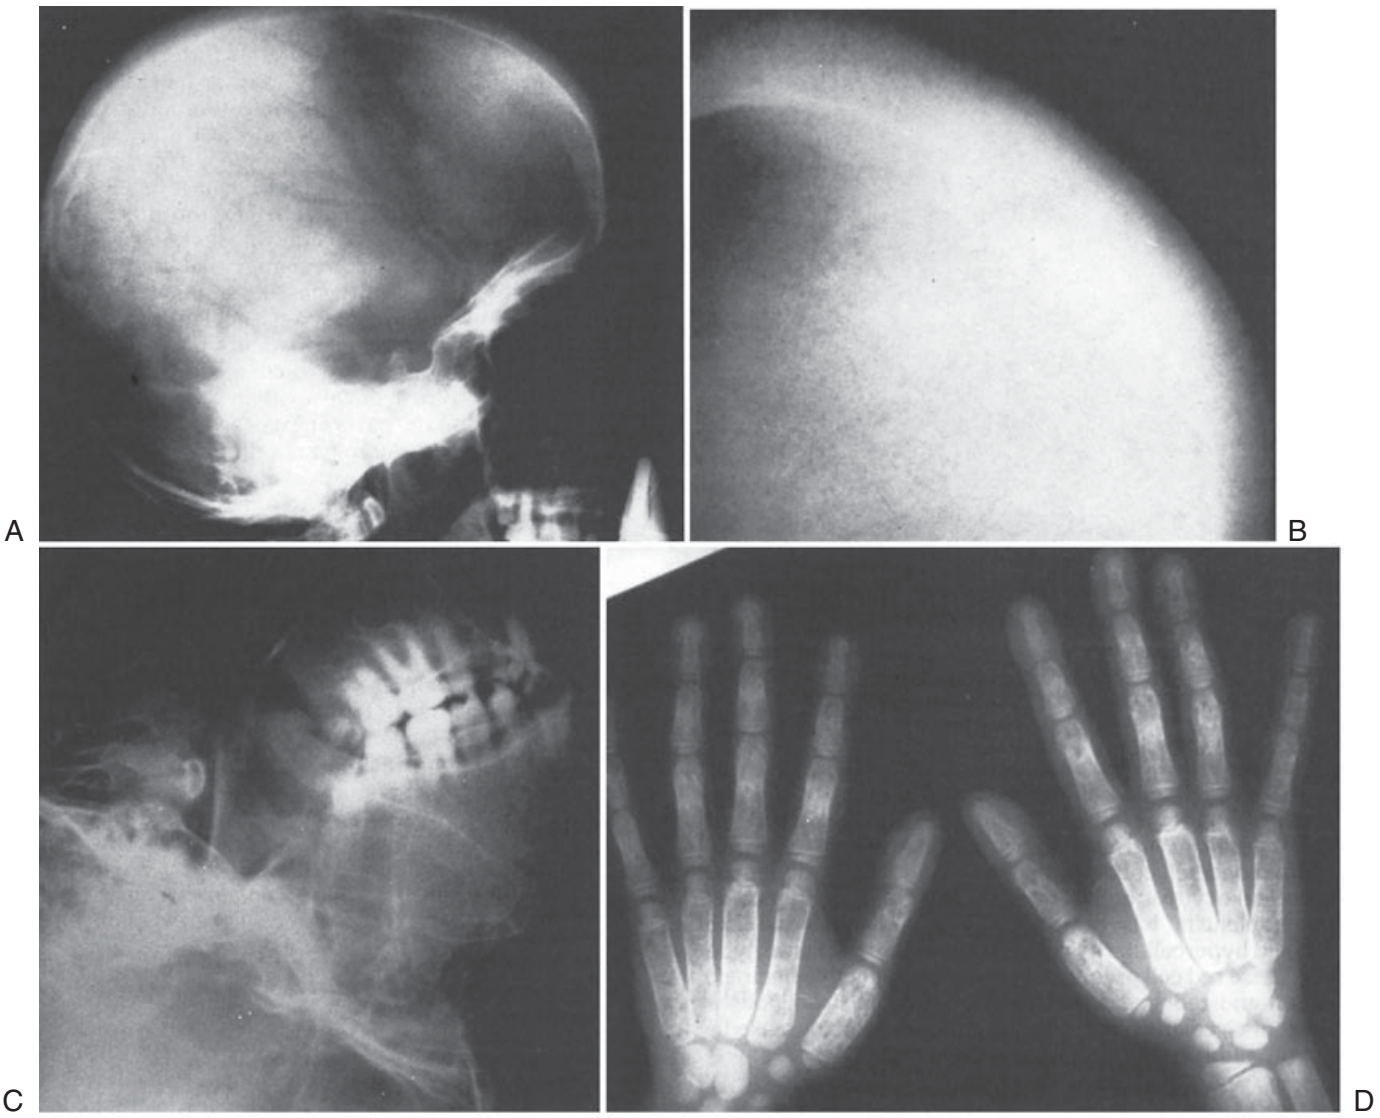

Figure 41–9 Bony abnormalities in a patient with severe β-thalassemia. **A** and **B**, "Hair-on-end" appearance of the skull, especially obvious in the close-up view shown in part **B**. **C**, Distortion of the maxillary bones, as well as poor development of the sinus cavities due to opaque masses of extramedullary erythropoiesis. **D**, Squaring and convexity abnormalities of the hands. *(From Pearson HA, Benz EJ Jr: Thalassemia syndromes. infrequently observed in patients with thalassemia intermedia whose marrow is not suppressed by regular transfusions (see the section Thalassemia Intermedia).

The character and degree of the bone lesions change significantly with age. In older children, the bone lesions regress in the more distal portions of the skeleton (hands, arms, and legs), a feature correlating with the normal developmental replacement of red marrow by fatty marrow. The characteristic changes of the hands and other peripheral areas are thus diminished and may disappear in later life.[55,223] However, in the skull, spine, and pelvis (which are sites of active, persistent erythropoiesis), the radiographic changes become more conspicuous.[75]

Growth and Endocrine Status

Growth retardation, including skeletal and dental deformities,[224] was common even in young children until the use of hypertransfusion regimens restored relatively normal growth during the first decade. Without iron chelation therapy, the adolescent growth spurt is often delayed or absent; most patients, even those well maintained by

transfusion, may not attain normal stature, in part because of iron-induced damage to the hypothalamic–pituitary axis.[36,225,226] Menarche is frequently delayed. Breast development may be poor, and many female patients have primary or secondary amenorrhea. Boys are frequently immature, with sparse facial and body hair. Although spermatogenesis may be normal, libido is often decreased. A multicenter study of 250 adolescent patients in northern Italy showed that despite hypertransfusion and 7 to 10 years of deferoxamine iron chelation therapy, two-thirds of male patients and one-third of female patients older than 14 years of age were 2 SDs or more below the mean for height.[227] Many adolescents between 12 and 18 years of age lacked any secondary sexual changes of puberty. However, the mean serum ferritin level in the entire group was 3500 ng/mL, indicating persistence of a high level of excess iron burden in most of this group.

Regular chelation therapy started early in the first decade of life frequently will allow normal onset of puberty and development of secondary sexual changes.[228] Administration of recombinant human growth hormone in conventional doses increases height velocity in patients with growth hormone deficiency.[229,230] Normal or higher doses of recombinant human growth hormone increase growth velocity in patients with normal growth hormone reserve but low levels of insulin-like growth factor I.[231,232] For patients with a functional hypothalamic–pituitary axis, treatment with gonadotropin-releasing hormone may induce pubertal changes.[233] In others, administration of sex steroids is necessary to induce secondary sexual characteristics.

More than 100 pregnancies either have been achieved spontaneously in patients with normal menstrual function or have been induced in patients with primary or secondary amenorrhea.[234–239] Transfusion requirements frequently increase during pregnancy, especially during the third trimester.[234] Diminished ventricular contractility during pregnancy and the death from heart disease of at least one mother within a year of delivery argue strongly for the careful consideration of the overall clinical condition and degree of iron loading before planning a pregnancy.[237,240] The safety of chelation therapy during pregnancy is discussed above. At least one successful pregnancy has occurred in a woman with thalassemia after bone marrow transplantation that included ablative therapy with busulfan and cyclophosphamide.[241]

Abnormal carbohydrate metabolism is common in older patients with thalassemia major. Prepubertal children usually have normal glucose metabolism, but pubertal patients exhibit impaired responses to glucose load. Higher than normal insulin levels despite normal glucose levels are also encountered during puberty.[242] The defect in these patients appears to be related to insulin resistance, with insulin deficiency developing later in the progression to diabetes. Rates of diabetes are reported close to 6% to 8%.[154] Diabetes occurs more frequently in patients with hepatitis C and hepatic dysfunction.[243–245] Oral hypoglycemic agents have been used to regulate hyperglycemia and may reduce the rate of further deterioration of glucose metabolism.[246]

Laboratory findings of hypothyroidism and hypoparathyroidism are present in approximately 14% of patients with thalassemia major.[247–251] Clinical findings associated with these deficiencies are uncommon.[252]

Low Bone Mass

With improved survival in patients with thalassemia major, the problem of osteoporosis has assumed greater importance. The widespread prevalence of osteoporosis in thalassemia major patients was first observed across all ages in 1995.[253] Subsequently, others reported a high frequency of abnormal *Z* scores in pediatric, adolescent, and adult patients. Abnormal bone mineral density has been reported in pediatric and adolescent thalassemia major patients.[254–256] The Thalassemia Clinical Research Network has identified the prevalence of fractures in a contemporary sample of 702 patients with α-and β-thalassemia. The overall fracture prevalence was 12%, with fractures occurring more frequently in thalassemia major (17%) and intermedia (12%) compared to β-E (7%) and α-thalassemia (2%). Facture prevalence increased with age and with sex hormone replacement therapy.[257] More recently an observational study by the Thalassemia Clinical Research Network has demonstrated a high prevalence of low bone mass across all the thalassemia syndromes, including β-thalassemia major, intermedia, β-E, hemoglobin H, H-Constant Spring, and homozygous α-thalassemia, which progresses with aging. Low bone mass is associated with high prevalence of fractures, hypogonadism, and increased bone turnover.[254,257,258] Bone resorption is usually increased and new bone formation is decreased.[259] Treatment with some but not all bisphosphonates improves bone mineral density.[260–263] Vitamin D and calcium supplementation with age-appropriate hormone replacement therapy are important preventive measures, although low bone mass may still occur in treated patients. Gonadal steroid replacement of hypogonadal patients has been shown to improve bone mass in some studies.[258,264]

Liver and Gallbladder

Hepatomegaly occurring prior to the initiation of transfusion therapy in severely affected patients is primarily a consequence of extramedullary hematopoiesis. With the amelioration of the anemia, the liver diminishes in size. However, as transfusion therapy continues, iron accumulation provides a new reason for hepatomegaly and resultant liver injury. Iron deposition, first present in the Kupffer cells, ultimately engorges the parenchymal cells, resulting in an appearance that is indistinguishable from that of idiopathic hemochromatosis.[265–267] The hepatocellular injury of iron overload may be due to the liberation of hydrolases resulting from initiation by the ferrous form of iron and peroxidative damage of lysosomal membrane lipids.[268] Fibrosis is usually followed by cirrhosis and an increased risk of hepatocellular carcinoma. The risk of liver damage and the rate of progression may be increased by the concomitant presence of excessive iron with viral hepatitis. The concentration of liver iron that constitutes a threshold for liver damage in patients with thalassemia is similar to that found in patients with hereditary hemochromatosis. In contrast to hereditary hemochromatosis, however, death from liver failure or liver cancer is much less common than death from cardiac failure in patients with thalassemia.[153]

Regular chelation therapy is the key to maintaining normal or near-normal hepatic iron concentrations and preventing iron-induced hepatic fibrosis and cirrhosis. Treatment with deferoxamine slows or prevents iron-induced liver damage and may reduce the severity of preexisting fibrosis in some cases.[104,124,269] Results of treatment of hepatitis C in patients with thalassemia major are similar to those found in other patients. Sustained viral responses occur in 28% to 40% of patients treated with interferon alone and, in two smaller series, 46% to 72% of patients treated with interferon and ribavirin.[270–274] Transfusion requirements increase by 30% to 40% in patients treated with ribavirin as a result of drug-induced hemolysis.[271,273,274] Lower levels of viral RNA and non-1 genotypes are associated with better responses. Higher iron levels adversely affect the response to antiviral therapy in some studies but not in others.[270,272,275] The Thalassemia Clinical Research Network studied the use of pegylated interferon and ribavirin in 16 thalassemia patients. Fifty percent genotype 1 patients had sustained viral response as well as 25% of genotype 2 and 3 patients; median transfusion requirements increased by 44% after 24 weeks of treatment and liver iron concentration increase of more than 5 mg/g dry weight occurred in 29% of patients, but overall liver iron concentration remained stable over the course of the study. In addition, neutropenia occurred in 52% of patients.[274] Interferon therapy in patients with hepatitis C who have previously undergone bone marrow transplantation is as effective and safe as in nontransplanted patients.[276]

Pigmentary gallstones caused by high levels of bilirubin production are found in an increasing number of patients over 4 years old. Two-thirds of patients have multiple calcified bilirubinate calculi

after the age of 15 years.[277] Gallbladder surgery is not usually indicated unless biliary colic or obstructive jaundice has occurred.

Heart

Cardiac abnormalities are important causes of morbidity and mortality in patients with thalassemia major. Cardiac enlargement secondary to anemia is almost always present in untransfused children (see Fig. 41–9). Before the availability of chelation therapy, myocardial hemosiderosis and serious iron-induced cardiac diseases were inevitable during the second decade. These problems still occur often in older patients with thalassemia who are poorly compliant with chelation therapy, and heart disease, usually in the form of cardiac failure or serious arrhythmias, remains the most common cause of death in patients with thalassemia major.[153,155]

Left-sided heart failure predominates in patients with thalassemia major and is characterized by dyspnea and orthopnea.[278] Right-sided heart failure is less common but may be the presenting cardiac finding in older patients with more severe iron overload. Symptoms include hepatic pain, abdominal discomfort, and peripheral edema. Acute myocarditis, which occurs in approximately 5% of patients with thalassemia, is frequently followed by acute or chronic heart failure.[279]

Early electrocardiographic abnormalities include a prolonged P–R interval, first-degree heart block, and premature atrial contractions. Later, ST-segment depression and ventricular ectopic beats constitute ominous indicators of myocardial damage. Periodic evaluation of cardiac function is essential to detect iron-induced heart disease and to identify patients who will benefit from more intensive chelation therapy (see later). Unfortunately, by the time cardiac studies such as echocardiography and 24-hour rhythm monitoring become abnormal, clinical heart disease is imminent. Whether assessment of cardiac iron by MRI using T2* or other measures can better anticipate the development of clinical heart disease is currently under investigation.

In the absence of intensified chelation therapy, ventricular dysfunction progresses rapidly to chronic refractory congestive heart failure, and arrhythmias become increasingly difficult to control. In the past, death usually occurred within 1 year of onset of heart failure. More recent data demonstrate a survival rate of 48% at 5 years.[278] Survival is notably poorer in patients with heart failure after myocarditis or with heart failure accompanied by arrhythmias.[279]

In addition to standard therapy for heart failure and arrhythmias, including angiotensin-converting enzyme inhibitors, β blockers, diuretics, and antiarrhythmic agents, the pretransfusion hemoglobin level should be maintained between 10 and 12 g/dL. The volume of transfused red blood cells should be reduced as needed to prevent acute fluid overload. Because the iron-overloaded myocardium has little capacity to improve its performance unless excess iron is removed, intensive chelation therapy is a critical part of the management of heart disease in patients with thalassemia. Several studies have shown that heart failure can be reversed in many patients with the use of continuous treatment with deferoxamine.[145,280,281] The benefits of this approach may derive from the reduction in cardiac iron stores, the prevention of acute toxicity from non-transferrin-bound iron, or a combination of these two mechanisms. Recent data suggest that deferiprone may be more effective than deferoxamine in reducing the cardiac iron load and treating iron-induced cardiac disease, perhaps because of deferiprone's ability to enter cardiac cells more rapidly than deferoxamine.[170,194] Different iron chelators seem to have different accessibility to hepatic and extrahepatic iron stores. Deferoxamine works more rapidly and efficiently in removing liver iron than cardiac iron.[149,281] Deferiprone seems to remove iron from the heart effectively[282] despite its relative inefficiency in controlling hepatic iron content.[170,194] In the gerbil animal model, deferasirox and deferiprone were equally effective in removing cardiac iron and deferasirox removed even more hepatic iron for a given cardiac iron burden.[283] Deferasirox treatment for 1 to 2 years has also been shown to reduce cardiac iron and improve cardiac MRI T2* in patients with transfusional iron overload.[284,285] Additional studies are needed to confirm these observations and to establish the relative roles of deferiprone, deferasirox and deferoxamine or a combination thereof in the management of patients with established iron-related heart disease.[286] In patients who have undergone bone marrow transplantation, improvements in left ventricular contractility and diastolic function accompany the removal of excess iron by phlebotomy.[287] Heart transplantation and combined heart–liver transplantation have been performed successfully in patients with end-stage cardiac disease.[288–290]

Sterile pericarditis occurs in some patients with massive iron overload.[291] Although pericarditis is most often attributed to hemosiderosis, an association with β-hemolytic streptococcal infection and other infectious agents has also been suggested.[292] Therapy usually consists of bed rest, treatment of infection, management of superimposed congestive heart failure, and the use of salicylates or corticosteroids. Occasionally, pericardiectomy may be indicated.

Lungs

Mild abnormalities of pulmonary function are common in patients with thalassemia but rarely cause clinical problems. Some patients exhibit primarily restrictive defects[293,294]; others experience mild to moderate small-airway obstruction and hyperinflation.[295–297] Most patients have a decreased maximal oxygen uptake and anaerobic threshold; these do not normalize after transfusion.[298] Postsplenectomy thrombocytosis and other prothrombotic changes can predispose to pulmonary vascular occlusion and pulmonary hypertension.[299–302] Treatment with high doses of the iron chelator deferoxamine may also be associated with acute deterioration of pulmonary function.[140,141]

Kidneys

The kidneys are frequently enlarged, due in part to extramedullary hematopoiesis and in part to marked dilation of the renal tubules.[303] The urine is often dark brown, reflecting the excretion of products of heme catabolism.[304] The urine also contains large amounts of urates and uric acid.

Spleen and Splenectomy

Massive splenomegaly is unusual in regularly transfused patients, but moderate splenomegaly may be associated with findings of hypersplenism. Thrombocytopenia and neutropenia are usually mild, and infection and bleeding are distinctly unusual in the absence of other risk factors. The usual indication for splenectomy is a progressive increase in transfusion requirements due to hypersplenism. The transfusion requirements, and therefore the rates of iron loading, of splenectomized patients are often considerably less than those of patients whose spleens are intact.[69,70,305,306] A transfusion requirement of more than 180 to 200 mL/kg/year of packed red blood cells usually represents excessive red blood cell requirements.[305,306] For such patients, a 25% to 60% reduction in transfusion requirements after splenectomy is generally predictable. Before attributing increased transfusion requirements to hypersplenism, it is important to look for other causes, such as red blood cell alloimmunization or a change in the hematocrit of the units of donor blood. Red blood cell survival studies using ^{50}Cr-labeling are not usually of value for predicting response to splenectomy. Because of the greater risk of postsplenectomy sepsis in younger patients, surgery should be deferred until after 5 years of age whenever possible. For well-transfused and well-chelated patients, splenectomy may have little benefit, and some centers have noted a significant decline in the number of patients undergoing splenectomy in recent years.

Laparoscopic splenectomy has proved safe for patients with thalassemia and has dramatically shortened the recovery time compared

with open procedures.[307] Partial splenectomy and partial dearterialization of the spleen have been suggested as alternative approaches to reducing blood requirements without incurring the risk of sepsis.[308–310] The long-term benefits of this approach remain uncertain. Therapeutic embolization of the spleen avoids the need for surgery,[311–313] but this approach is frequently associated with postprocedure pain and fever and does not permit the removal of accessory spleens.

After splenectomy, striking thrombocytosis may occur. Increased numbers of nucleated red blood cells appear in the blood, and the presence of many red blood cells containing inclusion bodies composed of precipitated α-globin chains can be demonstrated by staining with methyl violet or brilliant cresyl blue.

A period of observation without transfusion after splenectomy may be helpful in identifying those patients who can now maintain an acceptable hemoglobin level without regular transfusions. This approach may be particularly useful for patients whose thalassemia mutations would predict a milder clinical course. Hemoglobin levels should be monitored weekly to determine whether transfusion therapy should be reinstituted.

Patients with thalassemia major are at significant risk for the development of overwhelming, often fatal, infection after splenectomy (postsplenectomy sepsis syndrome).[314] The problem is most common in young children. *Streptococcus pneumoniae* causes two-thirds of cases; *Hemophilus influenzae* type B and *Neisseria meningitidis* account for most of the remaining infections. Typically, there is a fulminant clinical course, proceeding from mild fever and headache to hyperpyrexia, prostration, shock, and death within 6 to 12 hours. Immunization against the most common pathogens before splenectomy, prophylaxis with antibiotics, and early assessment of fever after splenectomy have dramatically reduced the incidence of fatal postsplenectomy sepsis.

Splenectomy should generally be reserved for patients with excessive transfusion requirements due to hypersplenism and difficulty controlling iron overload. A large spleen alone does not usually cause significant clinical problems and should rarely, if ever, be the sole reason for splenectomy. If possible, splenectomy should be delayed until children with thalassemia are at least 5 years old. By this time, children are more likely to have developed humoral immunity to a broad range of bacteria. Before splenectomy, polyvalent pneumococcal, meningococcal, and *H influenzae* vaccines should be administered if they have not been given earlier in life.[315,316] Oral penicillin therapy, 250 mg twice daily, is generally used as prophylaxis against postsplenectomy infection in patients with thalassemia. However, the optimal duration of penicillin prophylaxis remains unknown, and compliance is frequently inadequate.[317] Although the risk of postsplenectomy sepsis decreases with age, it does not disappear, and fatal pneumococcal sepsis has occurred many years after removal of the spleen.[318]

Pneumococcal sepsis is not totally preventable, because not all pneumococcal strains are represented in the available vaccines. In addition, penicillin-resistant strains of *S pneumoniae* have emerged with a prevalence in the United States of 5% to 10%, or even higher in some localities. Therefore, it is particularly important that patients and families be instructed to seek medical attention immediately if significant fever or other signs of infection develop.

Vitamin Supplementation

Although folic acid deficiency is uncommon in patients receiving regular transfusions, daily supplementation with 1.0 mg of folic acid is reasonable, especially if dietary intake is not optimal. Therapy with large doses of vitamin E neither improves survival of transfused red blood cells nor decreases transfusion requirements.[319] Whether vitamin E supplementation decreases the toxic effects of iron overload on specific tissues remains uncertain. Zinc supplementation is appropriate for patients with clinical or laboratory findings of zinc deficiency, usually a result of intensive iron chelation therapy. One center has reported an enhancement of linear growth in children with thalassemia receiving zinc for 1 to 7 years.[320]

Table 41–2 Survival by Birth Cohort at Different Ages of Patients With Transfusion-Dependent Thalassemia

	Cohort		
Patient Age (Years)	**1970–1974**	**1975–1979**	**1980–1984**
10	98% (96–99)	98% (96–99)	99% (95–100)+
15	95% (92–97)	97% (94–98)	98% (93–100)
20	89% (85–92)	96% (93–98)	
25	82% (77–86)		

Data from Borgna Pignatti C, Rugolotto S, De Stefano X, et al: Survival and disease complications in thalassemia major. Ann N Y Acad Sci 850:227–231, 1998.

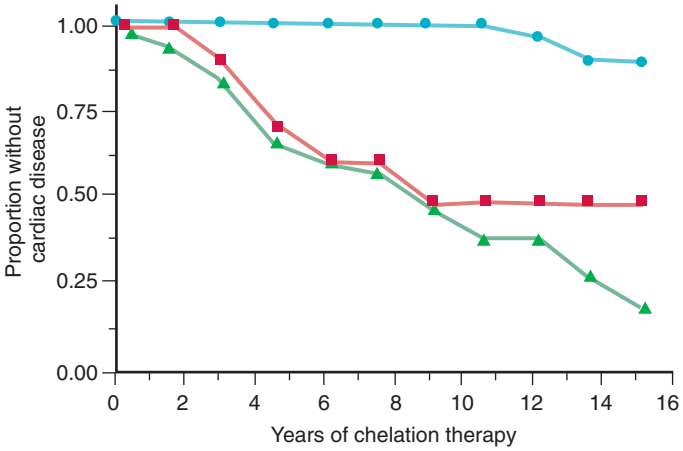

Figure 41–11 Survival without cardiac disease in patients with thalassemia major treated with deferoxamine according to the proportion of serum ferritin measurements greater than 2500 ng/mL. The *circles* show cardiac disease-free survival among patients in whom less than 33% of ferritin measurements exceeded 2500 ng/mL; *squares* show survival among patients in whom 33% to 67% of ferritin measurements exceeded 2500 ng/mL; and *triangles* show survival among patients in whom more than 67% of ferritin measurements exceeded 2500 ng/mL. *(Adapted from Olivieri NF, Nathan DG, MacMillan JH, et al: Survival in medically treated patients with homozygous beta-thalassemia. N Engl J Med 331:574, 1994.)*

Survival in Patients with Thalassemia Major

Improved transfusion therapy and the consistent use of iron chelation therapy have extended the life span of patients with thalassemia major.[61,153,155,321] In a multicenter study of 1079 patients in Italy, the probability of survival to age 20 was 96% for patients born between 1975 and 1979, the time at which chelation therapy became a regular part of the overall management of thalassemia major (Table 41–2).[153] In contrast, the probabilities of survival at 20 years of age were only 61% and 69% for those born in the periods of 1960 through 1964 and 1965 through 1969, respectively. Other investigators have shown that survival or prevention of life-threatening complications is strongly related to good chelation therapy, assessed either by compliance or by control of iron stores (Fig. 41–11).[119,147,155] The importance of good compliance with chelation therapy is further demonstrated by data from the United Kingdom showing that the probability of survival for the 1975 through 1984 birth cohort is to date not substantially different than the probability of survival for the 1965 through 1974 birth cohort.[321] The researchers attribute this poorer than expected survival rate, despite the availability of deferox-

amine, to a lack of adherence to the recommended schedule of treatment with this chelator.

Hematopoietic Stem Cell Transplantation

The first transplantation of allogeneic hematopoietic stem cells derived from the bone marrow of an HLA-identical sibling donor was reported in 1982.[322] There is now extensive experience with transplantation, with well over 1000 patients having undergone transplantation. The pioneering work of Lucarelli's group in Pesaro, Italy, has allowed for the prognostic classification of patients under the age of 17 years who receive an HLA-identical sibling donor with a preparative regimen including busulfan, cyclophosphamide, and cyclosporine. This risk classification is based on hepatomegaly, the degree of portal fibrosis, and the regularity of prior iron chelation therapy.[323] In class 1 without adverse factors, overall survival rate is 95% and the event-free survival rate (without thalassemia) is 90%; class 2 patients with one or two risk factors have 85% survival and 81% event-free survival; and class 3 patients with all three risk factors have only 64% and 62% overall and event-free survival rates (Fig. 41–12).[323] Advances in conditioning regimens have considerably improved the outcome of class 3 patients who are younger than 17. Preparatory chemotherapeutic regimens to enhance immunosuppression and eradicate thalassemic clones using hydroxyurea, azathioprine, fludarabine, busulfan, and cyclophosphamide have increased the survival rate of class 3 patients to 93% and the rejection rate fell to 8%.[324] These favorable results have not been reproduced in the older, more heavily iron-overloaded patients who remain high risk for transplant-related mortality.[325] Stem cell transplantation can fail or be lethal owing to its immunologic complications. The overall incidence of acute graft versus host disease is 17% to 32% depending on the prophylaxis regimen and the incidence of chronic graft versus host disease is 27% in patients receiving bone marrow hematopoietic stem cells from parental or sibling HLA-identical donor.[326]

Although hematopoietic stem cell transplantation is the only curative therapy available, its use has been limited by cost and the rarity of HLA-identical related donors.

Building on the success of bone marrow transplantation for patients with thalassemia major using HLA-identical related donors, investigators have explored alternative strategies to increase the safety and availability of transplantation. In pediatric patients, transplantation of stem cells from umbilical cord blood has been associated with a reduced risk of graft-versus-host disease compared with bone marrow transplantation.[327,328] Stem cells derived from sibling umbilical cord collections have increased in part the safety and availability of HLA-identical related donor transplantation. The probabilities of acute and chronic graft versus host disease are decreased to 11% and 6%, respectively, in patients who receive allogeneic related cord blood transplantation.[327] However, despite the 100% overall probability of survival, disease-free survival was only 79%.[328]

Reports of graft rejection and mixed chimerism using cord stem cells have occurred as well as a high rate of nonengraftment with secondary rejection at a median follow-up of 49 months.[328] The size of the cord blood collection and small number of cord stem cells transplanted relative to the number required to allow engraftment, sustain hematopoiesis, and prevent graft rejections are most likely responsible for failures. Rare case reports describe successful outcome with nonrelated cord blood transplantation.

Successful use of cord blood transplantation has led to the development of the Sibling Cord Blood Donor Program in the United States and 1617 cord blood collections have been processed for families with thalassemia. Some patients have received cord blood transplantation either alone or in combination with bone marrow or peripheral progenitor cells.[329] In addition, bone marrow donor registries have also developed worldwide to identify HLA-compatible unrelated donors with more that 10 million volunteers registered.

In an effort to increase the pool of potential recipients of stem cell transplantation for thalassemia, investigators have also explored the use of matched unrelated donor bone marrow transplantation. Extended haplotype and family segregation studies may identify suitable unrelated donors using HLA closely matched unrelated donor transplantation in thalassemia using high resolution molecular HLA typing. LaNasa reported 79% disease free and 66% event free survival, but 19% died of transplant related complications, 41% developed grade II–IV acute graft versus host disease and 25% had chronic graft versus host disease.[330] Most of the deaths occurred in patients with heavy iron overload or hepatic complications. The results suggested that engraftment and less graft versus host disease occurred when the recipient and donor were identical for one or two extended haplotypes.[330] Other reports also using unrelated hematopoietic stem cells selected according to stringent criteria of compatibility and using high-resolution molecular typing have indicated that unrelated donor transplantation may offer results comparable to those obtained with HLA-identical family donors for patients with limited iron overload.[331,332] Otherwise, the overall disease-free survival rate is only 60%, with a significant risk of chronic graft versus host disease. The results obtained with cord blood stem cell transplantation are encouraging but too little experience exists for definitive conclusions.[333]

Alternative unrelated matched or mismatched related donor transplantation is associated with greater risk of immune complications. The only well-established curative therapy is allogeneic stem cell transplantation from a matched related donor. Transplantation is an important consideration in management for the young thalassemia patient who has yet to accumulate excessive iron or those who have successfully controlled iron stores with chelation and who have an HLA-identical matched related donor.

The options of cord blood stem cell collection and cord blood or bone marrow transplantation discussions with families of the newly diagnosed are warranted as is a discussion of the long-term outcomes.

After a successful stem cell transplantation, some patients remain iron overloaded and require phlebotomy to prevent the risks of progressive hepatic fibrosis; other previously affected patients with hepatitis C require antiviral treatment[160,334] that may improve hepatic fibrosis and cirrhosis.[335]

Posttransplantation, some patients develop a state of mixed chimerism that may persist 10% to 30% of patients with a predominance of host cells in the marrow even though transfusion dependence may have dissipated.[336] However, 30% of patients with early mixed chimerism subsequently reject their graft.[337] Those patients with mixed chimerism and falling hemoglobin who require

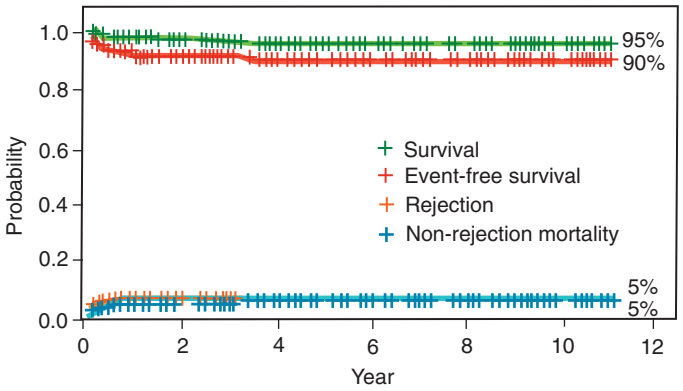

Figure 41–12 Kaplan–Meier probabilities of survival, event-free survival, rejection, and nonrejection mortality for 121 class 1 thalassemic patients younger than 17 years, receiving bone marrow transplants from HLA-identical donors after preparation with busulfan (14 mg/kg), cyclophosphamide (200 mg/kg), and cyclosporine alone, from January 2, 1986, through April 10, 1997, and calculated on May 15, 1997. *(Adapted from Lucarelli G, Galimberti M, Giardini C, et al: Bone marrow transplantation in thalassemia. Ann N Y Acad Sci 850:270, 1998.)*

supportive transfusion may successfully undergo a second transplant with nonmyeloablative conditioning to restore normal hemoglobin levels.[338]

Subsequent investigations to evaluate the effect of nonmyeloablative conditioning regimens as a primary approach to transplantation with the objective of causing a chimeric outcome have been attempted and are of questionable benefit.[331,339,340]

Allogeneic hematopoietic stem cell transplantation from a partially HLA-matched relative has also been investigated, with much less encouraging results. Gaziev has reported early or late graft-versus-host and graft failure in 55% of partial HLA familial matched without significant correlation between the degree of antigen disparities and graft failure. Graft-versus-host disease was a major factor contributing to death (50%) followed by infection (30%). The probability of overall survival and transfusion dependence were 65% and 21%, respectively, with a median follow-up at 2.5 years for surviving patients.[325]

In view of the available evidence, stem cell transplantation from a partially HLA-matched relative is not routinely advisable although it may be considered in extreme situations where transfusion support is impossible or life threatening when a patient is completely noncompliant with any type of iron chelation therapy.

The excellent results of bone marrow transplantation in young patients with thalassemia who have yet to accumulate excessive iron or who have successfully controlled iron stores have made transplantation an important consideration in their management. The option of bone marrow or umbilical cord blood transplantation should be discussed with families of newly diagnosed patients with thalassemia major and should be compared with long-term transfusion and chelation therapy. Both approaches should be addressed in terms of currently identified risks and benefits, the likelihood of future improvements, and the potential for new treatments such as gene therapy. In some centers, tissue typing of immediate family members is undertaken routinely, whereas in others this evaluation is performed only if the family wishes to consider transplantation as a treatment option. On the basis of the positive results with umbilical cord blood transplantation, parents of children with thalassemia should be encouraged to collect and store cord blood with future pregnancies.[329] The use of preimplantation diagnosis to identify an HLA-identical embryo unaffected with the sibling's blood disorder poses significant ethical dilemmas but has been used to create suitable donors for cord blood or bone marrow transplantation in cases of other hematologic diseases.[341–345] A related and also controversial approach is the use of both fetal and family HLA typing in pregnancies at risk of homozygous thalassemia to determine whether an HLA-identical sibling is available as a potential bone marrow donor if the fetus is affected and carried to term.[346,347]

The rate of success for bone marrow transplantation in children with more significant iron overload, in adults, and in patients without an HLA-identical sibling or parent suggests caution in the use of this approach. Transplantation has been recommended for such patients if they show progressive deterioration with conventional transfusion and chelation therapy. The availability of new chelating agents may significantly affect this balance, as may improvements in transplantation.

Some patients with thalassemia develop a state of mixed chimerism after transplantation. Approximately one-third of patients with early mixed chimerism subsequently reject their graft.[337] However, mixed chimerism may persist in 10% to 30% of patients, and the dependence on transfusion therapy often disappears despite a predominance of host cells in the bone marrow.[336] For patients with falling hemoglobin levels and renewed need for transfusion, a second transplant with nonmyeloablative conditioning may restore normal hemoglobin levels.[338] The clinical outcomes in patients with mixed chimerism have prompted the ongoing investigation of nonmyeloablative conditioning as the primary approach to transplantation for thalassemia.

Long-term complications of stem cell transplantation have also been reported, including gonadal dysfunction and fertility as well as growth failure and other endocrinopathies.[348,349]

In conclusion, hematopoietic stem cell transplantation with the use of matched related or unrelated donors is an alternative to standard transfusion and chelation therapy and generally results in excellent outcomes for low-risk patients. However, there are small risks of serious complications including death, graft failure or rejection, graft-versus-host disease as well as growth failure, infertility, and other endocrinopathies. Stem cell transplantion should be considered for class 1 and 2 children who have suitable donors. Unrelated HLA-matched donors, although an acceptable source of allogeneic stem cell for other conditions, are not yet considered suitable for children with thalassemia because of the relatively long-term survival associated with conventional therapy. Owing to the considerable risks and experiences of transplantation as well as the prospect of two or three decades of life with conventional management, discussions with the families of children who are potential candidates for transplant should be thorough.

Transplantation for those class 3 older patients and adults fare less well[350–352] and should be considered only for those who have a suitable donor or deteriorate with conventional treatment.[59]

Experimental Therapies

Enhancement of β and γ Gene Expression

Much recent effort has focused on stimulation of γ-globin gene expression or replacement of defective β-globin genes. Enhanced γ-globin gene expression would ameliorate the unbalanced globin chain synthesis and replace the missing adult hemoglobin with fetal hemoglobin. Normal β-globin genes, if introduced into stem cells in such a way as to allow them to function normally, would directly correct the β-globin chain deficit.

Active γ-globin genes are hypomethylated in utero but are methylated and inactive after birth. Hypomethylation of the γ-globin genes can be induced by the drug 5-azacytidine; indeed, short-term administration of this drug produced the predicted effect in vivo.[353–355] Despite much subsequent experimental work, it remains unclear whether the effect was due to direct stimulation of fetal genes by demethylation or to recruitment and accelerated differentiation of primitive burst-forming unit–erythroid (BFU-E) progenitor cells, which have greater potential to produce Hb F.[356–358] Hydroxyurea has an effect on BFU-E similar to that of 5-azacytidine and is a safer drug for long-term use.[357,359] Short-term as well as longer trials with hydroxyurea have been reported in a number of patients with thalassemia.[360–367] Hb F levels frequently increase without a proportionate increase in total hemoglobin level. A small improvement in total hemoglobin level occurs in some patients with thalassemia intermedia but usually does not exceed 1 to 2 g/dL.[364,365] Some patients report improvement in their overall sense of well-being even in the absence of an improvement in the anemia.[364] This may be a result of suppression of abnormal erythropoiesis, an effect that may also explain the value of hydroxyurea in the treatment of extramedullary hematopoietic masses (see later).[368] Although one patient with thalassemia major had sufficient improvement in his hemoglobin level to end his dependency on regular transfusions,[366] most transfusion-dependent patients have shown no clinical benefit. In a review of hydroxyurea therapy, Steinberg and Rodgers identified 52 patients with β-thalassemia who were treated with a variety of regimens.[367] They concluded that hydroxyurea alone had only a modest effect in thalassemia intermedia and did not look promising for thalassemia major.[369]

Recombinant erythropoietin has produced inconsistent responses in patients with thalassemia intermedia.[370–374] When the series are combined, approximately 40% of patients have an increase in hemoglobin level of 2 to 3 g/dL. Fetal hemoglobin levels are unchanged. The potentially adverse consequences of further stimulation of an already hyperactive bone marrow are uncertain. Erythropoietin has shown little benefit overall in patients with thalassemia major, although there are occasional reports of patients whose transfusion requirements were reduced or eliminated.[373,375]

Butyrate and other short-chain fatty acids have been demonstrated to augment Hb F production in various animal model systems as well as in humans.[376–378] These compounds are believed to act by altering chromatin configuration, perhaps due to inhibition of histone deacetylatase.[379–383] Short-term treatment with intravenous infusions of arginine butyrate in a limited number of patients resulted in increased levels of γ-globin chain production that were quite striking in some cases and resulted in a marked increase in γ/α-globin chain synthetic ratios.[379] One patient who was homozygous for Hb Lepore and could not be transfused because of alloimmunization was treated on a compassionate basis for a longer period of time, with a resulting rise in the total hemoglobin level (virtually all Hb F) from less than 5.0 g/dL to approximately 10.0 g/dL over approximately 60 days and healing of a leg ulcer.[379,384] In a subsequent longer-term trial, five patients with various other forms of severe β-thalassemia did not have a sustained hematologic response.[385] In yet another trial, administration of arginine butyrate intravenously in pulsed fashion to patients with sickle cell anemia and thalassemia resulted in favorable hematologic responses, raising the possibility of hematologic toxicity and suboptimal responses with continuous infusions of the drug.[386] Orally absorbable butyric acid compounds including sodium phenylbutyrate and isobutyramide also have been reported to result in an increase in F-cell and γ-globin chain production, but the effect was not as sustained or as quantitatively comparable to that originally obtained with intravenous arginine butyrate.[359,368,387–445] Total hemoglobin levels of patients with thalassemia intermedia showed little or no change,[444] although a study of isobutyramide in cases of thalassemia major found a reduction in transfusion requirements in two of eight patients.[445] No severe toxic side effects were observed in these relatively short-term trials in humans, but the infusion of high doses of butyrate into baboons did result in significant neurologic toxic effects.[446] Further studies will be required to assess the long-term safety and efficacy of therapy with butyrate.

Various combinations of hydroxyurea, butyrate, and erythropoietin have been used to try to achieve hematologic benefits that cannot be achieved with a single agent.[379–381,447] The addition of hydroxyurea to therapy with sodium phenylbutyrate led to a further increase in hemoglobin level in a patient with homozygous Lepore.[448] However, the combination of sodium phenylbutyrate and hydroxyurea was no better than hydroxyurea alone in other patients with thalassemia intermedia.[365] Combined therapy with hydroxyurea and erythropoietin produced marginally higher hemoglobin levels than either drug alone in only two of seven patients with thalassemia intermedia.[371] A more dramatic rise in hemoglobin level occurred in a patient with thalassemia major, but the relative contributions of pharmacologic therapy and splenectomy are unclear.[449]

Decitabine has been shown to result in a considerable sustained increase of Hb F and total hemoglobin in patients with sickle cell disease with the low likelihood of neutropenia and may have a similar effect in thalassemia but its therapeutic efficacy remains to be proven.[450,451]

Although the pharmacologic enhancement of fetal hemoglobin production remains an attractive strategy in the management of thalassemia, the results to date strongly suggest the need for new agents or new combinations of agents. At present, the primary clinical application of this approach is in the management of the severely affected patient who is unable to be transfused because of multiple alloantibodies or because of autoantibodies. This approach might also be used for patients with thalassemia intermedia who develop a need for frequent transfusions. However, studies suggest that the current approaches to fetal hemoglobin enhancement will usually be unsuccessful in either of these situations.

β-Globin Gene Therapy

Cure of thalassemia by genetic transfer of the normal β-globin gene into the pluripotent hematopoietic stem cell awaits further advances in molecular biology but is a goal of the foreseeable future.[396] β-Globin gene transfer and expression has been accomplished in thalassemia murine models, which have demonstrated that retroviral vectors are capable of transferring the human β-globin gene sequences and its promotor regions into murine stem cells[400,452] and into long-term repopulating hematopoietic cells of primates and humans.[453,454] Studies of a safe and efficient specific targeting vectors in humans are ongoing.[455] Techniques for obtaining long-term expression of human globin genes after transfer into murine hematopoietic stem cells have been developed.[394,395] Thus, there has been remarkable success in the use of globin gene transfer for "therapy" of murine models of β-thalassemia and sickle cell anemia.[396–401] However, clinical trials have suffered from problems of vector instability, low viral titers and variable expression of globin genes.[456] These formidable problems must be solved before it becomes routinely possible to transfer and effectively express globin genes in human hematopoietic stem cells, ensure their safe and active expression at effective levels, and preserve normal growth, differentiation, and proliferation of the genetically transformed stem cell. Nevertheless, protocols have been developed to carry out gene transfer experiments in humans and it is likely that there will be attempts to do so in the not-too-distant future.

Thalassemia Intermedia

Approximately 10% of patients with homozygous β-thalassemia exhibit a phenotype characterized by intermediate hematologic severity.[1–4] The balance of globin chain synthesis is better than in typical thalassemia major because of a less severe defect in β-globin chain synthesis, a decrease in α-globin chain synthesis as well as β-globin chain synthesis, or an increase in γ-globin chain synthesis. For example, homozygous β-thalassemia in African Americans, Portuguese, and other populations may be relatively mild, at least for the first two decades of life.[402,403] Homozygotes or mixed heterozygotes for forms of β-thalassemia associated with normal Hb A_2 and normal Hb F (silent carrier state) also tend to have mild to moderate disease.[404,405] Certain patients have a milder clinical phenotype because they have coinherited a form of α-thalassemia,[13–15] or because they carry one (or two) β-thalassemia chromosome(s) with a greater than usual potential for high levels of γ-globin gene expression.

The ability to maintain a hemoglobin level compatible with comfortable survival in the absence of regular transfusions is the generally accepted criterion for the diagnosis of thalassemia intermedia. In other words, distinguishing between thalassemia major and thalassemia intermedia, which in turn is the distinction between initiating a regular transfusion program or not, requires consideration of the hemoglobin level and the quality of life. These two parameters do not have a predictable relationship. Patients with thalassemia and hemoglobin levels of 7 g/dL may be relatively symptom-free, whereas patients with hemoglobin levels of 9 g/dL may have numerous problems related to ineffective erythropoiesis. Thus, the assessment of the patient rather than the hemoglobin level alone is essential in deciding who does not require regular transfusions and therefore, by definition, has thalassemia intermedia. Some nontransfused patients have normal growth and sexual development, few medical problems, and normal or near-normal survival rates. However, others develop disfiguring facial changes, markedly delayed growth and sexual maturation, heart failure, severe osteoporosis, repeated fractures, arthritis, and massive splenomegaly. Calling the condition of this latter group thalassemia intermedia implies a milder disease than thalassemia major but, in fact, the patients' quality of life does not compare favorably with the quality of life of patients with thalassemia major. Nonetheless, many families and physicians are reluctant to initiate a chronic transfusion program because of concern about the risks of long-term transfusion therapy and the inevitable need for iron chelation therapy. If the decision is made to manage the patient initially without regular transfusions, regular reassessments of the patient's clinical condition, including appearance, growth, and development, and bone expansion are crucial.[406] Short-term transfusion therapy may be useful during pregnancy or in the management of cardiac and other serious complications. The need for regular transfusions often develops in adults with thalassemia intermedia because of a further

decline in the hemoglobin level or a growing intolerance of the anemia.

Even in the absence of regular transfusions, many patients develop progressive iron overload because of increased absorption of dietary iron induced by ineffective erythropoiesis and, in many cases, the intermittent administration of red blood cell transfusions. By the third or fourth decade, the total iron burden may attain the levels seen in transfusion-dependent patients.[407] Ferritin levels may underestimate the degree of tissue iron loading in thalassemia intermedia, and assessment of liver iron concentration is more helpful in determining the need for chelation therapy. Deferoxamine as well as the orally active iron chelator deferiprone (L1) has proved effective in thalassemia intermedia.[408,409]

Splenectomy raises the hemoglobin level by 1 to 3 g/dL in many patients with thalassemia intermedia.[410,411] Removal of the spleen should receive careful consideration as a potential alternative to beginning transfusion therapy. As noted earlier, for patients who undergo splenectomy while on a chronic transfusion program, a period of careful monitoring of the hemoglobin level after surgery may occasionally identify individuals who are no longer transfusion-dependent and who can therefore be reclassified as having thalassemia intermedia.

Thromboembolic events represent a major complication of thalassemia intermedia, occurring in 10% to 34% of patients.[302,412] These events include stroke, pulmonary embolism, portal vein thrombosis, and deep vein thrombosis of the legs. A hypercoagulable state may also contribute to the pulmonary hypertension that commonly occurs in patients with thalassemia intermedia and is the primary cause of congestive heart failure.[413] Splenectomy is a risk factor for thromboembolic events in patients with thalassemia intermedia, resulting in thrombocytosis and allowing the prolonged circulation of damaged red blood cells that generate increased amounts of thrombin.[302] Some investigators consider the risk of thromboembolic events after splenectomy for thalassemia intermedia to be sufficiently high to warrant short-term anticoagulation in the perioperative period and during pregnancy.[302] Oral contraceptives should be used with extreme caution, if at all.

Extension of hematopoietic tissue beyond the confines of the bones occurs in patients with thalassemia intermedia as a result of the intense erythropoiesis. This complication occurs less frequently in patients with thalassemia major because of the partial suppression of erythropoiesis by regular transfusions. Masses of extramedullary hematopoietic tissue develop in the spinal epidural space, thorax, cranium, pelvis, and elsewhere.[368,414–424] These masses may be detected as incidental findings on imaging studies of the chest or abdomen.[415–421] In other instances, the masses produce symptoms by compressing neighboring structures. For example, patients with extramedullary hematopoietic masses may develop paraplegia from spinal cord compression or loss of visual acuity or visual fields caused by optic nerve compression.[414,417,423,424] Additional clinical presentations of hematopoietic masses include pleural effusions and upper airway obstruction.[419,420,422] Initiation of regular transfusions for patients with thalassemia intermedia or intensification of the ongoing transfusion program for patients with thalassemia major reduces the size of extramedullary hematopoietic masses and helps to prevent recurrences. Therapy with hydroxyurea has also been associated with shrinkage of hematopoietic masses.[368] Low-dose radiation therapy provides more immediate relief and may be particularly useful for acute neurologic complications.[425]

Reconstruction of the maxilla may be needed for some patients with thalassemia intermedia to provide cosmetic improvement of facial asymmetry and malocclusion.[426] Gallstones regularly occur by the second decade of life.[427] Leg ulcers often occur in late adolescence or afterward and may require red blood cell transfusions as well as local measures for healing. Because of the marked marrow hyperplasia, supplementation with folic acid is necessary to prevent megaloblastic anemia. Aplastic crises associated with parvovirus or other infections may result in exacerbations of the anemia.

Some patients with heterozygous β-thalassemia will have a moderately severe clinical disorder, with anemia, hemolysis, and splenomegaly. Some of these patients carry a greater than normal number of α-globin genes as a result of triplication of one of the α-globin gene loci: ααα/αα.[34,335,428,429] However, most heterozygous patients with triplicated α-globin gene loci are clinically similar to those with the simple β-thalassemia trait. Most patients with severe heterozygous β-thalassemia have so-called dominant β-thalassemia, which is due to the inheritance of a gene for a β-thalassemia hemoglobinopathy associated with a structurally abnormal, unstable, β-globin chain that may form inclusion bodies.[16,17] For those heterozygotes with disease of unusual clinical severity, splenectomy may be beneficial.

β-Thalassemia Minor (Thalassemia Trait)

Inheritance of a single β-thalassemia allele usually results in a mild hypochromic microcytic anemia. The hemoglobin level averages 1 or 2 g/dL lower than that seen in normal persons of the same age and gender. Hb F levels decline more slowly than usual in the first year of life and the diagnostic elevated Hb A_2 levels are established by approximately 6 months of age.[432–434] Strong intrafamilial correlations of both Hb A_2 and mean corpuscular volume (MCV) are noted.[435] Osmotic fragility is decreased; indeed, a one-tube osmotic fragility test has been used in the past for mass screening.[433] The red blood cell count is increased or normal. The red blood cells are characteristically hypochromic (mean corpuscular hemoglobin <26 pg) and microcytic (MCV <75 fL). The smear shows varying numbers of target cells, poikilocytes, ovalocytes, and basophilic stippling (Fig. 41–13). The reticulocyte count is normal or slightly elevated. Red blood cell survival is normal, iron utilization is decreased, and slight ineffective erythropoiesis is present.[434] Most patients are asymptomatic. Many patients who have thalassemia trait are erroneously believed to have iron deficiency. Testing to distinguish these two disorders is important for genetic counseling of carriers of thalassemia trait, for the avoidance of unnecessary investigations in patients incorrectly assumed to have iron deficiency and to prevent unwarranted supplementation with iron. Although a variety of indices calculated from blood count parameters have been suggested to differentiate thalassemia from iron deficiency, each has some degree of inaccuracy; most are no better than the MCV alone.[435,436] In general, the MCV is rarely greater than 75 fL or the hematocrit less than 30 in patients with β-thalassemia trait. In cases of iron deficiency, the hematocrit level usually falls to less than 30 before the MCV falls to less than 80 fL. Free erythrocyte porphyrin levels are normal in patients with thalassemia trait but are elevated in patients with iron deficiency (see Chapter 36).[1] Specific studies for iron deficiency, such as the serum iron level and total iron-binding capacity or the serum ferritin level, help to prevent misdiagnosis.

During pregnancy, the anemia of thalassemia trait often becomes more severe, but transfusions are rarely necessary. Because iron deficiency may occur during pregnancy, iron supplementation has been advised to avoid compounding the causes of anemia.[437,438]

There may be characteristic racial differences in the hematologic severity of β-thalassemia trait. In African Americans, the condition is invariably milder, red blood cell morphologic abnormalities are less marked, and β/α synthetic ratios are higher than in whites and Asians with the trait.[439]

The diagnosis of β-thalassemia trait is established in most instances by the demonstration of altered proportions of Hb A_2. The level of Hb A_2 in β-thalassemia trait averages 5.1% (range, 3.5%–7.0%), approximately twice the normal level (1.5%–3.5%); the Hb A_2/Hb A_1 ratio is 1 : 20 instead of the normal 1 : 40. This increase is probably due to a posttranslational (assembly) phenomenon with increased opportunity for δ-globin chains to combine with α-globin chains in the face of β-globin chain deficiency. If concomitant iron deficiency anemia occurs, Hb A_2 levels may fall, sometimes into the normal range.[440]

The Hb F levels are inconsistently elevated in β-thalassemia. In approximately one-half of cases, Hb F is within the normal range (<2.0%); in the remainder, it is moderately elevated (2.1%–5.0%). However, in almost every instance, a minor population of red blood

Note the profound hypochromia and microcytosis and the many target cells. *(From Pearson HA, Benz EJ Jr: Thalassemia syndromes. In Miller DR, Baehner RL, McMillan CW [eds.]: Smith's Blood Diseases of Infancy and Childhood, 5th ed. St. Louis, CV Mosby, 1984, p 439.)*

cells (F cells) containing substantial amounts of Hb F can be demonstrated by the Kleihauer technique.[1] Rarely, an individual with heterozygous thalassemia, as evidenced by a reduced β/α synthetic ratio or by virtue of having a child with thalassemia intermedia or major, has normal Hb A_2, Hb F, and hemoglobin electrophoresis, with minor (quiet carrier) or no (silent carrier) hematologic changes.[405] Rare individuals have been encountered who exhibit characteristically abnormal red blood cell morphology but normal levels of Hb A_2 and Hb F.[1] Such individuals are probably carriers of γδβ-thalassemia.[1] Iron deficiency must be excluded and globin-chain syn-

thesis or molecular studies done to establish a diagnosis with certainty.

The diagnosis of thalassemia trait assumes particular importance in women who are pregnant or considering pregnancy because of the potential for having a child with thalassemia major. The presence of a low MCV should be investigated further with levels of Hb A_2 and Hb F, as well as a hemoglobin electrophoresis to look for thalassemic variants such as Hb E and Hb Lepore (see later). If either the father or the mother is known to have thalassemia trait, the other person should be assessed using these more definitive studies rather than the MCV alone.

Prenatal Diagnosis of β-Thalassemia

Thalassemia mutations can now be routinely and reliably diagnosed by using fetal DNA obtained between the 8th and 18th weeks of gestation. The most reliable methods are based on identification of the abnormal gene by direct DNA analysis.[22,441,442] Both amniocentesis and chorionic villus sampling have been used with success. In experienced hands, the latter method is preferable because adequate amounts of DNA can be obtained safely at an earlier gestational age. New techniques have been developed for obtaining fetal DNA for prenatal diagnosis either directly from maternal plasma or by the isolation of fetal nucleated red blood cells from maternal peripheral blood.[438,444] The DNA is analyzed by a variety of polymerase chain reaction (PCR)-based or other methods for the presence of the thalassemia mutation.

The heterogeneity of thalassemia mutations complicates the approach to antenatal diagnosis. More than 175 independent mutations can cause β-thalassemia. However, a number of factors have improved the speed, efficacy, and reliability of DNA diagnosis. Extensive surveys of most populations in which these alleles are frequent have revealed that approximately 15 β-thalassemia mutations account for more than 90% of individuals afflicted worldwide. Within any given ethnic group, three to six mutations usually account for the vast majority of severe cases (see Table 41–1).[22] One can thus customize the search for mutations according to the ethnic origins of the family at risk. PCR techniques and exquisitely precise hybridization assays (allele-specific oligonucleotide hybridization), which detect single-base changes with great reliability, can now be combined to permit screening of minute DNA samples for several mutations very rapidly (Fig. 41–14). This procedure can also be done using nonradioactive oligonucleotide probes immobilized to filters, so-called reverse dot blot analysis.[445,446] Single-base mutations can also be detected by the PCR technique called amplification refractory mutation system (ARMS).[442,457] An amplification and direct sequencing of the β-globin genes (in cases in which the mutation is unknown) can also be carried out rapidly by use of PCR techniques.

Genetic counseling and antenatal diagnosis should be offered to all families at risk for severe α- or β-thalassemia. Prenatal diagnosis is one component of large-scale screening, education, and genetic counseling programs that are active in Italy, Greece, Cyprus, and other areas where the frequency of thalassemia is very high.[448] In some countries, particularly those with a high rate of consanguineous marriages, screening efforts can be refined to gain further efficiency in identifying at-risk couples.[449] Comprehensive programs of education, screening, and diagnosis have dramatically decreased the incidence of thalassemia major births in several countries (Fig. 41–15),[448,458,459] but they require a critical mass of expert professionals and laboratory back-up. Voluntary informed participation, confidentiality of results, and meaningful counseling must be ensured.

α-THALASSEMIA SYNDROMES

The α-thalassemias are more difficult to diagnose, because characteristic elevations in Hb A_2 or Hb F, seen in many cases of β-thalassemia, do not occur. However, the gene deletions responsible for the most common varieties are readily detectable by molecular biology methods.

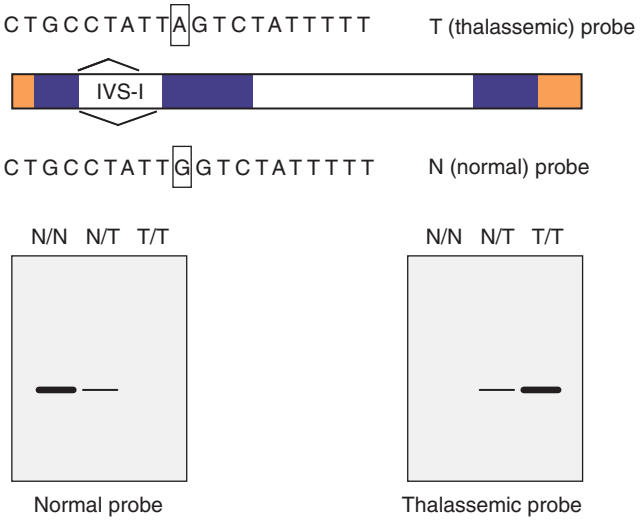

Figure 41–14 Example of the use of allele-specific oligonucleotide probes for diagnosis of a common form of β-thalassemia. The mutation shown is that discussed in Figure 35–2 and the text. Two oligonucleotide probes are synthesized, differing only at the position of the mutation. When hybridized under sufficiently stringent conditions, each probe will anneal only to the gene that is perfectly complementary by Watson–Crick base-pairing. Thus, a homozygous normal fetal DNA sample (N/N) will anneal only to the normal probe, homozygous β-thalassemic DNA (T/T) only to the thalassemic probe, and DNA from a heterozygote (N/T) to both probes, but with a reduced intensity to each. *(Adapted from High KA, Benz EJ Jr: The ABCs of molecular genetics: A haematologist's introduction. In Hoffbrand AV [ed.]: Recent Advances in Haematology. New York, Churchill Livingston, 1985, p 25.)*

Molecular Pathology and Pathophysiology

The four classic α-thalassemia syndromes are α^+-thalassemia trait, in which one of the four α-globin genes fails to function; α°-thalassemia trait, with two dysfunctional genes; Hb H disease, with three affected genes; and hydrops fetalis with Hb Bart, in which all four genes are defective. In the older literature, α°- and α^{++}-thalassemia are referred to as α-thalassemia-1 and α-thalassemia-2, respectively. These syndromes are usually caused by deletion of one, two, three, or all four of the α-globin genes, respectively (Fig. 41–16). Nondeletional forms of α-thalassemia, which account for 15% to 20% of patients, arise from mutations similar to those described for β-thalassemia.[460,461] Figure 41–17 illustrates the different α-thalassemia mutations and phenotypes. Structurally abnormal hemoglobins have also been associated with α-thalassemia. The Quong Sze α-globin chain ($\alpha^{125Leu\rightarrow Pro}$) is exceedingly labile and is destroyed so rapidly after its synthesis that no hemoglobin tetramers containing the mutant α chain can be formed.[462]

α^+-Thalassemia trait is an asymptomatic silent carrier state that is commonly associated with the deletion of a single α-globin gene. Offspring of an individual with α^+-thalassemia whose spouse has α°-thalassemia trait can inherit a form of α-thalassemia more severe than either of these, namely Hb H disease.

α°-Thalassemia trait results from deletion or nonfunction of two α-globin alleles. In Asian and Mediterranean populations, a deletion that removes both loci from the same chromosome (*cis* deletion) is common[460,461]; homozygosity for α^+-thalassemia (*trans* deletion) is also seen. In African Americans, both α-globin genes are only rarely deleted in *cis*, whereas homozygosity for α^+-thalassemia (*trans* deletion) is quite common.[463] Both genotypes produce asymptomatic hypochromia and microcytosis. Hb H disease usually results from coinheritance of the *cis* α°-thalassemia deletion and α^+-thalassemia trait. α-Globin chain production is only 25% to 30% of normal; excess γ-globin chains accumulate during gestation and excess β-globin chains during adult life (Fig. 41–17). The unpaired β-globin

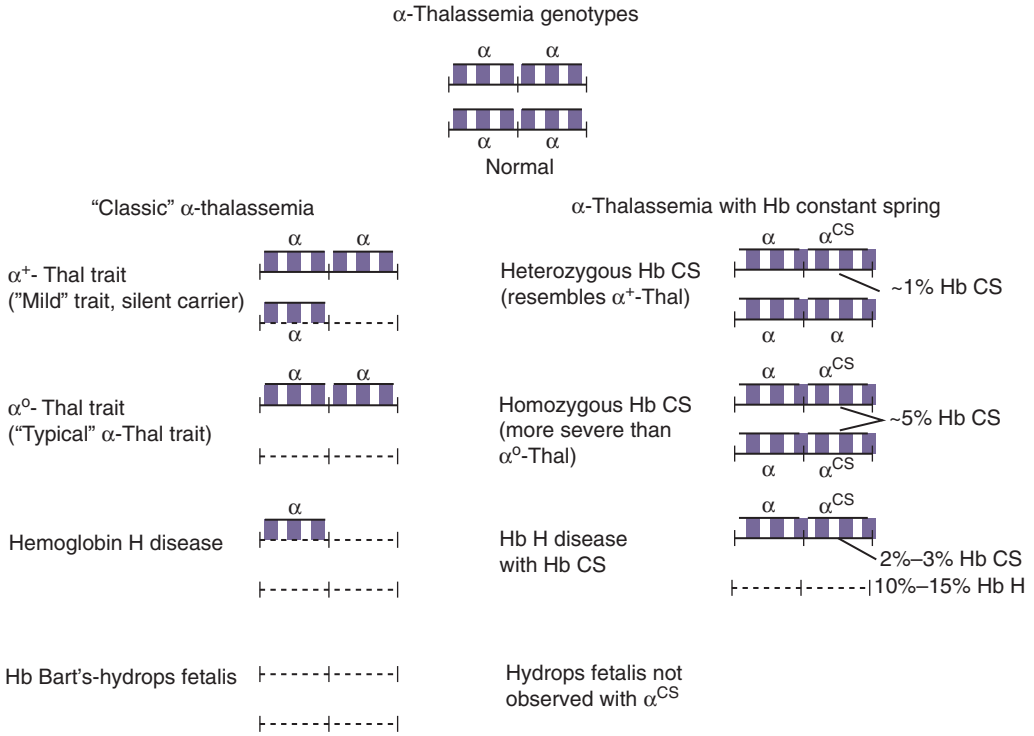

Figure 41–16 Genetic origins of the "classic" α-thalassemia syndromes due to gene deletions in the α-globin gene cluster. Hb Constant Spring (Hb CS) is an α-globin chain variant synthesized in such small amounts (1%–2% of normal) that it has the phenotypic impact of a severe nondeletion α-thalassemia allele; however, the α^{cs} allele is always linked to a functioning α-globin gene, so it has never been associated with hydrops fetalis.

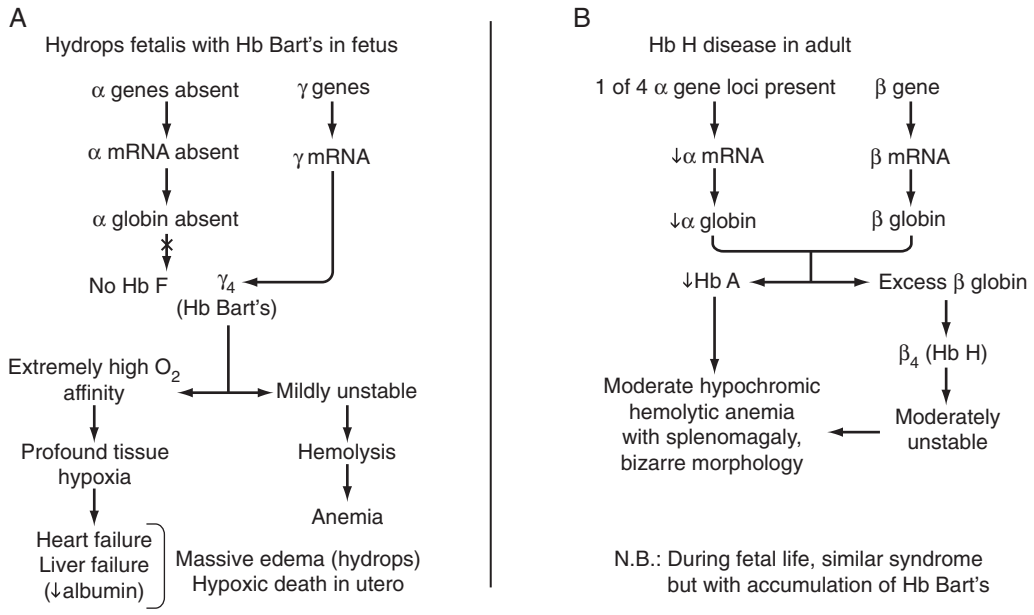

Figure 41–17 Pathophysiology of Hb H disease and hydrops fetalis with Hb Bart. *(Adapted from Benz EJ Jr: The hemoglobinopathies. In Kelly WN, DeVita VT [eds.]: Textbook of Internal Medicine. Philadelphia, JB Lippincott, 1988, p 1423.)*

chains are somewhat more soluble than the excess α-globin chains that accumulate in cases of β-thalassemia, forming recognizable β4 tetramers designated as Hb H. Hb H forms relatively few inclusions in erythroblasts; rather, it precipitates slowly within mature circulating red blood cells. Patients with Hb H disease thus have a moderately severe hemolytic anemia but relatively little ineffective erythropoiesis. Patients usually survive into adult life. These clinical observations illustrate the central role of unpaired globin chains and ineffective erythropoiesis as determinants of clinical severity.

Hydrops fetalis with Hb Bart results from the homozygous state for the α°-thalassemia *cis* deletion. The α-globin genes are totally absent; no α-globin is produced, so no physiologically useful hemoglobin accumulates beyond the embryonic stage. Free γ-globin chains accumulate, forming γ_4 tetramers called Hb Bart (see Fig. 35–13). Hb Bart has an extraordinarily high oxygen affinity, comparable with that of myoglobin. It binds oxygen delivered to the placenta but releases almost none of it to fetal tissues. Severe hypoxia occurs at the tissue level, causing profound edema (hydrops), congestive heart failure, and, in most cases, death in utero. These fatal complications do not occur in fetuses with Hb H disease because enough Hb F is made to sustain life.

α⁺-Thalassemia trait is very common in black patients, having a genetic frequency of 20% to 30% in some populations. However, the *cis* α°-thalassemia deletion is rare in black patients. Thus, even though α⁺-thalassemia trait and the *trans* deletion form of α°-thalassemia are very common, Hb H disease is rarely encountered, and hydrops fetalis has not yet been reported in black patients.[463,464]

Clinical Manifestations

Silent Carrier (α⁺-Thalassemia Trait)

α⁺-Thalassemia trait has no consistent hematologic manifestations. The red blood cells are not microcytic, and Hb A_2 and Hb F are normal. During the newborn period, small amounts (≤3%) of Hb Bart (γ_4) can be seen by electrophoresis or other techniques. This condition is most often recognized when an apparently normal individual becomes the parent of a child with Hb H disease after mating with a person with α°-thalassemia trait. The mild excess of β-globin chains is probably removed in erythroblasts by proteolysis.[465] α⁺-Thalassemia is particularly common in Melanesia, as well as in Southeast Asia and in African Americans, reaching a prevalence of more than 80% in north coastal Papua New Guinea. At the molecular level, α⁺-thalassemia has been found to be associated with two common gene deletions resulting from different nonhomologous crossing-over events between the two linked α-globin genes: a 3.7-kb rightward deletion ($-\alpha^{3.7}$) resulting in a fused α2α1-globin gene, and a 4.2-kb leftward deletion ($-\alpha^{4.2}$) resulting in loss of the 5′ (α2) gene.[460,461,466] The level of α-globin gene expression differs in the two conditions, as discussed in the following section.

α-Thalassemia Trait (α°-Thalassemia Trait)

Levels of Hb A_2 in the low to low normal range (1.5%–2.5%) and β/α synthetic ratios averaging 1.4 : 1 characterize α°-thalassemia trait. During the perinatal period, elevated amounts of Hb Bart are noted (3%–8%). Microcytosis is present in cord blood erythrocytes.

Studies of newborns from the archipelago of Vanuatu in the southwest Pacific and from Papua New Guinea indicate that homozygotes for the rightward $-\alpha^{3.7III}$ deletion (where only a fused α2α1-globin gene, mostly of the α2 type, remains) have lower Hb Bart levels (3.5% ± 0.8%) than those of infants homozygous for the leftward $-\alpha^{4.2}$ deletion (where only the α1-globin gene remains) (6.0% ± 1.4%). These results suggest that the 5′ α2-globin gene has a higher output than the 3′ α1-globin gene, a conclusion supported by direct measurement of α2/α1 mRNA ratios.[467,468]

Hb H is not detected in hemolysates of peripheral red blood cells, probably because of rapid proteolysis of Hb H or free β-globin chains. However, approximately 1% of erythroblasts and marrow reticulocytes have inclusions. When an α-thalassemia gene occurs in persons who are also heterozygous for β-globin chain variant hemoglobins, such as Hb S, Hb C, or Hb E, the proportion of the abnormal hemoglobin is lower than that seen in simple heterozygotes.[469] The lower level of the abnormal hemoglobin is due to posttranslational control because of higher affinity of β^A chains for a limited pool of α-globin chains,[470] coupled with proteolysis of the uncombined $\beta^{variant}$ chains.

Hb H Disease

Hb H disease is associated with a moderately severe but variable anemia resembling thalassemia intermedia, with osseous changes and splenomegaly.[471] However, the clinical phenotype may be consider-

ably milder in some patients and severe enough to cause hydrops fetalis in others.[472,473] It occurs predominantly in Asians and occasionally in whites (Mediterraneans) but is rare in blacks. Exacerbations of anemia during febrile illnesses are common and are usually characterized by increasing fatigue and jaundice.

Because Hb H is unstable and precipitates within the circulating red blood cells, hemolysis occurs. Hb H can be demonstrated by incubation of blood with supravital oxidizing stains such as 1% brilliant cresyl blue. Multiple small inclusions form in the red blood cells (see Fig. 41–17). Electrophoresis of a freshly prepared hemolysate at alkaline or neutral pH demonstrates a fast-moving component amounting to 3% to 30% of the total hemoglobin. Concomitant iron deficiency may reduce the amount of Hb H in the patient's red blood cells.[474] A syndrome of Hb H disease associated with mental retardation, other congenital anomalies, and large deletions on chromosome 16 has been noted in several white families.[475,476]

Hydrops Fetalis With Hb Bart

Hydrops fetalis with Hb Bart occurs almost exclusively in Asians, especially Chinese, Cambodians, Thais, and Filipinos. Affected fetuses usually are born prematurely and either are stillborn or die shortly after birth.[1–4] Marked anasarca and enlargement of the liver and spleen are present. Severe anemia usually is present, with hemoglobin levels of 3 to 10 g/dL. The red blood cells are markedly microcytic and hypochromic and include target cells and large numbers of circulating nucleated red blood cells. These morphologic abnormalities and a negative Coombs test result exclude hemolytic diseases due to blood group incompatibility. Hemoglobin electrophoresis reveals predominantly Hb Bart, with a smaller amount of Hb H. A minor component identified as Hb Portland ($\zeta_2\gamma_2$) migrating in the position of Hb A is also seen. Normal Hb A and Hb F are totally absent.[477]

Hydropic infants have massive hepatosplenomegaly. Extreme extramedullary erythropoiesis occurs in response to the profound hypoxia and hemolytic anemia characteristic of this disease. The universal edema characteristic of the hydrops fetalis syndrome is a reflection of severe congestive heart failure and hypoalbuminemia in utero. This is partly a consequence of anemia, but the strikingly abnormal oxygen affinity of the tetrameric Hb Bart is probably the most important determinant of the severe tissue hypoxia. The oxygen dissociation curve of Hb Bart lacks the normal sigmoid form because of noncooperativity during oxygen loading and unloading and is markedly shifted to the left. The shift is so great that little oxygen is released under conditions of low oxygen concentration in the tissues.

Infants with this syndrome do not die in an earlier trimester of pregnancy because of the presence of Hb Portland ($\zeta_2\gamma_2$). This hemoglobin does display cooperativity in a manner similar to that of Hb F and therefore has a much more favorable oxygen dissociation pattern than that of Hb Bart. A high incidence of toxemia of pregnancy has been described in women carrying severely affected infants, providing an increased rationale for prenatal diagnosis of this condition.

Prenatal Diagnosis of α-Thalassemia

Using molecular hybridization technology, Dozy and associates detected the complete absence of α-globin genes in fetal fibroblasts obtained by amniocentesis in a pregnancy at risk of homozygous α^o-thalassemia and the hydrops fetalis syndrome.[478] A quantitative PCR method provides similar information rapidly and accurately.[479] The presence of hydrops can also be detected by ultrasonography. DNA studies or globin synthesis evaluation may be used to confirm the diagnosis in utero. PCR-based assays are available for the detection of the common α-thalassemia deletions.[479–482]

Therapy

Fetuses with homozygous α^o-thalassemia usually die in utero because of severe hydrops fetalis and are stillborn. However, some infants have had successful blood exchange transfusion immediately after birth.[483–487] It is also possible to salvage affected fetuses by in utero blood transfusions.[488,489] Limb and urogenital defects are present in a substantial portion of infants with homozygous α^o-thalassemia who are rescued by these measures, and some infants have developmental delay or other neurologic abnormalities. Management after the perinatal period is similar to the management of patients with thalassemia major and includes transfusion and chelation therapy as well as the possibility of bone marrow transplantation.[490]

Many patients with Hb H disease do not require red blood cell transfusions. For patients with more severe disease, characterized by lower hemoglobin levels or frequent exacerbations of the anemia, splenectomy can be helpful. Oxidant drugs can accelerate precipitation of Hb H and exacerbate hemolysis; they should therefore be avoided.

Infants with heterozygous α^o-thalassemia trait lose their Hb Bart during the first few months of life and are left with the hematologic findings of α-thalassemia trait, a mild hypochromic microcytosis that persists throughout life.[1] The degree of morphologic abnormality varies greatly among different individuals. That α-thalassemia can be easily diagnosed by hemoglobin electrophoresis at birth gives some impetus to cord blood screening studies. Confusion between heterozygous α^o-thalassemia trait and iron deficiency may lead to unnecessary evaluations for possible blood loss or unnecessary supplementation with iron unless the overlap in hematologic findings is recognized and more specific diagnostic studies are performed.

De Novo and Acquired Forms of α-Thalassemia

Two distinct α-thalassemia syndromes have been described that are due to acquired or de novo mutations: (a) α-thalassemia associated with mental retardation and (b) Hb H disease associated with myelodysplastic syndromes.

α-Thalassemia Associated With Mental Retardation

α-Thalassemia or Hb H disease can occur as a de novo abnormality in a rare disorder called the α-thalassemia with mental retardation syndrome (or ATR).[475–476] In this disorder, affected patients have mental retardation and a number of other developmental abnormalities in association with α-thalassemia trait or Hb H disease that is inherited in a nontraditional manner. Two distinct types of the ATR syndrome have been identified. In some cases, there is the de novo appearance of large (2000 kb or so) deletions involving the entire α-globin gene cluster and adjacent DNA at the tip of chromosome 16, the so-called ATR-16 syndrome. In some of these patients, the deletion produces detectable cytogenetic abnormalities of chromosome 16, indicating that a very large segment of the chromosome is deleted, sometimes because of unbalanced chromosomal translocations involving the telomeres of the affected chromosomes. In some cases, one parent is heterozygous for α^+-thalassemia by various criteria and the other parent is completely normal; in such cases, the child has Hb H disease (−−/−α). In other cases, both parents are normal and the affected child has the hematologic phenotype of heterozygous α^o-thalassemia (−−/αα) without Hb H disease. In this form of ATR, the clinical findings, such as the degree of mental retardation and associated congenital abnormalities, are variable.

The second type of ATR syndrome is not associated with detectable deletions of the α-globin gene complex. The molecular basis of the disorder consists of mutations of a gene on the X chromosome and the condition has been called the ATR-X syndrome.[491] In contrast to patients with the ATR-16 syndrome who have a varied phenotype of developmental abnormalities, patients with the ATR-X

syndrome have a more uniform or consistent phenotype, in particular, severe mental retardation (with IQs of 50–70) and a characteristic dysmorphic facial appearance.[476]

The affected gene in this syndrome encodes a *trans*-acting factor, called ATRX, that is thought to influence the expression of the α-globin genes as well as that of other genes.[492,493] The structure of this large (280 kd) DNA-binding protein is complex and contains two major functional domains: an N-terminal cysteine-rich zinc finger–containing domain, called the ADD domain, that has structural features similar to those of DNA methyl transferases; and a C-terminal helicase/ATPase domain. The majority of the mutations associated with the ATR-X syndrome are located in the ADD domain or the helicase domain. The ATRX protein is widely expressed in many different tissues and its intracellular localization is within three different nuclear subcompartments: heterochromatin, ribosomal DNA arrays, and PML bodies. It has been shown to interact with other proteins such as the heterochromatin-associated protein HP1 and Daxx, one of the proteins localized in PML bodies. The prevailing opinion is that the ATRX protein is part of a large chromatin-remodeling complex of the SWI2/SNF2 family. It also has ATPase activity and has translocase activity, that is, it can move along DNA as a "molecular motor." The precise mechanism(s) by which ATRX influences the expression of α-globin (and other) genes remains unknown.

Acquired Hb H Disease Associated With Myelodysplastic Syndrome or ATMDS

Hb H disease has occasionally been observed to develop during the course of different types of myelodysplastic syndrome (MDS) and more rarely in patients with other hematologic malignancies.[494] The disorder usually affects elderly males over the age of 60. The degree of imbalance of globin chain synthesis and of α-globin mRNA deficiency in erythroid cells of affected patients is greater than that observed in the hereditary type of Hb H disease. It is conceivable that erythroid cells of the abnormal clone synthesize no α-globin chains at all and that the expression of all four α-globin genes is suppressed or silenced,[495] but this phenomenon is difficult to document in total blood as long as some normal erythroid cells are being produced.

Until recently, the molecular basis of this fascinating disorder remained unknown. Cytogenetic, gene mapping, gene sequencing, and gene or chromosome transfer studies failed to detect any deletion or mutation in the α-globin gene cluster or functional abnormality of α-globin gene of affected patients. The results of all of these prior studies suggested that the defect responsible for this disorder probably involved the abnormal expression or function of a *trans*-acting factor capable of influencing α-globin gene expression and, indeed, such a factor was recently identified. The discovery of the factor responsible for Hb H disease in MDS results from cDNA microarray analysis of RNA isolated from granulocytes of an affected patient. One of the genes that was found to be markedly underexpressed, when compared to results obtained with RNA of normal granulocytes, was the ATRX gene,[496] the same gene that is mutated in the α-thalassemia with mental retardation syndrome of the ATR-X type. Sequence analysis of the ATRX gene in the DNA of blood cells of affected individuals has identified a number of different mutations. It is noteworthy that the mutations of the ATRX gene associated with acquired Hb H disease associated with MDS (ATMDS) occur in the same regions of the gene as the mutations associated with the ATR-X syndrome, that is, in the ADD or helicase domains. In fact, some of the ATRX gene mutations identified in ATMDS are identical or similar in expected functional consequences to various mutations found in the ATR-X syndrome.

The hematologic features in the syndrome are characterized by the presence on blood smear of a dimorphic red cell population, one of which is hypochromic, microcytic, hypochromic, and poikilocytic. Incubation of the blood with the supravital stain brilliant cresyl blue results in the detection of typical Hb H inclusions. Hemoglobin electrophoresis or HPLC detects the presence of Hb H, usually in greater quantities than that typically observed in inherited Hb H disease. In typical MDS, the MCV of the erythrocytes is normal or elevated, frequently higher than 100 fL. However, in ATMDS, the MCV and MCH are low: MCV usually less than 80 fL and MCH usually less than 26 pg.[494] The amount of Hb H usually remains stable, but may actually decrease during the course of the disease and no longer persists after transformation of MDS to acute leukemia. This finding suggests that the Hb H-producing clone does not have a selective survival or growth advantage.

The hematologic phenotype, as reflected by the amount of Hb H present in blood, of ATMDS is much more severe than that of the ATR-X syndrome.[492] Some of this difference in severity may be due to the nature of the ATMDS mutations, some of which are null mutations that are likely to be lethal when present in germline DNA of ATR-X embryos. However, the difference in severity is also observed in the case of mutations found in both syndromes that are identical or similar in expected functional consequences. This finding suggests that additional abnormalities in gene expression in ATMDS contribute to the severity of the deficit in α-globin gene expression observed in this syndrome. Perhaps the responsible defective cofactor(s) is one or more of the proteins that interact with the ATRX protein to produce a fully functional macromolecular complex that can act as a transcriptional cofactor or that can influence the epigenetic control of α-globin gene expression.

THALASSEMIC STRUCTURAL VARIANTS

Certain structural hemoglobin variants are characterized by the presence of a biosynthetic defect as well as abnormal structure.[6] Thalassemic hemoglobinopathies are unusual forms of thalassemia caused by such structural variants.

Hb Lepore

Hb Lepore ($\alpha_2\beta\delta$) is the prototype of a group of hemoglobinopathies characterized by fused globin chains.[1–4] The chains begin with a normal δ-chain sequence at their N-terminus and end with the normal β-chain sequence at their C-terminus. These hemoglobinopathies arise by unequal or nonhomologous crossover or recombination events that fuse the proximal end of one gene with the distal end of a closely linked structurally homologous gene (Fig. 41–18). During meiosis, mispairing and crossover of the highly homologous δ- and β-globin genes can occur, resulting in a Lepore chromosome, which contains (in addition to γ-globin genes) only the fused δβ gene, and an anti-Lepore chromosome, which contains the reciprocal fusion product (βδ), as well as intact δ- and β-globin genes.[1]

Lepore globin is synthesized in low amounts, presumably because it is under the control of the δ-globin gene promoter, which normally sustains transcription at only 2.5% the level of the β-globin gene.[497] Patients with Hb Lepore have the phenotype of β-thalassemia, distinguished by the added presence of 5% to 15% Hb Lepore. In contrast, the anti-Lepore globin (Miyada) is not associated with a β-thalassemia phenotype because of the presence of an intact and functionally normal β-globin gene on the same chromosome.

Heterozygotes for Hb Lepore have the clinical phenotype of β-thalassemia trait; homozygotes are usually similar to patients with homozygous β-thalassemia. Compound heterozygotes for Hb Lepore and a "classic" β-thalassemia allele usually have severe thalassemia. Hb Lepore thus interacts with thalassemia in the same way that a severe β-thalassemia gene does, although occasional cases have a milder phenotype of the thalassemia intermedia variety, perhaps because of an associated higher than usual level of γ-globin gene expression. The presence of Hb Lepore should be suspected in individuals with a microcytic, hypochromic anemia who also have a small amount of an abnormal hemoglobin migrating in the position of Hb S on routine hemoglobin electrophoresis. Hb Lepore accounts for

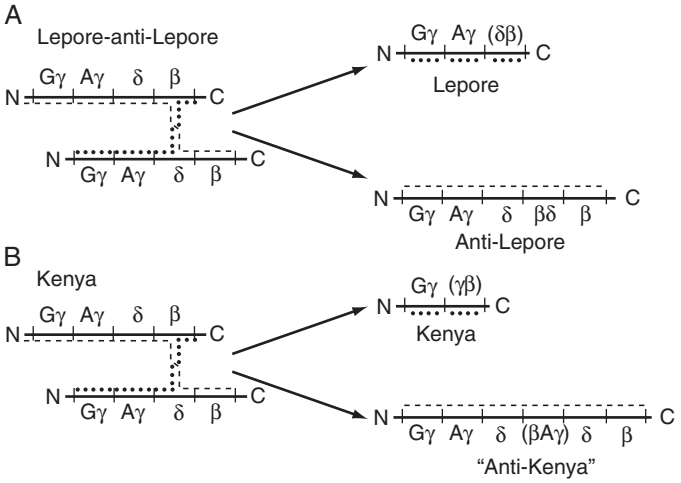

Figure 41–18 Genetic origins of Hb Lepore, anti-Lepore Hb, and Hb Kenya. *(Adapted from Benz EJ Jr: The hemoglobinopathies. In Kelly WN, DeVita VT [eds.]: Textbook of Internal Medicine. Philadelphia, JB Lippincott, 1988, p 1423.)*

5% to 10% of the β-thalassemias seen in Greek and Italian populations. Several forms of Hb Lepore have been described that differ in the position at which the transition from δ to β DNA and amino acid sequence occurs.

An analogous but rare variant, Hb Kenya [$\alpha_2(^{A}\gamma\beta)_2$], arises from nonhomologous crossing over between the $^{A}\gamma$- and β-globin genes[498] (see Fig. 41–14) and is associated with the phenotype of $^{G}\gamma$ HPFH. A DNA sequence approximately 600 bases downstream from the β-globin gene acts as a strong enhancer, promoting the erythroid-specific expression of the β-globin genes in adult cells.[3,4,21] The fused $^{A}\gamma\beta$ gene as well as the linked upstream $^{G}\gamma$ gene are believed to come under the influence of the enhancer, because of its abnormal proximity, and thus are expressed at high levels in adult life.

Hb E

Hb E ($\alpha_2\beta_2^{26Glu\rightarrow Lys}$) is a common variant (15%–30% of the population) in Cambodia, Thailand, parts of China, and Vietnam. Hb E is very mildly unstable, but this instability does not significantly alter the life span of red blood cells. Hb E trait resembles very mild β-thalassemia trait. Homozygotes exhibit more microcytosis but are still asymptomatic.[499] Compound heterozygotes for Hb E and a β-thalassemia gene (Hb E–β-thalassemia) resemble patients with β-thalassemia intermedia or β-thalassemia major. However, some problems such as infection and pulmonary hypertension may occur more commonly in Hb E–β-thalassemia than in homozygous β-thalassemia.[500]

The only nucleotide sequence abnormality found in the β^{E}-gene is a base change in codon 26 that causes the amino acid substitution. This mutation, which occurs in a potential cryptic RNA splice region, alters the consensus sequence surrounding a potential GT donor splice site and thus activates the cryptic site. Alternative splicing at this position occurs approximately 40% to 50% of the time, generating a structurally abnormal globin mRNA that cannot be translated appropriately.[501] The other mRNA precursors are spliced at the normal site, generating functionally normal mRNA, which is translated into β^{E}-globin because the mature mRNA retains the base change that encodes lysine at codon 26.

Hb E is important because it is so common in Southeast Asian populations. With increased emigration of Southeast Asians to North America, Hb E syndromes are being seen there with increased frequency.[502,503] Genetic counseling of these individuals should emphasize the potential consequences of the interaction of Hb E with β-thalassemia. Hb E is also an instructive example of the pleiotropic effects that point mutations can have on the amounts and types of gene products derived from a single mutant gene.

Hb Constant Spring

Hb Constant Spring (see Fig. 41–16) is an elongated α-globin variant resulting from a mutation that alters the normal translation termination codon.[504] Polyribosomes read through the usual translation stop site and incorporate an additional 31 amino acids until another in-phase termination codon is reached within the 3′ untranslated sequence. The amount of α^{cs} mRNA is markedly reduced, and α^{cs}-globin is synthesized in only minute amounts.[466,505] Six possible mutations of the normal translation termination codon (UAA) in α-globin mRNA could result in the generation of a "sense" codon.[506] Of these, five variants have been identified, each having a markedly underproduced abnormal variant, indicating that disruption of normal translation termination is in some way associated with abnormal mRNA accumulation, presumably due to instability of the mRNA.[466] The output of α-globin from the α^{cs} allele is only approximately 1% of normal, and the gene is thus rendered α-thalassemic. The α^{cs} allele has been identified only on chromosomes containing a *cis*-linked functionally normal α-globin gene.[1–4] Thus, α^{+}-thalassemia trait and Hb H disease ($^{-}/\alpha^{cs}\alpha$) associated with Hb Constant Spring are common, but hydrops fetalis due to four abnormal α-globin genes cannot occur in association with this variant. Homozygosity for the variant is associated with a relatively mild form of Hb H disease.[1]

EXTRAORDINARILY UNSTABLE HEMOGLOBINS

Rare cases of α-thalassemia (eg, Hb Quong Sze[462]) and β-thalassemia (eg, Hb Indianapolis, recently renamed Hb Terre Haute[507,508]) arise from mutations that produce extremely labile globin chains. The chains fail to pair with the complementary chain, or they precipitate and are degraded so rapidly that they never form tetramers. These posttranslational lesions have the same pathophysiologic effects on hemoglobin biogenesis as reduction of globin mRNA production or function. Another group of β-globin chain variants, usually due to mutations in exon 3 of the β-globin gene, are associated with inclusion body formation and a phenotype of dominant β-thalassemia intermedia.[16,17,509]

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

Hereditary persistence of fetal hemoglobin (HPFH) consists of a group of rare conditions characterized by continued synthesis of high levels of Hb F in adult life.[1,510–512] No deleterious effects on patients are observed, even when 100% of the hemoglobin produced in HPFH homozygotes is Hb F. These patients thus demonstrate convincingly that prevention or reversal of the Hb F–to–Hb A switch would provide efficacious therapy for β-thalassemia.

Two major types of HPFH have been described. Very high levels of fetal hemoglobin synthesis and uniform distribution of Hb F among all red blood cells characterize pancellular HPFH. Heterocellular HPFH results from inherited increases in the number of F cells (see Chapters 25 and 33).

HPFH shows ethnic differences. In black patients with heterozygous pancellular deletional HPFH, the Hb F is within a range of 15% to 35% and contains $^{G}\gamma$ and $^{A}\gamma$ chains in a ratio of 2:3. In Greeks with pancellular nondeletional HPFH, Hb F levels are lower, 10% to 20%, and the Hb F is 90% of the $^{A}\gamma$ type. Hb A_2 levels are lower than normal. There are usually no other hematologic abnormalities in these persons, although β/α-globin chain synthesis ratios may be lower in some black heterozygotes.

A few black patients have been described with homozygous HPFH. All hemoglobin within the red blood cells of these patients is Hb F. Mild microcytosis and hypochromia of the red blood cells are present without anemia. In fact, hemoglobin levels are mildly

elevated, presumably due to increased erythropoiesis stimulated by the left-shifted oxygen dissociation curve of red blood cells rich in Hb F. Globin chain synthesis reveals a γ/α synthetic ratio of approximately 0.5.

Pancellular HPFH can be divided into two classes. The deletional forms arise from large deletions within the β-globin gene cluster that remove the δ- and β-globin genes, part of the γδ intergenic DNA, and DNA downstream (to the 3′ side) from the β-globin genes.[1,510–512] The deletions appear to bring enhancer sequences into the proximity of the remaining γ-globin genes, promoting their high expression. Homozygotes for this condition produce only Hb F. In nondeletional HPFH, the β- and δ-globin genes are present. Single-base changes have been shown to occur in the promoter regions of either the ^{A}γ- or ^{G}γ-globin gene, resulting in overexpression of that form of Hb F.[1,510–512] In these individuals, Hb F levels rarely account for more than 20% of total hemoglobin.

A case of HPFH/β-thalassemia resembles β-thalassemia trait except for a higher proportion and regular distribution of Hb F in the red blood cells.[1]

In δβ-thalassemia and HPFH patients, persistence of Hb F after the period of perinatal Hb F to Hb A switching is more marked than in patients with the "classic" (high Hb A_2) forms of thalassemia. Indeed, δβ-thalassemia and HPFH represent various degrees of the same genetic phenomenon. Both conditions frequently arise from deletions of DNA that remove or inactivate the β-globin gene.[1,510–512]

Heterocellular HPFH appears to result in many cases from mutations outside the β-globin gene cluster.[512] One controlling locus resides on the X chromosome.[513,514] Patients with these conditions probably represent the extreme end of a distribution of polymorphic capacities to produce F cells in adult life. Hb F levels are usually much lower than those in the pancellular forms. In some situations, elevated levels of Hb F are seen in otherwise normal individuals. In others, the high levels of Hb F become apparent only when other factors producing erythroid stress are present.

CHAPTER 42

PATHOBIOLOGY OF SICKLE CELL DISEASE

Robert P. Hebbel

Since it was identified as the first molecular disease in 1949,[2] sickle cell disease which is caused by the mutant sickle cell hemoglobin (HbS), has provided the classic paradigm for understanding single-gene disorders. The predominant clinical features of this condition include hemolytic anemia, episodic painful events, chronic organ deterioration, and various acute complications.[1] However, the genesis of clinical sickle cell disease is exceedingly complicated, and an understanding of its pathophysiology integrates concepts from multiple disciplines, includes contributions from the red blood cell (RBC) membrane and the vascular wall endothelium, and recognizes the likely participation of multiple genetic influences. This chapter addresses the pathophysiology that underlies the sickle cell disease syndromes described in Chapter 43.

EARLY YEARS OF SICKLE CELL DISEASE RESEARCH

Sickle cell disease probably was recognized for centuries in some parts of Africa,[3] but it was first reported in the medical literature in 1910, when Herrick described a young Grenadan man with recurrent pain, anemia, and sickle-shaped red corpuscles in the blood (Fig. 42–1).[4] Early milestones in elucidating the basis of this disorder included demonstration that reversible sickling is induced by deoxygenation (Fig. 42–2), recognition of a carrier state, and observation that sickled RBCs contain protein having unusual properties.[5] In 1940, Ham and Castle[6] described a PO_2 threshold for concomitant induction of sickling and hyperviscosity, from which they postulated that sickle cell pathophysiology resulted from a "vicious cycle of erythrostasis" involving mutually promotive sickling and viscosity changes. In 1949, Neel[7] recorded the Mendelian genetics of sickle cell anemia, and Pauling and colleagues[2] used protein electrophoresis to directly demonstrate the presence of abnormal hemoglobin in patients and carriers. This was followed by observation of the reversible sol-gel transformation[8] and the insolubility[9] of deoxygenated HbS solutions. In 1957, Ingram[10] identified the molecular basis of the mutant HbS. Thereafter, increasingly detailed investigations began to reveal the striking complexities of sickle cell disease pathobiology.[1]

GENETIC CONSIDERATIONS

Molecular Context

The sickle mutation in the β-globin gene is a GAG→GTG conversion that creates a $\beta^{6Glu\rightarrow Val}$ substitution and thereby forms β^S globin chains. The β-globin gene is represented by a single copy on each chromosome 11, and other β-globin disorders can be allelic to the sickle gene and have a codominant impact on the clinical phenotype. Examples include the gene for the normal β chain (β^A), β mutants (eg, β^C), β°- or β⁺-thalassemia, and hereditary persistence of fetal hemoglobin (HPFH). Compound heterozygosity for β^S and each one of these forms results in well-defined clinical syndromes, such as HbAS (ie, sickle trait), HbSC disease, HbS β-thalassemia, and HbS HPFH. Eight percent of African Americans have a β^S gene, 3% have β^C, 1.5% have β-thalassemia, and 0.1% have HPFH.[11] Among African Americans, about 1 in 600 births results in the homozygous state, sickle cell anemia (HbSS), and about 1 in 400 results in a form of sickle cell disease.

Residing within a cluster of β-like genes, the β-globin gene is in linkage disequilibrium with multiple nearby polymorphic sites. Different combinations can be identified by restriction endonuclease cleavage, which thereby defines discrete β-locus haplotypes. This approach has revealed that the β^S gene tends to reside on one of several distinct chromosomal patterns, referred to as the Senegal, Benin, Bantu, Cameroon, and Arab-India haplotypes (Fig. 42–3A).[12] Each designation refers to an ethnographic region in which the sickle gene achieved polymorphic frequency (see Fig. 42–3B), with gene frequency peaking at 0.10 to 0.15 (perhaps even 0.20 in West Africa)[3] and diminishing as distance from the regional center increases.[12] Gene frequency is stated as fraction of all chromosomes, and the proportion of individuals with the mutation is about twice the gene frequency. The Cameroon haplotype occurs within a single ethnic group, beyond which expansion did not occur, and the India-Arab haplotype has two centers of high gene frequency, one in India and one in the eastern Arabian Peninsula. In most cases, the sickle gene resides on one of these five major haplotypes. Other haplotypes occur uncommonly, but these are largely explained by recombination events at a "hot spot" near the ψβ gene.[12]

Origin, Selection, and Dispersion of the Sickle Gene

Within the ethnographic regions defined by major β haplotypes, β^A and β^S alleles tend to reside on the distinct regional type of chromosome 11, suggesting that the sickle mutation arose independently in the five locations.[12] The β^C mutation arose only once. Historical and biologic data argue that frequency of the β^S gene greatly expanded in Africa 2000 to 3000 years ago and in Asia about 4000 years ago.[13] Its high prevalence suggests positive selection, and it is proposed that the introduction of iron tools led to adoption of an agricultural system that promoted increased human habitation density and favorable breeding conditions for the mosquito vector, *Anopheles.*[14,15] This allowed development of endemic *Plasmodium falciparum*, the most virulent of human malarias. In this context, high β^S gene frequencies were reached because of a balanced polymorphism, such that heterozygotes (HbAS) have an adaptive advantage over homozygotes (HbAA or HbSS). Consistent with this scenario, there is a remarkable concordance of geographic distributions of the sickle gene and of historical endemic malaria in the Old World (see Fig. 43–2B). Thus, it has been suggested that the sickle gene represents "a biologic solution to a cultural problem."[15]

In hyperendemic areas, *falciparum* malaria uniformly infects the young and is the primary killer of children with sickle cell disease. However, those with sickle trait are less likely to develop high-level parasitemia, to have severe malaria, or to die.[13,16] At the level of the RBC, this protection probably reflects steps after successful initial invasion, and a number of mechanisms have been proposed.[13] One that seems particularly plausible links protection to the instability of HbS (discussed later) and splenic function.[17] In support, infection of normal RBCs with *P. falciparum* leads to hemoglobin denaturation, clustering of membrane protein band 3, opsonization by band 3 autoantibody, and enhanced erythrophagocytosis, even of the early ring forms.[18] This scenario presumably would be augmented for infected HbS-containing trait cells, leading to their clearance by the spleen. In mice, the protective effect of HbS is lost after splenectomy,[13] indicating that an autosplenectomized state may contribute

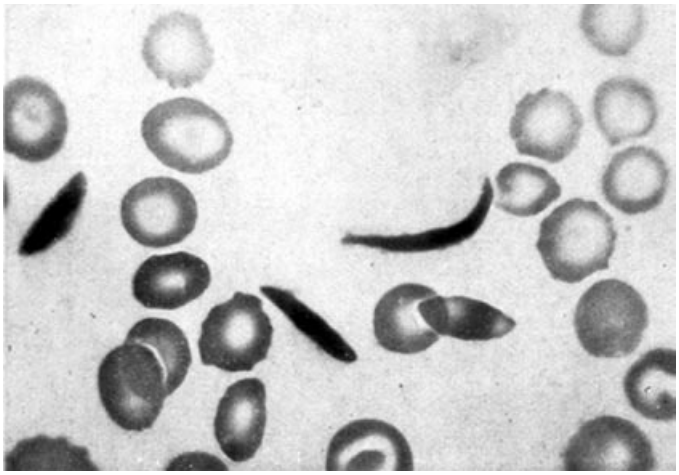

Figure 42–1 Blood smear from the first description of sickle cell disease. *(From Herrick JB: Peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia. Arch Intern Med 5:517, 1910.)*

to malarial virulence in HbS homozygotes. However, the timing of appearance of anti-band 3 autoantibodies in childhood is not defined, and the relationship of this scenario to the appearance of immune mechanisms of protection at about 2 years of age[19] is not known. Additional factors may be involved. Truncation mutations of CD36, a molecule implicated in the endothelial adhesion exhibited by sickle and *falciparum*-parasitized RBCs, exist at allelic frequencies in Gambians and may predispose them to severe malaria.[20]

Eventually, the sickle gene spread geographically by means of commerce, slave trading, and migration. This dispersion has been tracked by analyses of regional β haplotypes, a biologic marker that largely corroborates expectations of gene flow derived from known historical records.[12] As a generalization, it spread on the Benin haplotype to North Africa and then across the Mediterranean. All three major African haplotypes are present in the western Arabian Peninsula, but on the eastern side, the sickle gene tends to be on the Arab-India haplotype, as it is in south Asia. The gene arrived in the Americas mostly through the Atlantic slave trade, with Benin, Senegal, and Bantu haplotypes accounting for most β^S genes in the United States.

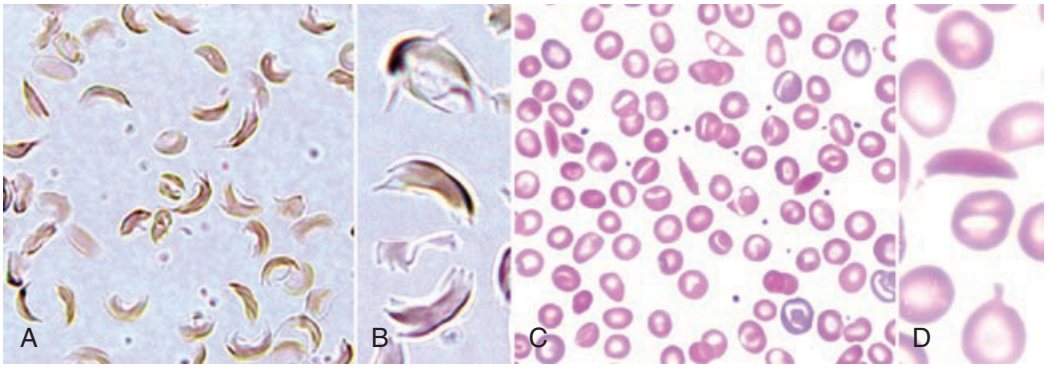

Figure 42–2 Sickle cells in deoxygenated sickle cell preparation compared to peripheral smear. Sickle cell preparation using sodium metabisulfate (**A, B**) to illustrate the marked degree of sickling of the majority of the cells in a deoxygenated state. Note the pointed ends of the sickle cells distorted due to the polymers of sickle hemoglobin. Some forms are called "holly-leaf" forms. In comparison, on the Wright-stained peripheral blood smear from same patient (**C, D**), the few sickle cells present are only those that remain irreversibly sickled due to membrane damage. These are referred to as "irreversibly sickled" cells.

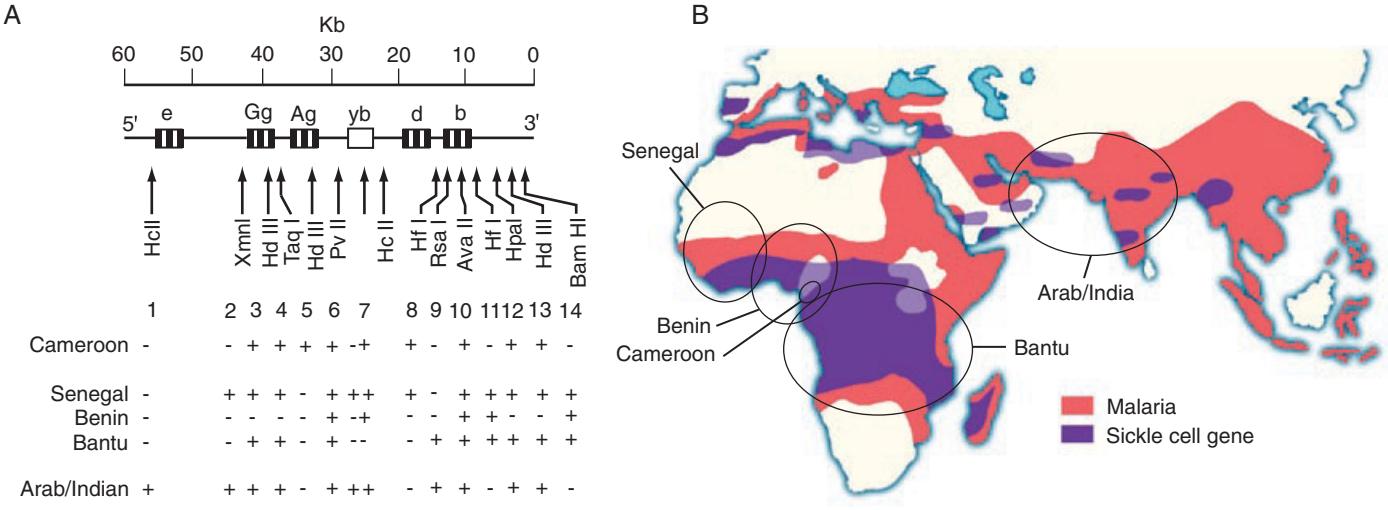

Figure 42–3 **A,** The β haplotypes are defined by polymorphic sites in the β-globin cluster. **B,** The corresponding regions in which the sickle gene achieved polymorphic frequency are superimposed on shading that identifies the Old World distribution of the sickle gene and of historical, endemic malaria. *(**A,** Adapted from Lapoumeroulie, Dunda O, Ducrocq R, et al: A novel sickle cell mutation of yet another origin in Africa: The Cameroon type. Hum Genet 89:333, 1992; **B,** adapted from Friedman MJ, Trager W: The biochemistry of resistance to malaria. Sci Am 244:154, 1981 and from Nagel RL, Steinberg MH: Genetics of the β^S gene: Origins, epidemiology, and epistasis in sickle cell anemia. Clinical Consequences of the Abnormal Molecular Behaviors of HbS

Tetramer assembly → RBC Hb composition
Genotype and diagnosis
Effect on sickling, therefore vasoocclusion
Hb stability → membrane defects
Hemolysis
Malaria resistance
Adhesion, therefore vaso-occlusion
Hb polymerization → sickling
Hemolysis
Vaso-occlusion

ABNORMAL MOLECULAR BEHAVIORS OF SICKLE HEMOGLOBIN

Because of its $\beta^{6Glu\rightarrow Val}$ substitution, entailing a loss of negative charge and gain in hydrophobicity, HbS exhibits three abnormal molecular behaviors of direct relevance to pathophysiology. (See box on Clinical Consequences of the Abnormal Molecular Behaviors of HbS.)

Hemoglobin S Charge and Tetramer Assembly

Formation of hemoglobin tetramers requires proximate assembly of stable dimers from unlike monomers (eg, $\alpha + \beta \rightarrow \alpha\beta$), which is governed by electrostatic attraction.[21] The normal α and β chains are positively and negatively charged, respectively. In heterozygous states for β-globin mutants, β-chain competition for dimer assembly is a determinant of the relative proportions of HbA versus non-HbA variants. Mutant β chains with lowered negative charge form $\alpha\beta$ dimers more slowly, and the relative rates for dimer association are $\alpha\beta^A > \alpha\beta^S > \alpha\beta^C$, with $\alpha\beta^A$ dimers formed about twice as rapidly as $\alpha\beta^S$ dimers.[21] This explains why individuals with sickle trait typically have only 40% rather than 50% HbS and why the proportion of HbS is higher in HbSC disease than in HbAS disease. It also explains the effect of concurrent α-thalassemia on the proportion of HbS in sickle trait; as availability of α chains becomes limiting, the percentage of HbS typically drops from 40% to 35% (one α deletion), 30% (two α deletions), or less than 25% (three α deletions).

Hemoglobin S Stability and Oxidant Formation

HbS is modestly unstable, observed in vitro as instability to various applied stresses,[22] but the underlying mechanism varies. Precipitation of HbS by mechanical agitation does not depend on hemoglobin oxidation, but rather reflects a surface denaturative tendency related to the hydrophobicity of the β^6 amino acid and tetramer-to-dimer dissociation. In contrast, the stresses that are more clearly physiologic depend on hemoglobin oxidation as a proximate event. HbS has an abnormal redox potential compared with HbA[23] that may underlie its increased autoxidation rate,[24] and it is unstable in response to oxidant drugs, adventitious iron, and interaction with aminophospholipids characteristic of the membrane's inner leaflet.[22] Although the physical-chemical basis for the destabilizing role of the β^6 valine in HbS is not known, this instability leads to accumulation of hemoglobin and iron on the RBC membrane and contributes to abnormal oxidative biochemistry at the cytosol-membrane interface.

Hemoglobin S Solubility, Hemoglobin S Polymerization, and Red Blood Cell Sickling

Oxy-HbS, oxy-HbA, and deoxy-HbA have very high solubilities, but deoxy-HbS aggregates into densely packed polymers, a process that is fully reversible on reoxygenation. This abnormal property forms the fundamental basis for the sickling disorders, the eponymous RBC shape change caused by polymer-mediated distortion.

Polymer Structure

Deoxygenation causes transformation of soluble HbS to a highly viscous and semisolid gel that behaves thermodynamically like a crystal in equilibrium with a solution of individual tetrameric Hb molecules.[25] Even complete deoxygenation does not convert all deoxy-HbS to polymer. The insoluble phase is a collection of domains of aligned polymers, the basic unit of which is a double strand in which two strings of deoxy-Hb tetramers make multiple contacts with each other (Fig. 42–4).[26] In the physiologic form of the polymer, the component strings of hemoglobin molecules in a double strand are half-staggered and have a slight twist, creating a fiber that is approximately 21 nM in diameter and is composed of one central and six peripheral double strands.[27] The crystal formed in vitro lacks the twist, but its molecular structure is known in detail.[28] Each HbS tetramer has two β chains, the β_1 and β_2 subunits. Deoxy-HbS undergoes a slight structural shift so that the A helix β^{6Val} "donor" site of the β_2 subunit in one tetramer can contact an EF helix "acceptor" site (formed mainly by β^{85Phe}, β^{88Leu}, and β^{70Ala}) in the β_1 subunit of a tetramer in the neighboring single string.[28] This critical, lateral association can be made only when HbS is in its deoxy conformation; the EF helix hydrophobic pocket is not a favorable acceptor site for the charged β^{6Glu} of Hb A. The β^{6Val} in the β_1 subunit is located so it cannot participate in such contacts. However, the β_2 subunit of the second single string can form chemically similar β^{6Val}-dependent contacts with the β_1 subunit of the first single string. There are multiple additional axial and lateral contacts, but these are largely the same for deoxy-HbA and deoxy-HbS and are not themselves sufficient to stabilize a polymeric structure.

Role of Hemoglobin S Solubility

The abnormal dehydration of sickle RBCs dominates the physiologic chemistry of HbS.[25,26] Because the solubility of deoxy-HbS, approximately 16 g/dL, is much lower than the mean corpuscular hemoglobin concentration (MCHC), deoxygenation can result in a deoxy-HbS concentration that would exceed its solubility limit. Macromolecular crowding confers nonideal behavior on cytoplasmic constituents (boosting activity above that predicted from concentration alone), and high total hemoglobin concentration helps promote deoxy-HbS polymerization even during partial deoxygenation.

In vitro studies of polymerization carried out under equilibrium conditions (i.e., stable oxygen tension and long time scale) corroborate crystallographic data on critical amino acids involved in atomic contacts by revealing the effect of other hemoglobins on HbS solubility.[26] When different hemoglobins are mixed together, the constituent dimers dissociate and intermix randomly to form hybrid tetramers. A mixture of 50% HbS and 50% HbX yields three types of tetramers: 25% $\alpha\beta^S/\alpha\beta^S$, 50% $\alpha\beta^S/\alpha\beta^X$, and 25% $\alpha\beta^X/\alpha\beta^X$. The impact of naturally occurring hemoglobin mixtures can be understood with this information in mind. In mixtures of HbS and HbA, overall solubility is improved because the hybrid $\alpha\beta^S/\alpha\beta^A$ tetramer integrates into polymer only one half as well as the $\alpha\beta^S/\alpha\beta^S$ tetramer. Addition of HbF to HbS has an even greater sparing effect because the hybrid $\alpha\beta^S/\alpha\gamma$ tetramer cannot be incorporated into polymer. In this regard, HbC has the same effect as HbA, and HbA_2 has the same effect as HbF (Fig. 42–5A). As studied under equilibrium conditions, this sparing effect of HbA is such that much lower hemoglobin oxygen saturation is required for polymer to form in HbAS than in HbSS RBCs (see Fig. 42–5B). A curiosity is that the oxygen dissociation curve of sickle RBCs is right shifted, which increases in proportion to the MCHC. This is caused by the extremely low oxygen affinity of extant deoxy-HbS polymer, and it should promote neither hemo-

globin polymerization (it results from it) nor tissue oxygenation (polymer would be virtually nonfunctional in oxygen delivery).

Kinetics of Polymerization

In normal physiologic conditions, sickle RBCs are not at equilibrium with a constant oxygen tension, and venous blood typically contains only about 20% sickled cells instead of the 90% predicted by equilibrium studies.[25] Measurements of polymerization kinetics, using nonphysiologic methods that create instantaneous and complete conversion of HbS from R (oxy) to T (deoxy) state, reveal a delay before onset of polymerization, which then occurs explosively.[25,26] Under in vitro conditions, this delay time is inversely related to an extremely high power of the initial Hb concentration; it is approximately 10 milliseconds at Hb of 40 g/dL, but it is 100,000 seconds at 20 g/dL (Fig. 42–6A). HbS solutions and sickle RBCs behave similarly in this regard. Delay times must then vary enormously from cell to cell because they are dominated by marked heterogeneity in the MCHC (ie, shorter delay for more dehydrated cells) and are influenced by presence of any non-S Hb (ie, longer delay for presence of HbA or C or F) (see Fig. 42–6E). Admixture of 20% to 30% HbA with HbS (simulating HbS-β$^+$-thalassemia) increases delay time 10^1- to 10^2-fold, and admixture of 20% to 30% HbF with HbS (simulating HbS-HPFH) increases it by 10^3- to 10^4-fold.[29]

Actual polymer formation is hypothesized to proceed by a two-step, double-nucleation mechanism (see Fig. 42–6F).[25,26] Accordingly, the initial *homogeneous nucleation* takes place in bulk solution, during which small numbers of tetramers associate, with accumulation not favored until a critical nucleus size develops (estimated to be 30 to 50 tetramers). Then, new tetramers can be added lengthwise to form a very large polymer. After this occurs, *heterogeneous nucleation* of new fibers takes place on the surface of the preexisting polymers, resulting in explosive, autocatalytic polymer formation. It is believed that the striking irreproducibility of long delay times (see Fig. 42–6B) reflects a stochastic formation of a single homogeneous nucleation event (or at least very few events) in cells that slowly polymerize and that very short delay times (see Fig. 42–6D) reflect simultaneous formation of multiple nucleation sites in cells that polymerize rapidly.[25,26,30]

An unresolved issue is whether the RBC membrane has any influence on polymerization. The good qualitative correspondence between polymerization in solution and in RBCs[25] argues that the fundamental mechanism is not altered by membranes, but it remains possible that the abnormal sickled cell membrane could contribute nucleation sites.[26] The two central features of the polymerization process, governance by MCHC and the delay time, are

highly dependent on the RBC membrane's control of cellular hydration.

Polymerization in Pathophysiology

Overall polymerization in RBCs in vivo is limited by the rate of physiologic deoxygenation, and this effectively imposes a lower limit on what delay times are physiologically relevant (≥1 second).[31] In aggregate, kinetic considerations argue that most red blood cells in the sickle patient are unlikely to sickle during their passage through the microcirculation, unless something slows their transit time.[25,26,31] Moreover, individual RBCs vary enormously in their likelihood of sickling because of heterogeneities in the MCHC and non-HbS content. For example, HbF is nonrandomly distributed among RBCs (except in the case of HPFH), and sickle blood contains F cells in which most of the HbF is found.[32] Variations in the number of F cells therefore have a large impact on the overall blood level of HbF, but individual cell behavior depends on the HbF content of individual cells.

The presence in RBCs of any preexisting polymer that did not completely depolymerize in the lung would shorten or even eliminate the delay time, because nucleation is already completed. Given the rapid RBC transit time through the lung (<1 second), even a slowed reoxygenation rate of sickled RBCs[33] should still allow less than 1% to reach the arterial circulation still containing polymer. However, under equilibrium conditions, only a small diminution in oxygen availability is required to promote polymer formation within HbSS cells.[34] The practical balance of these considerations in the patient with some arterial desaturation caused by lung disease has not been directly examined.

A consequence of polymerization is alteration in RBC shape, which in vitro can become classically sickled or assume holly leaf or granular forms, depending on deoxygenation rate (slow to rapid, respectively), which determines the number of nucleation domains created (see Fig. 42–6).[25,26,30,31] However, physiologic oxygen transits are rapid relative to those typically used in vitro, and granular cells seem most likely to be the dominant type to develop in vivo. The RBC shape is not particularly important (ie, shape is not a determinant of RBC deformability), but the corresponding presence of polymer causes cells to lose their deformability. This is critical for unimpeded passage through the microvasculature.[35,36]

Alternative Ligands: Nitric Oxide and Carbon Monoxide

Nitric oxide (NO) does not materially alter HbS solubility or oxygen affinity,[37] but it can promote conversion of oxy-Hb to met-Hb.[23] This species cannot carry oxygen, and its formation is the initial step in oxidative denaturation of hemoglobin.[22] NO reaction with hemoglobin may be important for its role in vasoregulation. Hemoglobin that is partially liganded with carbon monoxide (CO) is shifted to the R state, and the CO eliminates a portion of the oxygen carrying capacity and renders the remaining available hemoglobin as a high-affinity protein. Patients with sickle cell disease have elevated COHb levels (as high as 7.6% in children) because of their hemolytic anemia.[38] Notably, the possible effects of second hand smoke exposure on sickle pathobiology have not been evaluated.

ABNORMALITIES OF SICKLE RED BLOOD CELLS

Even oxygenated sickle RBCs exhibit a variety of membrane abnormalities that contribute to pathophysiology.[39] Some are the consequence of proximate polymer formation, and others result from oxidative biochemistry. Several of these defects present attractive targets for development of novel therapeutics.

Membrane Iron and Oxidant Generation

A potentially harmful, oxidative biochemistry takes place at the cytosol-membrane interface of the sickle RBC.[40] The oxidation of HbS in solution and interaction of Hbs with bilayer lipid[22] results in formation of superoxide and metHb, the proximate step in hemoglobin denaturation. Some denatured hemoglobin loses its heme, particularly to the lipid bilayer, where it is easily destroyed to liberate "free" iron. Membrane-associated free iron can form a redox couple with soluble oxy-Hb to promote further hemoglobin oxidation and denaturation. It is probable that this scenario accounts for the cytosol-membrane interface of the sickle RBC acquiring its abnormal deposits of hemoglobin, denatured hemichrome, free heme, and nonheme iron.[40] Much of this membrane iron is catalytically active and can use cytosolic reducing substances (eg, ascorbate, superoxide) to redox cycle and generate highly reactive oxidants such as hydroxyl radicals.

These processes probably lead sickle RBCs to spontaneously generate excessive oxidant.[41] The coincident membrane location of catalytic iron augments potential risk of any oxidant generation, because it effectively targets oxidative damage to membrane components. In sickle RBCs, this is evident as oxidation of membrane protein thiols and peroxidation of membrane lipids.[40] It is likely that deficient levels of RBC antioxidants (eg, vitamin E, glutathione, ascorbic acid), caused by oxidative consumption or dietary insufficiencies, contribute to this oxidative stress state. Among the many sickle membrane defects, evidence for an oxidative origin or contribution is strongest for band 3 clustering, abnormal membrane microrheology and protein function, aberrant cation homeostasis, and enhanced vesiculation and phagocytosis tendencies of sickle RBCs.[40] Removal of catalytic iron from the cytosol-membrane interface can ameliorate iron-dependent RBC membrane pathobiology (see box on Red Cell Membrane Defects).[42]

Cation Homeostasis and Dehydrated Cells

For normal RBCs, the MCHC averages about 32 g/dL and varies from 27 to 38 g/dL, with fewer than 1% of cells having an MCHC greater than 38 g/dL. In contrast, the MCHC for sickle RBCs averages about 34 g/dL and varies from 23 to 50 g/dL, with up to 40% of cells having an MCHC greater than 38 g/dL.[43] This extreme heterogeneity results from reticulocytosis (low-density, low-MCHC cells) and dehydrating mechanisms (high-density, high-MCHC cells) (Fig. 42–7).

The most dramatic ion-handling abnormality of the sickle RBC is a loss of monovalent cation content induced by sickling.[44] This depends on cell deformation[45] and may partly reflect an enhanced mechanosensitivity of the sickle membrane because of the presence of lipid hydroperoxides.[46] Experimental data[44] and mathematical modeling[47] suggest that the initial membrane permeability caused by sickling results in increased calcium ion (Ca^{2+}) influx and a slight acidification, occurring stochastically and only in some cells at any one time.[48] This is followed by net potassium ion (K^+) and water loss, mediated mostly by activation of a Ca^{2+}-activated K^+ channel and K–Cl cotransport. The latter can be activated by lowered pH, endo-

Red Cell Membrane Defects

Abnormal microrheology → ↓ deformability → occlusion, hemolysis
PS flip flop → coagulation acceleration → thrombotic risk
Abnormal cation homeostasis → ↑ RBC density → sickling, occlusion
Ig opsonization → hemolysis
Membrane oxidation → ↑ fragility, ↓ deformability → ISC shape, hemolysis

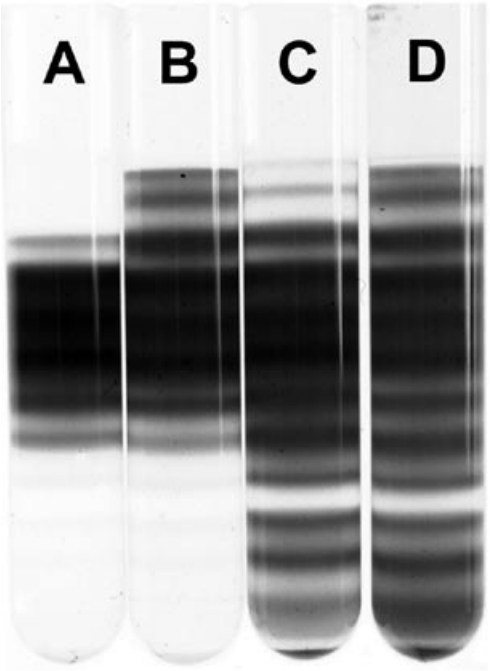

Figure 42–7 Marked heterogeneity in sickle red blood cell hydration. Compared with normal red blood cells (**A**) studied by discontinuous density-gradient centrifugation, red cells from a sickle subject with four α genes (**D**) include cells of unusually low density (usually reticulocytes) and abnormally high density (dehydrated cells). Sickle subjects with three and two α genes are shown in **C** and **B**, respectively. *(From Embury SH, Clark MR, Monroy G, Mohandas N: Concurrent sickle cell anemia and a-thalassemia. J Clin Invest 73:116, 1984.)*

thelin-1,[49] thiol oxidation (part of the reason in sickle cells[44]), and the presence of a relatively positively charged hemoglobin such as HbS or HbC (indicating an effect of a hemoglobin-membrane interaction).[44] It probably is influenced by macromolecular crowding of cytosolic proteins caused by the high MCHC.[50] Even at steady state, sickle RBCs contain increased Ca^{2+} because it is sequestered in cytoplasmic inside-out membrane vesicles,[51] providing evidence of prior cytosolic Ca^{2+} transients. Dense RBCs are not necessarily older cells, but rather can develop through these mechanisms very rapidly from young RBCs, with the cells having lower HbF levels being particularly susceptible.[52,53]

Dehydrated RBCs have decreased deformability[43] and increased propensity for sickling,[25] and the mutually promotive effects of dehydration and sickling constitute a vicious cycle. RBC dehydration is particularly likely to be exaggerated by the hypoxic and acidotic renal medullary environment, virtually the only focus of disease in persons with sickle trait, and very probably by nocturnal arterial desaturation.[54]

Deformability, Fragility, and Vesiculation

Even oxygenated sickle RBCs are poorly deformable.[43] The dominant cause of this is the high MCHC that entails increased cytoplasmic viscosity and a poorly understood, hemoglobin-induced effect on membrane stiffness. There may also be a smaller oxidation-related component to membrane stiffness.[40] On RBC deoxygenation in vitro, there is a temporal correspondence between appearance of polymer-induced shape change and deterioration of deformability, as measured by micropipette[35] and laser diffractometer.[36] On the other hand, filtration studies found decreased deformability before morphologic change,[55] and viscometry reveals a large deterioration in bulk viscosity caused by deoxygenated dense discocytes that show little shape change.[56]

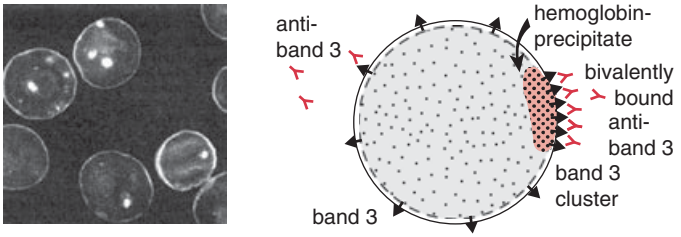

Figure 42–8 Colocalization of denatured hemoglobin on the membrane, clumping of band 3, and opsonization by naturally occurring anti-band 3 antibody. Clusters of band 3 are colocalized with immunoglobulin on the membranes of sickle red blood cells *(left)*. The drawing shows the colocalization scheme *(right)*. *(From Schluter K, Drenckhahn D: Co-clustering of denatured hemoglobin with band 3: Its role in binding of autoantibodies against band 3 to abnormal and aged erythrocytes. Proc Natl Acad Sci U S A 83:6137, 1986.)*

Sickle RBCs are somewhat mechanically fragile,[43] which may be a consequence of dehydration and a weakening of critical skeletal associations caused by oxidative protein damage. The tendency of sickle RBCs to lose membrane vesicles after sickling[57] may reflect separation of the bilayer from the underlying skeleton by spicules of polymerized hemoglobin[58] and enhanced susceptibility caused by protein thiol oxidation and dysfunction.[40]

Membrane Proteins

Abnormality of membrane proteins in sickle RBCs is dramatically illustrated by the fact that the membranes of irreversibly sickled cells (ISCs) are locked into that shape, irrespective of polymer content.[59] Sickle membrane ankyrin interactions with spectrin[60] and band 3[61] are abnormal; glycophorin and band 3 exhibit decreased mobility[62]; and β-actin from ISCs is abnormal and causes slow dissociation of the spectrin-actin-4.1 complex.[63] These abnormalities are most likely caused by oxidative damage, because sickle membranes exhibit abnormal thiol oxidation.[40] Band 3 is abnormally clumped because of binding of denatured HbS to its cytosolic portion, which causes sickle RBCs to attract opsonizing, naturally occurring anti-band 3 immunoglobulin and complement (Fig. 42–8).[64]

Membrane Lipids

The processes that normally enforce bilayer phospholipid asymmetry (ie, a scramblase that can move phosphatidylserine outward and be activated by calcium transits and a translocase that moves phosphatidylserine inward but can be inhibited by thiol oxidation) are impaired in sickle RBCs.[65] RBC sickling promotes externalization of phosphatidylserine, perhaps by separating lipid bilayer from the underlying protein skeleton.[58] This externalization is permanent for membranes of ISCs,[66] but a substantial portion of reticulocytes also exhibits this because of impaired translocase activity,[67] perhaps from thiol oxidation.[40] Other changes include presence of peroxidation by-products such as malondialdehyde, which can modify and cross-link proteins, and increased bilayer lipid hydroperoxides.[40]

Endothelial Adhesivity

Oxygenated sickle RBCs are abnormally adhesive to vascular endothelial cells in vitro[68] and in vivo (Fig. 42–9).[69] A number of mechanisms can underlie this, involving adhesogenic plasma proteins (eg, thrombospondin, high-molecular-weight von Willebrand factor, fibrinogen), adhesive structures specific to reticulocytes (eg, CD36, $\alpha_4\beta_1$) or present on all RBCs (eg, IAP, BCAM/Lu, exposed phosphatidylserine, glycated molecules), adhesion molecules on endothelium (eg, CD36, $\alpha_v\beta_3$, GPIb, vascular cell adhesion molecule [VCAM],

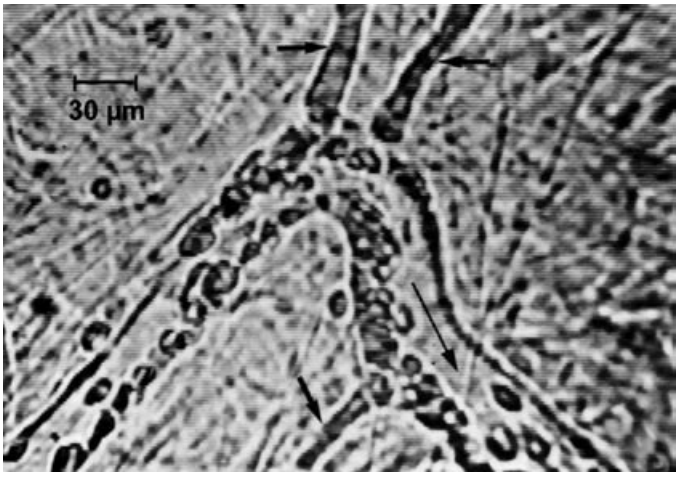

Figure 42–9 Sickle red blood cells adhere to the vascular wall endothelium under flow conditions in the microcirculation of a rat infused with human cells. Notice the two feeder microvessels *(arrows)* that have no flow because of the logjam of red blood cells. *(From Kaul DK, Fabry ME, Nagel RL: Microvascular sites and characteristics of sickle cell adhesion to vascular endothelium in shear flow conditions: Pathophysiological implications. Proc Natl Acad Sci U S A 86:3356, 1989.)*

P-selectin, glycated molecules, phosphatidylserine receptor), and possibly immobilized subendothelial matrix molecules (eg, thrombospondin, laminin, fibronectin). It seems probable that there is no single, most important mechanism. Rather, it is likely that multiple mechanisms participate, and mechanisms may vary between patients, from time to time within a single patient, and perhaps even with organ-to-organ or other regional differences.[68] For example, the role of adhesogenic plasma proteins can vary dramatically, depending on concurrent biology; for example, platelet activation can promote release of thrombospondin from α granules, and patient dehydration can elevate von Willebrand factor by means of vasopressin stimulation of endothelium.

A number of these mechanisms are high affinity and demonstrable under flowing conditions, but in the biologic context of tiny vessels in the microcirculation, even low-affinity adhesive mechanisms probably can be relevant.[68] The physiology may be governed to a significant extent by biologic modifiers of endothelial activation state, such as hypoxia, thrombin, interleukin-1 (IL-1), tumor necrosis factor (TNF), endotoxin, leukotriene B_4, endothelial injury (eg, viral infection), and other factors. Some adhesion mechanisms (eg, mediated by VCAM or P-selectin) are relevant only if the endothelium is activated. Others are activated if internal RBC signaling is triggered. It also is possible that biologic adhesivity involves mixed RBC interactions with adhesive leukocytes or platelets, or both, activated by inflammation and hemostatic activity.[70] Additional governing factors include the RBC hydration state, reticulocyte count, flow and shear rates, vessel diameter and geometry, and disturbances of flow regimens because of marginated white blood cells (WBCs). RBC adhesion can slow microvascular flow, providing the time extension needed to overcome the delay time requirement for HbS polymerization to occur.[25] Work in experimental animals suggests that occlusion is a two-step process in which adhesive RBCs initiate vasoocclusion, after which more dense and stiff cells provide propagation through a logjam effect (Fig. 42–10), all of which eventually results in RBC sickling.[69,71]

MACROPHAGE INTERACTION

Sickle RBCs are ingested abnormally readily by macrophages[72,73] because of membrane modification by malondialdehyde, externalization of phosphatidylserine, and opsonization by immunoglobulin. The latter process is triggered mainly by clustering of membrane protein band 3 because of the presence of denatured hemoglobin at the cytosol-membrane interface (see Fig. 42–8).[64] Because the densest cells have greater surface immunoglobulin[74] and high phosphatidylserine externalization,[67] they have the greatest interaction with macrophages.[72]

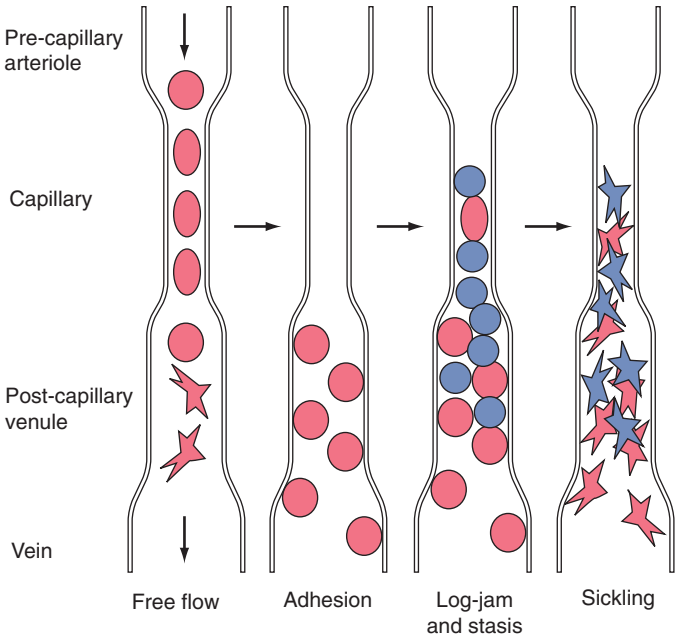

Figure 42–10 Occlusion may stem from a two-step process: initiation due to endothelial adherence and propagation caused by the logjam of poorly deformable cells.

Irreversibly Sickled Cells

The sickled RBCs seen on a blood smear are mostly ISCs. Except for having membranes locked into an elongated shape,[59] the characteristics of ISCs are similar to other equally dense but not elongated cells: high MCHC, poor deformability, externalized phosphatidylserine, and lower-than-average HbF content. Although still adhesive to endothelium, they are less so than other sickle subpopulations,[68] probably because of their lack of deformability, but they exhibit greater adherence to macrophages.[72] ISC counts on average are higher in male patients, perhaps reflecting their average lower levels of HbF. Most significantly, ISCs are very short lived.[75] The two fundamental requirements for ISC formation seem to be RBC dehydration and assumption of an elongated and fixed membrane shape. The elongation implies prior prolonged sickling, perhaps caused by a "conditioning" period caused by residence of adhesive but deoxygenated cells in the postcapillary venules. The locked-in shape probably derives from membrane protein thiol oxidation.[156] The clinical importance of ISCs lies in their ability to prompt diagnosis of a sickling disorder when seen on blood smear and their contribution to hemolytic rate. They probably contribute to the logjam in areas of partial obstruction (see Fig. 42–10), but there is soft evidence both for and against a correlation between ISC number and vasoocclusive manifestations.

ENDOTHELIAL BIOLOGY OF SICKLE CELL DISEASE

The vascular endothelium serves multiple critical functions in physiology,[76] and it is likely that many of these roles are involved in the pathobiology of sickle cell disease.[68]

Inflammation

Sickle cell disease is an inflammatory state with abnormal endothelial cell activation.[68] Evidence for this in humans includes the persistent

increase in leukocyte counts; ongoing activation of granulocytes and monocytes; chronic elevation of multiple proximate inflammatory mediators (eg, IL-6, TNF-α), acute-phase reactants (eg, C-reactive protein), and soluble adhesion molecules (eg, sVCAM-1); persistent activation of hemostatic systems; presence of nitrotyrosine-modified proteins in tissues; and exhibition of an activated, proadhesive and procoagulant phenotype for circulating endothelial cells. Clinically, leukocytosis in sickle cell disease is a risk factor for mortality,[77] clinical and silent stroke,[78,79] and acute chest syndrome,[80] and it helps predict which babies will develop a severe clinical course.[81] Acute vasoocclusive crises have been precipitated by growth factor induction of granulocytosis. In a large clinical trial demonstrating the efficacy of hydroxyurea, a drug that lowers the WBC count (among many other effects), the pain crisis rates correlated strongly with leukocyte counts.[82] Sickle transgenic mice seem to share with humans an inflammatory phenotype.[68]

Multiple mechanisms can underlie this inflammatory pathobiology. Infections and an iron-rich state may contribute. However, the pathobiology of sickle cell disease probably includes reperfusion injury physiology,[68,83–85] a postocclusive vascular pathobiology in which a cascade of events causes oxidative stress and induces inflammation.[86] This may involve a shift of xanthine oxidase from liver to plasma, with consequent deposition of this oxidant-generating enzyme on and in the vessel wall.[85] Reperfusion injury would damage the vascular wall and could lead to chronic vasculopathy. Adhesion of sickle RBCs itself incites an injury-like response by endothelial cells that may contribute to vascular pathobiology.[68] Another likely, but untested, possibility is that adherent sickle RBCs could directly activate blood monocytes and thereby incite inflammation. Regardless of proximate mechanism, the inflammatory phenotype of endothelium in sickle cell disease would highly promote RBC and WBC adhesion to the vessel wall.

Coagulation Activation

The coagulation system is chronically activated in sickle subjects, but more so during acute vasoocclusive episodes.[87] Described abnormalities include activation of plasmatic coagulation, platelets, and fibrinolysis, accompanied by thrombin generation and consumption of anti-thrombotic proteins. Tissue factor is abnormally expressed not only on blood monocytes, stimulated by C-reactive protein and other biologic mediators,[88] but also on circulating endothelial cells,[89] suggesting expression by vascular wall endothelium. Indeed, there are tissue factor positive endothelial cells in the sickle mouse.[90] Sickle blood contains tissue factor-positive microparticles derived from endothelial cells and monocytes, supporting the concept of an activation state. Correlative data indicate that the abnormally externalized phosphatidylserine on sickle RBCs plays a very significant accelerating role by providing a favorable surface template for lipid-dependent coagulation reactions.[91] About one half of sickle patients have antiphospholipid antibodies.[92] The role of thrombosis in sickle stroke and probably in pulmonary arteriopathy constitutes the most obvious involvement of the hemostatic system in sickle cell disease, but a contributory role for hemostatic activation in other clinical aspects of the disease has not been specifically excluded (see box on Coagulation Activation in Sickle Cell Anemia).

Coagulation Activation in Sickle Cell Anemia

Conversion of prothrombin to thrombin
Increased F 1.2 fragment
Thrombin generation
Increased thrombin : antithrombin complexes
Proteolysis of fibrinogen
Increased fibrinopeptide A
Degradation of cross-linked fibrin
Increased D-dimer
Formation and subsequent degradation of fibrin
Increased fragment E[a]
Activation of "intrinsic pathway"
Reduced factor levels
Activation of "extrinsic pathway"
Increased factor VII turnover
Inhibitor consumption
Reduced protein C, S, ATIII
Increased platelet activation
Activation antigen expression

Endothelial Biology of Sickle Cell Anemia

Coagulation activation →?thrombosis
Inflammation chronic →?vasculopathy
Abnormal vasoregulation → blood pressure, blood flow
Adhesion of WBC and RBC →?occlusion, inflammation
Abnormal NO bioavailability →?effects on coagulation and inflammation

Vasoregulation

Sickle cell disease is a state of diminished NO bioavailability,[93] as evidenced by abnormal functional flow dynamics.[94,95] This may derive in part from abnormal consumption of NO by plasma hemoglobin,[96] the levels of which tend to be elevated early in crisis,[97] although it is not known whether such elevations precede the crisis. Other factors may play a role, such as endothelial dysfunction, consumption of NO by myeloperoxidase,[98] or exaggerated superoxide generation derived from vessel wall xanthine oxidase[85] or oxidation-induced uncoupling of NO synthase.[99] NO bioavailability seems to be higher for females than males, who exhibit substantial non-NO regulation of flow.[95] A role has been proposed for heme-oxygenase-1,[100,155] which has vasoprotective and vasoregulatory functions.[93] It has been suggested that sickle cell disease constitutes a state of enhanced instability of vascular tone,[93] and sickle patients are observed to exhibit abnormal capillary flow dynamics in the skin.[101] Systemic blood pressure in subjects with sickle cell disease is lower than in nonanemic, race-matched controls but higher than in comparably anemic, race-matched β-thalassemic patients.[102] Experimental interference with NO generation precipitated acute vasoocclusion and stroke in a rodent model of sickle cell disease.[103] Diminished NO bioavailability would also be expected to harmfully augment endothelial expression of VCAM-1, inflammatory effectors, and tissue factor (see box on Endothelial Biology of Sickle Cell Anemia).[68]

PATHOGENESIS OF CLINICAL DISEASE

Hemolytic Anemia

At least three fundamental, proximate destructive mechanisms underlie the accelerated removal of sickle RBCs, which causes the anemia of sickle cell disease.

Poor Deformability

Deformability[43] and survival[75] are most abnormal for the very dense cell population, perhaps indicating some degree of causality.

Opsonization

Sickle RBCs are coated with immunoglobulin, which promotes their erythrophagocytosis.[72] Proximate triggers for this are mostly clustering of band 3 by means of denatured hemoglobin on the membrane[64] (see Fig. 42–8) and perhaps modification by malondialdehyde.[72] Externalized phosphatidylserine also promotes interaction with phagocytic cells.[74,104] The densest cells, including ISCs, have greater surface immunoglobulin[74] and high phosphatidylserine externalization,[67] and they exhibit greater erythrophagocytosis.[72]

Mechanical Fragility

Fragility plays some role, because it is estimated that about one third of RBC destruction takes place within the intravascular space.[105] The greatest stressor in this regard is likely to be cell sickling. A substantial portion of free hemoglobin in sickle plasma is encapsulated in microvesicles released from RBCs,[90] probably caused by sickling-induced perturbation of the bilayer[58] and augmented by protein oxidation[40] and dysfunction. The inverse relationship between (calculated) RBC polymer content and blood hemoglobin concentration is reported to be robust[106] or weak,[107] depending on rigor of the assumptions made. Hemolytic rate clearly is proportional to ISC count,[108] and life span is shortest for dense cells with low levels of HbF.[75] Improved RBC hydration caused by concurrent α-globin gene deletion improves survival and elevates the hemoglobin level.[109] The change in HbF levels in patients taking hydroxyurea is strongly associated with a change in RBC survival.[110]

Vasoocclusion

Vascular occlusion is believed to underlie the major clinical manifestations of sickle cell disease, particularly the most frequent event, the acute painful episode.[111] Notwithstanding the conceptual simplicity of the sickling phenomenon, it is likely that vasoocclusion is a complex and evolutionary process that involves multiple mechanisms and cell types. The likely roles of inflammation and reperfusion injury establish the probability that ongoing endothelial perturbation and activation may participate in disease genesis.[68] The endothelial biology of sickle cell disease can be influenced by concurrent illness. The long-held concept of a steady state of relative wellness between acute episodes can perhaps be more accurately described as an interlude in which the patient's symptoms do not reach the rather arbitrary threshold of requiring medical attention.[111] That steady state does not necessarily mean an absence of ongoing pathophysiology is supported by elevations and fluctuations of acute-phase reactants[68,112] and hemostatic markers[87] during the period. What is most striking in patients is a high level of clinical phenotypic diversity within a given genotype (eg, HbSS, HbSC).[1] It seems probable that this reflects the pathogenic participation of multiple biologic systems, even though HbS polymerization forms the fundamental, genetic basis for the clinical sickle syndromes.

Sickling

Intense sickling in the venous circulation probably contributes to the pathobiology of the pulmonary arterial system. Whether RBCs sickle elsewhere depends on the relationship between their inherent delay time and the degree and rate of deoxygenation.[25,26,31] Supporting the importance of polymerization are the facts that HbSC disease is clinically more severe than sickle trait (because the former has very dehydrated RBCs[44]) and that patients with Hb AS develop disease specifically in the hypoxic-acidotic renal environment. An inverse relationship between HbF and pain[113] and mortality[77] is supportive, but this is seen largely at the population level, and there is no such preventive effect for stroke.[114] Although the calculated polymer fraction is reported to correlate modestly with self-reported clinical severity,[115] more thorough analysis of polymer fraction using multiple physiologic variables showed no correlation with hospitalization rate.[107] Although α-gene deletion improves RBC hydration (and lowers ISC number), it does not improve clinical severity,[109] perhaps because of a resulting elevation of blood viscosity.

Adhesion and Inflammation

The fact that acute painful episodes often include multicentric pain[1] and are associated with distant flow changes in conjunctival vessels[116] perhaps indicates that the pain crisis is a systemic, rather than a strictly local, event. The ability of adherent WBCs or RBCs, or both, to slow the microvascular transit of RBCs may allow polymerization and occlusion.[25,26,31] Determinants of endothelial adhesivity, inflammation, and endothelial activation are probably important in this process. Supportive evidence from humans includes a clinical benefit from hydroxyurea,[82] which lowers RBC adhesivity[117,118] and WBC count.[82] Animal studies have been interpreted to suggest that adhesion-triggered occlusion occurs in the postcapillary venule,[69] but there are no confirmatory data from humans. Clinical vasoocclusive severity correlates with the endothelial adhesivity of sickle RBCs.[119]

Deformability

Deficient deformability[43] of RBCs can impede microvascular transit and even hinder the ability to enter the microvasculature in the first place. It has been proposed that precapillary arteriolar blockage might cause occlusion, but there is little evidence for this. Clinical vasoocclusive severity correlates with good deformability rather than the absence thereof.[120,121] There is no correlation between the fraction of cells having the highest density and crisis frequency,[122] and the least deformable cells seem to not correlate with clinical vasoocclusive severity.[123] However, in animals, poorly deformable cells begin to create a logjam and participate in occlusion after adhesive cells have initiated partial obstruction (see Fig. 42–10),[69,71] and there are changes of observable cell density associated with acute crisis.[43]

Other Factors

Activation of the coagulation system[87] may contribute to development of ischemic stroke and to pulmonary arterial disease, but the extent to which it contributes to other occlusive manifestations is insufficiently tested. A role for diminished NO bioavailability[93] and concomitant impairment of endothelial function[68] is beginning to be explored. Nonetheless, an acute change in NO bioavailability is an interesting candidate precipitant for occlusive events.

CHRONIC VASCULOPATHY

It is not clear whether the pathogenesis of the organ-specific clinical syndromes in sickle cell disease is the same or different from genesis of the acute painful episode. Development of complicating syndromes does not necessarily occur in those having the highest pain crisis frequency; for example, a low pain rate is a risk factor for silent stroke.[79] Sickle cell disease includes a component of chronic vasculopathy,[68,124] although this is an incompletely evaluated concept. The most information is available for disease in the large or medium vessels at the circle of Willis, where some children develop occlusive pathology characterized by intimal hyperplasia, fibrotic and proliferative changes, and damage to internal elastic lamina.[103] Similar pathologic changes have been observed in large vessels in the spleen in children,[125] in umbilical vessels,[126] and in the pulmonary arterial tree.[127] The accompanying clinical syndromes in these four high-flow organs are, respectively, ischemic stroke,[128] autosplenectomy,[129] fetal wastage and growth retardation,[130] and pulmonary hypertension.[131] Sickle vasculopathy shares with atherosclerotic disease a nonrandom-

ness of location, a likely proximate role for inflammation, and a fundamental pathologic change (ie, intimal hyperplasia). Although sickle vasculopathy does not include a fatty streak (sickle patients have low blood lipid levels[132]), in vitro stimulation of endothelial cells by an inflammatory mediator, IL-1β, promotes formation from the membrane of the same oxidized lipid species implicated in early development of the atherosclerotic lesion.[133] Other contributing factors may be persistently increased shear rates, chronic hypoxia, and ongoing perturbation by sickled or adherent RBCs. Thrombosis probably is a late aspect of this process in the brain,[103,128] but the timing of its development in lung[134] is unclear. It is not known whether the occurrence of vasculopathy in one organ correlates with its appearance in others, and the pace of its temporal development is not well defined. However, it recently has been suggested that the commonality of hemolypsis (and NO consumption) may link the various vasculopathy events.[157] Thus, the presence of the vasculopathy suggests that novel therapeutic approaches, such as use of statins and other antiinflammatory drugs, should be tested experimentally. Because NO and CO inhibit development of experimental intimal hyperplasia, the deficient NO and excessive CO in sickle cell disease may affect vessel wall biology.

MORTALITY

Adult patients with higher pain crisis rates (ie, three or more per year) have a higher mortality rate.[77] This relationship is not evident for children, possibly because time-dependent disease effects have not fully accumulated. It seems likely, but has not been demonstrated, that extent of presumed subclinical disease activity would be proportional to severity of clinically evident disease. Approximately one-third of deaths occur during acute complications such as pain, stroke, or acute chest syndrome, and many are caused by overt organ failure (usually renal). Infection continues to contribute. Notable risk factors for mortality are low HbF levels and a WBC count higher than 15,000 per μL.[77] A decade ago in the United States, the median age at death was 42 years for men and 48 years for women with sickle cell anemia; the comparable ages were 60 and 68 years, respectively, for HbSC disease.[77] This statistic improved markedly after the introduction of prophylactic penicillin for children,[135] indicating the dramatic loss of dominance for pneumococcal sepsis in disease natural history.

Stroke

Clinical and silent strokes are a frequent complication of sickle cell disease.[103,114,128] Ischemic stroke develops in early childhood and is particularly associated with large- and medium-vessel occlusive changes at the circle of Willis that involve hyperplastic intimal changes in the vessel wall.[128] However, a significant portion of patients also have small-vessel disease.[136] Identified risk factors include low blood levels of hemoglobin, high WBC counts, relatively high blood pressure, acute development of hypoxia, a prior neurologic event, presence of moyamoya, low pain crisis rate, and concurrent or antecedent inflammatory conditions.[79,114,128] The fact that a history of acute chest syndrome is a (see Chapter 43) notable antecedent event is of particular interest, in view of the relatively common role of *Chlamydia* infection in this syndrome[137] and the contrasting hypothesized role for this agent in atherosclerotic disease.[138] The classic inherited risk factors for thrombosis seem not to be associated with stroke in the sickle context, but concurrent α-thalassemia or HbSC disease lower the risk. However, the HbF level is not protective.[114] There is a familial tendency[139] and a relationship to human leukocyte antigen (HLA) type.[140]

For the most part, identified risk factors are those for any acute stroke event. It is not entirely clear whether the same or different risk factors account for the underlying vessel wall disease. Known facets of sickle cell disease that could play an etiologic role include activation of the coagulation system and antiphospholipid antibodies, inflammation and endothelial cell activation, RBC or WBC adhesion to the vascular wall, and disturbances of NO bioavailability.[68] It is possible that inherited differences in endothelial gene expression influence this clinical phenotype,[68] as has recently been shown for inflammation signalling.[158] The relationship of sickle stroke to the background of increased risk for stroke in the general African American population is not established. It is not clear whether ischemic stroke in adults involves exactly the same process as in children or additional processes supervene over time. Among persons with sickle cell disease, young adults have the highest rates of hemorrhagic stroke.[114]

Pulmonary Disease

Sickle pulmonary disease includes multiple pathologies, including fibrosis, pulmonary hypertension, infection, in situ and embolic thrombosis, and acute chest syndrome.[78,131,134,141,142] The lung is a common target organ of inflammation biology in general, and it seems likely that endothelial perturbation from the persistent flooding of the pulmonary arterial tree with sickled cells from the venous circulation plays a role in some pulmonary syndromes.[68]

Acute chest syndrome is particularly important as a life-threatening event and as a predictor of chronic lung disease[143] and stroke.[114] Risk factors include[80,142,159] leukocytosis, lower hemoglobin levels, and a lower level of HbF, implying etiologic roles for inflammation, deficient NO bioavailability, and RBC sickling, respectively. Infection plays a greater role in children, whereas in adults, acute chest syndrome often is associated with acute painful episodes.[142] Fat embolism is commonly associated with acute chest syndrome,[142] probably as a consequence of marrow infarction and accompanying elevation of blood phospholipase A_2 activity,[144] which can generate fatty acids that permeabilize pulmonary endothelium and augment the endothelial perturbing effects of hypoxia.[145] Additional contributing processes may include rib pain causing atelectasis, a tendency toward pulmonary endothelial permeability caused by elevated levels of vascular endothelial growth factor (VEGF)[68] and high-dose opioid administration, hypoxemia and sickling, RBC adhesion to endothelium, and even iatrogenic fluid overload. Deficient NO bioavailability[93,95] is implicated in pulmonary hypertension,[159] and it allows augmented tissue factor and VCAM expression, which are likely participants in the acute chest syndrome. It appears that multiple proximate triggering events (eg, rib pain, infection, fat embolism) lead to a syndrome in which inflammation, NO deficiency, and endothelial permeability conspire to augment the deleterious effects of hypoxia on the pulmonary endothelium.

Retinopathy

Sickle cell disease is associated with neovascularizing retinopathy; the risk is higher in HbSC disease than in sickle cell anemia.[146] Although this difference is postulated to be a consequence of higher blood viscosity in HbSC disease, the risk for retinopathy seems to be greater with a higher hemolytic rate (ie, higher reticulocyte count and lower hemoglobin concentration).[147] Greater anemia and increased numbers of adhesive RBCs can increase hypoxia, which stimulated the generation of VEGF, a major angiogenesis-promoting growth factor. VEGF has been found in human sickle retinopathy lesions,[148] and the blood concentration tends to be elevated in sickle cell disease.[149]

BASIS OF PHENOTYPIC DIVERSITY

The remarkable diversity of clinical phenotypes in sickle cell anemia is largely unexplained. This disease provides a dramatic illustration of a paradigm in which a single-gene disorder is exceedingly complex and produces a "polygenic" disease. The phenotype can be significantly influenced by geography, infectious disease, and other environmental factors.[3] In countries with lower infant mortality and

childhood infection rates, phenotypic variability is especially evident. An emerging story is a gender difference in apparent NO bioavailability,[93,95] which is unexplained but corresponds to the gender difference in longevity.[77] The benefits of coinherited genetic influences are probably understood virtually entirely by their impact on hemoglobin polymerization, the sickling phenomenon, and hemolysis.

Level of Hemoglobin F

After the fall in HbF level occurring during the first 6 months of life,[150] most of the protection from RBC sickling that derived from the high HbF level at birth is lost, but the HbF level still varies among adults over a 20-fold range. Viewed from a population level, protection from pain and mortality is conferred as a continuous function of the Hb F level,[77,113] but some clinical complications are forestalled by HbF (eg, acute chest syndrome[80]) and others are not (eg, stroke[114]). The HbF level reflects the number of F cells, the amount of HbF per F cell, and the preferential survival of F cells compared with cells containing low levels of Hb F.[32,53] The known determinants of the HbF level probably account for only about one half of its variance: the polymorphic *Xmn*I site 5′ to the Gγ gene (about 10% of the variance) in the Senegal and Arab-India β^S haplotypes (see Fig. 42–3A) and female gender (about 40% of variance).[109] The effect of gender may result in part from greater NO bioavailability,[95] because NO promotes HbF production.[151]

α-Thalassemia

Because of duplication of the α-globin gene, the normal genotype is αα/αα. About 30% of people in the United States with West African ancestry have a single α deletion (–α/αα),[109] so concordance with sickle cell disease is common, and homozygosity for the allele is seen (–α/–α). α-Thalassemia is uncommon in Greeks with sickle cell disease, but in eastern Saudi Arabia and India, α-thalassemia occurs in more than 50% of the sickle population.[12] An α-gene deletion has minimal effect on the HbF level but results in improved RBC hydration (see Fig. 42–7), a lower ISC count, improved RBC survival, and high blood levels of hemoglobin.[109] Surprisingly, there is no parallel amelioration of clinical severity, and some complications (eg, osteonecrosis, retinopathy) increase,[109] possibly because of increased blood viscosity. However, α-thalassemia may ameliorate HbSC disease somewhat.[152]

β-Globin Alleles

Compound heterozygosity for the sickle gene and another β allele can affect the clinical phenotype.[153] In deletional HPFH, coinheritance of a pancellular high level of HbF results in about 20% to 30% HbF (but no HbA) and a dramatic amelioration of disease severity. Benefit from concurrent β^+-thalassemia can be quite variable, depending on level of HbA (which ranges from approximately 10% to 30%). In contrast, concurrent β°-thalassemia has no HbA and manifests a typical sickle cell anemia-like syndrome. HbSC disease presents a unique case that should be clinically similar to sickle trait (see Fig. 42–5A), but interaction of HbC with the RBC membrane causes a striking stimulation of K–Cl cotransport and consequent RBC dehydration.[154] Combined with the somewhat higher HbS concentration (about 50% versus about 40% in HbAS) and higher blood hemoglobin level, this yields a clinical sickling disorder only somewhat less severe than sickle cell anemia and having an increased propensity for retinopathy and osteonecrosis.[152]

Other interesting situations are created by concurrence of HbS and HbD-Los Angeles ($\beta^{121Glu\rightarrow Gln}$) or HbO-Arab ($\beta^{121Glu\rightarrow Lys}$), which have unusually severe phenotypes that are hypothesized to result from heightened polymer stability (and reduced solubility) caused by β^{121} substitutions. An even more remarkable example is provided by the unique double mutation in HbS-Antilles ($\beta^{6Glu\rightarrow Val}$ and $\beta^{23Val\rightarrow Ile}$), which has such reduced solubility that it causes clinical sickle cell disease in the heterozygous state.[153]

Unexplained Phenotypic Diversity

Notwithstanding these well-defined influences, affected individuals still exhibit enormous unexplained variability in clinical phenotype. The complex diversity of physiologies that potentially participate in the vasoocclusive disease, chronic vasculopathy, and specific complicating syndromes predicts a variety of possibilities. It is likely that this complexity is influenced by underlying genetic variations in adhesion molecule biology, determinants of RBC cation homeostasis, inflammatory signaling or negative-feedback loops, propensity for angiogenesis or vessel wall injury, oxidant-antioxidant biology, hemostasis, or regulation of vascular tone and blood flow. It remains to be seen how substantial the influence of such differences may be.

It is likely that the contribution of such additional genetic influences will begin to be identified now that modern genomic approaches are being applied to the problem of phenotypic diversity in sickle cell disease. In this regard, studies of stroke are the most advanced.[158,160] Sadly, factors such as environment, nutrition, socioeconomic status, endemic infection rates, and availability of medical care also remain contributors.

CHAPTER 43

SICKLE CELL DISEASE—CLINICAL FEATURES AND MANAGEMENT

Yogen Saunthararajah and Elliott P. Vichinsky

INTRODUCTION

Sickle cell disease is an inherited disorder in which patients inherit specific mutated variants of the β-globin gene that lead to hemoglobin polymerization. The sickle mutation of the β-globin gene results in the production of an abnormal hemoglobin called sickle hemoglobin (Hb S). The sickle mutation has undergone positive selection during human evolution because individuals with one copy of the sickle gene and one normal β-globin gene (sickle cell trait) have a survival advantage in malaria-endemic regions. In individuals with two copies of the sickle gene (Hb SS or sickle cell anemia) or the sickle mutation and another mutated β-globin gene, for example, sickle cell–β° thalassemia (Hb S–β thal) or Hb SC disease (Hb SC), the less soluble Hb S can polymerize in deoxygenated regions of the circulation, resulting in hemolysis, red-cell rigidity, and red-cell adhesion to endothelium with consequent inflammatory and coagulation pathway activation and vasoocclusion.[1] The cardinal clinical manifestations of these processes are chronic hemolytic anemia, recurrent painful episodes, and chronic organ damage. A comprehensive approach directed at preventing pain crises, chronic organ damage and early mortality while effectively managing acute complications, offers the best method of management. The further exigency of living with a painful, life-threatening chronic disease in an ethnically diverse society provides additional complexity to the psychosocial aspects of this illness. This chapter presents the diagnosis and natural history and describes overall clinical management as well as specific management by organ complications. Clinical interventions are founded on an understanding of the pathophysiologic processes that underlie the disease. For a full discussion of the fascinating history and molecular pathology of this disease, please see Chapter 42. Normal hemoglobin synthesis, structure, and function are described in Chapter 33; the thalassemias are considered in Chapter 41.

Prevalence

The distribution and frequency of the sickle cell gene in different areas of the world have been influenced by evolutionary pressures[2] and transmission of the gene via trade routes and the slave trade.[3] Among African Americans, the prevalence of sickle cell trait is 8% to 10% among newborns,[4] and in this population the frequencies of the sickle cell (0.045), Hb C (0.015), and β thalassemia (0.004) genes[4] indicate that there are 4000 to 5000 pregnancies a year at risk for sickle cell disease. The burden of this disease in the United States is dwarfed by that in the rest of the world, as evidenced by a prevalence of the sickle cell gene as high as 25% to 30% in western Africa and an estimated annual birth of 120,000 babies with sickle cell disease in Africa.[5]

DIAGNOSIS

The diagnosis of a sickle cell syndrome is suggested by characteristic findings on the complete blood count and peripheral smear which then require confirmation with hemoglobin electrophoresis. If a diagnosis of sickle cell disease is confirmed, evaluation of the various organ systems at risk is required. These evaluations are outlined and discussed later in this chapter in the section on clinical management.

Complete Blood Count and Peripheral Blood Smear

The chronic hemolytic anemia of sickle cell disease is usually associated with mild to moderately low hematocrit and hemoglobin levels and a reticulocytosis of approximately 3% to 15%, accounting for high or high-normal MCV. If the age-adjusted MCV is not elevated, the possibility of sickle cell–β thalassemia, coincident α thalassemia, or iron deficiency must be considered. Additional laboratory findings of hemolysis are unconjugated hyperbilirubinemia, elevated lactate dehydrogenase, and low haptoglobin levels.

In the peripheral smear (Fig. 43–1), there may be sickled forms, target cells, polychromasia indicative of reticulocytosis, and Howell–Jolly bodies demonstrating hyposplenia. The red cells are normochromic unless there is coexistent thalassemia or iron deficiency. Sickled forms (ISCs) occur in the peripheral smear only in the sickle cell diseases and not in sickle cell trait. In Hb SS disease, ISCs predominate and target cells may be few; in sickle cell–β thalassemia, ISCs, target cells, and hypochromic microcytic discocytes are prominent; in Hb SC disease, target cells predominate and ISCs are rare.

White cell counts are higher than normal in Hb SS disease, particularly in patients under age 10 years. Mean white cell counts tend not to be elevated in Hb SC disease or sickle cell–β^+ thalassemia. Mean platelet counts are elevated in Hb SS disease, particularly in patients under age 18 years, but are usually normal in those with Hb SC disease and sickle cell–β^+ thalassemia.

Solubility Tests and Hemoglobin Electrophoresis

Solubility tests (eg, Sickledex) are positive in both sickle cell disease and sickle cell trait. All patients require definitive diagnosis with hemoglobin electrophoresis (which separates hemoglobin species according to amino acid composition) (Fig. 43–2) or DNA testing. Cellulose acetate electrophoresis at pH 8.4 is a standard method of separating Hb S from other variants. However, Hb S, G, and D have the same electrophoretic mobility with this method. Using citrate agar electrophoresis at pH 6.2, Hb S has a different mobility than Hb D and G, which comigrate with Hb A in this system (see Chapter 40).

Results from electrophoresis or thin-layer isoelectric focusing are similar in Hb SS disease and sickle cell–β° thalassemia: nearly all the hemoglobin consists of Hb S. Although differences in the Hb F (see Variant Sickle Cell Syndromes) and Hb A_2 levels may be useful in distinguishing these syndromes, the presence of microcytosis or of one parent without sickle cell trait is a more useful indicator of sickle cell–β° thalassemia. The diagnosis of Hb SC disease is straightforward; nearly equal amounts of Hb S and Hb C are detected. Sickle cell–β^+ thalassemia and sickle cell trait both have substantial amounts of Hb A and Hb S. This superficial electrophoretic similarity does not provide an obstacle to diagnosis: sickle cell trait is associated with neither anemia nor microcytosis and has an Hb A fraction more than 50%,[6] whereas sickle cell–β^+ thalassemia is associated with anemia, microcytosis, and an Hb A fraction that ranges from 5% to 30%.

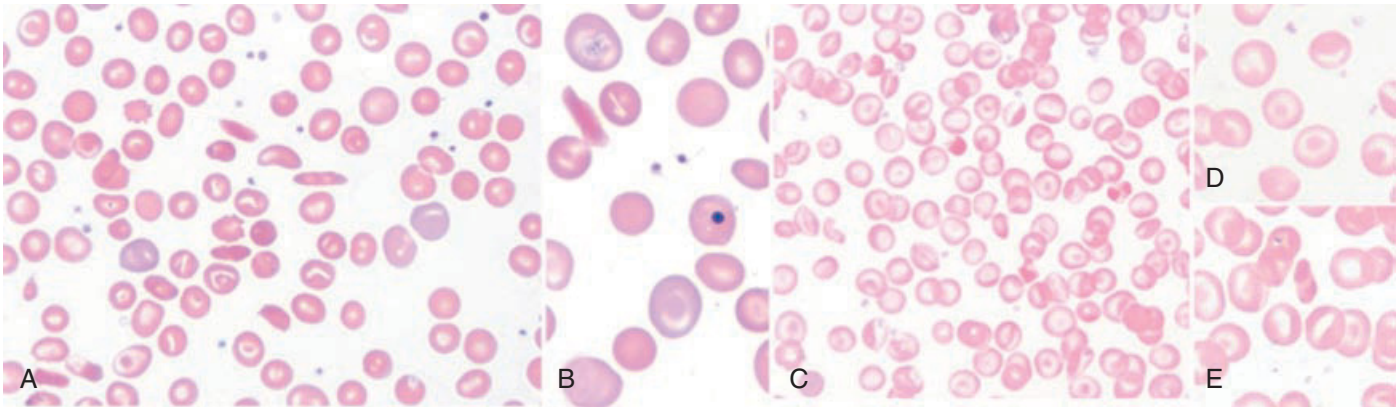

Figure 43–1 Sickle cell disease and Hb SC, peripheral blood smears (**A**–**E**). The peripheral smear in sickle cell disease (**A**) shows sickle cells that are mostly irreversibly sickled, and sometimes referred to as "cigar-forms." Higher power detail (**B**) shows sickle cell (upper left), red blood cell containing a Howell–Jolly body (middle right), and polychromatophilic cell (lower center). These indicate sickle cell anemia, splenic dysfunction, but marrow response with reticulocytosis, respectively. Peripheral smear of a patient with Hgb SC (**C**) shows no sickled cell, but there are target forms (**D**) and occasional cells (**E**) with hemoglobin condensed at each pole of the cell.

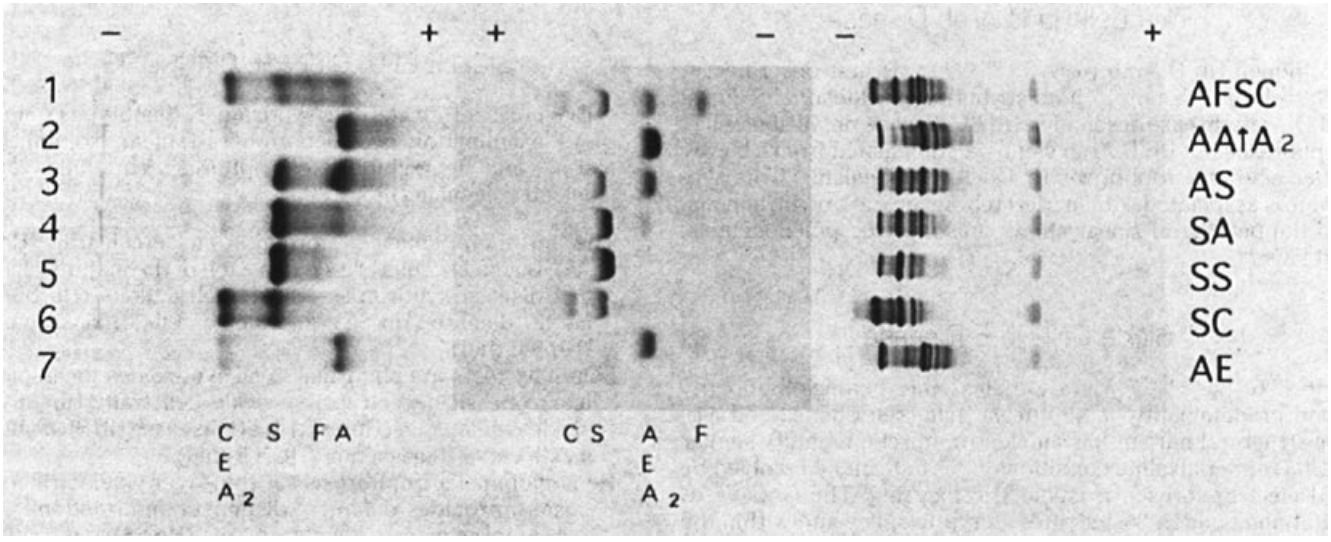

Figure 43–2 Comparative analyses of several mutant hemoglobins using alkaline electrophoresis, acid electrophoresis, and thin-layer isoelectric focusing. On the right are shown the components of the standard (at the top) and the phenotypes of the other six samples. Their analyses are shown by alkaline hemoglobin electrophoresis in the left panel, acid electrophoresis in the center panel, and thin-layer isoelectric focusing in the right panel. Locations of the various hemoglobin bands are shown below the left and center panels. *(Kindly provided by M. H. Steinberg.)*

The Hb F level is usually slightly to moderately elevated; the degree varies among patients. The amount of Hb F present is a function of the number of reticulocytes that contain Hb F, the extent of selective survival of Hb F-containing reticulocytes to become mature Hb F-containing erythrocytes (F cells), and the amount of Hb F per F cell.[7] The Arab–Indian and Senegal haplotypes are associated with higher levels of Hb F than the others.[8]

Newborn Screening

The use of prophylactic penicillin[9] and the provision of comprehensive medical care during the first 5 years of life have reduced mortality from approximately 25% to less than 3%, thereby providing impetus for early identification of infants with sickle cell disease. Based on its economy and superiority of detection, universal screening of all newborns is preferred over ethnically targeted approaches.[10,11] Blood samples for testing are obtained by heel stick and spotted onto filter paper for stable transport and subsequent high-performance liquid chromatography.[12] Results of solubility testing may be invalid because of the large amount of Hb F present.

Characterization of adult hemoglobins is challenging in the fetal and newborn periods because of the predominance of Hb F, which confounds reliable detection of Hb S by solubility testing. In infancy, the diagnosis of sickle cell disease is also influenced by the absence of anemia. As Hb S increases and Hb F declines in the first months of life (Fig. 43–3), the clinical manifestations of sickle cell disease emerge.[13] ISCs can be seen on the peripheral blood smear (Fig. 43–4) of children with sickle cell anemia at 3 months of age, and by 4 months of age moderately severe hemolytic anemia is evident.

A requirement for tests used in newborn screening is the capability to distinguish Hb F, S, A, and C. The patterns of hemoglobins present are described in descending order according to the quantities detected. Therefore, a newborn with sickle cell anemia who has predominantly Hb F, with a small amount of Hb S and no Hb A, is described as having an FS pattern. An FS pattern is obtained also in newborns who have sickle cell–β° thalassemia, sickle cell–hereditary persistence of fetal hemoglobin (HPFH), and sickle cell–Hb D or sickle cell–Hb G (ie, Hb D and E have the same electrophoretic mobility as Hb S). The newborn with sickle cell trait will have Hb F, Hb A, and Hb S (FAS pattern). The quantity of Hb A is greater than that of Hb S. If the quantity of Hb S exceeds that of Hb A, the

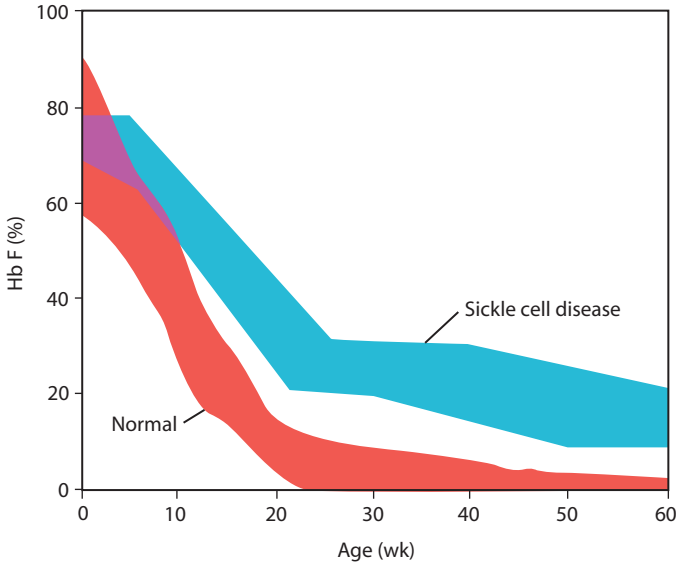

Figure 43–3 Hb F decline in children with hemoglobins AA and SS. *(Data from O'Brien, Mclatosh S, Aspnes AT, et al: Prospective study of sickle cell anemia in infancy. J Pediatr 89(2):205, 1976.)*

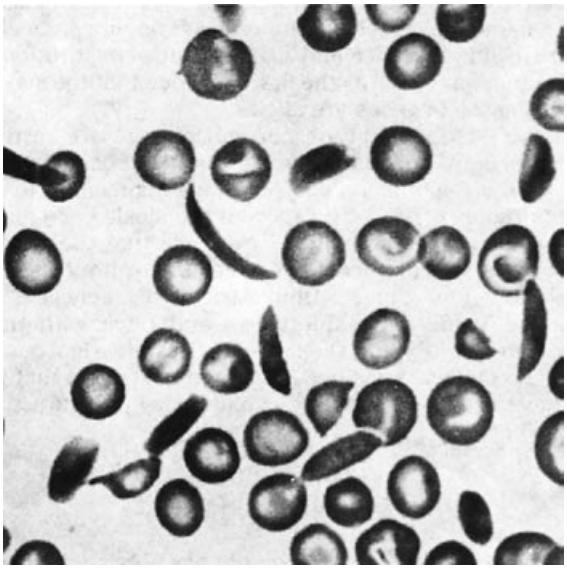

Figure 43–4 Peripheral blood smears showing the peculiar elongated forms of the red corpuscles (originally seen by Herrick). (*With permission from Herrick JB: Peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia. Arch Intern Med 6:517, 1910.*)

presumptive diagnosis is sickle cell–β^+ thalassemia (FSA pattern). It may not be possible to distinguish FAS and FSA patterns in newborns, so DNA-based testing or repeat hemoglobin testing at age 3 to 6 months is recommended.

Prenatal Diagnosis

One large survey found that parents at risk for having a child with sickle cell disease were interested in prenatal diagnosis and would consider termination of pregnancy for an affected fetus.[14] Community acceptance of reproductive genetic services depends on the effectiveness of education and counseling. One major ethical issue pertains to our diagnostic skills' having outstripped our ability to predict the severity of diagnosable conditions.

Fetal DNA samples are obtained by chorionic villus sampling at 8 to 10 weeks' gestation. Polymerase chain reaction (PCR)-based

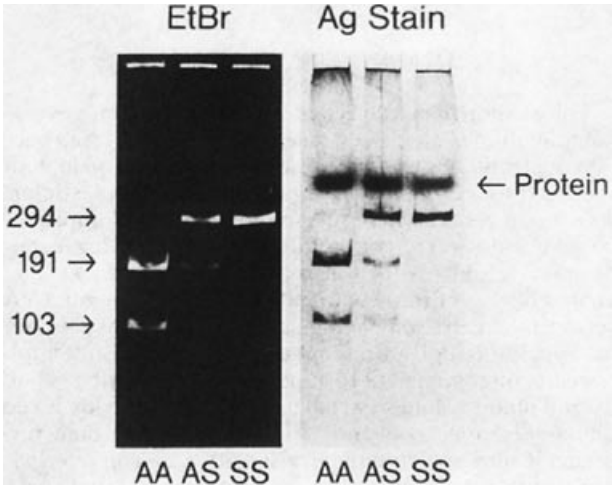

Figure 43–5 PCR-based restriction analysis for the sickle cell gene. The genotypes of the DNA samples tested are shown below. The size in base pairs for the undigested PCR product and the products resulting from Oxa NI are shown at left in base pairs. The fragments from normal β-globin DNA (AA) shows complete Oxa NI cleavage, from sickle cell trait DNA (AS) shows partial cleavage, and from sickle cell anemia (SS) shows no cleavage.

methods for detecting the sickle gene include restriction analysis (Fig. 43–5), allele-specific hybridization, reverse dot-blotting, and allele-specific fluorescence PCR. PCR-based diagnosis for Hb SC disease is possible using specific molecular methods for detecting the Hb C gene, and the diagnosis of sickle cell–β thalassemia can be made using reverse dot-blot methodology to screen the many African American β thalassemia mutations, as well as the Hb S and Hb C mutations, in a single hybridization reaction.

CLINICAL PRESENTATION AND MANAGEMENT

The cardinal clinical manifestations of sickle cell disease are chronic hemolytic anemia, recurrent painful episodes, and chronic organ damage, particularly of the spleen, bones, brain, kidneys, lungs, skin, and heart. The pattern of disease varies among the major genotypes of Hb SS, Hb SC, and Hb S–β thalassemia but also within the same genotype. Some of this variability results from additional inherited genotypes, for example, α thalassemia or HPFH (discussed at the end of this chapter). Typically, patients are anemic but lead a relatively normal life punctuated by painful episodes. However, it is important to realize that chronic organ damage and decreased survival occur even in patients who do not have recurrent pain. This section begins with a brief overview of natural history and survival followed by a discussion of basic management that has as its aim improving this natural history (disease modification). This is followed by a discussion of organ-specific complications and their management.

Natural History and Life Expectancy

The manifestations of disease begin after the first few months of life as Hb F levels decline and Hb S levels increase. Certain complications predominate in particular age groups: between the ages of 1 and 3, splenomegaly and splenic sequestration (see Fig. 43–6), and pneumonia and meningitis from *Streptococcus pneumoniae* and other encapsulated organisms (because of functional hyposplenism), as well as a hand–foot syndrome; in early childhood, stroke, acute chest syndrome, and osteonecrosis; in midchildhood, pain crises, osteonecrosis, and acute chest syndrome; between ages 12 and 20, strokes, priapism, and pain crises; between ages 20 and 30, renal insufficiency, pulmonary hypertension, disabling osteonecrosis, retinopathy, leg

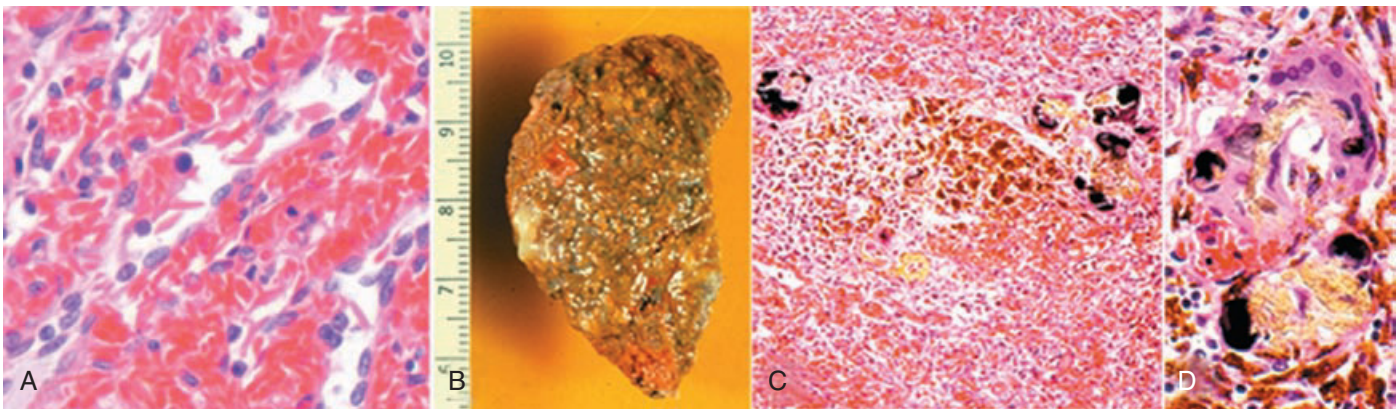

Figure 43–6 Spleen in sickle cell disease (**A–D**). Histologic section (**A**) of the splenic red pulp shows engorgement of the splenic cords with sickled cells. In infants, excessive pooling in cords can lead to a splenic sequestration crisis. Later in life the spleen undergoes autoinfarction. The gross pathology (**B**) shows a tiny 4.5-cm spleen with rough external surface due to scarring from repeated infarcts. Histologic section reveals classic Gamna-Gandy bodies (**C**, **D**) also due to repeated infarction. These comprise hemosiderin-laden macrophages, calcium deposits, and foreign body giant cells.

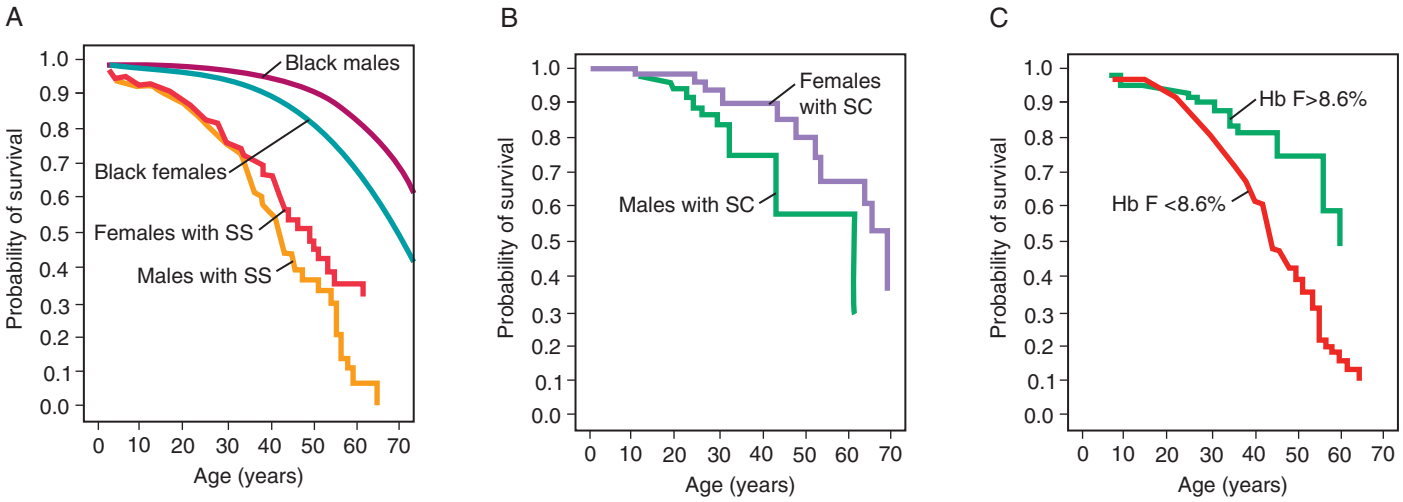

Figure 43–7 Life expectancy. *(From Platt OS, Brambilla DJ, Rosse WF, et al: Mortality in sickle cell disease. Life expectancy and risk factors for early death. N Engl J Med 330(23):1639, 1994.)*

ulcers, and pain crises; and at age more than 30, congestive heart failure, renal failure, and pain crises.

Patients have decreased life expectancy, although in the past 30 years, this has dramatically improved for patients in the West. In 1973 Diggs reported that the mean survival was 14.3 years[15]; in 1994 Platt et al reported that life expectancy was 42 years for men and 48 years for women with sickle cell anemia (Fig. 43–7).[16] This improvement in survival is most likely the result of improved general medical care, including prophylactic penicillin therapy and vaccination against *S pneumoniae*.[9] These survival profiles are likely to be relevant even today, although a cohort of patients followed since 1975 show improvement in the probability of survival to age 20 compared with patients born before 1975 (89% vs 79%).[17] The poor survival and litany of chronic organ damage in survivors emphasizes the need for disease-modifying interventions to prevent vasculopathy.[17] There are indications that disease-modifying agents such as hydroxyurea can improve survival.[18]

Table 43–1 Effect of α Thalassemia on the Level of Anemia in Sickle Cell Anemia

Reference	αα/αα*	−α/αα	−α/−α

*The different α-globin genotypes indicate the presence of four (αα/αα), three (−α/αα), or two (−α/−α) α-globin genes.
†The mean Hb level (g/dL) for each group is shown.
‡The number of subjects in each group is denoted by n.

Predictors of Disease Severity

The ability to predict clinical course would allow more rational tailoring of therapy to individual patients (e.g., selection of patients for high-risk but effective options such as stem cell transplant). Higher HbF levels and the coinheritance of an α thalassemia trait have been identified as favorable disease modifiers in multiple studies (Table 43–1).[19–21] The level of chronic anemia (which is influenced by the presence of an α thalassemia trait and by Hb F levels) is of considerable predictive value. Patients with more severe anemia are more likely to develop infarctive and hemorrhagic stroke,[22] to have glomerular dysfunction,[23,24] and perhaps to give birth to low-birthweight babies.[25,26] Conversely, they have fewer episodes of acute chest syn-

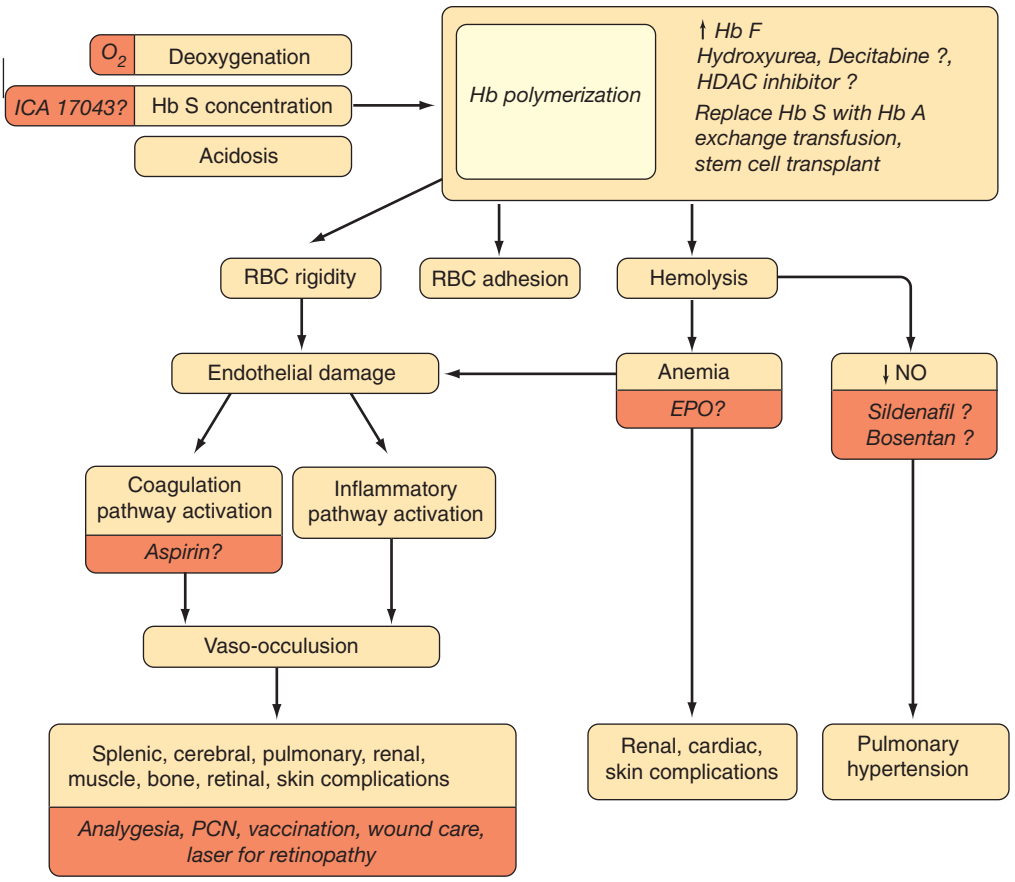

Figure 43–8 Where therapeatics intervene in the pathophyrsiological cascade.

drome,[27] and (after age 20 years) a lower mortality rate.[27] Progressive anemia from renal endocrine deficiency and/or decrease in bone marrow function from vasoocclusion is associated with early death.[18]

There are a number of other genetic polymorphisms that may be relevant to disease severity, for example, with regards to the risk of stroke. However, most of these markers are not widely used to guide decision making.[20]

Principles of Management

The twin pillars of therapy are disease modification (prevention of crises, complications, chronic organ damage, and early mortality) and compassionate, prompt, effective and safe relief of acute crises, including pain episodes. Therefore, outpatient clinic management is mostly directed at initiating measures to prevent pain crises, prevent organ complications and improve survival. An effort should be made to identify existing organ complications and initiate measures to prevent further deterioration. Outpatient management can thus be divided into baseline evaluations, basic treatment or disease modification, and additional treatment dictated by the organ complications that are identified. The suggested treatments are based on current understanding of sickle cell disease pathophysiology. As shown in Fig. 43–8, some treatments address only one aspect of pathophysiology whereas others may have a broader impact. Inpatient management is directed at effective and safe relief of acute crises.

Baseline Evaluations

Baseline blood, urine, and other evaluations are directed at quantifying the chronic hemolytic anemia and organ-specific complications (Table 43–2). They also provide baseline parameters that can be followed to assess response to therapeutic interventions.

In pediatric patients, at least annual assessment of cerebral blood flow in the internal carotid artery and the middle or anterior cerebral artery using transcranial Doppler ultrasonography (TCD) is recommended. This evaluation is a validated predictor of stroke risk. Primary prevention with chronic transfusion is effective in such patients.[28] In adults, magnetic resonance imaging (MRI)/ magnetic resonance angiography (MRA) of the brain should be used instead of TCD[29] to assess thrombotic or hemorrhagic stroke risk, especially those with a previous history of stroke or seizure. The recognition of pulmonary hypertension as a cause of early mortality in sickle cell disease warrants evaluation for this condition with either echocardiogram or brain natriuretic peptide (BNP) levels; potential interventions for this condition are being evaluated in clinical trials. Retinal evaluation is begun at school age and continued on an annual basis. More frequent retinal evaluations will be necessary if retinopathy is noted.

Basic Management and Disease Modification

There is sufficient evidence to suggest that a number of treatments should be considered in all patients. These treatments have been demonstrated to decrease symptoms/complications, increase survival, or both (Table 43–3) (disease modification). There are other treatments for which there are sufficient scientific grounds and/or clinical data to suggest a potential impact on disease natural history. However, there is presently insufficient clinical data to make firm recommendations (Fig. 43–8, Table 43–3). Although treatments such as vaccination and penicillin prophylaxis do not directly affect the sickling process or vasculopathy, they have had an impact on survival and therefore are included under the umbrella of disease-modifying therapies.

Therapeutic options are further discussed in the sections describing organ specific complications.

Table 43–2 Baseline Evaluations to Consider

	Tests
Blood tests	-CBC with differential -Reticulocyte count -Hemoglobin electrophoresis -LDH -Renal function tests -Liver function tests -Mineral panel -Uric acid -Serum iron, ferritin, TIBC -Erythropoietin level -Hepatitis B sAg -Hepatitis C antibody -Red cell alloantibody screen -Red cell typing -D-dimer* -C-reactive protein* -Brain natriuretic peptide†
Urine/kidney tests	-Urinalysis -Renal ultrasound‡
Radiology	-MRI/MRA brain (adults) or transcranial Doppler ultrasonography starting at age 2 (children) -CXR§ -Hip or shoulder x-ray and/or MRI§ -Bone density in teenagers and adults
Cardiology/Pulmonary	-Echocardiogram -Right heart catheter† -Six-minute walk test†
Neurocognitive	-Neurocognitive testing¶

Key: *Consider following as a surrogate marker after initiation of disease modifying intervention; †to further evaluate pulmonary hypertension; ‡if hematuria with red blood cells in urine; §as clinically indicated; ¶if poor school performance, abnormal memory, or abnormal MRI.

Table 43–3 Disease Modifying Treatments to Consider (See Text for Specific Indications and Limitations)

Robust clinical data	-Penicillin prophylaxis -*S pneumoniae* vaccination -Hydroxyurea -Chronic exchange transfusion -Iron chelation for chronic iron overload*
Limited clinical data	-Folate supplementation† -H. influenzae vaccination -Influenza vaccination -Erythropoietin -Phlebotomy
Experimental	-ICA 17043 (decreasing Hb S concentration) -Decitabine (Hb F reactivation) -Nutritional supplements (eg, glutamine, zinc, multivitamins)

*Best data from thalassemia patient experience; †risks minimal (however, can mask B12 deficiency), therefore it is generally done.

Vaccination and Penicillin Prophylaxis

Children should be immunized against *S pneumoniae*, *H influenzae*, hepatitis B, and influenza.[30] Vaccination and penicillin prophylaxis can reduce the risk of serious pneumococcal infections.[9,31] Vaccination schedules recommend inoculation with heptavalent pneumococcal conjugated vaccine (PCV_7) at 2 months followed by two more doses 6 to 8 weeks apart (primary series) and a booster at 12 months. This is followed by pneumovax at age 2 and 5 years. In adults, the pneumovax should be readministered every 5 years (www.cdc.gov/vaccines/pubs/vis/default.htm).

For children under age 5 years, prophylactic penicillin recommendations are 125 mg penicillin V orally twice daily until age 2 to 3 years, and 250 mg thereafter.[30] Penicillin prophylaxis begins at 2 months. Randomized, double-blind, placebo-controlled studies of prophylactic penicillin beginning in infancy, including the PROPS study, have found that this therapy reduced the incidence of *S pneumoniae* bacteremia by 84% in children younger than 3 years.[9,31] A randomized, double-blind, placebo-controlled study, the PROPS II study, concluded that it is safe to stop prophylactic penicillin therapy at age 5 years in children who have not had prior severe pneumococcal infection or splenectomy and are receiving regular follow-up care.[32] However, the power of the study was restricted by the limited number of *S pneumoniae* systemic infection events. In an analysis of a patient population receiving penicillin prophylaxis and the pneumovax, the rate of severe *S Pneumoniae* infections was 2.4 per 100 patient-years. This was favorable compared to the historical pre-penicillin prophylaxis rate of 3.2 to 6.9 per 100 patient-years.[33] These measures reduce risk but do not remove it. The risk of recurrent *S pneumoniae* sepsis and death in patients who have had previous sepsis is much increased; all patients having a history of pneumococcal sepsis should remain on penicillin prophylaxis indefinitely and are not candidates for outpatient management of febrile episodes.[34] Parents must be aggressively counseled to seek medical attention for all febrile events.

Hydroxyurea and Fetal Hemoglobin (Hb F) Reactivation

The level of HbF in erythrocytes plays a critical role in determining patient outcomes. Individuals who have sickle cell disease and another condition called HPFH have 70% hemoglobin S (HbS) in their red blood cells, but are neither anemic nor symptomatic.[35] The uniform distribution of HbF among their red cells interferes with HbS polymerization, increases its solubility, and prevents red cell sickling.[36,37] Even at lower levels of HbF seen in patients without HPFH, crisis rate and mortality are inversely proportional to HbF level.[18–21] These findings prompted the idea that pharmacologic reactivation of HbF production might be of benefit to patients.

Hydroxyurea (HU) is an inhibitor of ribonucleotide reductase and a cytotoxic agent that can elevate Hb F levels. A double-blind, placebo-controlled, intention-to-treat multicenter study of HU as treatment of pain crisis in sickle cell disease found that HU produced definite hematologic changes. Hydroxyurea was started at 0.15 mg/kg/day and escalated to 0.30 mg/kg/day as tolerated and to maintain an absolute neutrophil count no lower than $2000 \times 10^9\ L^{-1}$. There were significant increases in the levels of hemoglobin, Hb F, F cells, F reticulocytes, PCV, and MCV and declines in the mean level of leukocytes, PMN, reticulocytes, and dense sickle cells (Table 43–4).[38] The significant clinical changes were decreased rate of acute painful episodes, longer interval to first and second acute painful episode, fewer episodes of acute chest syndrome, and diminished number of subjects and units transfused (Table 43–5).[39] In follow-up analysis, higher pre- or posttreatment Hb F levels were associated with a reduction in mortality (although no significant changes were observed in the incidence of stroke, hepatic sequestration, or death in the initial study).[18] No short-term toxicity due to HU was observed. One child born to a subject taking HU and two born to partners of subjects taking HU were normal at birth. Although the follow-up analyses suggest the importance of induced Hb F to the improved outcomes produced by HU, some HU-induced changes in sickle cell erythrocytes, such as reduced neutrophil count, increased water content, and decreased HbS concentration,[40] may be independent of Hb F.

In the original study, only patients with two or more pain crises per year requiring hospitalization were eligible. However, other at-

Adapted from data in Charache et al.[253]

risk patients should be considered for hydroxyurea therapy. These include patients with evidence of chronic organ damage, patients with severe anemia (<9 g/dL, consider erythropoietin if the reticulocyte count is <250,000 μL^{-1}), and patients with indications for chronic transfusion but who have alloantibodies. After obtaining the baseline evaluations per Table 43–2, hydroxyurea is usually started at 500 to 1000 mg/day with monitoring of the complete blood count every 4 to 8 weeks to ensure that neutropenia (absolute neutrophil count $<2 \times 10^9\ L^{-1}$) is not produced. The dose is increased to a stable maximum NGF response or neutropenia, but most patients receive between 1000 and 2000 mg/day. Response is defined clinically and by a persistent and significant (>0.5 g/dL) increase in total hemoglobin/fetal hemoglobin and a decrease in the LDH. These improvements in symptomatology and hematologic indices may take 3 to 4 months of therapy to manifest but can be seen after approximately 6 weeks. Lower doses may be required in patients with renal insufficiency. If the reticulocyte count is less than 250,000 μL^{-1}, then the possibility of erythropoietin deficiency should be considered (see section on erythropoietin).

In studies of HU as a therapy for children with sickle cell disease, the drug was well tolerated and produced favorable hematologic changes similar to those seen in the adult population.[41] In approximately 10% of the children treated, the increase in Hb F was less than 2%. Baseline Hb F levels, baseline total hemoglobin levels, and compliance were associated with the final Hb F level.[42] Other studies in children have documented a decrease in the number of days of hospitalization and suggest a decreased incidence of vasoocclusive crises.[43] The favorable changes in hematologic indices suggest that HU therapy might be an alternative to blood transfusions for the prevention of recurrent stroke in children with sickle cell disease.[44,45] HU therapy appears to lower transcranial Doppler velocities in children with sickle cell disease.[46] Studies in the United States and in Belgium support the potential role of hydroxyurea in the prevention of cerebral vascular accidents.[45,47,48] HU was found to improve, but not correct, the abnormal cerebral oxygen saturation associated with sickle cell disease.[49]

A persistent concern pertaining to the use of HU in sickle cell disease is its putative leukemogenic effect. This concern derives from reports on HU treatment of myeloproliferative diseases, conditions associated with an inherent propensity for leukemic conversion. Although the use of HU combined with ^{32}P or alkylating agents is associated with increased leukemic conversion in patients with myeloproliferative disease,[50] reports claiming a leukemogenic effect for HU alone in polycythemia vera either lacked controls[51] or were not designed to assess this issue.[52] In children with the nonmalignant underlying condition of erythrocytosis secondary to inoperable cyanotic congenital heart disease, no leukemic conversion was observed.[53]

Vitamin or Nutritional Supplementation

Chronic hemolysis results in increased utilization of folic acid stores. Megaloblastic crises from folic acid deficiency have been reported.[54,55] Pediatric patients with sickle cell disease had higher homocysteine levels than age-matched control African American patients.[56] Folic acid, 1 mg orally per day, is administered as a standard of care.[57] B_{12} deficiency can also be seen in sickle cell disease patients. Folate replacement can mask and possibly exacerbate B_{12} deficiency.[58]

A growing body of research indicating that sickle cell patients have widespread mineral and vitamin deficiencies, including zinc, vitamin C, vitamin E, acetylcysteine, calcium, vitamin D, vitamin A, and others.[59] Fifty percent of children with sickle cell disease have evidence of osteoporosis or osteopenia that is associated with inadequate calcium and vitamin D intake.[60–62] Recently, zinc supplementation in a prospective trial documented significant improvement in linear growth and weight gain in children with sickle cell disease.[63]

Despite increased intestinal absorption of iron in sickle cell disease, the combination of nutritional deficiency and urinary iron losses results in iron deficiency in 20% of children with sickle cell disease.[64] The diagnosis of iron deficiency may be obscured by the elevated serum iron levels associated with chronic hemolysis, necessitating the detection of a low serum ferritin level or an elevated serum transferrin level for the diagnosis.

Transfusion Therapy

There are two main approaches to transfusion in sickle cell disease—simple transfusion and exchange transfusion. These transfusions can be administered in an episodic fashion or in a chronic fashion. Therefore, transfusion therapy in sickle cell disease is of the following types: episodic simple, episodic partial exchange, or chronic partial exchange. In both simple and exchange transfusion, the target hemoglobin level is 10 to 11 g/dL (hematocrit 30%).[65,66] Transfusing to a higher hemoglobin or hematocrit level is avoided because a hematocrit level greater than 30% is associated with hyperviscosity if there is a substantial proportion of Hb S in the blood. In exchange transfusion, an additional objective is to achieve an HbS percentage of less than 30% (or sometimes <50%). In partial-exchange transfusion, a proportion of the patient's diseased red cells are removed before transfusion of normal donor red blood cells; this can be done manually through phlebotomy followed by transfusion or concurrently using an automated device. In those patients who need chronic transfusion, partial exchange is recommended because of the reduced iron burden

Table 43–6 Transfusion Formulas

A. Simple transfusion
PRBC volume (PRBCV) (mL) = $(Hct_d - Hct_i) \times TBV \times Hct_{rp}B$. Dilutional effects of transfusion on Hb S
Hb $S_f = 1 - (PRBCV \times Hct_{rp})(TBV \times Hct_i) + (PRBCV \times Hct_{rp}) \times$ Hb S_iC. Manual partial-exchange transfusion*
Exchange volume (mL) = $(Hct_d - Hct_i) \times TBVHct_{rp} - (Hct_i + Hct_d)2D$. Automated exchange transfusion
RBC volume (mL) = $Hct_i \times TBV$

TBV, estimated total blood volume in mL (children 80 mL/kg, adults 65 mL/kg, nomograms are available)†; Hct_d, desired hematocrit; Hct_i, initial hematocrit; Hct_{rp}, hematocrit of replacement cells (usually 0.75); Hb S_i, initial Hb S; Hb S_f, final Hb S.

In these formulas Hct and Hb S are fractions (eg, 40% = 0.4).

*From Nieburg and Stockman,[826] with permission. Copyright 1977, American Medical Association.

†From Linderkamp et al,[827] with permission. Copyright 1977 by Springer-Verlag GmbH & Co, KG.

of this approach. Partial exchange is also indicated if the baseline hemoglobin level is more than 10 g/dL. Simple transfusion in this context risks exacerbating the clinical condition through increased viscosity. For critical illness, exchange transfusion is also preferred. Although the target Hb S level should be less than 30% in exchange transfusion, decreasing Hb S levels to less than 50% may suffice depending on the severity of the complication being treated.

The volumes required for simple and exchange transfusions (Table 43–6) are particularly important for transfusing children. For normal-size adults, the general rule is that each unit of red cells infused increases the hemoglobin level approximately 1 g/dL. One approach to manual partial-exchange transfusion in adults is to phlebotomize 500 mL, infuse 300 mL normal saline, phlebotomize another 500 mL, then infuse 4 to 5 units of packed red cells.[67]

Episodic simple transfusion should be considered for blood volume replacement in aplastic crisis and splenic sequestration crisis, and protection during severe illness such as septicemia or severe vasoocclusive crisis/hyperhemolysis associated with a more than 20% decrease in hemoglobin from baseline or hemoglobin levels of less than 5 g/dL. Episodic simple or exchange transfusion should be considered for acute chest syndrome, priapism, and preoperatively. The choice of simple versus exchange transfusion is determined by the pretransfusion total hemoglobin level and the severity of the illness.

In the preoperative setting, simple transfusion to increase the total hemoglobin level to 10 g/dL was as effective in preventing perioperative complications and was associated with fewer transfusion-associated complications than an aggressive exchange transfusion regimen to decrease Hb S levels to less than 30%.[68] The efficacy of preoperative partial-exchange transfusion in patients with Hb SC disease undergoing abdominal surgery suggests that this type of transfusion be performed preoperatively in this group of patients.

Chronic partial-exchange transfusion is indicated in primary and secondary prevention of cerebral thrombosis as discussed in the section on neurologic complications.

Transfusion complications include alloimmunization, delayed hemolytic transfusion reactions (discussed in Exacerbations of Anemia), iron overload, and transmission of viral illness. The incidence of alloimmunization is between 19% and 30% and usually occurs with less than 15 transfusions.[69] Some patients seem to tolerate multiple transfusions without developing alloantibodies whereas others are readily allosensitized. The high rate of alloimmunization in transfused sickle cell patients is due in part to minor blood group incompatibilities between the recipient and donor pool, which often differ in ethnicity.[69,70] Antibodies against the C and E antigens of the Rh group, Kell (K) and Lewis, Duffy (Fya, Fyb), and Kidd (Jk) are common.[69] In the Stroke Prevention Trial in Sickle Cell Anemia, the routine use of WBC-reduced RBCs matched for E, C, and Kell decreased the allosensitization rate compared to historical data from 3% to 0.5% per unit transfused and decreased the rate of hemolytic transfusion reactions by 90%.[71] Therefore, the recommended approach to preventing alloimmunization is to reduce leukocytes and perform limited phenotype matching for all patients (ABO, C, D, E, and Kell) and extended phenotype matching for patients with alloantibodies.[66] The management of a delayed hemolytic transfusion reaction and transfusional iron overload are discussed under Exacerbations of Anemia below.

Transmission of HIV, hepatitis B and C, and human T-cell leukemia/lymphoma virus-1 has diminished with improved screening of banked units but remains an issue. In addition to better screening programs, the use of leukocyte-depleted red cell transfusions can reduce this hazard.[72]

Stem Cell Transplantation

At this time, allogeneic stem cell transplantation remains the only curative option for sickle cell disease. The largest series to date has been in a pediatric population with severely symptomatic sickle cell disease failing to respond to hydroxyurea. Using myeloablative conditioning and HLA-matched or one-mismatch (two cases) sibling donors, with bone marrow as the source of stem cells in the majority, there was a 10% mortality rate with 90% overall survival and 82% event-free survival at a median follow-up of 54 months.[73] Similar results were obtained when related, HLA-matched umbilical cord blood was used as the source of stem cells.[74] According to these results, stem cell transplant is a therapeutic option for the severely symptomatic child with an HLA-matched sibling donor. Non-myeloablative conditioning approaches may allow a further decrease in transplant-related mortality. Extended molecular phenotyping may decrease the risks of matched unrelated stem cell transplantation for those patients without matched sibling donors.[75] The issue of the cost-effectiveness of BMT gains perspective from the comparative costs in the United States of $150,000 to $200,000 for an uncomplicated BMT versus up to $112,000 annually for conventional medical care of a chronically transfused, iron-overloaded patient.[76]

Education

Education regarding the nature of the disease, genetic counseling, and psychosocial assessments of patients and their families are best accomplished during routine visits. Parents of small children are instructed regarding early detection of infection and palpating enlarging spleens.

Phlebotomy

As mentioned, a hemoglobin level of more than 10 to 11 g/dL (hematocrit 30%) in the presence of substantial amounts of Hb S (>30%) is associated with hyperviscosity. There are some data to indicate that phlebotomy, to reduce the hematocrit and viscosity (and which may also address iron-overload), can decrease the frequency of crises in Hb SC or Hb S–β^+ disease.[77] In Hb SS disease, phlebotomy has successfully been used in combination with hydroxyurea (which increases the hemoglobin level) in secondary stroke prevention in patients previously treated with chronic transfusion.[78] Phlebotomy alone has also been used in Hb SS disease with baseline Hb levels of more than 9.5 g/dL with favorable results on the frequency and duration of pain crises. This benefit may have resulted from decreased hematocrit and viscosity and also from a decrease in intracellular hemoglobin concentration from iron deficiency.[79] One approach to phlebotomy is to remove approximately 10 mL/kg of blood over 20 to 30 minutes followed by infusion of an equal volume of normal saline. This is repeated every 2 weeks until the target hemoglobin level of 9 to 9.5 g/dL is achieved.

Erythropoietin or Darbepoietin

Generally low erythropoietin levels are seen in sickle cell disease,[80] one contributing factor could be increased uptake by the massive compensatory reticulocytosis. Therefore, erythropoietin levels in isolation are difficult to interpret in sickle cell disease. However, inappropriately low erythropoietin levels are more severe in adults than in children,[80] and relative reticulocytopenia (reticulocyte count $<250{,}000 \times 10^9\ L^{-1}$) is associated with evidence of renal damage such as proteinuria, suggesting that erythropoietin deficiency should be considered in cases of progressive anemia or relative reticulocytopenia, even if the creatinine levels are within the normal range. Relative reticulocytopenia is a risk factor for early death,[81] and reversing the resulting progressive anemia may have benefits. The cumulative published experience of erythropoietin use in sickle cell disease is limited (52 patients).[82] Although erythropoietin by itself has been reported to increase HbF levels, the most important role for erythropoietin may be as replacement therapy for erythropoietin deficiency that results in relative reticulocytopenia and progressive anemia. As noted above, erythropoietin deficiency may be clinically significant even when creatinine levels are in the normal range. Erythropoietin replacement can also facilitate enhanced hydroxyurea dosing and HbF augmentation.[82] In using recombinant human erythropoietin, caution must be exercised not to elevate the hematocrit to levels that result in hyperviscosity. Also, the reticulocyte fraction is the most adhesive, and it is possible that erythropoietin could exacerbate or trigger sickle cell crises.[82] Sickle cell patients may be relatively resistant to erythropoietin and require doses higher than those used in other patients with chronic renal failure. The reasons for erythropoietin resistance are unclear but may include increased inflammation-mediated suppression of erythropoiesis.[83]

Erythropoietin therapy is probably not indicated in patients receiving chronic transfusion therapy in whom encouraging endogenous HbS containing erythropoiesis may be counterproductive.

Iron Chelation

Early death is well described in association with iron overload from β-thalassemia and hereditary hemochromatosis.[84,85] Similarly, iron overload is likely to be a problem in chronically transfused sickle cell disease patients although the clinical significance may critically depend on the degree and duration of overload. Chelation guidelines for patients with sickle cell disease are similar to those for other chronically transfused, iron-overloaded patients; iron chelation indicated when the total body iron level is elevated (ferritin >2000, quantitative liver iron by dry weight of 2000, transfusion history >1 year of monthly transfusions).[86] Notably, the serum ferritin level may underestimate clinically significant iron overload.[87,88] Iron chelation options in the USA are deferoxamine (via continuous IV or SQ infusion) or deferasirox (orally), both of which appear to have similar efficacy although the oral route of administration and toxicity profile may favor deferasirox.[20,89,244]

Newer FDA-approved methods of quantitating iron burden by Ferriscan of the liver[90] can avoid the need for liver biopsies. T2* MRI of the heart indicates hemosiderosis of cardiac tissue, and when it is abnormal, aggressive chelation is mandated.[91]

Alternatives to HU for HbF Induction

Alternatives to HU for pharmacologic induction of HbF that are being studied in clinical trials include the methyltransferase inhibitor 5-aza-2′-deoxycytidine (decitabine) and histone deacetylase inhibiters.[92] These classes of agents act on chromatin processes that regulate gene transcription.

The methyltransferase inhibitors 5-azacytidine and 5-aza-2′-deoxycytidine have produced the largest increases in HbF of any of the pharmacologic reactivators of HbF that have been tested.[93,94] Responding patients include those who did not respond to hydroxyurea, consistent with a different mechanism of action for decitabine. Although improvements in a number of surrogate clinical endpoints have been demonstrated, larger studies to confirm safety and clinical effectiveness with chronic use are required. In the United States, decitabine has been approved by the Food and Drug Administration (FDA) for the treatment of myelodysplastic syndrome.

The efficacy of the class of agents known as histone deacetylase inhibitors in HbF reactivation has been reviewed.[95,96] However, the absence of large clinical trial data, practical issues with administration and stability of some agents, and the lack of FDA approval for many drugs in this class are limitations.

Preventing Red Cell Dehydration With Ion Channel Inhibitors

Polymerization of HbS is related to the HbS concentration within the cell. Therefore a therapeutic strategy could be to reduce the intracellular HbS concentration by improving cellular hydration. Potential therapeutic options to maintain red-cell hydration for which there is preliminary clinical data include cetiedil citrate, imidazole inhibitors of the Gardos pathway,[97] novel Gardos channel inhibitors[98] or magnesium supplements, which inhibit potassium chloride cotransport.[99]

It also is possible to reduce the hemoglobin concentration by reducing the hemoglobin content with iron deficiency. It has been observed that spontaneous or induced iron deficiency (see Phlebotomy above) sufficient to reduce the serum ferritin, mean corpuscular volume (MCV), and mean cell hemoglobin concentration (MCHC) resulted in variably improved HbS polymerization, red cell survival, level of anemia, and clinical status.[100]

Anticoagulation or Antiplatelet Therapy

Although there is clear evidence of activation of the coagulation system in sickle cell disease, the role of thrombogenesis in vasoocculsive crisis remains unclear.[101] D-dimer levels (a degradation product of cross-linked fibrin) increase during acute vasoocclusive crisis.[102]

Heparin

Minidose heparin, 5000 to 7500 units every 12 hours, administered to four patients for 2 to 6 years, reduced hospitalization and emergency room time by 75%, and pretreatment pain frequency recurred after heparin was discontinued.[103] Larger clinical studies will be required to better understand the risks and benefits of heparin therapy for acute vasoocclusive crisis in sickle cell disease. Heparin has not been studied for acute arterial stroke in patients with sickle cell disease but has a role in sickle cell-associated dural venous sinus thrombosis.[104] The management of stroke is fully discussed under Specific Complications and Their Management.

Oral Anticoagulants

Acenocoumarol was administered in low doses that achieved a mean INR of 1.64 and reduced the elevated levels of prothrombin activation fragment (fragment 1+2) to 50% of pretreatment levels.[105] Clinical endpoints were not measured. In a crossover study, 29 patients were treated with acenocoumarol to target an INR of 1.6 to 2.0. No effect on crisis frequency was noted, although again, there were significant reductions in markers of coagulation system activation.[106] In 37 acutely ill sickle cell patients with elevated D-dimers, the effect of low-dose warfarin therapy (1 mg without a target INR) in 12 of them was examined. In multivariate analysis, low-dose warfarin was the only variable associated with a significant decrease in D-dimer levels, suggesting a warfarin-induced decrease in thrombin activity.[102] Therefore, oral anticoagulation, even at low doses, is associated with

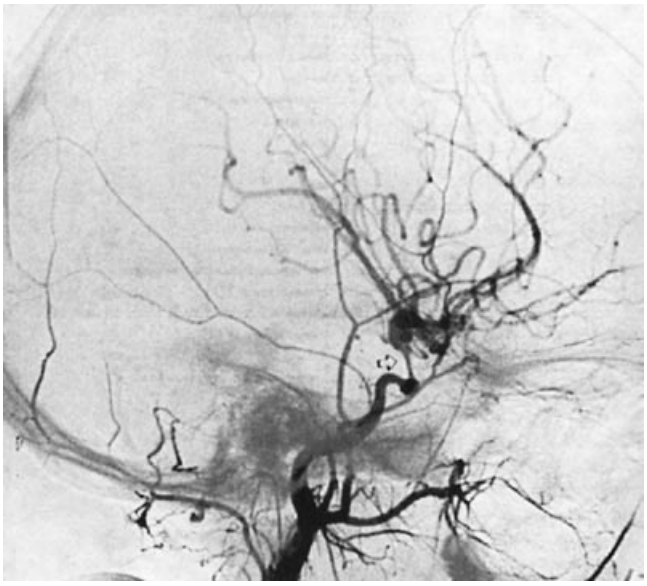

Figure 43–9 Right common carotid arteriogram taken in anteroposterior projection, demonstrating complete occlusion of the origin of the right anterior cerebral artery (arrowhead). *(From Stockman JA, Nigro MA, Mishkin MM, Oski FA: Occlusion of large cerebral vessels in sickle-cell anemia. N Engl J Med 287(17):846, 1972.)*

a decrease in laboratory markers of coagulation pathway activation in sickle cell disease; however, further clinical trials are required to understand the clinical risks and benefits.

Aspirin

Aspirin was compared with placebo in 49 pediatric sickle cell disease patients in a double-blind crossover study. The frequency and severity of crises were not affected by aspirin therapy.[107] Cerebral thrombosis, which accounts for 70% to 80% of all cerebrovascular accidents (CVAs) in sickle cell disease, results from large-vessel occlusion (Fig. 43–9) rather than the more typical microvascular occlusion of sickle cell disease. In the United States, there is an ongoing clinical trial testing the safety and efficacy of aspirin in diminishing the incidence and progression of cognitive defects and overt or silent stroke in pediatric patients.

The management of stroke risk and stroke is fully discussed under Specific Complications and Their Management.

Experimental Therapies

A number of therapies are in early stages of clinical evaluation and could have a role in disease modification of sickle cell disease. These include agents that directly address sickle erythrocyte adhesion to endothelium (recombinant PSGL–IgG conjugate), agents that increase the production of nitric oxide (NO) (glutamine), and herbal extracts with unknown mechanisms of action (niprisan).[108]

Specific Complications and Their Management

Pain Crisis

Acute Pain Episode or Crisis

Acute pain is the first symptom of disease in more than 25% of patients and is the most frequent symptom after age 2 years.[109] Pain is the complication for which patients with sickle cell disease most commonly seek medical attention.[110] An episode of acute pain was originally called a "sickle cell crisis" by Diggs, who used the expression "crisis" to refer to any new rapidly developing syndrome in the life of a patient with sickle cell disease.[111] The basic mechanism is believed to be vasoocclusion of the bone marrow vasculature causing bone infarction, which in turn causes release of inflammatory mediators that activate afferent nociceptors.[112]

Although a general correlation of vasoocclusive severity and genotype has been posited,[113] there is tremendous variability within genotypes and in the same patient over time. In one large study of patients with Hb SS disease, one-third rarely had pain, one-third were hospitalized for pain approximately two to six times per year, and one-third had more than six pain-related hospitalizations per year.[114] Over a 5-year period in the National Cooperative Study of Sickle Cell Disease, 40% of patients had no painful episodes and 5% of patients accounted for one-third of the emergency room visits. Pain is more frequent with the Hb SS genotype, low levels of Hb F, higher Hb levels[27] and sleep apnea.[115] The frequency of pain peaks between ages 19 and 39 years. After the age of 19 years, more frequent pain correlates with a higher mortality rate.[27] Medical personnel who see patients only in the emergency department gain a biased view of sickle cell disease skewed by a frequently afflicted minority with severe disease.[116,117]

Pain may be precipitated by events such as cold, dehydration, infection, stress, menses, and alcohol consumption. Any underlying cause should be searched for and corrected, but the majority of painful episodes have no identifiable cause. It can affect any area of the body, most commonly the back, chest, extremities, and abdomen, may vary from trivial to excruciating, and is usually endured at home without a visit to the emergency department. There may be premonitory symptoms.[117] The duration averages a few days, with hospital admissions typically lasting between 4 and 10 days. Painful episodes are biopsychosocial events caused by vasoocclusion in an area of the body having nociceptors and nerves.[112] Pain is an affect and, as such, consists of sensory, perceptual, cognitive, and emotional components. Frequent pain generates feelings of despair, depression, and apathy that interfere with everyday life and promote an existence that revolves around pain. This scenario may lead to a chronic debilitating pain syndrome; fortunately, this is rare.

There is no specific clinical or laboratory finding pathognomonic of pain crisis. The diagnosis is established by history and physical examination. Changes in steady-state Hb values, sickled cells on blood smear, WBC counts, etc, are not reliable indicators. Numerous laboratory tests, leukocytosis, D-dimer fragments of fibrin, and markers of platelet activation have been found to lack specificity as indicators of acute vasoocclusion. Often patients can tell if it is a typical pain crisis or something more sinister. It is thus good practice to ask the patient if it feels like usual pain crisis pain.

Initial medical assessment should focus on detection of triggers or medical complications requiring specific therapy: infection, dehydration, acute chest syndrome (fever, tachypnea, chest pain, hypoxia, and chest signs), severe anemia, cholecystitis, splenic enlargement, neurologic events, and priapism.[118] Pain management should be aggressive to make the pain tolerable and enable patients to attain maximum functional ability. To make the patient pain-free is an unrealistic goal and risks oversedation and hypoventilation, which must be avoided. A pain chart should be started, and analgesia titrated against the patient's reported pain together with medical assessment of their overall clinical status, paying particular attention to avoiding oversedation. When clinicians consistently observe a disparity between patients' verbal self-report of their pain and their ability to function, further assessment should be performed to ascertain the reason for disparity. Patients are often undertreated for pain because many physicians and other health care providers are overly concerned with the potential for addiction. Undertreatment of pain is no more desirable than overtreatment and oversedation; undertreatment can prolong the duration of a painful episode and can poison the relationship between the patient and the health care system. In assessing patient responses to conventional doses of analgesia, it must be remembered that those with sickle cell disease metabolize narcotics rapidly.[119]

The pain pathway should be targeted at different points with different agents, avoiding toxicity with any one class (Table 43–7). The

Table 43–7 Recommended Dose and Interval of Analgesics Necessary to Obtain Adequate Pain Control in Sickle Cell Disease

	Dose/Rate	Comments
Severe/moderate pain		
1. Morphine	Parenteral: 0.1–0.15 mg/kg q 3–4 h. Recommended maximum single dose 10 mg PO: 0.3–0.6 mg/kg q 4 h	Drug of choice for pain; lower doses in the elderly and infants and in patients with liver failure or impaired ventilation
2. Meperidine	Parenteral: 0.75–1.5 mg/kg q 2–4 h. Recommended maximum dose 100 mg PO: 1.5 mg/kg q 4 h	Increased incidence of seizures. Avoid in patients with renal or neurologic disease or those who receive monoamine oxidase inhibitors.
3. Hydromorphone	Parenteral: 0.01–0.02 mg/kg q 3–4 h PO: 0.04–0.06 mg/kg q 4 h	
4. Oxycodone	PO: 0.15 mg/kg/dose q 4 h	
5. Ketorolac	Intramuscular: Adults: 30 or 60 mg initial dose, followed by 15–30 mg. Children: 1 mg/kg load, followed by 0.5 mg/kg q 6 h	Equal efficacy to 6 mg MS; helps narcotic-sparing effect; not to exceed 5 days. Maximum 150 mg first day, 120 mg maximum subsequent days. May cause gastric irritation.
6. Butorphanol	Parenteral: Adults: 2 mg q 3–4 h	Agonist-antagonist. Can precipitate withdrawal if given to patients who are being treated with agonists.
Mild pain		
1. Codeine	PO: 0.5–1 mg/kg q 4 h. Maximum dose 60 mg	Mild to moderate pain not relieved by aspirin or acetaminophen; can cause nausea and vomiting
2. Aspirin	PO: Adults: 0.3–6 mg q 4–6 h. Children: 10 mg/kg q 4 h	Often given with a narcotic to enhance analgesia. Can cause gastric irritation. Avoid in febrile children.
3. Acetaminophen	PO: Adults 0.3–0.6 g q 4 h. Children: 10 mg/kg	Often given with a narcotic to enhance analgesia
4. Ibuprofen	PO: Adults: 300–400 mg q 4 h. Children: 5–10 mg/kg q 6–8 h	Can cause gastric irritation
5. Naproxen	PO: Adults: 500 mg/dose initially, then 250 q 8–12 h. Children: 10 mg/kg/day (5 mg/kg q 12 h)	Long duration of action. Can cause gastric irritation.
6. Indomethacin	PO: Adults: 25 mg q 8 h. Children: 1–3 mg/kg/day given 3 or 4 times	Contraindicated in psychiatric, neurologic, renal diseases. High incidence of gastric irritation. Useful in gout.

Adapted from Charache et al,[330] with permission.

mainstays are NSAIDs, acetaminophen, and opioids. NSAIDs can be used to control mild to moderate pain and may have an additive role in combination with opioids for severe pain. The most potent NSAID is ketorolac. NSAIDs should be used with caution in those with a history of peptic ulcer, renal insufficiency, asthma, or bleeding tendencies. Within limits, use the agents that the patients know work for them—avoid meperidine (Demerol), which should only be used under very exceptional circumstances. Sedatives and anxiolytics alone should not be used to manage pain, because they can mask the behavioral response to pain without providing analgesia.

Treatment of persistent or moderate to severe pain should be based on increasing the opioid strength or dose.[118] One approach is to administer morphine 0.1 mg/kg intravenously or subcutaneously every 20 minutes until pain is controlled. The patient should be checked at 20-minute intervals for pain, respiratory rate, depth and quality, and sedation until the patient is stable with adequate pain control. Subsequently, the patient should receive a maintenance dose of 0.05 to 0.15 mg/kg intravenously or subcutaneously every 2 to 4 hours. A rescue dose of 50% of the maintenance dose can be considered on an as-needed basis every 30 minutes for breakthrough pain.

During maintenance with opioids, pain control, respiratory rate, depth and quality, and oxygen saturation should be monitored approximately every 2 hours. If respiratory depression is noted, omit the maintenance dose of morphine. For severe respiratory depression or oxygen desaturation, administer naloxone. Incentive spirometry and mandatory time out of bed are helpful in patients with chest pain to decrease the risk for hypoventilation. Adjuvant medications to consider include NSAIDs, acetaminophen, antiemetics, and antihistamines. Laxatives or stool softeners should be prescribed in keeping with close monitoring for constipation.

After 2 to 3 days, consider decreasing the dose and switching from parenteral to oral administration of opioids. For adult patients whose pain requires several or many days to resolve, a sustained-release opioid preparation is appropriate and provides a more consistent analgesia.

Hydration is a critical part of management. However, cardiac function may be significantly impaired, especially in adult patients, and standard discipline must be followed with IV fluid management to avoid iatrogenic fluid overload. Sickle cell patients cannot concentrate their urine and are at risk for dehydration when not taking adequate fluids (60 mL/kg/24 h in adults). Intravenous hydration is indicated when the patient is not taking oral fluids adequately. Ideally the urine specific gravity should be kept under 1.010 by daily testing when in hospital. Hemoglobin may decrease by 1 to 2 g/dL in an uncomplicated pain crisis, blood transfusion is not routinely indicated for an uncomplicated pain crisis.

Equianalgesic doses of oral opioids should be prescribed for home use when necessary to maintain the relief achieved in the emergency department or hospital ward. Care should be taken to appropriately taper opioids in patients who have received daily opioids over many days. In these patients, there may be physical opiate dependence, which is characterized by the onset of acute withdrawal symptoms upon cessation of opioid administration. For patients at risk for physical dependence, opiates should be titrated downward by 15% to 20% per day to zero. Physical dependence is a physiological problem, addiction is a psychological problem characterized by craving—behavior that is overwhelmingly directed at obtaining drug, use of the drug for purposes other than pain control, and use of the drug despite negative physical, social, legal, or psychological consequences.

If the patient is not on a disease-modifying agent such as hydroxyurea, consideration should be given to initiating such therapy either as an inpatient or during follow-up in the outpatient setting.

Table 43–8 Hematologic Variables Associated With Sickle Cell Anemia and the Different Sickle Cell-β Thalassemia Syndromes

Genotype	Hb*	%Hb A†	%Hb F†	%Hb A_2*	MCV*	Reticulocytes*	No.
Hb SS‡	7.83	0	4.56	2.87	85.9	10.18	~123
Hb S-β° thal‡	8.85	0	5.86	5.02	69.3	7.2	~41
Hb S-β⁺ thal, type I§	8.37	3–5	6.8	4.90	63.7	9.7	3
Hb S-β⁺ thal, type II§	10.28	8–14	5.2	4.68	70.0	6.6	14
Hb S-β⁺ thal, type III‖	11.55	18–25	5.1	4.66	73.3	1.27	76
Hb S-HPFH¶	14.6	0	25.8	1.95	81.7	2.4	4

*The mean data for each variable are shown. Units of measure are g/dl for Hb, percentage of total hemoglobin for Hb F and A2, fl for MCV, and percentage of total red cells for reticulocytes.

†Percentage Hb A that defines the Hb S-β⁺-thalassemia type.[245]

Chronic Pain

Chronic pain in sickle cell disease usually (but not always) has an identifiable basis such as vertebral fractures, femoral head necrosis, early degenerative changes/osteoarthritis, or chronic skin ulcers. Most patients without such identifiable complications will not require chronic pain medications similar to those used for terminal cancer because the pain from a typical vasoocclusive crisis is episodic. Inappropriately maintaining patients without chronic musculoskeletal degeneration on long-acting opiates can impair their overall psychosocial functioning. On the other hand, adequate analgesia with long-acting opiates (such as long-acting morphine preparations similar to those used in cancer patients) is important to maintain the psychosocial functioning of patients who do have complications that cause chronic pain. Also consider agents such as amitriptyline or antiseizure medications[120] that can address neuropathic components and help decrease the sleep impairment and depression that can occur with chronic pain. If the patient is not on a disease-modifying agent such as hydroxyurea, consideration should be given to initiating such therapy.

Chronic Anemia

Chronic hemolytic anemia is one of the hallmarks of sickle cell disease. Sickle erythrocytes are destroyed randomly, with a mean life span of 17 days.[121] The overall hemolytic rate reflects the number of ISCs.[122] The degree of anemia is most severe in sickle cell anemia and Hb S–β° thalassemia, milder in Hb S–β⁺ thalassemia and Hb SC disease,[123] and, among patients with sickle cell anemia, less severe in those who have coexistent α thalassemia (Tables 43–8 and 43–1).[124]

As already noted, erythropoietin deficiency, from otherwise subclinical chronic renal damage, may also contribute to a decline in Hb levels below baseline. The level of chronic anemia is a significant prognostic marker.

The treatment options for the chronic anemia of sickle cell disease have already been mentioned. These strategies attempt to decrease hemolysis by increasing HbF (HU and the experimental approaches with erythropoietin, decitabine and histone deacetylase inhibitors) or decreasing the intracellular Hb S concentration by preventing red cell dehydration (Gardos channel inhibitors).

Exacerbations of Anemia

The rather constant level of hemolytic anemia may be exacerbated by additional events such as aplastic crises, acute splenic sequestration, acute hepatic sequestration, chronic renal disease or renal endocrine deficiency that may be present without overt renal failure, bone marrow necrosis, deficiency of folic acid or iron, delayed hemolytic transfusion reactions, autoimmune hemolytic anemia, or hyperhemolysis (hemolytic exacerbations) of unknown etiology. Laboratory evaluations that are very useful in the evaluation of a patient with anemia exacerbation are the reticulocyte count, the LDH, alloantibody screening, the direct antiglobulin (Coombs) test, and an erythropoietin level.

Aplastic Crises

Aplastic crises are transient arrests of erythropoiesis characterized by abrupt falls in hemoglobin levels, reticulocyte number, and red cell precursors in the marrow without necessarily an increase in the LDH. Although these episodes typically last only a few days, the level of anemia may be severe because the hemolysis continues unabated in the absence of red cell production. Although the mechanisms that impair erythropoiesis in inflammation are operative in infections of all types (see Chapter 24), human parvovirus B19 specifically invades proliferating erythroid progenitors, which accounts for its importance in sickle cell disease (see Chapters 19 and 24).[125] Parvovirus B19 (Fig. 43–10) accounts for 68% of aplastic crises in children with sickle cell disease,[126] but the high incidence of protective antibodies in adults makes parvovirus a less frequent cause of aplasia in this age group (see also Infections later in this chapter). Other reported causes of transient aplasia are infections by *S pneumoniae*, salmonella, streptococci, and Epstein–Barr virus. Bone marrow necrosis, which too may be the result of parvovirus infection, characterized by fever, bone pain, reticulocytopenia, and a leukoerythroblastic response, also causes aplastic crisis.[127,128]

Inhaled oxygen therapy also causes transient red cell hypoproduction; supraphysiologic oxygen tensions curtail erythropoietin production promptly and suppress reticulocytosis within 2 days.[129]

The mainstay of treating aplastic crises is red cell transfusion. When transfusion is necessitated by the degree of anemia or cardiorespiratory symptoms, a single transfusion usually will suffice, because reticulocytosis resumes spontaneously within a few days. Transfusion may be avoided by keeping severely anemic patients at bed rest to prevent symptoms and by avoiding supraphysiologic oxygen tensions. A useful guideline for transfusion in the context of an aplastic crisis is the reticulocyte count. A patient having an aplastic crisis with a reticulocyte count that is recovering is less likely to require urgent transfusion than one with a normal or low absolute reticulocyte count.

Sequestration Crisis (Spleen or Liver)

Acute splenic sequestration of blood is characterized by acute exacerbation of anemia, persistent reticulocytosis, a tender, enlarging spleen, and sometimes hypovolemia.[130] The LDH may remain stable

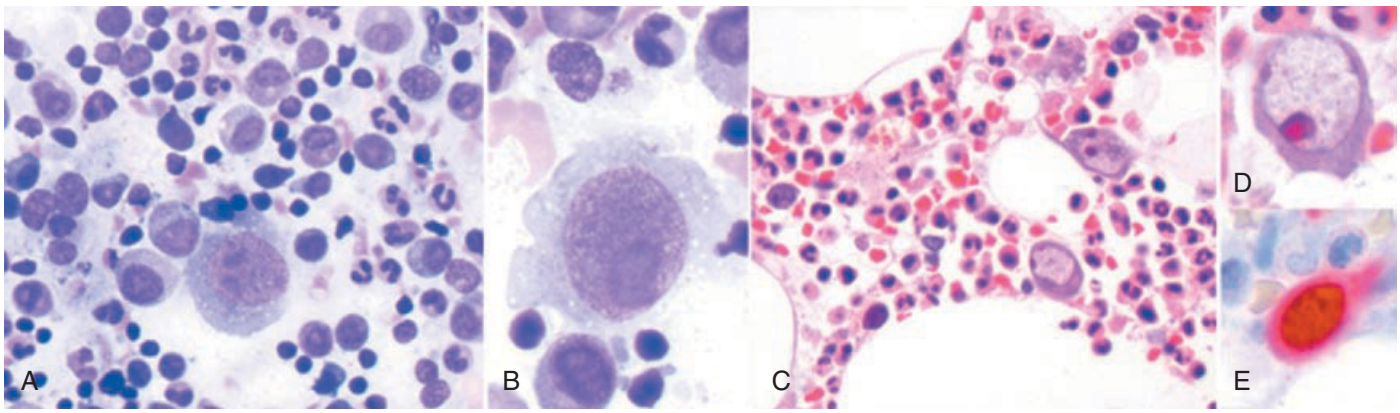

Figure 43–10 Parvovirus (**A**–**E**). Bone marrow aspirate in a patient with sickle cell disease and aplastic crisis (**A**). Note the absence of red blood cell precursors except for the single, large degenerating pronormoblast (lower center). Such pronormoblasts contain large nuclear inclusions (**B**) as a result of replication of parvovirus B19. The same can be seen in the tissue sections of a bone core biopsy (**C**, **D**). The parvovirus can now be recognized immunohistochemically with an immunostain (**E**).

or increase. Patients susceptible to this complication are those whose spleens have not undergone fibrosis—young patients with sickle cell anemia and adults with Hb SC disease or sickle cell–β^+ thalassemia. Sequestration may occur as early as a few weeks of age and may cause death before sickle cell disease is diagnosed. In one study, 30% of children had splenic sequestration over a 10-year period and 15% of the attacks were fatal.[131]

The basis of therapy is to restore blood volume and red cell mass. Because splenic sequestration recurs in 50% of cases, splenectomy is recommended after the event has abated. Alternatively, chronic transfusion therapy is used in young children to delay splenectomy until it can be tolerated safely. Because recurrence is possible during transfusion therapy, parents should be trained to detect a rapidly enlarging spleen and to seek immediate medical attention in this event. Less common sites of acute sequestration include the liver and possibly the lung.[132,133]

Delayed Hemolytic Transfusion Reaction and Autoimmune Hemolytic Anemia

Approximately 30% of patients are predisposed to develop alloantibodies, in part because of minor blood group incompatibilities in racially mismatched blood.[69,70] The corollary is that the other patients can receive multiple transfusions without demonstrating alloantibodies. Following alloimmunization, there is a subsequent decrease in antibody titer that can fall below serologically detectable levels. Therefore, antigen-positive red blood cells appear compatible in cross-matching and are transfused. This can result in a delayed hemolytic transfusion reaction produced by the amnestic response of the immune system (as opposed to the immediate hemolytic reaction that occurs with preformed antibody). The delayed hemolytic transfusion reaction consists of an unexplained fall in Hb, elevated LDH, elevated bilirubin above baseline, and hemoglobinuria, all occurring between 4 and 10 days after the red cell transfusion. Delayed hemolytic reactions and hyperhemolysis have been shown to occur in 11% of pediatric patients with sickle cell disease and a history of alloantibodies.[134] In sickle cell disease, the delayed hemolytic transfusion reaction can be particularly devastating because it can be accompanied by reticulocytopenia, which together with a bystander effect of destruction of recipient blood (not just donor blood) can result in unanticipated worsening of anemia to levels below that seen before transfusion.[135] In addition to the manifestations of a delayed hemolytic transfusion reaction as listed above, patients may develop acute congestive heart failure, acute renal failure, or acute chest syndrome (accompanied by vasoocclusive pain crisis). Subsequent transfusions may further exacerbate the anemia.

Resolution of severe anemia may only occur after withholding further transfusions with subsequent reticulocyte count recovery. Corticosteroids at high doses (eg, intravenous methylprednisolone 500 mg QD for 2 to 3 days) should be considered if the anemia is life-threatening or if further transfusion is deemed necessary to save life. Intravenous immunoglobulin can also be considered, with proper attention paid to avoiding iatrogenic fluid overload. Approaches to minimizing this complication include transfusing extended-matched (see Basic Management and Disease Modification), phenotypically compatible blood.[69–71] This syndrome may or may not recur with further transfusions after a recovery period.[136]

Hyperhemolytic Crisis

Hyperhemolytic crisis is the sudden exacerbation of anemia with increased reticulocytosis and bilirubin level. If suspected, the approach to management should first be to look for an underlying etiology which may be one of the events listed above: aplastic crisis (during the recovery phase when the reticulocyte count may not be decreased), sequestration crisis, delayed hemolytic transfusion reaction or autoimmune hemolysis. Another possible cause is G6PD deficiency.[137]

Erythropoietin Deficiency

This entity is discussed under Basic Management and Disease Modification.

Nutritional Deficiencies: Folate, Iron, or B_{12} Deficiency

This entity is discussed under Basic Management and Disease Modification.

Hypothyroidism

Iron overload in sickle cell disease can result in hypothyroidism.[138] Therefore, hypothyroidism is another etiology to consider in a sickle cell disease patient with an otherwise unexplained decrease in hemoglobin below baseline.

Infections

Immune Deficit

The propensity of children with sickle cell disease to contract *S pneumoniae* infection is related to impaired splenic function[139] and diminished serum opsonizing activity. Even before the anatomic autoinfarction of the spleen in patients with sickle cell anemia, defective splenic function is demonstrable by Howell–Jolly bodies on the peripheral blood smear, visible "pits" on the surface of red blood cells, and abnormal results of radionuclide spleen scanning.[140] Specific

Table 43–9 Bacteria and Viruses That Most Frequently Cause Serious Infection in Patients With Sickle Cell Disease

Microorganism	Type of Infection	Comments
Streptococcus pneumoniae	Septicemia	Common despite prophylactic penicillin and pneumococcal vaccine
	Meningitis	Less frequent than in years past
	Pneumonia	Rarely documented except in infants and young children
	Septic arthritis	Uncommon
Haemophilus influenzae, type b	Septicemia	
Meningitis		
Pneumonia	Much less common in recent years because of immunization with conjugate vaccine	
Salmonella species	Osteomyelitis	
Septicemia	Most common cause of bone and joint infection	
Escherichia coli and other gram-negative enteric pathogens	Septicemia	
Urinary tract infection		
Osteomyelitis	Focus sometimes inapparent	
Staphylococcus aureus	Osteomyelitis	Uncommon
Mycoplasma pneumoniae	Pneumonia	Pleural effusions; multilobe involvement
Chlamydia pneumoniae	Pneumonia	
Parvovirus B19	Bone marrow suppression (aplastic crisis)	High fever common; rash and other organ involvement infrequent
Hepatitis viruses (A, B, and C)	Hepatitis	Marked hyperbilirubinemia

From Buchanan,[431] with permission.

syndromes exhibiting greater rates of hemolysis cause loss of splenic function at earlier ages—sickle cell anemia → Hb SC disease → sickle cell–β^+ thalassemia.

Infectious complications of sickle cell disease are a major cause of morbidity and mortality,[141] even with current vaccination and prophylactic antibiotic regimens. The infections caused by particular organisms are shown in Table 43–9 and the specific organisms affecting different target organs are shown in Table 43–10. By 5 years of age, almost all patients are functionally asplenic, contributing to infectious susceptibility. Historically, pneumococcal sepsis has been the predominant cause of death in those less than 20 years of age.[142]

Evaluation

The most critical aspect of infectious illness in sickle cell disease is the evaluation and treatment of the febrile child. Routine evaluation includes a physical examination, a complete blood count, blood and urine cultures, a lumbar puncture if meningitis is suspected, and a chest x-ray to evaluate for pneumonia. Results of the complete blood count are compared to baseline values. A left shift in the differential count suggests bacterial infection.

Penicillin Prophylaxis and Pneumonia Vaccination

Data and recommendations regarding penicillin prophylaxis and pneumonia vaccination are discussed under Basic Management and Disease Modification.

S pneumoniae, H influenzae, Atypical Mycobacteria, and Acute Febrile Illness

S pneumoniae bacteremia is accompanied by leukocytosis, a left shift, aplastic crisis, sometimes disseminated intravascular coagulation, and a 20% to 50% mortality rate.[141] Although concerns about *S pneumoniae* sepsis are largely for young children, this complication also occurs in adults, often with devastating results.[143] *S pneumoniae* is the major cause of meningitis in infants and young children with sickle cell disease, and occurs in the setting of bacteremia.

The second most common organism responsible for bacteremia in these children, *Hemophilus influenzae* type b, accounts for 10% to 25% of episodes. *H influenzae* bacteremia affects older children and is less fulminant than *S pneumoniae* bacteremia, but it may be fatal.[141] Conjugated *H influenzae* type b vaccines produce excellent antibody responses in children with sickle cell disease and now are administered in early infancy (www.cdc.gov/vaccines/recs/schedules/child-schedule.htm).

Owing to the high mortality rate of bacteremia, hospitalization, blood and CSF cultures, and parenteral antibiotics has been the standard of care for children with fevers higher than 38.5°C. Prompt attention to fever can reduce the risk of severe pneumococcal sepsis. Rapid administration of antibiotics has resulted in a lower incidence of meningitis among bacteremic patients than 20 years ago, when the incidence was 50%.[144] The efficacy of ceftriaxone therapy for *S pneumoniae* and *H influenzae* infection[145] has led to new treatment algorithms that recommend outpatient therapy for most patients. However, resistant *S pneumoniae* have emerged, necessitating a thorough knowledge of local resistance patterns to guide the choice of alternate antibiotics (in particular, vancomycin, to which resistance has not been observed).

Table 43–10 Organ-Related Infection in Sickle Cell Disease

Primary Sites of Infection	Most Common Pathogen(s)	Other Pathogens	Pathophysiology	Prevention	Management
Septicemia	*Streptococcus pneumoniae*	*Haemophilus influenzae* type b *Escherichia coli* *Salmonella* sp.	Defective splenic function; deficiency of opsonic antibody	Vaccines* Prophylactic penicillin	Empiric intravenous antibiotics for fever
Meningitis	*S pneumoniae*			Same as for septicemia	
Osteomyelitis and septic arthritis	*Salmonella* species *S pneumoniae*	*E coli* *Proteus* species *Staphylococcus aureus*	Ischemic or infarcted tissue, prolonged course	—	Surgical drainage, intravenous antibiotics
Pneumonia	*Mycoplasma pneumoniae* Respiratory viruses	*Chlamydia pneumoniae* *S pneumoniae*	Concomitant infection and intrapulmonary vasoocclusion leading to infarction and/or sequestration	Vaccines[a]	See Pulmonary and Therapy sections for management of acute chest syndrome.

*Against *S pneumoniae* and *H influenzae* type b.
From Buchanan,[431] with permission.

Please see Pulmonary Complications for further discussions regarding pneumonia and acute chest syndrome.

Meningitis

Meningitis therapy should cover *S. pneumoniae* and probably *H. influenzae* type b and should be continued for at least 2 weeks.

Salmonella and Osteomyelitis

In this patient population, osteomyelitis is commonly caused by *Salmonella* species.[146] *Staphylococcus aureus*, the most common etiology in patients without sickle cell disease, accounts for less than 25% of sickle cell disease cases. Infection usually affects long bones, often at multiple sites.

Diagnosis is confirmed by culture of blood or infected bone. Parenteral antibiotics that cover *Salmonella* and *S. aureus* are given, and antibiotic therapy is based on culture results. Parenteral antibiotics are continued for 2 to 6 weeks.[146] Surgical drainage or sequestrectomy may be required. Most patients are cured by this approach, but there may be recurrences.[146]

Articular infection is less common and is often due to *S. pneumoniae*.[146]

Parvovirus B19 (see also Aplastic Crisis)

The specificity of the parvovirus B19 for erythroid precursor cells, coupled with the accelerated erythropoiesis in hemolytic anemias, leaves sickle cell patients vulnerable to infection by this agent.[147] In sickle cell disease, parvovirus infection is a common cause of aplastic crisis, especially in children. It has been reported to cause bone marrow necrosis, acute chest syndrome, pulmonary fat embolism, hepatic sequestration, and glomerulonephritis.[125–128]

Urinary Tract Infections

Patients with sickle cell disease are at a higher risk for urinary tract infections and pyelonephritis than the general population. *Escherichia coli* is the most common uropathogen and can cause septicemia in these patients. Persistent urinary tract infections may be secondary to renal papillary necrosis. All urinary tract infections in this patient population should be considered complicated, requiring 10 to 21 days of appropriate antibiotic therapy.

Neurologic Complications

Neurologic complications occur in 25% or more of patients with sickle cell disease.[148] Neurologic complications include cerebrovascular accidents (CVAs: consisting of transient ischemic attacks [TIAs], overt and silent cerebral infarction, cerebral hemorrhage), seizures (which can be a presenting feature of CVA), unexplained coma, spinal cord infarction or compression, central nervous system infections, vestibular dysfunction, and sensory hearing loss.[149]

Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation[150]

Histopathologic evaluation of large-vessel involvement in sickle cell disease shows a pattern of smooth muscle proliferation with overlying endothelial damage and fibrosis. Smaller arterioles and capillaries demonstrate distension, thrombosis, and vessel wall necrosis.[151,152] Aneurysmal dilation associated with hemorrhagic stroke occurs at regions of intimal hyperplasia.[153] The vessel wall changes are likely multifactorial in origin related to endothelial injury from high and turbulent flow, RBC adherence, and hypoxia. But in addition, it has been speculated that depletion of nitric oxide (NO) by the free hemoglobin released through intravascular hemolysis may also play a role.[153] The age-specific pattern of stroke risk in sickle cell disease may be related to the higher cerebral flow rates in early childhood.[153] Cerebral thrombosis, which accounts for 70% to 80% of all CVAs in sickle cell disease, results from large-vessel occlusion (Fig. 43–9) rather than the more typical microvascular occlusion of sickle cell disease.[154] Silent infarcts are thought to result from microvascular vasoocclusion or thrombosis or chronic hypoxia in the periphery stemming from large-vessel disease.[155] In 30% of patients with sickle cell disease, major-vessel stenosis results in the formation of friable collateral vessels that appear as puffs of smoke (*moyamoya* in Japanese) on angiography.[156] Moyamoya disease predisposes to thrombotic and hemorrhagic strokes, seizures, and cognitive disability.[157]

The relative risk for stroke is 200 to 400 times higher in children with sickle cell disease compared to the children without sickle cell disease. The prevalence of clinically overt stroke is 11%. Clinically silent infarction detectable by MRI affects 17% to 20% of patients by age 20.[158] Silent infarcts are associated with cognitive impairment. Even in patients without silent or overt cerebral infarction, cognitive functioning can be impaired.[159] Almost 50% of the children with "silent" infarcts eventually require lifelong support or custodial care because of neuropsychologic deficits.[160] Infarctive strokes were common in children and those more than 30 years of age, whereas hemorrhagic stroke was most common between ages 20 and 30 years.[22]

Sickle cell-specific risk factors for CVA include increased cerebral blood flow velocity[161] (discussed further under Primary Prevention of Cerebrovascular Accidents), a previous history of overt or silent cerebral infarction,[162] nocturnal hypoxemia,[163] more severe anemia, higher reticulocyte counts, lower Hb F levels, higher white cell counts, the Hb SS genotype (rather than Hb SC disease or sickle cell–β thalassemia), nocturnal hypoxemia or sleep apnea, migraines, elevated homocysteine levels, "relative" systolic hypertension (ie, those at the high end of the lower-than-normal range characteristic of sickle cell disease).[22,164,477] Genetic markers of increased risk are the Central African Republic haplotype and the absence of α thalassemia.[153,165] Both small-vessel and large-vessel thrombosis can occur. Specific HLA alleles separately correlate with small- versus large-vessel stroke risk, suggesting that different pathologic processes may be involved.[153]

In addition to these sickle cell-specific predictors of stroke, one must also consider the well-documented modifiable risk factors for stroke that are operational in the general population; these are hypertension, exposure to cigarette smoke (active smoking or passive exposure), diabetes, atrial fibrillation, dyslipidemia, carotid artery stenosis, postmenopausal hormone therapy, poor diet, physical inactivity, obesity, and fat distribution. Less well-documented but potentially modifiable risk factors include alcohol or drug use, oral contraceptive use, and sleep-disordered breathing.[158]

CVAs are heralded by focal seizures in 10% to 33% of cases and by TIAs in 10%. CVAs are fatal in approximately 20% of initial cases, recur within 3 years in nearly 70%, and are the cause of motor and cognitive impairment in the majority. Intracranial hemorrhage results in the same signs as thrombosis, but in addition neck stiffness, photophobia, severe headache, vomiting, and altered consciousness may occur. Coma suggests hemorrhage rather than thrombosis. A typical presentation is coma and seizures without hemiparesis. Although the mortality rate may be as high as 50%, the morbidity of survivors is low. Hemorrhage may be subarachnoid, intraparenchymal, or intraventricular, which can be differentiated by angiography. The favorable neurosurgical outcome in subarachnoid hemorrhage due to ruptured aneurysm justifies an aggressive approach to diagnosis, transfusion, vasodilatory therapy, and surgery.

Primary Prevention of Cerebrovascular Accidents

The overall risk of stroke in pediatric patients with sickle cell disease is 1% per year; however, in the subset of patients with transcranial Doppler evidence of a high (>200 cm/s) cerebral blood flow velocity in the internal carotid artery or middle cerebral artery the stroke risk is in excess of 10% per year (although this is still much lower than the risk of recurrent stroke in a sickle cell patient after a first event, which is approximately 70%). In the Stroke Prevention Trial in Sickle Cell Disease (STOP), 130 children diagnosed as having clinically silent cerebral artery stenosis on the basis of high cerebral flow rates were randomized to receive chronic transfusion therapy or not. Over a period of more than 2 years, the risk of stroke was reduced to less than 1% per year in the transfused group[161] (a risk reduction of >90%). The ability of transfusion to curtail progression of large-vessel stenosis has also been proven with angiography.[166]

Because of the risks of iron overload and allosensitization with chronic transfusion, a randomized controlled trial of withdrawal of transfusion was conducted (STOP 2). This trial evaluated discontinuation of transfusion after at least 30 months in children who had not had an overt stroke and in whom the cerebral flow rates decreased to low risk (<170 cm/s) with transfusion. This study was terminated early because of a high rate of reversion to high-risk TCD flow rates (34%) and stroke (5%) in the patients taken off transfusion compared to the group who continued transfusion.[167]

In children, MRI can also be used to assess stroke risk: 8.1% of children with an asymptomatic MRI lesion versus 0.5% of those with a normal MRI had a stroke during the ensuing 5 years.[162] A randomized trial of MRI-guided prophylactic transfusion is in progress (Silent Infarct Treatment Trial [SITT]). In adults, MRI/MRA of the brain should be used[29] to assess thrombotic or hemorrhagic stroke risk.

Chronic transfusion is associated with a significant complication rate. Therefore, there is a need for alternatives, especially because some patients and physicians feel that the 10% annual stroke risk does not warrant the risks and burdens of chronic transfusion.[150] The role of aspirin in ischemic stroke prevention in sickle cell disease is being evaluated (see Basic Management and Disease Modification). Hydroxyurea significantly lowered the TCD velocity values in a group of 24 children with Hb SS disease compared to an age-matched control group.[46] The role of hydroxyurea is being formally evaluated in secondary stroke prevention (see Secondary Prevention below). Stem cell transplantation has resulted in stabilization of cerebral vasculopathy[168] but there is a mortality risk with this procedure of between 6% and 10%.

Other modifiable risk factors for stroke (see Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation above) should be identified and treated. Notably, in the general population, hypertension is particularly associated with a risk for hemorrhagic stroke, and effective treatment of hypertension can produce a relative risk reduction of 26% for ischemic stroke and 49% for hemorrhagic stroke.[169] In patients with sickle cell disease followed through the Cooperative Study of Sickle Cell Disease, both diastolic and systolic blood pressures were noted to be lower than for matched controls. Patients with systolic pressures in the higher range for the sickle cell group, even with systolic pressures less than 140 mmHg, had an increased risk of first ischemic stroke (there were insufficient events to make firm conclusions regarding hemorrhagic stroke).[164] Therefore, at a minimum, it seems reasonable to follow population-wide recommendations for blood pressure control in patients with sickle cell disease.

Evaluation and Management of Acute Cerebrovascular Accidents

Patients with symptoms and signs of CVA should be evaluated immediately using computed tomographic (CT) scanning or magnetic resonance imaging to distinguish TIA, cerebral thrombosis, and hemorrhage. In those with hemorrhage, angiography or magnetic resonance angiography is indicated, after partial-exchange transfusion is performed to avoid complications associated with the injected contrast material. In both thrombosis and hemorrhage, prompt partial-exchange transfusion is performed, and chronic direct transfusion to maintain the Hb S level below 30% is instituted to prevent recurrent events (see also Basic Management and Disease Modification) and promote resolution of arterial stenoses.[166]

Secondary Prevention of Cerebrovascular Accidents

The risk of recurrent stroke is approximately 70%, a risk that is reduced to around 13% with chronic transfusion.[170] Although recurrent CVAs during chronic transfusion have been reported, this therapeutic modality provides the best means of preventing recurrence (Fig. 43–11). This treatment also provides incidental protection against pain crises, bacterial infections, acute chest syndrome, and hospitalization.

Based on the data from STOP 2 (see Primary Prevention of Cerebrovascular Accidents above), chronic transfusion is continued

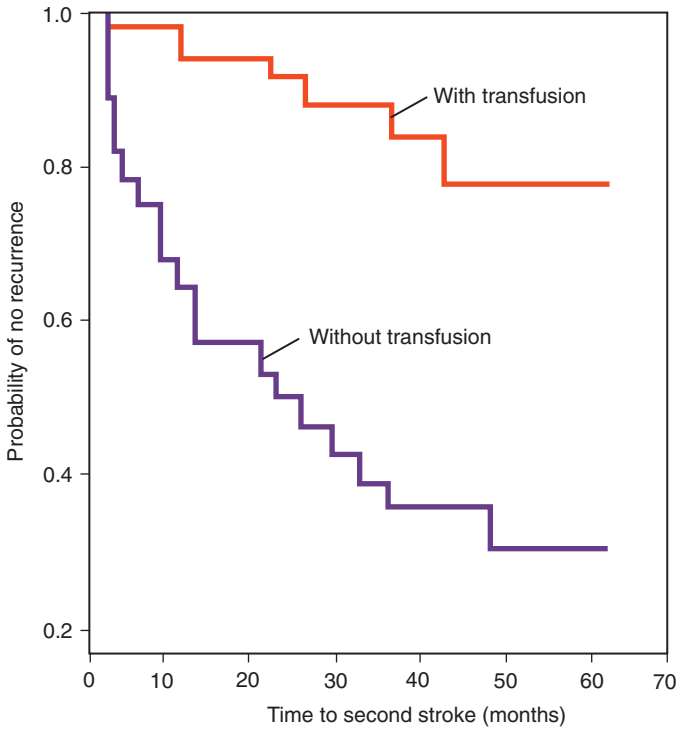

Figure 43–11 Comparison of stroke recurrence over 62 months in a transfused group and in untransfused historical control groups.[467,823] *(Adapted from Pegelow et al, with permission.)*

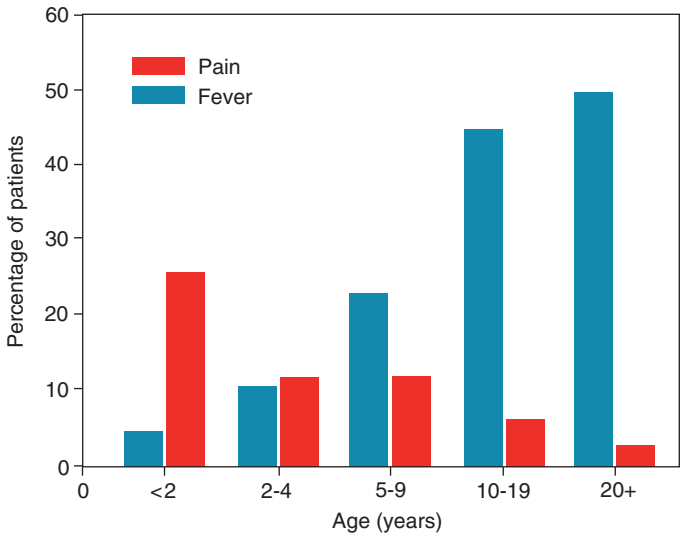

Figure 43–12 Age-specific associated events within 2 weeks preceding acute chest syndrome. *(Adapted from Vichinsky et al with permission.)*

indefinitely. This may not be feasible for administrative reasons or because of allosensitization or iron overload for which the patient is unable or unwilling to undergo treatment. Therefore, clinical trials to determine if disease modifiers such as hydroxyurea or decitabine can reduce stroke risk are indicated. In patients with a history of CVA transitioned from chronic transfusion to hydroxyurea, the recurrent stroke rate remained stable and in the range seen with continued transfusion.[78]

Per primary prevention, all other identified modifiable risk factors for stroke should be identified and treated.

In patients with moyamoya disease, surgical approaches to therapy, such as extracranial–intracranial bypass, have been useful in improving the perfusion of affected regions of the brain.

Stem cell transplantation has resulted in stabilization of cerebral vasculopathy,[168] but the risk of a second neurologic event is higher in the peritransplant period and mortality with this procedure is between 6% and 10%.[168]

Seizures

Seizures occur more commonly among patients with sickle cell disease. In one study, 21 of 152 patients in a pediatric clinic had seizures, 4 of which were related to meperidine therapy. Most had nonfocal CT and MRI studies but focal electroencephalographic changes.[171] CVAs are heralded by focal seizures in 10% to 33% of cases. Therefore, seizures in sickle cell disease ultimately may be related to the underlying vasculopathy.

Pulmonary Complications

Pulmonary disease is the leading cause of death in sickle cell disease.[16] Both acute and chronic pulmonary complications are common. The common acute complications are pneumonia and acute chest syndrome, and the common chronic complication is pulmonary hypertension.

Pneumonia

Pneumonia is defined as chest infiltrates on chest x-ray or chest CT scan associated with fever and an identified infectious etiology.

The risk for and increased frequency of *S pneumoniae* infections is discussed under Infections above. In addition, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* are also relatively common causes of pneumonia in sickle cell disease. Antibiotic therapy for pneumonia or acute chest syndrome should cover these agents in addition to pneumococcus and *H influenzae*.

When antibiotics are used to treat the acute chest syndrome, they should cover *S pneumoniae*, *H influenzae* type b, *M pneumoniae*, and *C pneumoniae*. The combination of cefuroxime and erythromycin is recommended.

Acute Chest Syndrome

Acute chest syndrome occurs in approximately 30% of patients.[172] Acute chest syndrome is defined as a new infiltrate on chest x-ray or chest CT scan associated with one or more new symptoms: fever, chest pain, cough, sputum production, dyspnea, or hypoxia. This entity is included in discussions of sickle cell disease because processes other than infection, such as vasoocclusion, could also lead to pulmonary symptoms, signs, and chest x-ray changes. However, it should be borne in mind that the usual etiology might be both vasoocclusion and infection simultaneously, and in almost all cases of chest syndrome, antibiotics should be administered. Many episodes in which common pathogens are not cultured are due to "atypical" agents (*Mycoplasma*, *Legionella*, and *Chlamydia*), suggesting that antibiotic therapy include agents directed at atypical agents. Pulmonary fat embolus, evidenced by stainable fat in pulmonary macrophages obtained by bronchoalveolar lavage or sputum induction, is found in 44% to 60% of cases of acute chest syndrome.[173] Acute chest syndrome due to pulmonary fat embolus is associated with more severe hematologic and clinical abnormalities. In adults the mortality rate is four times higher than in children.[3,174]

Acute chest syndrome is often preceded by febrile episodes in children and by vasoocclusive pain crisis in adults (Fig. 43–12).[174] Elevation of serum phospholipase A2 (sPLA2) was detected in patients admitted with vasoocclusive pain crisis 24 to 48 hours before acute chest syndrome was clinically diagnosed.[175] Pulmonary fat embolus is often preceded by an acute painful episode. Some patients have a rapidly progressive course associated with a precipitous decrease in arterial oxygen tension; they may require intensive care treatment.

If there are clinical signs of respiratory distress, or when arterial oxygen tension cannot be maintained above 70 mmHg with inhaled oxygen, partial-exchange transfusion is indicated. Artificial ventilation may be required.

In patients with pneumonia or chest syndrome, antibiotics should cover *S pneumoniae*, *Mycoplasmal Chlamydia pneumoniae*, *H influenzae*, and *Legionella* species.

Pulmonary Hypertension

Chronic complications such as pulmonary hypertension occur in as many as 60% of patients.[176–178] There does not appear to be an association with the occurrence of acute chest syndrome,[177] emphasizing that the pathophysiology of these two conditions may differ in some key features. The pathophysiology may involve thrombi in large and small arteries,[179,180] cardiac decompensation from progressive anemia and potentially reversible increases in vascular tone from nitric oxide depletion and medial and intimal hypertrophy.[180] The recognition that pulmonary hypertension is a feature of hemolytic syndromes other than sickle cell, and that markers of hemolysis correlate with the risk of pulmonary hypertension, supports the idea that depletion of nitric oxide (NO) through scavenging by free hemoglobin may have an important role in the pathophysiology of this disease.[177,181] Pulmonary hypertension usually occurs in adults and carries a poor prognosis.[182]

The association with early death and the emerging availability of candidate treatments suggest that efforts should be made to diagnosis this condition in all patients with sickle cell disease.[176,181] Routine clinical exam and routine tests like the CXR are not sufficient to make the diagnosis, because changes in these assessments may be evident only in very late stages of chronic lung damage. The feasibility of an echocardiogram determined tricuspid regurgitant jet (TR-jet) velocity measurement of 2.5 m/s to make the diagnosis was suggested by selective cardiac catheterization in a cohort of 195 patients[176]; however, the sensitivity and specificity of this test may have limitations.[181] Elevations in brain natriuretic peptide (BNP) levels correlate with an increased TR-jet and risk of early death. The gold standard for diagnosing pulmonary hypertension remains right heart catheterization.

Although there have been no completed definitive treatment trials of pulmonary hypertension in sickle cell disease, there are a number of options that have demonstrated efficacy in other populations with pulmonary hypertension and for which there is pilot data and/or ongoing trials in sickle cell disease. These options include sildenafil, arginine, and bosentan.[183–186] These patients should also be considered for disease modification (see Basic Management and Disease Modification).

Other Pulmonary Complications

Other findings include restrictive and obstructive lung disease and hypoxemia.[187] High-resolution, thin-section CT scanning of the lungs may show chronic interstitial fibrosis. Airway hyperreactivity occurs in nearly two-thirds of children with sickle cell disease not diagnosed as having asthma. Thirty-six percent of 53 children with sickle cell disease were found to have sleep-related upper-airway obstruction, 16% had hypoxemia, and all 15 who underwent adenotonsillectomy were symptomatically improved and had improved hypoxemia.[188] Sleep apnea may be associated with surgically reversible exacerbations of painful episodes and strokes. Blood gas and pulmonary function measurements should be obtained as baseline data for all patients.

Hepatobiliary Complications

Hepatobiliary complications in sickle cell disease include cholelithiasis, cholecystitis, acute hepatic cell crisis, acute hepatic sequestration crisis, and sickle cell intrahepatic cholestasis.[189] Chronic transfusion also places patients at risk for infection with hepatitis viruses and for transfusional hemasiderosis. Non–transfusion-related hepatic hemasiderosis can also be seen.

The serum bilirubin level is higher in sickle cell anemia (Hb SS) than in Hb SC disease or sickle cell–β^+ thalassemia as a result of a greater hemolytic rate. The level rises after the first decade, possibly as a result of chronic hepatobiliary dysfunction. AST and ALT levels are often elevated, particularly in adult patients with sickle cell anemia, but mean levels are normal. Alkaline phosphatase levels are elevated in all genotypes until puberty, which occurred later in males and in those with sickle cell anemia. Percutaneous liver biopsy is associated with a high risk of severe complications and death in sickle cell disease patients with acute hepatic syndromes.[190]

Cholelithiasis and Cholecystitis

The prevalence of pigmented gallstones in sickle cell disease is directly related to the rate of hemolysis.[191] In sickle cell anemia, gallstones occur in children as young as 3 to 4 years of age and are eventually found in approximately 70% of patients. Some have recommended the surgical removal of asymptomatic gallstones to avoid subsequent difficulty in distinguishing gallbladder pain from acute painful episodes. This approach has become more feasible with the availability of laparoscopic cholecystectomy.[192]

Acute Hepatic Cell Crisis

Acute hepatic cell crisis presents with tender hepatomegaly, worsening jaundice, and fever.[189] The likely etiology is hepatocellular cell ischemia. The AST and bilirubin are elevated, but rarely above 300 IU/L and 255 μM, respectively. This syndrome usually resolves within 3 to 14 days with supportive care alone but can progress to liver failure and fatal outcome; therefore, patients should be monitored closely and exchange transfusion initiated if there are signs of progressive liver dysfunction (eg, increasing AST).

Acute Hepatic Sequestration Crisis

Acute hepatic sequestration crisis presents with acute hepatic enlargement and a dramatic fall in hemoglobin concentration, the most likely mechanism being sequestration of sickled erythrocytes in the liver. Management is with supportive care and transfusions.

Intrahepatic Cholestasis

Sickle cell intrahepatic cholestasis results in severe, asymptomatic hyperbilirubinemia without fever, pain, leukocytosis, hepatic failure, or death.[193] Asymptomatic hyperbilirubinemia without signs of progressive liver dysfunction (eg, increasing AST) does not require specific therapy. Evidence of progressive liver dysfunction should prompt consideration of acute hepatic cell crisis and exchange transfusion.

Hepatitis C Infection

Chronic hepatitis C infection in sickle cell disease occurs with a prevalence that is related to the number of transfusions received; it may be a leading cause of cirrhosis. Liver transplantation has been used successfully as therapy for this complication.[194] If indicated, interferon-ribavarin can be used to treat hepatitis C in sickle cell disease patients.[195]

Obstetric and Gynecologic Issues

Gynecologic complications (delayed menarche, dysmenorrhea, ovarian cysts, pelvic infection, and fibrocystic disease of the breast) are more common in women with sickle cell disease. Pregnancy entails increased risks to mother and child compared to the general population.

Pregnancy

Pregnancy in patients with sickle cell disease is associated with increased risks to both the mother and fetus, although these risks are not so great as to prohibit continuation of pregnancy.[196,197] The fetal complications of pregnancy, most of which are related to compromised placental blood flow, are the increased incidence of spontaneous early abortion, intrauterine growth retardation, low birthweight, and fetal death. Maternal complications include increased rates of painful episodes, severe anemia due to iron or folate deficiencies, exaggeration of the physiologic "anemia of pregnancy," increased infections (urinary tract, pneumonias, endometritis), preeclampsia, and death.[197] It is controversial whether the degree of anemia predicts the birth of babies with low birthweight. The occurrence of a perinatal death in a previous pregnancy and the presence of twins in the present pregnancy are two major risk factors for an unfavorable outcome. The course of pregnancy is more benign in Hb SC disease than in sickle cell anemia.

Better fetal and maternal outcomes in recent years are largely due to generally improved antenatal and obstetric care. The patient should be followed in a high-risk obstetric clinic in addition to the hematology clinic and receive the usual vitamin, mineral, and folate supplements. A high-calorie, high-protein diet can be considered. There is no specific therapeutic or preventive treatment for intrauterine growth retardation. Some experts recommend prophylactic transfusion, but a large controlled study showed no improvement in fetal outcome from this management option although maternal symptoms are reduced. In addition to the usual indications for transfusion therapy in sickle cell disease, transfusion therapy is indicated for patients with cardiac or respiratory compromise, in preparation for C-section, preeclampsia, twin pregnancy, acute chest syndrome, hemoglobin levels more than 20% below steady state or less than 5 g/dL, and previous history of perinatal mortality. If the hemoglobin is between 8 and 10 g/dL, and transfusion is indicated for any of the reasons above, partial exchange should be performed (eg, phlebotomy of 400–500 mL and transfusion of 2 units PRBC).[196] The type of delivery does not appear to represent a problem, and both spontaneous delivery and cesarean section are well tolerated.

Some experts advise that hypertonic saline injections are contraindicated for elective termination of pregnancy because of the risk of sickling-induced vasoocclusion. However, most methods of abortion are well tolerated. There are anecdotal reports of a higher incidence of acute painful episodes after therapeutic abortion; inpatient intravenous hydration before and for the 24 hours after the procedure is recommended.

Birth Control

Modern non–estrogen-containing intrauterine devices should be considered. Although depot injections of medroxyprogesterone (Depo-Provera) given every 3 months may be safe with regards to stroke risk,[198] there is a risk of bone loss, a consideration in patients with sickle cell disease and their propensity to skeletal complications. Oral contraceptives containing low doses of estrogen can be considered with no clear evidence of increased stroke demonstrated to date, although the patients' overall stroke risk should probably still be taken into consideration until there is more phase IV follow-up on the clinical experience. Another caution with low-dose estrogen oral contraception is the risk of contraceptive failure with less than excellent compliance. There may be risks to contraception, but against this must be weighed the risks of unintended pregnancy. Sexually active women should have routine pelvic exams and birth control instructions.

Renal Complications

Hypertension, proteinuria, hematuria, increasing anemia, and nephrotic syndrome reliably predict progression to renal failure, clinical indices to pay attention to because the serum creatinine may be misleading. Patients with sickle cell anemia exhibit an increased proximal tubular secretion of creatinine. Thus, patients may have a significant decline in renal function before it is detectable by measuring creatinine clearance.[199] The mean age at presentation with end-stage renal disease is 41 years.[200] Serum creatinine levels are low in all genotypes until age 18 years, when males experience a rise, apparently related to increasing muscle mass. Creatinine levels increase with age in all genotypes, presumably due to declining renal function (see also organ-specific complications, kidney).

Other risk factors for the development of chronic renal failure include use of nonsteroidal antiinflammatory drugs[201] and genetic predisposition associated with the CAR β-globin haplotype; the latter has been suggested as an indication for bone marrow transplantation to prevent this outcome.[202] Acute renal failure from infarction may result from hypovolemia, sepsis, hepatorenal syndrome, cardiac failure, renal vein thrombosis, and rhabdomyolysis. These patients typically survive and recover their renal function with no increased risk of developing chronic renal failure.

There are seven well-described nephropathies that affect patients with either sickle cell trait or disease. These are gross hematuria, papillary necrosis, nephrotic syndrome, renal infarction, inability to concentrate urine, pyelonephritis, and renal medullary carcinoma.[199]

Renal transplantation is recommended for patients with sickle cell and end-stage renal diseases.

Renal Endocrine (Erythropoietin) Deficiency

This is discussed under Basic Management and Disease Modification.

Gross Hematuria

Hematuria may result from microthrombi formation in the peritubular capillaries of the renal medulla or from frank papillary necrosis. Significant hematuria may resolve with high urinary flow through oral hydration and bed rest. Hematuria that lasts longer than 1 to 2 weeks or the need for transfusion may require maintenance of a high urinary flow using a combination of hypotonic fluids and loop diuretics and urinary alkalinization using sodium bicarbonate and acetazolamide. These therapies are aimed at changing the acidic, hypertonic environment of the renal medulla that favors erythrocyte dehydration, increased HbS concentrations, and HbS polymerization. If bleeding persists for 72 hours despite these measures then alternative treatment should be considered. These may include oral urea,[203] ε-aminocaproic acid, and vasopressin. Embolization or nephrectomy should be reserved for prolonged, life-threatening cases of hematuria that require multiple transfusions.

Increased hematuria can also be seen as a consequence of delayed hemolytic transfusion reactions (discussed in Exacerbations of Anemia).

Papillary Necrosis

Papillary necrosis is most often detected incidentally by imaging or microscopic examination of urine in asymptomatic patients. Sloughed papilla may cause ureteral obstruction and urinary tract infection. In addition to broad-spectrum antibiotics, this occurrence requires emergent relief of the obstruction with a retrograde ureteral stent or placement of a percutaneous nephrostomy tube. Nonsteroidal antiinflammatory agents should be avoided in patients with papillary necrosis. Otherwise treatment is as for hematuria.

Proteinuria

Proteinuria has been found in 20% to 30% of patients with sickle cell disease. Increasing age and low hemoglobin levels correlate with proteinuria. Proteinuria can progress to nephrotic syndrome characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia. Angiotensin-converting enzyme inhibitors produce a significant

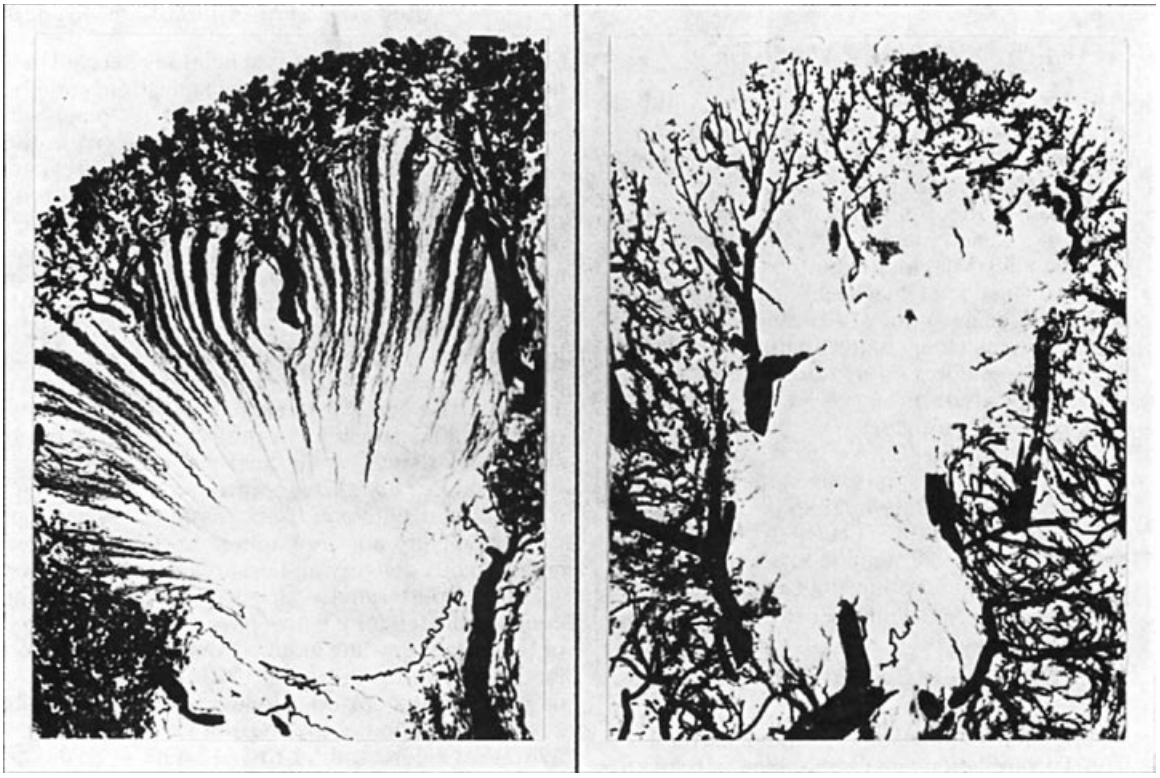

Figure 43–13 Postmortem microangiographic studies of the vasa recta in a normal individual (left) and a patient with sickle cell anemia (right). *(From Bertles JF, Döbler J: Reversible and irreversible sickling: A distinction by electron microscopy. Blood 33:884, 1969, with permission.)*

reduction in sickle proteinuria although it is unclear if ACE inhibitors might slow or halt the progression of proteinuria to nephrotic syndrome and renal failure.[204,205] Angiotensin II inhibitors are being studied for a potential role in decreasing sickle cell-related proteinuria and renal function deterioration.

Hyposthenuria and Other Abnormalities of Tubular Function

The inability to maximally concentrate urine (hyposthenuria) in response to water deprivation is an early finding of sickle cell nephropathy. Both sickle cell trait and disease patients may be affected. Hyposthenuria is the cumulative result of recurrent microinfarcts in the vasa recta due to sickling (Fig. 43–13). When water-deprived, these patients cannot maximally concentrate their urine, developing hypovolemia and dehydration.

Other abnormalities of renal tubular dysfunction found in sickle cell anemia include an incomplete form of distal renal tubular acidosis with hyperchloremic metabolic acidosis and hyperkalemia.[206] The hyperkalemia may respond to oral sodium bicarbonate.

Urinary Tract Infections

Urinary tract infections and pyelonephritis are discussed under infectious complications.

Renal Medullary Carcinoma

Sickle cell trait has been reported to be associated with renal medullary carcinoma.[207] Presentation is with gross hematuria, abdominal and or flank pain, or significant weight loss. The disease may be metastatic at diagnosis and the prognosis is poor. There is a weak association of renal medullary carcinoma with Hb SC disease but no identified association with sickle cell anemia. The reason for these patterns of disease are not known.

Priapism

Priapism is a condition that is characterized by sustained erection that does not result from sexual desire and is not relieved by sexual activity. Stuttering priapism is a separate entity that is characterized by multiple, brief episodes of sustained unwanted erection. It has been reported to affect 6.4% to 42% of males with sickle cell disease[208] and can also occur in sickle cell trait. Its peak frequencies are between ages 5 and 13 years and 21 and 29 years. Priapism is most likely to develop in patients with lower Hb F levels and reticulocyte counts, increased platelet counts, and the Hb SS genotype. Priapism caused by sickle cell disease is usually ischemic, or low-flow, priapism (high-flow priapism is caused by unregulated arterial flow and can be distinguished from low-flow priapism by a blood gas obtained from the corpora). Most likely, priapism begins with a physiologic erection. The relative stasis of blood within the corpora leads to a decrease in oxygen tension and development of acidosis, predisposing to HbS polymerization in the corporal sinusoids, venous occlusion, and low-flow priapism. Pain develops as the corpora become increasingly ischemic after approximately 4 hours of erection. In a minority of patients, usually postpubertal, the engorgement also affects the corpus spongiosum and glans. The mild acidosis that accompanies hypoventilation during sleep may also contribute to the pathophysiology. Impotence is the primary complication of priapism although patients with a history of multiple episodes of priapism and significant corporeal fibrosis may report fair erections and maintain active sex lives. Corporeal ischemia during priapism may induce local inflammation, causing the fibrosis responsible for impotence.

The goal of treatment is to relieve priapism and maintain potency. Patients should be educated to seek medical attention for unrelenting erection of more than 2 hours' duration. Detumescence within 12 hours is optimal to retain potency. After 72 hours, impotence is more likely. The strategy is prompt initiation of supportive medical therapy with intravenous hydration and analgesia, and involvement by a urology consultant if the priapism persists for more than 4 hours;

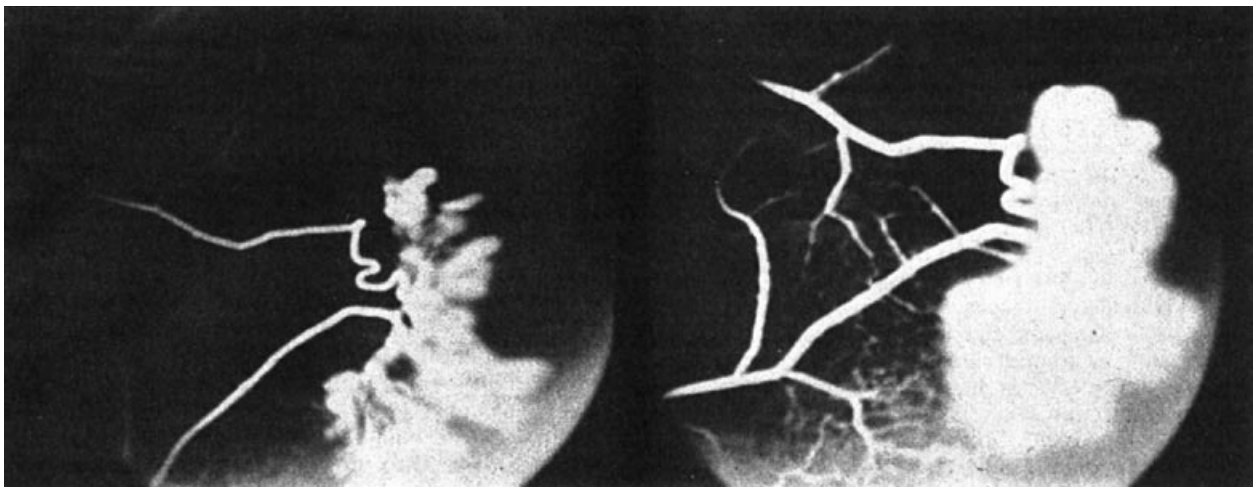

Figure 43–14 Fluorescein angiography demonstrating a "sea fan" appearance of sickle proliferative retinopathy. *(Kindly provided by WC Mentzer.)*

aspiration of blood from the corpora with or without irrigation and injection of an α-adrenergic agonist should be considered (Guidelines of the American Urological Association, www.guideline.gov). If priapism persists 12 hours, options include partial-exchange transfusion to reduce the Hb S level to less than 30% with a total hemoglobin of less than 10 g/dL and/or irrigation as outlined above. The latter procedure is less effective after 36 hours of priapism. Irrigation should be performed using penile anesthesia (dorsal nerve block, circumferential penile block, or subcutaneous, local, penile shaft block). All pediatric irrigation should be performed under conscious sedation. There is anecdotal evidence for the use of hydralazine to treat acute priapism.[209]

Preventing recurrent priapism is an important component of management. Strategies include hydroxyurea administration, chronic transfusion, the antiandrogen bicalutamide,[210] self-administration of the α-adrenergic agent etilefrine orally and, for episodes lasting over an hour, by intracavernous injection, and monthly administration of intramuscular gonadotropin-releasing hormone analogue.[211,212] Prophylactic pseudoepinephrine (Sudafed) appears beneficial in preventing recurrent mild episodes.

Surgical creation of shunts is reserved for severe cases resistant to the above interventions. As many as 45% of patients who have priapism develop some degree of impotence.[213] When impotence persists 12 months, a semirigid penile prosthesis may be implanted.

Ocular Complications[214]

The retina is particularly vulnerable to vasoocclusion, and annual retinal examination is part of routine health care maintenance for patients with sickle cell disease. Superficial retinal hemorrhages have a pink "salmon patch" appearance. Deeper retinal hemorrhages have a "black sunburst" appearance. Other manifestations of sickle cell retinopathy include iridescent spots, retinal neovascularization, and retinal detachment. More subtle signs of sickle cell retinopathy are optic nerve head vascular changes, vascular tortuosity, macular changes (eg, microaneurysms and vascular loops), and peripheral arteriovenous anastamoses. Other ophthalmologic complications are anterior chamber ischemia, tortuosity of conjunctival vessels, retinal artery occlusion, and angioid streaks. Sickle cell retinopathy is best seen by fluorescein angiography (Fig. 43–14). The earlier onset and greater frequency of proliferative retinopathy in Hb SC disease and sickle cell–β^+ thalassemia compared to sickle cell anemia and sickle cell–β° thalassemia suggest that retinal vessels are more susceptible to occlusion by more viscous blood than by more rigid individual cells. Peripheral sickle retinopathy may require vision-saving therapy with laser photocoagulation. Orbital compression syndrome due to vasoocclusion of the periorbital marrow space and subperiosteal hemorrhage has been observed to result in headache, fever, and palpebral edema. In this situation, culture, CT scan, and MRI should be used to rule out infectious, neoplastic, and other hemorrhagic etiologies. Conservative therapy, including local measures, analgesia, fluids, transfusion, and careful ophthalmalogic surveillance, is recommended, unless compression of the optic nerve ensues, in which case surgical decompression should be considered.

Bone Complications

Chronic tower skull, bossing of the forehead, and fish mouth deformity of vertebrae are the result of extended hematopoietic marrow, causing widening of the medullary space, thinning of the trabeculae and cortices, and osteoporosis. Osteonecrosis may cause a steplike depression of vertebrae, selected shortening of the cuboidal bones of the hands and feet, and acute aseptic or avascular necrosis. The excruciating pain of bone infarction in the "hand–foot syndrome" that occurs around age 2 years is often the first symptom of sickle cell disease (Fig. 43–15).[215] This dactylitis resolves spontaneously and is treated with hydration and analgesia. Bone infarcts are demonstrable using nuclear medicine scintigraphy or MRI. Serial scans specific for bone osteoclasts, bone marrow macrophages, and inflammatory cells may be useful adjuncts for distinguishing bone marrow infarction from osteomyelitis, but it is essential to obtain cultures directly from the affected tissue before starting antibiotics. Treatment of osteomyelitis was addressed in the Infection sections.

Bone necrosis occurs with equal frequency in the femoral and humeral heads, but the femoral heads more commonly undergo progressive joint destruction as a result of chronic weight bearing. The process is associated with increased intraosseous pressure, and is most sensitively detected by MRI. Aggressive physical therapy appears to prevent progression in mild cases and should be considered in the therapy of avascular necrosis. Core decompression surgery to relieve increased intraosseous pressure can be used in early-stage osteonecrosis (ie, no radiographic evidence of bone collapse) to prevent disease progression. In more advanced disease, joint replacement can be considered. There is a 30% likelihood that a second hip revision will be required within 4 to 5 years of prosthetic hip placement in patients with sickle cell disease.[216]

Arthritic pain, swelling, and effusion may be related to periarticular infarction or gouty arthritis.

Bone marrow infarction causes reticulocytopenia, exacerbation of anemia, a leukoerythroblastic picture, and sometimes pancytopenia.[127,128] Pulmonary fat embolism is a rare complication of marrow infarction.[217] It is associated with fat globules in the sputum and refractile bodies visible in the optic fundi. It is a life-threatening event

Figure 43–15 Radiogram showing the bone infarctions in the hands of a child with the "hand–foot syndrome" dactylitis. *(Kindly provided by WC Mentzer.)*

that may require prompt exchange transfusion and perhaps the use of heparin and corticosteroids.[217]

Dermatologic Complications

Leg ulcers are major causes of morbidity in sickle cell disease as a result of their frequency, chronicity, and resistance to therapy. Most occur near the medial or lateral malleolus (Fig. 43–16), may be associated with venous hypertension[218] and hemolytic rate,[219] and are frequently bilateral.[220] They may begin spontaneously or as a result of trauma and may become infected, most commonly by *S aureus*, *Pseudomonas*, streptococci, or *Bacteroides*. Systemic infection, osteomyelitis, and tetanus are rare complications. Ulcers are resistant to healing and tend to be recurrent in well over half the cases. Their incidence has been reported to vary from 25% to 75%.[221] Ulcers rarely occur in patients younger than age 10 years and are most common in sickle cell anemia, less common in sickle cell–β^{o} thalassemia, and nonexistent in Hb SC disease and sickle cell–β^{+} thalassemia.[220] The incidence in sickle cell anemia patients declines substantially in those who have coexistent α thalassemia.[220] Low steady-state Hb levels and low fetal hemoglobin levels are associated with an increased risk of leg ulceration.[222] Males have a threefold greater risk for developing leg ulcers than females. Treatment of leg ulcers requires persistence and patience; healing usually takes weeks. Therapy[223] begins with gentle debridement to remove nonviable, superficial tissue from more vital areas. Wet-to-dry dressings and Duoderm hydrocolloid dressings facilitate devitalization. Once debridement is complete, zinc oxide-impregnated Unna boots are used to promote healing. Bed rest speeds healing,[224] and topical antibiotics may be required. It may be necessary to use elastic wraps or leg elevation to control edema. Rapid healing of leg ulcers has been reported in patients treated with intravenous arginine butyrate.[225] Oral zinc, local hyperbaric oxygen, chronic transfusion, recombinant erythropoietin, propionyl-L-carnitine, skin grafts, pentoxifylline, and becaplermin (platelet-derived growth factor) may have therapeutic roles and should be considered in individual cases but have not been formally tested for their effectiveness in accelerating resolution of sickle cell-associated leg ulcers.

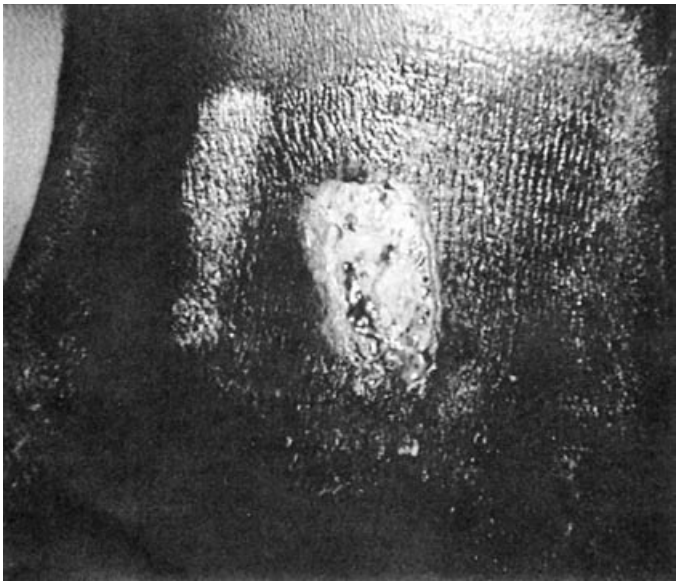

Figure 43–16 Chronic leg ulcer near the medial malleolus. *(Kindly provided by WC Mentzer.)*

Myofascial syndromes consist of soft-tissue swelling in subcutaneous edema that may have a *peau d'orange* appearance. These may be large or discrete lesions a few centimeters in diameter. These lesions are probably the result of dermal or subdermal vasoocclusion. Treatment is symptomatic.

Cardiac Complications

The chronic anemia of sickle cell disease is compensated by high cardiac output, which results in chronic chamber enlargement and cardiomegaly, and mild to moderate mitral and tricuspid regurgitation, even in young children. The electrocardiogram shows evidence of left ventricular hypertrophy, and less often first-degree block and nonspecific ST-T wave changes. Left ventricular dilation correlates with age and inversely correlates with total hemoglobin.[226] An age-dependent loss of cardiac reserve may predispose to heart failure in adult patients stressed by fluid overload, transfusion, exacerbation of anemia, hypoxia, or hypertension. Cardiac function can be improved by transfusion.[227] Acute myocardial infarction in the absence of coronary disease has been reported, and in one autopsy series 9.7% of 72 consecutive patients with sickle cell disease had myocardial infarction.[228] It appears that myocardial infarction may occur with normal coronary arteries as a result of increased oxygen demand exceeding limited oxygen-carrying capacity, or as a result of microcirculatory impairment. As mentioned earlier, pulmonary hypertension (>30 mmHg) is a relatively common finding in sickle cell disease and can be associated with right ventricular hypertrophy. It has been suggested that the increased rate of sudden death observed in sickle cell disease may be related to cardiac autonomic dysfunction, as detected by abnormal heart rate variability in response to selected postural maneuvers.[229]

Multiorgan Failure

This disastrous acute event involves multiple organ systems, including the lungs, brain, kidneys, liver, hematologic system, and heart, and usually leads to death.[230] It may be precipitated by infection, vasoocclusion, or fat embolus and consists of a constellation of life-threatening processes, including hypoxemia, acidosis, inflammation, vascular permeability, severe anemia, disseminated intravascular

coagulation, renal failure, and hepatic failure. In addition to therapy specific for these processes, exchange transfusion, plasma infusion or exchange, and corticosteroids should be considered.

Psychosocial Issues

Modern insights into the psychosocial adjustment of patients with sickle cell disease have provided a level of understanding that allows interventional therapy. Although most patients with sickle cell disease are generally well adjusted,[231] there are risks of depression, low self-esteem, social isolation, poor family relationships, and withdrawal from normal daily living.[231] Particular stressors are recurrent and unpredictable pain and the response to it, curtailed activity due to pain, misinterpretation of the meaning of pain, and depression leading to learned helplessness. Although some patients with sickle cell disease become addicted to narcotics, this is uncommon and usually is the result of social influences rather than pain therapy. Well-adjusted patients have active coping strategies, family support, and support from the extended family unit common in African American society. Interventional approaches should emphasize recognizing and reinforcing individual strengths, confronting pathologic behavior, and establishing coping skills through reinterpreting pain, diverting attention from pain, and using support systems.[232] Attention to psychosocial concerns is vital to the psychosocial well-being and integration into society of patients with sickle cell disease (see Chapter 93).

Growth and Development

By age 2 years, children with sickle cell disease have detectable growth retardation that affects weight more than height and has no clear gender difference.[233] By adulthood, normal height is achieved, but weight remains lower than that of controls. More severe growth delay is noted in children with sickle cell anemia and sickle cell–β° thalassemia; Hb SC disease is associated with a less severe growth delay. Girls with sickle cell disease have retarded sexual maturation that is greater in those with sickle cell anemia and sickle cell–β° thalassemia than those with Hb SC disease and sickle cell–β$^+$ thalassemia[233]; it is associated with elevated gonadotropin levels for the stage of sexual development and delayed menarche. Boys also have delayed sexual maturation, which is more severe in those with sickle cell anemia than those with Hb SC disease.[233] Retarded sexual maturation in males can be due to primary hypogonadism, hypopituitarism, or hypothalamic insufficiency. The etiology of these multiple endocrine deficiencies may relate to underlying sickle cell pathophysiology and/or iron overload and emphasizes the importance of a comprehensive basic management and disease modification approach as outlined earlier in this chapter. Improved growth has been reported with hydroxyurea,[234] transfusion,[234] folic acid supplementation, zinc supplementation,[235] and nutritional supplementation.[236] When children have both sickle cell disease and hypersplenism, splenectomy may result in improved protein turnover, metabolic rate, and growth parameters.[237]

VARIANT SICKLE CELL SYNDROMES

The sickle cell syndromes that result from inheritance of the sickle cell gene in simple heterozygosity or in compound heterozygosity with other mutant β-globin genes are sickle cell trait, Hb SC disease, and sickle cell–β thalassemia. These and other less common compound heterozygosity syndromes are reviewed.

Sickle Cell Trait

The prevalence of sickle cell trait is approximately 8% to 10% in African-Americans and as high as 25% to 30% in certain areas of western Africa.[4] There are approximately 2.5 million people in the United States and 30 million in the world who are heterozygous for the sickle cell gene. Sickle cell trait is largely a benign carrier condition with no obvious laboratory hematologic manifestations under basal conditions: red cell morphology, red cell indices, and the reticulocyte count are normal, and sickle forms (ISCs) are not seen on the peripheral blood smear. The usual partition of Hb A and Hb S in sickle cell trait is 60:40 owing to a greater posttranslational affinity of α chains for β^A than for β^S chains.[6] When α thalassemia is coinherited with sickle cell trait, the preferential affinity results in a decreased percentage of hemoglobin S relative to the number of α-globin genes deleted (ie, αα/αα 40% Hb S; −α/αα 35% Hb S; −α/−α 29% Hb S; −−/−α 21% Hb S).[124]

There are a few clinical complications of sickle cell trait: splenic infarction occurs at high altitude.[238] It is a cause of hematuria and hyposthenuria.[239] The frequency of urinary tract infection may be increased. There is an association with renal medullary carcinoma.[207] There is an increased risk for venous thrombosis with an approximately twofold increase in risk and sickle trait explaining 7% of thrombotic episodes in African Americans.[240] Recruits in basic training with the sickle-cell trait have a substantially increased, age-dependent risk of exercise-related sudden death.[241]

Despite the known complications, past experiences with discrimination in the employment market and health insurance industry provide reminders that the rare clinical events in sickle cell trait provide no real justification for regarding it as anything but a benign carrier condition.[242] Newborn screening programs detect a large number of infants with sickle cell trait; for these parents, genetic counseling is essential. Parents should understand that their child has a benign hereditary condition with some risks as above, but that there is a risk for a subsequent child to be born with sickle cell disease.

In individuals who appear to have sickle cell trait but are symptomatic, the laboratory diagnosis must be verified. Hemoglobins other than S that polymerize may account for reports of "sickle cell trait" associated with clinical problems. Examples are heterozygous Hb S Antilles and Hb Quebec-CHORI. In the latter case, the hemoglobin variant was distinguished from Hb A using mass spectroscopy.

Hb SC Disease

The gene for Hb C ($\alpha_2\beta_2^6$Glu→Lys) is approximately one-fourth as frequent among African Americans as the sickle cell gene.[8] Although oxygenated Hb C forms crystals, Hb C does not participate in polymerization with deoxy-Hb S. However, HbC sustains potassium chloride cotransport and red cell dehydration, raising the intraerythrocytic concentration of Hb S to levels that support polymerization, sickling, and clinical symptoms. As a result of a longer circulatory survival of Hb SC red cells compared to Hb SS cells (ie, 27 vs 17 days),[121] the degree of anemia and reticulocytosis is frequently mild: 75% of the patients have a milder level of anemia (hematocrit level >28%) than is usually seen in sickle cell anemia. The predominant red cell abnormality on the peripheral smear is an abundance of target cells; folded ("pita bread") cells, ISCs, "billiard ball" cells, and crystal-containing cells also may be seen.

Splenomegaly may be the only physical finding, and the frequency of acute painful episodes is approximately half that in Hb SS disease, with a life expectancy two decades longer.[16] Nonetheless, significant morbidity can occur. The incidence of fatal bacterial infection is less than in sickle cell anemia, but there is still an increased risk of *S pneumoniae* and *H influenzae* infection. Osteonecrosis occurs in approximately 15% of patients.[243] There is a higher incidence of peripheral retinopathy in Hb SC disease than in sickle cell anemia. Coexistent α thalassemia reduces risk of chronic organ complications.[243] There is an association between renal medullary carcinoma and Hb SC disease.

Sickle Cell–β Thalassemia

The gene frequency of β thalassemia among African Americans is 0.004, one-tenth that of the sickle cell gene,[8] and hence there is one-

tenth the prevalence of compound heterozygous sickle cell–β thalassemia in this population. Sickle cell–β thalassemia is divided into sickle cell–β^+ thalassemia and sickle cell–β° thalassemia, which have, respectively, reduced or no amounts of Hb A present. Most β thalassemia mutations among African Americans result in β^+ thalassemia. Sickle cell–β^+ thalassemia is subclassified according to the percentage of Hb A present: type I has 3% to 5%; type II has 8% to 14%; and type III has 18% to 25%. Eighty percent of African American α-thalassemia mutations are due to the promoter region mutations [−88 (C to T) and −29 (A to G)] that result in a type III phenotype. Compound heterozygous sickle cell–β° thalassemia occurs infrequently.

In sickle cell–β thalassemia, the red cells are hypochromic and microcytic. The ISCs present on the peripheral blood smear are more numerous in sickle cell–β° thalassemia than in sickle cell–β^+ thalassemia. The hematologic and clinical severity is a function of the amount of Hb A inherited (Table 43–8).

Additional mitigating influences in sickle cell–β thalassemia are elevated levels of Hb A_2 and, in sickle cell–β^+ thalassemia, levels of Hb A up to 30%. These affect both the solubility and polymerization of Hb S. Hb F is a more active inhibitor of polymerization than Hb A, as shown by Hb S solutions with 15% to 30% Hb A (resembling sickle cell–β^+ thalassemia) having delay times 10 to 100 times longer than pure Hb S solutions, and Hb S solutions with 20% to 30% Hb F (resembling Hb S–HPFH) having delay times 1,000 to 1,000,000 times longer. A further influence mitigating the polymerization, sickling, and clinical aspects of sickle cell–β thalassemia is the reduced MCHC, which retards Hb S polymerization. Hematologic values for sickle cell anemia, the sickle cell–β thalassemias, and Hb S–HPFH are found in Table 43–8.

Sickle Cell–Hb Lepore Disease[244]

The Hb Lepore gene is a crossover fusion product of the δ- and β-globin genes, the product of which, in the case of Hb Lepore Boston, has the same alkaline electrophoretic mobility as Hb S. Therefore, patients with the Hb Lepore trait can appear to have sickle cell trait, but with only 12% Hb S from thalassemic expression of the abnormal fusion gene. Again, because of the electrophoretic similarity with HbS, compound heterozygous Hb S–Hb Lepore Boston resembles sickle cell anemia or sickle cell–β° thalassemia electrophoretically but clinically have less severe anemia, resembling that of sickle cell–β^+ thalassemia. The diagnosis is also suggested by the low to low-normal Hb A_2 levels that result from the incapacitation of one δ-globin gene by the crossover. Hb F levels vary. The peripheral smear shows microcytosis, hypochromia, and ISCs. Vasoocclusive complications occur, and splenomegaly is common.

Sickle Cell–Hb D Disease[245]

Because Hb D Punjab or Hb D Los Angeles ($\alpha_2\beta_2^{121}$Glu→Gln) has a similar electrophoretic mobility to Hb S under alkali conditions, Hb SD disease was first reported as an unusual case of sickle cell anemia. Hb D can be distinguished from Hb S by acid electrophoresis or isoelectric focusing. There is moderately severe hemolytic anemia, and the peripheral smear shows marked anisocytosis and poikilocytosis, target cells, and ISCs. The clinical manifestations of this syndrome are similar to those of sickle cell anemia (see Chapter 40).

Sickle Cell–Hb O Arab Disease[246]

Although Hb O Arab ($\alpha_2\beta_2^{121}$Glu→Lys) was first described in an Israeli Arab family, its distribution is widespread. Sickle cell–O Arab disease resembles Hb SC disease on alkaline electrophoresis, but Hb O Arab can be distinguished from Hb C by acid electrophoresis or isoelectric focusing. This syndrome is associated with moderately severe hemolytic anemia, and the peripheral smear shows anisocytosis, poikilocytosis, and ISCs (see Chapter 40).

Sickle Cell–Hb E Disease[247]

Hb E ($\alpha_2\beta_2^{26}$Glu → Lys) is a β-thalassemic hemoglobinopathy found predominantly in southeast Asia (see Chapter 41). The structural mutant has an electrophoretic mobility similar to Hb C under alkaline conditions but can be resolved by acid electrophoresis or isoelectric focusing. The GAG→AAG mutation in codon 26 activates a cryptic splice site within the first intron of the β^E gene, causing alternate splicing and decreased expression of the structural mutant. As a result, Hb E makes up only 30% of the total hemoglobin in compound heterozygosity for the sickle cell and Hb E genes. Hb SE disease is essentially benign in at least 50% and possibly most patients, with only mild hemolysis, no vasoocclusive complications, and no remarkable abnormality of red blood cell morphology. However, vasoocclusive complications and manifestations of chronic hemolytic anemia such as pain crisis, splenic infarction, recurrent pneumonia, and frontal bossing have been reported.

Coinherited Hemoglobin Abnormalities That Interact With Sickle Cell Disease: Hereditary Persistence of Fetal Hemoglobin and α-Thalassemia Trait

Sickle Cell–Hereditary Persistence of Fetal Hemoglobin

Adult hemoglobin (or in the case of sickle cell anemia Hb S) replaces Hb F as a result of the switch from γ- to β-globin synthesis that occurs in the fetus. Because of the inhibitory effect of Hb F on Hb S polymerization and cellular sickling (please see Chapter 42), the high fraction of Hb F at birth masks the expression of sickle cell disease until Hb S levels increase to 75% at approximately 6 months of age (Fig. 43–3). Conditions that preserve elevated levels of Hb F into adulthood similarly modulate the course of sickle cell disease. The compound heterozygous conditions sickle–hereditary persistence of fetal hemoglobin (Hb SS–HPFH) and sickle cell–β° thalassemia–HPFH both have higher Hb F levels and milder clinical courses than are characteristic of sickle cell anemia.[113]

Hereditary persistence of fetal hemoglobin results from one of several large deletions of the δ- and β-globin genes that retard the switch from the production of Hb F to adult hemoglobin (see Chapters 22 and 29). A more recently discovered variety of HPFH is not due to a deletion but to one of many point mutations that upregulate the expression of the γ-globin gene. The clinical expression of deletional and nondeletional HPFH differs in that the 15% to 35% Hb F in the former is distributed in a pancellular fashion, the 1% to 5% Hb F in the latter is distributed in a heterocellular fashion, and certain mild types of nondeletional HPFH express high Hb F levels not in simple heterozygosity but only in conditions of erythropoietic stress, such as compound heterozygosity with the sickle cell gene. It is likely that many cases of apparent sickle cell anemia with unexplained elevations of Hb F are the result of a nondeletion HPFH mutation.

The gene frequency of the deletional HPFH locus is 0.0005 among African Americans, resulting in a calculated incidence for compound heterozygous sickle cell–deletional HPFH of 1/100 that of sickle cell anemia. Sickle cell–deletional HPFH provided the first evidence that Hb F was a potent inhibitor of Hb S polymerization: individuals with pancellular distribution of 25% Hb F were generally neither anemic nor afflicted with vasoocclusive manifestations (Table 43–8).[248] Hemoglobin electrophoresis revealed only Hb S, F, and A_2, which resembles sickle cell anemia, sickle cell–β° thalassemia, and sickle cell–$\delta\beta^\circ$ thalassemia. Notable differences, however, are the pancellular distribution of 15% to 35% Hb F, Hb A_2 levels less than 2.5%, and the absence of anemia.[249] The generally benign course of

sickle cell–deletional HPFH is uncommonly associated with vasoocclusive complication.

Sickle Cell Anemia With Coexistent α Thalassemia

Prevalences of the silent carrier of α-thalassemia syndrome (genotype -α/αα) and α-thalassemia trait (genotype −α/−α) among African Americans are approximately 30% and 2%, respectively.[250] The peripheral blood smear contains less polychromasia and fewer sickle forms and more hypochromia and microcytosis, commensurate with the numbers of α-globin genes deleted. There are increased Hb A_2 levels associated with increasing α-globin gene deletions; the Hb F levels are not consistently affected.

Clinically, the impact of α-globin gene deletions on sickle cell is not as consistent as that of high Hb F.[20] Because of the powerful effect of Hb S concentration on the kinetics and extent of Hb S polymerization (please see Chapter 42), the lower MCHC from α-globin gene deletions decreases the hemolytic rate, and anemia is milder in subjects with both α-thalassemia syndrome (genotype -α/αα) and trait (genotype −α/−α) (Table 43–1). There is a decreased incidence of leg ulcers but an increased incidence of osteonecrosis. The frequency of retinal vessel closure is higher, but not the incidence of retinopathy. Complications related to hemolysis (eg, leg ulcers, chronic renal damage) may be decreased, but the heterogeneity of the patients in previous studies and mixed results make conclusions difficult. Similarly, the influence of α-gene deletions on survival in patients with sickle cell disease is not well understood.[20]

CHAPTER 44

HEMOGLOBIN VARIANTS ASSOCIATED WITH HEMOLYTIC ANEMIA, ALTERED OXYGEN AFFINITY, AND METHEMOGLOBINEMIAS

Edward J. Benz, Jr. and Benjamin L. Ebert

Hemoglobinopathies are inherited diseases caused primarily by mutations affecting the globin genes. Nearly 1000 mutations that alter the structure, expression, or developmental regulation of individual globin genes, and the hemoglobins they encode, have been described; most do not produce clinical disease. Many are highly instructive for students of gene structure, function, and regulation, but further consideration of most is not warranted in a clinically oriented textbook. The gene mutations that cause sickle cell anemia and the thalassemia syndromes are by far the most important mutations that cause clinical morbidity, in terms of both the complexity of the clinical syndromes they cause and the number of patients affected. These conditions are considered in detail in other chapters (see Chapters 42 and 43). This chapter reviews other abnormalities of the hemoglobin molecule that produce clinical syndromes. Each variant is uncommon. In the aggregate, however, hemoglobinopathies represent important problems for hematologists because they must be considered as possible causes for conditions about which hematologists are often consulted: hemolytic anemia, cyanosis, polycythemia, jaundice, rubor, splenomegaly, and reticulocytosis.

The major hemoglobinopathies producing clinical symptoms, other than sickle cell anemia and thalassemias, can be classified as those hemoglobins exhibiting altered solubility (unstable hemoglobins), hemoglobins with increased oxygen affinity, hemoglobins with decreased oxygen affinity, and methemoglobins (Table 44–1). A few acquired conditions in which toxic modifications of the hemoglobin molecule are important (eg, carbon monoxide poisoning) are also considered briefly.

The sections that follow emphasize hemoglobinopathies that produce the most severe or dramatic alterations in clinical phenotype and those in which a single clinical abnormality (eg, hemoglobin precipitation) predominates. It is important to emphasize at the outset, however, that although more than 100 mutations affect solubility or affinity, only a few are clinically important. The abnormal functional properties of most mutant hemoglobins can be detected readily in sophisticated research laboratories, but only a few mutant hemoglobins produce laboratory or clinical abnormalities relevant to clinical practice. Moreover, many mutations are pleiotropic, affecting several functional properties of the hemoglobin molecule. Thus, a single mutation can increase oxygen affinity and reduce solubility, or produce methemoglobinemia and reduce solubility.

Table 44–2 summarizes the major forms of structurally abnormal hemoglobin, with examples. This table serves as a point of reference for the remaining sections of the chapter.

UNSTABLE HEMOGLOBINS

The term *unstable hemoglobins* refers to hemoglobins exhibiting reduced solubility or higher susceptibility to oxidation of amino acid residues within the individual globin chains. More than 100 unique unstable hemoglobin mutants have been documented. Most exhibit only mild instability in in vitro laboratory tests and are associated with minimal clinical manifestations. Both α- and β-globin variants can cause this condition. Approximately 75% of the mutations described, however, are β-globin variants. This probably reflects the potential for α-globin variants to exert pathologic effects in utero. Clinical symptomatology of unstable hemoglobins also depends in part on the quantitative proportion of the abnormal hemoglobin. Because the α-globin genes are duplicated, mutations in an individual locus generally produce only 25% to 35% abnormal globin. By contrast, a simple heterozygote at the single β-globin locus usually produces approximately 50% of the abnormal variant.

The mutations that impair hemoglobin solubility usually disrupt hydrogen bonding or the hydrophobic interactions that either retain the heme moiety within the heme-binding pockets or hold the tetramer together (Fig. 44–1). Some alter the helical segments (eg, Hb Geneva [$\beta^{28Leu\rightarrow Pro}$]), others weaken contact points between the α and β subunits (eg, Hb Philadelphia [$\beta^{35Tyr\rightarrow Phe}$]), and still others derange interactions of the hydrophobic pockets of the globin subunits with heme (eg, Hb Köln [$\beta^{98Val\rightarrow Met}$]). The common pathway to reduced solubility invariably involves weakening of the binding of heme to globin. Actual loss of heme groups can occur, for example, in Hb Gun Hill, in which five amino acids, including the F8 histidine, are deleted. In other cases, mutations that introduce prolines into helical segments disrupt the helices and interfere with normal folding of the polypeptide around the heme group. Another feature of these mutations is disruption of the integrity of the tetrameric structure of globin chains. Only the intact hemoglobin tetramer can remain dissolved at the high concentrations that must be achieved within the circulating red blood cell (see Chapter 33).

Pathophysiology of Unstable Hemoglobin Disorders

The mechanisms by which unstable hemoglobin mutations produce hemoglobin precipitation remain incompletely understood. However, the major outlines of the process have been described (Fig. 44–2). The fundamental step in pathogenesis appears to be derangement of the normal linkages between heme and globin. Loss of appropriate globin chain folding and interaction may ultimately destabilize the heme–globin linkage or lead to partial proteolysis of the chain, thereby releasing heme from that linkage. Once freed from its cleft, heme probably binds nonspecifically to other regions of the globin molecule, forming precipitated hemichromes, which lead to further denaturation and aggregation of the globin subunits. These form a precipitate containing α- and β-globin chains, globin fragments, and heme, called the *Heinz body*.

Heinz bodies interact with delicate red blood cell membrane components (see Chapter 33), thereby reducing red blood cell deformability. These rigid cells tend to be detained in the splenic microcirculation and "pitted," reflecting attempts by the splenic macrophages to remove the Heinz bodies. Red blood cell damage can be aggravated by the release of free heme into the red blood cell. Several biochemical perturbations correlate with the presence of free heme, such as generation of reactive oxidants (ie, hydrogen peroxide, superoxide, and hydroxyl radicals). The end result of this process is premature destruction of the red blood cell, producing the hemolytic anemia.

Individual unstable hemoglobins vary in their propensity to generate Heinz bodies and hemolysis. For example, Hb Zurich exhibits relatively mild insolubility. Hemolysis is virtually absent in patients with this variant. Hemolysis may become clinically apparent only in the presence of additional oxidant stresses, such as infection, fever, or the ingestion of oxidant agents. Because of the propensity of these

Table 44–1 Classification of Hemoglobinopathies

Structural hemoglobinopathies—hemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties
Abnormal hemoglobin polymerization—Hb S
Altered oxygen affinity
High affinity—polycythemia
Low affinity—cyanosis, pseudoanemia
Hemoglobins that oxidize readily
Unstable hemoglobins, hemolytic anemia, jaundice
M hemoglobins—methemoglobinemia, cyanosis
Thalassemias—defective production of globin chains
α Thalassemias
β Thalassemias
δβ, γδβ, αβ Thalassemias
Structural hemoglobinopathies—structurally abnormal Hb associated with coinherited thalassemia phenotype
Hb E
Hb Constant Spring
Hb Lepore
Hereditary persistence of fetal hemoglobin—persistence of high levels of Hb F into adult life
Pancellular—all red blood cells contain elevated Hb F levels
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellular—only specific subpopulation of red blood cells contain elevated levels of Hb F
"Acquired hemoglobinopathies"
Methemoglobin due to toxic exposures
Sulfhemoglobin due to toxic exposures
Carbonoxyhemoglobin
Hb H in erythroleukemia
Elevated Hb F in states of erythroid stress and bone marrow dysplasia, usually heterocellular

Table 44–2 Mutations Producing Abnormal Hemoglobin Molecules*

Residue	Mutation	Common Name(s)	Molecular Pathology
Abnormal solubility			
β6	Glu→Val	S	Polymerization
β6	Glu→Lys	C	Crystallization
β121	Glu→Gln	D-Los Angeles, D-Punjab	Increases polymer in S/D heterozygote
β121	Glu→Lys	O-Arab	Increases polymer in S/O heterozygote
Increased oxygen affinity			
α92	Arg→Gln	J-Capetown	Stabilizes R state
α141	Arg→His	Suresnes	Eliminates bond to Asn 126 in T state
β89	Ser→Asn	Creteil	Weakens bonds in T state
β99	Asp→Asn	Kempsey	Breaks T state intersubunit bonds
Decreased oxygen affinity			
α94	Asp→Asn	Titusville	Alters R state intersubunit bonds
β102	Asn→Thr	Kansas	Breaks R state intersubunit bonds
β102	Asn→Ser	Beth Israel	Breaks R state intersubunit bonds
Methemoglobin			
α58	His→Tyr	M-Boston, M-Osaka	Heme liganded to Tyr not His
α87	His→Tyr	M-Iwate	Heme liganded to both His and Tyr
β28	Leu→Gln	St. Louis	Opens heme pocket
β63	His→Tyr	M-Saskatoon	Tyr ligand stabilizes ferri-heme
β67	Val→Glu	M-Milwaukee-I	Negative charge stabilizes ferri-heme
β92	His→Tyr	M-Hyde Park	Bond of His to heme disrupted
Unstable			
α43	Phe→Val	Torino	Loss of heme contact
α94	Asp→Tyr	Setif	Alters subunit contacts

molecules to be hypersensitive to oxidation, some patients with unstable hemoglobins can exhibit episodic hemolysis in response to many of the same oxidative stressors as those exacerbating the clinical phenotype of glucose-6-phosphate dehydrogenase (G6PD)-deficient patients (see Chapter 45).

Patterns of Inheritance and Clinical Manifestations

Unstable hemoglobins are usually inherited as autosomal dominant disorders. However, the rate of spontaneous mutation appears to be high, so the absence of affected parents or siblings does not rule out the presence of an unstable hemoglobin in an individual family. Nonetheless, the presence of a positive family history can be a useful adjunct to diagnosis and should provoke consideration of an unstable hemoglobin as the cause of the familial hemolytic diathesis.

The clinical syndrome associated with unstable hemoglobin disorders is often called *congenital Heinz body hemolytic anemia*. This term derives from the fact that only the most severe cases were detected before the widespread availability of sophisticated methods for detecting and characterizing abnormal hemoglobins. Clinical manifestations are highly variable, ranging from a virtually asymptomatic state in the absence of environmental stressors to severe hemolytic anemia manifesting at birth. Patients with chronic hemolysis present with variable degrees of typical symptoms, including anemia, reticulocytosis, hepatosplenomegaly, jaundice, leg ulcers, and a propensity toward premature biliary tract disease.

For hemoglobin variants with a given degree of reduced solubility, the degree of anemia may fluctuate because some of these variants also exhibit altered oxygen affinity. Thus, Hb Köln has increased oxygen affinity, resulting in relatively higher levels of tissue hypoxia and erythropoietin stimulation at any given level of hematocrit (see next section); therefore, patients with Hb Köln tend to have higher hematocrit levels than expected on the basis of hemolytic severity because of increased erythropoietin stimulation. By contrast, Hb Hammersmith exhibits decreased oxygen affinity, improving oxygen delivery and allowing patients to function at a lower hematocrit level.

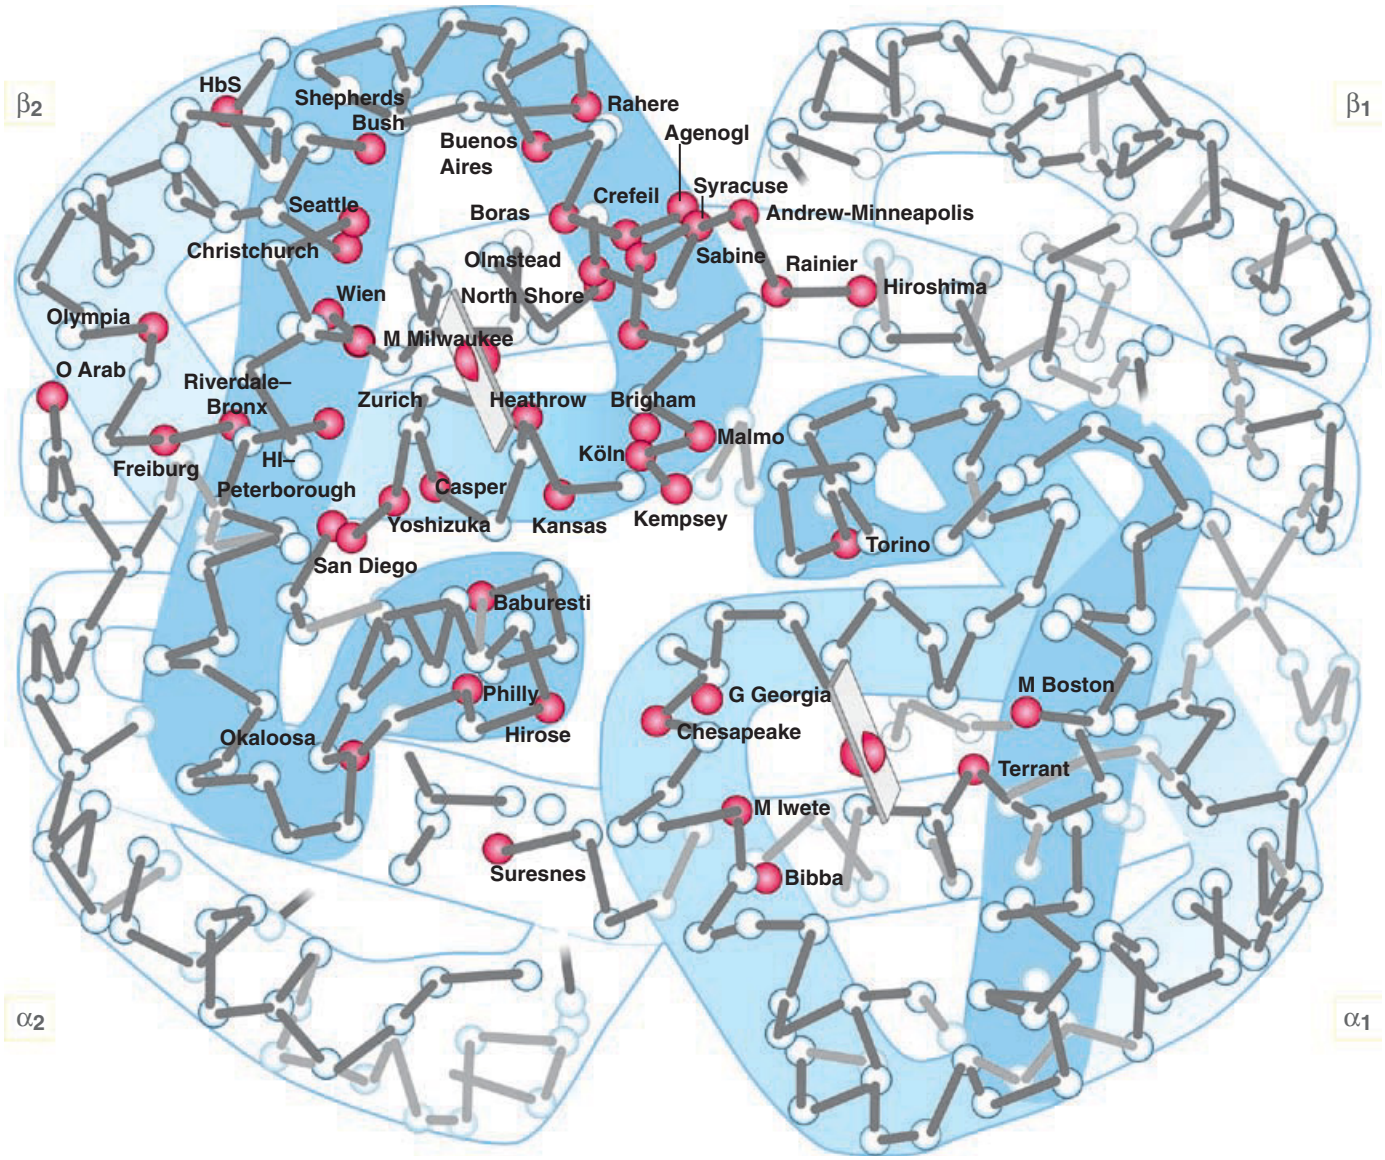

Figure 44–1 Hemoglobin tetramer showing the position of the more common, clinically significant hemoglobin mutants. Most of those that have been described occur on the β chain at invariant residue sites, near critical intermolecular contacts, or in proximity to the prosthetic heme-binding site. *(Modified from Dickerson RE, Geis I: Hemoglobin: Structure, Function, Evolution, and Pathology. Menlo Park, CA, Benjamin-Cummings, 1983. Copyright Irving Geis.)*

Hb Zurich possesses, for complex molecular reasons, a higher-than-normal affinity for carbon monoxide. A high hemoglobin carbon monoxide level develops in patients with Hb Zurich who also smoke. Binding of carbon monoxide protects Hb Zurich from denaturation, thus reducing hemolysis, so these people tend to exhibit lesser degrees of hemolytic anemia than do nonsmoking relatives.

Diagnosis

The presence of an unstable hemoglobin should be suspected in patients with one or more stigmata of accelerated red blood cell destruction: chronic or intermittent hemolytic anemia or jaundice, premature development of bilirubin gallstones or biliary tract disease (as a result of accelerated red blood cell turnover), unexplained reticulocytosis, or bouts of intermittent symptoms that can be related to exposure to oxidant drugs or infections. Other suggestive symptoms include dark urine, transient jaundice, and leg ulcers.

Laboratory diagnosis depends on identification of a mutant hemoglobin that precipitates more easily than normal hemoglobin. The peripheral blood smear may or may not show evidence of hemolysis (ie, poikilocytosis, polychromasia, or shift cells; see Fig. 44–3A). The morphologic evidence for precipitated hemoglobin is the Heinz body, the intraerythrocytic inclusion body detected by staining the peripheral blood smear with a supravital dye, such as brilliant cresyl blue or new methylene blue (see Fig. 44–3B,C). The spleen removes Heinz bodies efficiently, especially if hemolysis is not particularly acute or brisk. Thus, Heinz bodies may not be demonstrable at all times. Two provocative laboratory maneuvers are used to aid detection, both of which unmask the tendency of unstable hemoglobins to precipitate: the heat instability test (heating of a hemoglobin solution to 50°C) or the isopropanol instability test (insolubility in 17% isopropanol).

Hemoglobin electrophoresis should be performed but *should not be relied on as the major diagnostic criterion for ruling in or ruling out a hemoglobinopathy.* Many amino acid substitutions that have a profound effect on solubility do not change the overall charge on the hemoglobin molecule. For example, Hb Köln, the most common of

the unstable hemoglobin mutations, arises from a mutation changing the valine at position 98 to a methionine. This mutation is electrically neutral; it does not alter electrophoretic mobility. Therefore, these variants do not form an abnormal band on an electrophoresis gel. Demonstration of an abnormal band would clearly add strong evidence in support of the diagnosis. A normal electrophoretogram, however, should never be regarded as strong evidence against the presence of a mutant hemoglobin, especially if the clinical picture or family history otherwise supports the diagnosis.

Sophisticated analyses of hemoglobin can be obtained from reference laboratories if detailed characterization seems warranted. For example, abnormal hemoglobin or globin bands migrating to novel positions on an isoelectric focusing gel can result from hemoglobin or globin moieties lacking heme in groups. When heme is added to the sample and the proteins are reanalyzed, these bands disappear. This behavior is nearly diagnostic of an unstable variant.

Detection of unstable hemoglobins is occasionally compromised by the selective precipitation of the unstable variant into Heinz bodies. Because most patients are heterozygotes, this phenomenon greatly reduces the apparent percentage of the variant in soluble form. Thus, even a variant possessing altered electrophoretic mobility may be very difficult to detect. Indeed, some unstable hemoglobins, such as Hb Geneva or Hb Terre Haute, are so unstable that no mutant gene product can be detected in the steady state. These abnormal hemoglobins actually produce a thalassemic phenotype. They are detectable only by isotope labeling studies or direct analysis of the globin genes.

The amino acid sequence predicted from genetic sequencing may rarely be inaccurate because of posttranslational conversion into an unstable hemoglobin. For example, in the first reported case of congenital Heinz body hemolytic anemia due to Hb Bristol, the DNA sequence predicts a valine-to-methionine substitution at β67. Through posttranslational modification, the methionine is altered to aspartate, a hydrophilic residue that disrupts the heme pocket.

The differential diagnosis of unstable hemoglobin variants is usually straightforward if the general category of hemolytic disorders is suspected. The most common form of G6PD deficiency can also manifest with bouts of intermittent or chronic hemolysis exacerbated by oxidant drugs or infection (see Chapter 45). This diagnosis should be considered, as should other causes of chronic or intermittent hemolytic anemia, such as red blood cell membrane disorders (eg, hereditary spherocytosis) or immune hemolytic anemias. Spherocytes are relatively rare in patients with unstable hemoglobin disorders; this is sometimes a useful discriminant.

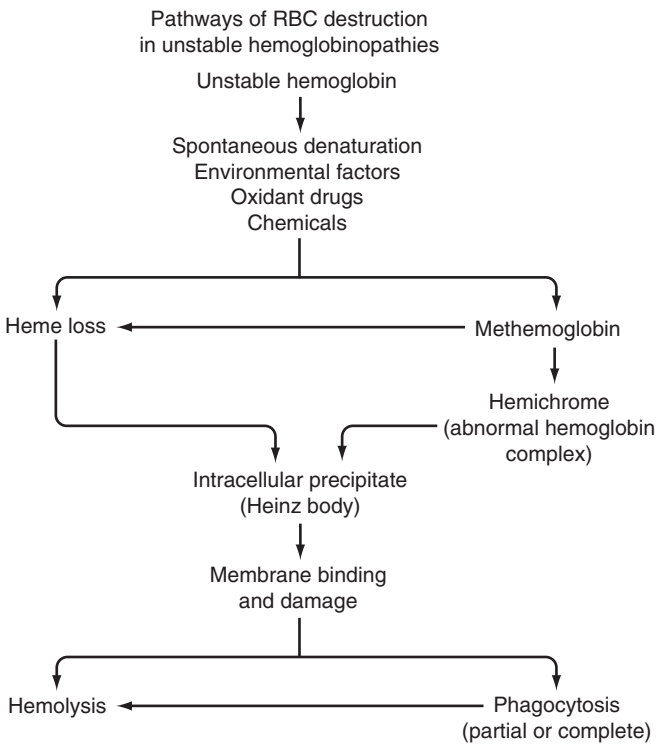

Figure 44–2 Presumed mechanisms by which denaturation of hemoglobin leads to erythrocyte destruction. The rate of travel through the various pathways probably differs for the different hemoglobin variants and for a variety of stresses to which the protein is subjected. RBC, red blood cell. *(From Wynngaarden JB, Smith LH Jr, Bennett JC [eds.]: Cecil Textbook of Medicine. Philadelphia, WB Saunders, 1992.)*

Management

The severity of the clinical complications of unstable hemoglobins varies enormously. Many patients can be managed adequately by observation and education to avoid agents that provoke hemolysis. Some patients require transfusions during bouts of severe acute hemolytic anemia. Patients who have significant morbidity because of chronic anemia or repeated episodes of severe hemolysis should be considered candidates for splenectomy, especially if hypersplenism has developed. Children with severe hemolysis may require transfusion support until they are old enough (at least 3 or 4 years of age) to undergo splenectomy without unacceptable immunologic compromise. Splenectomy is usually effective for abolition or reduction of anemin. However, splenectomy should be used only as a last resort because of the long term risks of out whelming sepsis and thrombosis. Infection often exacerbates hemolysis. Fever should therefore prompt close monitoring of patients for evidence of hemolysis or anemia.

HEMOGLOBINS WITH INCREASED OXYGEN AFFINITY

Efficient oxygen delivery by hemoglobin depends on the sigmoid shape of the hemoglobin–oxygen affinity curve. During the transition from the fully deoxygenated to the fully oxygenated state, the initial oxygenation steps occur with difficulty. In fact, the act of binding the first oxygen molecule increases the affinity of the molecule for subsequent oxygen-binding events, thus creating the sigmoid shape of the curve. The necessary intramolecular reorganization occurs only when the precise arrangement of hydrogen bonds, hydrophobic inter-

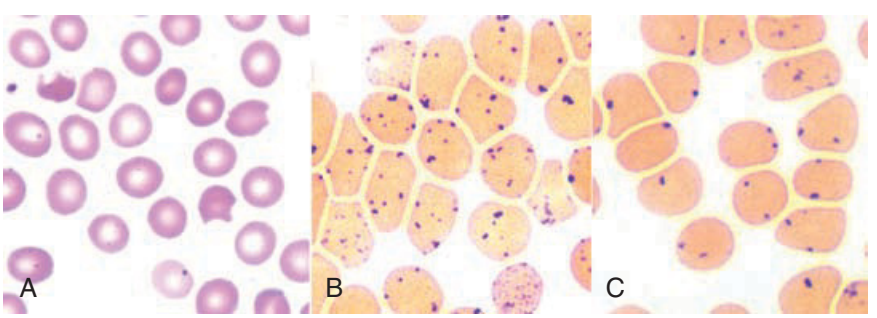

Figure 44–3 Unstable hemoglobins; peripheral blood smear and Heinz body preparation: **A–C**. The peripheral smear (**A**) shows "bite" cells with pitted out semicircular areas of the red blood cell membrane as a result of removal of Heinz bodies by macrophages in the spleen. The Heinz body preparation (**B**) shows increased Heinz bodies in the same specimen, when compared to a control (**C**).

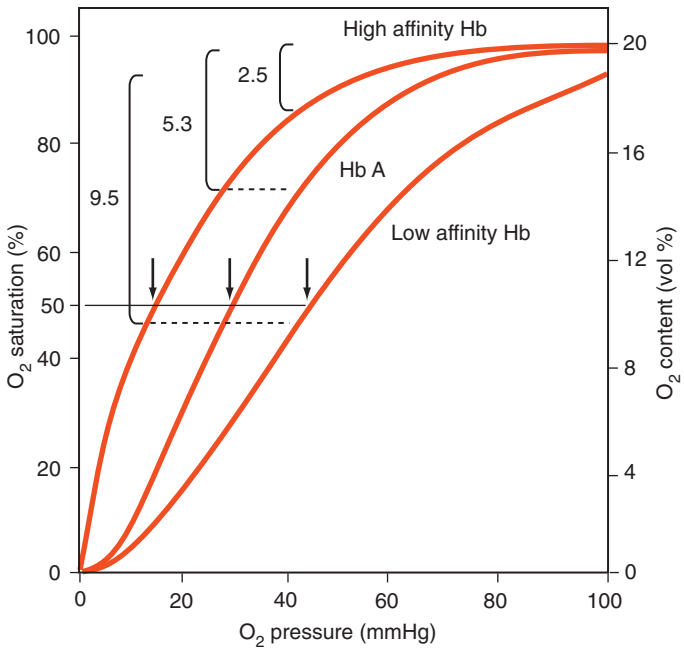

Figure 44–4 Hemoglobin–oxygen dissociation curves are illustrated for normal hemoglobin (Hb A) and for model abnormal hemoglobins with high and low oxygen affinities. On the abscissa, the partial pressure of oxygen is indicated in millimeters of mercury. On the left ordinate, the saturation of hemoglobin with oxygen is indicated as a percentage; on the right ordinate, the oxygen content of the hemoglobin is expressed as volumes percent. The three inverted arrows show the P_{50} for the three hemoglobins (the Po_2 at which the hemoglobin is 50% saturated). This value is lowest for the high-affinity hemoglobin. As the Po_2 drops from 100 (arterial) to 40 (tissues), hemoglobin desaturates, giving up a portion of its bound oxygen; the numbers on the brackets indicate the amount of oxygen unloaded by the three hemoglobin types expressed as volumes percent. Note that the high-affinity hemoglobin delivers less than one-half the oxygen that Hb A gives to the tissues, resulting in tissue anoxia, increased erythropoietin secretion, and erythrocytosis. Conversely, the low-affinity hemoglobin is even more efficient than Hb A in supplying tissues with oxygen, resulting in diminished erythropoietin production and anemia. *(From Wynngaarden JB, Smith LH Jr, Bennett JC [eds.]: Cecil Textbook of Medicine. Philadelphia, WB Saunders, 1992.)*

actions, and salt bridges are broken and formed in the proper sequence.

Mutant hemoglobins exhibiting altered oxygen affinity arise from amino acid substitutions at the interface between α and β chains or in regions affecting the hydrogen bonds, hydrophobic interactions, or salt bridges that influence the interaction of heme with oxygen. A second major class of mutations alters binding to 2,3-diphosphoglycerate (2,3-DPG), which in turn alters oxygen affinity when bound to hemoglobin.

Pathogenesis and Pathophysiology

High-affinity hemoglobins exhibit higher avidity for oxygen, causing the oxygen dissociation curve to shift to the left; an example is Hb Kempsey ($\beta^{99Asp\rightarrow Asn}$) (Fig. 44–4). These hemoglobins bind oxygen more readily than normal and retain more oxygen at lower Po_2 levels. They thus deliver less oxygen to tissues at normal capillary oxygen pressures. The Po_2 in the normal lung (Po_2 = 90–100 mmHg) is well above that needed to saturate hemoglobin fully with oxygen (60 mmHg). These variant hemoglobins cannot acquire any additional oxygen in the lung despite their higher affinity. At capillary Po_2 (35–45 mmHg), however, high-affinity hemoglobins deliver *less* oxygen. At normal hematocrit levels, a mild tissue hypoxia results, triggering increased production of erythropoietin and red blood cells, thus resulting in polycythemia. In extreme cases, hematocrit levels of 60 to 65% can be encountered.

Many types of mutations can increase oxygen affinity. Some alter interactions within the heme pocket, others disrupt the Bohr effect or the salt-bond site, and still others impair the binding of Hb A to 2,3-DPG. Loss of 2,3-DPG binding results in increases in oxygen affinity. These and numerous other examples that have been analyzed at the molecular level have greatly aided our understanding of the molecular basis for reversible oxygen binding.

Diagnosis

High-affinity hemoglobins are a cause of familial unexplained erythrocytosis (see Chapter 30). Functional testing of the hemoglobin is the key to diagnosis. Oxygen affinity is usually measured as P_{50}, the partial pressure of oxygen at which hemoglobin is 50% saturated with oxygen (see Fig. 44–4). The hemoglobin preparation is exposed to increasing oxygen pressures and the relative percentages of oxyhemoglobin and deoxyhemoglobin are determined. The values are plotted on a curve, and the 50% saturation point is determined. A shift to the left means that the hemoglobin reaches 50% saturation at a lower partial pressure of oxygen. High-affinity variants are thus associated with a lower-than-normal P_{50} value. Hemoglobin electrophoresis can, but may not, reveal an abnormal band.

The most common cause of a low P_{50} value is carbon monoxide. Carbon monoxide stabilizes hemoglobin in the R "oxy" state without the need for oxygen binding. The oxygen affinity curve is therefore extremely left-shifted and is hyperbolic, rather than sigmoidal, in shape. The clinical consequences of mild chronic CO poisoning are the same as those seen with high-affinity hemoglobin variants. The most common cause of carbon monoxide toxicity is cigarette smoking, although chronic carbon monoxide exposure can elevate the hematocrit level in people such as caisson workers or tunnel toll collectors. Severe acute CO poisoning can cause rapid death as a result of tissue hypoxia.

Management

Most patients with high-affinity hemoglobins have mild erythrocytosis; they do not require intervention. Very rarely, the hematocrit level is very high (>55–60%). The blood viscosity is then sufficiently elevated to require therapeutic phlebotomy. Carbon monoxide poisoning is treated with supplemental oxygen. When a patient breathes room air, the half-life of carboxyhemoglobin is 4 to 6 hours, but the half-life is 40 to 80 minutes with the use of normobaric oxygen and 15 to 30 minutes with the use of hyperbaric oxygen. Carbon monoxide detectors, designed to detect occult CO poisoning, are now required in many municipalities and are predicted to prevent numerous fatalities from occult carbon monoxide poisoning.

HEMOGLOBINS WITH DECREASED OXYGEN AFFINITY

Pathogenesis

Low-affinity hemoglobin variants, such as Hb Kansas ($\beta^{102Asn\rightarrow Thr}$), arise from mutations that impair hemoglobin–oxygen binding or reduce cooperativity. In cases of Hb Kansas, the threonine position, β^{102}, cannot form a hydrogen bond with aspartic acid at position α^{94}. Because this aspartate residue stabilizes the R (oxy) state, Hb Kansas

binds oxygen less well and exhibits a right-shifted P_{50} value (see Fig. 44–4).

Most low-affinity variants possess enough oxygen affinity to become fully saturated in the normal lung. At the low capillary PO_2 in other tissues, these hemoglobins deliver *higher* than normal amounts of oxygen. They become more desaturated than normal hemoglobins. Two abnormalities result from this high level of oxygen delivery. First, because tissue oxygen delivery is so efficient, normal oxygen requirements can be met by lower than normal hematocrit levels. This situation produces a state of "pseudoanemia," in which the low hematocrit level is deceiving because both oxygen delivery and the patients are completely normal. Second, the amount of desaturated hemoglobin circulating in capillaries and veins can be greater than 5 g/dL. Cyanosis may thus be associated with these variants. This usually ominous finding is entirely misleading in these individuals, because it reflects no morbidity.

Diagnosis

Patients with unexplained anemia or cyanosis who appear to be entirely well in all other respects should be evaluated, especially if there is a positive family history. Testing for the abnormal variant follows the same reasoning as that just described for high-affinity variants. The O_2 dissociation curve will be shifted to the right, and the numeric value of the P_{50} will be higher than normal.

Management

Patients with low-affinity hemoglobins are usually asymptomatic. No treatment is required. It is important to document that a low-affinity hemoglobin is the cause of an apparent anemia or cyanosis to preempt inappropriate workups and provide reassurance to the patient. Cyanosis in some patients can pose a cosmetic problem, but correction with transfusions is rarely justified.

METHEMOGLOBINEMIAS

Methemoglobin results from oxidation of the iron moieties in hemoglobin from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Normal oxygenation of hemoglobin causes a partial transfer of an electron from the iron to the bound oxygen. Iron in this state thus resembles ferric iron and the oxygen resembles superoxide (O_2–). Deoxygenation returns the electron to the iron, with release of oxygen. Methemoglobin forms if the electron is not returned. Methemoglobin constitutes 3% or less of the total hemoglobin in normal humans. Under normal circumstances, these levels in humans are maintained at 1% or less by the methemoglobin reductase enzyme system (nicotinamide adenine dinucleotide [NADH]-dehydratase, ADH-diaphorase, erythrocyte cytochrome b_5).

Pathogenesis and Clinical Manifestations

Methemoglobinemias of clinical interest arise by one of three distinct mechanisms: (a) globin chain mutations that result in increased formation of methemoglobin, (b) deficiencies of methemoglobin reductase, and (c) "toxic" methemoglobinemia, in which normal red blood cells are exposed to substances that oxidize hemoglobin iron to such a degree that normal reducing mechanisms are subverted or overwhelmed (see Chapter 45; Table 44–3).

Abnormal hemoglobins producing methemoglobinemia (M hemoglobins) arise from mutations that stabilize the heme iron in the ferric state. Classically, a histidine in the vicinity of the heme pocket is replaced by a tyrosine; the hydroxyl group of the tyrosine forms a complex that stabilizes the iron in the ferric state (Fig. 44–5). The oxidized heme iron is relatively resistant to reduction by the methemoglobin reductase system.

Table 44–3 Types of Methemoglobinemia

Congenital
Defective enzymatic reduction of Fe^{3+}-hemoglobin to Fe^{2+}-hemoglobin

Cytochrome b_3 deficiency
Abnormal hemoglobins resistant to enzymatic reduction (M hemoglobins)
Acquired
Excessive (toxic) oxidation of Fe^{2+}-hemoglobin
Environmental chemicals
Drugs

Methemoglobin has a brownish to blue color that does not revert to red on exposure to oxygen. Patients with methemoglobinemia thus appear to be cyanotic. In contrast to truly cyanotic people, however, Pao_2 values are usually normal. Patients with these hemoglobins are otherwise asymptomatic because methemoglobin is rarely greater than 30 to 50, the levels at which symptomatology becomes apparent.

Hereditary methemoglobinemia resulting from methemoglobin reductase deficiency (cytochrome b_5 reductase deficiency) is very rare. Mutations in the b_5 reductase gene cause two distinct phenotypes. In cases of type I methemoglobin reductase deficiency, patients suffer solely from cyanosis; in cases of type II disease, patients manifest both cyanosis and severe mental retardation. One isoform of the b_5 reductase gene is expressed in diverse tissues for participation in a variety of cellular processes. A second isoform, produced by alternative splicing, is expressed in erythrocytes, producing a soluble protein that reduces methemoglobin. Mutations causing type I methemoglobin reductase deficiency occur throughout the gene and result in an unstable protein. Such mutations are primarily significant in erythrocytes that, without nuclei, cannot replace the degraded protein. Mutations causing type II disease occur in the critical NADH or FAD binding domains, causing inactivation of the protein in all tissues and the more severe clinical phenotype.

Like patients with M hemoglobins, patients with methemoglobin reductase deficiency exhibit slate-gray "pseudocyanosis." Even homozygotes, however, rarely accumulate more than 25% methemoglobin, a level compatible with minimal symptoms. Heterozygotes can have normal methemoglobin levels but are especially sensitive to agents causing methemoglobinemia.

A third toxic form of methemoglobinemia is caused by exposure to certain chemical agents and drugs that accelerate the oxidation of methemoglobin (Table 44–4). Some compounds directly oxidize hemoglobin, whereas other compounds produce reactive oxygen intermediates that oxidize hemoglobin. Nitrite compounds are especially notorious and common. Some of these compounds also have a propensity to exacerbate G6PD deficiency and the precipitation of unstable hemoglobins.

Nitrates are a frequent environmental cause of toxic methemoglobinemia. Nitrates do not directly interact with either hemoglobin or the reductase pathway but are converted to nitrites in the gut. Well water is a frequently encountered source of excessive nitrates. In general, substantial intake of these agents is required before significant amounts of methemoglobin are generated. Very young infants have lower levels of methemoglobin reductase in erythrocytes and are therefore more susceptible to these agents than are adults. However, all age groups are at risk, given sufficient exposure. Systemic acidosis, particularly in young infants suffering from diarrhea and dehydration, can also cause clinically significant methemoglobinemia.

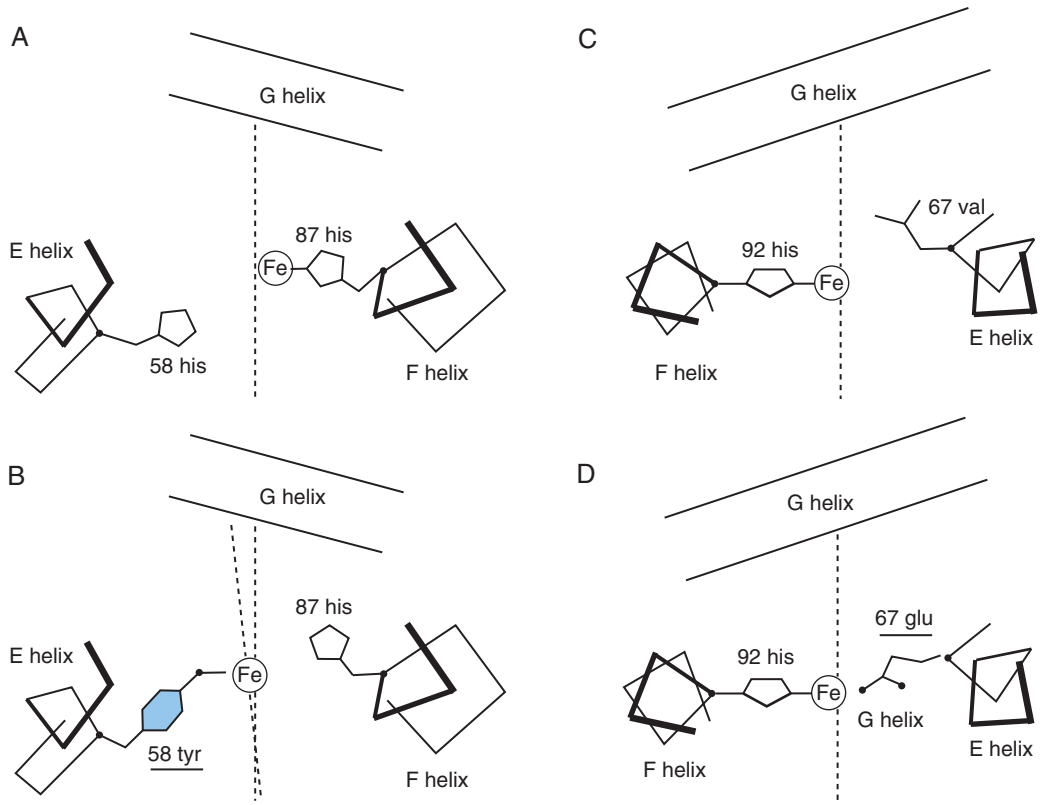

Figure 44–5 Modifications of the heme and its environment that account for two common M hemoglobins. **A**, Hemoglobin A has a His residue at the α58(E7) position. **B**, In hemoglobin M-Boston, the histidine is replaced by a tyrosine, the phenolic side chain of which is capable of covalently binding to the heme iron, resulting in stabilization in the oxidized form. **C**, Hb A has a Val residue at position β67(E11). **D**, Hb M-Milwaukee has a glutamic acid substitution for the β67 valine. The carboxylic side chain of the Glu forms a bond with iron, shifting the equilibrium toward the ferric state. *(Modified from Dickerson RE, Geis I: Hemoglobin: Structure, Function, Evolution, and Pathology. Acquired methemoglobinemia is virtually the only situation in which life-threatening amounts of methemoglobin accumulate. In general, the only symptom produced when methemoglobin comprises less than 30% of total hemoglobin is the cosmetic effect of cyanosis. As levels of methemoglobin rise to greater than 30%, however, patients begin to exhibit symptoms of oxygen deprivation, such as malaise, giddiness, and other alterations of mental status. The symptoms reflect a true lack of oxygen availability at the tissue level. Methemoglobin is a markedly left-shifted hemoglobin that delivers little oxygen to the tissues. When methemoglobin accounts for more than 50% of total hemoglobin, loss of consciousness, coma, and death can rapidly ensue. At this level, the blood is chocolate brown.

Diagnosis

Methemoglobinemia should be suspected in patients with unexplained cyanosis. It is obviously a medical emergency when any patient has cyanosis and altered mental status; a normal Pa_{O_2} should trigger a consideration of methemoglobinemia. The ingestion of nitrites as a suicidal gesture, especially in people knowledgeable with respect to chemistry, medicine, or pharmacology, should be considered. Methemoglobinemia can be suspected from the brownish color of blood when it is drawn. Laboratory detection is simple; methemoglobin exhibits characteristic peaks of absorption at 630 and 502 nm, rendering it easily distinguishable from normal hemoglobin. Pulse oximetry, utilizing a ratio of

absorption at 660 nm and 940 nm, gives an inaccurate reading of 85% O_2 saturation for blood with 100% methemoglobin. The inherited M hemoglobin mutants are frequently detectable by altered electrophoretic mobility, especially if ferricyanide treatment in vitro is used to convert all the hemoglobin solution to methemoglobin.

In the case of toxic methemoglobinemia, recognition of exposure to an appropriate agent provides the most important historical clue. Acute poisoning can represent a life-threatening emergency; therefore, laboratory evaluation for methemoglobin should be requested for any person displaying atypical cyanosis or cyanosis occurring along with normal blood gas values. Methemoglobin due to deficiencies of the reductase system can be further evaluated in reference laboratories by direct analysis of these enzymes.

Management

Patients with M hemoglobins are usually asymptomatic and require no management. The secondary cyanosis can present a cosmetic problem. The cyanosis is not reversible because ascorbic acid and methylene blue are usually ineffective.

Patients with deficiency of the reductase system usually do not require treatment. Cyanosis in these cases can be improved by treatment with oral methylene blue, 100 to 300 mg/day, or 500 mg/day of oral ascorbic acid. Riboflavin (20 mg/day) has also been reported to be effective and may be the preferred agent, because methylene blue produces discolored (blue) urine, and ascorbic acid can cause sodium oxalate stones.

Emergency treatment of high levels of toxic methemoglobinemia begins with 1 to 2 mg/kg of intravenous methylene blue as a 1% solution in saline. It is usually infused rapidly (over 3–5 minutes); the dose can be repeated at 1 mg/kg after 30 minutes if necessary. This treatment is usually effective. Methylene blue acts through the NADPH reductase system, which in turn requires G6PD activity. The method is therefore ineffective in patients who also have G6PD deficiency. These patients, or patients who are severely affected, may require exchange transfusion. Oral ascorbic acid is not useful for emergency situations because it acts too slowly. Follow-up maintenance management, however, can be accomplished with either ascorbic acid or oral methylene blue.

Mild cases of methemoglobin intoxication do not require treatment. The patient can be monitored for 1 to 3 days, during which time methemoglobin levels gradually return to normal if the offending agent is eliminated. The most important follow-up therapy for patients with toxic methemoglobinemia involves a thorough search for the offending agent and its removal from the environment.

CHAPTER 45

RED BLOOD CELL ENZYMOPATHIES

Xylina T. Gregg and Josef T. Prchal

Clinically significant abnormalities of red blood cell enzymes cause diverse clinical abnormalities, including hemolytic anemia, polycythemia, and methemoglobinemia. Deficiencies of some red cell enzymes may also provide a protective advantage to external challenges. Common mutations of glucose-6-phosphate dehydrogenase (G6PD) likely reached their prevalence by providing some protection against lethal malarial complications. In other instances, although there is no detectable red blood cell phenotypic abnormality, enzymes from easily accessible red blood cells can be assayed to diagnose systemic disorders such as galactosemia, adenosine deaminase deficiency, and deficiencies of some vitamins, for example, riboflavin. In addition, the study of red blood cell enzymes has helped to uncover important biologic principles, such as X-chromosome inactivation, and provided the groundwork for important principles of population genetics, biochemistry, and molecular biology.

Mature erythrocytes are the product of a highly specialized cellular process involving loss of the nucleus prior to release from the bone marrow and loss of mitochondria and ribosomes after 1 to 2 days in circulation. Unable to carry out oxidative phosphorylation and protein synthesis, the erythrocyte still has to sustain an active metabolism to maintain its viability and to preserve hemoglobin in its functional form to ensure adequate oxygen delivery to tissues.

Red blood cell enzymes allow erythrocytes to accomplish these tasks by supporting glycolysis and the pentose shunt, and by providing protection against oxidants by maintaining a high ratio of reduced (GSH) to oxidized (GSSG) glutathione (Fig. 45–1). Glycolysis and the pentose shunt generate four important metabolic intermediates: NADH; NADPH; 2,3-BPG; and adenosine triphosphate (ATP). Under physiologic conditions, approximately 90% of glucose is consumed in the glycolytic pathway and approximately 10% is utilized in the pentose shunt. Under conditions of increased oxidant stress, however, the contribution of the pentose shunt may be significantly increased.

To provide proper oxygen delivery, the erythrocyte must (a) maintain a high ratio of NADH to NAD for continuous reduction of methemoglobin to reduced hemoglobin; (b) maintain a high ratio of NADPH to NADP (generated in the pentose shunt from the glycolytic intermediate glucose-6-phosphate) for reduction of glutathione and protection against oxidant damage; (c) maintain a high concentration of 2,3-BPG generated in the Rapoport–Luebering shunt of glycolysis to ensure optimal oxygen delivery to the tissue; and (d) maintain the flexibility and integrity of the red blood cell membrane using ATP from glycolysis.

Glycolytic enzymes also have diverse, nonenzymatic functions, including stimulation of cell movement, control of apoptosis, and modulation of oncogene regulation. These other roles of glycolytic enzymes may explain some of the nonerythroid effects of mutations of the glycolytic enzyme genes.

Other erythrocyte enzymes such as pyrimidine 5′ nucleotidase participate in nucleotide degradation and salvage and are essential for the removal of nucleotide precursors that may be toxic to erythrocytes. In addition, erythrocytes contain enzymes, such as glutamine-oxaloacetic transaminase, with no obvious physiologic function; these may be remnants of its nucleated past.

RED CELL ENZYMOPATHIES CAUSING METHEMOGLOBINEMIA

Methemoglobin Formation

Methemoglobin is a derivative of hemoglobin in which the ferrous (Fe^{2+}) irons are oxidized to the ferric (Fe^{3+}) state. Oxygen binds easily to the ferrous form of iron present in deoxyhemoglobin. In the formation of oxyhemoglobin, one electron is partially transferred from iron to the bound oxygen, forming a ferric–superoxide (Fe^{3+}–O_2^-) anion complex.[1] During deoxygenation, some of the oxygen leaves as a superoxide (O_2^-) radical. The partially transferred electron is not returned to the iron moiety, thus leaving the iron in the ferric state and forming methemoglobin (Fig. 45–2). This autoxidation of hemoglobin occurs spontaneously at a slow rate, creating 0.5% to 3% methemoglobin per day.[2]

Methemoglobin is also formed from the oxidation of hemoglobin in other reactions with endogenous compounds and free radicals, including hydrogen peroxide (H_2O_2), nitric oxide (NO), O_2^-, and hydroxyl radical (HO^-).[3] Exogenous compounds can oxidize hemoglobin to methemoglobin directly, by a metabolic derivative, or by generating O_2^- and H_2O_2 during their metabolism.

A balance to methemoglobin formation is antioxidant protein 2 (AOP2), which is present in high concentrations in human and mouse red cells. This member of the peroxiredoxin protein family binds to hemoglobin and prevents spontaneous as well as oxidant-induced methemoglobin formation.[4] Mutations of this gene or its acquired deficiency are theoretical candidates responsible for congenital and acquired methemoglobinemia.

The ferric hemes of methemoglobin are unable to bind oxygen. In addition, the oxygen affinity of the accompanying ferrous hemes in the hemoglobin tetramer is increased.[5] As a result, the oxygen dissociation curve is left-shifted and oxygen delivery is impaired.

Methemoglobin Reduction

Although several potential mechanisms exist to reduce methemoglobin back to hemoglobin, only the NADH-dependent reaction catalyzed by cytochrome b_5 reductase (b5R) is physiologically important. Cytochrome b5R, previously known as diaphorase[6] and methemoglobin reductase,[7] contains a noncovalently bound prosthetic flavin adenine dinucleotide (FAD) group that acts as an electron acceptor.[8,9] NADH generated from glycolysis reduces FAD to $FADH_2$, which then reduces the heme protein cytochrome b_5. Electrons from the reduced cytochrome b_5 are in turn transferred to methemoglobin, reducing iron back to the ferrous state (Fig. 45–3).

An alternative pathway mediated by NADPH-flavin reductase uses NADPH generated by glucose-6-phosphate dehydrogenase (G6PD) in the hexose monophosphate shunt as a source of electrons to reduce redox dyes, such as methylene blue, and flavin (Fig. 45–4).[10] Reduced methylene blue, or leukomethylene blue, then reduces methemoglobin. Because these electron acceptors are not physiologic, this electron transfer is not significant under normal conditions, and NADPH-flavin reductase deficiency does not cause

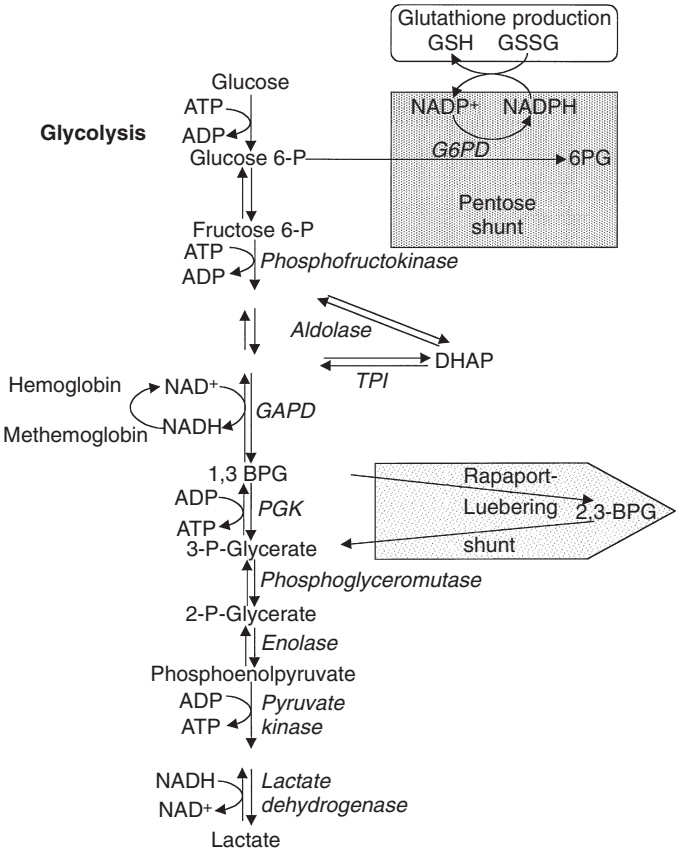

Figure 45–1 Glycolysis (Embden–Meyerhof pathway). 2,3-BPG, 2,3-bisphosphoglycerate; DHAP, dihydroxyacetone-P; GAPD, glyceraldehyde phosphate dehydrogenase; G6PD, glucose-6-phosphate dehydrogenase; GSH, reduced glutathione; GSSG, oxidized glutathione; 6PG, 6-phosphogluconate.

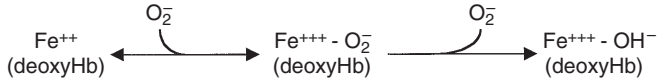

Figure 45–2 Autoxidation of hemoglobin. Iron is in the ferrous state (Fe^{2+}) in deoxyhemoglobin. When oxygen is bound, an electron is partially transferred from the iron moiety to the bound oxygen, forming a ferric–superoxide anion complex (Fe^{3+}–O_2^-). During deoxygenation, some of the oxygen leaves as a superoxide (O_2^-) radical. The partially transferred electron is not returned to the iron moiety, leaving the iron in the ferric state (Fe^{3+}) and forming methemoglobin (metHb).

methemoglobinemia.[11] However, methylene blue is useful in the treatment of acute toxic methemoglobinemia by providing an alternative to an overwhelmed cytochrome b_5 reductase pathway. Because the reduction of methemoglobin by methylene blue is dependent on NADPH generated by G6PD, methylene blue may be ineffective in the treatment of methemoglobinemia in individuals with G6PD deficiency.[12] In addition, the use of methylene blue in these patients is potentially dangerous because it may produce hemolysis.[12]

Methemoglobin can also be reduced directly by ascorbic acid, reduced glutathione, and reduced flavin; however, these reactions occur slowly and play a minor role in methemoglobin reduction.

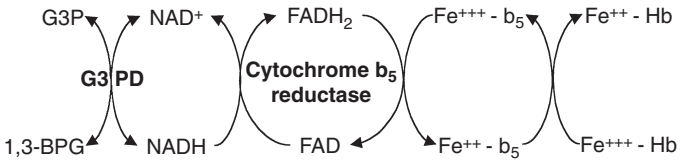

Figure 45–3 NADH-dependent methemoglobin reduction. NADH is generated during glycolysis in the reaction mediated by glucose-3-phosphate dehydrogenase (G3PD). A pair of electrons from NADH is transferred to the FAD prosthetic group of cytochrome b_5 reductase, reducing it to $FADH_2$. Two molecules of ferric (Fe^{3+}) cytochrome b_5 are then sequentially bound and reduced, forming ferrous (Fe^{2+}) cytochrome b_5. An ionic complex between ferrous (Fe^{2+}) cytochrome b_5 and a ferric (Fe^{3+}) subunit of a hemoglobin (methemoglobin) tetramer is formed and an electron transferred between the two hemes, creating ferrous (Fe^{2+}) hemoglobin. 1,3-BPG, 1,3-bisphosphonate glyceraldehyde; G3P, glyceraldehyde-3-phosphate.

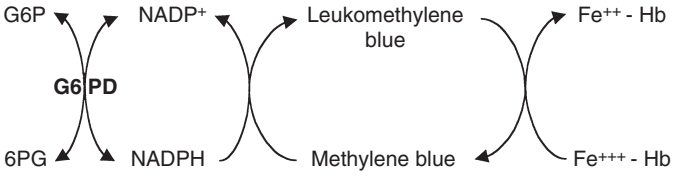

Figure 45–4 NADPH-dependent methemoglobin reduction. NADPH methemoglobin reduction can be activated by exogenously administered methylene blue. G6P, glucose-6-phosphate; G6PD, glucose-6-phosphate dehydrogenase; 6PG, 6-phosphogluconate.

METHEMOGLOBINEMIA

Normally, the formation and reduction of methemoglobin by the mechanisms described act to maintain a steady-state level of methemoglobin of 1% or less of total hemoglobin. Methemoglobinemia occurs when an imbalance due to either increased methemoglobin production or decreased methemoglobin reduction is present.

Acquired or Acute Toxic Methemoglobinemia

Most cases of methemoglobinemia are acquired, resulting from increased methemoglobin formation by various exogenous agents. Many drugs and toxins have been implicated.[13–17] Benzocaine, a topical anesthetic, is a frequently reported cause of acquired methemoglobinemia. The estimated incidence in a population undergoing transesophageal echocardiography was 0.115%.[18] The true incidence of drug-induced methemoglobinemia due to less frequently used agents is not known. Although flutamide has been reported to cause methemoglobinemia, in 50 consecutively studied patients with prostate cancer treated with flutamide, none developed clinically significant methemoglobinemia.[19] Furthermore, it is unknown whether the development of methemoglobinemia is dose related or idiosyncratic. In a retrospective review of 138 cases of acquired methemoglobinemia,[20] 42% were caused by dapsone. Topical benzocaine was responsible for five severe cases of methemoglobinemia, including one fatality. However, a cause could not be identified in 56 cases of mild methemoglobinemia; many of these cases were detected incidentally during intraoperative monitoring. Methemoglobinemia occurred equally between males and females and over a wide range of ages. The vast majority (94%) of the patients who developed methemoglobinemia were anemic.

Substances Associated with Methemoglobinemia

- Acetaminophen (nitrobenzene derivative)
- Acetanilide
- Aniline dyes
- Local anesthetics
  - Benzocaine
  - Lidocaine
  - Prilocaine
- Celecoxib
- Dapsone
- Flutamide
- Ifosfamide
- Metoclopramide
- Nitric oxide
- Nitrites
  - Amyl nitrite
  - Isobutyl nitrite
  - Sodium nitrite
  - Nitrates (bacterial conversion to nitrites)
- Nitrobenzenes/nitrobenzoates
- Nitroethane (nail polish remover)
- Nitrofurans
- Nitroglycerin
- Paraquat/monolinuron
- Phenacetin
- Phenazopyridine (Pyridium)
- Primaquine
- Rasburicase
- Sulfamethoxazole

In some instances, methemoglobinemia clearly occurs in the setting of overdoses or poisoning, but it may also occur at standard doses of drugs, particularly in individuals with partial deficiencies of b5R.[21,22] Infants are more susceptible to the development of methemoglobinemia because their erythrocyte b5R activity is normally 50% to 60% of adult activity.[23,24] Activity in the premature infant is even lower. Although b5R levels rise to those of an adult within months of birth, young infants are unusually vulnerable to developing toxic methemoglobinemia upon ingestion of nitrates.[25] Nitrates do not oxidize hemoglobin directly but are converted to nitrites by intestinal bacteria. Methemoglobinemia caused by nitrates in well water continues to be a problem in infants in rural areas.[26] Infants fed homemade preparations of vegetables with high nitrate content have developed methemoglobinemia.[27] Topical lidocaine used as an anesthetic for circumcision is another reported cause of methemoglobinemia in infants.[28]

Methemoglobinemia has also been associated with diarrheal illnesses in infants without known toxin exposure.[29] The exact mechanism leading to methemoglobinemia is unknown but may involve increased endogenous nitrite production.[30] An association with weight in the lower percentiles has been reported.[31,32]

Although individuals with congenital, chronically elevated methemoglobin concentrations are generally asymptomatic, acute acquired methemoglobinemia can be associated with symptoms at similar methemoglobin levels. The "cyanosis" or slate-blue color of the skin and mucous membranes results from the different absorbance spectrum of methemoglobin compared to oxyhemoglobin. Cyanosis is clinically discernible when the absolute level of methemoglobin exceeds 1.5 gm% (10%–15% methemoglobin at normal hemoglobin concentrations).[33] Symptoms of methemoglobinemia are related to impaired O_2 delivery to tissues. Early symptoms include headache, fatigue, dyspnea, and lethargy. At higher levels, respiratory depression, altered consciousness, shock, seizures, and death may occur.[13]

Hereditary Methemoglobinemia

There are three types of hereditary methemoglobinemia. In our experience, most cases are due to a deficiency of the red blood cell enzyme b5R (see section on cytochrome b_5 reductase deficiency). This enzyme deficiency is inherited in an autosomal recessive pattern and was the first hereditary condition in which an enzyme deficiency was identified.[7]

Deficiency of cytochrome b_5 is a rare disorder that also causes congenital methemoglobinemia. Only one well-documented case of cytochrome b_5 deficiency has been described,[34] as compared with more than 500 reported cases of b5R deficiency. This patient, a product of an Israeli consanguineous marriage, was also a male pseudohermaphrodite. Further analysis revealed that he was homozygous for a splicing mutation in the cytochrome b_5 gene, resulting in a premature stop codon and truncated protein.[35] Another family with probable cytochrome b_5 deficiency, as other causes of methemoglobinemia were excluded, was described prior to the recognition of this entity.[36] However, the inheritance pattern in this family was autosomal dominant.

The third type of hereditary methemoglobinemia, hemoglobin M (Hb M) disease (see Chapter 44), is caused by an abnormal globin and is autosomal dominant. It is associated with an abnormal pattern of spectrophotometric absorbance and sometimes with abnormal migration on hemoglobin electrophoresis.

Owing to the relative rarity of hereditary methemoglobinemia, it is unknown which type is the most common. However, even if we do not consider endemic Navajo, Athabascan, and Yakutsk congenital methemoglobinemia due to b5R deficiency, the literature over the last several decades suggests that congenital methemoglobinemia is far more frequently due to b5R deficiency than to hemoglobin M. Furthermore, in the experience of one of the authors supervising a red blood cell disorder reference laboratory, more than 20 new cases of hereditary methemoglobinemia were due to b5R deficiency, compared with only one case with hemoglobin M.

CYTOCHROME b_5 REDUCTASE DEFICIENCY

Function of Cytochrome b_5 Reductase

b5R, a housekeeping enzyme and a member of the flavoenzyme family of dehydrogenases–electron transferases, is involved in the transfer of electrons from the NADH generated by glyceraldehyde 3-phosphate in the glycolytic pathway to cytochrome b_5.[37] b5R exists in both cytosolic and membrane-bound forms, which participate in a variety of reactions. In erythrocytes, b5R transfers electrons to methemoglobin to reduce it to hemoglobin. In other cells, b5R transfers electrons from cytochrome b_5 to stearyl-CoA in the endoplasmic reticulum.[38] This reaction plays an important role in cholesterol biosynthesis, fatty acid elongation and desaturation, and drug metabolism.[39–41] The crystal structure of erythrocyte b5R has been solved[42]; this information should be useful to understand the differences between ubiquitously and erythrocyte-restricted b5R deficiency states and their radically different clinical outcomes.

b5R Gene and Isoforms

The b5R gene locus (*DIA1*) has been mapped to chromosome 22.[43] Multiple isoforms of b5R are generated from a single gene by a combination of alternative promoters and alternative initiation of translation.[44,45] Both a cytosolic isoform and a membrane-bound isoform are found in erythrocytes; the cytosolic isoform is involved in methemoglobin reduction.[46,47] Although the membrane-bound isoform contributes only 20% to 25% of erythrocyte b5R activity in adult humans, it represents a greater proportion in infants owing to a decreased cytosolic form.[48] Other isoforms have been described; however, there are significant interspecies differences in the structure

of isoforms, so findings from animal studies may not be applicable to humans.[49]

b5R Gene Mutations

To date, more than 30 mutations have been described that result in b5R deficiency.[50] The mutations occur in all racial and ethnic groups. Although most of the mutants have been found in white populations, five unique mutations were found in Chinese,[51] at least three in Thai,[52,53] and two in African Americans.[54] The b5R mutations that cause endemic autosomal recessive congenital methemoglobinemia in Yakutsk, Navajo, and Athabascans have not been defined. Furthermore, an additional mutation of *b5R* (*116 T > S*) is not a disease-causing mutation but a high-frequency African-specific polymorphism that does not cause any appreciable disruption of the b5R secondary structure.[55]

There are two clinical types of b5R deficiency. The inheritance pattern is autosomal recessive, and a history of consanguinity is often present in sporadic cases. Mutations in cases of type I b5R deficiency are usually missense mutations leading to decreased stability of the enzyme. Thus, although b5R is abnormal in all cells, only mature red blood cells, which cannot synthesize proteins and replace the enzyme, are significantly affected in patients with type I b5R deficiency. On the other hand, type II mutations affect the catalytic site or lead to marked structural changes because of aberrant splicing, generation of premature stop codons, or partial gene deletions and all cells have decreased b5R activity.[56,57]

Clinical Features of b5R Deficiency

Type I b5R Deficiency

The majority of cases of enzymopenic congenital methemoglobinemia are type I, in which the functional deficiency of b5R is limited to erythrocytes. Homozygotes or compound heterozygotes[58] have methemoglobin concentrations of 10% to 35% and appear cyanotic but are usually asymptomatic, even with levels up to 40%.[33] Some patients have reported nonspecific symptoms of headache and easy fatigability. Life expectancy is not shortened and pregnancies occur normally. Significant polycythemia (erythrocytosis) is only rarely observed. The cyanosis is of cosmetic significance only but can be treated with methylene blue or ascorbic acid, both of which facilitate the reduction of methemoglobin through alternate pathways.[59]

In contrast to the chronically methemoglobinemic homozygotes (or compound heterozygotes) who are asymptomatic, heterozygous individuals are normal under basal conditions, but at risk for developing acute, symptomatic methemoglobinemia after exposure to exogenous methemoglobin-inducing agents. The report from Cohen and colleagues[21] of acute toxic methemoglobinemia in US military personnel receiving malarial prophylaxis in Vietnam is a classic description of this phenomenon.

Type I b5R deficiency is distributed worldwide but is endemic in Athabascan Alaskans,[60,61] Navajo Indians,[62] and Yakutsk natives of Siberia.[63,64] The Navajo Indians and the Athabascan Indians of Alaska are known to share a common ancestor, and the high frequency of b5R deficiency in these groups suggests a common origin for all three of these populations. However, it remains to be determined whether the molecular defect resulting in b5R deficiency is identical in these populations. In other ethnic and racial groups, the defect occurs sporadically. Although cyanosis is difficult to detect because of skin pigmentation, type I deficiency has been reported in two unrelated African American families.[65]

Type II b5R Deficiency

In type II b5R deficiency, b5R is deficient in all cells. Type II b5R deficiency represents 10% to 15% of cases of enzymopenic congenital methemoglobinemia and has a sporadic distribution. In addition to methemoglobinemia and cyanosis, patients exhibit mental retardation and developmental delay with failure to thrive.[66] Other neurologic symptoms may be present, including microcephaly, opisthotonus, athetoid movements, strabismus, seizures, and spastic quadriparesis. Life expectancy is significantly shortened, and death in infancy is typical. The mechanism resulting in the neurologic problems is currently unknown but it has been suggested that it may involve abnormal lipid elongation and desaturation in the central nervous system.[67] Another possible molecular basis for the neurotoxicity and failure to thrive may be failure to keep the heme iron in hemoglobin-related globins, including neuroglobin, cytoglobin, and myoglobin, in the ferrous state.[68–70]

Methylene blue or ascorbic acid improves the cyanosis, as in type I b5R deficiency; however, this therapy has no effect on the neurologic and other systemic defects in type II b5R deficiency. Theoretically, a bone marrow or liver transplant would alleviate the neurologic problems of individuals with type II deficiency if they are caused by a problem with circulating fatty acids. Nevertheless, these approaches have not yet been tested, and because the aberrantly elongated fatty acids may not be the primary cause of the pathophysiology, they may not work. In addition, because the enzyme defect is found in fibroblasts, analysis of b5R activity in cultured amniotic cells for prenatal diagnosis is possible.[71,72]

Assays of Enzyme Activity

Types I and II b5R deficiency are distinguished by their clinical phenotype and by analysis of enzymatic activity in erythroid and nonerythroid cells. Reports of decreased b5R activity are difficult to compare because several different assays of b5R activity, varying in their substrate and in their normal values, have been used.[58,60,64,65,73,74] These assays also vary in their technical difficulty.[75] Currently, the most prevalent assay uses ferricyanide as an enzyme substrate.[76] Although not as rigorous as previous assays, it is simple and has proved to be reliable. Type I and type II b5R deficiencies can be readily differentiated because patients with type I deficiency have normal enzyme activity in platelets, fibroblasts, Epstein–Barr virus-transformed lymphocytes, and granulocytes, whereas in type II deficiency the activity in nonerythroid tissues is markedly to moderately decreased.[54,65,76]

Two families with type III deficiency, in which b5R activity was decreased not only in erythrocytes but also in platelets and leukocytes, have been described.[77] However, the existence of this entity is difficult to accept because these individuals did not exhibit the neurologic abnormalities characteristic of type II deficiency. Reevaluation of one of the patients with a rigorous assay using recombinant cytochrome b_5 confirmed b5R activity in the platelets, leukocytes, and fibroblasts consistent with type I deficiency.[78]

DIAGNOSIS OF METHEMOGLOBINEMIA

Methemoglobinemia can be clinically suspected when cyanosis occurs in the presence of a normal partial arterial pressure of oxygen (Pao_2), as obtained by assessment of arterial blood gases. Methemoglobinemia causes clinically discernible cyanosis when the absolute level of methemoglobin exceeds 1.5 gm%; this correlates with approximately 10% to 15% methemoglobin.[33] Sulfhemoglobin in concentrations greater than 0.5 gm% also causes cyanosis with a normal Pao_2 and may be erroneously measured as methemoglobin. The laboratory diagnosis of methemoglobinemia is based on analysis of its absorption spectra. A fresh specimen should always be obtained because methemoglobin levels tend to increase with storage. Methemoglobin has peak absorbance at 631 nm. The standard method of assaying methemoglobin utilizes a microprocessor-controlled, fixed wavelength co-oximeter. This instrument interprets all readings in the 630 nm range as methemoglobin; thus, false-positive readings may occur in the presence of other pigments, including sulfhemoglobin and meth-

Suspecting, Detecting, and Treating Methemoglobinemia

Methemoglobinemia should always be suspected when cyanosis is present with normal oxygen saturation. Methemoglobin levels interfere with the measurement of oxygen saturation by conventional pulse oximetry; thus, an oxygen saturation discrepancy between values obtained from pulse oximetry and from arterial blood gas may be a diagnostic clue. The initial screening for methemoglobinemia can be performed in the arterial blood gas laboratory, which uses a cooximeter to detect the different absorption spectrum of methemoglobin. Methemoglobin detected by cooximetry should be confirmed by the specific Evelyn–Malloy method.

If the patient is symptomatic, acute toxic methemoglobinemia is likely and, after the diagnosis is confirmed, treatment with methylene blue 1 mg/kg over 5 minutes should be initiated. However, methylene blue should not be used in patients with known or suspected G6PD deficiency (including heterozygous females who may not be detected by routine G6PD screening tests). Instead, the preferred treatment for these patients is ascorbic acid, although the rate of response to this therapy is considerably slower than for methylene blue.

Because cooximetry detects methylene blue as methemoglobin, it cannot be used in following methemoglobin levels after treatment with methylene blue; however, the specific Evelyn–Malloy method can be used for this purpose.

Treatment is not indicated for patients with asymptomatic chronic methemoglobinemia, except for cosmetic reasons.

ylene blue.[79,80] Methemoglobin detected by cooximeter should be confirmed by the specific Evelyn–Malloy method.[81] In this assay, cyanide (CN^-) is added and binds to the positively charged methemoglobin, eliminating the peak at 630 to 635 nm in direct proportion to the methemoglobin concentration. The subsequent addition of ferricyanide converts the entire specimen to cyanomethemoglobin for measurement of the total hemoglobin concentration. Methemoglobin is expressed as a percentage of the total concentration of hemoglobin.

Distinguishing the hereditary forms of congenital methemoglobinemia requires interpretation of family pedigrees as well as biochemical analyses. Cyanosis in successive generations suggests the presence of the autosomal dominant Hb M disease, whereas having normal parents but possibly affected siblings implies autosomal recessive b5R deficiency or the very rare cytochrome b_5 deficiency. Incubation of blood with methylene blue distinguishes b5R deficiency from Hb M disease, because this treatment results in the rapid reduction of methemoglobin through the NADPH-flavin reductase pathway in cases of b5R deficiency but not in cases of Hb M disease.[82,83] Measurement of the level of b5R activity in erythrocyte and nonerythroid cells is required to distinguish type I from type II b5R deficiency; however, these assays are not commercially available. Differentiating b5R deficiency from cytochrome b_5 deficiency is usually based on measurement of b5R activity, because currently only one or two research laboratories can perform cytochrome b_5 quantitation.

TREATMENT

Offending agents in cases of acquired methemoglobinemia should be discontinued. No other therapy may be required, but if the patient is symptomatic, which is often true in cases of deliberate or accidental overdoses or toxin ingestion, specific therapy is indicated. Methylene blue, 1 to 2 mg/kg over 5 minutes, provides an artificial electron acceptor for the reduction of methemoglobin via the NADPH-dependent pathway. Response is usually rapid; the dose can be repeated in 1 hour, but frequently this is unnecessary. Caution should

When to Suspect a Red Blood Cell Enzymopathy

The following clinical situations should raise suspicion for a red blood cell enzymopathy:

1. Chronic hemolytic anemia without specific morphologic red blood cell abnormalities.
2. Chronic hemolytic anemia with basophilic stippling (pyrimidine 5′ nucleotidase deficiency).
3. Acute hemolysis occurring after exposure to oxidant drugs (G6PD deficiency)
4. Whenever Heinz bodies are observed on the blood film, although the absence of Heinz bodies does not exclude a red blood cell enzymopathy (G6PD, glutathione synthase, and reductase deficiencies).
5. Chronic hemolytic anemia in association with other congenital disorders such as myopathy, mental retardation, and metabolic acidosis.

be exercised to avoid overdosage because large (>7 mg/kg) cumulative doses have been reported to cause dyspnea, chest pain, and hemolysis.[84] Because co-oximetry detects methylene blue as methemoglobin, it cannot be used in following methemoglobin levels after treatment with methylene blue; however, the specific Evelyn–Malloy method[81] allows discrimination of methemoglobin from methylene blue. Methylene blue should not be administered to patients with G6PD deficiency. If methylene blue is contraindicated, ascorbic acid can be given. Red blood cell exchange transfusion has also been reported to be an effective treatment in symptomatic methemoglobinemic patients with coexistent G6PD deficiency.[85]

Treatment of the cyanosis in individuals with types I and II b5R deficiency is indicated for cosmetic reasons only. Treatment options include methylene blue (100–300 mg/day orally) or ascorbic acid (300–1000 mg/day orally in divided doses), although this therapy has been associated with renal calculi formation. The use of riboflavin (20–30 mg/day) has also been reported.[86] Unfortunately, there is currently no effective therapy for the neurologic disorder associated with type II deficiency.

RED BLOOD CELL ENZYMOPATHIES ASSOCIATED WITH HEMOLYTIC ANEMIA

The red blood cell enzyme deficiencies causing hemolytic anemia can be divided arbitrarily into those directly or indirectly involved with the maintenance of a high ratio of reduced to oxidized glutathione, those participating in the glycolytic (Embden–Meyerhof) pathway, and, lastly, one enzyme in the nucleotide degradation and salvage pathway (pyrimidine 5′ nucleotidase).

INHERITANCE

G6PD and phosphoglycerate kinase are encoded on the X chromosome and are subject to dosage compensation by X chromosome inactivation. The remaining enzymes are present on the autosomal chromosomes; deficiencies of these enzymes can cause a clinical phenotype if the subject is either homozygous or doubly heterozygous for separate defects affecting both alleles.

CLINICAL AND LABORATORY MANIFESTATIONS

The hemolysis associated with a red blood cell enzyme deficiency may be chronic or acute intermittent. Acute intermittent hemolysis is typically seen in patients with enzyme disorders affecting glutathione

metabolism, such as G6PD. During the hemolytic episodes, either normal red blood cell morphology or nonspecific abnormalities (anisocytosis, polychromasia) can be observed. In defects of enzymes affecting glutathione metabolism, the morphologic sequelae of the oxidative denaturation of hemoglobin, Heinz bodies, can be seen either directly on microscopic evaluation of the blood film or after the red blood cells are preincubated with oxidants such as phenylhydrazine.[87] Although "bite cells" are reported in many textbooks as pathognomonic for G6PD deficiency, the authors of this chapter have never observed bite cells during acute hemolytic episodes in G6PD-deficient subjects nor in patients with severe G6PD enzyme defects causing rare chronic hemolytic anemia (G6PD Dothan, G6PD Birmingham). The only enzyme deficiency associated with hemolysis that causes consistent morphologic abnormalities is pyrimidine 5′ nucleotidase deficiency wherein basophilic stippling is observed. Although laboratory screening tests such as the "autohemolysis test"[88] were previously advocated to detect enzyme disorders causing hemolysis, they do not have a sound physiologic basis and should play no role in modern hematology practice.[89]

ENZYMOPATHIES OF GLUTATHIONE METABOLISM

Glutathione Metabolism

Erythrocytes contain a remarkably high concentration of glutathione (approximately 2 mM),[90] more than any other cell in the body. Oxidant damage converts reduced glutathione (GSH) to the oxidized form (GSSG) and also forms mixed disulfides of proteins (such as hemoglobin) containing free –SH groups. A high GSH to GSSG ratio is the major mechanism protecting the red blood cell proteins from oxidant damage. Enzymes involved in this metabolic pathway (Fig. 45–5) include γ-glutamyl cysteine synthase and GSH synthase, which synthesize glutathione; glutathione reductase, which reduces GSSG to GSH; and G6PD, which generates the NADPH needed for the reduction of GSSG.

An additional protective mechanism against oxidant damage involves unidirectional active transport of oxidized glutathione out of the erythrocyte.[91,92] GSH is actively synthesized in the red blood cells, but its half-life is only 3 to 4 days because of the efflux of oxidized glutathione by an active transport mechanism. This transport mechanism provides additional protection from severe oxidative stress; thus far, no disorder involving this pathway has been described.

G6PD deficiency is very common, but deficiencies of other enzymes of the glutathione pathway are rare. Deficiencies of these enzymes are expected to resemble G6PD deficiency with precipitation of hemolysis and formation of Heinz bodies after exposure to certain drugs, infections, and other oxidant stresses. However, these enzyme defects can also be associated with additional clinical manifestations.

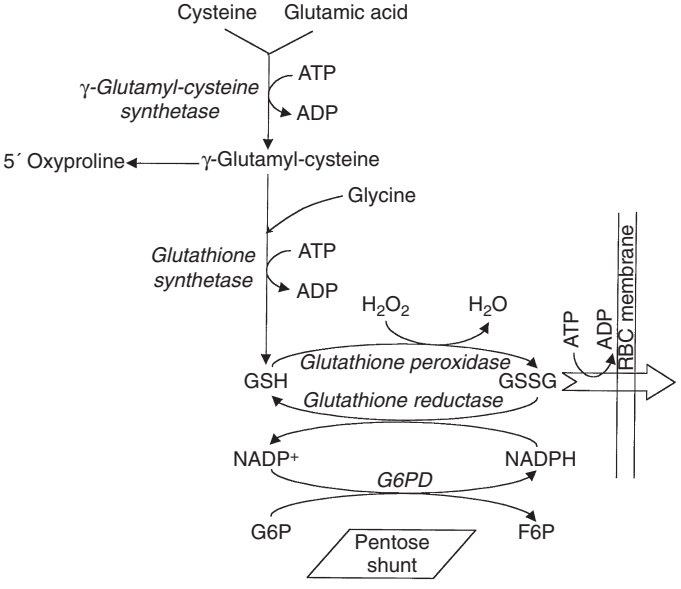

Figure 45–5 Glutathione pathway. G6P, glucose-6-phosphate; G6PD, glucose-6-phosphate dehydrogenase; GSH, reduced glutathione; GSSG, oxidized glutathione; 6PG, 6-phosphogluconate.

G6PD Deficiency

History

The discovery of G6PD deficiency represents a legendary example of clinical investigation that led to the delineation of important biochemical and genetic principles. During the investigation of a newly developed malaria drug, primaquine, Beutler and colleagues[93,94] noted that although the drug was tolerated by the majority of the male volunteers, some developed acute hemolytic episodes. These episodes were short-lasting and typically did not recur after immediate reintroduction of the drug but could recur when the drug was reintroduced after a period of several months. These drug-induced reactions were seen in subjects of particular ethnic groups, including African Americans and individuals of Mediterranean extraction. Biochemical analysis of erythrocytes during an acute hemolytic episode revealed a decrease in reduced glutathione (GSH).[94] Shortly thereafter, Carson[95] found that the cause of the GSH decline was a deficiency of the first step of pentose shunt-G6PD. Subsequent studies of carrier females led to the codiscovery of X chromosome inactivation.[96–98] Further investigations of this phenomenon have played a pivotal role in our understanding of the hierarchy of hematopoiesis,[99–101] clonality of malignant neoplasms,[102] and the mechanism of X chromosome inactivation.[96,103]

Biology and Molecular Aspects

G6PD is a housekeeping enzyme that plays an essential role not only in the reduction of NADPH from NADP but also in the generation of five-carbon sugars. In the reaction catalyzed by G6PD, electrons generated by the conversion of glucose 6 phosphate to 6-phosphogluconate are transferred to NADP. The *G6PD* gene spans approximately 20 kilobases with 13 exons.[104,105] G6PD activity decreases significantly as erythrocytes age, with a half-life of approximately 60 days.[106] Reticulocytes have five times higher enzyme activity than the oldest erythrocyte subpopulation.[107]

G6PD-Deficient Variants

More than 300 G6PD variants have been defined; most are sporadic but some occur at a high frequency. G6PD variants can be divided into three categories, based on the type of hemolysis they cause. Most common are those variants associated with acute intermittent hemolytic anemia; some of these variants are endemic (Mediterranean, A-, some Southeast Asian variants). In contrast, the variants associated with chronic hemolytic anemia are very rare. The third type of variant is associated with no obvious risk of hemolysis and is also uncommon. A detailed list of these variants is continuously updated and can be found elsewhere.[108,109]

In the past, new variants were defined by their enzyme activity, thermal stability, K_M for normal (G6P, NADP) and artificial (2-deoxy G6P, deamino-NADP) substrates, K_i for NADPH, and electrophoretic mobilities under various conditions.[110] When the nucleotide sequence variations for the wild-type G6PD enzyme, designated G6PD B, were established,[105] some of these previously described variants were found to represent identical mutations.[111] Interestingly, they arose independently in some cases on different haplotypes of the *G6PD* gene.[112]

The vast majority of the *G6PD* mutations are missense. Mutations associated with chronic hemolysis tend to cluster in the vicinity of the NADP-binding domain of the *G6PD* gene, whereas those associated with acute intermittent hemolysis or no hemolysis are scattered throughout the gene. Unlike disease-causing mutations of other genes, deletions and insertions causing frame shift and stop codon mutations are not observed; these null mutation events would be expected to be fatal, because *G6PD* is a housekeeping gene essential for basic cellular functions.[113] One intronic mutation of the *G6PD* gene (G6PD Varnsdorf) has been described[114]; this mutation is associated with chronic hemolysis, but the molecular consequences of this mutation have not been fully elucidated.[115]

Of the G6PD-deficient variants that occur at a high frequency, the best known are African G6PD A$^-$ and the Mediterranean variants; several variants are also present in Southeast Asia. All of these variants cause acute intermittent hemolysis. African G6PD A$^-$ and the Mediterranean variant of G6PD deficiency have been particularly well studied. G6PD A$^+$, another well-studied isoenzyme variant, is associated with no obvious hematologic phenotype and has a gene frequency similar to that of G6PD A$^-$ among African Americans.[116] The *G6PD A*$^-$ mutation (G202A) arose on a *G6PD A*$^+$ chromosome (A376G).[117]

Epidemiology

G6PD deficiency is one of the most prevalent disease-causing mutations worldwide, affecting hundreds of millions of people.[114,118] Most of the G6PD isoenzymes with decreased activity are associated with only moderate health risks without a significant effect on longevity.[90,119]

In the United States, G6PD deficiency is seen frequently among African Americans (G6PD A$^-$), affecting approximately 10% of males. The Mediterranean variant of G6PD deficiency is common in the southern part of Italy, Greece, Spain, and Corsica, and among Arabs and Sephardic Jews. In some populations of Kurdish Jews, the gene frequency exceeds 50%. This variant is heterogeneous at the nucleotide level and is composed of several distinct mutations.[120,121] Several variants are pandemic in Asia. G6PD Mahidol is common in Thailand and India[122]; G6PD Chinese-1, G6PD Chinese-2, G6PD Chinese-3, and G6PD Canton are frequent in China and Southeast Asia.[123] G6PD Viangchan (871G > A) is the most common mutation among Cambodians and is also found in Thais and Laotians.[124] It is assumed that malaria provided a positive selection pressure, accounting for the high gene frequency of these G6PD variants (see discussion following), whereas mutations that arose in parts of the world not plagued by malaria are sporadic.

Acute Hemolysis and G6PD Deficiency

Hemoglobin is maintained in solution in a high concentration in the cytoplasm of the erythrocyte. Oxidant damage leads to the oxidation of free –SH groups of hemoglobin, forming disulfide bridges that in turn lead to decreased hemoglobin solubility. The precipitated hemoglobin may be morphologically recognized as Heinz bodies. The high ratio of reduced-to-oxidized glutathione represents the major defense against the oxidative damage of hemoglobin. The enzymatic activity of G6PD generates NADPH that is utilized for glutathione reduction (see Fig. 45–5). Reduced glutathione (GSH) reconstitutes –SH groups of hemoglobin, maintaining the solubility of hemoglobin.

In cases of G6PD deficiency, this process is variably impaired, depending on the type of the G6PD mutation. In a subject with an acute hemolytic G6PD deficient variant, there is no clinical or laboratory evidence of hemolysis unless the individual is exposed to certain clinical situations. The severity of hemolysis in those inheriting the rare chronic hemolytic G6PD variants ranges from mild to transfusion dependent. Predictably, exposure to the oxidants that cause hemolysis in the acute hemolytic G6PD variants further exacerbates hemolysis.

An acute insult, most commonly drugs, infections, or fava bean ingestion, typically precipitates hemolysis. In spite of continuation of the drug or persistence of infection, hemolysis is short-lasting, presumably because of the elimination of a subpopulation of red blood cells with very low G6PD activity. The younger red blood cells and reticulocytes, which have higher G6PD activity, are typically not hemolyzed. The Mediterranean variant is more severe than the African A$^-$ G6PD-deficient variant and is thus prone to more severe hemolytic episodes.

Pharmaceutical agents are the best-defined precipitants of hemolysis. Although many drugs have been alleged to precipitate hemolysis in G6PD-deficient subjects, relatively few have withstood scrutiny.[125] Many of these agents are now obsolete and unlikely to be used. A discussion of a selected number of these agents follows.

Methylene blue administration to subjects with acute toxic methemoglobinemia is a well-known cause of severe hemolysis[125] that may be life-threatening in a subject with already compromised oxygen delivery due to methemoglobinemia (see section on methemoglobinemia earlier in this chapter). Infections have been widely recognized as a cause of hemolysis in G6PD-deficient subjects. It is assumed that diffusion of oxidants from neutrophils undergoing oxidative bursts leads to the formation of disulfide bridges of hemoglobin.

Fava beans are a staple food in many parts of the world where G6PD deficiency is found at a high gene frequency. The hemolysis precipitated by fava bean ingestion, favism, has been widely recognized in the Mediterranean region[130,131] and occurs only in subjects who are also G6PD deficient. However, not all G6PD-deficient variants are prone to favism. Subjects with the G6PD A$^-$ variant are typically not susceptible (although a rare exception to this rule was reported),[132] and not all subjects with the more severely deficient Mediterranean variant of G6PD deficiency are sensitive. It is assumed that the hemolytic risk of fava beans depends on the source and preparation of the beans[133] as well as individual variation due to an additional genetic component that has not yet been characterized.[134] Two fava bean metabolites, divicine and isouramil, are presumed oxidants and have been reported as possible causes of favism.[133]

In infants, a large study from Taiwan showed that neonatal jaundice is far more common in G6PD-deficient infants.[135] Furthermore, those G6PD-deficient subjects who also coinherit a promoter variant of uridine-5²-diphosphate-glucuronyl transferase have an even greater risk of neonatal hyperbilirubinemia.[136,137]

Nonerythroid Effect of G6PD Deficiency

Although patients with the common endemic G6PD variants are not at increased risk for infections, neutrophil dysfunction has been described in patients with some rare, severely deficient G6PD variants.[138,139]

Substances to Be Avoided in Cases of G6PD Deficiency

- Acetanilid
- Doxorubicin[126]
- Isobutyl nitrite[127]
- Methylene blue
- Naphthalene[128]
- Nitrofurantoin (Furadantin)
- Phenazopyridine (Pyridium)[129]
- Phenylhydrazine
- Primaquine
- Sulfacetamide
- Sulfamethoxazole (Gantanol)
- Sulfanilamide
- Sulfapyridine

Evolutionary Benefit of G6PD Deficiency

Shortly after the discovery of G6PD deficiency, it became apparent that the geographic distribution of populations with a high gene frequency of deficient variants overlapped closely with the prevalence of malaria. On the basis of this association, it was suggested that G6PD deficiency might be protective against malaria.[140,141] Unexpectedly, in the initial studies of acutely infected subjects, no protective effect of the G6PD deficiency was found for hemizygous G6PD-deficient males.[142] However, an apparent protection was found for heterozygous females[142] who, because of X-chromosome inactivation, are mosaics for deficient and nondeficient cells. This led to elegant studies demonstrating that although the malarial parasite does not initially thrive in a G6PD-deficient environment,[119] it adapts after several days of residence in a G6PD-deficient erythrocyte by increased production of malarial G6PD.[143,144] This strategy counteracts the evolutionary defense of G6PD deficiency in males; however, when the parasites infect the variably deficient and nondeficient erythrocytes of heterozygous females, malarial G6PD production is not efficient.[144] However, more recent epidemiologic and population genetic studies indicate that even G6PD-deficient males have some protection against malarial virulence[145,146] and suggest that the G6PD A^- variant arose only recently in human evolution and presumably spread rapidly as a result of positive selection by malaria infection.[146,147] Increased removal of G6PD-deficient erythrocytes containing ring-stage parasites was shown to be a likely mechanism of malarial protection.[148]

Diagnosis

The diagnosis of G6PD deficiency is based on the generation of NADPH from NADP as detected by either quantitative spectrophotometric analysis[149] or, more conveniently, by a rapid fluorescent screening test.[150] False-negative results are not unusual, especially if enzymatic analysis is performed shortly after resolution of acute hemolytic episodes.[90] After acute hemolysis, reticulocytes and young erythrocytes, which have much higher enzymatic activity, predominate. These false-negative test results are more likely to occur when a screening test rather than a quantitative spectrophotometric analysis of the enzyme activity is used. A high proportion of young red blood cells, which could contribute to a falsely "normal" result, can be conveniently estimated by concomitant spectrophotometric analysis of hexokinase, another red blood cell enzyme whose activity is markedly dependent on red blood cell age.

G6PD-deficient erythrocytes of heterozygous females are also prone to hemolysis, but because of the natural mosaicism for X-chromosome enzymes in females, females heterozygous for G6PD deficiency are particularly difficult to diagnose.[90] In populations of African ancestry, the faster electrophoretic mobility of G6PD A^- discriminates it from the wild-type G6PD B isoenzyme, but electrophoresis does not differentiate G6PD A^- from the other African polymorphic nondeficient isoenzyme G6PD A^+.[90] However, now that the nucleotide substitutions of many G6PD-deficient isoenzymes have been established, molecular diagnostic methods can be more reliably used for the accurate diagnosis of females who are heterozygous for G6PD deficiency.[90]

Therapy

Drugs that are known to precipitate hemolysis in G6PD-deficient subjects should be avoided. In subjects with G6PD A^- deficiency, hemolysis is typically short-lasting in spite of continuous use of the offending agent. This is not always the case in patients with the more severe Mediterranean variant of G6PD deficiency, and the precipitating agent should be always withdrawn. When anemia is severe and symptomatic, blood transfusion may be necessary.

γ-Glutamyl Cysteine Synthase Deficiency

γ-Glutamyl cysteine synthase catalyzes the first metabolic step of glutathione synthesis. Only two families with a defect of this enzyme have been reported.[151,152] The first family had hemolytic anemia and progressive neurologic defects; the other family had hemolytic anemia but was neurologically normal.[152]

Glutathione Synthase Deficiency

Glutathione synthase deficiency is an autosomal recessive disorder; patients are homozygous or compound heterozygotes for mutations in the glutathione synthase gene. The clinical presentation is variable; classification into mild, moderate, or severe phenotypes has been proposed.[153] Mildly affected patients have only hemolytic anemia, whereas moderately affected individuals have both hemolytic anemia and severe metabolic acidosis because of the accumulation of 5-oxoproline (see Fig. 45–5). Severely affected patients also have neurological symptoms (seizures, psychomotor retardation), which are progressive. Although mutations causing frameshifts, premature stop codons, or aberrant splicing are associated with the moderate or severe phenotype, other factors including environmental factors and other modifier genes likely affect the clinical phenotype because there may be considerable phenotypic variability even among the siblings affected by the same mutations.[154] High levels of 5-oxyproline in the urine (found in all severely and moderately affected but in only some of the mildly affected patients) suggests the diagnosis, which is confirmed by documenting deficiency of the enzyme.

Deficiency of this enzyme in neutrophils has also been alleged to cause intermittent neutropenia in some families,[155] and recurrent bacterial infections have been described.[153] One affected African American patient was also an albino,[156] suggesting the participation of this enzyme in melanin metabolism. Therapy with vitamins E and C has been recommended[153] but is not always effective.[156]

Glutathione Reductase Deficiency

Glutathione reductase requires the riboflavin-derived cofactor FAD for full activity. Its in vitro activity with and without exogenously added FAD can be conveniently used for diagnosing riboflavin deficiency.[149] The first reported case of an inherited deficiency of this enzyme was a Dutch family with two affected siblings who had unstable GSH and developed a hemolytic crisis after eating fava beans[157]; their disease resulted from a homozygous large glutathione reductase gene deletion. In the second reported family, which was also Dutch, the propositus had severe neonatal jaundice and was a compound heterozygote for two different mutations than that found in the first family.[158] Acquired deficiency of this enzyme secondary to riboflavin deficiency does not appear to have any hematologic phenotype.

Glutathione Peroxidase Deficiency

Glutathione peroxidase contains selenium. Selenium deficiency is particularly common in New Zealand, where many individuals with decreased enzyme activity have been found.[159] This acquired decreased activity has not been associated with a recognizable phenotype, and no clear-cut congenital deficiency of this enzyme has been reported. Knockout of this gene in mice results in only a mild defect with propensity to cataracts.[160]

ENZYMOPATHIES OF THE GLYCOLYTIC PATHWAY

The enzyme deficiencies of the glycolytic pathway differ from those enzyme abnormalities of glutathione pathway metabolism in several ways: (a) they do not have any characteristic morphologic abnormali-

ties such as Heinz bodies; (b) they are not subject to hemolytic crises after exposure to oxidants; and (c) their mechanism of hemolysis is not clearly understood. Furthermore, the clinical phenotypes are highly variable and appear to be specific for each enzymatic defect. Diagnosis of these disorders depends on the quantitation of enzyme activity in a hemolysate prepared from leukocyte- and platelet-depleted washed red blood cells.[149]

Pyruvate Kinase Deficiency

Pyruvate kinase (PK) deficiency is the most common genetic defect causing congenital enzymopathic hemolytic anemia. Although this disorder is far less common than G6PD deficiency, the vast majority of patients with G6PD deficiency never suffer an acute hemolytic episode and those G6PD variants associated with chronic hemolytic states are rare. PK deficiency, in contrast, exhibits high penetrance of the hemolytic phenotype.

Pyruvate Kinase Isoenzymes and Molecular Biology

The PK isoenzymes, M_1, M_2, L, and R, are products of two distinct genes. The *PK-M* gene, which is expressed in muscle, leukocytes, platelets, brain tissue, and other cells, is located on chromosome 15q22.[161] The M_1 and M_2 isoforms result from differential processing of a single transcript of this gene.[162] PK-M_2 is the dominant fetal form of PK (including fetal erythroid cells). In adult life it is largely replaced in muscle and brain by PK-M_1 but persists in leukocytes, platelets, and early erythroid progenitors.[163]

A gene on chromosome 1q21 encodes the L and R PK isoenzymes.[164] This gene utilizes two different tissue-specific promoters initiating transcription at different exons.[165] The L isoform is found in hepatocytes, the renal cortex, and the small intestine. The R form is present in two isoforms; the smaller of the two is the result of proteolytic degradation. These two PK peptides are unique to erythrocytes and gradually replace the M_2 isoform as erythroid cells mature. The crystal structure of the R form composed of the larger R peptides was published,[166] but it is not clear how relevant it is to in vivo red cell PK, which exists in two different forms. The complexity of PK isoforms is further accentuated by the fact that the functional enzyme is a tetramer and that heterotetramers exist.

An allosteric enzyme with one substrate-binding site, PK converts phosphoenol pyruvate to lactate, generating ATP in the process. PK also interacts with fructose diphosphate (FDP). Similar to the interaction of hemoglobin with 2,3-BPG, this interaction changes the conformational structure of PK and decreases its Michaels enzymatic constant (K_M) for its substrate phosphoenol pyruvate, thus dramatically increasing the activity (V_{max}) of the enzyme.[167,168] PK-M_1 is the only isoform that does not allosterically interact with FDP. The PK M variants also have quite different kinetic properties than the adult erythrocyte PK isoform R.

PK Mutations

More than 150 mutations of *PK* have been reported.[169,170] There appears to be some correlation with the location of the mutation and the severity of the hemolytic anemia.[170] Affected individuals are either homozygous for the same mutation or doubly heterozygous for two different PK defects. PK deficiency is distributed worldwide, but it has been reported that the gene is more common among people of northern European extraction[171] and perhaps among Chinese[172] and certain other ethnic and racial groups. In these populations, the frequency of heterozygosity may exceed 1% and the affected subjects are more likely homozygous for common mutations.[171,172] Single nucleotide substitutions have been described as well as intronic mutations, deletions, and insertions.[173] The three most prevalent mutations are 1456T, 1468T, and 1529A; 1529A is the most common mutation in the United States and Northern and Central Europe. 1456T is most common in Spain, Portugal, and Italy whereas 1468T is more frequent in Asia.[170]

An additional molecular mechanism for PK deficiency has been reported.[174] Combined heterozygosity for the common 1529A PK mutation and a unique promoter mutation on the other allele that markedly reduced its allelic transcription resulted in a severe hemolytic variant.

Malaria protection

PK deficiency is associated with protection against malaria in mice.[175] A similar effect in humans has not yet been established, and there is no indication of a positive selection pressure in the geographic distribution of human PK deficiency.

Mechanism of Hemolysis and Physiologic Implications of PK Deficiency

The mechanism of hemolysis is not clear. Although it has been postulated that the defect in ATP generation contributes to the hemolytic process,[176] this explanation is insufficient because ATP deficiency is difficult to demonstrate in many patients,[177] and other disorders with more severe ATP deficiency are not associated with significant hemolysis.[178]

It has been suggested that the anemia of PK deficiency is better tolerated than a comparable level of anemia seen in patients with hexokinase deficiency, because the block in glycolysis occurs after the Rapoport–Luebering shunt (see section on 2,3-BPG deficiency). The accumulation of 2,3-BPG in this downstream glycolytic defect leads to higher 2,3-BPG concentrations and thus better oxygen delivery to the tissue and superior tolerance of anemia.[179]

Patients with hemolytic anemia who undergo splenectomy, with a resultant decrease in the hemolytic process and improvement of anemia, have a higher number of reticulocytes than they did before the splenectomy.[180,181] This perplexing observation indicates that our knowledge of the regulation of erythropoiesis and reticulocyte kinetics remains incomplete.

PK deficiency may affect both the survival of red cells and the maturation of erythroid progenitors, although this has only been studied in splenic erythroid progenitors. This results in premature cell death, that is, apoptosis, as demonstrated in a splenectomized PK-deficient patient,[182] and more conclusively in the splenic erythroid progenitors of a PK-deficient mouse.[183]

However, it remains to be established whether the apoptosis of erythroid progenitors in PK deficiency extends to marrow erythroblasts, whether this observation accounts for the previously unexplained postsplenectomy reticulocytosis, and whether PK activity has any role in the apoptotic pathway in other tissues.[184]

Indications for Splenectomy in a Patient with Enzymopathy-Induced Hemolysis

The only proven benefit of splenectomy is in patients with severely hemolytic (ie, significantly anemic, or transfusion dependent) variants of pyruvate kinase deficiency and glucose phosphoisomerase deficiency, and possibly in pyrimidine 5′ nucleotidase deficiency. Although splenectomy will decrease the biochemical parameters of hemolysis such as lactate dehydrogenase and total bilirubin and decrease or eliminate transfusion requirements, the reticulocyte count will rise in pyruvate kinase deficiency and in pyrimidine 5′ nucleotidase deficiency.

Diagnosis

There are no specific clinical findings or morphologic abnormalities in patients with PK deficiency. No routinely available laboratory measurements aid in diagnosis.

A screening test, using crude hemolysate with one concentration substrate, has been employed for detection of pyruvate deficiency.[149] However, this screening test misses the PK variants characterized by increased K_M and those with abnormal FDP interaction. Furthermore, because leukocytes have much higher PK activity than red cells, care must be taken to rigorously remove the leukocytes by reliable means such as filtration of the blood by special leukocyte- and platelet-retaining columns.[149] Specialized laboratories can perform quantitative PK enzyme analysis with various concentrations of substrate with and without FDP (the native FDP must first be removed by dialysis).[149] The mutant enzyme can be further analyzed by comprehensive kinetic and electrophoretic studies of the partially purified enzyme.[178] However, these studies have now been largely replaced by the detection of specific mutations of the enzyme at the cDNA or genomic level.[185] Because most sporadic cases of PK deficiency are compound heterozygotes, testing of obligate heterozygote family members facilitates the diagnosis.[170]

Clinical Presentation and Therapy

The severity of hemolysis in PK-deficient patients is highly variable. It ranges from rare hydrops fetalis due to homozygosity for PK null mutations, to life-threatening transfusion-requiring hemolytic anemia present at birth, to a mild, fully compensated hemolytic process without anemia. The degree of severity is typically similar among siblings of a given family.[170] Hemolysis may be exacerbated in acute infections and during pregnancy.

Patients with severe hemolysis may be chronically jaundiced and may develop the clinical complications of chronic hemolytic states, including gallstones, transient aplastic anemia crises (often due to parvovirus infection), folate deficiency, and, infrequently, skin ulcers. As with any autosomal recessive disorder, the defect is more common in a group with a history of inbreeding or consanguinity. A high frequency of this disorder has been well documented among Pennsylvania Amish.[186]

Splenomegaly is frequently seen but is not invariable. The beneficial effect of splenectomy on hemolysis is well documented; typically, the degree of hemolysis and anemia is ameliorated and in severe cases the transfusion requirement is generally abolished or markedly decreased. The increase in hemoglobin concentration in non–transfusion-requiring patients after splenectomy ranges from 1 to 3 gm%.[170] However, as stated earlier, reticulocytes invariably rise after splenectomy. Unless the patient is transfusion dependent, it is advisable to delay splenectomy until after the age of 3 years when the risk of pneumococcal, *Haemophilus influenzae*, and meningococcal infections declines. Furthermore, in most cases the degree of hemolysis declines after infancy, by a not fully understood pathophysiologic mechanism. In severely affected subjects, who are typically transfusion dependent, iron overload has been reported.[170] Although folic acid replacement is frequently used, it may not always be necessary; however, it is inexpensive and safe. One PK-deficient boy with severe hemolysis was apparently cured by an allogeneic marrow transplant.[187]

Glucose Phosphoisomerase Deficiency

Glucose phosphoisomerase deficiency is one of the three most common red blood cell enzyme defects causing chronic hemolytic anemia (including pyruvate kinase deficiency and pyrimidine 5′ nucleotidase deficiencies). More than 100 families have been described. In some families, the hemolysis is severe enough to necessitate chronic blood transfusions.[188] Very severe hemolysis was seen in a girl who also coinherited a mild G6PD deficiency, suggesting an additive role of these two defects.[189] Neonatal jaundice is common in patients with this disorder,[190] and hydrops fetalis has also been reported.[191] Although no specific therapy is available, it has been suggested that splenectomy provides a moderate benefit.[192]

Hexokinase Deficiency

Hexokinase catalyzes the initial step of glycolysis and produces glucose 6-phosphate, which is utilized in both glycolysis and the pentose pathway (see Fig. 45–1). Fewer than 50 cases have been reported. Most are of individuals of northern European extraction,[193] although one case was found in a Chinese individual.[194] Because the metabolic defect is proximal to the generation of 2,3-BPG, it has been suggested that the resultant decreased level of 2,3-BPG leads to a left-shifted hemoglobin–oxygen dissociation curve and a more symptomatic anemia than comparable levels of anemia seen in patients with other red blood cell disorders.[195]

Phosphofructokinase and Aldolase Deficiencies

Deficiencies of phosphofructokinase and aldolase are rare causes of glycogen storage disease and chronic nonspherocytic hemolytic anemia. As in the cases of patients with other rare autosomal recessive disorders, consanguinity is frequent.

Phosphoglycerokinase Deficiency

Deficiency of this X-chromosome-encoded enzyme is associated with hemolytic anemia, mental retardation, and myoglobinuria. The cDNA for the phosphoglycerokinase gene has been cloned[196] and several mutants described.

Triosephosphate Isomerase Deficiency

Triosephosphate isomerase deficiency is a rare red blood cell defect reported to cause congenital hemolytic anemia and other severe organ dysfunctions, including progressive neurologic abnormalities and early death.[197] An increased susceptibility to bacterial infections has also been described.[198] No specific therapy for this disorder is available. In a single reported case, splenectomy did not ameliorate hemolysis.

PYRIMIDINE 5′ NUCLEOTIDASE DEFICIENCY

Enzyme Classification and Function

Red cell pyrimidine 5′ nucleotidase is a member of a family containing at least seven genes encoding 5′ nucleotidases.[199] Other members of this family play a role in activation of antiviral compounds (cN-II) and in T cell activation and cell adhesion (ecto-5′ nucleosidase, also known as CD73). Previously thought to be a single entity, red cell 5′ nucleotidase is composed of two enzymes encoded by two different genes.[200] Pyrimidine 5′N type 1 (P5'N-1), also designated cytosolic 5:nucleosidase II (cN-III), participates in degradation of pyrimidine ribonucleotides, whereas pyrimidine 5′N type 2, more efficiently degrades deoxyribonucleotides. Only P5′N-1 deficiency has been associated with a clinical syndrome of hemolytic anemia. P5′N-1 activity is much higher in reticulocytes than mature red cells, and its activity rapidly declines during the first few days of red cell maturation.

The accumulation of pyrimidines in the red blood cells due to a deficiency of P5′N-1 is presumed to be toxic and a cause of hemolysis. However, deficiency of P5′N-1 is at least partly compensated in vivo by other nucleosidases or other nucleotide metabolic pathways.[201]

P5′N-1 Mutations

The P5′N-1 gene is localized to chromosome 7p15-14. Three transcripts are produced by alternative splicing; one transcript is ubiquitously expressed, but two are predominantly expressed in reticulocytes.[200] More than 20 different mutations in *P5′N-1* have been reported; all but two patients are homozygous.[200]

Clinical Features and Differential Diagnosis

Deficiency of P5′N-1is the third most common enzymatic deficiency resulting in hemolysis. Inherited in an autosomal recessive manner, it is the only congenital hemolytic anemia due to a red blood cell enzyme deficiency that has a specific, consistent morphologic abnormality, that is, basophilic stippling.[202] Thus, morphologic examination of the peripheral blood smear provides simple and inexpensive screening. Basophilic stippling is also found in cases of hemolytic anemia due to acute lead toxicity. Lead is a powerful inhibitor of P5′N-1,[203] and determination of lead levels should be included whenever the constellation of acquired hemolytic anemia, P5′N-1 deficiency, and basophilic stippling is found.

The degree of hemolysis in hereditary P5′N-1 deficiency is generally constant but may be exacerbated by infection and pregnancy; the severity ranges from compensated hemolysis without anemia to transfusion-dependent anemia. In several reported instances, splenectomy was beneficial, with an average improved hemoglobin concentration of approximately 3 gm%, and curiously their reticulocyte count also increased after splenectomy.[200]

The coinheritance of P5′N-1 deficiency and hemoglobin E was reported to be associated with severe hemolytic anemia, suggesting that this enzyme is particularly susceptible to oxidative damage resulting from the instability of hemoglobin E.[204] However, pyrimidine 5′ nucleotidase deficiency may increase oxidative stress on its own because it partially inhibits G6PD activity and reduces GSH by an as yet unknown mechanism.

POLYCYTHEMIA DUE TO CONGENITAL RED BLOOD CELL ENZYME DEFICIENCY

The polycythemias (also known as *erythrocytosis*) comprise a group of etiologically different disorders.[205] Absolute polycythemias may be primarily due to an intrinsic defect of hematopoietic progenitors or, more commonly, secondarily due to stimulation of normal hematopoietic progenitors by extrinsic factors such as erythropoietin. Although most polycythemias are acquired, some are congenital.[206] One rare cause of congenital secondary polycythemia is familial 2,3-bisphosphoglycerate (2,3-BPG, previously known as 2,3-DPG) deficiency, which results from a deficiency of the red blood cell enzyme bisphosphoglyceromutase (BPGM). Present in a very high concentration in red blood cells, 2,3-BPG binds hemoglobin, allosterically changing hemoglobin conformation and modulating its ability to bind oxygen. A decreased 2,3-BPG level shifts the hemoglobin oxygen dissociation curve to the left (increases hemoglobin affinity for oxygen), resulting in decreased delivery of oxygen into the peripheral tissues and compensatory polycythemia.

Biochemistry

The formation of 2,3-BPG constitutes the Rapoport–Luebering shunt,[207] which is often called an *energy switch* because it bypasses the formation of ATP in the reaction mediated by the glycolytic enzyme phosphoglycerate kinase (Fig. 45–6). A single multifunctional enzyme, BPGM, with both synthase and phosphatase activity, controls this shunt. BPGM is a homodimer of two identical 258-amino-acid subunits. The *BPGM* gene has been mapped to 7q34-7q22; transcripts of the gene have been detected in higher levels in erythroid cells than in nonerythroid cells, although no erythroid-specific promoter region has been identified.[208]

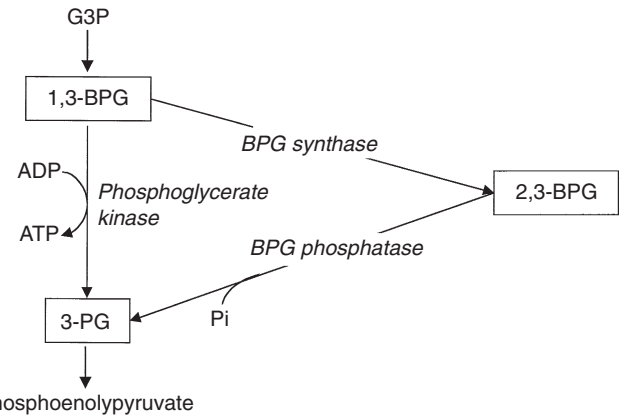

Figure 45–6 Rapoport–Luebering shunt. 2,3-BPG metabolism is regulated by a multifunctional enzyme, bisphosphoglycerate mutase, with both synthase (BPG synthase) and phosphatase (BPG phosphatase) activity. This reaction bypasses the formation of ATP in the glycolytic pathway. 1,3-BPG, 1,3-bisphosphoglycerate; 2,3-BPG, 2,3-bisphosphoglycerate; G-3-P, glyceraldehyde-3-phosphate; 3-PG, 3-phosphoglycerate; Pi, inorganic phosphate.

The conversion of 1,3-bisphosphoglycerate to 2,3-BPG is catalyzed by the synthase activity of BPGM. 2,3-BPG is then metabolized to 3-phosphoglycerate (3-PGA), an intermediate of the glycolytic pathway, by BPGM-phosphatase activity residing in the same protein molecule.[209–213] The synthase activity of BPGM is activated by alkalosis, whereas the phosphatase activity of BPGM is enhanced by acidosis.[214]

Clinical Manifestations and Inheritance

Deficiency of BPGM leads to a marked decrease in 2,3-BPG levels. The resultant increased hemoglobin oxygen affinity decreases the amount of oxygen released peripherally, leading to a compensatory polycythemia. Only one family with this deficiency has been well studied. The propositus and his sister were compound heterozygotes for two different BPGM mutations and had complete deficiency of BPGM synthetase activity and marked polycythemia. Some of their heterozygote relatives had a milder decrease of 2,3-BPG levels and a mild polycythemia.[215–219]

Other reports of reduced BPGM activity and decreased 2,3-BPG levels are difficult to interpret or do not pass rigorous biochemical and molecular biologic scrutiny.[220–223] In some of these reports, the phenotype included hemolysis; however, other causes of hemolysis were not definitively excluded. Because of the rarity of complete BPGM deficiency, it is not possible to predict the phenotype of heterozygous individuals; however, it is likely that some individuals heterozygous for this enzyme deficiency will have a mild to moderate polycythemia and in these families an apparent autosomal dominant pattern of inheritance may be observed.[216,218,219,224]

Diagnosis and Therapy

Determination of hemoglobin–oxygen association kinetics is the best initial-screening laboratory test for congenital secondary polycythemia If a cooximeter is not available, the P_{50} can be estimated from a venous blood gas measurement using a relatively complex mathematical formula.[225] An Excel spreadsheet formula that rapidly obtains the PSO value from venous blood gases by entering venous Po_2, O_2 saturation and PN has been published[225a] providing that both the venous Pao_2 and the hemoglobin oxygen saturation are measured. A

decreased P_{50} usually results from a mutant hemoglobin (see Chapter 44). Once a hemoglobin mutant has been excluded, a biochemical assay of freshly obtained erythrocytes may be used to detect decreased erythrocyte 2,3-BPG.[149] If 2,3-BPG deficiency is found, it should be followed by an assay of BPGM activity and, if desired, analysis for the gene mutation. Because inheritance of this defect in some families is autosomal recessive, a family history of this rare deficiency may not be present and, as in all rare recessive disorders, consanguinity should be suspected.

Only limited clinical experience with this disorder is available; the polycythemia would be expected to compensate fully for the decreased tissue oxygen delivery and no significant health impairment would be foreseen. However, a superimposed anemia, such as that caused by blood loss or nutritional deficiency, would be expected to be more symptomatic than the same level of anemia seen in subjects with normal enzyme activity and normal levels of 2,3-BPG.

NONENZYMATIC FUNCTIONS OF RED CELL ENZYMES

It is increasingly recognized that enzymes of the glycolytic pathway also have nonenzymatic functions. Many of these discoveries stemmed from the work of Otto Warburg on respiration and energy metabolism of cancer cells and the different regulation of cancer cells by hypoxia, which is now partially explained by the constitutive upregulations of hypoxia-inducible factor HIF-1. Glycolytic enzymes play a role in tumor metastasis and cell motility. Glucose-6-phosphate isomerase acts as an autocrine motility factor in cell migration and appears to be important in cancer metastasis.[226,227] Other glycolytic enzymes help regulate apoptosis. Mitochondrial hexokinase appears to inhibit apoptosis via interaction with the proapoptotic protein BAD, whereas glyceraldehyde phosphate dehydrogenase appears to have a proapoptotic function.[226,228] Other glycolytic enzymes, including hexokinase, GAPD, enolase, and lactic dehydrogenase, have important roles in the regulation of the transcription of an array of genes by multiple mechanisms.[226]

DIAGNOSTIC AND OTHER USES OF BLOOD CELL ENZYMOPATHIES

Deficiencies of some erythrocyte enzymes, such as lactate dehydrogenase or catalase, have no discernible phenotypes. Even when red blood cell enzymopathies do not cause abnormalities of the erythrocyte, they can be useful diagnostically. Easily obtainable red blood cells can serve as a convenient source of material for diagnosing systemic diseases. The red blood cell is capable of metabolizing galactose, but abnormalities of galactose metabolism do not have any hematologic phenotype. Galactose kinase deficiency is associated with cataracts, and galactose uridinyl-1-transferase is associated with classic galactosemia (ie, cataracts, congenital deafness, and mental retardation). Adenosine deaminase deficiency is associated with profound immunologic disturbance, but no red blood cell abnormalities. Measurement of adenosine deaminase in erythrocytes is a convenient diagnostic tool. The activity of erythrocyte glutathione reductase, which requires the riboflavin-derived coenzyme FAD, can be measured with and without FAD, serving as a convenient indicator of riboflavin deficiency.

CHAPTER 46

RED BLOOD CELL MEMBRANE DISORDERS

Patrick G. Gallagher and Petr Jarolim

Progress in the characterization of the structure and function of red blood cell membrane proteins and their genes has led to considerable advances in the understanding of the molecular pathology of red blood cell membrane disorders. This has led to the definition and characterization of mutations of membrane proteins as a well-defined cause of hereditary hemolytic disease. Likewise, knowledge of the molecular mechanisms underlying changes in red blood cell deformability, structural integrity, and shape has advanced. Red blood cell shape abnormalities often provide a clue to the pathobiology and diagnosis of the underlying disorder. This chapter categorizes red blood cell membrane disorders according to the following morphologic and clinical phenotypes: (1) hereditary spherocytosis (HS); (2) hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP) and related disorders; (3) Southeast Asian ovalocytosis (SAO); (4) hereditary and acquired acanthocytosis; and (5) hereditary and acquired stomatocytosis (Tables 46–1 and 46–2). The structure and function of the normal red blood cell membrane are described in Chapter 33; a review of that chapter will facilitate understanding of the material in this chapter.

VERTICAL AND HORIZONTAL INTERACTIONS OF MEMBRANE PROTEINS AND DISORDERS OF RED BLOOD CELL SHAPE

Palek and colleagues first proposed dividing membrane protein-protein and protein-lipid interactions into two categories, vertical and horizontal interactions.[1] Vertical interactions, which are perpendicular to the plane of the membrane, stabilize the lipid bilayer. These interactions include spectrin-ankyrin-band 3 interactions, spectrin-protein 4.1R-junctional complex proteins linkage, spectrin-ankyrin-Rh multiprotein complex linkage, and the weak interactions between the skeletal proteins and the negatively charged lipids of the inner half of the membrane lipid bilayer. Horizontal interactions, which are parallel to the plane of the membrane, support the structural integrity of erythrocytes after their exposure to shear stress. Horizontal interactions involve the spectrin heterodimer association site, where spectrin heterodimers assemble into tetramers, the principal building blocks of the membrane skeleton, and the contacts of the distal ends of spectrin heterodimers with actin and protein 4.1R within the junctional complex. Although interactions between proteins of the erythrocyte membrane are more complex than can be classified by this model of horizontal and vertical interactions,[2] the model serves as a useful starting place for understanding erythrocyte membrane protein interactions, particularly in reference to membrane-related disorders.

According to the vertical/horizontal model, HS is considered a disorder of vertical interactions (Fig. 46–1). Although the primary molecular defects in HS are heterogeneous (including deficiencies or dysfunctions of α- and β-spectrin, ankyrin, band 3, and protein 4.2; see Etiology and Pathobiology), one common feature of HS red blood cells is a weakening of the vertical contacts between the skeleton and the overlying lipid bilayer membrane together with its integral proteins.[3] Consequently, the lipid bilayer membrane is destabilized, leading to release of bilayer lipids from the cells in the form of skeleton-free lipid vesicles. This lipid loss, in turn, results in membrane surface area deficiency and spherocytosis.

In most patients with HE and the related disorder HPP (see Hereditary Elliptocytosis and Related Disorders), the principal lesion involves horizontal membrane-protein associations, primarily spectrin dimer-dimer interactions. In a subset of HE patients with a deficiency or a dysfunction of protein 4.1R or glycophorin C, the horizontal defect resides in the junctional complex, where the distal ends of spectrin tetramers connect to actin, with the aid of the 4.1R protein. In patients with severely dysfunctional spectrin mutations, the weakened spectrin dimer-dimer self-association disrupts the skeletal lattice, leading to a marked skeletal instability and cell fragments. In patients with mildly dysfunctional spectrins, red blood cell shape is that of biconcave elliptocytes. It is speculated that elliptocytes are permanently deformed cells because the weakened horizontal interactions facilitate a shear stress-induced rearrangement of skeletal proteins, precluding recovery of the normal biconcave shape (for details, see the discussion under Hereditary Elliptocytosis and Related Disorders). This hypothesis is not applicable to all forms of elliptocytosis. For example, in SAO, the elliptocytic/ovalocytic cells containing mutant band 3 protein are rigid and "hyper-stable" rather than unstable.

Acanthocytosis, Stomatocytosis, and the Bilayer Couple Hypothesis

The mechanism of acanthocytosis and stomatocytosis associated with defects of membrane proteins is much less clear. Most forms of acanthocytosis are associated with either acquired or inherited abnormalities of membrane lipids (eg, acanthocytosis in end-stage liver disease or abetalipoproteinemia). In rare subjects with acanthocytosis, membrane protein abnormalities have been detected, but the mechanism whereby they lead to acanthocyte formation is unknown. These abnormalities occur in the McLeod phenotype, the chorea-acanthocytosis syndromes, and other rare disorders. In acanthocytosis erythrocytes, agents that interact with the lipids of the inner lipid bilayer leaflet normalize the shape. These studies suggest that the shape abnormalities reflect an asymmetry in the distribution of membrane lipids between the two halves of the red blood cell lipid bilayer as predicted by the bilayer couple hypothesis (Fig. 46–2). This hypothesis is based on the well-established idea that the lipid bilayer is highly asymmetric, with phosphatidylcholine and sphingomyelin the main phospholipids of the outer face of the bilayer leaflet.[4] According to the bilayer hypothesis, the shape of the red blood cell reflects the ratio of the surface areas of the two hemileaflets of the bilayer. The preferential expansion of the outer leaflet leads to red blood cell crenation (echinocytosis or acanthocytosis), whereas expansion of the inner lipid bilayer produces a cup shape (stomatocytosis) and surface invaginations.

Hereditary Spherocytosis

Definition, Prevalence, and History

The typical features of HS include a dominantly inherited hemolytic anemia of mild to moderate severity, spherocytosis on the peripheral blood film, and a favorable response to splenectomy.[1,3–6] The

Table 46–1 Erythrocyte Membrane Abnormalities in Hereditary Spherocytosis, Hereditary Elliptocytosis, and Related Disorders

Gene	Disorder	Comment
α Spectrin	HS, HE, HPP, NIHF	Location of mutation determines clinical phenotype. α–Spectrin mutations are most common cause of typical HE.
Ankyrin	HS	Most common cause of typical, dominant HS.
Band 3	HS, SAO, NIHF, HSt	In HS, pincerlike spherocytes on smear presplenectomy. SAO erythrocytes have transverse ridge or bar
β Spectrin	HS, HE, HPP, NIHF	Location of mutation determines clinical phenotype. In HS, acanthocytic spherocytes on smear presplenectomy.
Protein 4.2	HS	Common in Japanese HS.
Protein 4.1	HE	
Glycophorin C	HE	Concomitant protein 4.1 deficiency is likely basis of HE in glycophorin C defects.

HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; NIHF, nonimmune hydrops fetalis; HS, hereditary spherocytosis; HSt, hereditary stomatocytosis; SAO, Southeast Asian ovalocytosis.

Table 46–2 Peripheral Blood Film Evaluation in a Patient With Red Cell Membrane Disorder

Shape	Pathobiology	Diagnosis
Microspherocytes	Loss of membrane lipids leading to a reduction of surface area resulting from deficiencies of spectrin, ankyrin, or band 3 and protein 4.2. Removal of membrane material from antibody coated red cells by macrophages. Removal of membrane associated Heinz bodies, with the adjacent membrane lipids, by the spleen	HS Immunohemolytic anemias Heinz body hemolytic anemias
Elliptocytes	Permanent red cell deformation resulting from a weakening of skeletal protein interactions (such as the spectrin dimer-dimer contact). This facilitates disruption of existing protein contacts during shear stress induced elliptical deformation. Subsequently, new protein contacts are formed that stabilize elliptical shape.	Mild common HE Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Poikilocytes/Fragments	Weakening of skeletal protein contacts resulting from skeletal protein mutations	Hemolytic HE/HPP Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Schistocytes, fragmented red cells	Red cells "torn" by mechanical trauma (fibrin strands, turbulent flow)	Microangiopathic hemolytic anemia associated with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, vasculitis, heart valve prostheses
Acanthocytes	Uptake of cholesterol and its preferential accumulation in the outer leaflet of the lipid bilayer Selective accumulation of sphingomyelin in the outer lipid leaflet	Spur cell hemolytic anemia in severe liver disease Abetalipoproteinemia Neuroacanthocytosis, chorea-acanthocytosis syndrome, McLeod phenotype, malnutrition, hypothyroidism
Echinocytes	Expansion of the surface area of the outer hemileaflet of lipid bilayer relative to the inner hemileaflet	Hemolytic anemia associated with hypomagnesemia and hypophosphatemia in malnourished patients, pyruvate kinase deficiency; in-vitro artifact of low blood storage (ATP depletion), contact with glass or elevated pH Hemolysis in long-distance runners, renal failure
Stomatocytes	Expansion of the surface area of the inner hemileaflet of the bilayer relative to the outer leaflet	Exposure of red cells to cationic anesthetics in vitro; in vivo, the drug concentrations may not be sufficient to produce similar effect Alcoholism, inherited disorders of membrane permeability (hereditary stomatocytosis)
Target cells	Absolute excess of membrane lipids (both cholesterol and phospholipids: "symmetric" lipid gain), followed by an increase of cell surface area Relative excess of surface area because of a decrease in cell volume	Obstructive jaundice, liver disease with intrahepatic cholestasis Thalassemias and some hemoglobinopathies (C, D, E)

HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis.

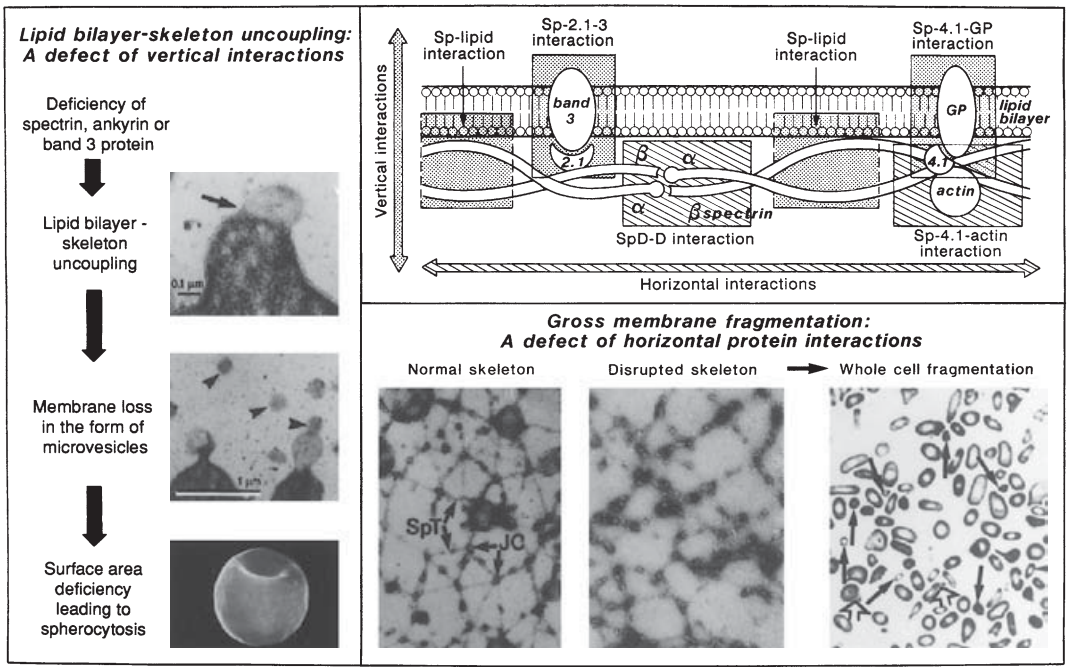

Figure 46–1 The red blood cell membrane lesion in hereditary spherocytosis (HS). (*Left*) Partial deficiencies of spectrin, ankyrin, or band 3 protein lead to uncoupling of the membrane lipid bilayer from the underlying skeleton (*arrow*), followed by a formation of spectrin-free microvesicles of approximately 0.2 to 0.5 mm in diameter (*arrowheads*). These vesicles can be visualized by transmission electron microscopy, but they are not seen on examination of a peripheral blood film. The subsequent loss of cell surface area and a decrease in the surface/volume ratio lead to spherocytosis. (*Right*) Two distinct pathways lead to reduced membrane surface area in HS. (**A**) Primary defects of spectrin, ankyrin, or protein 4.2 lead to reduced density of the membrane skeleton (*solid rectangles*). This causes destabilization of the lipid bilayer with the resultant loss of band 3-containing microvesicles. (**B**) Primary defects of band 3 (*black ovals*) result in band 3 deficiency. This leads to the loss of the lipid-stabilizing effect of band 3 with the release of band 3-free microvesicles from the membrane. Both pathways ultimately result in the loss of membrane material with a reduction in membrane surface area. The ensuing decrease in membrane surface area with the formation of spherocytes is paralleled by a decrease in erythrocyte deformability that predisposes the cells to splenic entrapment and conditioning. The spleen plays a secondary, but important, role in the pathobiology of HS. Splenic destruction of abnormal erythrocytes with decreased deformability is the primary cause of hemolysis experienced by HS patients.

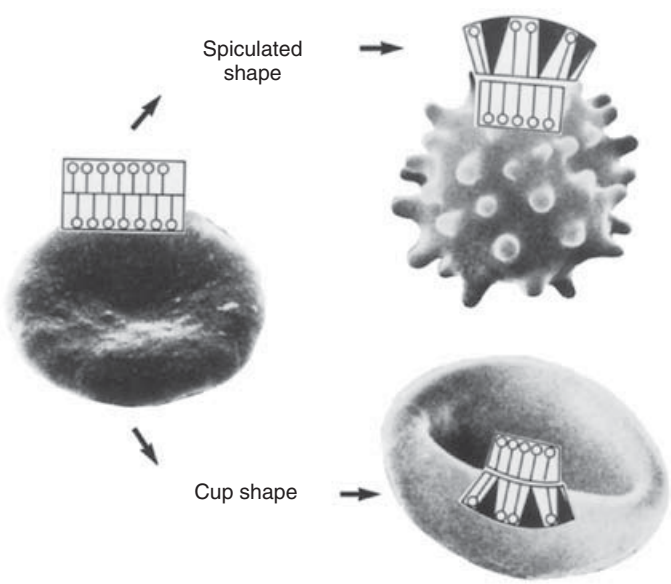

Figure 46–2 Bilayer couple hypothesis and the discocyte-echinocyte-stomatocyte transformation. Red blood cell shape is determined by the ratio of the surface areas of the two hemileaflets of the lipid bilayer. Compounds (*black triangles*) that preferentially accumulate in the outer hemileaflet produce its expansion, followed by red blood cell crenation (echinocytosis or acanthocytosis). In contrast, expansion of the inner lipid bilayer leaflet leads to a cup shape (stomatocytosis) and surface invaginations.

clinical spectrum of HS is variable and includes both mild and asymptomatic forms as well as severe forms that appear in infancy. The previously reported HS prevalence in Western populations of 1 in 5000 persons is an underestimation, because milder forms of HS might be asymptomatic, suggesting a prevalence of 1 in 2000 individuals.[7,8] HS has been reported worldwide, particularly in Japanese and African populations, but its prevalence in other ethnic groups is unknown.[9]

Hereditary spherocytosis was first described in 1871 by Vanlair and Masius and rediscovered 20 years later by Wilson and Minkowski. The next major contributions were Chauffard's description of increased osmotic fragility, reports of correction of hemolysis by splenectomy, and the studies by Ham and Castle implicating the spleen in the conditioning of hereditary spherocytes.[10] Soon thereafter, HS membranes were found to be leaky to sodium and to exhibit a loss of lipids, leading to surface area deficiency. An abnormality of the erythrocyte membrane was suspected; subsequently, molecular defects of membrane proteins and their genes were identified. A historic overview of HS is available.[11]

Etiology and Pathobiology

Two major factors are involved in HS pathophysiology (1) an intrinsic red blood cell defect, and (2) an intact spleen that selectively retains and damages abnormal HS erythrocytes. An inherited deficiency or dysfunction of proteins of the erythrocyte membrane leads to a multistep process of accelerated HS red blood cell destruction. Destabilization of the lipid bilayer facilitates a release of lipids from the membrane, leading to surface area deficiency and formation of

poorly deformable spherocytes that are selectively retained and damaged in the spleen (see Fig. 46–1).

Molecular Pathology

The molecular basis of HS is heterogeneous. Based on densitometric quantitation of membrane proteins separated by polyacrylamide gel electrophoresis, HS can be divided into the following subsets: (1) isolated deficiency of spectrin, (2) combined deficiencies of spectrin and ankyrin, (3) deficiency of band 3 protein, (4) deficiency of protein 4.2, and (5) no abnormality identified.

Isolated Spectrin Deficiency

The reported mutations of isolated spectrin deficiency include defects of both α- and β-spectrin. Mutations of the β-spectrin gene have been identified in a number of patients with dominantly inherited HS associated with spectrin deficiency.[12,13] A few cases have been associated with de-novo β-spectrin gene mutations.[14] With the exception of $\beta\text{-spectrin}^{\text{Houston}}$,[13] a frameshift mutation identified in several kindreds, these mutations are private and may be associated with decreased β-spectrin mRNA accumulation. $\beta\text{-Spectrin}^{\text{Kissimmee}}$, a point mutation located in the highly conserved region of β-spectrin involved in the interaction with protein 4.1R, is dysfunctional in its in-vitro binding to protein 4.1R and thereby the linkage of spectrin to actin.[12]

In nondominantly inherited HS associated with isolated spectrin deficiency, the defect involves α-spectrin.[14,15] In normal erythroid cells, α-spectrin is synthesized in large excess of β-spectrin. Thus, subjects with one normal and one defective α-spectrin allele are expected to be asymptomatic, because α-spectrin production remains in excess of β-spectrin synthesis, allowing normal amounts of spectrin heterodimers to be assembled on the membrane. Patients who are homozygotes or compound heterozygotes for α-spectrin defects will suffer from severe HS. Wichterle and associates described a patient with severe HS who was a compound heterozygote for two different α-spectrin gene defects: in one allele, there was a splicing defect associated with an upstream intronic mutation, α^{LEPRA}; in the other allele, there was another mutation, α^{PRAGUE}. The α^{LEPRA} allele produces approximately six times less of the correctly spliced α-spectrin transcript than the normal allele.[16] Further studies have shown that in many patients with nondominant, spectrin-deficient HS, including a number of the patients originally described by Agre and associates, $\alpha\text{-spectrin}^{\text{LEPRA}}$ is in linkage disequilibrium with $\alpha\text{-spectrin}^{\text{Bug Hill}}$, which carries an amino acid substitution in the αII domain.[17] Thus, it appears that the combination of the α^{LEPRA} allele with other defects of α-spectrin in *trans* leads to significant spectrin-deficient spherocytic anemia.[18]

Combined Deficiency of Spectrin and Ankyrin

The biochemical phenotype of combined spectrin and ankyrin deficiency is the most common abnormality found in the erythrocytes of HS patients.[19] Ankyrin represents the principal binding site for spectrin on the membrane; thus, it is not surprising that ankyrin deficiency is accompanied by a proportional decrease in spectrin assembly on the membrane despite normal spectrin synthesis. Similar to HS associated with β-spectrin mutations, most ankyrin defects are private point mutations in the coding region of the ankyrin gene associated with decreased messenger RNA accumulation.[3,20] In some cases, mutations of the ankyrin promoter leading to decreased ankyrin expression have been found.[21,22] Approximately 15% to 20% of ankyrin gene mutations reported are de-novo mutations.[23]

A number of patients with atypical HS associated with karyotypic abnormalities involving deletions or translocations of the ankyrin gene locus on chromosome 8p have been described.[24] Ankyrin deletions may be part of a contiguous gene syndrome with manifestations of spherocytosis, mental retardation, typical facies, and hypogonadism.

Deficiency of Band 3 Protein

Deficiency of band 3 protein is found in a subset of HS patients who present with a phenotype of a mild to moderate dominantly inherited HS with mushroom-shaped or pincerlike red blood cells.[25] Most, if not all, of these patients also have concomitant protein 4.2 deficiency. More than 50 different band 3 mutations associated with HS have been reported. These mutations are spread throughout band 3 in both the cytoplasmic domain and the membrane-spanning domains.

A number of band 3 mutations clustered in the membrane-spanning domain that replace highly conserved arginines have been described.[26] These arginines, which are all located at the cytoplasmic end of a predicted transmembrane helix, exhibit defective cellular trafficking from the endoplasmic reticulum to the plasma membrane.[27]

Alleles have been identified that influence band 3 expression and that, when inherited in *trans* to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical severity of the disease.[28]

Deficiency of Protein 4.2

Recessively inherited HS caused by mutations in protein 4.2 is relatively common in Japan.[29] In these cases, an almost total absence of protein 4.2 from the erythrocyte membranes of homozygous patients is detected. Protein 4.2-deficient erythrocytes can also have a decreased content of ankyrin and band 3. Protein 4.2 deficiency also occurs in association with band 3 mutations, probably as a result of abnormal binding of protein 4.2 to the cytoplasmic domain of band 3.[30]

A detailed listing of HS mutations can be found at the Human Gene Mutation Database Web site (www.hgmd.cf.ac.uk/ac/index.php) maintained by Institute of Medical Genetics in Cardiff.

Molecular Basis of Surface Area Deficiency

Hereditary spherocytes are intrinsically unstable, releasing lipids under a variety of in-vitro conditions, including adenosine triphosphate (ATP) depletion or exposure of cells to shear stress. The loss of membrane material occurs through the release of 0.2 to 0.5 μm vesicles containing integral proteins devoid of spectrin.[31] During in-vitro incubation, the loss of membrane material is sufficient to augment the surface area deficiency, as evidenced by increased osmotic fragility of the cells after incubation.[31,32] It is assumed but not proved that a similar process takes place in vivo.

The molecular basis of HS is heterogeneous; thus, it is likely that surface area deficiency is a consequence of several distinct molecular mechanisms whose common denominator is either a weakening of the vertical connections between the skeleton and the lipid bilayer membrane or a weakening of the stabilizing effect of transmembrane proteins on adjacent lipid molecules of the plasma membrane. Three distinct hypothetic pathways that can lead to surface area deficiency are depicted in Fig. 46–1. In patients with isolated spectrin deficiency or a combined deficiency of spectrin and ankyrin, the loss of red blood cell (RBC) surface may be caused by an uncoupling of the lipid bilayer membrane from the underlying skeleton. In normal red blood cells, the skeleton forms a nearly monomolecular submembrane layer occupying more than one-half of the inner surface of the membrane. Consequently, spectrin deficiency leads to a decreased density of this network. As a result, areas of the lipid bilayer membrane that are not directly supported by the skeleton are susceptible to release from the cells in the form of microvesicles.

In HS associated with a deficiency of band 3 protein, two hypothetic pathways may lead to a loss of surface area. One mechanism may involve a loss of band 3 protein from the cells. Because band 3

protein spans the lipid bilayer membrane many times, it is likely that a substantial amount of "boundary" lipids are released together with the band 3 protein, thus leading to surface area deficiency. Another possible mechanism may involve a formation of band 3-free domains in the membrane, followed by the formation of membrane blebs, which are subsequently released from the cells as microvesicles. Such a hypothesis is based on the observation that aggregation of intramembrane particles (composed principally of band 3) in ghosts leads to the formation of particle-depleted domains from which membrane lipids bleb off as microvesicles. Additional evidence supporting the latter model comes from the band 3 knockout mouse model and from human, cow, and zebrafish cases of complete band 3 deficiency.[33–36] Erythrocytes lacking band 3 spontaneously shed membrane vesicles, leading to severe spherocytosis and hemolysis.

Alterations in Cation Content and Permeability

HS red blood cells, particularly those collected from the spleen, are somewhat dehydrated and abnormally permeable to monovalent cations, presumably as a consequence of the underlying membrane defect. The cellular dehydration may be caused by activation of pathways causing a selective loss of potassium and water or a hyperactive Na+/K+ pump.[37,38]

Entrapment of Nondeformable Spherocytes in the Spleen

The importance of the spleen in the pathophysiology of hemolysis in HS was appreciated in the original description of the disease and has been substantiated by subsequent studies. HS cells are selectively destroyed in the spleen because of their poor deformability and because of the unique anatomy of the splenic vasculature that acts as a microcirculation filter.

The poor red blood cell deformability is principally a consequence of a decreased cell surface-to-cell volume ratio resulting from the loss of surface material.[39] Normal discocytes have an excess surface, which allows them to deform and pass through narrow microcirculation openings. In contrast, HS red blood cells lack this extra surface, and their poor deformability may be further impaired by cellular dehydration.[38,39]

The principal sites of red blood cell entrapment in the spleen are fenestrations in the wall of splenic sinuses, where blood from the splenic cords of the red pulp enters the venous circulation.[40] In the rat spleen, the length and width of these fenestrations, 2 to 3 μm and 0.2 to 0.5 μm, respectively, are approximately one-half the red blood cell diameter. Electron micrographs of spleen show that very few HS red blood cells traverse these slits. Consequently, the nondeformable spherocytes accumulate in the red pulp, which becomes grossly engorged.[41]

Splenic Conditioning and Destruction

Once trapped in the spleen, HS red blood cells undergo additional damage or conditioning marked by further loss of surface area and an increase in cell density, as is evident in cells removed from the spleen at splenectomy.[42,43] Some of these conditioned red blood cells reenter the systemic circulation, as revealed by the "tail" of the osmotic fragility curve, indicating the presence of a subpopulation of cells with a markedly reduced surface area. After splenectomy, this red blood cell population disappears.

Contributions to conditioning may include a relatively low pH in the spleen as well as in the sequestered red blood cells that may further compromise the poor HS red blood cell deformability, and contact of red blood cells with macrophages that may inflict additional damage on the red blood cell membrane. The conditioning effect of the spleen appears to represent a cumulative injury. The average residence time of HS red blood cells in the splenic cords is between 10 and 100 minutes compared to 30 to 40 seconds for normal red blood cells, and only 1% to 10% of blood entering the spleen is temporarily sequestered in the congested cords, whereas the remaining 90% of blood flow is rapidly shunted into the venous circulation.

Inheritance

The HS genes are assigned to several chromosomes, including chromosome 1 (α-spectrin), chromosome 8 (ankyrin), chromosome 14 (β-spectrin), chromosome 15 (protein 4.2), and chromosome 17 (band 3). In approximately two-thirds of HS patients, inheritance is autosomal dominant.[3] In the remaining patients, inheritance is nondominant. In many of these patients, HS is caused by a de-novo mutation,[14,23] which is inherited in an autosomal recessive fashion in subsequent generations.[10,42] Recessively inherited HS cases manifesting with severe hemolytic anemia have been reported. The majority of the affected patients were found to be severely deficient in red blood cell spectrin, associated with α-spectrin defects. The remaining cases characterized by a recessive inheritance pattern are caused by a defect in protein 4.2,[29] deficiency which is associated with relatively mild hemolysis.

Only a few cases of homozygous HS have been reported.[36,44,45] These patients have a severe hemolytic anemia, whereas their mostly consanguineous parents have a mild to moderate form of the disease or are asymptomatic.

Although the clinical severity of HS is highly variable among different kindreds, in general it is relatively uniform within a given family, in which HS is typically inherited as an autosomal dominant disorder. However, HS kindreds have been described in which there was great variability in the clinical severity of affected family members. Several explanations might account for these observations, including variable penetrance of the genetic defect, a de-novo mutation, presence of a mild recessive HS in the kindred, presence of a modifier allele that influences the expression of a membrane protein, or a tissue-specific mosaicism of the defect.[3]
