To test the validity of this approach, an International Study directed by Dr J Armitage sought to determine the applicability and reproducibility of the REAL classification among a group of independent expert pathologists.[4] Other goals included determining the role of immunophenotyping and clinical data in the diagnosis of disease entities and the usefulness of clinical groupings for clinical trials and practice. This study concluded that indeed the REAL classification enhanced diagnostic accuracy and reduced subjectivity on the part of pathologists. Immunophenotyping improved reproducibility and was essential in some specific entities such as most peripheral T cell lymphomas.[5] This study also stressed the importance of clinical factors, such as the International Prognostic Index (IPI), for predicting prognosis and providing a guide to clinical management.[6] Applying the IPI, a wide range of survival was observed across most disease entities. This observation would suggest that it can be misleading to stratify different diseases into risk groups based only on histologic criteria. Moreover, when diseases were grouped according to posttreatment survival (as previously done in the Working Formulation), it was noted that not only were the entities included in each group heterogeneous but also they required markedly different treatment modalities. It became evident that there was a need to approach each disease entity individually considering the diagnosis, the patient's risk factors, and the known idiosyncrasies of each disease with regard to treatment.

Based on these data, the World Health Organization (WHO) adopted the approach of the REAL classification for developing a classification of lymphoid malignancies (List 1)[7]; in addition a Clinical Advisory Committee (CAC) composed of expert hematologists and oncologists was formed to advise the pathologists and confirm the clinical usefulness of the new classification scheme.[8] In 2007 in preparation for a timely revision of the classification, CACs again met in Chicago, IL, and Airlie, VA, to consult on revisions and agreement regarding new entities. The WHO classification recognizes three main categories of lymphoid neoplasms: B-cell neoplasms, T- and NK-cell neoplasms, and Hodgkin lymphoma (HL).

The WHO classification represents a significant achievement in terms of cooperation, communication, and consensus among pathologists, hematologists, and oncologists. Furthermore, it recognizes, as in the REAL classification, that any classification system is an evolving process and should incorporate new data resulting from recent technologic advances in the field of hematopathology and is subjected to periodical review and revisions.

This chapter focuses on the classification of neoplasms derived from mature B cells, T cells, and NK cells with emphasis on malignant lymphomas. We provide a brief review of lymphoblastic malignancies emphasizing the solid-tissue aspects, although these diseases are discussed in greater detail in the chapters of pediatric and adult acute lymphoblastic leukemias, Chapters 62 and 65.

PRECURSOR B-CELL AND T-CELL NEOPLASMS

B-Lymphoblastic Leukemia/Lymphoma

Although most B-lymphoblastic leukemia/lymphoma (B-LBL) present as leukemia, lymphomatous presentations occur in approximately 5% to 10% of cases.[9–11] Frequent sites of involvement include

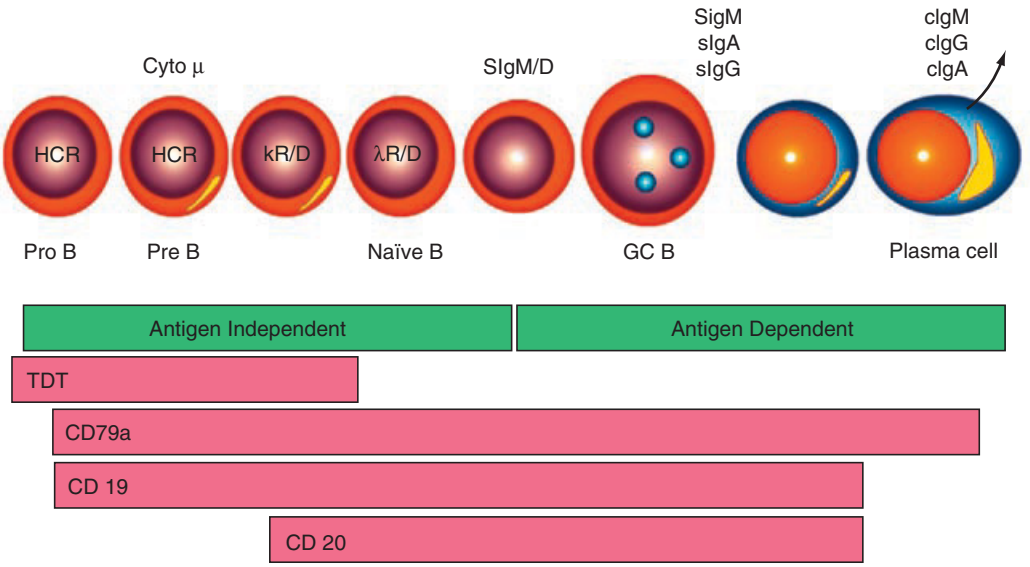

Figure 78–1 B-cell neoplasms relate to different stages of B-cell differentiation. Precursor B-cell lymphomas/leukemias are at an antigen-independent stage of differentiation. CD79a is expressed from early B cells to the plasma cell stage of differentiation. CD20 is acquired at the time of light-chain gene rearrangement. HCR, heavy-chain rearrangement; κR/D, kappa light-chain gene rearrangement/deletion; λR/D, lambda light-chain gene rearrangement/deletion; GC, germinal center; cyto μ, cytoplasmic mu heavy chain.

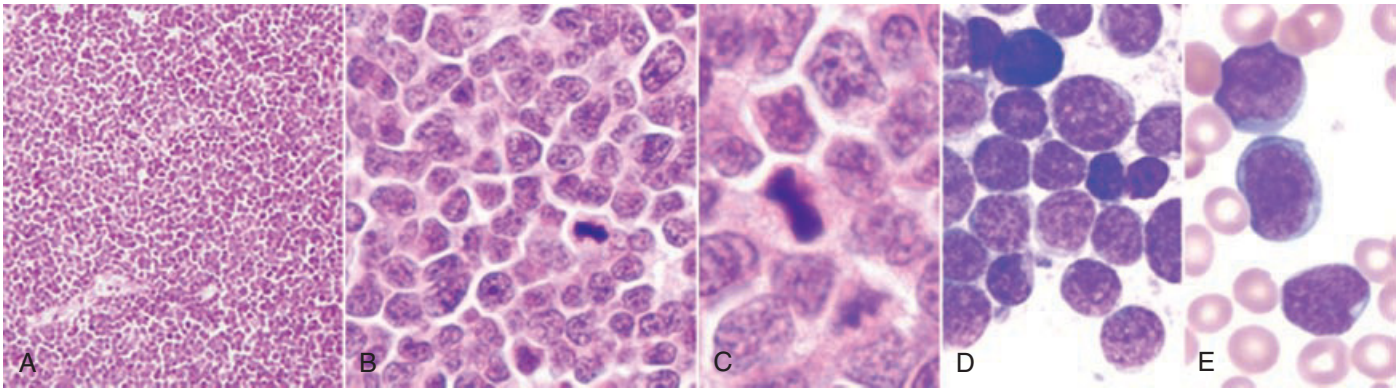

Figure 78–2 Lymphoblastic lymphoma. Low power (**A**) and higher power (**B**) showing a diffuse infiltrate of intermediate-sized cells with high mitotic rate and finely dispersed "blastic" nuclear chromatin (**C**). Touch imprints performed at the time of the biopsy (**D**) illustrate the fact that the lymphoma cells are identical to circulating lymphoblasts seen in acute lymphoblastic leukemia (**E**).

lymph nodes, skin, and bone. Skin lesions in children frequently present in the head and neck region, including the scalp.[9] Progression to leukemia will occur in the vast majority of cases if a complete remission is not obtained. The disease is most common in children and young adults.

Cytologically, it is composed of lymphoblasts that are usually somewhat larger than a small lymphocyte, but smaller than the cells of diffuse large B-cell lymphoma (Fig. 78–2). The cells have finely stippled chromatin with very sparse cytoplasm and inconspicuous nucleoli. The nuclei may be round or convoluted, and the presence or absence of nuclear convolutions is not useful in predicting immunophenotype in lymphoblastic malignancies. Mitotic figures are frequent, in keeping with the high-grade nature of this neoplasm. The differential diagnosis of B-LBL includes the blastic variant of a mantle cell lymphoma (MCL).[12] The clinical presentation is useful in that MCL is much more common in adults. In some cases immunophenotypic studies will be required for the differential diagnosis. The blastic variant of MCL is TDT^- and has a mature B-cell phenotype, in contrast to B-LBL.

Although B-LBLs do not normally express immunoglobulin, other markers of B-cell lineage, such as CD19, PAX5, and CD79a will be present (Fig. 78–1).[13] These antigens are expressed at the time of heavy-chain gene rearrangement, usually indicating commitment to the B-cell lineage. The CD20 antigen is not acquired until the stage of light-chain gene rearrangement, and is expressed in approximately 50% of cases.[14] Thus, pre-B-LBL are often negative for CD20 in paraffin sections. PAX-5, a B-cell transcription factor, is a useful diagnostic marker in CD20-negative ALL[15]; however, it should be noted that PAX-5 is not restricted to B-cell lineage and it has also been described in neuroendocrine carcinomas, in particular Merkel cell carcinoma, which is often in the differential diagnosis of small blue round cell tumors involving the skin.[16]

Both T-and B-LBL may be negative for the leukocyte common antigen (CD45). In addition, they both express CD99, the *MIC2* gene product, in a high proportion of cases. This antigen is expressed in Ewing sarcoma, a nonlymphoid malignancy presenting in children and young adults, often with lytic bone lesions of the distal extremities. Because of potentially overlapping histologic and clinical fea-

tures, an extensive immunohistochemical panel may be required for accurate differential diagnosis.[17]

T-Lymphoblastic Lymphoma/Leukemia

Most T-Lymphoblastic Lymphoma/Leukemias (T-LBLs) are cytologically indistinguishable from their B-cell counterparts. The cells have finely distributed chromatin, inconspicuous nucleoli, and sparse, pale cytoplasm. Nuclear irregularity is variable. This is a disease of adolescents and young adults, with an increased male-to-female ratio. Fifty to 80 percent of patients present with an anterior mediastinal mass, usually with involvement of the thymus gland. This is a high-grade lymphoma; the rapidly growing mass may be associated with airway obstruction. Bone marrow involvement is common, and progression to a leukemic picture will occur in the absence of effective therapy. This tumor also has a high frequency of involvement of the central nervous system. T-LBL is the tissue equivalent of T-cell ALL, although the lymphomatous forms usually exhibit a more mature T-cell phenotype.[18]

In lymph nodes, T-LBL has a diffuse leukemic pattern of infiltration. There is very little stromal reaction, and the cells diffusely infiltrate the lymph node parenchyma. Streaming of cells in the medullary cords may be prominent, especially around vascular structures. A starry sky pattern is seen in approximately one-third of cases. Mitotic figures are readily observed.

By immunophenotypic studies, the cells have an immature T-cell phenotype that correlates with different stages of intrathymic maturation (Fig. 78–3). The earliest T cell-associated antigen with some lineage specificity is CD7. However, it is also expressed in rare cases of acute myeloid leukemia, where it may represent evidence of lineage infidelity, often seen in primitive hematopoietic malignancies. CD3, linked to the T-cell antigen receptor, is expressed in the cytoplasm prior to its presence on the surface and thus may be negative when examined by immunofluorescence techniques on living cells.[19] In this situation, a T-cell LBL may be CD3 positive in tissue sections but negative by routine flow cytometry. However, techniques that permeabilize the cell membrane are available to detect cytoplasmic antigens by flow cytometry. It should be noted that the normal thymocytes encountered in a lymphocyte-rich thymoma are phenotypically similar to the cells of a T-cell LBL. Immunohistochemical analysis are necessary to detect the thymic epithelial cells numerous in the former condition.[20]

The classification of pre-B and pre-T LBL has attained greater precision through the application of gene expression profiling into the various cytogenetic and molecular subtypes.[21,22]

MATURE B-CELL NEOPLASMS

Chronic Lymphocytic Leukemia / Small Lymphocytic Lymphoma

Chronic lymphocytic leukemia / small lymphocytic lymphoma (CLL/SLL) usually presents in adults with generalized lymphadenopathy, frequent marrow and blood involvement, and often hepatosplenomegaly. Presentation as leukemia, that is, CLL, is more common than as lymphoma, SLL. Even in patients with a lymphomatous presentation, careful examination of the blood may disclose a circulating monoclonal B-cell component. Nevertheless, there are some patients who will present with generalized lymphadenopathy, and whereas progression to leukemia is frequent, it does not necessarily occur in all cases.[23]

Histologically, the lymph nodes involved by CLL/SLL show diffuse architectural effacement (Fig. 78–4), although occasional residual naked germinal centers may be present. In this regard, the process may simulate a mantle cell lymphoma, but usually can be readily distinguished from MCL on cytologic grounds. The predominant cell is a small lymphocyte with clumped nuclear chromatin, but a spectrum of nuclear morphology is generally seen. Pseudofollicular growth centers or proliferation centers are present in the majority of cases and contain a spectrum of cells ranging from small lymphocytes to larger prolymphocytes and paraimmunoblasts. The prolymphocytes and paraimmunoblasts have somewhat more dispersed chromatin and usually centrally placed prominent nucleoli.

In some cases, the small lymphoid cells may show nuclear irregularity. This feature has caused confusion with mantle cell lymphoma. However, the presence of pseudofollicles and paraimmunoblasts argues strongly in favor of a diagnosis of CLL/SLL over MCL. It has been shown that cases with cleaved nuclear morphology and pseudofollicles retain the indolent clinical behavior of CLL/SLL and not the more aggressive clinical course of MCL.[24,25] If needed, immunophenotypic studies can be helpful in this differential diagnosis. CLL/SLL is characterized by CD5$^+$, CD23$^+$, B cells expressing dim CD20, and usually dim surface immunoglobulin (sIg).[26] The absence of staining

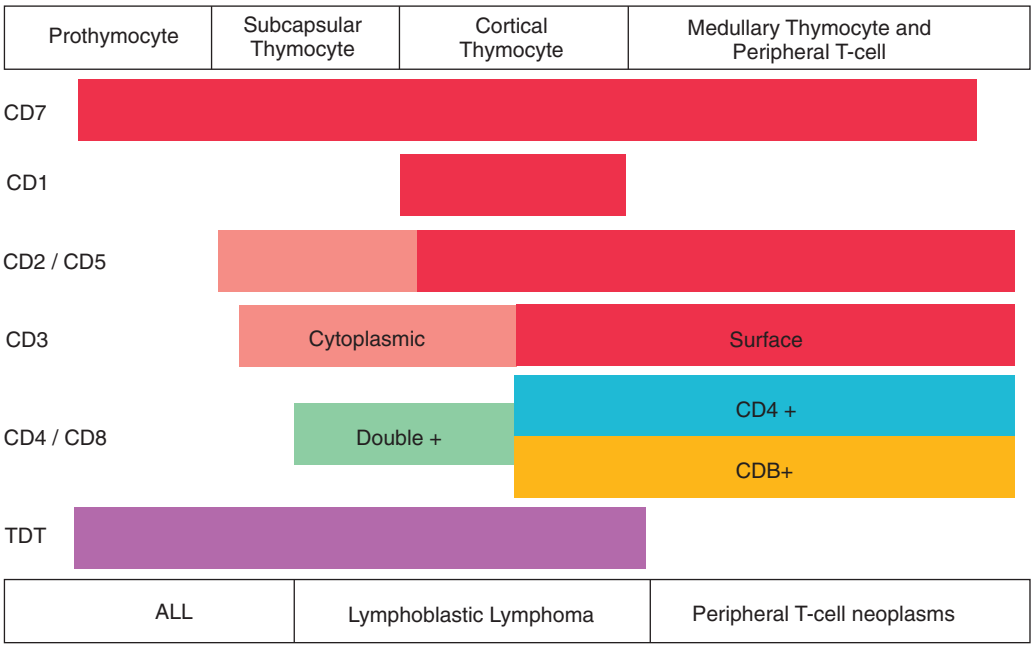

Figure 78–3 T-cell neoplasms related to stages of T-cell differentiation. ALL, acute lymphoblastic leukemia.

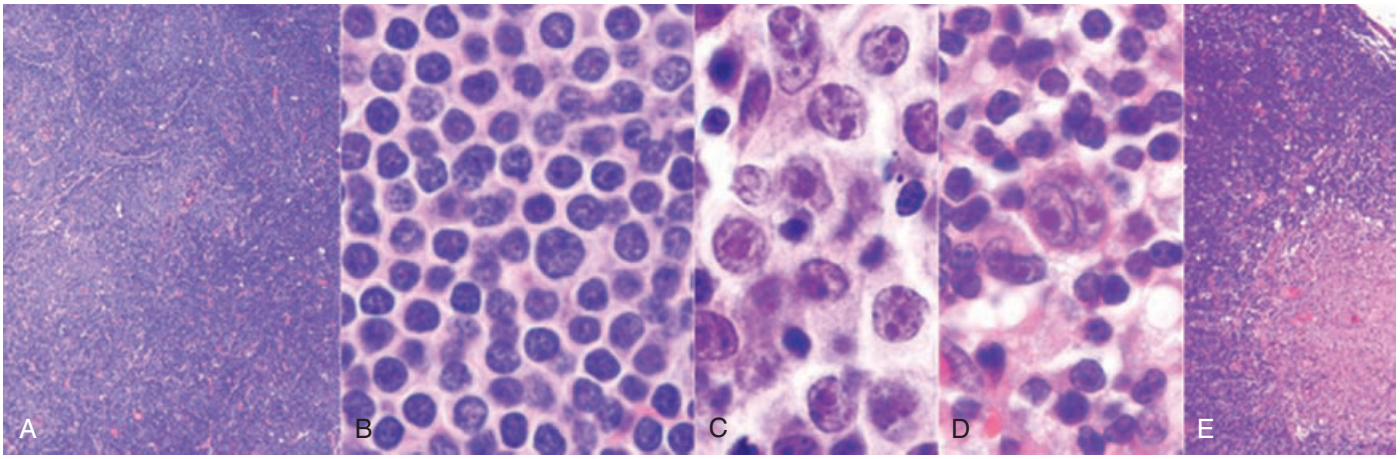

Figure 78–4 Small lymphocytic lymphoma (SLL). Low power illustrates a diffuse effacement of the lymph node. A monotonous population of small lymphocytes is seen at higher power (**B**). These have fairly round nuclear contours, condensed nuclear chromatin, and inconspicuous or absent nucleoli. Only rare larger cells are present. SLL can transform to large cell lymphoma (**C**) and occasionally to Hodgkin lymphoma (**D**). Patients can also develop worsening lymphadenopathy as a result of viral infections such as Herpes Simplex Virus, where the node typically shows focal necrosis (**E**).

Table 78–1 Differential Diagnosis of "Small" B-Cell Lymphomas

Disease	CD5	CD10	CD23	CD43	Cyclin D1	Ig Class
FL	–	+	+/–	–	–	IgM, IgG
MCL	+	–	–	+	+	IgM/IgD
CLL/SLL	+	–	+	+	–	IgM/IgD
LPL	–	–	–	+/–	–	IgM (c)
MALT	–	–	–	+/–	–	IgM (c, s)
SMZL	–	–	–	–	–	IgM/IgD
HCL	–	–	–	–	–/+	IgG

c, cytoplasmic Ig; CLL/SLL; chronic lymphocytic leukemia/ small lymphocytic lymphoma; FL, follicular lymphoma; HCL, hairy cell leukemia; Ig class, most commonly expressed heavy-chain classes; LPL, lymphoplasmacytic lymphoma; MALT; marginal-zone lymphoma of MALT type; MCL, mantle cell lymphoma; s, surface Ig; SMZL; splenic marginal zone lymphoma.

for cyclin D1 can help rule out the diagnosis of MCL (Table 78–1).[27] CLL has been shown to be heterogeneous with respect to somatic mutation of the VH genes, and a similar heterogeneity has been identified in SLL.[28] The use of flow cytometry and immunohistochemistry for ZAP70 is a partial surrogate for mutation status; ZAP-70 expression correlates with an unmutated status and poorer prognosis.[29–31] In fact, ZAP70 expression has been suggested to be more clinically relevant than mutation status, when the two markers are discordant. The use of CD38 as surrogate marker for mutational status is less useful, but its high expression is also associated with a poor prognosis.[32] Cytogenetic abnormalities also occur in a subset of patients and also correlate with mutational status and prognosis.[33] Mutations in micro-RNAS have recently been described in CLL and also are associated with an adverse prognosis.[34]

Histologic transformation over time may occur in CLL, a phenomenon known as Richter syndrome.[35] Short of progression to diffuse large B-cell lymphoma (DLBCL), lymph nodes may show increased numbers of prolymphocytes and paraimmunoblasts. A Hodgkin-like transformation has also been described in CLL/SLL. This transformation can take one of two forms. In some cases, Reed–Sternberg (RS) cells and mononuclear variants are seen in a background of small round B lymphocytes, consistent with CLL.[36] The process lacks the rich inflammatory background characteristic of Hodgkin lymphoma, such as eosinophils, plasma cells, and histiocytes. However, patients with this type of Hodgkin transformation appear to progress to a process that is more typical of Hodgkin lymphoma, with loss of the B-cell small lymphocytic component. In other instances, classical Hodgkin lymphoma of the mixed cellularity or nodular sclerosis subtype may be seen in patients with a history of CLL.[37] Studies have implicated Epstein–Barr virus (EBV) in the Hodgkin type of Richter transformation.[38] The RS cells and variants are EBV^+ and in some cases have been shown to be derived from the CLL clone.[39] In other instances, diverse clonal origins are shown.[40,40a]

In some cases of CLL/SLL, limited plasmacytoid differentiation may occur.[41] The overall cytology may resemble that of CLL/SLL, but the cells contain moderate amounts of cytoplasmic immunoglobulin. In such cases, a small monoclonal immunoglobulin spike may be detected in the serum. These cases conform to the lymphoplasmacytoid subtype of immunocytoma in the Kiel classification.[42] However, because such cases retain the immunophenotype of classical CLL, they are regarded in the WHO classification as a variant of CLL.[43]

Lymphoplasmacytic Lymphoma

This lymphoma subtype conforms in most cases to the clinical picture of Waldenstrom macroglobulinemia. This is a disease of adult life that usually presents with generalized lymphadenopathy, vague constitutional symptoms, anemia, and splenomegaly. Autoimmune hemolytic anemia is a common complication. Peripheral blood involvement with an absolute lymphocytosis is less common in lymphoplasmacytic lymphoma (LPL) than in B-cell CLL/SLL. IgM monoclonal gammopathy may be associated with increased serum viscosity leading to neurologic and vascular complications.[44] However, this phenomenon may also be observed in other lymphomas. The course is chronic and indolent and the disease is not generally curable with available treatment. Waldenstrom macroglobulinemia is associated with a significant familial disposition,[45] although this does not appear to hold true for all low-grade B-cell lymphomas with plasmacytic differentiation. The tumor consists of a diffuse proliferation of small lymphocytes, plasmacytoid lymphocytes (cells with abundant basophilic cytoplasm but lymphocyte-like nuclei), and plasma cells, with or without Dutcher bodies. The growth pattern is often interfollicular with sparing of the sinuses.[46]

The neoplastic cells have surface and cytoplasmic Ig, usually of IgM type, usually lack IgD, and express B cell-associated antigens (CD19, 20, 22, 79a), $CD5^-$, $CD10^-$, $CD43^{+/-}$; CD25 or CD11c may be faintly positive in some cases.[42,47–49] Lack of CD5 and the presence of strong cIg are useful in distinction from CLL.

Deletion of 6q21–22.1 are confirmed in most WM patients in the marrow[50]; however, these deletions were not confirmed in nodal cases.[51] The postulated normal counterpart is thought to be a memory

B cell,[49,52] based in part on the presence of somatic mutations in the Ig heavy- and light-chain variable region genes.[53] New, interesting gene expression profiling data suggest that WM has a relatively homogeneous profile and is more closely related to CLL than multiple myeloma.[54] The identification of interleukein-6 (IL-6) by this technique as a distinctive marker for WM provides additional support to the clinical observation of increased levels of serum IL-6 in these patients and its association with disease severity and tumor burden.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is a distinct entity that has been more precisely defined in recent years through the integration of immunophenotypic, molecular genetic, and clinicopathologic studies. Early on it was noted that this tumor tended to surround residual naked germinal centers, and a derivation from the follicular lymphoid cuff was postulated.[55,56] Tumors with a very conspicuous mantle zone pattern of growth were also termed "mantle zone lymphoma."[57]

Mantle cell lymphoma occurs in adults (median age 62), with a high male-to-female ratio. Most patients present with advanced stage at diagnosis.[58–61] Common sites of involvement include lymph nodes, spleen, bone marrow, and lymphoid tissue of Waldeyer ring. Gastrointestinal tract involvement is frequent and is associated with the picture of lymphomatous polyposis.[62] The hallmark of MCL is a very monotonous cytologic composition. In the typical case, the cells are slightly larger than a normal lymphocyte with finely clumped chromatin, scant cytoplasm, and inconspicuous nucleoli (Fig. 78–5). The nuclear contour is usually irregular or cleaved. Some cytologic variants, blastoid (blastic) and pleomorphic, tend to be associated with a more aggressive course, and adverse biological features, such as tetraploidy or p53 mutation/deletion.[12,63,64] However, because of the overall poor prognosis and the lack of statistical significance of these cytologic changes, the WHO classification considers mantle cell lymphoma and its variants as one group.[7,27] The use of morphologic variants is optional. The variant with the greatest clinical significance is the blastoid or blastic form. A high mitotic rate and high proliferative index have been found to be an adverse prognostic indicator.[65] More recently, a proliferation signature identified by gene expression profiling of MCL was shown to correlate with survival[66]; this signature has been further refined by quantitative gene expression study.[67]

Immunophenotypic and genotypic studies have been helpful in precisely defining MCL. The immunophenotype is distinctive (IgM/IgD$^+$, CD5$^+$, CD10$^-$, and CD23$^-$). The postulated normal counterpart is the CD5$^+$ "virgin" B cell, IgM$^+$, and IgD$^+$ that can be found in the blood and in the mantle of reactive germinal centers. Mutational analysis of the rearranged immunoglobulin variable region genes shows few or no somatic mutations.[68]

The chromosomal translocation t(11;14) involving *CCND1* is associated with MCL but absent in most other low-grade and high-grade B-cell malignancies.[69,70] By Northern analysis, virtually 100% of cases of MCL have shown overexpression of cyclin D1.[71,72] However, rare cyclin D1-negative cases with otherwise identical features have been identified.[73] Additional alterations involving other cell cycle regulatory molecules such as RB, p53, and CDK inhibitors (p16 and p27) have been described in the more aggressive forms of MCL.[63,74–78]

Follicular Lymphoma

Follicular lymphoma (FL) is the most common subtype of non-Hodgkin lymphoma within the United States and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades, and is rare under the age of 20. Men and women are equally affected. FL is less common in black and Asian populations. Most patients have stage 3 or 4 disease at diagnosis, with generalized lymphadenopathy.[79] Staging evaluation will usually detect bone marrow involvement. Approximately 10% of patients will have circulating malignant cells.[80] However, careful immunophenotypic or molecular analyses may disclose peripheral blood involvement in a higher proportion of patients.[81] A more accurate prognostic index than the IPI, which was originally designed for aggressive B-cell lymphomas, has been recently proposed[82] and it has become widely accepted as a more accurate predictive measure for FL.

The natural history of the disease is associated with histologic progression in both pattern and cell type (Fig. 78–6). A heterogeneous cytologic composition is one of the hallmarks of FL. Usually, all of the follicle center cells are represented, but in varying proportions.[83] It should be stressed that the variation in cytologic grade is a continuum, and therefore precise morphologic criteria for subclassification are difficult to establish. Most studies have shown that sub-

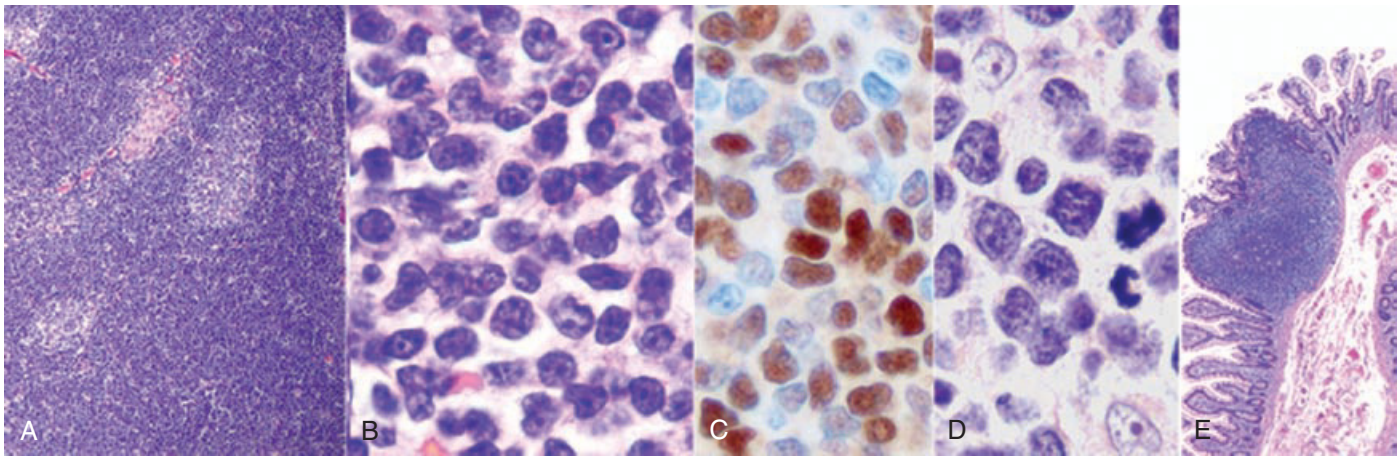

Figure 78–5 Mantle cell lymphoma (MCL). At low power mantle cell lymphoma can show a diffuse, vaguely nodular, or a mantle zone pattern. In the latter, the neoplastic mantle zones are expanded and can become confluent, leaving "naked" germinal centers (**A**). At higher power, the lymphoma cells are small or slightly enlarged. They have irregular nuclear contours, especially compared to SLL, and a dense chromatin. (**B**) Typically cases are positive for cyclin D1 expression (**C**) which is related to the t(11;14) involving IgH and *CCND1*. Some cases can develop a "blastoid" transformation (**D**), although some cases can present as a blastoid variant. Such cases are characterized by cells with an intermediate size, a high mitotic rate, and finely dispersed blastic chromatin. Sometimes when the blastoid cases develop a leukemic phase, they can be difficult to distinguish from ALL, morphologically. Flow immunophenotyping is needed to resolve the differential. Mantle cell lymphoma can also present with gastrointestinal involvement (**E**) as in lymphomatoid papulosis.

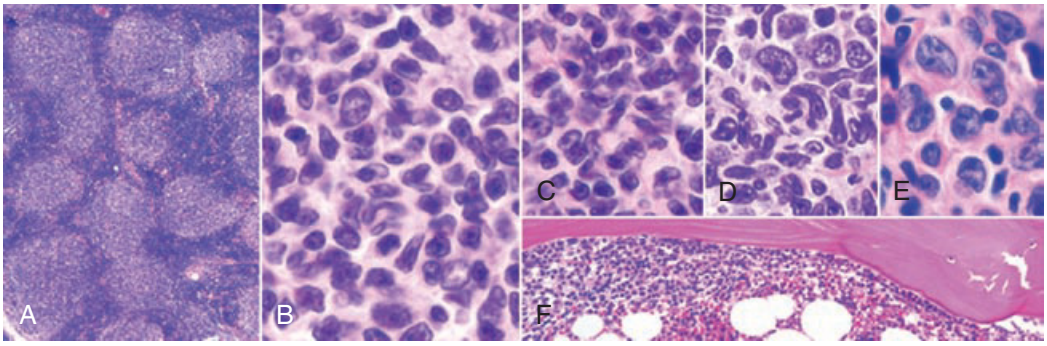

Figure 78–6 Follicular lymphoma (FL). Follicular lymphoma shows effacement of the normal lymph node architecture because of an accumulation of neoplastic lymphoid follicles that lack the features of reactive follicles (**A**). They are crowded, show back-to-back localization, lack distinct mantle zones, and show no polarity. The lymphoma cells are highly irregular (**B**) with elongated, twisted, or clefted nuclear contours and dense chromatin. Follicular lymphoma is typically graded into grade 1, 2, or 3 (**C**, **D**, and **E**) depending on the number of large cells seen at higher power (see text). Follicular lymphoma typically involves the bone marrow, with lymphoma cells spreading along the bone (**F**). This localization is termed "para-trabecular."

classification of follicular lymphoma is difficult to reproduce among groups of pathologists.

The current WHO classification (using the Mann/Berard method) maintains three major grades: grade 1 (<5 centroblasts/high power field [hpf]); grade 2 (5–15 centroblasts/hpf); grade 3 (>15 centroblasts/hpf).[84] In addition, grade 3 FL is further subdivided into grade 3a (>15 centroblasts/hpf, but centrocytes still present) and grade 3b (solid sheet of centroblasts). Recent studies indicate that FL grade 3b may be more closely related to DLBCL.[85,86] These data might provide a biological explanation for the greater curability of grade 3 FL with aggressive therapy,[87] although other studies have not found support for this hypothesis.[88] Differences in diagnostic criteria might account for this apparent discrepancy. In light of the significance of clinical and possibly genetic factors in the prognosis of FL, histologic grading is assuming less importance in clinical trials and clinical practice.[4,89,90]

The vast majority of FL (approximately 85%) are associated with a t(14;18) involving rearrangement of the *BCL2* gene.[91] This translocation appears to result in constitutive expression of Bcl-2 protein, which is capable of inhibiting apoptosis in lymphoid cells.[92] The cells of FL accumulate and are at risk to acquire secondary mutations, which may be associated with histologic progression. The proportion of FL expressing Bcl-2 protein varies with histologic grade, and is lowest in grade 3 FL.[93] It has been postulated that the *BCL2/JH* translocation occurs during immunoglobulin gene rearrangement in the bone marrow at the pre-B cell stage of development. This fact might contribute to the difficulty in eradicating the neoplastic clone with chemotherapy. However, more recent studies have suggested that the *BCL2/JH* translocation might occur in a mature B cell within the germinal center.[94,95] In some instances, FL may be restricted to isolated germinal centers within a lymph node, termed an in situ pattern of localization.[95] This pattern may be seen with FL at other sites of disease, or the only manifestation of disease in some patients. The risk for progression in this latter group is not fully established, but it appears that in some cases the *BCL2*/JH translocation is necessary but not sufficient for the development of FL. Indeed, this translocation can be found in the peripheral blood and lymphoid organs of healthy individuals.[96,97]

The cells have a mature B-cell phenotype with expression of the B-cell antigens CD19, CD20, and CD22. SIg is positive, with most commonly expression of IgM, but IgG or IgA can be seen in many cases. CD10 is positive but CD5 is negative.[98] The presence of CD10 in the interfollicular region can be a diagnostic clue, as this pattern is not seen in normal lymph nodes.[99] As evidence of the germinal center origin of FL, Bcl-6 is nearly always expressed.[100]

Follicular lymphoma was one of the first lymphomas for which an immunophenotypic derivation from a normal lymphoid equivalent was shown[98,101,102] and represent the neoplastic counterpart of the reactive germinal center cells.[103] Consistent with their normal counterpart, intraclonal heterogeneity with a high number of somatic mutations and ongoing mutations of the Ig genes was detected in these cells (Fig. 78–7).[104] In addition, the complexity of the reactive germinal center and the different components lend support to the data obtained from gene expression profiling in nodal FL on the prognostic implication of the accompanying immune cells.[105]

Most cases of FL present in lymph nodes. A subset of cases with the morphologic features of FL may present in skin.[106] Clinically, these tumors are usually localized and infrequently associated with lymph node involvement; cytologically they are predominantly composed of large centrocytes. They have an excellent prognosis, and complete remissions may be obtained with either surgical excision or local radiation therapy.[107,108] Interestingly, these cutaneous FL frequently lack the *BCL2* translocation associated with nodal FL. For these reasons both the WHO classification and the WHO-EORTC classification for cutaneous lymphoma consider this a separate variant, primary cutaneous follicle center lymphoma.[7,109]

Other unusual variants of FL have been described. There is a form of FL involving the intestinal mucosa that is often localized, with risk of local recurrence but low risk of dissemination. These cases are generally Bcl-2 protein positive and positive for the *BCL2/JHR*.[110–112] They appear to represent another form of in situ FL, because in most patients the polypoid lesions remain confined to the intestinal mucosa, without progression.

Although FL are generally rare in children, the nasopharyngeal and palatine tonsils and the gastrointestinal tract are among the most common sites of follicular lymphomas in children.[113,114] In contrast to follicular lymphomas in adults, these tumors are usually Bcl-2 protein negative and lack *BCL2* gene rearrangements. They are typically grade 3, with a predominance of centroblasts and a high mitotic rate. Pediatric FL may also present as an isolated testicular mass.[115] Follicular lymphoma in the pediatric age group is probably a biologically distinct disease.

Extranodal Marginal-Zone B-Cell Lymphoma of Mucosa-Associated Lymphoid Tissue Type

Most lymphomas of marginal-zone derivation present in extranodal sites and have the histopathologic and clinical features identified by Isaacson and Wright as part of the spectrum of mucosa-associated lymphoid tissue (MALT) lymphomas.[116,117] MALT lymphomas are characterized by a heterogeneous cellular composition that includes marginal-zone or centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells (Fig. 78–8A). In most cases, large transformed cells are infrequent. Reactive germinal centers are nearly always present. Therefore, it is not surprising that based on the heterogeneous cellular composition and presence of reactive follicles,

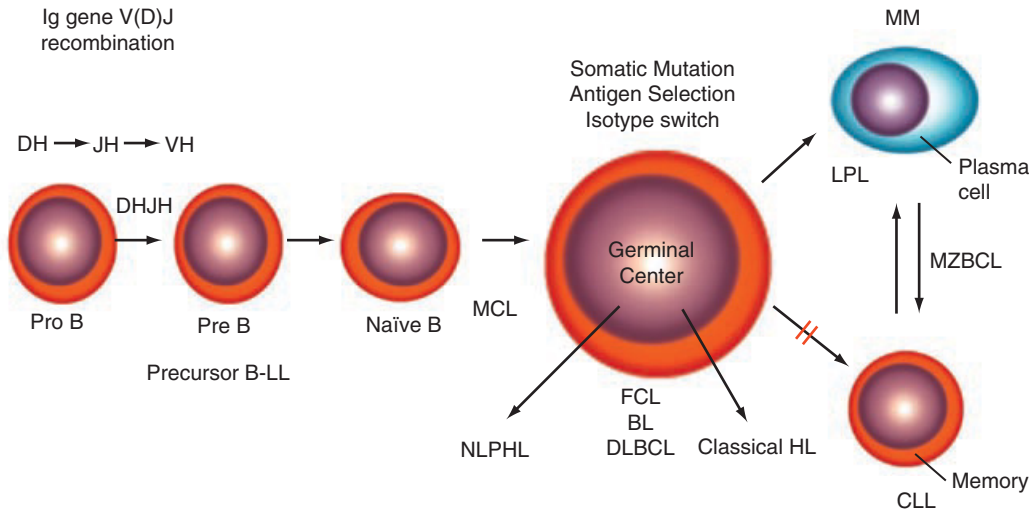

Figure 78–7 B-cell differentiation scheme and associated B-cell neoplasms. Precursor B-LL, precursor B-cell lymphoblastic lymphoma/leukemia; MCL, mantle cell lymphoma; FL, follicular lymphoma; BL, Burkitt lymphoma; DLBCL, diffuse large B-cell lymphoma; NLPHL, nodular lymphocyte-predominant Hodgkin lymphoma; MM, multiple myeloma; MZBCL, marginal-zone B-cell lymphoma; CLL, chronic lymphocytic leukemia.

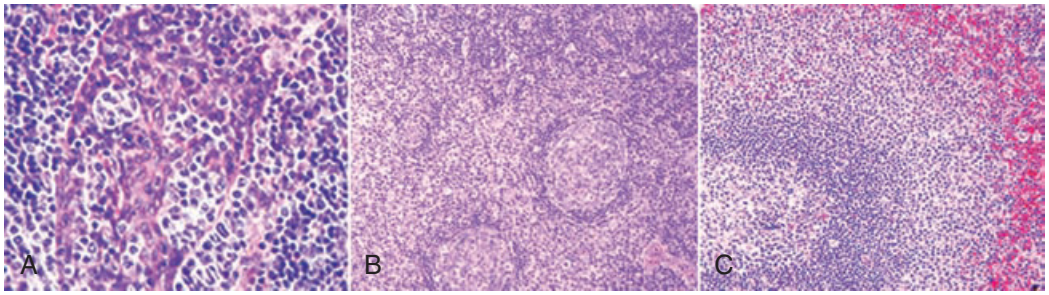

Figure 78–8 Marginal-zone lymphoma. Marginal-zone lymphomas commonly occur at extranodal sites from mucosa associated lymphoid tissue (MALT). MALT-lymphomas are composed of small- to intermediate-sized cells with abundant cytoplasm. These typically infiltrate or invade into epithelial structures resulting in lymphoepithelial lesions (**A**). Normal lymph nodes do not have a marginal zone, but primary nodal marginal-zone lymphomas (NMZL) can occur. They infiltrate the node in what would be a marginal-zone (peripheral to mantle cells) pattern (**B**). The spleen does have a normal marginal zone, and this can give rise to a splenic marginal-zone lymphoma (SMZL). Early on, these show expansion of the marginal-zone areas (**C**) but later can become more diffuse, infiltrating the red pulp. In the case illustrated, the spleen weighed 1700 g.

most MALT lymphomas were diagnosed in the past as pseudolymphomas or atypical hyperplasias. However, recent studies have shown the majority to be composed of monoclonal B cells. The follicles usually contain reactive germinal centers, but the germinal centers may become colonized by neoplastic cells. When follicular colonization occurs, the process may simulate follicular lymphoma.[118] The plasma cells are usually found in the subepithelial zones and are monoclonal in up to 50% of cases.

MALT lymphomas have been described in nearly every anatomic site but are most frequent in the stomach, lung, thyroid, salivary gland, and lacrimal gland.[52,119] Other less common sites of involvement include the orbit, breast, conjunctiva, bladder and kidney, and thymus gland.[120] Most patients present with localized disease, although regional lymph node involvement is common in gastric and salivary gland MALT lymphoma. The involved lymph nodes in those cases resemble monocytoid B-cell lymphoma, and it is thought that monocytoid B-cell lymphoma is the nodal equivalent of a MALT lymphoma.[121–124] Widespread nodal involvement is infrequent, as is marrow involvement. The clinical course is usually quite indolent, and many patients are asymptomatic. MALT lymphomas tend to relapse in other MALT-associated sites.[52]

MALT lymphomas of the salivary gland and thyroid are usually associated with a history of autoimmune diseases. Helicobacter gastritis is frequent in most patients with gastric MALT lymphomas, and it has been suggested that antigen stimulation is critical to both the development of a MALT lymphoma and the maintenance of the neoplastic state.[125] Indeed antibiotic therapy and eradication of *Helicobacter pylori* has led to the spontaneous remission of gastric MALT lymphoma in some cases.[126] Antibiotic treatment is currently advocated as first-line therapy. However, the therapy of MALT lymphomas is still controversial. Isolated lesions readily amenable to surgical excision should be removed. Systemic chemotherapy may be warranted for more widespread disease, and local radiation therapy may play a role in the control of localized tumor masses, especially for gastric and orbital MALT lymphomas.

Immunophenotype is helpful in the differential diagnosis of MALT lymphomas from cytologically similar lymphomas such as CLL/SLL and MCL. MALT lymphomas are positive for B cell-associated antigens CD19, CD20, and CD22 but are negative for CD5, in contrast to most systemic small lymphocytic malignancies. The absence of cyclin D1 is useful in ruling out MCL, especially in intestinal disease. Rare cases of MALT lymphoma have been reported to be CD5-positive, and in some but not all instances this has been associated with more aggressive disease.[127–129]

MALT lymphomas also have a commonly recurring cytogenetic abnormality the t(11;18) observed in 50% of extranodal cases.[130–133] The genes involved in the translocation have been identified as *CIAP2 (BIRC3)*, a gene encoding for an inhibitor of apoptosis, and a novel gene on 18q21 named *MALT1* (of unknown function).[134] It has been speculated that the fusion protein may lead to increased inhibition of apoptosis conferring a survival advantage to the neoplastic cells.[134] The t(1;14) involving *BCL10* is more infrequent.[135]

However, both translocations appear to result in overexpression of BCL-10 in the neoplastic cells and are thought to activate the NF-κB pathway.[136,137] Another translocation has been recently identified involving the *MALT1* gene and the immunoglobulin heavy-chain gene. This translocation, t(14;18)(q32;q21), appears to be absent in gastric MALT lymphoma, but may be more common in MALT lymphomas presenting in the ocular adnexae, liver, and skin.[138]

The translocation t(11;18)(q21;q21) is associated exclusively with low-grade extranodal MALT and it is not detected in cases with simultaneous low- and high-grade tumors or in "primary" extranodal large cell lymphomas, raising the question of whether these primary extranodal lymphomas are in fact related to low-grade MALT.[133,139–141] The WHO Clinical Advisory Committee recommended that the term high-grade MALT not be used for extranodal large cell lymphomas in a "MALT" site, and in fact stated that this term should be avoided because of its ambiguity.[142] The clinical significance of increased transformed cells is still uncertain.[143] The putative cell of origin of MALT lymphoma is a memory B cell (post–germinal center).[144,145]

Nodal Marginal-Zone B-Cell Lymphoma

The existence of primary nodal marginal-zone B-cell lymphoma (NMZL) has been controversial, with many cases representing secondary involvement by extranodal MALT lymphomas.[146–148] However, the existence of the primary extranodal disease may not be immediately apparent. Relapses in nodal sites may occur many years after primary diagnosis. However, in recent years there are several well-documented reports of primary nodal lymphomas with features of MZL.[149,150] These patients often have marrow involvement and tend to have a more aggressive clinical course than extranodal MALT.[147,149,150]

The neoplastic proliferation is polymorphous and composed of monocytoid B cells, plasmacytoid cells, with interspersed large blast-like cells. There is an expansion of the marginal-zone area, often with preservation of the nodal architecture (see Fig. 78–8B). The mantle zone may be intact, attenuated, or effaced.[146]

The immunophenotype is similar to other MZL, that is, $CD20^+$, CD5, $CD10^-$, with variable expression of IgD (weak to negative). Some nodal MZL have a morphology and immunophenotype similar to that of splenic MZL (see Splenic Marginal Zone Lymphona). These cases are IgD positive.[146] Because there are no precise immunophenotypic or genotypic markers of NMZL, the diagnosis is sometimes one of exclusion. A continuing problem is the differential diagnosis with LPL, which has overlapping morphologic and immunophenotypic features.[46] The presence of marked plasmacytic differentiation with prominent Dutcher bodies favors LPL. Clinical correlation is important in this distinction.

A morphologically similar but biologically distinct phenomenon is monocytoid B-cell differentiation in a primary nodal lymphoma. Cells resembling monocytoid B lymphocytes have been described in many low-grade lymphomas, most commonly FCL.[151] The monocytoid B-cell component appears to occupy the marginal zone. Nevertheless, the immunophenotype and genotype of the neoplastic cells is that of FCL. Monocytoid differentiation is an interesting morphologic variant, but does not yet have proven clinical or biological significance. One study suggested that cases with MZL differentiation have a more aggressive clinical course,[152] but these results have not yet been confirmed.

Splenic Marginal-Zone Lymphoma

Splenic marginal-zone lymphomas (SMZLs) present in adults and are slightly more frequent in females than males.[153] The clinical presentation is splenomegaly, usually without peripheral lymphadenopathy. The majority of patients have marrow involvement, but there is usually only a modest lymphocytosis, with elevations in the lymphocyte count usually less than that seen in CLL. Some evidence of plasmacytoid differentiation may be seen and patients may have a small M component. The abundant pale cytoplasm evident in tissue sections may also be seen in blood smears. The cytologic features may be mistaken for hairy cell leukemia. The disorder described as splenic lymphoma with villous lymphocytes (SLVL) appears closely related to SMZL.[154,155] The course is reported to be indolent, and splenectomy may be followed by a prolonged remission.[156]

Histologically, the spleen shows expansion of the white pulp, but usually some infiltration of the red pulp is present as well.[157–160] In early cases, preferential involvement of the marginal zone may be seen with residual mantle cells present (see Fig. 78–8C).[161] A characteristic

World Health Organization Classification of Lymphoid Tumors*

B-Cell Neoplasms
B-cell lymphoblastic leukemia/lymphoma
Chronic lymphocytic leukemia/small lymphocytic lymphoma
B-cell prolymphocytic leukemia
Lymphoplasmacytic lymphoma
Mantle cell lymphoma
Follicular lymphoma
Primary cutaneous follicle center lymphoma
Marginal-zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT)-type
Nodal marginal-zone B-cell lymphoma
Splenic marginal-zone B-cell lymphoma
Hairy cell leukemia
Diffuse large B-cell lymphomas
Subtypes: mediastinal (thymic), T-cell/ histiocyte-rich large B-cell lymphoma, intravascular, primary effusion lymphoma, plasmablastic, ALK^+ large B-cell lymphoma, primary cutaneous diffuse large B-cell lymphoma, leg-type.
Burkitt lymphoma
Plasmacytoma
Plasma cell myeloma

T-Cell Neoplasms
T-cell lymphoblastic leukemia/lymphoma
T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Aggressive NK-cell leukemia
Hepatosplenic T-cell lymphoma
Extranodal NK- and T-cell lymphoma, nasal type
Angioimmunoblastic T-cell lymphoma
Peripheral T-cell lymphoma (unspecified)
Adult T-cell leukemia/lymphoma
Anaplastic large cell lymphoma, ALK-positive
Anaplastic large cell lymphoma, ALK-negative
Enteropathy-associated intestinal T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Primary cutaneous gamma-delta T-cell lymphoma
Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders
Lymphomatoid papulosis
Primary cutaneous anaplastic large cell lymphoma
Mycosis fungoides
Sezary syndrome

Hodgkin Lymphoma
Nodular lymphocyte-predominant Hodgkin lymphoma
Classical Hodgkin lymphoma
Hodgkin lymphoma, nodular sclerosis
Classical Hodgkin lymphoma, lymphocyte-rich
Hodgkin lymphoma, mixed cellularity
Hodgkin lymphoma, lymphocytic depletion

*Includes updates proposed in the WHO-EORTC classification of cutaneous lymphomas (2005).[109]

biphasic pattern in the neoplastic white pulp has been described,[155] in which a peripheral zone of larger cells that resembles marginal-zone cells surrounds a central zone of small lymphocytes. In this instance, the residual polytypic mantle is no longer present. Progression to diffuse large B-cell lymphoma, often involving the spleen, can be seen.[162]

In the marrow, large ill-defined non-paratrabecular aggregates are seen. A characteristic feature is the propensity of the neoplastic cells to infiltrate marrow sinusoids.[158] Splenic hilar lymph nodes usually show diffuse infiltration, often with preservation of lymph node sinuses.

Immunophenotypic studies are useful in distinguishing SMZL from CLL/SLL involving the spleen. Whereas typical CLL/SLL are $CD5^+$, SMZL are $CD5^-$.[160] Careful attention to the cytologic features in these cases indicates that the cells have somewhat more abundant cytoplasm than those of typical CLL/SLL and resemble the lymphocytes of the normal splenic marginal zone. The nuclei are usually predominantly round but may be slightly irregular. They have a moderate amount of pale cytoplasm. The phenotype of these cells resembles the other marginal-zone B-cell lymphomas; however, the IgD expression is more frequently positive.[158]

Although the molecular pathogenesis of SMZL has not been delineated, a frequent cytogenetic alteration involving deletions of the region 7q 22-32 is seen.[153,163] Studies of the Ig variable genes have also revealed the presence of mutations suggesting a postfollicular origin,[145,164] but variations in this profile have been observed.[165]

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) is one of the more common subtypes of non-Hodgkin lymphoma, representing up to 40% of cases. It has an aggressive natural history but responds well to chemotherapy. The complete remission rate with modern regimens is 75% to 80%, with long-term disease-free survival approaching 50% or more in most series.[166] This lymphoma may present in lymph nodes or in extranodal sites. Frequent extranodal sites of involvement include bone, skin, thyroid, gastrointestinal tract, and lung.

Because there is variation in the responsiveness to chemotherapy, and because large B-cell lymphoma is one of the more common subtypes, there has been great interest over the years in identifying morphologic or immunophenotypic features that might be prognostically important. In most studies there is the suggestion that tumors composed predominantly of centroblasts have a better prognosis than those composed predominantly of immunoblasts.[79,167,168] However, the differences have not been consistently reproducible, possibly reflecting diverse criteria for the designation of a lymphoma as immunoblastic. At present, although morphologic features are useful in identifying the spectrum of appearances that one may encounter diagnostically, morphologic features do not appear to be important prognostically.

DLBCLs are composed of large, transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (see Fig. 78–9A,B). The nuclei generally have vesicular chromatin, prominent nucleoli, and basophilic cytoplasm, resembling the centroblasts of the normal germinal center. Marked variation in the nuclear contour may be seen, and the cells may be polylobated or cleaved.[169] The immunoblastic variant is characterized by cells with prominent central nucleoli, and abundant deeply staining cytoplasm. According to the Kiel classification, 90% of the cells must have this appearance for the tumor to be classified as immunoblastic in type.[170]

T-cell/histiocyte-rich large B-cell lymphoma is a morphologic variant of DLBCL. It has been associated with aggressive clinical behavior, and often presents with advanced stage and bone marrow involvement.[171,172–174] It may mimic classical Hodgkin lymphoma, or even peripheral T-cell lymphoma.[175] Some cases appear related to nodular lymphocyte-predominant Hodgkin lymphoma, with the neoplastic cells being epithelial membrane antigen (EMA)-positive and having a popcorn-like morphology.[176]

Cutaneous lymphomas differ in some respect from lymphomas in other sites.[109,177] Primary cutaneous follicle center lymphomas may be composed predominantly of large B cells in some cases but nevertheless have an indolent clinical course. By contrast, the entity primary cutaneous diffuse large B-cell lymphoma, leg-type, is clinically more aggressive.[178] By gene expression profiling and immunophenotype, it resembles the activated B-cell type of nodal DLBCL.[179] As with nodal DLBCL, Bcl-2 expression is an adverse prognostic factor.[180]

Acknowledging the heterogeneity of DLBCL, there is greater promise for molecular studies to dissect out biologically relevant subgroups. The use of RNA gene expression arrays has identified biologically distinct subtypes. Staudt and colleagues showed that at

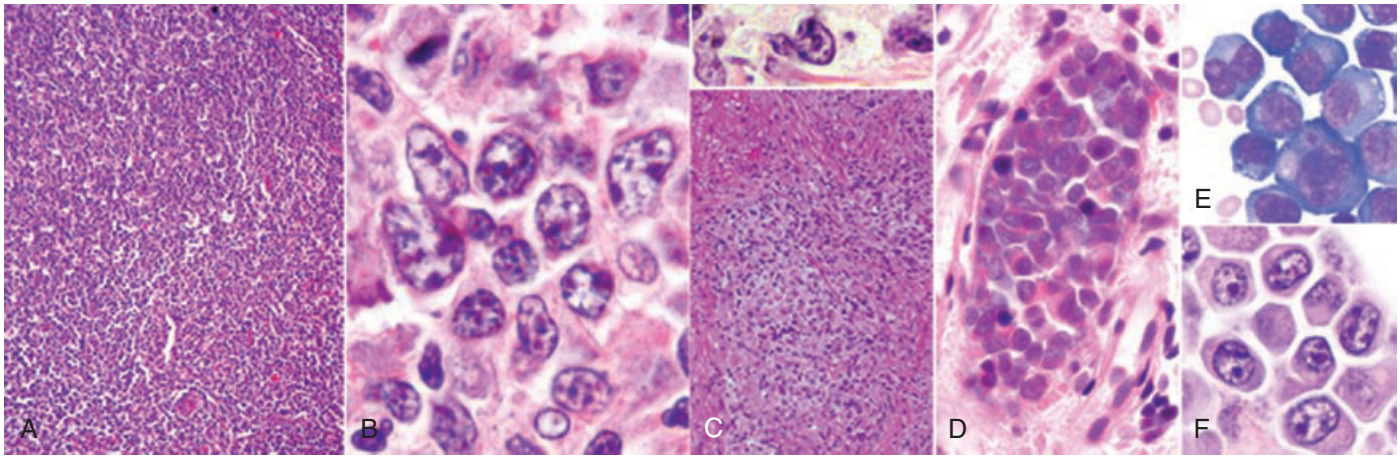

Figure 78–9 Diffuse large B-cell lymphoma (DLBCL). The low-power illustration (**A**) demonstrates the diffuse nature of the process (**A**). At high power (**B**), there are sheets of large cells with vesicular nuclear chromatin and variable numbers of nucleoli. A number of distinct types of large B-cell lymphoma have been described. These include mediastinal large B-cell lymphoma (**C**), intravascular large B-cell lymphoma (**D**), primary effusion lymphoma (**C**), and plasmablastic lymphoma (**F**). Mediastinal large B-cell lymphoma typically shows sclerosis and large B cells enmeshed in the fibrosis (**C**, top). In intravascular lymphoma, also know as angiotropic lymphoma, the large B cells are confined to the inside of vessels (**D**). Paradoxically, they do not spread to the blood. Primary effusion lymphoma must be diagnosed from cytologic preparations (**E**) and by flow cytometric and molecular techniques, as the lymphoma does not form a solid mass. Plasmablastic lymphoma cells have a distinctive appearance with large size, eccentric nuclei, and amphophilic cytoplasm (**F**), all resembling plasma cells.

least two major types of DLBCL can be identified, with expression profiles resembling either germinal center B cells (GCB) or activated B cells (ABC).[181,182] In two studies, tumors with a germinal center profile were found to have a better prognosis, irrespective of other clinical factors. Shipp et al, using a similar approach, identified a series of genes associated with treatment failure in DLBCL.[183]

The cDNA microarray-based classification of DLBCLs has been validated by an immunohistochemical approach using tissue arrays.[184] This study used immunohistochemistry to identify surrogate markers of the gene expression profile. The expression of CD10 correlated with a good prognosis, whereas the expression of MUM1/IRF4 was associated with a poor prognosis.

DISTINCT SUBTYPES OF DIFFUSE LARGE B-CELL LYMPHOMA

Mediastinal (Thymic) Large B-cell Lymphoma

Mediastinal large B-cell lymphoma (MLBCL) has emerged in recent years as a distinct clinicopathologic entity.[185–187] Cytologically, it resembles many other large B-cell lymphomas and is composed of large transformed cells that can resemble centroblasts or even immunoblasts. A constant feature is relatively abundant pale cytoplasm, often with distinct cytoplasmic membranes.[187] Many cases have fine compartmentalizing sclerosis, which may even lead to misdiagnosis as an epithelial tumor, such as thymoma (see Fig. 78–9C). The tumor appears to be derived from medullary B cells within the thymus gland.[186,188,189] These cells express CD20 and CD79a, but do not express surface Ig.[189] CD30 is often positive, and in some cases the distinction from nodular sclerosis can be difficult, so-called grey-zone lymphomas.[190] Mediastinal large B-cell lymphomas may also occur as a secondary malignancy following nodular sclerosis Hodgkin lymphoma, further supporting the potential of a biological relationship between these lymphomas.[191–193] The use of transcription factors such as Pax-5, Oct-2, BOB.1 and Pu.1 by immunohistochemistry in MLBCL may help in the differential diagnosis.[194,195]

Recently, expression of the *MAL* gene has been detected in MLBCL and not in other DLBCLs.[196] This observation further supports the distinctive nature of this lymphoma. Mediastinal large B-cell lymphoma usually lack rearrangement for *BCL2*, *BCL6*; however, *MYC* abnormalities and *REL* amplification have been described.[197,198] A common cytogenetic abnormality seen in approximately 50% of cases includes gains in 9p, which may be associated with amplification of *JAK2*. Recently, gene expression profiling studies have found that MLBCL bears a distinct molecular signature that differs from that of other DLBCLs and shares features of classical Hodgkin lymphomas.[199,200] Additionally, there are lymphomas, termed mediastinal grey-zone lymphomas, that appear to bridge the gap between MLBCL and classical Hodgkin lymphoma.[193] These cases exhibit intermediate histologic and immunophenotypic features. Interestingly, in contrast to both MLBCL and classical Hodgkin lymphoma, grey-zone lymphomas are more common in males than females.[193,201]

Clinically, mediastinal large B-cell lymphoma is much more common in females than males.[202] It is common in adolescents and young adults with a median age at presentation in the fourth decade. The clinical presentation is that of a rapidly growing anterior mediastinal mass with frequent superior vena caval syndrome and/or airway obstruction. Nodal involvement is uncommon at presentation and also at relapse. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, gastrointestinal tract, and central nervous system. Earlier studies suggested that the tumor was associated with an unusually aggressive clinical course with poor responses to conventional chemotherapy. This may have been due to inadequate therapy, because the tumor usually presents with low-stage disease, Stage I or II. More recent studies have reported cure rates similar to those seen for other large B-cell lymphomas with combined chemotherapy and irradiation.[203]

Intravascular Large B-Cell Lymphoma

Intravascular large B-cell lymphoma is a rare form of DLBCL characterized by the presence of lymphoma cells only in the lumens of small vessels, particularly capillaries.[204] This lymphoma is composed of a disseminated intravascular proliferation of large lymphoid cells, nearly always of B-cell phenotype (see Fig. 78–9D). The tumor cells are large, with vesicular nuclei and prominent nucleoli, resembling centroblasts or immunoblasts. Lymph node involvement is rare, and the tumor presents in extranodal sites, most readily diagnosed in the skin.[205] Neurologic symptoms associated with plugging of small vessels in the central nervous system are common. The disease is often not diagnosed until autopsy, because of the lack of definitive radiologic or clinical evidence of disease, and diverse symptomatology.

Primary Effusion Lymphoma (HHV8/KSHV-Associated)

Primary effusion lymphoma (PEL) is a novel lymphoproliferative disorder associated with human herpesvirus 8 (HHV8) infection.[206] Most PEL develop in HIV-seropositive individuals and are usually coinfected with EBV. Most patients are young to middle-aged homosexual males.[207] The disease also occurs in areas with high seroprevalence for HHV8 infection, such as the Mediterranean, usually in elderly males.[208] Many affected patients also have a history of Kaposi sarcoma, and less commonly multicentric Castleman disease.[209] The most common sites of involvement are the pleural, pericardial, and peritoneal cavities. Some cases may present with tumor masses involving the gastrointestinal tract, soft tissue, and other extranodal sites.[210]

The cells usually have plasmablastic or immunoblastic morphology, with some cells having more anaplastic morphology (see Fig. 78–9E). The cytoplasm is very abundant and deeply basophilic. This disease should be distinguished from pyothorax-associated DLBCL, which usually presents with a pleural mass lesion, and is EBV-positive but HHV8-negative. The cells often have a "null-cell phenotype" with loss of B-cell surface markers, in keeping with a late B-cell stage of differentiation. However, sIg and cIg are often absent. Activation and plasma cell-related markers such as CD30, CD38, and CD138 are usually demonstrable.[211] Aberrant cytoplasmic CD3 expression has been reported.[212] Because of the markedly aberrant phenotype, it is often difficult to assign a lineage with immunophenotyping. Genotypic studies usually show IgH gene arrangement, but aberrant rearrangement of T-cell receptor genes has also been reported. The nuclei of the neoplastic cells are positive by immunohistochemistry for the HHV8/KSHV-associated latent protein, which is a useful diagnostic test.

Plasmablastic Lymphoma

The plasmablastic variant of DLBCL is more than a single entity.[213] The name is most commonly associated with plasmablastic lymphoma (PBL) of the oral cavity, usually diagnosed in the setting of HIV infection.[214] Most cases are EBV-positive. The tumor cells have immunoblastic or plasmablastic features but do not show evidence of ongoing plasmacytic differentiation (see Fig. 78–9F). Other rare examples of PBL may complicate multicentric Castleman disease and contain HHV8.[215] Although these lymphomas are indistinguishable from some examples of immunoblastic lymphoma on morphologic grounds, the lymphoma cells are negative for CD20 and CD45 but express plasma cell markers such as CD138.[216] Still another type of PBL is ALK-positive large B-cell lymphoma.[217] This lymphoma expressing the ALK tyrosine kinase usually expressed in T cell-derived anaplastic large cell lymphoma. The mechanism of overexpression is complex, and most cases express full-length ALK, although translocations involving the ALK gene and other partners such as clathrin and nucleophosmin have been described recently. The tumor presents in adults (M > F), with aggressive disease and frequent sinusoidal invasion in lymph nodes.

Burkitt Lymphoma

Burkitt lymphoma (BL) is most common in children and accounts for up to one-third of all pediatric lymphomas in the United States.[218] It is the most rapidly growing of all lymphomas, with 100% of the cells in cell cycle at any time. It usually presents in extranodal sites. In nonendemic regions, such as the United States, frequent sites of presentation are the ileocecal region, ovaries, kidneys, or breasts. Jaw presentations, as well as involvement of other facial bones, are common in African or endemic cases and are seen occasionally in nonendemic regions. Some cases present as acute leukemia with diffuse bone marrow infiltration and circulating Burkitt tumor cells (formerly known as L3-ALL in the FAB classification). Even in patients with typical extranodal disease, bone marrow involvement is a poor prognostic sign.

Burkitt lymphoma is one of the more common tumors associated with the human immunodeficiency virus (HIV).[219] It can present at any time during the clinical course. In some patients with HIV infection, Burkitt lymphoma may be the initial acquired immunodeficiency syndrome (AIDS)-defining illness.

The pathogenesis of Burkitt lymphoma is undoubtedly related to the translocations involving the *MYC* oncogene that are seen in virtually 100% of cases.[220,221] Most cases involve the Ig heavy-chain gene on chromosome 14. Less commonly the light-chain genes on chromosomes 2 and 22 are involved in the translocation. African Burkitt lymphoma occurs in regions endemic for malaria and it has been postulated that immunosuppression associated with malarial infection puts patients at increased risk for Burkitt lymphoma.[91] In this regard, the pathogenesis appears similar to that seen with HIV infection.

EBV is closely linked to Burkitt lymphoma in endemic regions but is less frequently seen (15%–20%) in European and North American cases.[218] In other regions, characterized by low socioeconomic status and EBV infection at an early age, Burkitt lymphoma is often EBV-positive, in the range of 50% to 70%.[222] These data support the concept that the EBV is a cofactor for the development of Burkitt lymphoma. Differences in the proportion of cases associated with the two EBV strains (types 1 and 2) have also been shown in sporadic and endemic EBV-positive Burkitt lymphomas.[223]

Cytologically, Burkitt lymphoma is monomorphic (Fig. 78–10). The cells are medium in size with round nuclei, moderately clumped chromatin, and multiple (2–5) basophilic nucleoli. The cytoplasm is deeply basophilic and moderately abundant. These cells contain cytoplasmic lipid vacuoles, which are probably a manifestation of the high rate of proliferation and high rate of spontaneous cell death. The starry sky pattern characteristic of Burkitt lymphoma is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells.

Burkitt lymphoma has a mature B-cell phenotype. The cells express CD19, CD20, CD22, CD79a, and monoclonal surface Ig, nearly always IgM. CD10 is positive in nearly all cases, and CD5 and CD23 are consistently negative.[224]

The WHO includes three clinical variants of BL that are associated with different clinical settings: endemic BL, sporadic BL, and AIDS-associated BL. In addition, three morphologic variants are defined: classical BL, atypical BL, and BL with plasmacytoid differentiation. The last variant is most often seen in association with HIV infection, whereas the other two variants can be encountered in both endemic and sporadic clinical settings. The distinction of BL from morphologically similar aggressive B-cell lymphomas has been problematic for pathologists and clinicians. The category of small non–cleaved cell lymphoma or non-Burkitt in the working formulation was biologically and clinically heterogeneous. In addition, the *MYC* translocation as a secondary event is not associated with identical clinical consequences.[225]

The *atypical variant* of BL is composed of medium-sized Burkitt cells and shows other features of BL (high degree of apoptosis, high mitotic index). However, in contrast to classical BL, the cells show greater pleomorphism in nuclear size and shape. Nucleoli are more prominent and fewer in number. The diagnosis requires a growth fraction of 100% and the appropriate immunophenotype for BL.

Because of imprecision in the cytologic features, molecular studies to identify a *MYC* translocation are highly desirable, if not required, for diagnosis, especially in cases with atypical cytology. In the clinical setting, fluorescence in situ hybridization (FISH) is the most practical method and can be performed on routinely fixed and processed paraffin sections.[226] Recent studies have shown that BL has a characteristic gene expression profile and that infrequent cases morphologically resembling DLBCL may exhibit an identical profile.[227,228]

Although the *MYC* translocation is the hallmark of BL, it may occur as a secondary event in other lymphomas, including follicular lymphoma, mantle cell lymphoma, and DLBCL.[225,229] In follicular lymphoma, secondary *MYC* translocations have been associated with high-grade transformations showing Burkitt-like and lymphoblastic cytologies.[230–232] Mantle cell lymphomas with *MYC* deregulation are aggressive or blastic in appearance, but very rare.[233]

T- AND NK-CELL LYMPHOMAS

Overview of the Classification of T-Cell Neoplasms

Although the definition of precursor T-cell or lymphoblastic neoplasms is straightforward, the classification of peripheral T-cell lymphomas has been controversial. These are uncommon, representing less than 10% of all non-Hodgkin lymphomas. Most previously published classification schemes for the malignant lymphomas in the United States or Europe have been based on B-cell malignancies, as these are far more common than their T-cell counterparts. T- and NK-cell lymphomas show significant variation in incidence in different geographic regions and racial populations.[234]

The classification of T- and NK-cell neoplasms proposed by the WHO emphasizes a multiparameter approach, integrating morphologic, immunophenotypic, genetic, and clinical features. Clinical

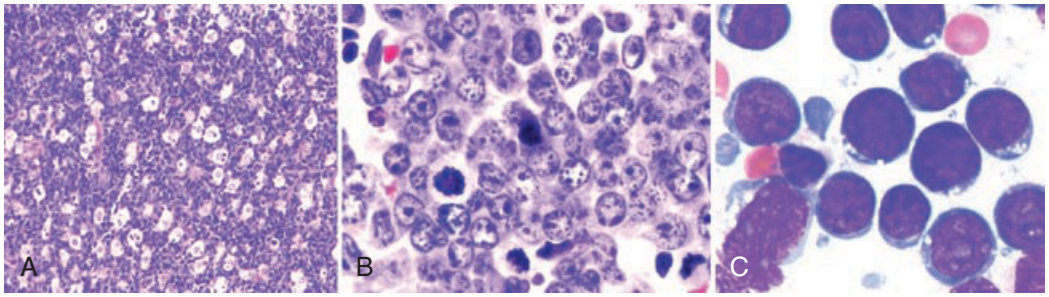

Figure 78–10 Burkitt lymphoma (BL). At low power, Burkitt lymphoma gives a classic "starry sky" appearance as a result of numerous histiocytes or tingible body macrophages with clear cytoplasm (stars), in a background of darkly stained tumor cells (sky) (**A**). At high power, the cells exhibit a very high mitotic rate, and are intermediate in size with an almost stippled nuclear chromatin (**B**). On a Wright-stained touch preparation or in the blood or bone marrow, the cells also have a characteristic appearance, with deep blue cytoplasm typically with vacuoles (**C**).

features play particular importance in the subclassification of these tumors, in part due to the lack of specificity of other parameters. T-cell lymphomas show great morphologic diversity, and a spectrum of histologic appearances can be seen within individual disease entities. The cellular composition can range from small cells with minimal atypia to large cells with anaplastic features. Such a spectrum is seen in anaplastic large cell lymphoma, adult T-cell lymphoma/leukemia, and nasal T- and NK-cell lymphoma, as selected examples. Moreover, there is morphologic overlap between disease entities. Many of the extranodal cytotoxic T- and NK-cell lymphomas share similar appearances, including prominent apoptosis, necrosis, and angioinvasion.[235]

In contrast to B-cell lymphomas, specific immunophenotypic profiles are not associated with most T-cell lymphoma subtypes. Although certain antigens are commonly associated with specific disease entities, these associations are not entirely disease-specific. For example, CD30 is a universal feature of anaplastic large cell lymphoma but can be expressed, usually to a lesser extent, in other T- and B-cell lymphomas. CD30 is of course also positive in classical Hodgkin lymphoma. Similarly, although CD56 is a characteristic feature of nasal T- and NK-cell lymphoma, it can be seen on other T-cell lymphomas, and even malignant plasma cell neoplasms.[236–238]

Presently, specific genetic features have not been identified for many of the T- and NK-cell neoplasms. One of the few exceptions is anaplastic large cell lymphoma, which is strongly associated with the t(2;5) and other variant translocations.[239,240] However, the molecular pathogenesis of most T- and NK-cell neoplasms remains to be defined. The lack of specific genetic and immunophenotypic markers increases the importance of clinical features for the mature T-cell lymphomas.

Angioimmunoblastic T-Cell Lymphoma

Angioimmunoblastic T-cell lymphoma (AILT) was initially proposed as an abnormal immune reaction or form of atypical lymphoid hyperplasia with a high risk of progression to malignant lymphoma.[241] Because the majority of cases show clonal rearrangements of T-cell receptor genes, it is now regarded as a variant of T-cell lymphoma.[242] The median survival is generally less than 5 years, so that the designation as lymphoma is warranted on clinical grounds.[243]

The nodal architecture is generally effaced, but peripheral sinuses are often open and even dilated. The abnormal infiltrate usually extends beyond the capsule into the surrounding tissue. Hyperplastic germinal centers are absent. However, there may be regressed follicles containing a proliferation of dendritic cells and blood vessels. At low power there is usually a striking proliferation of postcapillary venules with prominent arborization (see Fig. 78–11A). The cellularity of the lymph node usually appears reduced or depleted at low power. Clusters of lymphoid cells with clear cytoplasm may be seen. The neoplastic cells are admixed with a polymorphous cellular background containing small normal-appearing lymphocytes, basophilic immunoblasts, plasma cells, and histiocytes, with or without eosinophils. The abnormal cells are usually CD4-positive T cells that show expression of CD10, and sometimes BCL-6[244]—features that suggest the neoplastic cells may derive from germinal center-associated T helper cells.[245] Recently, several groups have identified increased expression of a chemokine, CXCL13, in AILT,[246,247] providing further evidence that AILT derives from follicular helper T cells. This link is also supported by recent gene expression profiling of AILT.[248]

In paraffin sections, a helpful diagnostic feature is the presence of numerous $CD21^+$ dendritic reticulum cells, which are especially prominent around postcapillary venules.[249] EBV-positive large B-cell blasts are nearly always present in the background,[250,251] and progression to EBV-positive DLBCL has been reported in rare cases. The EBV-positive cells may have an RS-like appearance, simulating Hodgkin lymphoma.[252] Atypical B-cell proliferations that are negative for EBV also occur, presumably related to the function of the neoplastic cells in promoting the activation and migration of bystander B cells.[253]

Angioimmunoblastic T-cell lymphoma presents in adults. Most patients have generalized lymphadenopathy, hepatosplenomegaly, skin rash, and prominent constitutional symptoms. There are usually signs of B-cell hyperactivity, including polyclonal hypergammaglobulinemia and other hematologic abnormalities such as Coombs-positive hemolytic anemia. Rituximab has been used in some recent clinical trials, in an attempt to control some of the effects of B-cell hyperactivity in this disease.[253] Patients may also show evidence of immunodeficiency with recurrent opportunistic infections that may ultimately lead to their demise.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a distinct clinicopathologic entity originally described in southwestern Japan that is associated with the retrovirus HTLV-1.[254,255] HTLV-1 is found clonally integrated in the T cells of this lymphoma. HTLV-1 is also endemic in the Caribbean, where clusters of ATLL have been described, predominantly among blacks.[256,257] It is seen with lesser frequency in blacks in the southeastern United States.[258] The median age of affected individuals is 45 years. Patients in the Caribbean tend to be slightly younger than those in Japan.[259] Patients may present with leukemia or with generalized lymphadenopathy. The leukemic form predominates in Japan, whereas lymphomatous presentations are more common in the western hemisphere. Other clinical findings include lymphadenopathy, hepatosplenomegaly, lytic bone lesions, and hypercalcemia.[260] The acute form of the disease is associated with a poor prognosis and a median survival of under 2 years.[258] Complete remissions may be obtained but the relapse rate is nearly 100%.

Chronic and smoldering forms of the disease are seen less commonly.[261] These are associated with a much more indolent clinical course. There is usually minimal lymphadenopathy. The predominant clinical manifestation is skin rash, with only small numbers of atypical cells in the peripheral blood. In the chronic and smoldering

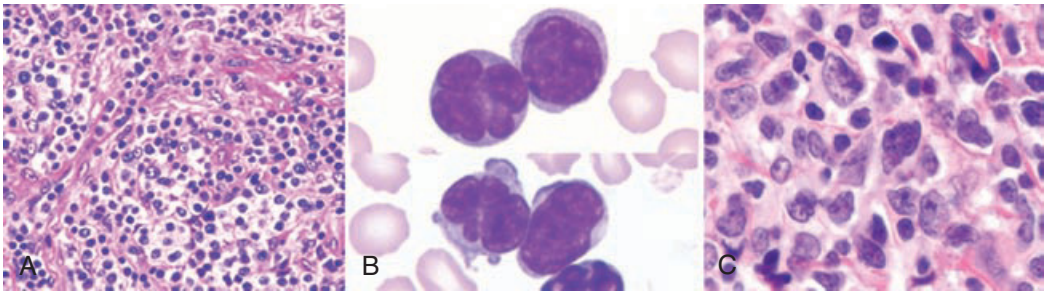

Figure 78–11 T-cell lymphoma: angioimmunoblastic T-cell lymphoma (AILT), adult T-cell leukemia/lymphoma (ATLL), and peripheral T-cell lymphoma (PTCL). In AILT the lymph node shows effacement as a result of a vascular proliferation of postcapillary venules, and clustered large cells with clear cytoplasm in the background of plasma cells, immunoblasts, and small lymphocytes (**A**). The peripheral blood in ATLL has classic "flower cells" (**B**). PTCL is heterogeneous, but typically there is a mixture of small and large neoplastic T cells (**C**).

forms, HTLV-1 virus is also found integrated within the atypical lymphoid cells.

The cytologic spectrum of ATLL is extremely diverse (see Fig. 78–11B). The cells may be small with condensed nuclear chromatin and markedly polylobated nuclear appearance.[258,262] Larger cells with dispersed chromatin and small nucleoli may be admixed and predominate in some cases. RS-like cells can be seen, simulating Hodgkin lymphoma.[263] The RS-like cells represent EBV-infected B cells, expanded secondary to underlying immunodeficiency.[264] In the smoldering form of ATLL, the cells may show minimal cytologic atypia and may even be diagnosed as small lymphocytic lymphoma. The larger cells usually show abundant cytoplasmic basophilia. Skin involvement is seen in approximately two-thirds of patients, and the cutaneous infiltrates often show prominent epidermotropism, simulating mycosis fungoides. Immunophenotypically, the neoplastic cells are positive for T cell-associated antigens, such as CD2, CD3, and CD5; they are typically $CD4^+/CD8^-$, and in almost all cases express CD25.

Peripheral T-Cell Lymphomas, Unspecified

Peripheral T-cell lymphoma (PTCL) is a diagnosis of exclusion and is admittedly a heterogeneous category. Most cases are nodal in origin. Peripheral T-cell lymphomas are characterized by a heterogeneous cellular composition. There is usually a mixture of small and large atypical lymphoid cells (see Fig. 78–11C). An inflammatory background is frequent, consisting of eosinophils, plasma cells, and histiocytes. If the epithelioid histiocytes are numerous and clustered, the neoplasm fulfills the criteria for the *lymphoepithelioid cell variant* of PTCL.[265,266] The *T-zone variant* is composed of small- to medium-sized cells that preferentially involve the paracortical regions of the lymph node.[267,268]

Clinically, PTCL most often presents in adults. Most patients exhibit generalized lymphadenopathy, hepatosplenomegaly, and frequent bone marrow involvement. Constitutional symptoms, including fever and night sweats, are common, as is pruritus. The clinical course is aggressive, although complete remissions may be obtained with combination chemotherapy.[269–271] However, the relapse rate is higher than in aggressive B-cell lymphomas, including DLBCL.[271]

Peripheral T-cell lymphoma, as defined in the WHO classification, remains heterogeneous. It is likely that individual clinicopathologic entities will be delineated in the future from this broad group of malignancies. Thus far, immunophenotypic criteria have not been helpful in delineating subtypes. Most cases have a mature T-cell phenotype, and express one of the major subset antigens: CD4 > CD8. These are not clonal markers, and antigen expression can change over time. Loss of one of the pan T-cell antigens (CD3, CD5, CD2, or CD7) is seen in 75% of cases, with CD7 most frequently being absent.[272]

Anaplastic Large Cell Lymphoma—ALK positive or ALK negative

Anaplastic large cell lymphoma (ALCL) is characterized by pleomorphic or monomorphic cells, which have a propensity to invade lymphoid sinuses (see Fig. 78–12A).[273] Because of the sinusoidal location of the tumor cells, and their lobulated nuclear appearance, this disease was previously interpreted as a variant of malignant histiocytosis. Misdiagnosis as metastatic carcinoma or melanoma was also common.

A consistent feature is the expression of the CD30 antigen, which is a hallmark of this disease.[274] The older terminology of $Ki\text{-}1^+$ lymphoma is not favored because CD30 expression is not specific for ALCL and can be seen in a variety of conditions, of course, including classical Hodgkin lymphoma (Table 78–2).[275,276] Systemic ALCL is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35) involving *NPM/ALK* genes respectively.[277] A number of variant translocations have been identified that involve partners other than *NPM*. All lead to an overexpression of *ALK*, although the cellular distribution of ALK varies according to the gene partner.[278,279]

The cells of classical ALCL have large, often lobated nuclei. Nucleoli are present but tend not to be prominent and are frequently basophilic. In some cases the nuclei may be round. The cytoplasm is usually abundant, amphophilic, and there are distinct cytoplasmic borders. A prominent Golgi region is generally visible. Cells with lobulated and indented nuclei, so-called hallmark cells, are a constant feature.[240,280]

The cells exhibit an aberrant phenotype with loss of many of the T-cell associated antigens. Both CD3 and CD5 are negative in greater than 50% of cases. CD2 and CD4 are positive in the majority of cases. CD8 is usually negative. ALCL cells, despite the $CD4^+/CD8^-$ phenotype, exhibit positivity for the cytotoxic associated antigens TIA-1, granzyme B, and perforin. By molecular studies, in most of the cases a T-cell receptor rearrangement is found, confirming a T-cell origin.

Anaplastic large cell lymphoma is most common in children and young adults. A marked male predominance is noted. Although most patients present with nodal disease, a high incidence of extranodal involvement has been reported (involving skin, bone, and soft tissue). Approximately 75% of cases present with advanced-stage and systemic symptoms.[281] Although these lymphomas have an aggressive natural clinical history, they respond well to chemotherapy. Overall

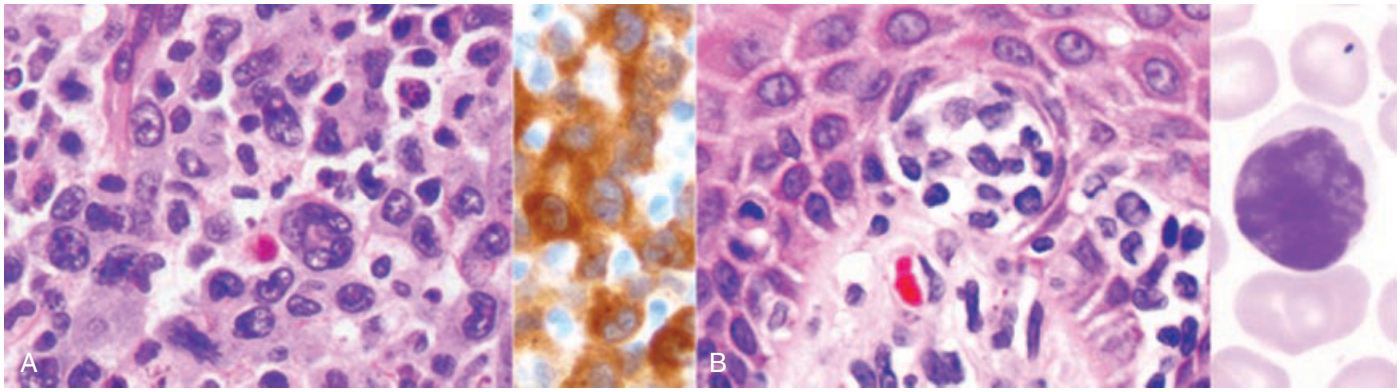

Figure 78–12 T-cell lymphoma: anaplastic large cell lymphoma (ALCL) and mycosis fungoides/Sezary syndrome (MF/SS). ATCL is characterized by a mix of pleomorphic malignant large T cells (**A**), which include "wreath cells" (*center*) and "hallmark cells" (*bottom right*). The presence of ALK staining with nuclear and cytoplasmic localization (*right*) is associated with the t(2;5). In MF there is a dermal infiltrate with some malignant T cells infiltrating into the epithelium (Pautrier microabscesses) (**B**). A Sezary cell with convoluted nuclear folding is seen to the right.

Table 78–2 Differential Diagnosis of Anaplastic Large Cell Lymphoma

Disease	CD30	CD15		LCA	CD3	TIA-1	EMA	Clu	ALK	CD20
ALCL	+	–	+	–/+	+		+		+	+
CHL	+	+	–	–	–	–	–	–		–/+
NLPHL	–	–	+	–	–	+/–	–	–	+	+
PTL	–/+	–	+	+	–/+	–	–	–	–	–
DLBCL	–/+	–	+	–	–		+/–	–	–	+

ALCL, anaplastic large cell lymphoma; cHD, classical Hodgkin lymphoma; DLBCL, diffuse large B-cell lymphoma (includes T-cell rich large B-cell lymphoma); NLPHD, nodular lymphocyte predominant HL; PTL, peripheral T-cell lymphoma, unspecified.

survival and disease-free survival are significantly better among ALK$^+$ vs ALK$^-$ cases.[281,282,282a] Recent studies suggest that the IPI is prognostically useful, in contrast with early reports.[281,282]

Anaplastic large cell lymphoma negative for ALK represents approximately 15% to 20% of cases of ALCL, with otherwise classical morphologic and immunophenotypic criteria. Because CD30 can be expressed in a wide variety of lymphoma, stringent morphologic and immunophenotypic criteria are required for the diagnosis of ALK-negative ALCL. These include the presence of a cytotoxic T-cell immunophenotype. Although ALK-negative ALCL has a worse prognosis than ALK-positive cases, recent studies have indicated a better prognosis than PTCL-unspecified, with suggestive evidence of a plateau in the survival curve.[282a]

Primary Cutaneous Anaplastic Large Cell Lymphoma

A primary cutaneous form of ALCL is closely related to lymphomatoid papulosis, and differs clinically, immunophenotypically, and at the molecular level from the systemic form.[283–286] Lymphomatoid papulosis and cutaneous ALCL are part of the spectrum of CD30$^+$ cutaneous T-cell lymphoproliferative diseases. Small lesions are likely to regress. Patients with large tumor masses may develop disseminated disease with lymph node involvement. However, primary cutaneous ALCL is a more indolent disease than other T-cell lymphomas of the skin. Because the skin nodules may show spontaneous regression, usually a period of observation is warranted before the institution of any chemotherapy.[287] Cutaneous ALCL is CD30$^+$ but ALK-negative, lacking translocations involving the *ALK* gene.[285,286]

Mycosis Fungoides/Sézary Syndrome

Mycosis fungoides/Sézary syndrome (MF/SS) by definition present with cutaneous disease. Skin involvement may be manifested as multiple cutaneous plaques or nodules, or with generalized erythroderma (see Fig. 78–12B). Lymphadenopathy is usually not present at presentation and, when identified, is associated with a poor prognosis.[288] In early stages, enlarged lymph nodes may only show dermatopathic changes (Category I). If malignant cells are present in significant numbers and are associated with architectural effacement (Category II or III), the prognosis is significantly worse.[7]

Cytologically, the small cells of MF/SS demonstrate cerebriform nuclei with clumped chromatin, inconspicuous nucleoli, and sparse cytoplasm. The larger cells may be hyperchromatic or have more vesicular nuclei with prominent nucleoli. RS-like cells may be seen, especially in advanced lesions. Epidermotropism is usually a prominent feature of the cutaneous infiltrates.

The typical phenotype is CD2$^+$, CD3$^+$, CD5$^+$, CD4$^+$, and CD8$^-$. The absence of CD7 is a constant feature but may also be seen in reactive conditions, and therefore is of limited diagnostic value.[289] Aberrant expression of other T-cell antigens may be seen but mainly occurs in the advanced (tumor) stages.

T-cell receptor genes are clonally rearranged in most cases, and the identification of clonality is clinically useful, but not entirely specific as benign cutaneous infiltrates also may be clonal by PCR.[290] Inactivation of p16 (*CDKN2A*) and *PTEN* have been identified in some cases and may be associated with disease progression.[291–293] Although Sezary syndrome is much more aggressive, the presence of common genetic pathways supports a close relationship between MF and SS.[294] Transformation to a large T-cell lymphoma may occur and is associated with an adverse prognosis. The expression of CD30 in these cases does not appear to have prognostic significance.[295] Some cases of MF may be associated with classical Hodgkin lymphoma or a T-cell lymphoma closely resembling classical Hodgkin lymphoma.[296–299]

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) usually presents with subcutaneous nodules, primarily affecting the extremities and trunk. The nodules range in size from 0.5 cm to several centimeters in diameter. Larger nodules may become necrotic. In its early stages the infiltrate may appear deceptively benign, and lesions are often misdiagnosed as panniculitis.[300,301] However, histologic progression usually occurs and subsequent biopsies show more pronounced cytologic atypia, permitting the diagnosis of malignant lymphoma.

The cytologic composition of SPTCL may vary. The lesions may contain a predominance of small- to medium-sized lymphoid cells with clear cytoplasm or larger cells with hyperchromatic nuclei. Admixed reactive histiocytes are frequently present, particularly in areas of fat infiltration and destruction. The histiocytes are frequently vacuolated, because of ingested lipid material. Vascular invasion may be seen in some cases, and necrosis and karyorrhexis are common (see Fig. 78–13A).

The neoplastic cells are CD8+ T cells, and display an activated cytotoxic immunophenotype (TIA-1$^+$, granzyme-B$^+$ and perforin$^+$).[238] These proteins may be responsible for the cellular destruction seen in these tumors. In the original definition of SPTCL, cases of alpha-beta and gamma-delta T-cell derivation were included.[238,302] However, because of the worse prognosis of gamma-delta T-cell cases, and other clinical and pathologic differences, the WHO-EORTC classification restricts the definition of SPTCL to cases of alpha-beta derivation.[109,303] Primary cutaneous gamma-delta T-cell lymphoma is considered a distinct entity, which may in some cases have a panniculitis-like pattern.[304] The cells are EBV-negative but show clonal rearrangement of T-cell receptor genes.

A hemophagocytic syndrome is a frequent complication of SPTCL and is associated with an adverse prognosis in both alpha-beta and gamma-delta derived tumors.[300] Patients present with fever, pancytopenia, and hepatosplenomegaly. It is most readily diagnosed in bone marrow aspirate smears where histiocytes containing erythrocytes, platelets, and other blood elements may be observed. The cause of the hemophagocytic syndrome appears related to cytokine production by the malignant cells. Interferon gamma, tumor necrosis factor-alpha, granulocyte–monocyte colony-stimulating factor, and

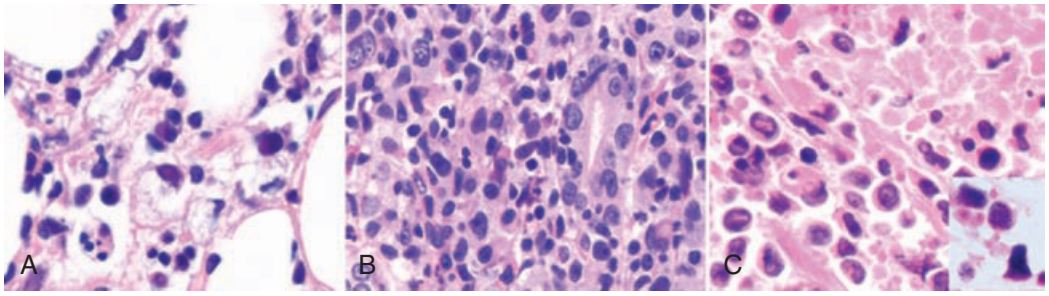

Figure 78–13 T-cell lymphoma: subcutaneous panniculitis-like T-cell lymphoma (SPTCL), enteropathy-type T-cell lymphoma (ETL), extranodal NK- and T-cell lymphoma, nasal type. A case of SPTCL is illustrated and shows an abnormal lymphoid infiltrate in the subcutaneous fat (**A**). This is associated with hemophagocytosis (*bottom left*) and necrosis. In ETL, there is an abnormal T-lymphoid proliferation with infiltration into the gastrointestinal glandular elements (*center-right*). Extranodal NK- and T-cell lymphoma typical has marked necrosis (**C**). The malignant cells are Epstein–Barr virus (EBV)-positive by in situ hybridization for EBV RNA (*insert*).

MIP-1alpha have been identified.[301,305,306] Dissemination to lymph nodes and other organs is uncommon and usually occurs late in the clinical course.

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) was originally termed malignant histiocytosis of the intestine.[307] However, the demonstration of clonal T-cell gene rearrangement indicated that it was a T-cell lymphoma. The small bowel usually shows ulceration, frequently with perforation. A mass may or may not be present. Two morphologic and immunophenotypic types are recognized[308]: (a) monomorphic with small- to medium-sized cells, CD56$^+$, CD3cyto$^+$, alphabeta$^{+/-}$, CD8$^+$, CD4$^-$, CD5$^-$, CD57$^-$, TIA-1$^+$ and (b) pleomorphic with large to medium sized cells with a morphology most consistent with anaplastic large cell, CD56$^-$, CD3$^+$, CD7$^+$, CD5$^-$, CD8$^-$, CD4$^-$, TIA-1$^+$, which also express the homing receptor CD 103 (HML-1) (see Fig. 78–13B).[309] The strong association with gluten-sensitive enteropathy is seen only with the latter histologic type. Anaplastic cells strongly positive for CD30 may be present. Genetically, EATL are remarkably homogeneous and are characterized by chromosomal gain on 9q33–34, which is usually not detected in other PTCLs.[310] The cells express cytotoxic molecules, a feature shared by nearly all extranodal T-cell lymphomas and appear to be part of the innate immune system.[311] EBV is generally negative. EBV has been detected in some intestinal T- and NK-cell lymphomas in certain geographic regions, such as Mexico and Asia, but it is likely that such cases represent extranodal T- and NK-cell lymphomas involving the intestine.[312,313] The gastrointestinal tract is a common site of secondary involvement by extranodal T- and NK-cell lymphoma, nasal type.[314]

This disease occurs in adults, the majority of whom have either overt or clinically silent gluten-sensitive enteropathy. Most patients have the HLA DQA1*0501, DQB1*0201 genotype. The adjacent small bowel usually shows evidence of villous atrophy.[315] Although celiac disease is usually associated with an increase in intraepithelial gamma-delta T cells, the cells of EATL are usually of alpha-beta origin.[316] T-cell receptor beta and gamma genes are clonally rearranged. Similar clonal rearrangement may be found in adjacent intestine, suggesting that the associated increase in intraepithelial T cells constitutes a neoplastic or preneoplastic population.[317] Patients usually present with abdominal symptoms, including pain, small bowel perforation, and associated peritonitis. The clinical course is aggressive, and most patients have multifocal intestinal disease.

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma presents with marked hepatosplenomegaly in the absence of lymphadenopathy.[318,319] The great majority of cases are of gamma-delta T-cell origin.[320,321] Most patients are male, with a peak incidence in young adults.[321] Although patients may respond initially to chemotherapy, relapse has been seen in the vast majority of cases, and the median survival is less than 3 years. Rare long-term survival has been seen following allogeneic hematopoietic cell transplantation.[321]

The cells of hepatosplenic T-cell lymphoma are usually moderate in size, with a rim of pale cytoplasm. The nuclear chromatin is loosely condensed, with small inconspicuous nucleoli. The liver and spleen show marked sinusoidal infiltration, with sparing of both portal triads and white pulp, respectively. Abnormal cells are usually present in the sinusoids of the bone marrow but may be difficult to identify without immunohistochemical stains. The neoplastic cells have a phenotype that resembles that of normal resting gamma-delta T cells. They are often negative for both CD4 and CD8, although CD8 may be expressed in some cases. CD56 is typically positive.[319,321] A small percentage of cases appear to be of alpha-beta origin.[322–324] The neoplastic cells express markers associated with cytotoxic T cells, such as TIA-1. However, perforin and granzyme B are usually negative, suggesting that these cells are not activated.[321,325] Isochromosome 7q is a consistent cytogenetic abnormality, and is often seen in association with trisomy 8.[326–328]

Although hepatosplenic T-cell lymphoma is a tumor of inactive or immature gamma-delta T cells, other forms of gamma-delta T-cell lymphoma exist. A gamma-delta phenotype can be seen in cases of T LBL/ALL.[329] Most tumors of activated gamma-delta T cells arise in mucocutaneous sites.[304,330] These lymphomas are positive for granzyme B, perforin, and TIA-1, and express granzyme M, characteristic of innate cytotoxic effector T cells.[311]

Extranodal NK- and T-Cell Lymphoma, Nasal-Type

Extranodal NK- and T-cell lymphoma, nasal type, is a distinct clinicopathologic entity highly associated with EBV.[331,332] It affects adults (median age 50) and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema may be prominent.[333] NK- and T-cell lymphomas have been reported in other extranodal sites, including skin, soft tissue, testis, upper respiratory tract, and gastrointestinal tract. Aggressive NK-cell leukemia/lymphoma is a closely related leukemic disorder.[334,335] The clinical course is usually highly aggressive, with a slightly improved median survival in patients with localized disease. However, the outcome remains poor with current chemotherapy. Radiation therapy may be effective in localized disease. A hemophagocytic syndrome is a common clinical complication and adversely affects survival in extranodal NK- and T-cell lymphoma, nasal type. It is likely that EBV plays a role in the pathogenesis of the hemophagocytic syndrome.

Extranodal NK- and T-cell lymphoma, nasal type, is much more common in Asians than in Europeans. Clusters of the disease also

have been reported in Central and South America in individuals of Native American heritage, suggesting that ethnic background i.e., genetic risk factors, may play a role in the pathogenesis of these lymphomas.[336]

Extranodal NK- and T-cell lymphoma, nasal type, is characterized by a broad cytologic spectrum (see Fig. 78–13C). The atypical cells may be small or medium in size. Large atypical and hyperchromatic cells may be admixed, or may predominate. If the small cells are in the majority, the disease may be difficult to distinguish from an inflammatory or infectious process. In early stages there may also be a prominent admixture of inflammatory cells, further causing difficulty in diagnosis.[337]

Although the cells express some T cell-associated antigens, most commonly CD 2, other T-cell markers, such as surface CD3, are usually absent.[338] The cells express cytoplasmic CD3ε and are usually CD56-positive. Cytotoxic markers such as granzyme B and TIA-1 are present. Molecular studies are negative for T-cell gene rearrangement, despite clonality being shown by other methods.[338–340]

CHAPTER 79

CLINICAL MANIFESTATIONS, STAGING, AND TREATMENT OF INDOLENT NON-HODGKIN LYMPHOMA

John G. Gribben

Non-Hodgkin lymphoma (NHL) refers to all malignancies of the lymphoid system with the exception of Hodgkin lymphoma. Development of the lymphoid system is a highly regulated process characterized by differential expression of a number of cell-surface and intracytoplasmic proteins and antigen receptor gene rearrangements, somatic hypermutation and class switching. Dysregulation of this orderly process can result in humoral deficiency, autoimmunity, or malignancy. The indolent B cell lymphomas are mature peripheral B-cell neoplasms that exclude those diseases associated with an aggressive clinical course. Despite differences in cell of origin, molecular biology, clinical presentation, and clinical course, the indolent lymphomas share common features, including frequent localization to the principal lymphoid organs, a propensity for marrow infiltration and leukemic presentation, and generally an indolent clinical course. The classification of NHLs has been a challenge for pathologists as well as practicing physicians. A variety of classifications have been proposed over the years, leading to considerable confusion and difficulty in comparison of outcomes of clinical trials performed using different pathologic classifications. The World Health Organization (WHO) lymphoma classification[1] is based on cell of origin and pathophysiology of the lymphoma and is used throughout this chapter. The WHO classification does not include the terminology *indolent lymphoma*. This is a clinical and not pathological term and defines those lymphomas that tend to grow and spread slowly and produce few symptoms (www.nih.gov/). The frequency of the indolent lymphomas by the WHO classification is shown in Table 79–1.

The indolent lymphomas encompass the low-grade and some categories of intermediate-grade NHL in the Working Formulation. Mantle cell lymphoma was previously classified as a low-grade lymphoma and is included here although it is generally now considered a more aggressive lymphoma.

EPIDEMIOLOGY

Almost 60,000 new cases of NHL were diagnosed in the USA in 2006[2] and the incidence is similar in Europe.[3] The incidence rates increased dramatically during the second half of the twentieth century and doubled since the early 1970s to 2000. Non-Hodgkin lymphoma is extremely heterogeneous in its molecular pathophysiology, histology, and clinical course. There are major differences in the incidence of subtypes in different geographic locations and among different racial and ethnic populations. For most subtypes of NHL and particularly for the indolent lymphomas, the age-specific incidence rates are higher in men than in women, and appear higher in whites compared with blacks. Indolent lymphomas are observed much more frequently in the Western world and are rare in Asia. There are familial clusters, especially in small lymphocytic lymphoma/chronic lymphocytic leukemia, and an increased incidence in family members of affected individuals. Therefore, differentiation of complex environmental factors from true inherited factors remains difficult. The complexity of the epidemiology of NHL mirrors the complexity of the disease and the complexity of the immune system. Because lymphomas do not constitute a single disease, it should come as no surprise that there is no single etiologic factor. The influence on immune dysregulation of viruses, chemicals, radiation, diet, and aging remains unclear. Immune suppression leads to increased incidence of aggressive lymphomas, but not usually indolent lymphomas. The role of hepatitis C virus (HCV) in the pathogenesis of indolent lymphomas has been controversial. A significant association between B cell-derived NHL and HCV infection has been reported in Italian subjects[4] and subsequently confirmed by international studies.[5–7] However, discordant data appeared in northern European and North American surveys,[8–10] and it is now evident that a clear south/north gradient of prevalence exists, in part reflecting different HCV infection prevalence in the general population and suggesting the contribution of environmental and/or genetic factors.[6] A great deal of attention has been paid recently to the complex interaction between the malignant B cell, the host,[11] and the tumor microenvironment.[12–14]

CLINICAL PRESENTATION

Although specific subtypes may be associated with specific presenting features, there are many common features and the majority of patients present with lymphadenopathy. Extranodal disease is common and can affect any organ. The most common sites of extranodal disease include the marrow, skin, gastrointestinal tract, and bone. Symptoms may be nonspecific or related to the site of disease involvement. Many patients with indolent lymphomas are asymptomatic, but some, particularly those with bulky disease, may present with B symptoms defined as fever, drenching sweats, or weight loss of more than 10% of body weight. Patients may present with evidence of bowel obstruction from intraabdominal lymphadenopathy and retroperitoneal disease may manifest as obstructive uropathy. Inguinal disease may cause compression of the venous system with deep venous thrombosis. Central nervous system involvement can occur, but is uncommon in indolent lymphomas.

DIAGNOSIS OF INDOLENT LYMPHOMAS

Suggested guidelines for the diagnosis of indolent lymphomas have been outlined by the National Comprehensive Cancer Network (guidelines available at www.nccn.org/) and by the European Society for Medical Oncology.[15] In all cases diagnosis should be confirmed by excisional biopsy of an accessible lymph node with review by a hematopathologist with expertise in lymphoma diagnosis. Fine needle aspiration is not appropriate for diagnosis, and sufficient material must be obtained for immunophenotyping and genetic studies as required for diagnosis and prognostic markers. In patients without easily accessible peripheral nodes, computed tomography (CT) or ultrasound guided biopsy are typically well tolerated. Where possible, consent should be obtained for the procurement and storage of use of excess tissue from lymph node biopsies at the time of presentation and at each subsequent relapse of disease for research purposes to investigate the molecular biology of these diseases. Marrow biopsy provides essential information and should be performed routinely. The yield of bilateral marrow biopsy is moderately higher (15%) than that of unilateral biopsy.

Initial investigations are shown in Table 79–2. Physical examination should include careful examination of all peripheral lymph node

Table 79–1 Frequency of Indolent Lymphomas Among All Lymphomas in the WHO Classification

Follicular lymphoma	22.1%
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue type	7.6%
Small lymphocytic lymphoma/chronic lymphocytic leukemia	6.7%
Mantle cell	6.0%
Splenic marginal zone lymphoma	1.8%
Lymphoplasmacytic lymphoma	1.2%
Nodal marginal zone B-cell lymphoma (±monocytoid B cells)	1.0%

groups including the cervical, supraclavicular, axillary and inguinal chains and examination of Waldeyer ring. Abdominal examination should focus on evaluation of any intraabdominal masses, with particular attention paid to detection of enlargement of the liver or spleen. The skin should be carefully examined. Patients may present with pleural or pericardial effusions, although this is less common than in the aggressive lymphomas.

Laboratory investigations should include a complete blood count to evaluate for cytopenias, which may be evidence of marrow infiltration or of autoimmunity. A white blood cell count with differential and examination of the peripheral blood smear may indicate leukemic involvement. Baseline electrolytes including calcium and phosphate, creatinine, and liver function tests are important to determine organ dysfunction that may be related to direct infiltration by lymphoma. Elevation of lactate dehydrogenase is an important prognostic factor and may be a useful indicator of transformation from indolent to aggressive lymphoma. Assessment of immunoglobulin levels and serum electrophoresis are useful, particularly in lymphoplasmacytic lymphoma, to evaluate for monoclonal protein. Cryoglobulins may also be present, particularly in marginal zone lymphoma in association with hepatitis C. A Coombs test and reticulocyte count may be indicated in patients with anemia.

Initial staging workup also includes a CT scan of the chest, abdomen, and pelvis, with particular attention to sites of bulk disease and to the number of involved sites. Gastrointestinal tract workup and biopsy are indicated in mantle cell lymphoma and in patients with mucosa-associated lymphoid tissue (MALT) lymphomas. Liver biopsy may be indicated on the basis of abnormal imaging or laboratory values.

STAGING

The Ann Arbor Classification is currently used to stage NHL (Table 79–3). CT scans have replaced lymphangiography. The impact of newer technologies such as positron emission tomography (PET), which are included in the revised guidelines for aggressive lymphomas,[16] have been much less studied in the indolent lymphomas. There is considerable heterogeneity in uptake of fluorine-18 fluorodeoxyglucose based on histology, but PET demonstrates 94% sensitivity and 100% specificity for staging in follicular lymphoma (FL).[17] Whereas there is insufficient data yet to recommend PET scans routinely in patients with indolent lymphomas, these scans can be useful to direct biopsy in cases where transformation is suspected.

Table 79–2 Initial Evaluation of Indolent Non-Hodgkin Lymphomas

Physical examination with attention to peripheral nodes, abdomen
Complete blood count, evaluation of peripheral blood
Liver function tests; lactate dehydrogenase
CT scans of chest, abdomen, pelvis
Lymph node biopsy with review by an expert lymphoma histopathologist
Bone marrow biopsy/aspirate
Other studies as indicated

Table 79–3 Ann Arbor Staging

Stage	Criteria
I	Involvement of 1 lymph node (I) or 1 extralymphatic organ or site (IE)
II	Involvement of ≥2 lymph nodes on same side of diaphragm (II) or localized extralymphatic organ or site and ≥1 involved lymph node on same side of diaphragm (IIE)
III	Involvement of lymph nodes on both sides of diaphragm (III) or same side with localized involvement of extralymphatic site (IIIE), spleen (IIIS), or both (IIIS + E)
IV	Diffuse or disseminated involvement of extralymphatic organ or tissues with or without lymph node enlargement

CLASSIFICATION OF INDOLENT LYMPHOMAS

Follicular Lymphoma

Follicular lymphoma is by far the most common of the indolent lymphomas and is the second most common subtype of lymphoma worldwide. FL accounts for approximately 20% of malignant lymphomas in adults, but 40% of all lymphomas diagnosed in the USA and in Western Europe.[18] FLs are derived from germinal center B cells and maintain the gene expression profile of this stage of differentiation.[12] Morphologically, the disease is composed of a mixture of centrocytes and centroblasts and is graded from I to III dependent on the proportion of large cells per high power field. Grades I and II are indolent disease. The rare subtype Grade IIIb is more aggressive and is managed as diffuse large B-cell lymphoma (DLBCL). FL cells express CD19, CD20, CD22, and surface immunoglobulin and 60% express CD10. A hallmark of the disease is the t(14;18) contributing to overexpression of the antiapoptotic protein BCL2. Median age at presentation is 60 years and males and females are equally affected. Patients usually present with asymptomatic lymphadenopathy, most cases are advanced stage, and 50% have marrow involvement at presentation. Lymphadenopathy may wax and wane and spontaneous remissions can occur, albeit rarely.[19] Disease transformation to a more aggressive histologic type is a common terminal event.[20] Until recently there was little evidence that the natural history of FL had changed over the last 30 years, and the median survival from diagnosis has been approximately 10 years.[21] Recent studies, however, suggest that the introduction of therapy combining monoclonal antibodies and chemotherapy has led to a longer median survival of 12 to 14 years.[22,23] The clinical course is extremely variable. Some patients have an extremely aggressive course and die within 1 year, whereas others may live for more than 20 years and never require therapy. The Follicular Lymphoma International Prognostic Index (FLIPI) is a five-factor prognostic index based on the clinical characteristics of age, stage, number of nodal sites, and hemoglobin and lactate dehydrogenase levels (Table 79–4), and defines three prognostic risk groups of almost equal numbers of patients.[24] This tool is useful in assessing the need for early treatment and potential outcome, as well as in comparing the outcomes of different clinical trials.

Marginal Zone Lymphomas

The WHO classification lists three forms of marginal zone lymphomas (MZLs) including extranodal, nodal, and splenic marginal zone

Table 79–4 Factors Having Prognostic Significance in the Follicular Lymphoma International Prognostic Index[24]

Parameter	Adverse Factor	RR	95% CI
Age	≥60 years	2.38	2.04–2.78
Ann Arbor stage	III–IV	2.00	1.56–2.58
Hemoglobin level	<120 g/L	1.55	1.30–1.88
Serum LDH level	>ULN	1.50	1.27–1.77
Number of nodal sites	>4	1.39	1.18–1.64

LDH, lactate dehydrogenase; RR, relapse rate.

Management of Follicular Lymphoma

Patients most often present with asymptomatic lymphadenopathy. The diagnosis should be made by excisional biopsy and reviewed by an expert hematopathologist. In the absence of symptoms requiring treatment, a watch and wait approach is the treatment of choice. Although in this phase of treatment, patients should be followed every 3 to 6 months, with history, physical, and laboratory examination and radiologic restaging as clinically indicated. Once a decision to treat has been made, there is no clear treatment algorithm and a number of treatment options are available. The treatment goal, whether palliative or with curative intent, is dependent on the age and performance status of patients. Enrollment in clinical trial should be a priority. For younger patients in whom high-dose therapy may be indicated later in their disease course, it is best to avoid myelotoxic regimens. The role of maintenance therapy in first remission using interferon-α remains controversial and the role of rituximab maintenance therapy in first remission remains the focus of ongoing clinical trials. The choice of therapy after first relapse is also dependent on the goal of therapy, but is also dependent on the previous therapy given and the response and duration of response. Autologous or allogeneic hematopoietic cell transplantation has a role to play in selected younger patients with this disease.

lymphomas. However, there are still uncertainties as to whether they represent a homogeneous group of tumors. These lymphomas behave differently than most indolent lymphomas and require different treatment approaches.

The marginal zone (MZ) corresponds to the outer part of secondary follicles. It is well developed and easily recognizable in the spleen, intraabdominal lymph nodes, and mucosa-associated lymphoid tissue. Most MZ cells express CD19 and CD20 and have the phenotypic profile of memory B cells and are strongly positive for IgM, IgG, or IgA, with only a small subpopulation exhibiting weak IgD staining. They also express CD21, CD27, and Bcl-2 protein, but are negative for CD5, CD10, CD23, CD43, and CD75. A subset of splenic MZ cells shares phenotypic features with mantle B elements by showing positivity for IgM, IgD, and Ki-B3 and negativity for CD21 and CD27. Most, but not all, splenic MZ B cells show somatic hypermutation of Ig genes contain point mutations of the Ig genes at frequencies found in postfollicular memory B elements. However, a small subset of the same MZ B cells displays a low load of Ig gene point mutations, as usually found in mantle B cells. Therefore, although belonging to the same anatomic compartment, splenic MZ B elements do show a certain phenotypic and molecular variability, the vast majority of them being likely part of the recirculating memory B-cell pool. Interestingly, splenic MZ B cells can bind polysaccharide antigens with one of two results, depending on the follicle microenvironment. First, they can migrate into the germinal centers (GCs) and present the antigen to GC B cells. If follicular dendritic cells have surface Ig that binds to the presented antigen, they proliferate and give rise to the GC cell reaction. Second, antigen in association with cytokines released by T cells can rapidly induce differentiation of MZ B cells into plasma cells, which in turn synthesize and release antigen-specific Ig. MALT lymphomas (extranodal marginal zone lymphomas) and monocytoid B-cell NHLs (nodal marginal cell lymphomas) are included within the WHO terminology as marginal zone lymphomas. Both types share the presence of positive surface immunoglobulin CD19, CD20, and CD22 and are negative for CD5 and CD23.[25] Monocytoid B-cell lymphoma is the nodal form of marginal zone lymphoma. These patients do well, with rates of disease-free and overall survival similar to the other low-grade lymphomas, as shown in studies conducted by the Southwest Oncology Group (SWOG).[25]

Extranodal Marginal Zone Lymphoma

In the WHO classification, the term *extranodal marginal zone lymphoma* is restricted to tumors consisting of small elements provided with centrocyte-like or monocytoid morphology and associated or not with plasmacytoid differentiation, which resemble normal MALT MZ cells and share with them phenotypic and molecular characteristics, including the IRTA-1 gene expression. In the original description, these neoplasms were called MALT lymphomas.

MALT lymphomas typically arise in the mucosal lymphoid tissue or glandular epithelium, including stomach, salivary glands, lungs, or thyroid, with gastrointestinal tract involvement being the most common presentation. There is a clear association with autoimmune diseases such as Sjogren syndrome and Hashimoto thyroiditis.[26] Molecular analysis demonstrates that extranodal MZLs are characterized by the occurrence of different chromosomal aberrations, t(11;18), t(1;14), and t(14;18), which influence invasive potential and possibly the response to therapy. t(11;18)(q21;q21) is detected in 30% to 35% of gastric extranodal MALT lymphomas producing the fusion gene *API2-MALT1*, leading to the overexpression of the *API2* gene, which inhibits apoptosis via the caspase system. Presence of the t(11;18) is associated with antibiotic resistance, a higher potential of local infiltration and metastasis and progression to a more aggressive tumor.[27] This translocation is found even more frequently in the lung than in the stomach[28] and is found also in approximately one-half of the rare examples of gastric *Helicobacter pylori* (HP)-negative MZL,[29] further supporting the concept that tumors carrying t(11;18) do not need HP stimulation for their growth and maintenance. The t(1;14)(p22;q32) is exceedingly rare and causes transfer of the *BCL10* gene close to the Ig enhancer on chromosome 14. The role of the t(14;18)(q32;q21) in MZL has been the subject of much debate in the literature, with confusion with the translocation found in FL. Although the t(14;18) of MZLs does not affect *BCL2*, it affects *MALT1* by possibly following the same pathogenetic pathway as the t(1;14). Bacterial infection with the gram-negative rod *H pylori* is associated with 92% of gastric MALT lymphomas.[30]

Large B-cell lymphoma can arise at an anatomic site containing MALT, which has been named "high-grade MZ/MALT lymphoma," a term not included in the WHO classification. There is no evidence that large B-cell lymphoma occurring de novo at a MALT site is derived from MZ cells; and the clonal relationship between an MZL and a large B-cell neoplasm simultaneously detected in the same organ should be proven molecularly, as the latter can represent the blastic phase of the former, but might also develop as a second unrelated neoplasm.

Nodal Marginal Zone Lymphoma

In the WHO classification, nodal marginal zone lymphoma (NMZL) is defined as a primary nodal B-cell neoplasm that morphologically resembles lymph nodes involved by MZ lymphoma of the extranodal

or splenic type, but without evidence of extranodal or splenic disease. This suggests that the terms *extranodal*, *nodal*, and *splenic MZL* refer to different clinical presentations of the same disease.

Nodal marginal zone lymphoma is clinically more aggressive than the extranodal and splenic forms and has a higher incidence of advanced-stage disease and lower 5-year overall and disease-free survival.[31] In addition, 10% to 20% of cases transform into a DLBCL. Most cases display a distinct "monocytoid" appearance, and the tumor was originally termed *monocytoid B-cell lymphoma*. Molecular studies strengthen the concept of significant differences among the three types of MZL. The t(11;18) does not occur in nodal MZL. Analysis of IgV_H gene demonstrates that some nodal MZLs carry somatic mutations whereas others do not, suggesting derivation from post-GC and virgin B cells, respectively. Among mutated cases, usage of specific IgV_H gene segments seems to occur frequently and to discriminate between HCV-positive and -negative patients.[32] None of the translocations characteristically recorded in splenic MZL, including del(7q), del(13q14), and del(10)(q22,q24), has been detected in nodal MZL.

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphoma is generally characterized by splenomegaly and leukemic spread, although at times cases with disseminated disease or exclusively leukemic presentation have been reported. In approximately half of the cases, circulating neoplastic cells display cytoplasmic villous projections, which justify the term *splenic lymphoma with villous lymphocytes* used formerly. Infiltration of the marrow occurs in most if not all patients. Molecular studies have shown that splenic MZL is a heterogeneous tumor[33] with chromosomal abnormalities including del(7q), del(13q14), and del(10)(q22,q24).

Lymphoplasmacytic Lymphoma/Waldenstrom Macroglobulinemia

Lymphoplasmacytic lymphoma (LPL) is rare, accounting for less than 2% of all NHL. Lymphoplasmacytic lymphoma was defined initially as a small B-cell lymphoma with plasmacytoid or plasmacytic features. Because other types of small B-cell lymphoma, particularly marginal zone B-cell lymphoma, may exhibit plasmacytic differentiation, the WHO classification has defined LPL more narrowly to exclude other small B-cell lymphomas. Waldenstrom macroglobulinemia (WM) was combined with LPL and designated LPL/WM. The consensus group at the Second International Workshop on WM in 2002 redefined WM as a distinct clinicopathologic entity characterized by marrow infiltration with LPL and IgM monoclonal gammopathy.[34]

Variations in the immunophenotypic profile exist, but the typical immunophenotype consists of expression of CD19, CD20, CD22, cytoplasmic Igs, FMC7, BCL2, PAX5, CD38, and CD79a; CD10 and CD23 are usually absent. CD5 is variably expressed in up to 20% of cases. The immunophenotypic profile in combination with the presence of somatic mutations of IgVH genes without intraclonal diversity strongly suggests that the malignant cells originate from cells at a late stage of differentiation derived from a B cell arrested after somatic hypermutation in the germinal center and before terminal differentiation to a plasma cell. Most patients with WM have symptoms attributable to tumor infiltration or monoclonal serum protein. Lytic bone disease is rare. Extensive marrow infiltration leads to cytopenias, and progressive anemia is the most common indication for initiation of treatment. The neoplastic clone can also infiltrate other organs, including lymph nodes, liver, and spleen, presenting as organomegalies. In rare cases, diffuse lymphoplasmacytic infiltration of the lung, stomach, or bowel can occur. The Bing–Neel syndrome (long-standing hyperviscosity altering the vascular permeability and leading to perivascular malignant infiltration) consists of headache, vertigo, impaired hearing, ataxia, nystagmus, diplopia, and eventually coma. Serum hyperviscosity is the most distinguishing feature of WM, but is observed only in less than 15% of patients at diagnosis. Symptoms of hyperviscosity usually appear when the normal serum viscosity of 1.4 to 1.8 cP reaches 4 to 5 cP (corresponding to a serum IgM level of at least 30 g/L) and include constitutional symptoms, bleeding, ocular, neurologic, and cardiovascular manifestations. High-output cardiac failure may develop because of the expanded plasma volume arising from increased osmotic pressure. Abnormalities in bleeding and clotting times occur from the interaction of IgM with coagulation factors and platelets. Cryoglobulins may be detected in 20% of patients. IgM deposition can occur in the kidney, intestine, and skin, presenting as proteinuria, diarrhea, and macroglobulinemia cutis (papules and nodules). Primary amyloidosis occurs mainly in the heart, peripheral nerves, kidneys, soft tissues, liver, and lungs due to deposition of monoclonal light chains. Secondary amyloidosis is rarely seen in WM. Although most patients have detectable light chains in the urine, renal insufficiency and cast nephropathy are rare. The median survival of patients with WM ranges from 5 and 10 years. Prognostic factors include age, hemoglobin, serum albumin level, and β_2-microglobulin level. IgM levels have no prognostic value.[35]

Small Lymphocytic Lymphoma

Historically, small lymphocytic lymphoma (SLL) was considered a different disease from chronic lymphocytic leukemia (CLL). In the WHO classification, SLL and CLL are classified as different clinical manifestations of the same disease.[36] When the disease involves the blood and marrow, it is called CLL. When lymph nodes or other tissues are infiltrated by CLL cells in the absence of leukemia, it is called SLL. Only 5% of CLL/SLL patients present with clinical features of SLL without the leukemic component. The National Cancer Institute guidelines recommend that the threshold for diagnosis of CLL should require a lymphocytosis of greater than 5000/μL.[37] However, if diagnostic immunophenotypic features are clearly those of typical CLL/SLL, the diagnosis can be made in the presence of a blood lymphocyte count of less than 5000/μL. CLL/SLL is largely a disease of the elderly, with a median age at diagnosis of 70 years. It is extremely rare at less than 30 years of age, but the incidence increases with increasing age and occurs almost twice as frequently in males than females. The variation in international incidence patterns among the leukemias and lymphomas is most marked for SLL/CLL, with a 26-fold increase in incidence for men and a 38-fold increase for women in North America when compared to the incidence in Japan.[38] Genetic rather than environmental factors probably underlie these differences, because the disease is rare among Japanese Americans.[39] Among the strongest risk factors for SLL/CLL is a family history of this or other lymphoid malignancies, and a number of familial clusters of CLL/SLL have been reported.[40]

The diagnosis of SLL is made by the detection of a clonal population of small B lymphocytes in the lymph node biopsy showing cells expressing the characteristic morphology and immunophenotype. Full immunophenotype is required to make the diagnosis. Chronic lymphocytic leukemia cells express CD19, dim CD20, dim CD5, CD23, CD43, and CD79a and weakly express surface IgM and IgD. Occasional cases lack expression of CD23, and this can lead to a differential diagnosis of mantle cell lymphoma. The dim expression of CD20 and surface immunoglobulin can be useful in distinguishing SLL from mantle cell lymphoma. Expression of CD38 is variable and has prognostic significance. Detection of specific cytogenetic and molecular features can be helpful in making the definitive diagnosis.

SLL usually presents with marrow and blood involvement and typically runs an indolent course. Transformation into DLBCL (Richter syndrome) may occur. Although it is reasonable to assume that a similar profile of molecular cytogenetic lesions may characterize

SLL and CLL, no formal studies have been performed to demonstrate this conclusively. However, the molecular changes and their incidence appears identical in SLL and CLL. Fluorescence in situ hybridization studies found an approximate 50% incidence of cryptic 13q14 deletions and a 5% to 10% incidence of 17p13 deletions. Structural changes of 11q, mostly deletions involving the q22–23 segment (del(11q)), were detected in 10% to 20%. Trisomy 12 was seen in 10% to 30% of the cases and other trisomies, involving chromosomes 3 (+3) and 18 (+18) in approximately 10% of the cases. Deletions/translocations of 6q21–23 were detected in 15% to 25% of the cases and correlated with leukemic involvement by large prolymphocytoid cells. The t(14;19)(q32;q13.3) deletions/translocations 14q22 and the t(11,14)(q13;q32) were reported in several cases. Other chromosome 14q32 translocations with 1p32 and other unknown partners may be found in SLL; in general, those cases with a 14q anomaly require a precise histologic characterization because distinction from mantle cell lymphomas and marginal zone B-cell lymphomas may pose difficult diagnostic problems.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) was recognized as a separate clinicopathologic entity in 1992. It has been previously referred to as intermediate lymphocytic lymphoma, mantle zone lymphoma, centrocytic lymphoma, and lymphocytic lymphoma of intermediate differentiation. In the Rappaport and Working Formulation classifications, the majority of cases of diffuse small cleaved cell lymphomas on re-review were found to be MCLs; however, cases were also found in the small lymphocytic and follicular categories. Histologically, MCL is composed of small cells with irregular nuclei, although the cells may be larger in the blastic variant. Immunophenotype is characterized by the coexpression of the T-cell antigen CD5, with the B-cell markers CD20, CD19, CD22, and CD79a. It is distinguished from CLL by the lack of expression of CD23, by bright CD20 and surface immunoglobulin, and by expression of cyclin D1. The t(11;14) occurs in virtually all cases of MCL. The histologic pattern of MCL may be diffuse, nodular, or mantle zone, or a combination of the three. It has been reported that there is a better prognosis for cases with a mantle zone pattern. Most cases are composed exclusively of small- to medium-sized lymphoid cells, with slightly irregular, or "cleaved," nuclei. However, the morphology can range from lymphocyte-like to large cleaved or lymphoblast-like. Despite the small size and bland appearance of these cells, there is often more mitotic activity than in other histologically low-grade lymphomas. Single epithelioid histiocytes may be present, but clusters and granulomas are not seen. Transformed cells with basophilic cytoplasm (centroblast- or immunoblast-like cells) are extremely rare or absent, aside from residual germinal centers. Mantle cell lymphoma is thought to arise from naïve cells from the follicle mantle, although a number of studies have suggested that somatic hypermutation can occur in a subset of patients.

Mantle cell lymphoma is an aggressive, generally incurable subtype of NHL that accounts for approximately 5% to 6% of all NHL cases.[18] Approximately 3000 to 4000 new MCL cases occur annually in both the USA and Europe. The median age of presentation is 65 years, with a strong male preponderance. Most cases are at an advanced stage at presentation,[41] and extranodal involvement is common, especially in the gastrointestinal tract.[42] A small number of patients who present with limited-stage disease may potentially be cured by modified extended field radiation therapy. MCL has the poorest long-term survival of all the lymphoma subtypes, and a watch and wait approach is generally not justified. Factors associated with poor prognosis include poor performance status, splenomegaly, anemia, and age.[43] The international prognostic index is of limited value in predicting outcome. Mantle cell lymphoma has one of the poorest prognoses of all NHL subtypes.[18] With standard therapies, median failure-free survival is 8 to 20 months and median survival is approximately 3 to 4 years.[25,41,44,45]

TREATMENT OF INDOLENT LYMPHOMAS

For most cases of indolent lymphoma, the goal of therapy has been to maintain the best quality of life and to treat only when patients develop symptoms. Any alteration to this approach requires demonstration of improved survival with early institution of therapy, or identification of criteria that define patients sufficiently high-risk to merit early therapy. There are many available therapies and no consensus on an optimal first-line or relapse treatment. Despite a paucity of data demonstrating any benefit for early therapy, patients are being treated earlier in their disease course. There is no clear cut treatment pathway for patients with indolent lymphomas and little or no data regarding the optimal sequencing of treatment approaches in these diseases. In the absence of such data, treatment choices remain empiric and should always involve discussion regarding patient choice and goal of therapy. Decisions concerning therapy are likely to become even more complicated because many novel agents are currently being investigated in preclinical and clinical studies, particularly, novel monoclonal antibodies and agents that alter the antiapoptotic pathways. Enrollment of patients on properly conducted clinical trials should be encouraged until we have a clear-cut established treatment approach that leads to cure for the majority of patients.

Options for treatment of low-grade lymphomas include a watch and wait approach, single-agent chemotherapy, or monoclonal antibody therapy with rituximab, combination chemoimmunotherapy, and the use of autologous or allogeneic hematopoietic cell transplantation (HCT) (Table 79–5). Patients remaining on an expectant course should be followed every 3 months with history, physical examination, and blood counts, including lactate dehydrogenase. Special attention should be paid to any change in symptoms that might be suggestive of transformation, which should be an indication for repeat biopsy to examine for histologic evidence to confirm transformation. The role of routine repeat scanning remains unclear.

Because there is no clearly defined treatment algorithm for most patients with indolent lymphomas, eligible patients should be included whenever possible in clinical trials. This ensures delivery of optimal care and helps inform design of subsequent trials, hopefully leading to cure. Information on available clinical trials can be found at www.clinicaltrials.gov.

WHEN TO INSTITUTE THERAPY

With the exception of patients enrolled in clinical trials assessing the impact of early therapy, expectant management is the treatment of

Table 79–5 Treatment Strategies for Indolent Lymphomas

Advanced Stage Disease
"Watchful waiting"
Alkylating agents
Purine analogs
Combination chemotherapy
Monoclonal antibodies
Unconjugated
Conjugated – radioimmunoconjugates and immunotoxins
Chemotherapy + monoclonal antibodies (chemoimmunotherapy)
High dose chemotherapy plus autologous/allogeneic hematopoietic cell transplantation
Reduced intensity conditioning allogeneic transplantation.
Palliative radiotherapy
Localized Disease
Radiotherapy
"Watchful waiting"

Table 79–6 Criteria for Delaying Treatment

Groupe pour l'Etude de Lymphome Folliculaire (GELF)[48]
All of the following
Maximum diameter of disease <7 cm
Fewer than three nodal sites
Absence of systemic symptoms
Spleen <16 cm on CT
No significant effusions
No risk of local compressive symptoms
No circulating lymphoma cells or marrow compromise (Hb ≤10 g/dL, WBC <1.5, or platelets <100,000/dL)
British National Lymphoma Investigation (BNLI)[49]
Absence of all of the following
B symptoms or pruritus
Rapid generalized disease progression
Marrow compromise (Hb ≤10 g/dL, WBC <3.0, or platelets <100,000/dL)
Life-threatening organ involvement
Renal infiltration
Bone lesions

choice for asymptomatic patients with low bulk disease until clear indications for initiation of treatment are seen. This approach is based on the demonstration of no survival advantage for institution of immediate compared with deferred treatment until time of progression.[46] Three randomized trials, performed in the pre-rituximab era, confirmed no survival benefit for early therapy.[47–49] In the National Cancer Institute study in 104 newly diagnosed patients with FL, deferred treatment was compared with immediate treatment with ProMACE-MOPP followed by total nodal irradiation. An updated analysis of the data is long overdue, but there was no difference in overall survival (OS) between the two arms at the time of the last analysis.[47] The Groupe pour l'Etude de Lymphome Folliculaire (GELF) used defined criteria for patients in whom immediate therapy was not felt to be indicated (Table 79–6) and randomized 193 patients to deferred treatment or to receive prednimustine 200 mg/m^2/day for 5 days per month for 18 months or interferon-alpha (IFN-α) 5 MU/day for 3 months, then 5 MU three times per week for 15 months.[48] The median OS time was not reached and was the same in all three arms of the study. The British National Lymphoma Investigation[49] compared treatment in 309 patients with asymptomatic advanced-stage, indolent lymphoma in whom 158 patients were randomized to receive immediate therapy with oral chlorambucil 10 mg per day continuously and 151 patients randomized to deferred treatment until disease progression (Table 79–6). In both arms, local radiotherapy to symptomatic nodes was allowed. There was no difference in OS or cause-specific survival between the two groups with 16 years' median follow-up. A meta-analysis of more than 2000 patients with early-stage CLL/SLL showed no difference in survival between early versus deferred therapy using alkylating agents.[50]

A major clinical trial question is whether identification of clinical or molecular risk factors can identify which patients are candidates for early therapy. A survival predictor score has also been developed from gene expression profiling studies.[12] The results from this study suggest that the molecular determinants of biological heterogeneity are already present in the diagnostic lymph node biopsies rather than by the later acquisition of secondary genetic changes. A major component of the gene expression prognostic signature is related to immune cells in the tumor microenvironment.[13,14,51] Future guidelines for treatment will likely be based on clinical staging systems, genetic profiles, and immune response signatures, but these factors do not yet help us to decide who should receive immediate therapy.

From available data, there is little to suggest that we should change our practice of "watch and wait" for asymptomatic low bulk patient, but data demonstrate that this practice is becoming much less common in the USA.[52] The National Lymphocare Study is a prospective observational study designed to assess presentation, prognosis, treatment, and clinical outcomes in newly diagnosed FL. The treating physician determines management according to clinical judgment with no prescribed treatment regimen and data regarding histology, stage, therapy, response, relapse, and death are recorded. Among 1493 patients enrolled at 237 centers, 26% of initially observed patients had switched to active therapy after a median of 2.8 months on observation since diagnosis, and by the first follow-up visit only 19% of patients continued on watch and wait at 6 months (Table 79–7). This observation is in stark contrast to the data from the British National Lymphoma Investigation (BLNI) study demonstrating that (censored for nonlymphoma death) 19% of patients and 40% for those older than 70 years who were randomized to expectant management still did not require therapy at 10 years.[49]

TREATMENT APPROACHES

Treatment is indicated in patients with symptomatic disease, bulky lymphadenopathy, and/or splenomegaly; risk of local compressive disease; marrow compromise; or rapid disease progression. Once indicated, numerous treatment approaches are available (Table 79–5). The concept that the approach can be to "do nothing" or discuss an approach with considerable morbidity and mortality such as hematopoietic cell transplantation is a confusing one for the newly diagnosed patient (as well as for the physician), and considerable consultation time is required to review available treatment approaches. Staging of response in indolent lymphomas is by the revised response criteria.[16] Depending on the treatment approach used, restaging after two to three cycles of therapy can be useful to ensure responsiveness with full restaging after completion of therapy. Whereas curative approaches are being sought in indolent lymphomas, the failure to achieve complete remission (CR) does not have the same implication in indolent lymphomas as in aggressive lymphomas, and a PR may be a sufficient response to therapy to alleviate symptoms.

Optimal first-line treatment is enrollment in randomized clinical trials. In the National Lymphocare Study,[52] academic sites are more likely than community sites to treat patients on clinical trials (12% vs 4%), but it is lamentable that such a small proportion of these patients are enrolled in clinical trials. For patients who are not eligible

for or who refuse entry into clinical trials, there are data demonstrating higher response rates and longer duration of responses, and perhaps improved survival with chemoimmunotherapy. Many investigators favor alkylator- over fludarabine-based regimens for FL, based on concerns regarding the ability to obtain stem cells for later use for autologous HCT in fludarabine-treated patients.[53] It is suggested that more aggressive first-line therapy should be offered to patients who progress within 1 year of presentation, because these patients have a worse outcome.[48] Elderly patients or those with poor performance status remain candidates for single-agent chlorambucil. Single-agent monoclonal antibody therapy is appropriate for patients who chose to avoid chemotherapy and is a reasonable treatment choice based on the results of clinical trials of prolonged or maintenance therapy with rituximab. Although data suggest a survival advantage with the use of IFN-α in combination with chemotherapy, this is associated with a significant side effect profile and this agent is rarely used in the USA. Optimal results are seen when radioimmunoconjugates are used earlier in the disease course. There is no indication for the use of high-dose therapy and HCT in first remission in FL except in the context of a properly conducted clinical trial.

Data from the National Lymphocare study[52] demonstrate that chemoimmunotherapy is now the treatment of choice of physicians in the USA (Table 79–7). No randomized trials demonstrate a benefit for the addition of anthracyclines, but cyclophosphamide, adriamycin, vincristine, prednisone, and rituximab (CHOP-R) is heavily favored over cyclophosphamide, vincristine prednisone, and rituximab (CVP-R) or fludarabine-based regimens. Choice to initiate therapy was associated with FLIPI, stage, and grade but FLIPI was not associated with the decision to utilize a specific treatment approach. Significant regional and center differences were observed, strongly suggesting that physician preference is the predominant factor that drives initial therapy. For example, initial "watch and wait" was used in 31% in the Northeast, but in 13% in the Southeast, whereas fludarabine-based chemoimmunotherapy was used in 18% of patients in the Southwest and only 3% in the Northeast.

Alkylating Agents

The alkylating agents chlorambucil and cyclophosphamide with or without prednisone and CVP or CHOP, and other alkylator-based combination chemotherapy regimens, have been the standard of therapy for decades. Single-agent alkylators at different doses and schedules produce overall response (OR) rates of 50% to 75% in FL.[54,55] Comparable response rates but higher complete remission rates with longer progression-free survival (PFS) are seen with CVP compared to chlorambucil, but there is no survival advantage.[56,57] The addition of anthracyclines has not improved the response rate or duration of the response,[58,59] but its use may be associated with a lower risk of histologic transformation.[47,60] This finding has to be confirmed, particularly in the era of chemoimmunotherapy.

Purine Analogues

The purine analogues have been studied extensively in various types of indolent lymphoma. Fludarabine monotherapy produces response rates of 65% to 84%, with 37% to 47% CR in previously untreated FL patients.[61] In a randomized trial of 381 previously untreated indolent lymphoma patients, CR rates were higher with fludarabine than CVP.[62] Fludarabine combinations result in increased response rates, with 89% CR rate in an Eastern Cooperative Oncology Group trial combining fludarabine and cyclophosphamide,[63] whereas fludarabine and mitoxantrone produced a 91% overall response rate, 43% CR, and 63% 2-year disease-free survival.[64] A higher CR rate was seen with fludarabine and mitoxantrone (68%) compared to CHOP (42%) in a randomized trial.[65] The use of alkylator-based regimens or purine analog-based regimens appears to vary geographically, suggesting personal preference for the use of regimens in which the clinician has experience, rather than alterations of practice based on the results of the published studies. In CLL/SLL, fludarabine is associated with a higher response rate and longer duration of response than chlorambucil,[66] but no OS advantage. The use of fludarabine in combination with cyclophosphamide is associated with a higher response rate and longer duration of response compared with fludarabine alone in randomized trials.[67] The highest response rates have been with fludarabine, cyclophosphamide, and rituximab.[68]

Biologic Therapy

IFN-α is approved by the Food and Drug Administration (FDA) for the treatment of advanced-stage FL in combination with anthracycline-based chemotherapy, based on improved survival in a clinical trials[24,69,70] and meta-analysis of phase III trial data.[71] IFN-α has been widely used in Europe but not in the USA, where it is felt that its toxicity profile outweighs any potential benefit. In the SWOG study,[72] 571 patients with stage III and IV indolent lymphoma were treated with ProMACE-MOPP, and 279 responding patients were randomized to 24 months of observation versus treatment with IFN-α. No statistically significant difference in PFS or OS was observed between observation and IFN-α groups at 4 years.

Monoclonal Antibody Therapy

Monoclonal antibodies are the most exciting agents to emerge in the treatment of indolent lymphomas, and recent data suggest their use may finally be leading to improvement in patient survival.[22,23] The most widely used monoclonal antibody is rituximab, a chimeric unconjugated antibody against the CD20 antigen licensed by the FDA[73] and the European Agency for the Evaluation of Medicinal Products[74] for treatment of patients with relapsed or refractory, CD20-positive low-grade FL; for the first-line treatment of CD20-positive FL in combination with CVP chemotherapy; and for the treatment of CD20-positive low-grade NHL in patients with stable disease or who achieve a PR or CR following first-line treatment with CVP chemotherapy.

Following phase I studies,[75] rituximab at a dose of 375 mg/m^2 weekly for 4 weeks was selected for the pivotal phase II trial and this remains the standard dose.[76] In relapsed indolent lymphoma patients, OR was 48% and 60% in FL. Median PFS for responders was 13 months. Factors associated with lower response rates include chemoresistant disease,[76] bulky disease,[77] and treatment late in the disease course.[78] The incidence of OR was 73% in previously untreated patients with low bulk disease,[79] and some of these patients have needed no further treatment and have no evidence of polymerase chain reaction-detectable minimal residual disease after 7 years.[80] Extended use with 8 weeks instead of four is associated with improvement in OR and duration of response.[81] Comparable or even longer durations of response have been observed with retreatment.[82]

A number of trials in front-line and in relapsed/refractory patients have investigated the potential benefits of extended or maintenance rituximab treatment[83–87] and all demonstrated prolonged time to progression in patients receiving maintenance rituximab (Table 79–8). The results from the E1496 randomized trial from the Eastern Cooperative Oncology Group and the Cancer and Leukemia Group B comparing CVP alone to CVP followed by rituximab in patients with advanced-stage FL demonstrated that addition of rituximab maintenance significantly improved OS[83] and led to FDA approval for rituximab therapy in patients responding to CVP chemotherapy. A problem with interpretation of the role of maintenance therapy or in recommending a specific regimen is that there is no standard schedule and trials have been performed in rituximab-naïve patients as well as in patients treated with previous rituximab monotherapy or combination chemoimmunotherapy, as shown in Figure 79–1.

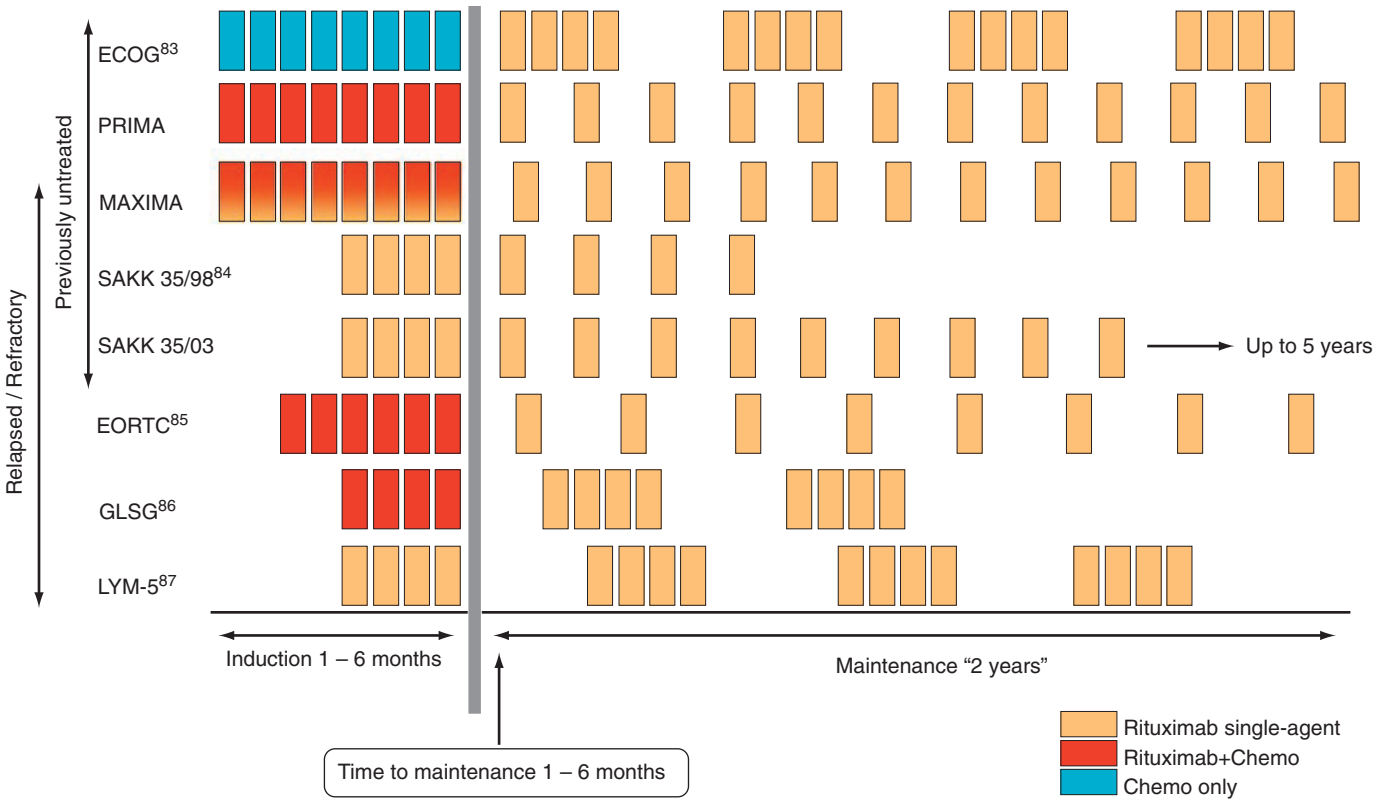

Figure 79–1 Clinical trials examining rituximab maintenance therapy. The induction phase has included the use of chemotherapy alone, rituximab alone or chemoimmunotherapy. The PRIMA and MAXIMA studies are ongoing randomized studies examining the use of chemoimmunotherapy followed by rituximab maintenance. Studies included previously untreated and treated patients.

Table 79–8 Studies of Rituximab Maintenance Therapy in Indolent Lymphomas

Trial	Disease Setting	Diseases Included	Previous Therapy
ECOG[83]	First line	Follicular Small lymphocytic	CVP
SAKK[84]	First line Relapsed/refractory	Follicular Mantle cell	Rituximab
EORTC[85]	Relapsed/refractory	Follicular	CHOP vs R-CHOP
GLSG[86]	Relapsed/refractory	Follicular Mantle cell	FCM vs R-FCM
LYM-5[87]	Relapsed/refractory	Follicular Small lymphocytic	Rituximab

CHOP, cyclophosphamide, adriamycin, vincristine, and prednisone; R-CHOP, rituximab with cyclophosphamide, adriamycin, vincristine, and prednisone; FCM, fludarabine, cyclophosphamide, mitoxantrone; R-FCM, rituximab with fludarabine, cyclophosphamide, mitoxantrone; ECOG, Eastern Co-operative Oncology Group; SAKK, Schweizerische Arbeitsgemeinschaft für klinische Krebsforschung; EORTC, European Organisation for Research and Treatment of Cancer; GLSG, German Low Grade Lymphoma Study Group; LYM-5, Lymphoma 5 trial.

Chemoimmunotherapy

In a phase II study, 40 patients with indolent lymphoma were treated with six infusions of rituximab (375 mg/m^2 per dose) in combination with six doses of CHOP chemotherapy (R-CHOP).[88] Overall response was 95%, with a CR of 55% and OR of 45% in patients with bulky disease. In a phase II study of 40 patients with indolent lymphomas, rituximab in combination with fludarabine produced OR of 90% and CR of 80%, with similar response rates in treatment-naïve and previously treated patients.[89]

A number of randomized trials show a benefit for the use of rituximab with chemotherapy compared to chemotherapy alone (Table 79–9).[85,90–93] Each study showed an improvement in time to treatment failure. More recent follow-up data suggest improved OS in patients treated with chemoimmunotherapy compared to chemotherapy alone. A meta-analysis of these trials demonstrates that OS, OR, and disease control are significantly better in those on chemoimmunotherapy compared to chemotherapy for FL and mantle cell lymphoma.[94] Data from the German Low-Grade Study Group suggest that it is the addition of rituximab that has led to the recent improvement in survival of patients with FL.[23] A recent independently assessed analysis of the clinical benefits provided by rituximab in relation to cost concluded that it is highly cost-effective.[95]

Conjugated Radiolabeled Monoclonal Antibody Therapy

Binding a radioisotope to a monoclonal antibody (radioimmunoconjugate) might be expected to improve efficacy over antibody therapy alone. Tositumomab joins ^{131}I to the anti-B1 antibody and has been studied extensively in the treatment of heavily pretreated[96] and untreated[97] lymphomas and for retreatment of indolent lymphomas.[98] Best responses are seen in previously untreated FL patients with a 95% OR and 75% CR. Eighty percent of assessable patients achieved eradication of polymerase chain reaction-detectable minimal residual disease after a single treatment course with tositumomab.[97] Median PFS was 6.1 years, with 40 patients remaining in remission for 4.3 to 7.7 years and no cases of myelodysplastic syndrome observed. A SWOG study investigated chemoimmunotherapy with six cycles of CHOP chemotherapy followed 4 to 8 weeks later by tositumomab in 90 patients with previously untreated, advanced-stage FL.[99] The OR was 91%, including 69% CR and at median

Table 79–9 Randomized Trials of Chemotherapy vs Chemoimmunotherapy

Study	Treatment, No. of Patients	Median FU, Months	OR %	CR %	Median TTF, Months	OS %
M39021[90]	CVP, 159	53	57	10	15	77

					$P < .0001$	$P = .029$

CR, complete remission; CHOP, cyclophosphamide, adriamycin, vincristine, and prednisone; CHVP-IFN, cyclophosphamide, doxorubicin, teniposide, prednisone, and IFN-α; CVP, cyclophosphamide, vincristine, and prednisolone; FU, follow-up; GLSG, German Low Grade Lymphoma Study Group; MCP, mitoxantrone, chlorambucil, and prednisolone; OR, overall response; OS, overall survival; R-CHOP, rituximab with cyclophosphamide, adriamycin, vincristine, and prednisone; R-CHVP-IFN, rituximab with cyclophosphamide, doxorubicin, teniposide, prednisone, and IFN-α; R-CVP, rituximab, cyclophosphamide, vincristine, and prednisolone; R-MCP, rituximab with mitoxantrone, chlorambucil, and prednisolone; TTF, time to failure.

follow-up time of 5.1 years, the estimated 5-year OS was 87% and PFS 67%. These results were significantly better than results of therapy with CHOP alone on previous SWOG protocols. Ibritumomab Tiuxetan is a ^{90}Y-labeled anti-CD20 antibody and produced an OR of 74% and CR of 15% in 57 FL patients refractory to rituximab.[100] Toxicity is primarily hematologic, with nadir counts occurring at 7 to 9 weeks and lasting approximately 1 to 4 weeks. The risk of hematologic toxicity increased with dose delivered and with degree of baseline marrow involvement.[101] An acceptable safety profile was observed in relapsed patients with less than 25% lymphoma marrow involvement, adequate marrow reserve, platelets greater than 100,000 cells/μL, and neutrophils greater than 1500 cells/μL.

High-Dose Therapy as Consolidation of First Remission

The role of high-dose therapy and autologous HCT in FL patients during first remission was explored in phase II trials,[102,103] and in three phase III randomized trials.[104–106] The German Low-Grade Study Group trial[104] recruited 307 previously untreated patients up to 60 years of age. Patients who responded after induction chemotherapy with 2 cycles of CHOP or mitoxantrone–chlorambucil–prednisone were randomized to autologous HCT or IFN-α maintenance. Among 240 evaluable patients, the 5-year PFS was 64.7% for autologous HCT and 33.3% in the IFN-α arm ($P < .0001$). Acute toxicity was higher in the autologous HCT group, but early mortality was below 2.5% in both study arms. Longer follow-up is necessary to determine the effect of autologous HCT on OS. In the Groupe Ouest Est des Leucemies Aigues et des Maladies du Sang study, 172 newly diagnosed advanced FL patients were randomized either to cyclophosphamide, doxorubicin, teniposide, prednisone (CHVP) and IFN-α or to high-dose therapy followed by purged autologous HCT.[105] Patients treated with high-dose therapy had a higher response rate than patients who received chemotherapy and IFN-α (81% vs 69%, $P = .045$) and a longer median PFS (not reached versus 45 months), but this did not translate into a better OS because of an excess of secondary malignancies after transplantation. A subgroup of patients with a significantly higher event-free survival rate could be identified using the FLIPI. The GELF-94 study enrolled 401 previously untreated advanced-stage FL patients who were randomized to receive CHVP plus IFN-α compared with four courses of CHOP followed by HDT with total body irradiation and autologous HCT. Overall response rates were similar in both groups (79% and 78%, respectively), and 87% of eligible patients underwent autologous HCT. Intent-to-treat analysis after a median follow-up of 7.5 years showed no difference between the two arms for OS ($P = .53$) or PFS ($P = .11$). Long-term follow-up demonstrated no statistically significant benefit in favor of first-line autologous HCT in patients with FL. In view of these results, autologous HCT should be used in first remission only in the setting of clinical trials.

TREATMENT OF RELAPSED INDOLENT LYMPHOMA

The treatment options after relapse remain the same as for first-line therapy (Table 79–5), and relapsed patients should ideally be treated in clinical trials. Relapsed asymptomatic disease is not necessarily an indication for treatment and patients can again be managed expectantly. A number of factors must be taken into account in planning therapy and it is not possible to define treatment at relapse without considering the goal of therapy (palliative vs potentially curative) performance status, previous therapy, response, and duration of response. Single agent rituximab is approved for relapsed lymphoma and is widely used in this setting. A multicenter randomized trial in relapsed patients has demonstrated a survival advantage for chemoimmunotherapy with CHOP-R or CHOP followed by R compared to CHOP alone, and a further benefit for rituximab maintenance therapy.[85] For younger patients who are suitable candidates for autologous HCT or reduced-intensity conditioning (RIC) allogeneic transplantation, referral to a transplant center should be considered early to discuss the potential role and timing of transplantation. Best results are seen when transplantation is considered early in the course of disease before patients become chemorefractive. Hematopoietic cell transplant approaches must be considered in the context of the improving results that are being seen with salvage therapy alone. The results of autologous HCT have been disappointing for CLL/SLL;[107] however, RIC allogeneic transplants appear promising in selected patients with this disease.[108]

The Role of Transplant in Relapsed Indolent Lymphomas

Unlike aggressive lymphomas, the use of high-dose chemotherapy with autologous HCT in the treatment of indolent lymphomas has not yet been fully established. The rationale for considering transplantation is that the disease is incurable using standard approaches, and promising results have been observed in a number of phase II studies.[109–111] Detection of minimal residual disease has been a useful

surrogate marker for tracking long-term PFS in patients examining the autologous stem cells or serial samples after transplantation.[111–115] A major concern relates to the risk of secondary myelodysplasia/acute myeloid leukemia.[116] The European Bone Marrow Transplant Registry-sponsored CUP study (conventional chemotherapy, unpurged, purged autograft) is the only prospective randomized trial to assess the role of autologous HCT in patients with relapsed FL.[117] The results of the study suggest a PFS and OS advantage of autologous HCT over conventional chemotherapy, with a 4-year OS of 46% for the chemotherapy arm, versus 71% for the unpurged and 77% for the purged autologous HCT arms. The study was closed early because of slow accrual with 140 of the planned 250 patients accrued and only 89 randomized. In CLL/SLL, the use of autologous HCT was not associated with improved outcome in patients transplanted in first remission compared to those transplanted later in their disease course.[107]

Allogeneic Hematopoietic Cell Transplant

There is a trend toward increasing use of allogeneic HCT in the management of indolent lymphomas. In a report of the International Bone Marrow Transplant Registry, results after HCT are described for 904 patients with FL.[118] Among these patients, 176 patients underwent allogeneic HCT, and 131 patients underwent autologous HCT using a purged inoculum and 597 using an unpurged autologous inoculum. The treatment-related mortality (TRM) in these three groups was 30%, 14%, and 8%, respectively, disease recurrence in 21%, 43%, and 58% and 5-year OS was 51%, 62%, and 55%, respectively. The use of total body irradiation-containing regimens was associated with increased TRM but decreased risk of relapse. The use of allogeneic HCT was associated with increased TRM but significantly lower risk of disease recurrence in keeping with a graft-versus-lymphoma effect in this disease. It should be noted that the majority of allogeneic transplant recipients reported in these studies received a fully myeloablative regimen. Long-term PFS has been observed after allogeneic SCT even in patients with refractory FL.[119] In 29 FL patients, 11 of whom had refractory disease, the nonrelapse mortality was 24% and there was a 23% incidence of relapse. The 5-year OS was 58%, with 53% event-free survival. Patients who have relapsed after previous autologous HCT have a very poor prognosis. The outcome following myeloablative allogeneic HCT of 114 such patients has been reported from the International Bone Marrow Transplant Registry.[120] The TRM was 22% and the probability of disease progression was 52% at 3 years. The use of total body irradiation conditioning regimens and achievement of CR at the time of allogeneic HCT were associated with improved outcome. The use of RIC regimens appears to be associated with improved outcome. In 20 such patients, there was only one TRM from fungal infection and the 3-year progression-free survival was an excellent 95%.[121] The out-come following RIC transplant regimen incorporating alemtuzumab immunosuppressive therapy has been reported for 81 patients with lymphoma, including 41 with low grade, 37 with high/intermediate grade, and 10 patients with MCL, 31 of whom had relapsed following previous autologous HCT.[122] Patients received a conditioning regimen consisting of alemtuzumab, fludarabine, and melphalan, and received short-course cyclosporine as GVHD prophylaxis. The use of this conditioning regimen was associated with a low incidence of GVHD and TRM was decreased in patients with low-grade compared to higher-grade histology. The 3-year progression-free survival was 65% for patients with low-grade lymphoma, 50% for patients with MCL, and 34% for high-grade lymphoma ($P = .002$). Donor lymphocyte infusion was given to 36 patients, 21 for relapsed or persistent disease and 15 for persistence of mixed chimerism. Investigators hypothesize that the use of donor lymphocyte infusion to treat relapse after allogeneic HCT will stimulate an effective graft-versus-lymphoma response. In one series, seven patients with FL and SLL who had relapsed after prior allogeneic HCT received donor lymphocyte infusion. Six patients responded and four experienced CRs, which have been maintained for 43 to 89 months. The effectiveness of donor lymphocyte infusion to treat relapse after allogeneic HCT provides very strong evidence for a graft-versus-lymphoma effect that can be exploited in indolent lymphomas.[107,122]

SPECIAL CONSIDERATIONS FOR TREATMENT

Waldenstrom Macroglobulinemia

The aim of treatment in Waldenstrom macroglobulinemia is to improve the quality and duration of life with minimal adverse effects in the most cost-effective manner. Whether achievement of CR confers clinical benefit is still debatable. Treatment should be reserved for symptomatic patients and should not be initiated on the basis of serum monoclonal protein levels alone. The main choices for primary treatments are alkylating agents (chlorambucil, cyclophosphamide, melphalan), purine analogues (cladribine, fludarabine), and monoclonal antibody (rituximab). Plasma exchange is indicated for the acute management of patients with symptoms of hyperviscosity because 80% of the IgM protein is intravascular. Patients may be candidates for initial combination therapy with purine nucleoside analogues or antibody therapy.

Mucosa-Associated Lymphoid Tissue Lymphomas

Bacterial infection with the gram-negative rod *H pylori* is associated with 92% of gastric MALT lymphomas.[30] Large-scale epidemiologic studies have confirmed a statistical association between *H pylori* infection and the subsequent development of gastric MALT lymphoma,[123] suggesting that gastric MALT lymphoma is "driven" by *H pylori.* These observations have led to clinical trials of antibiotic therapy in an attempt to treat MALT lymphomas. Using a combination of antibiotics and a histamine blocker for eradication of *H pylori* produces CR rates of approximately 70% in patients with localized gastric MALT lymphomas, with some molecular CRs. Of interest, responses may occur as long as 18 months after completion of antibiotic therapy. In a series of 158 patients with gastric MALT lymphoma, 54 were found to have disseminated disease, yet antibiotic treatment resulted in equivalent CR rates (74%), independent of local or disseminated disease, with overall 5- and 10-year survival rates of 86% and 80%, respectively, and median PFS of 5.6 years.[124] The importance of this findings is the suggestion that outcome can be improved with eradication of a factor that drives proliferation of the malignant cells, although putative factors driving other indolent lymphomas have yet to be identified.

The prognosis is also good for nongastrointestinal MALT lymphomas with CRs and PRs of 79% and 21%, respectively, in patients receiving various treatment approaches, including local radiation therapy, IFN-α, and/or chemotherapy.[125]

Monitoring of these patients should be performed according to guidelines such as those shown here. Morphology represents the most effective tool to assess lymphoma regression, as polymerase chain reaction can remain positive years following therapy in the absence of any sign of disease relapse.[126]

Splenic Marginal Zone Lymphoma

No consensus has been achieved on the optimal therapeutic approach in this disease. Most studies have suggested better outcomes for those patients who underwent splenectomy, suggesting that splenectomy may be the first-line treatment choice,[127] but this can be delayed until the occurrence of symptoms or cytopenia and seems to be sufficient for correcting cytopenic manifestations, improving quality of life and increasing survival (with median values of between 9 and 13 years).[33] The utility of alternative approaches, including chemotherapy, radiotherapy, or immunotherapy, is the subject of prospective clinical trials. Adverse prognostic predictors include hemolytic anemia, immune thrombocytopenia, M-component in the serum, elevated

Management of Gastric Malt Lymphoma

For patients presenting with gastric MALT lymphoma, diagnosis is usually made by endoscopic biopsy, which should be reviewed by an expert lymphoma pathologist. The stomach specimen should be tested for *Helicobacter pylori*. The disease is staged by CT scan and marrow biopsy. Treatment with antibiotics is appropriate only if the lymphoma is confined to the stomach and infection with *H pylori* is found. If the lymphoma is more advanced and has spread to surrounding lymph nodes, radiation therapy may be added. After treatment, endoscopy with biopsy should be repeated after 3 months. For advanced-stage disease, chemotherapy may be given if there are reasons for treatment, including bleeding from stomach, vital organ damage, large tumor, steady growth of lymphoma, symptoms, or enrollment in a clinical trial. For stages III and IV, treatment is similar to that used for follicular lymphoma (FL).

Endoscopy should be repeated after 3 months. If neither lymphoma nor *H pylori* is found, no further treatment is needed. If the *H pylori* is gone but lymphoma persists, then 3 more months of observation is suggested or radiation therapy delivered to the stomach, particularly if there are symptoms. If the lymphoma is gone but *H pylori* persists, then another course of different antibiotics should be given. If both the lymphoma and *H pylori* are still present, a second course of different antibiotics can be given if the lymphoma is not growing. If it is growing, then radiation therapy to the stomach and surrounding area is suggested.

A further endoscopy and biopsy should be performed at 6 months and a similar algorithm followed. Endoscopy and biopsy should be repeated again, although the exact timing is not known. If the lymphoma has not gotten smaller and radiation therapy has not been given, then the lymphoma is treated like an FL. If antibiotics have been given, then it is treated with radiation therapy.

Summary: For localized disease with *H pylori*, treat with antibiotics. If the lymphoma is gone, no more treatment is needed. If the lymphoma returns after antibiotic therapy, radiation therapy should be given. If the lymphoma returns after radiation therapy, it should be treated with chemotherapy as for FL. If it has spread to a site away from the stomach, it should be treated with chemotherapy as for FL.

β2-microglobulin level, leukocyte count >20,000/μL, lymphocytes >9000/μL, and p53 overexpression by neoplastic cells.[33,127] Progression to DLBCL has been recorded rarely.

Mantle Cell Lymphoma

The treatment of mantle cell lymphoma merits special attention. The treatment of choice in this disease is entry into a clinical trial because there is no generally accepted therapeutic approach, treatment options are often limited, and chemoresistance is common. Therefore, novel therapies are required for relapsed and/or refractory MCL. There is widespread acceptance of the use of anthracycline-based combination chemotherapy, despite the fact that the only randomized trial examining this question showed no benefit for CHOP compared to COP.[128] Despite response rates of up to 97% with first-line standard or high-intensity chemotherapy, most patients relapse with or without autologous hematopoietic cell transplantation.[41,45,129–132] Single-agent fludarabine produces a 41% overall response rate with few CRs.[133] Single-agent rituximab has moderate activity in MCL, with response rates of 38% in both previously untreated and treated patients, with some patients achieving CR. The median duration of response was 15 months.[133] Longer survival has been reported with high-intensity

Management of Mantle Cell Lymphoma

The management of mantle cell lymphoma represents a great challenge. This disease has the worst prognosis among all of the B-cell lymphomas and carries the incurability of the indolent lymphomas with a more aggressive clinical course. Aggressive chemotherapy regimens are being explored. Rituximab with cyclophosphamide, adriamycin, vincristine, and prednisone (R-CHOP) or R-EPOCH are suitable for elderly patients, but promising results have been obtained using the R-Hyper-CVAD regimen. Once relapse has occurred, experimental treatment approaches are indicated and promising results have been obtained using bortezomib, particularly in combination with rituximab. Prolongation in progression-free survival has been observed with the use of high-dose chemoimmunotherapy and autologous hematopoietic cell transplantation. There is evidence for a graft-versus-lymphoma effect and in the setting of clinical trials, ablative and nonmyeloablative allogeneic hematopoietic cell transplantation may be indicated.

regimens such as hyper-CVAD, especially when used in combination with rituximab.[130,131] A Cochrane analysis has shown that the addition of rituximab to chemotherapy is superior to chemotherapy alone.[134] After the first relapse, prognosis is considered very poor, with median survival of less than 2 years.[41] Novel treatment approaches include the investigation of bortezomib, which shows activity in MCL,[135–138] particularly in combination with rituximab.

Several phase II studies have suggested a role for consolidation with high-dose therapy and autologous HCT.[139,140] However, on longer-term follow-up, this does not appear to be curative.[141] The European MCL Network have reported results of a randomized trial comparing consolidation with myeloablative radiochemotherapy followed by autologous HCT compared to maintenance in first remission.[142] Patients 65 years of age or younger with advanced-stage MCL were assigned to autologous HCT or IFN-α after achievement of complete or partial remission using a CHOP-like induction therapy. Among 122 patients enrolled, 62 patients proceeded to autologous HCT and 60 received IFN-α. Patients in the autologous HCT arm experienced a significantly longer PFS (median 39 months) compared with patients in the IFN-α arm (median 17 months). The 3-year OS was 83% after autologous HCT versus 77% in the IFN group ($P = .18$). The study demonstrated that consolidation by myeloablative radiochemotherapy followed by autologous HCT is feasible and results in a significant prolongation of PFS in advanced-stage MCL, but longer follow-up is needed to determine the effect on OS.

Long-lasting remissions can be achieved using allogeneic HCT, but this can be associated with high morbidity and mortality in the more elderly patients with this disease.[143] Recent results have suggested that RIC approaches prior to allogeneic transplantation may be associated with decreased mortality and good disease control.[144]

CHAPTER 80

DIAGNOSIS AND TREATMENT OF NON-HODGKIN LYMPHOMA (AGGRESSIVE)

Kieron Dunleavy and Wyndham H. Wilson

INTRODUCTION

The term "aggressive" non-Hodgkin lymphoma (NHL) encompasses several distinct disease entities that are defined in the World Health Organization (WHO) classification of tumors of the lymphoid system (Table 80–1). Although the approach to the diagnosis of these diseases is similar, management varies according to the lymphoma subtype, and for this reason an accurate histological diagnosis is of utmost importance.

CLINICAL FEATURES

The clinical presentation of aggressive NHL is variable and depends on a number of factors including histology, patient age and immune status. Aggressive NHL typically presents with lymphadenopathy that can range from relatively asymptomatic to causing organ compromise such as ureteral obstruction or spinal cord compression. Certain histological subtypes are associated with distinct features at diagnosis such as ileocecal involvement in Burkitt lymphoma (BL) and lymphomatoid polyposis in mantle cell lymphoma (MCL). In most aggressive NHL, bone marrow involvement is less common than with low-grade lymphomas.

Patients may have constitutional manifestations from the production of inflammatory molecules and a variety of other cytokines and chemokines produced by the lymphoma cells or host tissues. Such manifestations include weight loss, malaise, fevers, night sweats, and loss of appetite. Of these, unexplained weight loss of more than 10% of body weight and temperature higher than 38°C (100.4°F), and drenching night sweats are referred to as *B symptoms*.

INVESTIGATION

History and Physical Examination

Patients should be questioned about systemic symptoms and performance status should be assessed (Table 80–2). It is important to determine if there is a history of potential causative factors such as prior malignancy, chemotherapy or radiation treatment and/or autoimmune or immunodeficiency disease. A history of infection with, or exposure to various pathogens including HIV, hepatitis C and HTLV-1 should be excluded. A detailed physical examination should be performed with detailed attention to lymph node regions.

An accurate histological diagnosis is imperative to determine prognosis and treatment; therefore the single most important diagnostic test is a properly evaluated and technically adequate lymph node biopsy. With few exceptions, fine needle aspiration is inadequate for diagnosis. Aggressive lymphoma should be diagnosed by an experienced pathologist familiar with the nuances and pitfalls of lymphoma diagnosis.

Laboratory Investigations

Laboratory tests should include a complete blood count, serum chemistry (including lactate dehydrogenase [LDH]), human immunodeficiency virus (HIV), and hepatitis serology tests. Other viral tests such as human T-lymphocyte virus-1 (HTLV-1) should be included as indicated. Epstein Barr virus (EBV) viral loads may also be useful in specific lymphomas such as posttransplant lymphoproliferative disorders (PTLD) and nasal NK/T-cell lymphoma.[1,2] An elevated LDH has prognostic implications for certain lymphoma subtypes.

Imaging and Staging

It is important to determine sites of disease involvement (Table 80–3) Imaging studies should include chest radiography and computed tomography (CT) scanning of the chest, abdomen and pelvis. (Fig. 80–1 and 80–2) The need for additional imaging studies such as magnetic resonance imaging (MRI) and positron emission tomography (PET) scanning will depend on the clinical presentation and sites of disease. For example, if central nervous system (CNS) involvement is highly suspected, evaluation of the head by MRI may be indicated. Involvement of the bone is best evaluated by MRI and PET scans. Although PET scanning is widely used for lymphoma imaging, it does not have an established role in the initial staging of aggressive NHL.[3] However, it may be a useful adjunct to CT for staging in certain clinical situations.

While marrow involvement is highly variable in aggressive lymphomas, presence of lymphoma cells in marrow affects management and should be assessed in all patients at initial staging. Patients at increased risk of central nervous system (CNS) involvement should undergo lumbar puncture with evaluation of the cerebrospinal fluid (CSF) by cytology and flow cytometry.[4] Specifically, histological subtypes such as BL, and clinical presentations such as extranodal disease in diffuse, large B cell lymphoma (DLBCL) are associated with an increased risk of CNS disease.[5]

Aggressive NHL is staged according to the Ann Arbor staging system (Table 80–4), which was originally designed for Hodgkin lymphoma (HL). However, because of the heterogeneity and hematogenous pattern of dissemination in NHL, in contrast to contiguous lymph node spread with HL, the staging system has more limited value. At the same time, important modifications to the Ann Arbor staging system made at the Cotswold Conference have made it more applicable to NHL.[6]

Prognosis

To identify prognostic factors in NHL, an international project to correlate clinical variables and outcome in 2031 patients with untreated aggressive lymphoma was undertaken.[7] The following parameters were associated with inferior outcome: age over 60 years, Ann Arbor stage III or IV disease, serum LDH above normal range, Eastern Cooperative Oncology Group (ECOG) performance status of two or higher, and involvement of two or more extranodal sites. A clinical prognostic model, termed the International Prognostic Index (IPI) was developed using these five factors (Table 80–5). In this model, one point was allocated for each feature and nicely stratified patients into 4 groups with 5-year survivals of 73%, 51%, 43% and 26% for 0–1, 2, 3, and 4–5 risk factors, respectively, with

History and physical examination	Other viral studies
CBC and chemistry (including LDH)	CT or MRI head
HIV and hepatitis B and C serology	Body PET scan
Chest radiograph	Additional imaging
CT scan of chest, abdomen, and pelvis	CSF evaluation by cytology/flow cytometry
Bone marrow aspirate and biopsy	Other tests indicated by results of staging

CHOP-based treatment.[7] Based on this model, the IPI has become the standard for assessing clinical prognosis, and treatment stratification within and comparison between clinical trials. Although it has yet to be fully revalidated in the rituximab era, a revised prognostic model for R-CHOP, termed R_{evised}-IPI, was recently published based on a limited retrospective series (Table 80–6).[8]

Although not yet routinely performed in aggressive NHL, gene expression profiling is emerging as an important prognostic tool.[9–12] In DLBCL, for example, morphologically indistinguishable tumors can show marked heterogeneity in gene expression, and these patterns

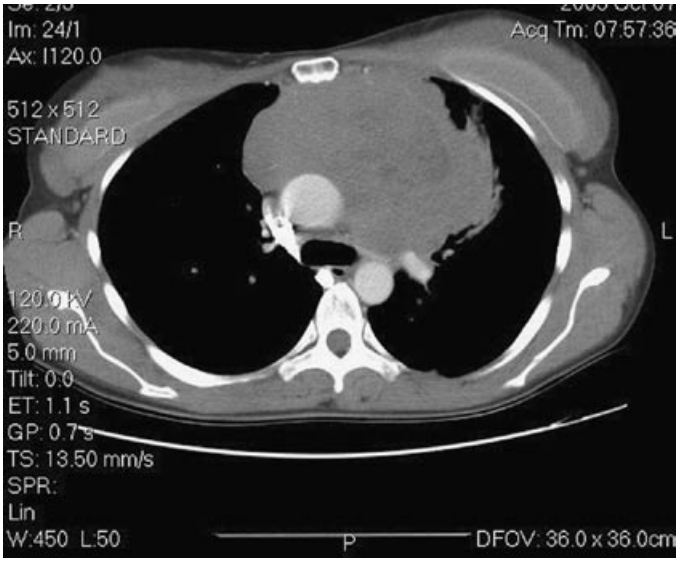

Figure 80–1 Computed tomography scan of the chest showing a large 17 cm anterior mediastinal mass. A biopsy was consistent with primary mediastinal B-cell lymphoma (PMBL).

Figure 80–2 Computed tomography scan of the abdomen showing a large left-sided psoas mass. A biopsy was consistent with diffuse large B-cell lymphoma.

of expression may be classified into signatures that correspond with the cellular origin of the lymphoma according to its stage of differentiation. On the basis of these signatures, DLBCL can be divided into at least 3 different subtypes: germinal center B-cell (GCB) like, activated B-cell (ABC) like and primary mediastinal B-cell lymphoma (PMBL). Overall survival is different in each group and superior in patients with the GCB compared to the ABC type. Using gene expression profiling, a molecular prognostic model of survival, independent of the IPI, has been also been developed for CHOP treated DLBCL.[10] This model is based on four signatures: germinal-center B cells, proliferating cells, reactive stromal and immune cells in the lymph node and major-histocompatibility-complex class II cells. This molecular prognostic model has not yet been applied to rituximab based treatment. An immunohistochemical (IHC) model has also been developed to predict GCB and non-GCB subtypes of DLBCL.[13] Although this IHC model requires further validation, its application in two recent studies suggest that the addition of rituximab to chemotherapy ameliorates the adverse outcome of non-GCB DLBCL.[14,15]

Recently, the gene expression profile of BL has been elucidated. Of note, some cases of DLBCL by histology had gene expression profiles consistent with BL.[16,17] Since BL does not respond well to CHOP based treatments, gene expression profiling may be important

Table 80–4 Ann Arbor Staging System for Lymphomas

Stage*	Cotswold Modification of Ann Arbor Classification
I	Involvement of a single lymph node region or lymphoid structure
II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is considered a single site, whereas the hilar lymph nodes are considered bilaterally); the number of anatomic sites should be indicated by a subscript (e.g., II_3)
III	Involvement of lymph node regions on both sides of the diaphragm: III_1 (with or without involvement of splenic hilar, celiac, or portal nodes) and III_2 (with involvement of para-aortic, iliac, and mesenteric nodes)
IV	Involvement of one or more extranodal sites in addition to a site for which the designation E has been used

All cases are subclassified to indicate the absence (A) or presence (B) of the systemic symptoms of significant fever (>38.0° C [100.4° F]), night sweats, and unexplained weight loss exceeding 10% of normal body weight within the previous 6 months. The clinical stage (CS) denotes the stage as determined by all diagnostic examinations and a single diagnostic biopsy only. In the Ann Arbor classification, the term pathologic stage (PS) is used if a second biopsy of any kind has been obtained, whether negative or positive. In the Cotswold modification, the PS is determined by laparotomy; X designates bulky disease (widening of the mediastinum by more than one third or the presence of a nodal mass >10 cm), and E designates involvement of a single extranodal site that is contiguous or proximal to the known nodal site.

Table 80–5 International Prognostic Index for Aggressive Lymphomas[7]

Risk Group	IPI Score	CR Rate (%)	5 year overall survival (%)
Low	0, 1	87	73
Low intermediate	2	67	51
High intermediate	3	55	43
High	4,5	44	26

*One point is given for the presence of each of the following characteristics: age >60 years, elevated serum LDH level, ECOG performance status ≥ 2, Ann Arbor stage III or IV, and more than two extranodal sites.
CR, complete response; ECOG, Eastern Cooperative Oncology Group; IPI, International Prognostic Index; LDH, lactate dehydrogenase.

No. of IPI Factors	IPI Score	Outcome	Overall Survival
0	0	Very Good	94%
1–2	1–2	Good	79%
3, 4, or 5	3–5	Poor	55%

*One point is given for the presence of each of the following characteristics: age >60 years, elevated serum LDH level, ECOG performance status ≥ 2, Ann Arbor stage III or IV, and more than two extranodal sites.
ECOG, Eastern Cooperative Oncology Group; IPI, International Prognostic Index; LDH, lactate dehydrogenase.

in rare cases that would otherwise be diagnosed as DLBCL. Gene expression profiling has also generated survival predictors in mantle cell lymphoma (MCL) and is being applied to T-cell lymphomas.[12,18,19] Although molecular profiling remains an experimental technique that is not widely available, it will undoubtedly help to improve pathologic diagnostic accuracy, predict outcome with greater precision and help elucidate pathways of lymphomagenesis. This should lead to the identification of novel cellular targets and subsequent personalized therapy. The integration of immunostaining and gene expression profiling into large prospective clinical trials is imperative in order to facilitate the investigation and development of new and useful prognostic models that may guide therapeutic choices.

Figure 80–3 Infiltration of the right lower anterior chest wall with diffuse large B-cell lymphoma (DLBCL).

AGGRESSIVE B-CELL LYMPHOMAS

The most common aggressive B-cell lymphomas are DLBCL, BL, and MCL. They have variable natural histories and in the case of MCL, a quarter of patients have an indolent clinical course.[12] Unlike indolent B-cell lymphomas, these aggressive subtypes are more rapidly progressive and with the exception of MCL, are potentially curable. For this reason, it is imperative to promptly evaluate patients and expeditiously institute appropriate therapy.

Diffuse Large B Cell Lymphoma (DLBCL)

Diffuse large B-cell lymphoma is the most prevalent histologic subtype of NHL and compromises 30% to 40% of these diseases.[20] Though the median age at diagnosis is in the seventh decade, DLBCL affects children and adults of all ages. Patients may present with localized or disseminated disease and with nodal or extra-nodal involvement. (Fig. 80–3) Within DLBCL, there are several morphological variants that include centroblastic, immunoblastic, T-cell rich/histiocyte rich and anaplastic subtypes, and progress in molecular profiling is further advancing this taxonomy.[10,21] There are also several clinical-pathologic variants of DLBCL. Primary mediastinal B-cell lymphoma (PMBL) represents one such variant that more commonly presents in young women and usually remains localized to the mediastinum. It is important to recognize that DLBCL can also arise as a result of histologic transformation from an indolent lymphoma. Though this differentiation may not affect treatment choice initially, it will affect prognosis and natural history and therefore needs to be recognized at diagnosis.

The mainstay of treatment for DLBCL is systemic chemotherapy; radiation treatment alone is inadequate and associated with high recurrence rates.[22] For early stage disease, whether or not radiation treatment adds benefit to chemotherapy has been controversial. Based on a randomized study that showed a survival advantage of limited course CHOP plus involved field radiation compared to full course CHOP in early stage (I/II) aggressive lymphoma, combined modality therapy became the standard.[23] However, longer patient follow-up showed a convergence of the overall survival curves due to late systemic relapses in the combined modality arm—thus reopening the debate on radiation.[23,24] In this regard, a recent prospective Groupe d'Etude des Lymphomes de l'Adulte (GELA) study randomized 576 elderly patients with favorable early stage aggressive lymphoma to receive CHOP alone (4 cycles) or CHOP plus radiation and found that combined modality therapy was not superior to chemotherapy alone.[25] Given these results and the improved outcome of CHOP with rituximab (R-CHOP), it is difficult to justify the routine use of radiation in early stage disease.

A possible exception to the omission of radiation, however, is in the treatment of primary mediastinal DLBCL (PMBL), depending on the chemotherapy regimen. In a study of 50 untreated patients with PMBL who received MACOP-B followed by radiation, 66% had persistently positive gallium scans after chemotherapy, suggesting active disease. Following consolidation radiotherapy, however, only 19% of patients had a positive gallium scan and 80% were event free at 39 months median follow-up.[26] This important study suggested that radiotherapy was necessary following chemotherapy. Furthermore, there is historical evidence that dose intense regimens such as MACOP-B or VACOP-B are superior to CHOP for PMBL, raising yet another question about the optimal chemotherapy for this disease.[27–29] Recent results with the pharmacodynamically dose adjusted regimen of doxorubicin, vincristine and etoposide infused over 96 hours with bolus intravenous cyclophosphamide, rituximab and oral prednisone (DA-EPOCH-R) may be challenging the need for radiation in PMBL.[30,31] In a phase II study of DA-EPOCH-R in 26 patients with PMBL, 100% and 91% are alive and event free at a median 4.2 year follow-up, respectively, and only 2 patients required radiation treatment.[32] These results suggest that DA-EPOCH-R obviates the need for radiation in most patients with PMBL, thus eliminating the risk of long-term toxicities such as secondary malignancies and heart disease. This is particularly important given that patients afflicted with PMBL are typically young and often women, and are at increased risk of breast and other cancers as well as late term toxicities. Of course, it is possible that patients who receive R-CHOP may also not require radiation therapy, but this question needs to be carefully studied.

Systemic treatment is required for advanced DLBCL (Table 80–7). The CHOP regimen was developed some 30 years ago and established as the standard by a randomized trial which showed CHOP was equally effective to three other common albeit more

Table 80–7 Treatment Regimens for Diffuse Large B-cell Lymphoma

Study	Therapy	Patient group	Event-free Survival	Overall Survival	Reference

*CHOP like regimens included CHOP, CHOEP, MACOP-B, PmitCEBO.

ACVBP: doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisone; CHOEP: cyclophosphamide, doxorubicin, vincristine, etoposide, prednisone; DA-EPOCH-R: dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin; DSHNHL: Deutsche Studiengruppe für Hochmaligne Non-Hodgkin' Lymphome; GELA: Groupe d'Etude Lymphomes d'Adultes; MACOP-B: methorexate, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin; MINT: MabThera International Trial; NCI: National Cancer Institute; PmitCEBO: prednisone, mitozantrone, cyclophosphamide, etoposide, bleomycin, vincristine; R-CHOP: rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone.

complex and/or toxic regimens.[33] The fact that only 44% of patients achieved complete remissions with CHOP, however, left significant room for improvement and spawned multiple studies aimed at improving treatment outcome.[33,34] Many of these studies have focused on modifications to the CHOP platform. A GELA study compared doxorubicin; cyclophosphamide, vindesine, bleomycin and prednisone (ACVBP) to CHOP in elderly patients with aggressive lymphoma and showed a superior 5 year EFS of 39% and OS of 46% compared to 29% and 38% for CHOP, respectively.[35] Much of the benefit in the ACVBP arm, however, was due to a lower incidence of central nervous system (CNS) progression, which could be attributed to the use of CNS prophylaxis with ACVB. Furthermore, a previous study of ACVBP in low IPI patients showed no benefit over m-BACOD, which was shown to be equivalent to CHOP.[36]

In aggressive lymphomas, high tumor proliferation determined by Ki-67 or MIB-1 immunohistochemistry has been shown to be an adverse prognostic finding with CHOP chemotherapy, suggesting that "kinetic" failure is a problem.[10,37] One strategy to overcome "kinetic" failure is to increase dose density through frequent chemotherapy administration. The Deutsche Studiengruppe für Hochmaligne Non-Hodgkin' Lymphome (DSHNHL) group evaluated the effect of dose density and etoposide in two four-arm studies of CHOP administered every 14 or 21 days, with or without etoposide (CHOEP), in patients older than 60 years and low-risk patients 60 years or younger.[38,39] In younger patients, CHOEP-21 showed the best overall results with a CR rate of 88% versus 79%, and EFS of 69% versus 58% at 5 years compared to standard CHOP-21, respectively.[39] In older patients, however, dose dense CHOP-14 showed the best outcome with a CR rate of 76% versus 60%, and EFS of 44% versus 33% at 5 years compared to standard CHOP-21.[38] While these studies provided the best evidence that outcome could be improved through specific changes to the CHOP chemotherapy platform, it remains unclear why optimal treatment differed in the studies given the continuum in disease biology across age.[10] The question of whether dose intensity or the addition of etoposide can improve outcome has been and continues to be addressed in various other studies.[40,41]

An alternative strategy to dose density is to increase the fractional cell kill or efficacy of chemotherapy, thereby reducing the number of tumor cells that can survive and proliferate between cycles. Longer drug exposure may take advantage of the increased sensitivity of cycling cells, and in vitro studies have shown that prolonged low concentration exposure to vincristine and doxorubicin, compared with brief higher-concentration exposure, can increase cytotoxicity by up to one log.[42] This approach was translated into the pharmacodynamically dose adjusted DA-EPOCH regimen, which showed a promising PFS and OS of 70% and 73%, respectively, at 5 years median follow-up in newly diagnosed DLBCL.[30] Interestingly, high tumor proliferation was not found to be an adverse biomarker in this study.[30]

It has been the development of rituximab that has made the single greatest impact on the treatment of DLBCL since CHOP was first introduced over 30 years ago. The first study to show the benefit of rituximab was performed by GELA where patients over 60 years were randomized to receive CHOP or CHOP with rituximab (R-CHOP).[43] In this study, the complete remission (CR) (76% versus 63%) and 5-year event free survival (EFS) (47% versus 29%) were higher with R-CHOP than CHOP, respectively, making R-CHOP the de facto standard in DLBCL.[43,44] The benefit of rituximab was later confirmed by the US intergroup study in a similar patient population.[45]

With the benefit of rituximab established, investigators have gone on to explore its use in a variety of clinical settings and treatment strategies. The DSHNHL group explored the question of whether there was a difference in outcome between six or eight cycles of treatment in a randomized study of six versus eight cycles of CHOP-14, with or without rituximab, in elderly patients with DLBCL. In that study, termed the RECOVER-60 trial, they found no difference in outcome with six versus eight cycles of treatment.[46] Although they showed an excellent 3-year EFS of 66% with R-CHOP-14 over six cycles, which is somewhat better than the GELA and US intergroup study results, one cannot conclude that R-CHOP-14 is superior to standard R-CHOP-21, given all the caveats of interstudy comparisons. The MabThera International Trial (MInT) studied the benefit of rituximab with CHOP-based treatment in younger patients (= 60 years) with favorable characteristics defined as low IPI risk; furthermore, nearly half of patients received involved field radiotherapy.[47] Similar to the other randomized rituximab studies, patients who received rituximab fared significantly better with a 3-year EFS of 79%. As an interesting aside, the MInT study also showed that rituximab obviated the benefit of CHOEP in younger patients.[47]

Rituximab has also been tested in combination with the DA-EPOCH regimen.[48] In a recent report of 72 patients, 82% and 79% of patients were progression free and alive, respectively, at the median follow-up of 43 months. Furthermore, 93% and 64% of patients in the low and high IPI risk groups, respectively, had not progressed. While one must be cautious in interpreting preliminary results, it should be noted that these findings are consistent with a recent phase II of DA-EPOCH-R in which 91% and 45% of patients with high-Intermediate and high IPI, respectively, were event free at two years.[49] Evaluation of DA-EPOCH-R versus R-CHOP in untreated DLBCL is currently ongoing in the Cancer and Leukemia Group B (CALGB) cooperative group in conjunction with microarray analysis.

While it is clear that rituximab has significantly improved the overall outcome of DLBCL, several studies suggest its benefit is limited by tumor pathobiology.[50–52] Two studies found rituximab benefit was primarily in Bcl-2 positive DLBCL, while another study showed benefit was limited to Bcl-6 negative DLBCL.[50–52] These biomarkers suggest that rituximab may primarily benefit tumors derived from a post-germinal center B cell.[10,11,53] At this point, though, it is not possible to accurately identify who will benefit from rituximab, and further progress is critical to help identify new strategies and molecular targets for patients who do not benefit from rituximab.

The role of high dose chemotherapy and autologous hematopoietic cell transplantation (HCT) in the initial treatment of DLBCL remains controversial.[54,55] Although some studies have suggested benefit, they were performed in the pre-rituximab era.[56] Autologous HCT is also associated with late toxicities, including leukemia and secondary myelodysplasia, which must be considered in the risk benefit of treatment.[57]

Primary Central Nervous System Lymphoma (PCNSL)

Primary central nervous system lymphoma (PCNSL) is a rare and highly aggressive lymphoma confined to the CNS, and is usually of diffuse large B-cell histology. (Fig. 80–4) Its unique radiographic findings presents challenges in evaluation which have been recently addressed in a report of an international workshop to standardize criteria for baseline evaluation and response.[58] The incidence of PCNSL is particularly high in the setting of HIV infection where it often presents with multifocal disease and is virtually always associated with Epstein Barr virus (EBV). In contrast, PCNSL in HIV negative patients often presents with solitary intracranial masses and is rarely associated with EBV.

Treatment of PCNSL differs from systemic DLBCL because many chemotherapy agents do not adequately penetrate the blood-brain barrier. Radiotherapy has been a mainstay of treatment because it is effective and side stepped the limitations of chemotherapy, but responses are usually short-lived and virtually all patients relapse. High-dose methotrexate (HD-MTX) on the other hand is a cytotoxic agent with good CNS penetration, but when used alone progression-free survival is a relatively short 7 months.[59] A logical step was to combine HD-MTX followed by whole brain radiotherapy and produced an impressive 82% to 88% complete remission and median progression free-survival rates of 32 to 40 months.[59–61] Unfortunately, such combined modality treatment is associated with severe long-term neurotoxicity.[59,62] For this reason, there has been much interest in developing regimens that obviate or defer the need for radiation until relapse. Most promising, in this regard are combinations of high

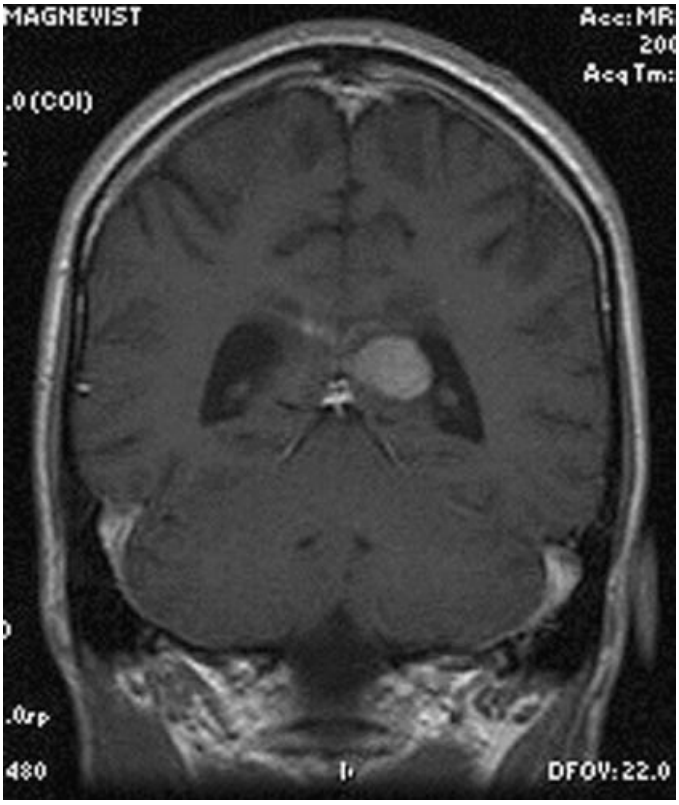

Figure 80–4 This gadolinium enhanced MRI scan of the brain shows an enhancing infiltrative mass in the major forceps of the corpus callosum. A biopsy was consistent with primary central nervous system lymphoma (PCNSL).

dose methotrexate with systemic agents that cross the blood brain barrier, such as cytarabine, vincristine and ifosfamide, particularly in patients under 60 years of age.[63] The Bonn group and others have adopted such an approach and have reported promising results with chemotherapy and deferred radiation in younger patients.[63,64] These results require further validation in trials. Studies are also addressing the role of immunochemotherapy with rituximab and other novel agents which promise to improve the outcome of PCNSL.[65]

Burkitt Lymphoma (BL)

Burkitt lymphoma (BL) most commonly occurs in the first two decades of life and accounts for some 2% of all lymphomas.[20] Burkitt lymphoma is highly aggressive as reflected by its 100% tumor proliferation by MIB-1 immunohistochemistry and high spontaneous apoptosis which accounts for its starry sky appearance. Biologically, BL is derived from a germinal center B cell as indicated by its CD20+, CD10+ and TdT negative immunohistochemical profile and gene expression profiling.[16] Three clinical variants are recognized: Endemic BL which is primarily found in equatorial Africa; Sporadic BL which presents worldwide but is the most common type in Western countries and; Immunodeficiency associated BL which is associated with HIV infection. There are important clinical differences in these variants. Endemic BL typically presents with jaw and facial bone disease and is virtually always associated with EBV. Sporadic BL usually presents with ileocecal disease and is associated with EBV in 30% to 50% of cases. Immunodeficiency associated BL usually occurs in HIV positive populations and is associated with nodal disease and is variably associated with EBV. Burkitt lymphoma may be associated with CNS involvement, particularly when there is bulky or disseminated disease. Rare cases present as acute leukemia and are included in the French-American-British (FAB) classification.[20]

Burkitt lymphoma requires chemotherapy for all disease stages. Several biological characteristics of BL have helped guide treatment strategies including its high proliferative fraction. The high tumor proliferation rate led to the use of dose intense regimens with a short cycle time to theoretically minimize tumor regrowth between cycles.[66,67] Multiple drugs, typically administered in alternating combinations, are employed and the high rate of spread to the CNS has led to the standard use of CNS prophylaxis.[68] A variety of dose-intense short duration regimens have achieved durable complete remissions in 47% to 84% of patients.[69–72] Included in these are the French LMB and German Berlin-Frankfurt-Munster (BFM) protocols and the National Cancer Institute CODOX-M/IVAC regimen. These regimens are similar in their drug composition, short cycle length and CNS prophylaxis. Although BL is most common in children, Magrath and colleagues demonstrated that adults have a similar disease outcome when treated with the same regimen.[66] Toxicity is an important clinical limitation of these regimens in adults, particularly in older patients where severe morbidity and even mortality occur. Therefore, one of the major therapeutic challenges in BL is to develop therapies that are as effective in achieving high cure rates as "standard" regimens but that improve the therapeutic index and reduce toxicity complications. This approach is being investigated in a pilot study of DA-EPOCH-R. Based on studies in DLBCL which suggested DA-EPOCH overcomes the adverse effect of high proliferation, likely due to its infusional schedule, it appeared to be a good candidate to test in adult BL.[30] Indeed, preliminary results in 17 patients with BL showed an EFS and OS of 92% and 100%, respectively, at a median follow-up of 28 months, with low toxicity compared to conventional regimens.[30,32]

Mantle Cell Lymphoma (MCL)

Mantle cell lymphoma (MCL) s a relatively rare B-cell lymphoma, which comprises some 3% of all lymphomas and has a median age of 60 years and male predominance.[21] Its pathobiology is characterized by dysregulation of the cell cycle with almost all cases showing the t(11;14) translocation and overexpression of cyclin-D1 (bcl-1). Hence, immunohistochemical detection of cyclin D1 along with CD20 and CD5 is virtually diagnostic of MCL.[20] The biological importance of cell cycle dysregulation in MCL was elegantly demonstrated by gene-expression profiling where the tumor proliferation signature was the best molecular predictor of survival.[12]

Most patients present with advanced stage disease and based on historical series have a median survival of 3 to 5 years. While overall survival appears to be improving with the development of more effective therapies, cure remains elusive for most patients.[73] Treatment approaches are constrained by the older median age of MCL with more aggressive regimens often preferred in younger patients. One of the more promising and aggressive regimens for MCL is fractionated cyclophosphamide administered with doxorubicin, vincristine, and dexamethasone (Hyper-CVAD), alternating with high-dose methotrexate and cytarabine.[74] In an initial phase II study of 45 previously treated and untreated patients, 38% achieved CR with an overall response of 94%; of these patients, 29 went on to receive autologous HCT consolidation.[74] Among the 25 previously untreated patients, EFS and OS at 3 years were 72% and 92%, respectively, which appeared significantly better than historical outcomes with CHOP based treatment.[75] Recently, a study of Hyper-CVAD with rituximab alternating with high-dose methotrexate and cytarabine was reported in untreated MCL.[76] In this study, 87% of patients achieved CR and at 3 years, 64% were failure free. Although effective, the unacceptable toxicity in older patients led the authors to recommend it only in patients younger than 66 years of age. Other studies have shown that the addition of rituximab to CHOP improves response rates and time to treatment failure, but not survival.[77,78] The DA-EPOCH-R regimen has also shown good efficacy in untreated MCL with 93% of patients achieving CR but similar to other studies, most patients ultimately relapse.[79]

There has been much interest in investigating the role of high-dose chemotherapy and autologous HCT in MCL, and several phase II studies show promising results.[80–83] While a number of these studies have shown excellent event free survival (EFS) and overall survival (OS), patient selection is by necessity biased and there is no convincing plateau on the Kaplan-Meier curves. Even in the absence of significant cures, it is possible that autologous HCT may prolong survival; however, this can only be judged in the context of a randomized study. Allogeneic HCT, frequently employing reduced intensity conditioning, has also been investigated in MCL.[84] In one study of 18 patients, 17 achieved CR, and there were only three progressions with 26 months median follow-up.[84] The 3-year EFS of 82% suggests that a graft-versus-lymphoma effect plays an important role.

Recently, the proteasome inhibitor bortezomib has shown promising activity in patients with relapsed or refractory MCL. After demonstrating activity in two small phase II studies, a large multicenter study reported a response rate of 33% with 8% CR in relapsed or refractory MCL.[85–87] The mTOR inhibitor temsirolimus has also shown interesting results with a response rate of 38%.[88] A small phase II study also reported a favorable response rate of 90% for the combination of rituximab and thalidomide.[89] Presently, combinations of bortezomib and chemotherapy are being investigated in MCL and it is likely in the near future, that other novel agents will find their way into clinical trials for untreated patients.

EBV Associated Lymphoproliferative Disorders

The loss of adequate EBV immune surveillance underlies the pathobiology of virtually all EBV associated lymphoproliferative disorders (LPD).[90] It is useful to consider the origin of the immune suppression as it affects disease biology and treatment. The most commonly recognized diseases are associated with iatrogenic immunosuppression, as exemplified by posttransplant LPD (PTLD) and MTX-associated LPD.[91,92] Diseases associated with acquired immunosuppression are heterogeneous and include senile EBV+ B-cell LPD and lymphomatoid granulomatosis.[93–95] Congenital immunodeficiencies comprise the last group and include such entities as Wiskott-Aldrich syndrome (WAS) and X-linked severe combined immunodeficiency (SCID) which are associated with EBV related LPDs.[90]

Posttransplant lymphoproliferative disorder (PTLD) encompasses a broad spectrum of diseases which occur in the setting of allogeneic hematological and solid organ transplantation; as a group, they show considerable heterogeneity.[92,94] PTLD is classically approached by withdrawal of immunosuppression, providing the possibility of organ rejection is not life threatening, and often in conjunction with rituximab. Chemotherapy, however, is frequently required, particularly in patients with monomorphic histology, where the clone is usually immune independent.[96] EBV+ LPD arising in the setting of chronic immune suppression with methotrexate can also respond to withdrawal of the offending agent, although most cases require chemotherapy.[91] Senile EBV+ B-cell LPD's are increasingly being recognized and are postulated to arise in the setting of age-related waning of EBV immune surveillance.[93] In general, they should be approached as other aggressive lymphomas while recognizing that highly localized disease with limited involvement by EBV+ large B-cells may be self-limited. Lymphomatoid granulomatosis (LYG) is a rare EBV associated LPD which primarily occurs in otherwise healthy patients who on examination have evidence of immune deficiency.[94,95] LYG virtually always involves extranodal sites and can be treated with interferon or immunochemotherapy, depending on the grade of disease.[94]

AGGRESSIVE T/NATURAL KILLER (T/NK) CELL LYMPHOMAS

Lymphomas of T/NK cells are relatively uncommon and account for approximately 15% of all NHL.[20,97] They are distributed over at least 14 different subtypes, all of which are infrequent and not well studied. Those tumor types with an identifiable clinical-pathobiology are classified by name, whereas the other cases are simply described as "peripheral T-cell lymphoma, unspecified" ($PTCL_{us}$); which by design is a heterogeneous group. Generally, T/NK cell lymphomas are clinically aggressive, though some can behave quite indolently, and unlike their aggressive B-cell cousins, most are incurable. Important exceptions to cure include anaplastic large cell lymphoma (ALCL) and early stage T/NK cell, nasal type lymphoma.

To help define the outcome of aggressive T/NK and B-cell lymphomas in the international arena, the Non-Hodgkin Lymphoma Classification Project examined all newly diagnosed cases of lymphoma over a 2-year period from multiple international centers.[98] A survival analysis predictably demonstrated a poor outcome of $PTCL_{us}$ compared with DLBCL. Similar to DLBCL, the IPI was predictive of outcome in $PTCL_{us}$. At 5 years, only one quarter of low-IPI patients were alive without disease. This is in contrast to the anaplastic large cell lymphoma (ALCL) subtype in which 80% of patients were alive at 5 years regardless of the IPI score.

Three large series of PTCL treated with CHOP-based therapy have been reported.[99–101] The overall CR varied from 49% to 65% and in all series, ALCL had a favorable outcome. Like the NHL Classification Project, IPI score predicted outcome with 5-year survivals of 60% to 80% in low (0–1), 20% in intermediate (2–3) and 0% in high (4–5) IPI patients.[102]

Anaplastic Large Cell Lymphoma (ALCL)

ALCL is a CD30 positive T-cell lymphoma with an excellent prognosis and unlike the other PTCLs, it frequently can be cured. It typically occurs in children and young adults and compromises approximately 3% of all lymphomas in adults. In some 80% of cases, ALCL is associated with the t(2;5)(p23;q35) translocation, resulting in expression of the nucleophosmin anaplastic lymphoma kinase (ALK).[103] While ALK positive ALCL has a significantly better prognosis than ALK negative cases, patients with ALK negative disease should still be approached with curative intent.[103] In adults, CHOP-based therapy is considered the standard of care and produces durable remissions in approximately 65% of ALK+ and 35% of ALK negative ALCL.[104]

Extranodal T/NK-cell Lymphoma; Nasal Type

This is a rare extranodal lymphoma characterized by a broad morphological spectrum. It is more prevalent in Asia and Central/South America and is almost always associated with EBV.[21] It has a predilection for the nasal cavity, nasopharynx, palate, skin, gastrointestinal tract, and testis. Hemophagocytic syndrome is a devastating event associated with this tumor type.[105] Disease outside the nasal cavity is usually highly aggressive and associated with a poor prognosis. Because of its rarity and lack of prospective clinical trials, optimal therapy has not been defined. However, disease localized to the nasal cavity can be cured with radiotherapy. The beneficial of chemotherapy in this setting has yet to be defined.[106]

Angioimmunoblastic T-cell Lymphoma (AILT)

Angioblastic T cell lymphoma is characterized by systemic symptoms, skin rash, organomegaly, hypergammaglobulinemia, and hemolytic anemia. It most commonly afflicts older patients and frequently presents with peripheral lymphadenopathy, hepatosplenomegaly, skin rash, and constitutional symptoms, which distinguish it from other peripheral T-cell lymphomas.[107] Patients often exhibit some degree of immunodeficiency, polyclonal hypergammaglobulinemia, and other hematological abnormalities, which are probably related to abnormal immune regulation.[108] The neoplastic T cells appear to be of germinal center origin, known as follicular B helper T (T_{FH}) cells.[109,110] A prominent histological feature of AILT is the near uni-

Table 80–8 Salvage Regimens for Aggressive Lymphoma

Therapy	Patient Group	CR Rate (%)	Overall response (%)	Survival	Reference
DHAP	Relapsed or refractory lymphoma	31%	57.5	OS: 25% at 2 years	135
ESHAP	Relapsed or refractory lymphoma	37%	70	OS: 31% at 3 years	136
EPOCH	Relapsed or refractory DLBCL	36%	70	OS: 30% at 6 years	139
R-ICE	Relapsed or refractory DLBCL	53%	88	NA	132

DHAP: dexamethasone, cytarabine, cisplatin; EPOCH: etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin; ESHAP: etoposide, methylprednisone, cytarabine, cisplatin;
R-ICE: rituximab, ifosfamide, carboplatin, etoposide.

versal presence of EBV positive B cells within the lesions.[111,112] Optimal therapy has not been defined for AILT but anthracycline-based regimens and purine analogs have shown some efficacy.[107,113] Recently, novel approaches such as the use of cyclosporine and anti-angiogenesis therapies such as bevacizumab have shown activity and warrant further investigation in the future.[114,115] Unfortunately, most patients succumb from infection or disease.

Hepatosplenic T-cell Lymphoma

This extranodal T-cell lymphoma presents with marked hepatosplenomegaly and bone marrow involvement.[116] Most cases have and T-cell receptor rearrangement which if present in other PTCLs, portends a particularly poor prognosis.[20,117] The disease often afflicts younger males and occurs with increased frequency in the setting of iatrogenic immune suppression.[118] Outcome is extremely poor and is characterized by rapid progression and death, although allogeneic transplantation has been associated with prolonged remission and potential cure.[119]

Peripheral T-cell Lymphoma, Unspecified

The poor outcome of $PTCL_{us}$ has prompted the search for new strategies and targeted agents. Purine analogs are associated with good response rates but are rarely curative.[120] Alemtuzumab, a monoclonal antibody that binds CD52 is expressed on most $PTCL_{us}$ and has shown a 36% response rate in one series of heavily pretreated patients. The success of immunochemotherapy in B-cell lymphomas has led to several ongoing studies of alemtuzumab and chemotherapy.[121] Other novel agents with activity in this disorder include denileukin, diftitox, and the histone deacetylase inhibitor depsipeptide.[122,123] While autologous HCT may provide some benefit, a recent report of a graft versus lymphoma effect in PTCL suggests that allogeneic HCT may have curative potential.[124,125]

Precursor B-cell and T-cell Lymphoma

Precursor B-lymphoblastic and T-lymphoblastic lymphomas (LBL) are highly aggressive diseases with primarily nodal presentations, but are cytologically identical to acute lymphoblastic leukemia (ALL).[20] Precursor T-LBL comprises approximately 90% of lymphoblastic lymphomas and typically presents in young males with a mediastinal mass and occasional involvement of the meningeal space. A variety of chemotherapy regimens have been used including ACVBP, leukemia-based regimens and autologous HCT.[126,127] A recent study published by the British Columbia Transplant Group reported an excellent outcome with induction chemotherapy followed by stem cell transplantation; in this study, 69% of patients were event-free at four years.[127] An earlier German study evaluated an ALL-type regimen in 45 adult patients with T-LBL and reported a 62% disease-free survival at seven years.[128] These studies highlight the need for very aggressive therapies in these diseases.

PROPHYLACTIC INTRATHECAL (IT) CHEMOTHERAPY FOR AGGRESSIVE B-CELL LYMPHOMA

Although secondary involvement of the CNS (central nervous system) in aggressive B-cell lymphoma is rare, it is usually a fatal complication and strategies aimed at preventing it are important. Certain clinical risk factors are associated with an increased risk of CNS relapse and the risk benefit appears to favor prophylactic intrathecal chemotherapy in such patients.

These risk factors include a diagnosis of Burkitt lymphoma (BL) and AIDS-related lymphoma (ARL), and diffuse large B-cell lymphoma that presents with diffuse bone or bone marrow involvement, or two or more extra-nodal sites with an elevated lactate dehydrogenase (LDH). Testicular involvement is also a high-risk disease site. All patients at risk should undergo lumbar puncture with CSF evaluation and a brain MRI scan. Recent studies indicate that flow cytometry is significantly more sensitive than conventional cytology for detection of CSF involvement and should be performed. Patients with evidence of CNS disease at diagnosis receive a treatment course of IT chemotherapy.

SALVAGE THERAPY

The salvage treatment of relapsed DLBCL should be approached in an individual manner as the choice of treatment is influenced by the time to recurrence, prior therapy, medical condition and the potential for cure. While most relapsed aggressive lymphomas require combination chemotherapy for adequate disease control, it is important to recognize that patients with local disease may be salvaged with radiation therapy. Examples include primary mediastinal DLBCL, which can remain local even at relapse, and PTLDs, which may have an isolated resistant EBV clone following chemotherapy.[129]

There are a variety of active salvage chemotherapy regimens for relapsed or refractory DLBCL (Table 80–8).[130–136] Platinum containing regimens, such as ESHAP and ICE, are currently among the most widely used salvage treatment.[132,134,137] It is a commonly held notion that salvage treatment should include different agents from past treatment to avoid drug resistance. Recent evidence indicates, however, that sensitivity to apoptosis is a central cause of drug resistance and that drug-specific mechanisms are less important.[10,138] Hence, salvage regimens developed around the most active up-front agents should show high activity.[139] This concept was tested with EPOCH chemotherapy in patients who had failed after receiving similar drugs on a bolus schedule.[139] In this study of 67 patients with relapsed/refractory

HOW WE TREAT PRIMARY MEDIASTINAL B-CELL LYMPHOMA (PMBL)

PMBL predominantly affects females in the third to fourth decade. Standard treatment usually involves doxorubicin-based chemotherapy and involved field radiation. Although combined modality therapy is highly effective, the inclusion of radiation increases the late risk of secondary tumors and cardiac disease. A recent study indicates that rituximab significantly improves the survival of PMBL when combined with DA-EPOCH chemotherapy and obviates the need for radiation in 92% of patients.

Based on these results, we treat PMBL with six cycles of DA-EPOCH-R. At the completion of therapy, we perform a CT (computed tomography) and PET (positron emission tomography) scan to determine complete response. Patients with proven residual disease receive consolidation radiation treatment. It is important to note, however, that PET scan abnormalities are common on treatment completion and may not represent residual disease. Because of the low specificity of PET, we usually perform a biopsy in patients with persistent or worsening PET abnormalities before commencing radiation treatment.

de novo aggressive lymphoma, 70% responded with 36% complete remissions. The addition of rituximab appears to enhance the activity of salvage regimens as demonstrated by results with R-ICE and ICE which showed a CR of 53% and 27%, respectively.[132,137]

Patients with chemotherapy sensitive disease have the best outcome with autologous HCT and is recommended at initial relapse. Autologous HCT used as salvage therapy in chemoresponsive patients has yielded OS and EFS in the range of 40% to 50% and 30% to 40%, respectively.[132,140] Autologous HCT rarely achieves cure in BL and LBL, but it is often successful in ALK positive ALCL. Lymphomas that are rarely cured with initial treatment, such as MCL and PTCL, are less likely to benefit from autologous HCT. It is important to consider, when assessing the outcome of autologous HCT, improvements in upfront therapy from rituximab have resulted in relapse population with greater resistance. The incorporation of rituximab or radioimmunoconjugate into conditioning regimens may also enhance the benefit of autologous HCT, thus underscoring the importance of controlled autologous HCT trials in the post-rituximab era.[132,140] Patients with chemotherapy resistant disease do poorly with autologous HCT, but may still benefit from allogeneic HCT.

LATE COMPLICATIONS OF TREATMENT

It is important to recognize that successful treatment may be associated with late complications that may not appear for decades. Among the major late term complications are secondary malignancies, ischemic heart disease, anthracycline-related cardiotoxicity, and radiation or bleomycin-induced pulmonary toxicity.[141] The risk of developing myelodysplastic disorders and acute myeloid leukemia is related to alkylator and topoisomerase inhibitor use and is enhanced by radiation. Radiation therapy increases the risk of malignancy in the treatment region and in particular, breast cancer in women and lung cancer in smokers. Indeed, it is imperative to consider late-term toxicity when selecting treatment.

A general guideline for follow-up after initial therapy involves visits every three months for two years, every six months for three years, and annually thereafter. During these visits, examination of the lymph node areas, abdomen, thyroid, and skin is important. CT scans are recommended in routine follow-up. It is important to note that CT scans are associated with a relatively high radiation exposure and should not be used unnecessarily.[142] PET scans are not recommended for routine follow-up because the high rate of false positive scans is unlikely to offset the value of early detection. Indeed, the role of PET sans in the overall treatment of lymphomas requires prospective studies.[143] Routine laboratory studies with blood counts, liver function tests, and LD should be performed. Patients with disease in the chest can be followed with chest radiographs. Thyroid-stimulating hormone levels should be monitored annually in patients who received neck radiotherapy. Mammography for women should begin ten years from diagnosis of lymphoma or at age 40, whichever comes first. Patients should be immunized against influenza yearly and against pneumococcus every six years.

FUTURE DIRECTIONS

There has been marked progress in our understanding of molecular events underlying aggressive lymphomas, particularly B-cell diseases. Powerful techniques such as gene expression profiling, array-CGH, and RNAi have paved the way for the identification of new targets and the development of small molecule inhibitors. Indeed, a number of targeted agents have entered clinical trials including inhibitors of mTOR, proteasome, histone deacetylation, and bcl-2. Other approaches such as incorporation of rituximab, autologous and even allogeneic HCT into algorithms for patient treatment are likely to have an impact on prolonged remission and cure of aggressive NHL. The challenge will be to determine the priority, sequence and combination of active agents needed for initial treatment and salvage therapy through well-designed clinical trials.

CHAPTER 81

MALIGNANT LYMPHOMAS IN CHILDHOOD

John T. Sandlund, Jr. and Michael P. Link

INTRODUCTION

Malignant lymphomas are the third most common malignancy among children and adolescents.[1–4] Among children less than 15 years of age, non-Hodgkin lymphoma (NHL) is more frequent; however, in patients up to 18 years of age, Hodgkin disease is predominant.[2] NHLs in children are usually extranodal diffuse high-grade tumors, whereas low- and intermediate-grade nodal lymphomas predominate in adults.[5] These differences are speculated to reflect maturational changes in the function and composition of the immune system.[6] The different histologies explain in part the differing clinical features, disease course, and treatment strategies used in adults and children.

The differences in treatment approach and disease subtypes are less striking in adults and children with Hodgkin disease. However, there are significant challenges in the management of children with Hodgkin disease. These primarily comprise the sequelae of therapy, such as radiation-induced bone growth abnormalities, endocrine dysfunction, and chemotherapy-related sterility. Of greater concern are the radiation- and chemotherapy-related second malignancies and late cardiac deaths. Current trials are under way to examine ways to reduce the toxicity of therapy without compromising the excellent outcome generally achieved. These issues, as well as differences between children and adults in the proportion of histologic subtypes, are covered in Chapter 74, which deals with the management of Hodgkin disease in adults.

EPIDEMIOLOGY

The incidence of NHL increases steadily throughout life, in contrast to Hodgkin disease, which has a bimodal age distribution with peaks in early and late adulthood.[2] Although the NHLs may occur at any age in childhood, they occur very infrequently among children younger than 3 years of age; the median age at presentation is approximately 10 years. NHL occurs 2 to 3 times more often in boys than in girls and is almost twice as common in whites as in African Americans—the reasons for these differences have yet to be determined.[7]

Specific populations at risk for the development of NHL include those with either congenital or acquired immunodeficiency conditions.[8–12] Inherited immunodeficiency syndromes include Wiskott–Aldrich syndrome, X-linked lymphoproliferative syndrome (XLP), and ataxia-telangiectasia (AT). The recognition of these syndromes in children with newly diagnosed NHL is important for appropriate therapeutic design. For example, involved field irradiation and the use of radiomimetics should be avoided in children with AT. Additionally, children with AT are at increased risk for the development of cyclophosphamide-induced hemorrhagic cystitis; therefore, they should receive vigorous hydration and uroprotectants (eg, MESNA) when administering any dose of cyclophosphamide. XLP should be considered in any male with a high-grade B-cell lymphoma who either develops a late recurrence (second occurrence) of a high-grade B-cell lymphoma or has a brother with either a high-grade B-cell lymphoma or fatal infectious mononucleosis. Children with acquired immunodeficiency conditions that predispose to the development of NHL include those who have received posttransplant immunosuppressive therapy and those with the acquired immunodeficiency syndrome (AIDS).

There are differences in both the incidence and proportion of histologic subtypes in different parts of the world. For example, the NHLs are very rare in Japan but occur quite frequently in equatorial Africa. Burkitt lymphoma, which accounts for about one-half of all childhood cancers in equatorial Africa, is the predominant NHL histologic subtype in both equatorial Africa and northeast Brazil.[13] There are also geographic differences in both the clinical and biologic features of certain NHL subtypes.[14,15] For example, Burkitt lymphoma in equatorial Africa ("endemic" Burkitt lymphoma) is clinically characterized by frequent involvement of the abdomen, jaw, paraspinal region, orbit, and central nervous system. In contrast, Burkitt lymphoma occurring in the United States and Western Europe ("sporadic" Burkitt lymphoma) typically involves the abdomen, nasopharynx, and bone marrow. The predominant chromosome 8 breakpoints among sporadic cases occur within the MYC gene, whereas those in endemic cases usually occur upstream of the MYC gene.[16,17]

In equatorial Africa, the region of high incidence of Burkitt lymphoma overlaps with the malaria belt.[18] This observation prompted investigators to search for an infectious cause for this disease. This effort led to the discovery of the association between Epstein–Barr virus (EBV) and this tumor. Although no direct pathogenic role has been demonstrated for this virus, it has been speculated that as a B-cell mitogen, EBV increases the target pool of cells for transformation. This hypothesis is supported by the observation that Rag gene expression can be induced by EBV, an event that may theoretically increase the chance of a translocation occurring in B cells that are rearranging their immunoglobulin genes.[19] The potential role of EBV in pathogenesis is also strengthened by the observation that lymphomas develop in mice that are transgenic for EBV nuclear antigen 1 (EBNA-1).[20] Moreover, an EBNA-1 variant has been found to be associated with the majority of EBV-positive Burkitt lymphoma cases, suggesting that this mutation may provide a growth advantage to lymphoma cells by modifying EBNA-1 function in some way.[21] A more direct role for EBV in lymphomagenesis is suggested by analyses of the EBV+ Burkitt lymphoma cell line, Akata.[22] When this cell line spontaneously loses EBV episome, it loses its malignant phenotype; however, on reinfection with EBV, a malignant phenotype is again observed. EBV is associated with 90% of African (endemic) Burkitt lymphoma cases, but with only 15% of cases in the United States (sporadic).[23–28] Disrupted and aberrant expression of the EBV genome has been identified in the host genome of sporadic Burkitt lymphoma cells that appeared to be EBV-negative by conventional EBNA testing.[29] This finding, together with the 50% EBV-positive rate among Burkitt lymphoma cases in other parts of the world (eg, South America) suggests that EBV has a widespread role in the pathogenesis of this malignancy.[13,30]

CLASSIFICATION

After Thomas Hodgkin described the disease bearing his name in 1832, various schemes emerged to classify the tumors now collectively referred to as the NHLs. Several classification schemes were developed based on histopathologic features and the putative cell of origin. In an attempt to reduce the confusion of multiple classification schemes, the National Cancer Institute (NCI) sponsored a

workshop to design a single classification scheme for clinical usage. This scheme published in 1982 and referred to as the NCI Working Formulation was widely accepted for almost two decades.[5] In the Working Formulation, the NHLs of childhood are predominantly diffuse high-grade tumors and can be divided among three major subgroups: lymphoblastic, small noncleaved cell, and large-cell lymphomas.

In the past decade, additional classification schemes were designed to improve on the NCI Working formulation. Because of the problems associated with attempts to classify lymphoid neoplasms into categories based on presumed normal cell counterparts, the International Lymphoma Study Group proposed a classification system for lymphoid neoplasms[31] predicated on a practical approach to categorization of these diseases using available immunologic and molecular genetic techniques in addition to the standard morphologic criteria. This Revised European-American Classification of Lymphoid Neoplasms (REAL Classification) has been endorsed by many of the world's leading lymphoma pathologists,[31,32] and it has served as the basis for the World Health Organization (WHO) classification of hematopoietic and lymphoid tumors.[33] Both the REAL and WHO classification systems include related lymphoid leukemias and recognize that NHL and acute lymphoblastic leukemia (ALL) represent different stages of evolution within specific morphologically and immunologically defined disease categories—an observation recognized by clinicians caring for children with lymphoid neoplasms and reflected in current clinical practice that prescribes similar therapies for lymphomas and leukemias of related phenotype.

In the REAL[31] and WHO[33] classification systems, the non-Hodgkin lymphomas that occur commonly in children appear in four major categories: precursor B-cell neoplasms (including precursor B-lymphoblastic leukemia/lymphoma); precursor T-cell neoplasms (including precursor T-lymphoblastic leukemia/lymphoma); mature (or peripheral) B-cell neoplasms (including Burkitt lymphoma/leukemia and the apparently related entity "high-grade B-cell lymphoma, Burkitt-like," diffuse large B-cell lymphoma and the subtype mediastinal [thymic] large B-cell lymphoma); and mature (or peripheral) T cell and NK-cell neoplasms (including anaplastic large-cell lymphoma, CD30$^+$, and T- and null-cell types).

The clinical and biologic characteristics of NHL in children are summarized in Table 81–1 and illustrated in Fig. 81–1.

Burkitt Lymphoma

The designation of "small noncleaved cell" lymphoma used in the NCI Working Formulation[5] has been replaced by the designation of "Burkitt's lymphoma" in both the REAL[31] and WHO[33] classification systems. The Burkitt lymphoma designation also includes the L3-ALL leukemia subtype (Burkitt leukemia) of the French–American–British classification system.[34] Histologically, Burkitt lymphoma is characterized by a diffuse infiltrative pattern of monomorphic small- to medium-sized cells with round nuclei, clumped chromatin, 1 to 3 nucleoli, and basophilic cytoplasm. Tingible body macrophages interspersed among lymphoma cells result in a "starry sky" appearance under low-power microscopic examination. An atypical or Burkitt-like lymphoma, which is also described in the WHO classification system, is characterized by a wider range in nuclear shape and size, and nucleoli that are larger but fewer in number.[33,35] The Burkitt-like lymphomas may be difficult to distinguish from the diffuse large B-cell lymphomas.

Burkitt lymphoma is a mature B-cell lymphoma expressing surface immunoglobulin (usually IgM, or less commonly IgA or IgG, and kappa or lambda light-chain restriction), as well as other B cell-associated antigens, including CD19, CD20, CD22, and CD79a.[33] CD10 may be detected in more than 50% of cases studied. CD21, the EBV receptor, is more frequently detected in the endemic than sporadic Burkitt subtype. There are very unusual cases of Burkitt lymphoma that express cytoplasmic mu but no surface immunoglobulin, as well as some cases that express neither.[36,37]

Cytogenetically, Burkitt lymphomas are characterized by the presence of one of three reciprocal chromosomal translocations.[38–40] The unifying feature in these translocations is the juxtaposition of the c-*myc* protooncogene on chromosome 8 with one of the three immunoglobulin genes, resulting in deregulation of the c-*myc* gene. The classical translocation t(8;14)(q24;q32), which involves the heavy-chain immunoglobulin locus, is identified in approximately 85% of cases. Each of two variant translocations, t(2;8)(p12;q24) and t(8;22)(q24;q11), involves one of the two light-chain immunoglobulin loci; these account for the remaining 15% of cases.

Expression of the c-*myc* gene is associated with cell proliferation. For example, in normal B cells, mitogenic stimulation results in increased rates of c-*myc* transcription. The c-myc protein induces cell cycle progression from G_1 to S phase through the activation of various target genes.[41] This DNA-binding protein forms heterodimers with related proteins (eg, MAX, MAD) that subsequently influence cell cycling.[42–45] In Burkitt lymphoma, it has been speculated that the deregulated expression of c-*myc* results in an increased proportion of MYC–MAX complexes, leading to tumor cell proliferation.[46]

There are various theories about the pathogenic mechanism of c-*myc* deregulation in Burkitt lymphoma.[47–50] The invariable presence of mutations (truncations or point mutations) in the translocated c-*myc* gene has led to speculation that these mutations result in deregu-

Table 81–1 Clinical and Biologic Characteristics of Non-Hodgkin Lymphoma in Children

Subtype	Proportion of Cases (%)[a]	Phenotype	Primary Site	Translocation	Affected Genes

ALCL	10	T cell, indeterminate	Mediastinum, abdomen, head and neck, bone, soft tissue or skin	t(2;5)(p23;q35)	*NPM-ALK*
DLBCL	16	B cell	Mediastinum, abdomen, head and neck		

ALCL, anaplastic large cell lymphoma; DLBCL, diffuse large B-cell lymphoma; TCR, T-cell receptor.
[a]Proportion at St. Jude Children's Research Hospital; other histotypes account for approximately 7%.
[b]B-cell-progenitor variants have also been described.

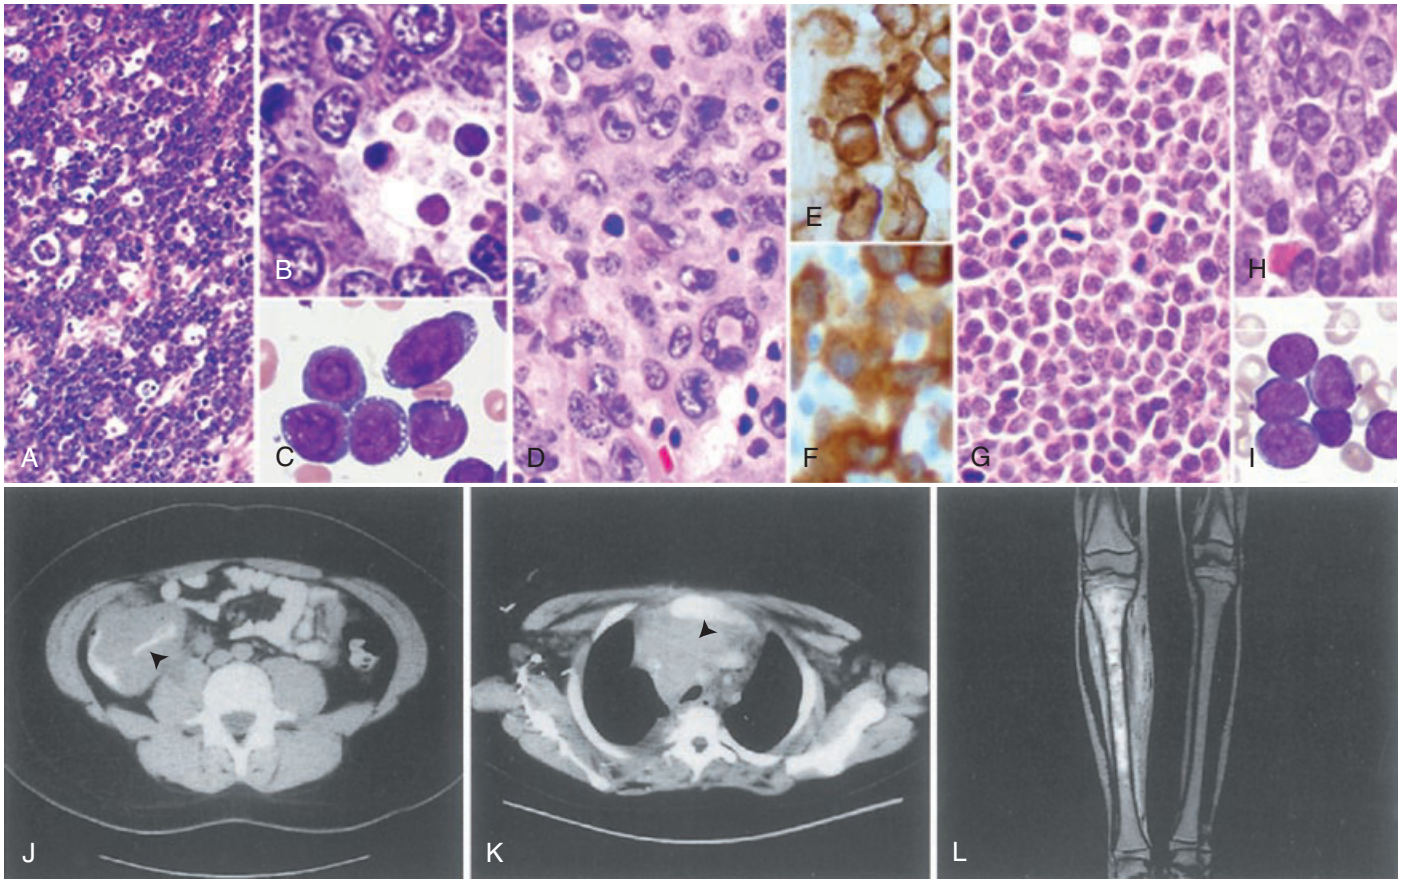

Figure 81–1 Burkitt lymphoma, anaplastic large-cell lymphoma, lymphoblastic lymphoma: **A–I**. Burkitt lymphoma (**A**) showing the classic "starry-sky" low power appearance of sheets of dark intermediate-sized lymphoma cells growing in syncytia, interspersed with scattered tingible body macrophages with abundant clear cytoplasm. At high power (**B**), the Burkitt cells have coarse chromatin, multiple nucleoli, and are adjacent to a large tingible body macrophage containing phagocytized debris. The Burkitt cells on a Wright-stained touch preparation or smear (**C**) have deep-blue cytoplasm with vacuoles. Anaplastic large-cell lymphoma (**D**) is composed of sheets of large bizarre cells including "wreath cells" (*lower right*) and "hallmark cells" (*upper middle*). These cells are CD30 (Ki-1)-positive (**E**), and ALK-positive (**F**). The ALK-positivity in the nucleus and cytoplasm corresponds to the classic t(2;5), which was present in this case. Lymphoblastic lymphoma (**G, H**) composed of sheets of small- to intermediate-sized blasts with high mitotic rate and fine chromatin. On a touch preparation (**I**), the cells are typical lymphoblasts with scant cytoplasm. The lower panels show common clinical presentations of the three histologic subtypes of lymphoma: encasement of the bowel lumen by Burkitt lymphoma on abdominal computed tomography (Panel J); airway compression by lymphoblastic lymphoma of the anterior mediastinum on computed tomography of the chest (Panel K); and bony destruction of the tibia by large-cell lymphoma on magnetic resonance imaging (Panel L). (Reproduced with permission from Sandlund JT, Downing JR, Crist WM: Non-Hodgkin's lymphoma in childhood. N Engl J Med 334:1238, 1996.)

lated expression. The mutations may occur in either the regulatory or coding regions of the gene. For example, mutations in the myc-inhibitory factor binding sites in the first intron-regulatory region negate the repressive effect of myc-inhibitory factor binding on transcription.[51] Gu et al[49] have demonstrated that in cases that contain a coding region mutation in the amino terminal transactivation domain where p107 would normally bind and block transactivation, tumor cells are no longer responsive to p107-mediated functional suppression. Other hypotheses focus on the juxtaposition of c-*myc* to the immunoglobulin loci. It has been suggested that the immunoglobulin gene usurps control over the translocated c-*myc* gene, perhaps through long-range enhancer sequences.[48,50] It is likely that multiple mechanisms deregulate c-*myc* in Burkitt lymphoma.

The apparent abrogation of the c-*myc* induction of apoptosis suggests that other factors besides deregulation of c-*myc* are involved in the pathogenesis of Burkitt lymphoma.[52] Data supporting this position have emerged from a transgenic mouse model in which insertion of a deregulated c-*myc* gene mimicking the abnormality in Burkitt lymphoma results in the development of B-cell malignancies.[53,54] The fact that these tumors are monoclonal and take 6 to 9 months to develop suggests that additional factors or molecular events are necessary for malignant transformation. The identity and potential role in pathogenesis of other oncogenes or tumor suppressor genes is currently under investigation.[52,55] In this regard, novel insights into pathogenesis have emerged from analyses of the ARF-mdm2-p53 apoptotic pathway in Eu-myc transgenic mice.[56–58] Abnormalities in this pathway, which were identified in 80% of the lymphomas that developed in these mice, included deletions of Ink34a/ARF (25%), overexpression of Mdm2 (50%), and mutations of p53 (30%). Studies of this pathway in human Burkitt lymphoma are currently under way. Abnormalities in the p53 gene have been identified in cases of human Burkitt lymphoma and B-cell acute lymphoblastic leukemia (ALL).[59,60] The mutations in these tumors differ from those seen in solid tumors such as lung, breast, and colorectal carcinomas. Beyond the mere association of p53 with these tumors, observed regulatory interactions between c-*myc* and p53 have supported the hypotheses regarding the role of p53 in pathogenesis.[60]

Lymphoblastic Lymphoma

The morphology of these tumor cells is similar to that of ALL. The distinction between lymphoblastic lymphoma and ALL is arbitrarily based on the degree of bone marrow involvement: patients with

between 5% and 25% replacement of the marrow by lymphoblasts are considered to have advanced-stage lymphoblastic lymphoma with marrow involvement, whereas those with 25% or more marrow blasts are designated as ALL. The lymphoblasts are small with round or convoluted nuclei, distinct nuclear membranes, inconspicuous nuclei, and a scant rim of basophilic cytoplasm. The vast majority (>95%) are of T-cell immunophenotype. A small percentage of cases have a B-cell progenitor immunophenotype and may be associated with cutaneous involvement.[61–63]

Because of the similarities in cellular origin, immunophenotype, morphology, and clinical features, it is generally assumed that lymphoblastic lymphoma and T-cell leukemia are different presentations of the same disease process; however, this is yet to be proved.[64] Most theories regarding the pathogenesis of lymphoblastic lymphoma are based on studies of T-cell ALL. The reciprocal chromosomal translocations identified in T-cell leukemia and lymphoblastic lymphoma typically involve one of the T-cell receptor genes and result in deregulation of the reciprocal partner gene.[65–73] The reciprocal partner gene is often a transcription factor gene such as *TAL1*, which is not usually operative in T cells.[66,67,72,73] In T-cell leukemia, a submicroscopic deletion of *TAL1* can be identified in up to 25% of cases, suggesting that this deletion may also be the most common molecular abnormality in lymphoblastic lymphoma.[72] Examples of other genes involved in translocations that have been described in these T-cell malignancies include the *HOX11* transcription factor gene and the *RHOMB* genes, whose products are members of a family of proteins that contain a cysteine-rich (LIM) protein–protein interaction domain.[68,70,71]

Diffuse Large B-cell Lymphoma

Approximately one-third of the non-Hodgkin lymphomas of childhood are not classifiable as either lymphoblastic or Burkitt lymphomas and fell into the categories of large-cell lymphoma in previous classifications. Many of these are now classified as diffuse large B-cell lymphomas (DLBCL) in the REAL and WHO classifications. These tumors are composed of large cells with nuclei at least twice the size of small lymphocytes with a high proliferative fraction. The diffuse large B-cell lymphomas are thought to arise from peripheral B cells of either germinal center or post–germinal center origin, and thus express a variety of pan-B-cell antigens with or without the expression of surface immunoglobulin.[33] Recent gene expression profiling studies of DLBCL in adults[74,75] have revealed further heterogeneity among these tumors that can now be divided among germinal center B-cell-like, activated B-cell-like, and type 3 phenotypes, and this subclassification was found to be prognostically important. The validity of such a subclassification among cases of childhood DLBCL is unknown, but such studies are ongoing.

Diffuse large B-cell lymphomas occur at a variety of sites, including the gastrointestinal tract, abdomen, head and neck region,[7] as well as primary sites of involvement that are unusual in childhood non-Hodgkin lymphomas such as bone and central nervous system. Lymphomas occurring in the setting of immunodeficiency are frequently of the large B-cell type. Mediastinal presentations also occur, and primary mediastinal (thymic) large B-cell lymphoma—a presentation more common in adolescents and young adults—is included as a recognized subtype of diffuse large B-cell lymphomas in both the WHO and REAL classifications.[31,33,76,77] Dense, compartmentalizing sclerosis and Reed–Sternberg-like cells are often present, leading to possible misdiagnosis of Hodgkin disease, particularly if only a small biopsy is available for review.

There is substantial overlap in the definition of diffuse large B-cell lymphomas and the Burkitt-like lymphomas,[31] and some investigators who have advocated immunophenotype-based therapies recommend that children with DLBCL be treated on protocols designed for Burkitt lymphomas with excellent overall results. However, there are several clinical distinctions, particularly the rarity of marrow and central nervous system involvement in DLBCL as compared to Burkitt lymphoma; thus, the very intensive central nervous system-directed therapy specified in regimens designed for Burkitt lymphoma may not be necessary for children with DLBCL.

Anaplastic Large-Cell Lymphoma

Most of the remaining childhood NHLs previously classified as large-cell lymphomas fall into the category of anaplastic large-cell lymphomas (ALCLs) in the REAL and WHO classification. This entity was first described in 1986 as a clinicopathologic variant of large-cell lymphoma with a predilection for young patients[78–89] (reviewed in references 92 and 96). The ALCLs are characterized by the proliferation of large, pleomorphic cells with multiple or single prominent nucleoli. The cells preferentially involve lymph node sinuses as well as extranodal sites (notably skin, bone, and soft tissue) where the cells grow in a cohesive pattern.[31,33] The cells express epithelial membrane antigen (EMA) as well as the CD30 (Ki-1) antigen—a 120-kd membrane-bound molecule now known to be a member of the tumor necrosis factor (TNF) receptor superfamily[80,90–92]—previously found in association with Hodgkin disease. A soluble (88-kd) form of the CD30 molecule is found in high levels in the serum of virtually all patients with ALCL.[92–94] Marked elevation of the level of soluble CD30 in patients with ALCL correlates with higher risk of relapse, and levels of soluble CD30 have been found to correlate with clinical disease status, returning to normal with attainment of complete remission and increasing with disease recurrence.

The anaplastic large-cell lymphomas have been found to be associated with chromosomal rearrangements involving the long arm of chromosome 5 at position q35.[86,95] In the majority of cases, this translocation involves material from chromosome 2p23 [t(2;5)(p23;q35)] resulting in the fusion of the NPM nucleolar phosphoprotein gene on chromosome 5q35 to ALK (anaplastic lymphoma kinase), a tyrosine kinase gene on chromosome 2p23. The hybrid protein produced from the translocation links the amino terminus of nucleophosmin (NPM) with the catalytic domain of ALK.[96] Deregulated expression of the truncated ALK may contribute to malignant transformation.[97] The chimeric NPM–ALK protein is clearly oncogenic, perhaps through triggering of antiapoptotic signals via phosphatidylinositol 3-kinase/Akt,[98] although secondary molecular events may be required for lymphomagenesis.

Immunologic and molecular biologic studies reveal that the majority of cases of Ki-1$^+$ anaplastic large-cell lymphomas are derived from activated T cells, although non-T, non-B-cell (null cell) cases, and more rarely B-cell cases have been described.[84,87,99] Based on extended testing for T-cell antigens and examination of the configuration of T cell receptor genes, many of the "null" cell cases are, in fact, T lineage-derived neoplasms, although a minority may be derived from natural killer (NK) cells.[92] The diagnosis of ALCL can be difficult to establish, and many cases are initially misdiagnosed as Hodgkin disease.[84] The use of molecular techniques (RT-PCR) to detect the presence of the fusion gene produced by the t(2;5) in many cases of ALCL allows the establishment of the correct diagnosis.[96,100–102] Variant translocations where *ALK* is involved with other partner genes on other chromosomes limits the application of RT-PCR for diagnosis. However, the t(2;5) results in the expression of the NPM–ALK fusion protein, whereas the variant translocations result in upregulation of *ALK*. The expression of the normal ALK protein is restricted to rare cells in the central nervous system in normal postnatal tissues, so the expression of either ALK or the NPM–ALK fusion protein is a marker for ALCL. The ALK1 monoclonal antibody that recognizes the formalin-resistant epitope of both the NPM–ALK chimeric protein and normal ALK thus serves as a useful diagnostic reagent for identifying cases of ALCL.[92,96,103] It should be recognized that the distribution of ALK staining has been found to vary depending on the translocation.[33] Further, ALK expression is also observed in inflammatory myofibroblastic tumors (IMT) as a result of rearrangements of chromosome 2p23 that occur in this family of tumors, as well as in other mesenchymal tumors[104]; however, confusion with ALCL can be minimized by testing for other

hematopoietic markers, and the distinction is usually not difficult for experienced pathologists.

ALCL is rare, accounting for approximately 8% to 12% of childhood NHLs and roughly 30% to 40% of the pediatric large-cell lymphomas.[89] Approximately one-third of the cases present with localized disease, whereas the majority have advanced-stage disease at presentation, although involvement of the bone marrow and central nervous system is uncommon.[89] A leukemic presentation of ALCL has been described but is uncommon; it may be associated with the small-cell variant of ALCL.[105] Systemic symptoms (fevers, weight loss) are frequently present in advanced-stage disease. Cutaneous lesions (which often spontaneously regress) sometimes accompany disease at other sites,[78] but skin involvement is not universal.[79] A variety of presenting sites—both nodal and extranodal—have been observed, including the mediastinum, gastrointestinal tract, and bone. The outcome of children with ALCL in most series has been good, with survivals ranging from 70% to 85%,[89,106,107] although inferior to that of children with Burkitt and diffuse large B-cell lymphomas.

Rare Subtypes

Other subtypes that are observed rarely in children deserve mention, but the rarity of these neoplasms in children makes generalizations and therapeutic recommendations difficult. Follicular lymphomas (characterized by the arrangement of malignant cells in aggregates separated by normal cells), which account for approximately 30% of NHLs seen in adults, are extremely rare in children.[108–113] Children with follicular lymphomas tend to present with cervical lymph node involvement (although primary tumors of the testis have been reported[114,115]) with early-stage disease and have an excellent prognosis.[108–113] Unlike most cases of follicular lymphoma in adults where aberrant expression of bcl-2 (usually as a result of the t(14;18) translocation) is thought to play an important role in lymphomagenesis, the majority of cases of follicular lymphomas in children demonstrate neither the t(14;18) nor bcl-2 expression. Bcl-2 expression appears to occur more frequently in older children and is associated with advanced-stage disease at presentation and a more aggressive clinical course.[113]

Marginal zone B-cell lymphomas arising in mucosa-associated lymphoid tissue (MALT) can arise in extranodal sites. They tend to present with localized disease and infrequently disseminate. Natural killer cell lymphoma and NK-like T-cell lymphomas usually involve the upper aerodigestive tract (midline lethal granuloma, angiocentric T-cell lymphoma), but can present in the skin as well.[116–118] They are rare in children, and follow a very aggressive clinical course, are often fatal, but may respond to high-dose chemotherapy with stem cell transplantation.[116] Peripheral T-cell lymphomas include a variety of neoplasms that have not yet been further specified. These lymphomas are rare in children, but advanced stage at presentation, often in association with systemic symptoms and hematophagocytic syndrome, is common, and an aggressive course is the rule.

CLINICAL FEATURES

The clinical features at presentation vary with both primary site (Table 81–2) and extent of disease spread.[7,119] There is a striking difference in primary site between the Burkitt and lymphoblastic histologic subtypes.[7] The primary site of Burkitt lymphoma may be either abdomen or head and neck, but rarely the mediastinum. In contrast, lymphoblastic lymphomas may primarily involve the mediastinum or head and neck, but rarely the abdomen. Children with large B-cell lymphoma and ALCL present with less predictable sites of involvement, although such patients may present with primary involvement of head and neck, abdomen, or mediastinum.[7] The bone marrow may be involved at diagnosis in any of the histologic subtypes.[120] The central nervous system (CNS) may be involved at diagnosis in both the Burkitt and lymphoblastic lymphomas, but rarely in large-cell lymphoma.[7,121,122]

Table 81–2 Distribution of Primary Sites of Tumor in Children and Adolescents With Non-Hodgkin Lymphoma

	St. Jude Children's Research Hospital	The Hospital for Sick Children
No. of cases	338	102
Intraabdominal	31%	40%
Mediastinal	26%	23%
Head and neck	29%[a]	11%[b]
Nodal	7%[c]	21%
Other[d]	7%	6%

[a]Includes Waldeyer ring and/or cervical lymph nodes.
[b]Includes only Waldeyer ring.
[c]Includes cases with primary nodal disease arising outside the head/neck region.
[d]Includes a variety of less common locations, including bone, skin, epidural space, thyroid.
(Modified from reference 7 with permission).

Children who have a mediastinal mass may present with a spectrum of symptoms ranging from cough to severe respiratory distress caused by direct airway compression—this condition may be worsened by an associated pleural effusion (Fig. 81–1K). Mediastinal disease may also compress the superior vena cava, resulting in swelling of the neck and shoulder (superior vena cava syndrome).

Primary involvement of the abdomen may be associated with nausea, vomiting, and abdominal pain. Abdominal lymphoma often arises from the distal ileum and may result in intestinal obstruction secondary to either intussusception or compression by an expanding mass encasing the bowel lumen (Fig. 81–1J). These tumors may invade adjacent structures and be associated with ascites and other intraabdominal sites of disease, including kidney, liver, and lymph nodes.

Involvement of the bone marrow may result in pancytopenia with associated pallor and bruising. Involvement of the CNS may be associated with cranial nerve palsies or symptoms of increased intracranial pressure such as headache and vision changes. Cutaneous involvement may also occur and is usually associated with $CD30^+$ anaplastic large-cell lymphoma[81,88]; however, lymphoblastic lymphoma (often non–T cell immunophenotype) may also involve skin.[61–63] Bone involvement may be associated with pain or limping (Fig. 81–1L).

LABORATORY EVALUATION

Initial laboratory evaluation should include a complete blood count with differential—these may identify abnormalities in children with bone marrow involvement. A chemistry profile, which should include electrolytes, blood urea nitrogen, creatinine, lactic dehydrogenase (LDH), calcium, phosphorus, and uric acid is also important, particularly for children with bulky Burkitt lymphoma, who often present with metabolic abnormalities such as hyperuricemia. A screen for human immunodeficiency virus should be performed on all patients with newly diagnosed B-cell lymphomas. These individuals may be at increased risk for therapy-related toxicity, specifically, life-threatening infections. Serologic studies for EBV infection and measurement of EBV viral load may be helpful in children in whom lymphoproliferative disease is highly suspected in the differential diagnosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The differential diagnosis of NHL includes both benign and malignant conditions. If the blood counts are normal and there is no mediastinal mass, a single 10- to 14-day trial of antibiotics for painless enlarged peripheral adenopathy is permissible to treat presumed bacterial adenitis. Other infectious causes for adenopathy-simulating lymphoma include histoplasmosis, tuberculosis, and EBV infection, for which serologic and skin testing may be helpful. If the diagnosis of NHL is suspected, consultation with a pediatric oncologist is indicated.

The diagnosis of NHL is usually established by examination of tissue obtained by open biopsy of the involved site (see Fig. 81–1). A comprehensive characterization of the biologic features of the tissue will help to distinguish NHL from the small round blue cell tumors of childhood, including Ewing sarcoma, neuroblastoma, and rhabdomyosarcoma. Sufficient tissue should be obtained not only for histology but also for immunophenotypic, cytogenetic, and molecular studies. In some cases, a patient is too unstable to undergo anesthesia for open biopsy, as in children with large anterior mediastinal masses and associated airway compression. In such cases, the diagnosis may be established by parasternal fine-needle aspiration or biopsy with local anesthesia. If there is an associated pleural effusion, thoracentesis with cytologic examination of pleural fluid is usually diagnostic. In cases of large abdominal Burkitt tumors, direct percutaneous aspiration of the mass for cytology and cytogenetics is often diagnostic, as is cytologic examination of associated ascitic fluid obtained by paracentesis. In children with suspected NHL, a bone marrow and cerebrospinal fluid examination may be diagnostic, averting the need for more invasive procedures and possible increased morbidity.

STAGING

It is imperative that a complete staging workup be performed because therapy is determined in part by location and degree of disease spread. Additionally, because NHL in children grows very rapidly, there should be no unnecessary delay in the staging workup or in starting appropriate therapy. The staging workup should include a complete history and physical, including the documentation of the presence or absence of systemic symptoms (eg, weight loss, sweats, and fever). Diagnostic imaging studies should include computed tomography scanning of the chest, abdomen, and pelvis, and bone scanning. Gallium scanning may also be helpful in selected cases, particularly in following residual masses that were gallium positive at diagnosis. FDG positron emission tomography (PET) scanning is proving to be more sensitive and will likely supplant the Gallium scan for this purpose. The cerebrospinal fluid and bone marrow must be examined in all patients. Bilateral posterior iliac crest aspiration and biopsy increases the chance of identifying marrow involvement, thus reducing the possibility of underestimating the disease stage.[123]

On completion of the above workup, the stage of disease is usually determined according to the staging system described by Murphy (Table 81–3),[124] which was developed to accommodate the noncontiguous nature of disease spread, predominant extranodal involvement, and involvement of the bone marrow and CNS. Stages I and II are considered limited-stage disease, whereas stage III represents advanced-stage disease. Stage IV is reserved for children with the bone marrow or central nervous system involvement—presentations associated with a less favorable prognosis.

THERAPY

General Principles

The dramatic improvement in treatment outcome achieved over the past 30 years is in large part due to the refinement in multiagent chemotherapeutic strategies through sequential clinical trials.[7,89,106,107,121,125–167] A randomized trial performed by the Children's Cancer Group (CCG) that compared two of the earliest effective treatment regimens for childhood NHL (COMP [cyclophosphamide, Oncovin, methotrexate, prednisone] and LSA_2L_2) provided data supporting a stage- and histology-directed approach to treating children with NHL.[126,168] In this trial, children with limited-stage disease had an excellent outcome regardless of histology or treatment regimen used. In contrast, among children with advanced-stage disease, outcome varied with histology and therapy. Children with Burkitt lymphoma had a better outcome with the cyclophosphamide-based COMP regimen, whereas children with lymphoblastic lymphoma had a better outcome with LSA_2L_2, a regimen designed for children with ALL. Among children with large-cell lymphoma, outcome did not vary with treatment protocol. In the United States, subsequent trials built on this histology- and stage-directed approach. In Europe, and more recently in some US trials, an immunophenotype-directed approach is used. Data suggest that immunophenotype-directed therapy may be particularly important for children with advanced large-cell lymphomas.[130]

There is a minimal role for radiation therapy and surgery in the management of childhood NHL.[7] Prospective randomized trials in children with either limited- or advanced-stage disease have shown there is no improvement in treatment result when involved-field radiation is included[165,169]; in fact, this modality may only add to treatment-related morbidity. Apart from the initial diagnostic biopsy or the complete resection of an isolated peripheral node, tonsil, or ileocecal primary tumor associated with mesenteric nodes only (see discussion on staging), there is no other clear indication for the surgical management of this disease.[170,171] Of note, aggressive debulking procedures are not indicated.

To prevent the spread of disease to the CNS, prophylactic intrathecal and high-dose systemic chemotherapy are used in most children. Prophylactic intrathecal therapy may not be necessary in children with limited-stage disease outside of the head and neck region. Some groups have included cranial radiation for CNS prophylaxis in pediatric lymphoblastic lymphoma; however, this approach is controversial.[155] Among children who present with overt CNS disease, intensification of both intrathecal and systemic chemotherapy is often needed, and with the exception of Burkitt lymphoma, the addition of cranial irradiation.

Table 81–3 Stages of Non-Hodgkin Lymphoma*

Stage I
A single tumor (extranodal) or involvement of a single anatomical area (nodal), with the exclusion of the mediastinum and abdomen.
Stage II
A single tumor (extranodal) with regional node involvement. Two or more nodal areas on the same side of the diaphragm. Two single (extranodal) tumors, with or without regional node involvement on the same side of the diaphragm. A primary gastrointestinal tract tumor (usually in the ileocecal area), with or without involvement of associated mesenteric nodes, that is completely resectable.
Stage III
Two single tumors (extranodal) on opposite sides of the diaphragm. Two or more nodal areas above and below the diaphragm. Any primary intrathoracic tumor (mediastinal, pleural, or thymic). Extensive primary intraabdominal disease. Any paraspinal or epidural tumor, whether or not other sites are involved.
Stage IV
Any of the above findings with initial involvement of the central nervous system, bone marrow, or both.

*Based on the classification proposed by Murphy.[124]

Limited-Stage Disease

The excellent prognosis for children with limited stage disease has prompted investigators to develop treatment strategies that reduce treatment-related morbidity while maintaining an excellent treatment result.[125,132,133,148,151,152,169] These studies have examined various ways to reduce treatment intensity. For example, in the first of two sequential trials performed by the Pediatric Oncology Group (POG),[133,169] it was demonstrated that involved-field radiation therapy could be safely deleted from a 33-week chemotherapy regimen that comprised three courses of CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) given over a 9-week period, followed by a 24-week maintenance phase consisting of daily oral mercaptopurine and weekly methotrexate. In the subsequent trial,[133] they demonstrated that the 24-week maintenance phase could be deleted without compromising the treatment result for those with either large cell or Burkitt lymphoma. The optimal therapeutic approach for children with limited-stage lymphoblastic lymphoma remains controversial. In the POG trial, one-third of these children treated with the 33-week regimen experienced treatment failure, but were successfully salvaged with leukemia-like therapy in most cases. French investigators have taken a different approach, treating children with limited-stage lymphoblastic lymphoma with the same regimen used for those with advanced-stage disease.[147] Although this approach may reduce the need for retreatment, it also increases the risk of treatment-related morbidity.

Table 81–4 Treatment Outcome for Advanced-Stage Burkitt Lymphoma

Protocol	Stage	No. of Patients	Event-Free Survival Rate	Reference
Total B	III	17	2-year EFS = 81%	131
	IV/B-ALL	4/8	2-year EFS = 17%	
POG 8616 (Total B)	III	64	2-year EFS = 79% (SE = 6%)	134
POG 8617	IV	34	4-year EFS = 79% ± 9%	135
	B-ALL	47	4-year EFS = 65% ± 8%	
LMB 89*	III	278	5-year EFS = 91% (95% CI, 87%–94%)	125
	IV	62	5-year EFS = 87% (95% CI, 77%–93%)	
	B-ALL	102	5-year EFS = 87% (95% CI, 79%–92%)	
BFM 90	III	169	6-year EFS = 86% ± 3%	152
	IV	24	6-year EFS = 73% ± 10%	
	B-ALL	56	6 yr EFS = 74% ± 6%	

*Includes patients with diffuse large B-cell Non-Hodgkin Lymphoma.

Advanced-Stage Disease

In the United States, efforts to improve the treatment outcome for children with advanced-stage disease have primarily examined strategies to increase treatment intensity in the framework of a histology-directed approach, whereas in Europe, an immunophenotype-directed strategy is generally used.

Burkitt Lymphoma

Advances in the treatment outcome of patients with Burkitt lymphoma represent one of the true success stories in pediatric oncology (Table 81–4). Following the CCG trial that demonstrated the efficacy of the cyclophosphamide-based COMP regimen for advanced-stage Burkitt lymphoma, improved treatment results were achieved by including high-dose methotrexate and cytarabine[129,131,134–137] even in regimens given over as short a period as 2 to 4 months.[136,140] Subsequent improvements were achieved by dose intensification of therapy and by the inclusion of additional active agents such as etoposide or ifosfamide.[125,152,154] For example, the LMB-89 regimen pioneered by the French Society of Pediatric Oncology (SFOP) has produced some of the best results to date.[125] This strategy features risk-adapted therapeutic arms of escalating intensity (groups A, B, and C). The least intensive arm (group A) is reserved for those with completely resected limited-stage disease, whereas the most intensive arm (group C) is designed for those with CNS disease or marrow involvement, with more than 70% replacement by lymphoma cells. All of the remaining patients are treated according to group B, which is of intermediate intensity. Group B features high-dose methotrexate at a dose of 3 g/m^2, whereas a dose of 8 g/m^2 is used in group C. In contrast to group C, which incorporates high-dose cytarabine and etoposide, group B features low-dose continuous-infusion cytarabine and no etoposide. The therapeutic components of Group A are restricted to vincristine, prednisone, cyclophosphamide, and doxorubicin (these agents are also included in Groups B and C). The total duration of therapy is approximately 2, 5, and 8 months for groups A, B, and C, respectively. Results from a recently completed international trial using the LMB 89 regimen confirm the excellent outcome achieved in the initial report from the SFOP and indicate that the intensity of LMB-89 therapy may be safely reduced for Group B patients,[172] whereas for Group C patients a reduction in treatment intensity was associated with a poorer outcome.[173] The German Berlin–Frankfurt–Munster (BFM) cooperative group has also achieved excellent results in the treatment of B-cell NHL and ALL with a regimen that incorporates high-dose methotrexate at a dose of 5 g/m^2, ifosfamide, etoposide, and steroids.[152] An improved outcome was also reported in an NCI trial that incorporated etoposide, high-dose cytarabine, and ifosfamide into a backbone of cyclophosphamide, doxorubicin, vincristine, and high-dose methotrexate.[154] These more aggressive therapeutic approaches, which have been effective in improving the outcome for children with Burkitt lymphoma and B-cell ALL, have also provided encouraging results when administered to adults with the same diseases.[153,157]

Lymphoblastic Lymphoma

Most of the regimens used successfully to treat lymphoblastic lymphoma are similar to or derived from those designed for children with high-risk T-cell ALL (Table 81–5).[126–128,142,143,147,150, 155]

A St. Jude study demonstrated the benefit of adding teniposide and cytarabine to an otherwise conventional antimetabolite-based regimen.[142] The SFOP demonstrated that an excellent response could be achieved by incorporating courses of high-dose methotrexate into an LSA_2L_2 backbone.[147] The BFM group has incorporated a reinduction phase into their treatment strategy and, in their most recent trial, has featured high-dose methotrexate pulses (5 g/m^2) as an early consolidation with outstanding results (ie, 90% event-free survival at 3 years).[155] Although the French and German studies suggest an important role for high-dose methotrexate in the management of advanced-stage lymphoblastic lymphoma, the multiagent nature of the regimens studied to date makes the relative value of individual components uncertain. In this regard, a current Children's Oncology Group (COG) study is examining whether high-dose methotrexate can be safely eliminated from a BFM-based regimen, if replaced by extended intrathecal chemotherapy administration. L-Asparaginase is a component of most successful treatment regimens for advanced-stage lymphoblastic lymphoma. Its importance was demonstrated in a randomized trial performed by the POG that reported a survival advantage for those patients who received additional L-asparaginase.[160] Other strategies to improve outcome have included

Table 81–5 Treatment Outcome for Advanced-Stage Lymphoblastic Non-Hodgkin Lymphoma

Protocol	Stage	No. of Patients	Event-Free Survival (EFS) Rate	Reference
LSA_2L_2 (modified) CCG-551	III/IV	124	5-year EFS = 64%	126,168
BFM 90	III	82	5-year EFS = 90% ± 3%	155
	IV	19	5-year EFS = 95% ± 5%	
X-H SJCRH	III/IV	22	4-year DFS = 73%	142
APO (Dana Farber)	III/IV	21	3-year DFS = 58% ± 23%	167
A-COP + (POG)	III	33	3-year DFS = 54% ± 9%	143
SFOP LMT81	III	33	57 mo EFS = 79% (SE, 4%)	147
	IV/ALL	43	57 mo EFS = 72% (SE, 4%)	
CCG: LSA_2L_2 (modified) vs ADCOMP	I–IV	243	5-year EFS = 74%	150
	I–IV	138	5-year EFS = 64%	
POG8704: no extra Asp vs extra Asp	III/IV	83	4-year CCR = 64% (SE, 6%)	160
	III/IV	84	4-year CCR = 78% (SE, 5%)	

the incorporation of other active agents (eg, epipodophyllotoxins) and delayed intensification or reinduction phases.[142,155,160]

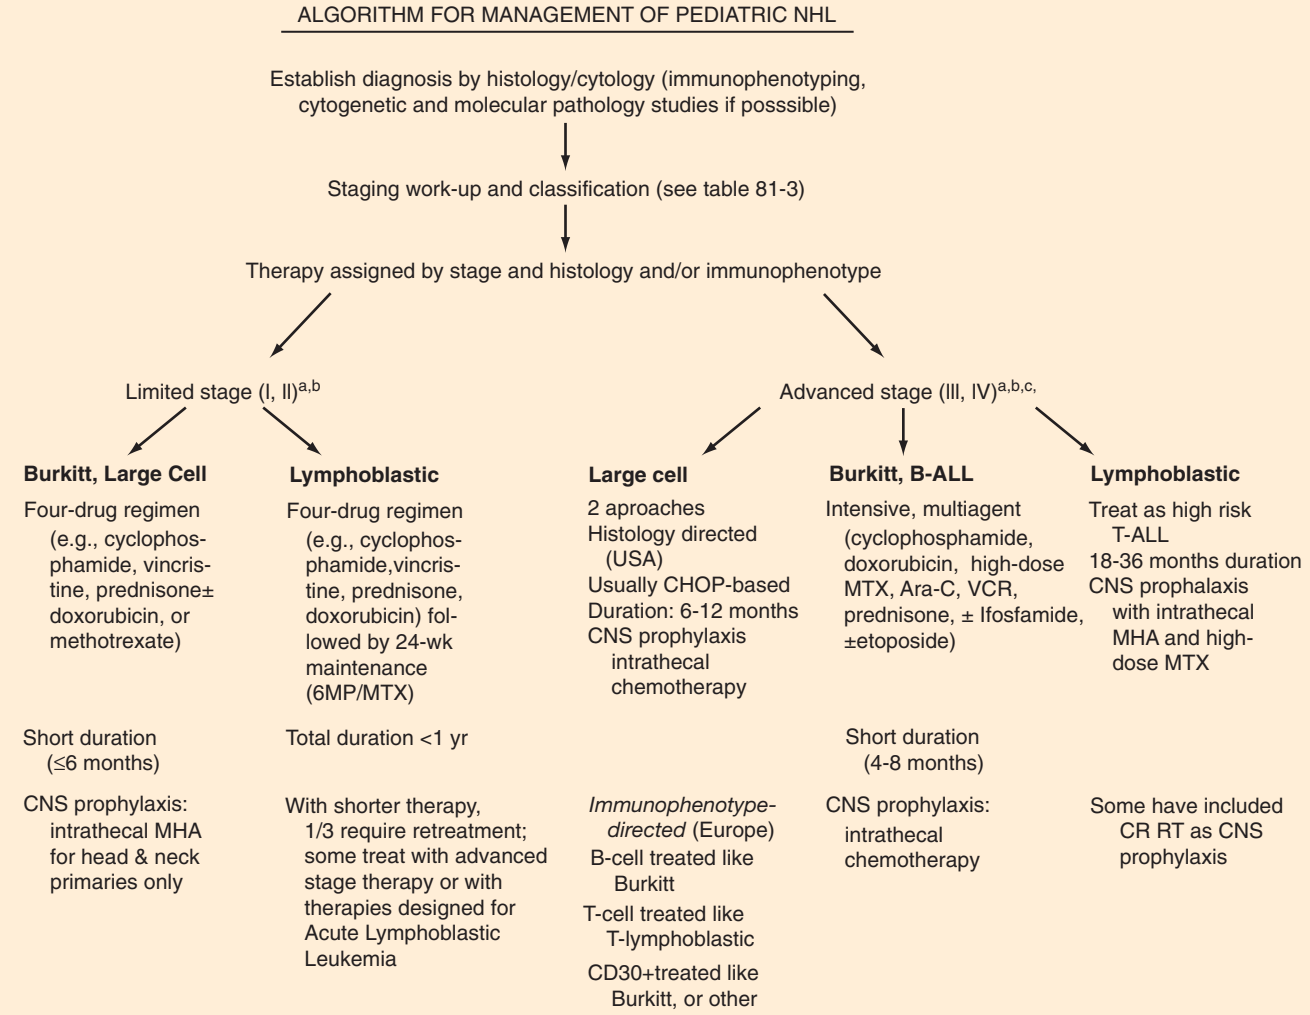
Large-Cell Lymphoma

The optimal approach to the treatment of advanced-stage large-cell lymphoma has been a challenge to identify, both because of the biologic heterogeneity of these tumors and the markedly varied treatment strategies reported. In the United States, children with large-cell NHL have historically been treated on histology-directed protocols (Table 81–6).[88,126,130,138,144–146]

Most of these histology-directed strategies are CHOP based, with current trials examining the benefit of adding agents such as carboplatin, high-dose cytarabine, etoposide, ifosfamide, and high-dose methotrexate. Some trials have examined the feasibility of eliminating individual agents with significant late effects, such as doxorubicin or cyclophosphamide.[138,159] In a POG trial, children with large-cell lymphomas of B-cell immunophenotype had a superior treatment result compared with those with a non-B-cell immunophenotype, suggesting that an immunophenotype-directed approach should be explored in future trials.[130] In this regard, European trials for children with large-cell NHL have generally been designed according to immunophenotype; children with B-cell tumors are treated like those with Burkitt lymphoma.[125] The SFOP reported that children with diffuse large B-cell lymphoma had an equally excellent outcome as compared to those with Burkitt lymphoma when treated with the same LMB-89 regimen.[125] However, those with mediastinal large B-cell lymphoma may have a somewhat inferior outcome compared to other diffuse large B-cell lymphomas.[77,172,174,175]

The anaplastic large-cell lymphomas account for the vast majority of large-cell lymphomas having a T-cell immunophenotype. The optimal treatment approach for patients with this type of lymphoma has yet to be elucidated, as evidenced by the wide range of treatment strategies that have been successfully implemented.[89] In the United States, children with $CD30^+$ ALCL have generally been treated with the same regimen used for non-ALCL large-cell lymphomas, with long-term event-free survival rates ranging from 60% to 70%.[89] In a randomized trial performed by the POG, the addition of intermediate-dose methotrexate and high-dose cytarabine did not improve upon the 70% 4-year event-free survival achieved with APO alone.[176,177] The BFM have reported among the best results to date (3-year event-free survival of approximately 80%) using a Burkitt lymphoma-based strategy.[106,166] Regimens designed specifically for children with $CD30^+$ ALCL have been developed by the French (SFOP) and German Groups.[106,107] The SFOP also reported the successful salvage of ALCL patients with the weekly administration of single-agent vinblastine.[162] The impact of incorporating vinblastine into two different front-line treatment for strategies for ALCL [the BFM B-cell approach (multinational European trial) and APO (COG trial in the United States)] is currently being studied in randomized fashion.

Table 81–6 Treatment Outcome for Advanced Stage Large-Cell Non-Hodgkin Lymphoma



Protocol	Stage	No. of Patients	Event-Free Survival Rate	Reference
CHOP	III & IV	21	3-year EFS = 62% ± 11%	121
MACOP-B	III & IV	11	3-year EFS = 55% ± 16%	146
COMP vs	III & IV	42	5-year EFS = 52%	
LSA_2L_2	III & IV	18	5-year EFS = 43%	126
APO vs	III & IV	62	3-year EFS = 72% ± 6%	
ACOP+	III & IV	58	4-year EFS = 62% ± 7%	159

EMERGENCY SITUATIONS

Various emergency situations may arise in the management of the child with newly diagnosed malignant lymphoma.[178] Those with a large anterior mediastinal mass may present with severe respiratory distress secondary to direct tracheal compression, a situation that may be worsened by an associated pleural effusion. If the diagnosis has been confirmed, appropriate chemotherapy should be started as soon as possible. If the diagnosis has not been established, efforts should be made to establish it expeditiously (see section on diagnosis). If the degree of respiratory compromise requires emergency management, involved-field irradiation of the tumor mass should be considered, with sparing of peripheral portions of the tumor so that a biopsy can be obtained when the patient is stable.[179] Steroids may also be considered; however, this approach risks altering the tumor histology, making it difficult to establish the correct diagnosis.[180]

Children with a large tumor burden, particularly those with Burkitt lymphoma, are at increased risk of significant metabolic abnormalities. Specifically, they may present with hyperuricemia, hyperkalemia, hyperphosphatemia, and associated renal dysfunction. This situation may only worsen with the massive tumor cell lysis that follows administration of chemotherapy (tumor lysis syndrome).[181–183] Some of these children develop renal failure, requiring dialysis. To help prevent this complication, children at risk should be vigorously

Algorithm for Management of Pediatric NHL

MHA, methotrexate, hydrocortisone, cytosine, arabinoside; VCR, vincristine, CR RT, cranial radiation.
[a]Relapses or induction failures should be treated with multiagent intensive chemotherapy; if shown to be chemosensitive, consider consolidation with haematopoietic stem cell support.
[b]No involved field radiation therapy up front, but may be considered for biopsy-proven induction failure or relapse.
[c]Bulky advanced stage Burkitt and lymphoblastic lymphoma will require prechemotherapy stabilization including vigorous hydration/alkalization/allopurinol.

hydrated (3–4 L/m^2/day with D5 1/4 NaCl and 40 mEq/L $NaHCO_3$; there should be no added potassium) and started on allopurinol, a xanthine oxidase inhibitor. The urine pH should be maintained at approximately 7.0; at a more alkaline pH, phosphorus is less soluble, and at a more acidic pH, uric acid is less soluble. In some cases, mannitol followed by furosemide is required to maintain urine output. Uricolytic agents (eg, uricozyme, which has been used for many years in Europe) directly cleave the uric acid molecule and result in a precipitous drop in serum uric acid levels within a few hours.[184] The use of uricolytic agents (eg, urate oxidase, uricase, rasburicase)[185–188] has proven to be superior to allopurinol to reduce rapidly the level of serum uric acid and improve renal function. This precludes the need for alkalinization, thus facilitating the excretion of phosphorus. The use of uricolytic agents and the initiation of induction therapy with a course of low-dose chemotherapy as a cytoreductive "pre-phase" have reduced the incidence of renal insufficiency from urate nephropathy in European trials.[125,151] Few children treated on recent trials for advanced-stage B-cell lymphomas conducted by the BFM Group and the SFOP have required hemodialysis during induction, and few early deaths have been encountered. A similar experience has been appreciated in recent North American trials.

Children with NHL may present with epidural masses and associated neurologic deficits caused by spinal cord compression. If the diagnosis is known, chemotherapy should be started as soon as possible. If the diagnosis is not known, or if there is a sluggish response to chemotherapy, low-dose radiation therapy may be considered in consultation with a radiation oncologist.

SALVAGE THERAPY

Children who fail initial therapy are generally considered to have a poor prognosis, particularly if they have received intensive therapy initially. Current approaches to the management of these patients incorporate intensive multiagent therapy, which may be followed by hematopoietic stem cell (peripheral blood or bone marrow-derived) transplantation. Various multiagent regimens have been studied. For example, VIPA[154] (etoposide, ifosfamide, and cytarabine) has been shown to be active in relapsed Burkitt lymphoma, and DHAP (dexamethasone, cytarabine, and cisplatin) has been shown to be active in relapsed large-cell NHL.[146] Other regimens, including ICE[189] (ifosfamide, carboplatin, and etoposide) and MIED (methotrexate, ifosfamide, etoposide, and dexamethasone) have also been studied. Children who have chemosensitive recurrent disease are considered candidates for an intensification phase with high-dose chemo- or radiotherapy and hematopoietic stem cell support (either autologous or allogeneic).

Autologous hematopoietic stem cell transplantation has been used successfully in children with relapsed large-cell lymphoma[190] and in certain cases of relapsed Burkitt lymphoma.[191,192] The European Lymphoma Bone Marrow Transplantation Registry has reported that among children with poor-risk Burkitt lymphoma, two groups of patients responded well to high-dose chemotherapy followed by autologous BMT: those with a partial response to induction therapy and those with chemosensitive relapse. These investigators emphasize that with intensive modern front-line protocols, postrelapse salvage with high-dose chemotherapy and autologous BMT may be less successful, and they suggest that novel approaches including antibody-targeted therapy or the graft-versus-lymphoma effect following an allogeneic BMT approach be explored.[193] There are limited published data on the comparative effectiveness of autologous and allogeneic BMT for children with relapsed NHL; however, most investigators would consider allogeneic BMT strategies in cases of relapsed lymphoblastic lymphoma if there is a matched related donor, whereas either an autologous or allogeneic approach would be considered for those with recurrent Burkitt lymphoma.

SUPPORTIVE CARE

Optimal supportive care is critical for the successful management of children with NHL. The increased intensity of many current regimens requires the availability of the appropriate expertise and resources to manage the complications encountered during periods of profound pancytopenia. The management of life-threatening infections requires the availability of appropriate broad-spectrum antibiotics and antifungals and an intensive care facility. The use of prophylactic trimethoprim-sulfamethoxazole is recommended in all patients to reduce the chance of *Pneumocystis carinii* pneumonitis; for patients on aggressive B-cell protocols, prophylaxis should be continued for approximately 6 months after chemotherapy is completed. Access to a blood bank that can quickly provide irradiated, leukocyte-depleted packed red blood cells and platelets is also important. The role of colony-stimulating factors such as granulocyte-CSF or granulocyte/macrophage-CSF has yet to be fully elucidated; however, the use of these cytokines provides the potential benefit of reducing the duration of neutropenia, thus reducing infectious morbidity. The placement of a permanent venous access device greatly facilitates the delivery of hydration fluids, chemotherapy, antibiotics, and blood products. Consultation with a nutritionist or nutritional support team regarding need for enteral or total parenteral nutritional support is often necessary, particularly for children on intensive advanced-stage B-cell NHL protocols, which are associated with significant gastrointestinal tract toxicity.

PROGNOSTIC FACTORS

Factors that are associated with treatment outcome include treatment era and tumor burden as reflected by both stage and serum LDH.[7] Those with limited-stage (I and II) disease generally have a better prognosis than those with advanced-stage (III and IV) disease; however, more intensive therapies for children with advanced-stage disease have resulted in approximately equal outcomes in the two groups, albeit at the expense of more toxicity for children with advanced-stage disease. Involvement of the CNS and bone marrow has historically been associated with an inferior outcome. However, for certain histologic subtypes, such as Burkitt lymphoma, modern intensive therapy has resulted in an improved prognosis for these patients as well.[125,135,152] Elevated serum LDH (>500 IU/L) and interleukin-2 receptor are associated with adverse outcome.[194,195] Within specific histologic subtypes, certain biologic features have prognostic value. For example, among those with large-cell NHL, one study suggested that those with a B-cell immunophenotype have a better treatment result than do those with a non-B-cell immunophenotype (ie, T-cell or non-B, non-T cell).[130] Prognostic factors are reflective of the specific treatment used, and will therefore continue to change as therapy improves.

FUTURE DIRECTIONS

Although there have been dramatic improvements in treatment outcome for children with NHL over the past 25 years, approximately 25% of children with these tumors either relapse or do not respond to initial therapy. Additionally, late effects such as anthracycline-related cardiomyopathy, secondary malignancies such as epipodophyllotoxin-related acute myeloid leukemia, and endocrine abnormalities such as cyclophosphamide-related azoospermia remain a concern.[196–198] Thus, a major goal for the future is to develop treatment strategies that will provide a cure for the remaining 25% while reducing treatment-related morbidity. There are several areas to target if this goal is to be achieved.

The identification of both clinical and biologic features at the time of diagnosis that predict treatment failure will enable investigators to refine existing risk-adapted therapeutic approaches. Various strategies to be considered for those children who remain at high risk for treatment failure may include the intensification of existing regimens and the incorporation of new active or novel agents. More intensive therapy may require either autologous or allogeneic hematopoietic stem cell support. The administration of colony-stimulating factors may be necessary in some cases, although their role in therapy remains controversial. Novel approaches may include the incorporation of immunotherapeutic agents into multiagent chemotherapy regimens. For example, the anti-CD20 antibody (rituximab) has been successfully used in the management of adults with B-cell lymphomas, including diffuse large B-cell lymphoma and follicular lymphomas.[199–201] A radiolabeled form of this product (Yttrium-90 Zevalin) has also yielded promising preliminary results.[202] These agents are currently under investigation in children. $CD30^+$ lymphomas such as anaplastic large cell (ALCL), mediastinal B-large cell and Hodgkin's disease are also potential candidates for antibody therapy. In this regard, a humanized anti-CD30 antibody (SGN-30) has been shown to have preclinical activity in both cell culture and xenograft mouse model systems of ALCL and Hodgkin disease.[203] Preliminary results from adult phase I and II single-agent trials of SGN-30 suggest that it is both well tolerated and active against $CD30^+$ lymphomas. Trials are currently ongoing to study this agent in children with ALCL. Novel immunotherapeutic approaches may also include the use of surface protein-specific cytotoxic T lymphocytes; this approach has been successful in both the prevention and treatment of EBV-related posttransplant lymphoproliferative disease.[204] Agents that target the specific molecular lesion are also being developed. In this regard, the use of small-molecule inhibitors for tumors such as ALCL that contain the NPM–ALK fusion gene would be very attractive; studies are currently ongoing.[205] The implementation of antiidiotype and antisense strategies are also being studied.[206]

The continued investigation of molecular abnormalities and pathogenic mechanisms of malignant transformation associated with childhood lymphomas is essential. The use of microchip gene arrays

has already been shown to identify clinically relevant subtypes of large B-cell lymphomas in adults.[74,75] The results of gene array analyses of Burkitt lymphoma,[207–210] anaplastic large cell lymphoma,[211] and T-lymphoblastic disease[212] have also been reported. Similar studies are ongoing for lymphomas occurring in children, with preliminary results for those with T-lymphoblastic lymphoma recently published.[213] Comprehensive molecular characterization of childhood lymphomas may help to further refine disease classification, provide a means of detecting minimal residual disease (MRD) during clinical remission and enhance our assessment of early response. In this regard, it has been demonstrated that the level of MRD in the peripheral blood is equivalent to that in the bone marrow of children presenting with advanced-stage lymphoblastic lymphoma.[214] In a current COG study of children with this lymphoma subtype, peripheral blood samples are being analyzed at various time points during induction to measure rates of early response. Additionally, a more complete understanding of the molecular pathogenesis of pediatric NHLs will provide clues to novel and more successful treatment strategies, including those directed toward tumor-specific molecular lesions.

CHAPTER 82

RADIOIMMUNOTHERAPY FOR B-CELL NON-HODGKIN LYMPHOMA

Thomas E. Witzig

INTRODUCTION

The most significant advances in the treatment of non-Hodgkin lymphoma (NHL) in the last decade have been anti-CD20 immunotherapy and radioimmunotherapy (RIT).[1] Rituximab is an unlabeled (*cold*) monoclonal antibody that targets the CD20 antigen on benign and malignant B-cells. In 1997, rituximab became the first monoclonal antibody to be approved by the Food and Drug Administration (FDA) for the treatment of cancer. The pivotal clinical trial treated 166 patients with relapsed B-cell NHL with rituximab 375 mg/m^2 weekly for four doses and demonstrated an overall response rate (ORR) of 48% with 6% complete remission (CR) and a 13-month time to tumor progression (TTP).[2] High response rates have also been demonstrated in previously untreated patients with follicular NHL.[3,4] Randomized trials have demonstrated the superiority of rituximab chemotherapy combinations in both indolent[5,6] and aggressive NHL.[7–10] The results of rituximab chemoimmunotherapy is further discussed in Chapters 79 and 80.

Despite these impressive results with immunotherapy and chemoimmunotherapy, patients cannot be promised cure, and there is room for improvement. Unlabeled monoclonal antibodies theoretically must target each tumor cell to kill. RIT involves the linking of a radionuclide to an antibody to form a radioimmunoconjugate (RIC) (Fig. 82–1). In RIT the goal is to attach a radionuclide with high energy but short path length to the antibody to focus radiation on the target cell population while sparing the effects of radiotherapy on the nearby normal tissue. The RIC kills tumor cells by the direct effects of the antibody, such as antibody-dependent cellular cytotoxicity (ADCC), as well as the effects of ionizing radiation. The radionuclide can potentially be attached to any antibody. The choice of antibody depends on the antigenic profile of the tumor cell to be targeted. Ideal targets are those antigens that are expressed on tumor cells but not normal cells so as to avoid toxicity to normal organs. Cell surface antigens that are not internalized or shed from the cell surface are preferred. The microscopic intratumoral dosimetry of the radionuclide appears to be important.[11]

The application of RIT to treat B-cell NHL was a logical choice because it has been known for many years that NHL are sensitive to radiation delivered by conventional external sources. Indeed, radiation therapy has been a mainstay in the treatment of bulky masses that are producing normal organ compromise and is effective at relieving pain from spinal cord compression. The difficulty with applying radiation therapy to indolent NHL relates primarily to the widespread nature of these tumors even at initial diagnosis. In addition, extensive radiation damages normal marrow making it difficult to provide effective chemotherapy or to collect stem cells at a later date. For these reasons conventional external beam radiotherapy (RT) has been typically limited to involved field applications in this disease.

Initial studies of RIT in lymphoma used polyclonal antibodies;[12] however, most RIC today are murine monoclonal antibodies.[13,14] Recent studies of RIT using a variety of tumor antigen targets on NHL cells have indeed demonstrated tumor regressions with very few side effects in normal organs other than myelosuppression.[15–41] This review will focus on RIC that target CD20 that are now in clinical use for FDA-approved indications.[13,42–49] The CD20 antigen has proven to be an excellent target for RIT because CD20 expression is restricted to normal B cells, almost all B-cell NHL express CD20, the antigen is not internalized within the cell or expressed on other normal tissue (including stem cells), and depletion of normal B-cells by these antibodies has not led to significant short or long-term side effects.

RADIONUCLIDES USED IN RADIOIMMUNOTHERAPY

There are many different radionuclides that have been attached to antibodies for the treatment of cancer.[50] The most common ones in current use and that are commercially available are yttrium 90 (^{90}Y) and iodine 131 (^{131}I). Administration of a RIC is preceded by a dose of cold antibody to deplete normal blood B-cells and block nonspecific binding sites resulting in improved tumor to normal organ biodistribution. There are several differences in the two radionuclides that affect the methods of delivery of the respective RIC in the clinic (Table 82–1). To date, these differences have not translated into any apparent clinical advantages of one radionuclide over another. The ^{131}I labeled antibodies can be used for imaging and dosimetry because they are γ emitters. In contrast, as ^{90}Y is a pure β emitter, imaging is performed with γ-emitting indium 111 (^{111}In)-labeled antibodies. For ^{131}I RIC, patient-specific dosing is used because of differences in renal excretion between patients. In the case of ^{90}Y, the dose for nonmyeloablative use is determined by the weight of the patient in kilograms (with a maximum of 32 mCi) rather than from dosimetry because only 7% of ^{90}Y is excreted from the kidneys over 7 days. ^{111}In imaging is still required to ensure there is normal biodistribution. In most states in the United States, ^{131}I -labeled RIC can be administered as an outpatient; however, outside the United States patients may be required to be hospitalized briefly after administration of ^{131}I RIC. ^{90}Y RIC can be administered to patients in the outpatient setting because they do not emit γ radiation. With ^{131}I RIC oral iodine is required before and after the RIT to block the thyroid; this is not necessary with ^{90}Y.

RIT must be handled and injected by personnel certified by the Nuclear Regulatory Commission. Administration of RIT is a team effort between the hematologist/oncologist who is caring for the patient and the nuclear medicine physician or radiation oncologist who will administer the RIT.[51,52]

CHARACTERISTICS OF RADIOLABELED MONOCLONAL ANTIBODIES TO CD20

Ibritumomab Tiuxetan (Zevalin)

Ibritumomab is a murine anti-CD20 antibody from which the human chimeric antibody rituximab (Rituxan and MabThera; Biogen IDEC Cambridge, MA and Genentech, Inc, South San Francisco, CA) was engineered. Ibritumomab, a murine anti-CD20 antibody, was attached to tiuxetan, a MX-DTPA linker-chelator to form Zevalin (Biogen IDEC Cambridge, MA). Tiuxetan forms a covalent, urea-type bond with ibritumomab and chelates the radionuclide through five carboxyl groups. Zevalin is then reacted with either ^{111}In for tumor imaging and dosimetry or with ^{90}Y for therapeutic RIT.

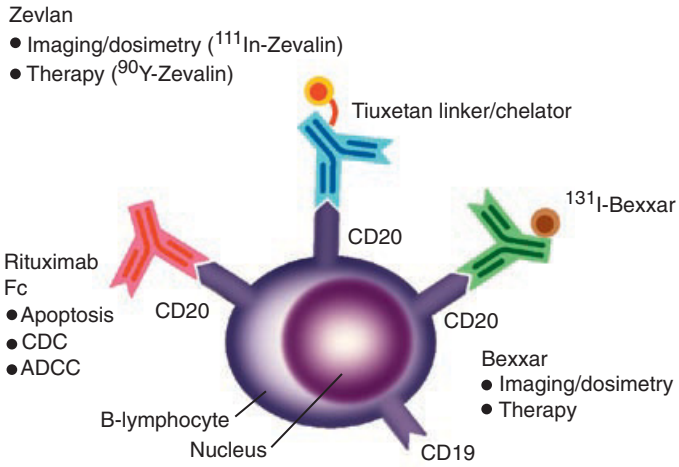

Figure 82–1. B-cell lymphoma cells express CD20, which can be targeted with unlabeled (rituximab) or labeled monoclonal antibodies. Ibritumomab tiuxetan (Zevalin) is the murine parent antibody from which the human chimeric antibody rituximab was engineered. Tiuxetan is a linker/chelator to which indium 111 (^{111}In) (for imaging and dosimetry) or yttrium 90 (^{90}Y) (for therapy) can be attached. In the case of tositumomab (Bexxar) the ^{131}I is directly attached to the murine antibody and the resulting radioimmunoconjugate used for imaging and dosimetry.

Table 82–1. Characteristics of Radionuclides Currently Used in Radioimmunotherapy

Parameter	^{131}Iodine	^{90}Yttrium
Gamma emission	Yes	No
β emission	Yes	Yes
β emission path length (mm)	0.8 mm	5 mm
Theoretical half-life	8 days	2.4 days
Free radioisotope	Thyroid/stomach	Bone
Administration	Outpatient in most states	Outpatient
Pretreatment cold antibody	Yes	Yes
Imaging	Yes	No (^{111}In required as a surrogate)

^{111}In, indium 111.

^{90}Y emits pure β radioactivity with a path length of approximately 5 mm. Because there is no γ emission, useful tumor and normal organ images cannot be obtained with ^{90}Y-Zevalin. ^{111}In emits γ rays, therefore ^{111}In-Zevalin is used to produce high-quality images of the tumor and normal organs for dosimetry and biodistribution studies.[52–56] Patients are imaged in anterior and posterior projections in a whole body area mode between day 1 (the day of ^{111}In-Zevalin injection) and day 7. In the research trials of Zevalin if the ^{111}In-Zevalin scans predicted that the delivered dose of radiation to any non-tumor organ was greater than 2000 cGy, or if the dose to the bone marrow was greater than 300 cGy, then no treatment with ^{90}Y-Zevalin was to be administered.[57,58] No patient in these trials failed dosimetry using these parameters.

The first phase I trial of Zevalin used cold ibritumomab before Zevalin and stem cells were cryopreserved in case of prolonged myelosuppression. Patients were treated with single doses of 20 to 50 mCi of Zevalin; doses equaling 40 mCi were not myeloablative.[25] The second phase I trial used rituximab 250 mg/m^2 as the unlabeled antibody before Zevalin, and patients were treated with one of three dose levels—0.2, 0.3, or 0.4 mCi/kg. If the patient weighed more than 80 kg the dose was capped at 32 mCi. Higher doses were not tested because stem cell cryopreservation was not required as part of the protocol eligibility. There was no provision for retreatment in this trial.[28] The FDA approved the Zevalin treatment program in February 2002. It delivers rituximab and ^{111}In-Zevalin on day 1 followed by one imaging session to determine biodistribution 48 to 72 hours later (images at other time points are optional). The amount of uptake of ^{111}In-Zevalin in a specific lesion is not predictive of tumor response;[59] therefore, the imaging is only performed for safety. If there is normal ^{111}In-Zevalin biodistribution, on day 8 the patient receives a second dose of rituximab followed by ^{90}Y-Zevalin over 10 minutes. The dose of Zevalin is determined by weight and baseline platelet count. If the platelet count is normal (>150,000 cells/mm^3) the recommended dose is 0.4 mCi/Kg; if the platelet count is between 100 and150,000 cells/mm^3, the dose is 0.3 mCi/Kg. The dose is capped at 32 mCi for patients weighing more than 80 kg.

Tositumomab (Bexxar)

Tositumomab is an IgG2a murine monoclonal antibody directed against CD20 (see Fig. 82–1). It was previously referred to as anti-B1[22,60] before being named tositumomab. For RIT, tositumomab has been radiolabeled with ^{131}I. Because ^{131}I emits γ as well as β radiation ^{131}I-tositumomab can be used for both dosimetry and treatment, that is, there is no need for ^{111}In.[61] The Bexxar treatment regimen consists of cold tositumomab and ^{131}I -tositumomab (GlaxoSmithKline, Research Triangle Park, NC). Tositumomab is administered intravenously on 2 treatment days with each day consisting of two separate infusions. Although both Zevalin and Bexxar require tumor imaging, for Bexxar the dosimetry is used to calculate a patient-specific therapeutic dose.[62] This is necessary because of the interpatient differences in body mass (weight), spleen size, tumor burden, and the metabolism and renal excretion of ^{131}I.[22,61–64] Because of the propensity of iodine to concentrate in the thyroid, saturated potassium iodide solution (SSKI; Lugol's) is started 1 day before the cold tositumomab and is continued for 2 weeks after the radiolabeled tositumomab. The first treatment is referred to as the *dosimetric dose*. It consists of tositumomab 450 mg over 1 hour followed by 5 mCi of ^{131}I- tositumomab. γ Scans to measure whole body counts are performed on day 1 and repeated within 2 to 4 days and 6 to 7 days after the dose. The results of the dosimetry determine the amount of radiation activity (as mCi of ^{131}I) needed for each patient to receive a specified total body absorbed radiation dose 75 cGy for patients who have platelet counts greater than 150,000 cells/mm^3 or 65 cGy for patients with platelets between 100,000 and 150,000 cells/mm^3. The therapeutic dose is given within 7 to 14 days of the dosimetric dose and consists of 450 mg of tositumomab followed by a 20-minute infusion of the patient-specific mCi amount of ^{131}I-tositumomab. The Bexxar therapeutic program can be given as an outpatient procedure for the vast majority of patients using the revised US Nuclear Regulatory Commission (NRC) regulations 10CFR 35.75, which allow outpatient release if the total effective dose equivalent to another person who is exposed to the treated patient is less than 500 mrem.[65,66]

CLINICAL RESULTS OF ANTI-CD20 RADIOIMMUNOTHERAPY FOR RELAPSED NHL

The clinical trials of the two anti-CD20 RIC that were performed to assess toxicity and efficacy have primarily been limited to patients with relapsed disease and excellent bone marrow and normal organ function. The eligibility requirements for both the Zevalin and Bexxar trials have been similar except for certain studies as mentioned below (see Phase I Bexxar Trial, Phase II Trials of Bexxar, and Pivotal Trial of Bexxar). Patients were to have measurable disease, bone marrow with less than 25% involvement with lymphoma, absolute neutrophil count ≥1500, platelet count ≥100,000 cells/mm^3, normal renal and liver function, and less than 25% of the bone marrow previously treated with external beam radiotherapy. Patients were excluded

from these trials if they had CNS lymphoma, HIV infection or HIV-related NHL, chronic lymphocytic leukemia (CLL), pleural or peritoneal fluid that was positive for lymphoma, known myelodysplasia, or history of a prior allogeneic or autologous stem cell transplant. Tables 82–2 and 82–3 describe the patient population included in each of the clinical trials, Table 82–4 summarizes the efficacy results, and Table 82–5 the hematologic toxicity (Fig. 82–2). In general, both Bexxar and Zevalin as single-agents in relapsed-indolent NHL produce an ORR of 80% with 30% CR and 20% of patients achieving long-term remissions without relapse to date. These agents can produce impressive responses in both nodal and extranodal disease without damage to adjacent normal structures (Fig. 82–3). The only side effect is reversible myelosuppression; there is no solid organ toxicity.

Table 82–2. Summary of the Clinical Trials of Ibritumomab Tiuxetan (Zevalin)

Trial	*N*	Goal
IDEC 106-02[25]	14	• Used cold ibritumomab prior to ^{90}Y-ibritumomab • Determine MTD
IDEC 106-03[28]	51	• Determine dose of rituximab prior to ^{111}In-ibritumomab • Determine MTD
IDEC 106-04[34]	143	• Randomized trial of rituximab vs ^{90}Y-ibritumomab to determine if efficacy of ^{90}Y-ibritumomab is superior
IDEC 106-05[35]	30	• Efficacy and toxicity of 0.3 mCi/kg ^{90}Y-ibritumomab for patients with platelet count of 100K–149K × 10^6/L
IDEC 106-06[76]	54	• Efficacy and toxicity of 0.4 mCi/kg ^{90}Y-ibritumomab for patients refractory to rituximab.
Safety analysis[73]	349	• Evaluate the side effects experienced by patients treated with ^{90}Y-ibritumomab on clinical trials

IDEC, IDEC Pharmaceuticals, San Diego, CA;^{111}In, indium 111; MTD, maximum tolerated dose; ^{90}Y, yttrium 90.

Phase I Bexxar Trial

The phase I trial of ^{131}I-tositumomab was designed to determine a dose that could be administered without stem cell support.[22,23,67] Patients were treated with 15 to 20 mg of intravenous anti-B1 (anti-CD20) mouse monoclonal antibody trace-labeled with ^{131}I (5 mCi) over 30 minutes. The first 10 patients received ^{131}I-tositumomab without cold tositumomab pretreatment. The next eight patients were given a small dose (135 mg) of cold tositumomab pre-^{131}I-tositumomab, and another two received 685 mg pretreatment.[22]

Table 82–3. Clinical Trials of ^{131}I-Tositumomab in Patients without the Use of Stem Cell Support

Trial	*N*	Goal
Phase I[22,23,67]	59	• Used single or multiple doses trace-labeled tositumomab prior to therapeutic ^{131}I-tositumomab • Determine MTD of ^{131}I-tositumomab
Phase II[37,68]	86	• Validate dose determined in phase I
Pivotal[32]	60	• Compared response to last qualifying chemotherapy to that obtained with ^{131}I-tositumomab
Cold versus hot[75]	48	• Establish improved efficacy of radiolabeled tositumomab compared to cold tositumomab
Rituximab-refractory[78]	38	• Evaluated response to ^{131}I-tositumomab in patients failing rituximab
Previously untreated[108]	76	• Evaluated overall and complete response rate in patients treated with ^{131}I-tositumomab as their first therapy

^{131}I, iodine 131; MTD, maximum tolerated dose.

Table 82–4. Response Rates in Trials without Stem Cell Support

Trial	Agent	*N*	ORR	CR	DR	DR/CR
Phase 1[22,23,67]	^{131}I-Tositumomab	59	71	34	8.9	18.3

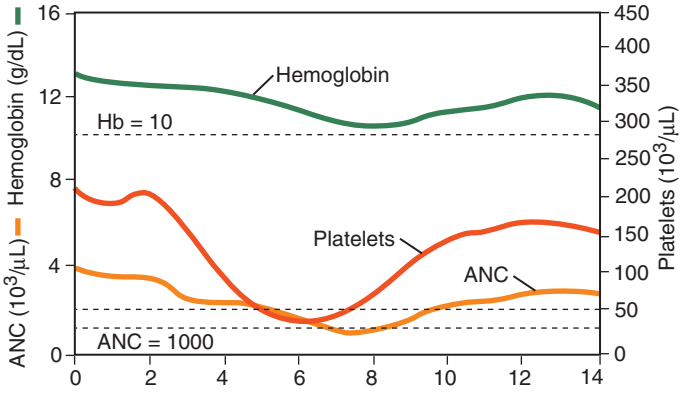

Figure 82–2. Median blood counts in 349 patients treated with ibritumomab tiuxetan (Zevalin) radioimmunotherapy.[73] ANC, absolute neutrophil count; Hb, hemoglobin.

Thirty-four patients were included in the next phase I report.[23] All patients received at least one tracer dose, and 68% (23:34) had more than one tracer dose. It was concluded that indeed the cold predose did improve tumor/normal organ biodistribution. The trial treated patients with doses calculated to deliver 25 to 85 cGy to the whole body. Of the 34 patients entering the trial, 28 (82%) received a therapeutic dose; three patients developed a human antimouse antibody (HAMA), and three had rapid progression during the tracer studies that precluded treatment.

The dose-limiting toxicity (DLT) was myelosuppression and occurred at 85 cGy when two of the three patients treated at this dose experienced grade 3 and 4 absolute neutrophil count (ANC) and platelets. The maximum tolerated dose (MTD) was therefore determined to be 75 cGy. Three patients in the trial who had been previously treated with a stem cell transplant had more severe myelosuppression. The ORR in the 28 patients receiving a therapeutic dose was 79% (22:28) with 50% CR (14:28). Six patients who had achieved a partial remission (PR) or minor response were administered a second dose, and three had a further response, but none of the three patients converted to a complete remission (CR). The disease remission (DR) for CR patients was 16.5 or more months; the DR was not reported for PR patients nor was the TTP. When patients relapsed it was in areas not previously involved by NHL in 75% (6:8) patients. Four patients were retreated at relapse, and all responded again (2 CR; 2 PR).[23]

The next report on this phase I/II trial concluded that a predose of 475 mg of cold tositumomab produced optimal tumor/normal organ biodistribution, and indeed that was the dose used in all the other trials discussed below (see Phase II Trials of Bexxar and Pivotal Trial of Bexxar).[67] The ORR was 71% (42:59) with 34% (20:59) CR. The patients with low-grade or transformed NHL had an ORR of 83% compared to 41% in those with intermediate-grade NHL. The median DR for all responders was 8.9 months (18.3 months for CR patients). Additional long-term followup of these 59 patients was described in 2000.[40]

Phase II Trials of Bexxar

Several dedicated phase II trials were conducted to validate the high ORR to Bexxar determined in the phase I/II trials.[22,23,67] Vose and colleagues[37] treated 47 patients with relapsed low-grade or transformed NHL with either 75 cGy or 65 cGy depending on baseline platelets. The calculated dose to the normal organs for patients receiving the 75 cGy total body dose was as follows: 499 cGy to the kidneys, 383 spleen, 225 liver, 214 bladder, and 183 to the lungs. The tumors were calculated to receive a mean dose of 795 cGy. The ORR was 57% (27:45) and 32% (15:45) had a CR. The median DR was 9.9 months for all responders and 19.9 months for responders that were CR. The median TTP for all patients was 5.3 months and 11.6 months for responders. There was no mention of any patient developing myelodysplastic syndrome or acute leukemia. One patient (2%) developed a HAMA.

A more recent phase II trial of single-agent Bexxar restricted the patient population to only one or two prior therapies.[68] The ORR was 76% (31:41) with 49% CR and unconfirmed/uncertain complete remission (CRu); the median DR for all responders was 1.3 years. The median DR in the CR patients has not yet been reached, but will be longer than 2.5 years. Seven of the patients had transformed histology, and the ORR was 71% (5:7) with 29% (2:7) CR/CRu. Patients with bulky disease (mass >5 cm) had a lower chance of ORR but a similar DR.

Pivotal Trial of Bexxar

The pivotal Bexxar trial enrolled 60 patients with relapsed low-grade (n = 36), transformed (n = 23), or mantle-cell (n = 1) NHL, and compared the ORR and DR to Bexxar with that achieved by the patient's last qualifying chemotherapy. The patients had received a median of four prior chemotherapies (range, 2–13 chemotherapies) and were required to have failed to respond or progressed within 6 months of the last chemotherapy regimen. The patients were a median of 54 months from initial diagnosis, 44% had an elevated

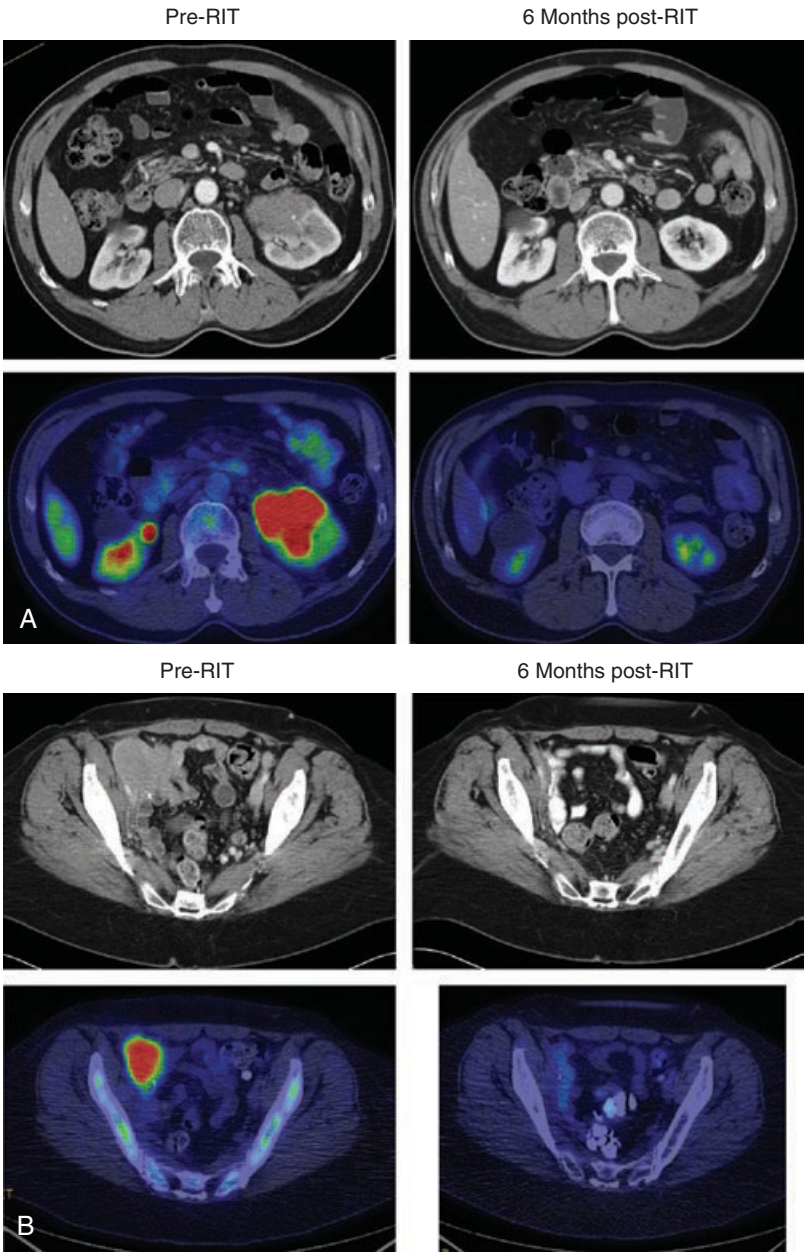

Figure 82–3. Computed tomography (CT) and positron emission tomography (PET) scans before and after ibritumomab tiuxetan (Zevalin) radioimmunotherapy in two patients with relapsed follicular lymphoma. (**A**) Extranodal disease—left renal mass that is PET-avid pretreatment is effectively treated with radioimmunotherapy. This is a good example of the clinical usefulness of RIT to treat extranodal disease with radiation with excellent preservation of underlying organ function. (**B**) Nodal disease-complete response in a bulky nodal mass in the pelvis.

lactate dehydrogenase (LDH), and 55% had bulky disease (mass = 5 cm). The primary end point was DR. Nineteen patients in the trial had responses equivalent to that of their last qualifying chemotherapy. Of the 41 cases where DR was not equivalent, 32 (78%) patients experienced a longer DR with Bexxar compared to nine (22%) patients who experienced a longer DR with chemotherapy ($P < 0.001$). The median DR from Bexxar was 6.5 months compared to 3.4 months with chemotherapy. The ORR was a secondary end point in the trial; it was 65% (39:60) with Bexxar compared to 28% (17:60) with chemotherapy ($P < 0.001$). Seventeen percent (10:60) had a CR with Bexxar compared to 3% (2:60) with chemotherapy ($P = 0.01$).[32]

After the initial trials of Bexxar demonstrated a high ORR with acceptable toxicity an expanded access study treated patients with relapsed low-grade or transformed NHL with standard doses of Bexxar (total body dose of 75 cGy for patients with platelets >150,000 cells/mm^3 and 65 cGy for platelets 100,000–150,000 cells/mm^3).[69,70] Ninety-eight percent (359:368) received Bexxar, and 273 are currently evaluable for efficacy. The ORR was 58% and 27% had a CR. The ORR in rituximab failures was 47% (55:118) with 19% CR (23:118). In patients with bulky tumors (mass >5 cm) the ORR was 47% (57:121) with 17% (20:121) CR. The TTP for all patients was 7.1 months; the median TTP and DR in responders have not yet been reached.

SAFETY OF BEXXAR RADIOIMMUNOTHERAPY

The potential adverse events with the Bexxar treatment program include a transient flu-like syndrome and bone marrow suppression. There is typically minimal infusion-related toxicity with cold tositumomab infusion, and only 7% and 2% of patients experienced an adverse event that required an adjustment to the rate of infusion during the dosimetric and therapeutic doses, respectively. The marrow toxicity has been summarized for 215 patients who received a 75 cGy total body dose.[71] The median neutrophil nadir was 1060 cells/mm^3 occurring at day 46 and recovering by day 66. Sixteen percent of patients developed grade 4 neutropenia with a median duration of 11 days. The median time to platelet nadir was 32 days, the platelet nadir was 70,000 cells/mm^3, and only 2% of patients developed grade

4 thrombocytopenia. The duration of grade 4 thrombocytopenia was 14 days, and the platelets recovered in a median time of 50 days from the day of treatment. The median hemoglobin nadir was 11.1 g/dL on day 46. Only 1% of patients developed grade 4 anemia, and the hemoglobin recovered a median of 61 days following the therapeutic dose. Seventeen percent of patients required hematologic supportive care with 8% receiving a platelet transfusion, 9% red blood cell (RBC) transfusion, and 12% growth factors (granulocyte colony-stimulating factor [GCSF], granulocyte-macrophage colony-stimulating factor [GM-CSF], or erythropoietin).

The hematologic nadirs varied by patient characteristics. For example, patients with a negative bone marrow pre-Bexxar had a 12% incidence of grade 4 neutropenia compared to 21% if the marrow was positive for NHL. Patients with no prior chemotherapy had a 5% incidence of grade 4 neutropenia compared to 21% if they had one to three prior regimens and 23% if they had four prior regimens. The need for hematologic supportive care ranged from 0% in previously untreated patients to 32% in patients with three prior therapies. There was no difference in incidence of grade 4 toxicity by age. The toxicity of Bexxar in the expanded access study showed similar results.[70] The HAMA rate was 8%. HAMA has not been reported to influence overall survival (OS) in the trials of Bexxar and Zevalin; however, in the trials of the Lym-1 RIC patients who developed HAMA actually had a superior OS.[72]

RESULTS OF CLINICAL TRIALS OF ZEVALIN

Five separate clinical trials of ^{90}Y-Zevalin have been conducted over the last 10 years (see Table 82–2). The results of these trials are briefly reviewed.

Phase I Trials of ^{90}Y-Zevalin

There were two phase I trials of Zevalin. The first study enrolled 14 patients with relapsed low or intermediate CD20$^+$ B-cell NHL.[25] The patients were imaged twice with ^{111}In-Zevalin—the first imaging was performed without unlabeled ibritumomab; the second was performed following unlabeled ibritumomab. A comparison of the two sets of ^{111}In-Zevalin images demonstrated that pre-dosing with cold ibritumomab improved biodistribution of the Zevalin. Patients were then treated with ^{90}Y-Zevalin with doses ranging from 13.5 to 50 mCi. All patients had stem cells harvested from peripheral blood or marrow prior to treatment with ^{90}Y-Zevalin; however, only two patients (both had received 50 mCi of ^{90}Y-Zevalin) required reinfusion of stem cells. The ORR was 79% (11:14) with 36% CR, and 43% PR.

A second phase I study of Zevalin was conducted to test the use of rituximab rather than cold ibritumomab before Zevalin. It was felt that rituximab was less likely to cause a HAMA or human antichimeric antibodies (HACA) than murine ibritumomab. An additional goal of the second phase I trial was to determine the maximum tolerated dose of ^{90}Y-Zevalin that could be given to patients without the use of stem cells or prophylactic growth factors. Fifty-one patients were enrolled, and the study demonstrated that 250 mg/m^2 was the optimal dose of rituximab to be used before ^{111}In-Zevalin imaging and ^{90}Y-Zevalin therapy.[28] Dosimetry predicted that all patients were eligible for ^{90}Y-Zevalin; that is, all normal non-tumor bearing organs were predicted to receive less than 2000 cGy and the bone marrow, less than 300 cGy.[58] The median age was 60 years, and 24% of patients were older than 70 years of age. In the low-grade group, 6% of patients had diffuse small lymphocytic, 27% follicular small cleaved, and 33% had follicular mixed lymphoma. All patients had received prior chemotherapy (median of two regimens), and 92% had received an anthracycline. Thirty-seven percent of patients had received prior external beam radiotherapy; 27% had two extranodal sites of disease; 59% had bulky disease (mass = 5 cm), and 43% had a bone marrow positive for NHL. The doses of ^{90}Y-Zevalin used in the phase I/II trial were 0.2 mCi to 0.4 mCi/kg; 5 patients received 0.2 mCi/kg, 15 received 0.3, and 30 patients received 0.4. All patients who received 0.4 mCi/kg were able to recover bone marrow function without prophylactic growth factors or stem cells. The dose was not increased to greater than 0.4 mCi/kg because substantial myelosuppression was already being obtained with 0.4 mCi/kg, and stem cells had not been collected pre-Zevalin. The efficacy portion of the phase I/II trial demonstrated a 67% ORR in all patients with 26% CR. In patients with low-grade NHL the ORR was even higher at 82% with 26% CR.[28] The median time-to-progression for responders was 15.4 months; the DR was 11.7 or more months.

Use of Zevalin in Patients with Mild Thrombocytopenia

Both of the phase I trials indicated that the DLT was reversible myelosuppression. Because of previous treatment some patients have mild thrombocytopenia and are therefore at increased risk of myelosuppression from RIT. To study this group of patients further a separate phase II trial using a reduced-dose ^{90}Y-Zevalin (0.3 mCi/kg) for patients with platelet counts between 100,000 to 149,000 $\times$ 10^6/L was designed. Thirty patients were treated in this study, and the ORR was 83% with 43% CR/CRu. The TTP was 9.4 months in all patients and 12.6 months in responders.[35] The median DR was 11.7 months (3.6–23.4 months). Hematologic toxicity was the primary toxicity with a median nadir absolute neutrophil count of 600 $\times$ 10^6/L (grade 4 in 33% of patients). The median nadir platelet count was 26,500 $\times$ 10^6/L (grade 4 in 13% of patients).

Safety of Zevalin Radioimmunotherapy

The safety of Zevalin RIT in 349 patients treated on all reported studies to date has been summarized.[73] Infusion-related toxicities were typically grade 1 or 2 and were associated with the rituximab infusion; there were no further infusion-related reactions when Zevalin was administered at the conclusion of the rituximab. No significant normal organ toxicity was noted. The main toxicity noted was myelosuppression (see Table 82–5) with the nadir hemoglobin, white blood cell (WBC), and platelet counts typically occurring at 7 to 9 weeks and lasting approximately 1 to 4 weeks depending on the method of calculation (see Fig. 82–2). Following the 0.4 mCi/kg dose, grade 4 neutropenia, thrombocytopenia, and anemia occurred in 30%, 10%, and 3% of patients, respectively, and following the 0.3 mCi/kg dose in 35%, 14%, and 8%. Bone marrow involvement with NHL at study entry was present in 146 patients (42%). Patients with any degree of bone marrow involvement had a significantly greater incidence of grade 4 neutropenia ($P = 0.001$), thrombocytopenia ($P = 0.013$), and anemia ($P = 0.040$) than patients with no bone marrow involvement. The incidence of grade 4 hematologic toxicity increased with increasing levels of bone marrow involvement at baseline.

Because in all of these trials prophylactic growth factors were not prescribed, it is not yet known whether grade 3 or 4 myelosuppression can be prevented if growth factors were integrated into the Zevalin program. Despite the substantial myelosuppression observed with RIT, only 7% of patients were hospitalized with infection (3% with neutropenia), and only 2% had grade 3 or 4 bleeding events. A recent case report documented skin necrosis after extravasation of Zevalin;[74] therefore, RIC should be considered vesicants.

RADIOLABELED RITUXIMAB

Another approach to anti-CD20 RIT is to radiolabel rituximab with ^{131}I. Leahy and colleagues[41] conducted a trial that enrolled 91 patients with relapsed CD20$^+$ B-cell NHL. The entry criteria were similar as the Bexxar and Zevalin trials except there were no restrictions on the level of marrow involvement. The ORR was 76% with 53% CR/

CRu. The median DR was 10 months (20 months for CR patients). Nine patients were enrolled with greater than 25% marrow involvement with NHL. These patients had a lower platelet nadir, but the incidence of grade 4 myelosuppression was not different than those patients with less than 25% marrow involvement.

RADIOIMMUNOTHERAPY VERSUS IMMUNOTHERAPY

At the conclusion of the initial phase I and II trials of RIT for NHL, it appeared that the ORR was higher with RIT than with the same corresponding cold monoclonal antibody. Two key trials were designed to further address the question as to whether RIT was superior to immunotherapy with the a similarly targeted antibody. The first trial, IDEC 106-04 (IDEC Pharmaceuticals, San Diego, CA), was a prospective, randomized trial of RIT verses rituximab in patients with relapsed CD20+ NHL that had never received rituximab. Patients were randomized to receive either 0.4 mCi/kg (maximum of 32 mCi) ^{90}Y-Zevalin or rituximab 375 mg/kg weekly in four doses.[34] One hundred forty-three patients were randomized in this trial—73 received Zevalin and 70 rituximab. The analysis of all 143 patients found an ORR (International Workshop NHL criteria [75]) of 80% with ^{90}Y-Zevalin compared to 56% for rituximab ($P = 0.002$). The CR rate of 30% in the ^{90}Y-Zevalin arm was also higher than the 16% found with rituximab ($P = 0.04$). The median DR was 14.2 months (0.9–28.9 months). The trial was not statistically powered to detect a difference in TTP. The Kaplan-Meier estimated median TTP was 11.2 or more months (range, 0.8–31.5 or more months) for the ^{90}Y-Zevalin group compared with 10.1 or more months (range, 0.7–26.1 months) for the rituximab group ($P = 0.173$). However, the estimated time to next therapy (TTNT) for patients with nontransformed histology indicates a significantly longer TTNT for Zevalin patients (17.8+ months; range, 2.1–21.7+ months) than for rituximab patients (11.2 months; range, 1.3–19.0+ months) ($P = 0.040$).

The second key trial addressing this issue used Bexxar. Seventy-eight patients with relapsed low-grade or transformed NHL were randomized to receive Bexxar or two doses of cold tositumomab.[75] The ORR was 67% (28:42) for Bexxar compared to 28% (10:36) for those who received cold tositumomab ($P < 0.001$). The CR rate was 33% (14:42) versus 8% (3:36) ($P = 0.01$) in the Bexxar and tositumomab arms, respectively. The DR was 18 months for tositumomab and has not been reached for Bexxar. The hematologic toxicity was higher in the RIT arm—17% (7:42) had grade 4 ANC and 5% (2:42) grade 4 thrombocytopenia. The HAMA rate was 17% (7:41) in the patients treated with Bexxar and 25% (9:36) in the cold tositumomab group.

RADIOIMMUNOTHERAPY IN RITUXIMAB-REFRACTORY PATIENTS

The current treatment of new and relapsed NHL includes rituximab; therefore, the more relevant clinical question today is—will patients who are refractory to rituximab respond to an anti-CD20 RIC? Several studies have addressed this, and the answer is—yes, they respond, but the TTP is shorter than if the patient was not rituximab refractory. Rituximab-refractory is currently defined as either no response to a standard course of rituximab or a response that lasts less than 6 months. The trial of Zevalin in this patient population included 54 patients meeting this definition.[76] All were treated with a single dose of 0.4 mCi/kg of ^{90}Y-Zevalin and were followed without further therapy. The median age was 54 years (range, 34–73 years), 95% of patients had follicular NHL, 32% had bone marrow involvement, and 74% had bulky disease (mass = 5 cm). The ORR using International Workshop criteria[77] was 74% with 15% CR. The median TTP estimated by the Kaplan-Meier method is 6.8 months (range, 1.1–25.9+ months) with 30% of data censored. Median TTP in the 40 responders is 8.7 months (range, 1.7–25.9+ months), with 28% of data censored. The median DR estimated by Kaplan-Meier is 6.4 months (range, 0.5–24.9+ months).

The study by Horning and coworkers[78] administered a standard dose of Bexxar to 38 patients who had relapsed after rituximab. This trial was slightly different than the Zevalin trial discussed above (see Phase I Trials of ^{90}Y-Zevalin) in that although all patients previously had rituximab, only 24 were rituximab refractory. Thirty-eight patients were treated, and 33 were evaluable for response. Fifty-eight percent of patients responded with 21% CR. In the 24 patients who were rituximab refractory (no prior response) the ORR was 57% (21 of the 24 evaluable), and 14% obtained a CR. Twelve patients had a rituximab response but it lasted less than 6 months. In the 11 patients evaluable the ORR was 55% with 27% CR. Two patients had experienced a response to rituximab that lasted longer than 6 months and the only patient evaluable obtained a CR. The median DR was 478 days (17 months); median TTP was 182 days for the entire group and 566 days for responders. No patient developed a HAMA.

It is apparent from these two important studies that the radiation portion of the RIT is important to the efficacy of RIT. RIT can overcome resistance of rituximab-refractory tumors; however, the responses are not as durable in this more heavily treated population. It is worth noting that these studies for the most part enrolled patients who were rituximab-refractory. This patient group is not the same as patients today who are treated with rituximab-based chemotherapy upfront and then relapse several years later.

RADIOIMMUNOTHERAPY FOR PREVIOUSLY UNTREATED PATIENTS

The high ORR in relapsed patients led to the development of a phase II study of Bexxar in 76 previously untreated patients with advanced stage (stages III or IV) follicular (70% grade 1; 29% grade 2) NHL (one patient had mantle-cell NHL).[18] This is the only trial where a RIC has been used in previously untreated patients. Sixty-four percent of the patients had bone marrow involvement, 30% had an elevated LDH, and 43% had bulky disease (mass = 5 cm). The median age was 49 years (range, 23–69 years). The ORR was 95% (72:76) with 75% (57:75) CR. The 5-year progression-free survival (PFS) for all patients is 59% with a median PFS of 6.1 years. The 5-year PFS for CR patients was 77%, and 70% of the CR patients remained in CR for 4.3 to 7.7 years after treatment. Patients with only a PR had a median TTP of 7 months, and none became long-term responders. Patients with bulky disease (mass >5 cm) and marrow involvement with NHL had a lower chance of obtaining a CR. To date, no patients in this previously untreated group have developed a myelodysplastic syndrome; however, 63% developed a HAMA. Whether the HAMA will wane with time and what impact this will have on the future ability to re-treat patients is unknown. In the studies of Bexxar on previously treated patients the HAMA rate has been approximately 10%. This is likely because of the fact that when patients are previously treated with chemotherapy they are more immunosuppressed and less likely to develop a HAMA. The HAMA rate in the studies with Zevalin has been less than 1%.[73]

RADIOIMMUNOTHERAPY FOR RELAPSED LARGE-CELL LYMPHOMA

Patients with diffuse large-cell NHL that relapse after rituximab, cyclophosphamide, hydroxydaunorubicin, vincristine (Oncovin), and prednisone (RCHOP) and respond to salvage chemotherapy are typically treated with high-dose chemotherapy with stem cell support.

Therefore, the available experience of RIT in aggressive NHL is limited to relapsed refractory disease in patients relapsed after, or not eligible for stem cell transplantation. In the initial phase I/II of Zevalin the ORR was 43% for the 14 patients with intermediate-grade histology.[28] A recent update on the long-term course of patients in that study demonstrated a 58% (7:12) ORR for the patients with diffuse large-cell NHL with a median DR of 49.8 months (1.3–67.6+ months).[79]

A more recent study with shorter followup evaluated Zevalin in the treatment of 104 elderly patients with relapsed and primary refractory diffuse large B-cell lymphoma that were not candidates for stem cell transplantation. The ORR in the entire group was 44%.[80] Patients not treated with rituximab-based chemotherapy had a 52% ORR compared with a 19% ORR in the group that had previously been treated with rituximab. The latter group appears to have been particularly high-risk as 37% were reported to be refractory to RCHOP. Although the treatment was generally well tolerated, four patients died because of adverse events. Three of these were cerebral hemorrhages associated with grade 4 thrombocytopenia; the other case was a late hemorrhage not attributed to RIT.

RADIOIMMUNOTHERAPY FOR TRANSFORMED LYMPHOMA

Patients who transform from low-grade to large-cell NHL are a difficult group to treat. Eligible patients are typically recommended for high-dose therapy with stem cell support. However, these patients may be elderly, lack stem cell reserve, or have other comorbidities that make transplant impossible. The largest clinical experience of treating transformed NHL with RIT has been with Bexxar.[81] There were 71 patients with transformed lymphoma who had been enrolled in the five studies since 1990. In addition to the transformed histology, 28% of patients had bone marrow involvement, 70% had bulky disease (mass >5 cm), 57% had elevated LDH, and 52% had an International Prognostic Index (IPI) score of three or more. The ORR was 39% with 25% CR. The median DR was 20 months (range, 10.8 months—not reached) for all responders and was 36.5 months (range, 14.7 months—not reached) for CR patients. The median TTP for all patients was 4.3 months (3.2–10.2 months), but for those who responded to treatment the median TTP was 20.2 months (12.4 months—not reached). Five patients remain in remission beyond 40 months.

THERAPY OF CENTRAL NERVOUS SYSTEM LYMPHOMA WITH RADIOIMMUNOTHERAPY

Primary central nervous system lymphomas (PCNSLs) are difficult to treat if the patient relapses after initial therapy. Whole-brain radiation therapy is useful but can produce long-term side effects. There has been minimal use of RIT for PCNSL, but several case reports show promise. Shah and coworkers[82] reported the first successful case of PCNSL treated with single-agent Zevalin. More recently, Pitini and colleagues[83] treated two patients with relapsed PCNSL with standard Zevalin and both entered CR. After recovery from myelosuppression the patients were treated with maintenance temozolomide and remain in CR. This is clearly an area that requires further investigation.

LONG-TERM RESULTS OF RADIOIMMUNOTHERAPY

Prolonged followup of the initial studies provides useful data on the long-term prognosis of patients with relapsed indolent NHL treated with RIT.[79,84–86] Long-term responses (LTRs) have been defined as CR or PR for at least 12 months. Fisher and coworkers[84] reported results on 250 patients with relapsed or refractory low-grade or transformed NHL who had been treated with Bexxar. LTRs were achieved in 81 (32%) of 250 patients; 23% had a PFS longer than 18 months, and 21% had a PFS longer than 2 years (Fig. 82–4A and B). Patients who became long-term responders were more likely to have had a CR (77% vs. 8%, respectively) and low-bulk disease (51% vs. 31%, respectively) than those without a LTR. Other characteristics that were predictive of a LTR with Bexxar treatment were sensitivity to the last therapy, history of fewer than three previous therapies, follicular histology, normal LDH level, and modified IPI score of 2. The LTR patient population had a median DR of 45.8 months with a median followup of 61 months. Those patients who attained a CR have done especially well; the median DR has not been reached, and 47% remain in CR ranging from longer than 2.7 years to longer than 10.2 years. In the previously untreated study the only patients with extended remissions were those who had a CR.[18] A smaller series of 18 patients treated with Bexxar also demonstrated that six of the eight patients with CR/CRu remained in unmaintained remission at 46 to 70 months.[86]

Long-term responses were seen in 37% (78:211) of patients treated on Zevalin trials for relapsed NHL.[85] Patients with bulky disease (masses >5 cm) were less likely to become long-term responders; however, if they did respond, the DR was similar to those with low-bulk disease. The achievement of a CR/CRu was a strong positive predictor of an LTR, with an odds ratio of 7.0 (95% confidence interval, 3.4–14.5). At a median followup of 53.5 months (range, 12.7–88.9 months) the median duration of response was 28.1 months, and the median time to progression was 29.3 months. The findings in patients with follicular lymphoma ($n = 59$) were similar to those in the overall population of long-term responders. The estimated overall survival at 5 years was 53% for all patients treated with Zevalin and 81% for long-term responders (see Fig. 84–4C and D). It is now apparent that even in the relapsed indolent patient population that LTR can be observed with single doses of RIT. Patients who are treated early in the relapse phase of disease have a higher rate of CR and a longer TTP than those who are treated after multiple relapses.[87]

RISK OF MYELODYSPLASIA WITH RADIOIMMUNOTHERAPY

Once it was determined that myelosuppression was the primary toxicity of RIT, there has been concern that these agents might increase the risk of myelodysplastic syndrome (MDS)/acute leukemia (AL). This issue has been followed closely in all the trials of RIC. In the Bexxar database of 995 patients who received a single dose of Bexxar for relapsed NHL, MDS or AL has been documented in 35 patients (3.5%). All 35 patients had also received chemotherapy for their NHL. The annualized rate of MDS/AL was 1.6%, a rate similar to that observed in chemotherapy-alone treated patients.[88] Although followup is short, to date there have been no patients with MDS in the previously untreated group of patients treated with Bexxar.[18,88]

A recent analysis of 746 patients treated with Zevalin between 1996 to 2002 included patients in the trials discussed earlier as well as the compassionate-use trials. A total of 17 cases of MDS/AL have now been identified for an incidence of 2.3% (17:746). The MDS/AL occurred at a median of 5.6 years (range, 1.2–13.9 years) after the diagnosis of NHL and 1.5 years (range, 0.1–5.8 years) after RIT. The annualized rates were 0.3% (95% confidence interval [CI], 0.2%–0.4%) a year after the diagnosis of NHL and 0.7% (95% CI, 0.4%–1.0%) a year after RIT.[89]

At this juncture, now more than 10 years after the initiation of the RIT trials, there is no evidence yet that RIT increases the risk of MDS/AL over that of chemotherapy alone and no cases of MDS/AL in patients treated only with RIT. This issue will need ongoing investigation. Actually, the issue of bone marrow damage may become more relevant as RIT is used earlier in the disease course because patients will have longer OS post-RIT with more time for MDS/AL to become apparent.

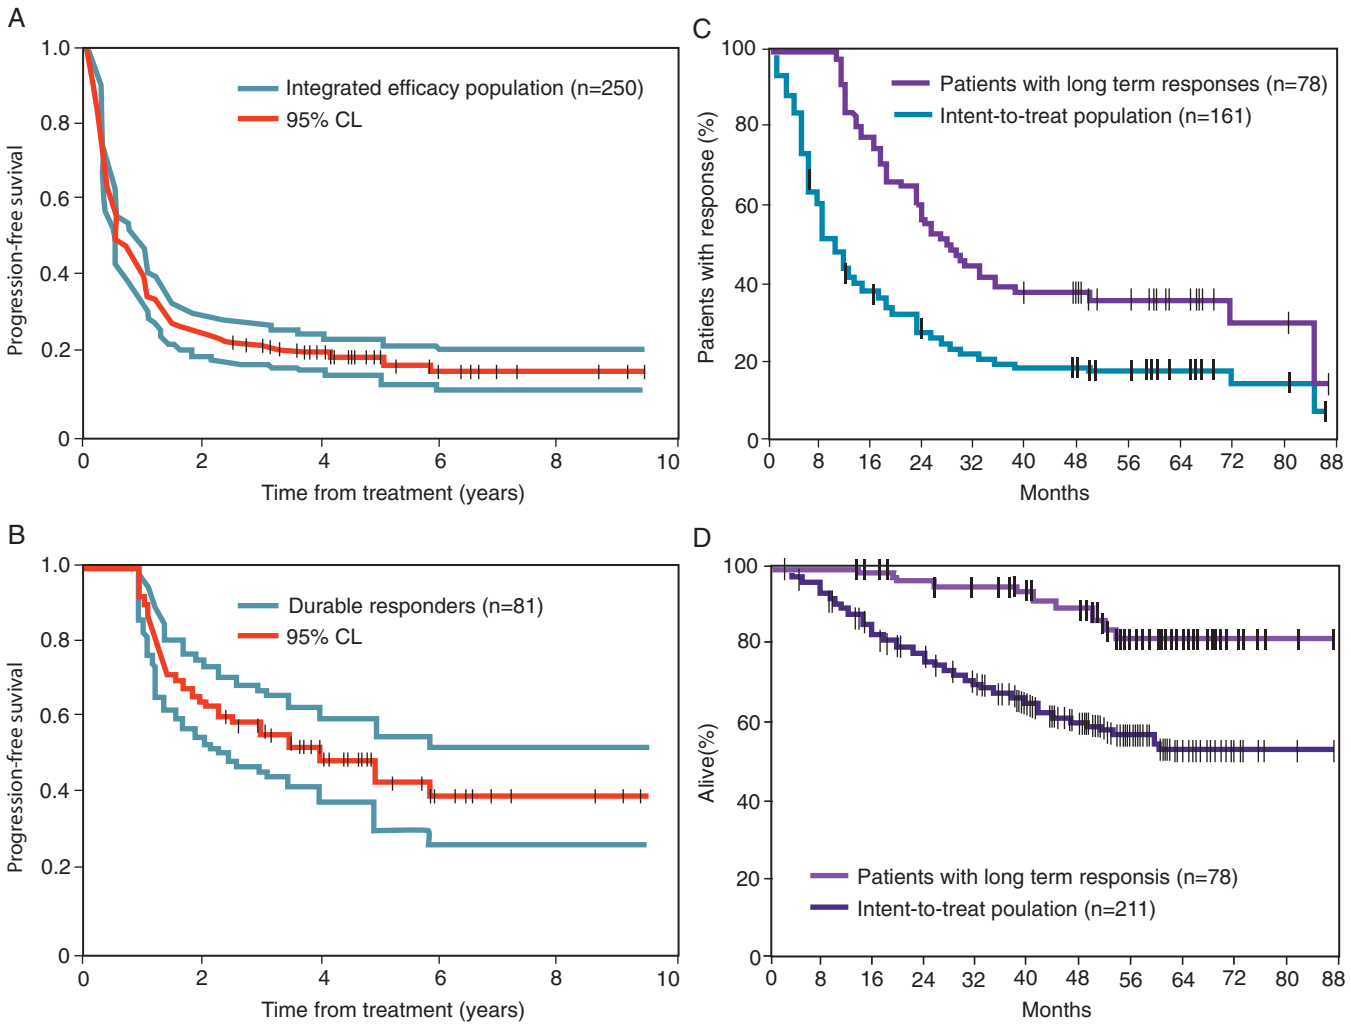

Figure 82–4. Survival results of patients with relapsed non-Hodgkin lymphoma treated with single-agent tositumomab (Bexxar) or ibritumomab tiuxetan (Zevalin) and no maintenance therapy. A long-term or durable response was defined as a response (complete or partial) that lasted longer than 1 year. (**A**) Progression-free survival of 250 patients treated on Bexxar clinical trials.[84] (**B**) Progression-free survival of the 81 patients who had a long-term response.[84] (**C**) Duration of response of all 161 responders compared to the 71 patients who achieved a long-term response after treatment on a Zevalin clinical trial. (**D**) Overall survival of the long-term response population ($n = 71$) compared to all 211 patients treated on Zevalin clinical trials. CL, confidence limits.

FEASIBILITY OF TREATMENT AFTER RADIOIMMUNOTHERAPY FAILURE

Because the CR rate with RIT when used for relapsed NHL is approximately 30%, most patients will at some point relapse and require additional therapy. The myelosuppression universally observed after RIT has raised the question of the feasibility of chemotherapy following RIT. Ansell and colleagues[90,91] examined the subsequent therapy administered to 58 patients who had relapsed after receiving 0.4 mCi/kg of ^{90}Y-Zevalin. The median number of therapies the patients had received before Zevalin was two (range, 1–7 therapies). Twenty-eight (48%) of the patients had transformed NHL—14 had the transformation before Zevalin and in 14 the transformation developed after Zevalin (8 at first relapse after Zevalin; 6 during the chemotherapy that followed Zevalin). The median WBC count at the time of the next therapy after Zevalin was 4.2×10^9/L (range, 0.9–8.7 cells), the median hemoglobin was 11.6 g/dL (range, 7.2–14.7 cells), and the median platelet count was 163,000 cells/mm^3 (range, 14,000–292,000 cells). The median number of subsequent treatments received was two (range, 1–7 treatments). Subsequent chemotherapy was feasible and tolerable. Peripheral blood stem cell collection was also feasible, with one of eight patients requiring marrow harvest after failing peripheral blood stem cell collection. All eight patients engrafted. An additional patient received an allogeneic transplant with adequate engraftment.

The issue of treatment after RIT has also recently been addressed using the Bexxar patient database. Sixty-eight patients who relapsed a median of 168 days after RIT were reviewed.[92] At the time of relapse, the median WBC was 4900 cells/mm^3 (range, 1100–24,100 cells) and the median platelet count was 130,000 cells/mm^3 (range, 9,000–440,000 cells); only the platelet count was significantly lower than the pre-RIT value. The 65% (44:68) of patients who received further chemotherapy were able to receive a median of two (range, 1–4 treatments) additional regimens using typical myelosuppressive agents. Thirteen patients went on to stem cell transplantation—3 had stem cells harvested prior to RIT; 10 after RIT.

Although these data are encouraging, it should not be interpreted that collection of stem cells will be feasible in all patients after RIT. It can be difficult to collect stem cells from patients that have received extensive chemotherapy or external beam radiation therapy even in the absence of RIT.[93] If the patient is considered to be a strong candidate for autologous transplant, stem cells should be collected before RIT.

COMBINATIONS OF RADIOIMMUNOTHERAPY AND CHEMOTHERAPY

The effectiveness of RIT in relapsed NHL has led to studies testing RIT as adjuvant therapy after induction chemotherapy. Leonard and collleagues[16] treated 35 patients with untreated follicular NHL using three cycles of fludarabine (25 mg/m^2/days × 5 days for 5 weeks × three cycles) followed by a single dose of Bexxar. The ORR to fludarabine was 89% (31:35) with a CR of 9% (3:35). After Bexxar the ORR was 100% with 86% CR (30:35). Five of six patients who had greater than 25% marrow NHL prior to fludarabine therapy were effectively cytoreduced to less than 25% following fludarabine and were thus eligible for RIT. Two patients developed a HAMA. At a median followup of nearly 5 years the median PFS had not been reached and will be longer than 48 months.

Press and coworkers[17] have recently reported long-term results of a phase II trial of cyclophosphamide, hydroxydaunorubicin, vincristine (Oncovin), and prednisone (CHOP) chemotherapy for six cycles followed by a single dose of adjuvant Bexxar. Ninety patients were treated, and 91% responded with 69% CR. After approximately 5 years of followup, the estimated 5-year PFS rate was 67%, and the OS rate was 87%. This approach is now being tested in a randomized trial where patients with new, untreated follicular NHL receive either CHOP/Bexxar or RCHOP. A similar approach using rituximab-based chemoimmunotherapy followed by adjuvant RIT with Zevalin has been reported.[94]

HIGH-DOSE RADIOIMMUNOTHERAPY WITH STEM CELL SUPPORT

The primary dose-limiting toxicity of RIT for NHL is myelosuppression. Some groups have overcome this limitation by collecting stem cells prior to RIT. This permits a higher dose of RIT that is now limited by other organ toxicity. The use of high-dose RIT and stem cell transplant (SCT) has been extensively studied but remains investigational.[95–97] In a phase I study, Press and colleagues[98] entered 43 patients, and 19 were able to receive therapeutic infusions of Bexxar. The ORR was 95% (18:19) and 84% (16:19) had a CR. An additional 25 patients were enrolled into the phase II trial,[26] and 84% (21:25) were treated. Tumor response was observed in 86% (18:21) with 76% CR. The stem cells were infused 12 to 18 days after Bexxar; the source of stem cells was bone marrow in 19 and blood stem cells in the other 2. Neutrophil recovery to greater than 500 and platelet count recovery to greater than 20,000 occurred a median of 23 days and 22 days, respectively, after stem cell infusion. HAMA was documented in 16%. Long-term followup (median 42 months) on these patients and those from the phase 1 trial demonstrated that the projected OS and PFS was 68% and 42%, respectively.[21]

These studies have been expanded to combine Bexxar with cyclophosphamide and etoposide with autologous stem cell support.[31] Fifty-two of the 55 enrolled received treatment. All patients were required to have a bone marrow that had less than 25% involvement with NHL. The study determined that a dose of Bexxar that delivered 25 Gy to critical normal organs could be safely combined with chemotherapy and stem cells. The estimated OS and PFS at 2 years was 83% and 68%, respectively. Gopal and coworkers[99] recently compared the long-term results of patients with relapsed follicular NHL treated with SCT. The 27 patients conditioned with high-dose Bexxar RIT had a superior OS and PFS compared to 98 patients treated with chemotherapy and total body irradiation or chemotherapy-alone. The estimated five-year OS and PFS were 67% and 48%, respectively, for high-dose Bexxar conditioning, and 53% and 29%, respectively, for chemotherapy alone or chemotherapy/TBI. Performing SCT with RIT-alone conditioning is well tolerated even in older adults.[100] Sixteen patients with mantle cell NHL have been treated with a similar protocol,[101] and all patients had a tumor response with 91% CR. The OS and PFS at 3 years were 93% and 61%, respectively.

WHEN TO USE RADIOIMMUNOTHERAPY?

The current dilemma with radioimmunotherapy is "when should it be used in the sequence of treatment for indolent B-cell lymphoma"? There is no doubt that RIT has the highest single-agent antitumor activity of any drug or treatment for this disease. However, when used as a single-agent for relapsed NHL the time to progression for most patients is 1 to 2 years. Current research is moving RIT to initial treatment by itself or as adjuvant therapy after debulking chemotherapy. If the current randomized trials demonstrate a survival advantage of adjuvant RIT in the initial treatment of follicular NHL, then RIT will be added to rituximab-chemotherapy for all patients. Fortunately, the current evidence supports the concept that RIT can be repeated. Initial treatment with RIT will not prevent the use of RIT at the time of relapse. Researchers are also searching for agents that can be used with RIT for relapsed disease and combining RIT with high-dose therapy with stem cell support. Until these trials are complete, the standard use of RIT is in the patient with relapsed NHL. Radioimmunotherapy should be considered as one of the first treatments given for relapse. In this way the patient receives early treatment with the most active agent, and one that has few side effects.

Nademanee and colleagues[102] have published the first phase I/II trial of high-dose ^{90}Y-Zevalin combined with chemotherapy and autologous stem cell support for patients with relapsed NHL. The patients received a dose of ^{90}Y-Zevalin calculated to deliver 1000 cGy to the highest normal organ followed by etoposide 40 to 60 mg/kg on day 4 and cyclophosphamide 100 mg/kg on day 2. Thirty-one patients were treated. Histology included follicular lymphoma (n = 12), diffuse large B-cell (n = 14), and mantle cell (n = 5). The median dose of ^{90}Y-Zevalin calculated to deliver 1000 cGy to the highest normal organ was 71.6 mCi (2649.2 MBq; range, 36.6–105 mCi; range, 1354.2–3885 MBq). Engraftment was prompt with the median times to reach an ANC greater than 500 cells/mm^3 and platelet count more than 20,000 cells/mm^3 were 10 days and 12 days, respectively. During followup there have been two deaths, and five patients have relapsed. The 2-year estimated OS is 92%, and the PFS is 78%. It is to be noted that in this trial the dose of ^{90}Y-Zevalin was not dose escalated beyond a dose calculated to deliver 1000 cGy to the liver. There is another trial combining ^{90}Y-Zevalin with BEAM conditioning chemotherapy and stem cells that is dose escalating the ^{90}Y-Zevalin in a typical phase I protocol. That trial has been published in abstract form.[103]

RETREATMENT WITH RADIOIMMUNOTHERAPY

The high ORR observed with single-agent RIT in relapsed NHL and the excellent toxicity profile has led to increased interest in retreatment. In the original phase I/II trials of Bexxar, 16 patients that responded to Bexxar and later relapsed received a second dose. The ORR with the second dose was 56% with 31% CR.[40] These encouraging results led to a multicenter, phase II trial that treated 32 patients.[19] The ORR was again 56% (18:32) with 25% of patients attaining a CR. Interestingly, 10 of the 18 responders had a DR after the second course of Bexxar that was longer than the DR with the first dose of Bexxar.

There has been limited experience with treating patients with a second dose of Zevalin.[25] Wiseman and coworkers[104] reported preliminary results on a phase I trial where all patients are treated with two sequential doses of Zevalin. The first dose was 0.4 mCi/kg, and the phase I dose levels for the second dose delivered 3 to 6 months after the first dose was 0.2 to 0.4 mCi/kg. In the report of ^{131}I-rituximab six patients with response to the first dose were re-treated at the

time of relapse, and four responded with a median DR of 11 months.[41]

RADIATION THERAPY AFTER RADIOIMMUNOTHERAPY

A recent report has demonstrated that patients who relapse or progress with RIT can respond to external beam radiation. Justice and colleagues[105] reviewed 19 patients who received radiation therapy after Zevalin. They found a 90% (26:29 sites radiated) ORR with 12 (41%) CR, 7 (24%) CCR, 7 (24%) PR, and 3 (10%) stable disease. Toxicities were generally transient, reversible, and corresponded to the anatomic regions irradiated.

SUMMARY

The results of the phase I, phase II, and randomized trials demonstrate that single doses of RIT are safe and efficacious in patients with relapsed B-cell NHL. Currently, RIT is used worldwide primarily for patients with indolent NHL that has relapsed after conventional therapy.[106] RIT produces a response rate of approximately 80%, 30% of patients obtain a CR, and 20% have not yet relapsed after years of followup. The primary toxicity is myelosuppression, and this is dose-limiting if stem cell support is not used. Patient acceptance of these agents has been very high, and there is an excellent quality of life.

RIT produces a higher response rate than cold unlabeled rituximab in rituximab-naïve patients. There is also a very high (75%–80%) response rate in rituximab-refractory patients but a shorter TTP in this patient group. RIT produces a longer time to next chemotherapy than rituximab. The rate of HAMA is variable between the two agents (<2% with Zevalin and approximately 10% in Bexxar). Patients who have received RIT have developed MDS and AL following therapy. To date, all of these patients have been previously treated with chemotherapy that included alkylating agents and/or purine nucleoside analogs. Previously untreated patients who received RIT have not developed MDS/AL. At this time, calculations suggest that the rate of MDS is no different in patients who received RIT than those treated with previous chemotherapy, although the time of followup is still relatively short.

There is a lower (approximately 40%), but significance response rate in patients with relapsed large cell lymphomas. The response rate in bulky disease (mass >5 cm) is lower than those patients with nonbulky disease. Preliminary studies indicate that after patients relapse after RIT they can undergo stem cell harvest and receive additional chemotherapy once their counts have recovered from RIT. Stem cell harvest and transplants after radioimmunotherapy are feasible.

FUTURE DIRECTIONS

Current trials are focusing on moving RIT earlier in the disease course with the goal of increasing the rate of CR and prolonging OS. For example, randomized trials are testing RIT as adjuvant therapy after induction rituximab-based chemotherapy for indolent and aggressive NHL (Table 82–6). The safety and efficacy of RIT with stem cell support has led to a randomized phase III trial testing Bexxar-BEAM versus rituximab-BEAM with stem cell support. This large trial will determine if RIT adds to TTP and OS in this patient population. Trials combining agents simultaneously with RIT are somewhat more difficult because of the issue of myelosuppression. The choice of agents to combine must also be made carefully, and the results may not be predictable.[107] These combinations are now being tested in phase I trials to maximize patient safety.

Although there are many studies evaluating the role of rituximab maintenance after chemotherapy or after response to rituximab, to date, there have been no studies providing rituximab maintenance following RIT. Although this certainly is feasible, it is not known whether response can be prolonged. The results of these exciting studies will establish the role of RIT in the overall treatment plan of patients with B-cell NHL.

Table 82–6. Methods to Improve the Clinical Efficacy of Radioimmunotherapy for Non-Hodgkin Lymphoma

Initial therapy in patients with asymptomatic but advanced-stage disease
Adjuvant therapy after chemoimmunotherapy induction
Standard dose RIT with high-dose chemotherapy and stem cell transplant
High-dose RIT with high-dose chemotherapy and stem cell transplant
Addition of immunostimulatory agents to improve killing by antibodies

RIT, radioimmunotherapy.

CHAPTER 83

CHRONIC LYMPHOCYTIC LEUKEMIA

Thomas S. Lin, Farrukh T. Awan, and John C. Byrd

INCIDENCE AND EPIDEMIOLOGY OF CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is one of the most common types of leukemia in the Western Hemisphere. SEER estimates for 2008 indicated that approximately 15,110 patients (8,750 men and 6,360 women) would be diagnosed in the United States and that 4,390 patients will die from CLL in 2008.[1] The median age at diagnosis for CLL was 72 years during 2000–2005 according to the SEER database. The incidence of CLL increases proportionately by decade, as shown in Fig. 83–1.[1] This figure illustrates that CLL is a very uncommon diagnosis under the age of 45 and infrequent (30% of total patients diagnosed) in patients under the age of 65. The age-adjusted incidence rate was 4 per 100,000 men and women per year; 0.46% of men and women born in 2008 are expected to be diagnosed with CLL during their lifetime.[1] The extended time of survival following diagnosis is 75.9% at 5 years, which explains the estimated prevalence of 95,123 patients living with CLL in the United States currently.[1] Similar to other types of leukemia, the risk of dying from disease-specific causes increases proportionately with increasing age. Another analysis of the SEER database comparing outcome of elderly patients with CLL to age- and sex-matched healthy controls demonstrated that CLL has the greatest impact on survival in the most elderly group of patients.[2] However, even for patients diagnosed with CLL before the age of 50, Montserrat and colleagues demonstrated that the median expected life span is only 12.3 years, compared with 31.2 years in age-matched controls.[3] Thus, CLL is a significant health problem affecting all ages of patients with this disease.

CLL is more common in men than women. Women diagnosed with CLL have 5- and 10-year overall survival (OS) rates that exceed those of men. CLL is most common in Caucasians and decreases in frequency in a descending order among blacks, Hispanics, American Indians and Native Alaskans, and Asians and Pacific Islanders. The rarity of CLL among Asians and Pacific islanders persists even in immigrants from these areas who have migrated to the Western Hemisphere. This implicates a possible genetic predisposition to the development of CLL. The relationship of environmental factors such as exposure to benzene and other chemicals to the development of CLL is not clearly defined.[4–6] However, CLL is recognized as a service-connected illness among Vietnam War veterans who were exposed to Agent Orange.[7] Occupational or environmental exposure to radiation does not appear to predispose patients to a higher risk of developing CLL.[8–11] For example, although the frequency of acute myeloid leukemia, chronic myeloid leukemia, and acute lymphoblastic leukemia were increased among survivors of the atomic bomb at Hiroshima, no increase in CLL was appreciated.[12] Recent studies of leukemia rates in inhabitants around the Chernobyl nuclear reactor accident site have supported this notion, where essentially all other types of leukemia were increased with the exception of CLL.[13,14]

FAMILIAL CLL

Up to 10% of CLL patients have a first- or second-degree relative with CLL,[15] making CLL one of the most common types of malignancy with familial predisposition. Unlike other types of familial cancer, it is very uncommon for CLL patients to have large pedigrees with many affected distant relatives throughout an extensive family tree. Rather, the more common finding is for most patients to have one or two first- or second-degree relatives with this diagnosis.[16] Large case–control studies concluded that the risk ratio (RR) for first-degree relatives of CLL probands to also have CLL was higher than that for most other cancers.[17] Although the average RR for all cancers in a US study was approximately 2.1, CLL showed an RR of 5.0, the fourth highest of all cancers.[17,18] Other studies in Swedish[19] and Icelandic populations[20] have demonstrated a similarly high RR. Relatives of patients with CLL also appear to have a higher frequency of other lymphoproliferative disorders and autoimmune diseases.[21,22] Unlike a variety of other cancers that have known predisposing genes, identification of these in CLL have been generally elusive. To date, only a single germline mutation of death-associated protein kinase (DAPK) has been convincingly linked to familial predisposition in a single CLL family.[23] Two other studies[16,24] were limited by weak evidence for linkage, and the occurrence at many loci were different between the two studies. Two loci at chromosome bands 11p11 and 13q21 were backed by statistically significant evidence, but no genes at these sites have been implicated in familial CLL. The role of anticipation in identifying other family members has been reported by several groups,[25,26] and patients with such a family history are generally diagnosed a median of 10 years earlier than other patients.[27] However, other clinical features of CLL at diagnosis do not appear to be different.[27] Thus, patients with familial CLL do not appear to be genetically or clinically different from individuals with sporadic CLL.

BIOLOGY AND GENETICS OF CLL

The complexity of the biology of CLL has become increasingly apparent as the knowledge of the basic science of this disease has expanded. Despite these advances, many questions remain unsolved, including (a) the cell of origin from which CLL is derived, (b) the existence of a CLL stem cell as occurs in other leukemias, (c) the biological etiology of the divergent natural histories of IgV_H-mutated versus unmutated CLL, and (d) the existence and identification of infectious or other naturally occurring antigens that may drive the B-cell clone in this disease. Nonetheless, significant advances in our understanding of the role of cytogenetics, immunology, and other relevant biological markers in predicting the natural history of disease progression and response to therapy in CLL make an understanding of the basic biology of CLL increasingly relevant and important to the clinician caring for CLL patients.

For many years, CLL was felt to represent a single disease that had a varied natural history. Basic research focused on understanding (a) the normal cell of origin from which CLL is derived, (b) the function of the B-cell receptor in CLL, (c) the maturational point in B-cell development at which CLL occurs, and (d) the relevance and contribution of a self- or acquired antigen to driving the disease. The normal counterpart to the cell of origin of transformed CLL remains unknown, and no stem cell for this disease has been identified. Indeed, CLL is one of the few adult leukemias that does not engraft and proliferate to recapitulate the disease when tumor cells are inoculated or transplanted into immunocompromised mice. Each of these observations are important scientific areas of active, ongoing study,

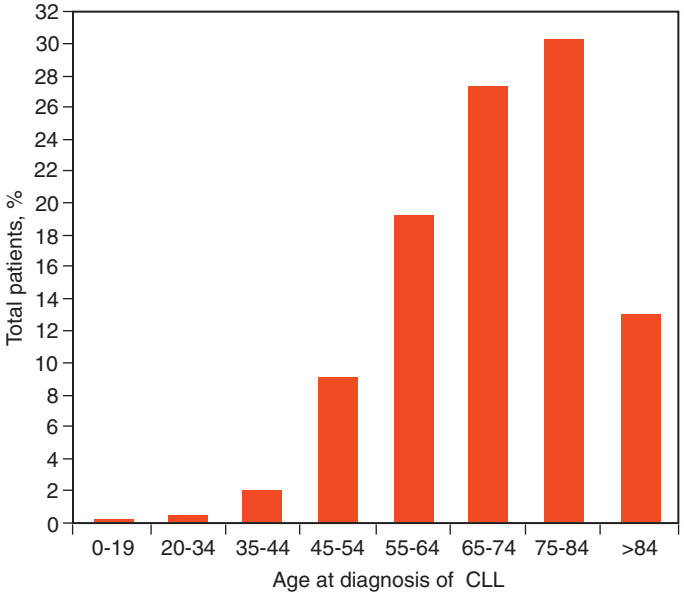

Figure 83–1 Illustration that CLL is a very uncommon diagnosis under the age of 45 and infrequent (30% of total patients diagnosed) in patients under the age of 65.

and the reader is referred to several recent definitive reviews for further information on the basic biology of CLL.[28–33] The biology and genetics covered within this chapter focuses predominately on areas relevant to the clinician who cares for patients with CLL.

IgV_H Mutational Status

Two seminal manuscripts demonstrated that the IgV_H gene had undergone somatic mutation, indicating that the patient's CLL arose after this point in B-cell maturation, in 60% of CLL patients at diagnosis.[34,35] The majority of IgV_H-unmutated CLL cells demonstrate evidence of syk activation and other essential B-cell receptor downstream activation signals following ligation of sIgM.[36] In contrast, virtually all IgV_H-mutated patients do not signal following ligation by sIgM but can often weakly signal through other alternative B-cell receptors, including sIgD and Ig-α. Thus, although gene expression profiling demonstrates all CLL cells to be most closely related to memory B cells,[37] IgV_H-unmutated and -mutated CLL cells differ significantly with respect to their ability to transduce intracellular signals following sIgM ligation.[36,38] A common repertoire of mutational changes among CLL patients has also been documented that differs significantly from that found in the normal adult B-cell repertoire.[39,40] These studies have prompted the hypothesis that CLL may represent an antigen-driven disease similar to other B-cell diseases including monocytoid B-cell lymphoma and gastric MALT lymphomas.[41]

Defective Apoptosis

Since its initial description and early characterization, CLL has been considered a disease of slow accumulation of tumor cells due to disrupted or defective apoptosis. Multiple studies have demonstrated that CLL cells overexpress several antiapoptotic proteins including bcl-2,[42,43] mcl-1,[44,45] bak,[44] and XIAP[46] and have diminished expression of compensatory proapoptotic proteins such as bax. Overexpression of bcl-2[42,43] and mcl-1[44] and an increase of the ratio of these proteins to bax[47,48] have correlated not only with disrupted apoptosis but also shortened overall survival and poor response to therapy. Why are these antiapoptotic genes overexpressed in vivo? Studies have demonstrated that CLL cells have constitutive activation of several antiapoptotic transcription factors including NF-κB,[49,50] NFAT,[51] and STAT3.[52,53] Each of these transcription factors can influence one or more of the antiapoptotic proteins that promote survival in vivo. The source of activation of these different transcription factors is not completely defined but may in part be due to autocrine and paracrine networks involving BAFF, APRIL, VEGF, IL-4, and CD40.[54–58] CLL cells are also maintained through contact with stromal cells (bone marrow and dendritic)[59–61] and nurse like cells through a complex interface of adhesion molecules and stromal survival factors such as SDF.[62–64] The importance of the in vivo environment to CLL survival is supported by the increase in apoptosis when CLL cells are cultured in vitro.

Genetic Abnormalities

Much of the advances in understanding the biology of acute leukemia has come from studying repetitively occurring cytogenetic abnormalities. Such detailed study of the genetics of CLL has been hindered by the inability to effectively induce proliferation of tumor cells for standard metaphase cytogenetic analysis and the poor response of CLL cells to B-cell mitogens. Nonetheless, several cytogenetic studies identified a variety of deletions, including del(11q22.3), del(17p13.1), del(13q14), and del(6q21-q23), as well as trisomy 12, as common abnormalities in CLL. The frequency of these abnormalities has been further refined through the use of interphase cytogenetic analysis, which does not require isolation of dividing cells. These studies have demonstrated that del(13q14) is by far the most common cytogenetic abnormality in CLL, followed by trisomy 12, del(11q22.3), del(17p13.1), and del(6q22.3). Stimulation studies with CpG oligonucleotides plus IL4 or CD40 confirmed the prevalence of these abnormalities and also identified unbalanced translocations not generally observed with traditional metaphase cytogenetics.[65] The prognostic significance of these unbalanced translocations appears to be important, yet the biological role of these translocations in the progression of CLL is not known and requires further study. Interestingly, balanced translocations, which are more frequently observed in acute lymphoblastic leukemia and acute myeloid leukemia, are generally not observed in CLL.

The presence of recurrent deletions in CLL suggests the possibility of unique tumor suppressor genes in these different regions. Extensive pursuit of such genes within the 13q14 region failed to identify a viable tumor suppressor gene candidate for many years. However, in 2002 Croce and colleagues identified miR15 and miR16, two noncoding microRNAs, in the deleted region of 13q14.[66] Noncoding RNAs range in size from 21 to 25 nucleotides and represent a newly recognized class of gene products whose function is to silence genes through binding to the 3′-untranslated region of specific genes to inhibit translation. This same group later showed that mir16 regulates expression of bcl-2, an antiapoptotic protein that is overexpressed in CLL and other B-cell lymphoproliferative disorders.[67] Other miRs have subsequently been shown to be expressed in CLL, and these miRs likely contribute to the pathogenesis of CLL.[68,69] Further study of miRs in CLL is under way to elucidate their full role in the pathogenesis and progression of CLL.

Methylation

In addition to genetic deletions and overexpression of miRs, gene expression can by modified by silencing of the promoter region through methylation. Gene silencing by methylation has been shown to regulate tumor suppressor gene expression in several types of cancer and leukemia. Recently, silencing of genes by methylation was shown to occur in CLL in a gene-specific manner that is greater than that observed in normal B cells. Select genes including ID4,[70] DERMO-1,[71] and SFRP family members[72] were found to be preferentially silenced in CLL, as compared to normal B cells. Additionally, epigenetic silencing of genes such as DAPK was recently noted to be present in 98% of CLL patients and to occur in familial CLL.[23] These

Initial Evaluation of Young Patients with Chronic Lymphocytic Leukemia

Only 10% of patients diagnosed with chronic lymphocytic leukemia (CLL) will be under the age of 50, and these patients often present a diagnostic and therapeutic dilemma to hematologists initially evaluating them. The great majority of patients diagnosed under the age of 50 will have early-stage CLL with a slightly higher predisposition to a prior first generation relative with this disease. Additionally, these patients are generally of a higher economic stature or have chronic fatigue or medical illnesses for which they have been undergoing routine blood testing, leading to diagnosis of CLL. Once the diagnosis of CLL is made, these younger patients have a more challenging time understanding how the disease will impact them. For those patients with no symptoms referable to CLL, I generally discuss complications of the disease during the first visit and have a detailed discussion regarding assessment of genetic risk factors predisposing to early disease progression, including select interphase cytogenetic abnormalities [del(17p13.1) and del(11q22.3) and IgV_H mutational status [unmutated]. During this time it is important to counsel patients that identification of high-risk genomic features can actually increase anxiety and still no treatment intervention will be considered in absence of symptoms outside of a clinical trial. In my experience, the great majority of patients desire this testing. Despite the potential benefit of allogeneic stem cell transplant in younger patients with CLL, I generally mention this as one treatment option used in this disease and do not pursue consultation or tissue typing of patient/siblings until patients are truly symptomatic from their disease. During the second visit 4 to 6 weeks later I review the results of these prognostic factors and answer additional questions that have arisen. Ultimately the majority of patients have low-risk disease, and knowing this allows patients to take partial control and move on. Serial assessment of the psychological well-being of the patient with CLL during this first year is incredibly important. At no place during the evaluation do I refer to CLL as being a good or favorable leukemia. In our experience, the most common reason for dissatisfaction toward the initial hematology evaluation is lack of explanation of the disease process or minimizing CLL as a "good leukemia to have."

For young patients presenting with other chronic medical problems and CLL who are asymptomatic, I follow the approach outlined above. More commonly these patients have fatigue, mild anemia, or other symptoms that could be referable to the CLL. Additionally, this group is more commonly overweight or obese. In either setting, it is important to first think like an internist and pursue other causes for symptoms potentially referable to CLL. In particular for fatigue, encouragement of both weight loss and a fixed exercise plan is encouraged and often improves quality of life and improvement in other medical comorbidities. It is very important to note that younger patients with CLL can often go a decade or more without therapy and early treatment of this patient group still offers no advantage. For this reason our group remains very conservative on starting therapy for the young patient with CLL.

findings provide support for the importance of epigenetic silencing of genes in CLL.

ESTABLISHING THE DIAGNOSIS OF CLL

The diagnosis of CLL, as defined by the NCI working group,[73] requires an absolute lymphocyte count of greater than 5000/μL. Morphologically, the lymphocytes must appear mature with fewer than 55% prolymphocytes (see Fig. 83–1A–E). The bone marrow aspirate smear must show greater than 30% of all nucleated cells to be lymphoid, or the bone marrow core biopsy must show lymphoid infiltrates consistent with CLL (see Fig. 83–1F, G). The overall cellularity must be normocellular or hypercellular. Immunophenotyping must reveal a predominant B-cell monoclonal population coexpressing the B-cell markers CD19, CD20, and CD23 and the T-cell antigen CD5 in the absence of other pan-T cell markers (see below section).

Table 83–1 Diseases That Can Mimic Chronic Lymphocytic Leukemia

Follicular lymphoma
Mantle cell lymphoma
Monocytoid B-cell lymphoma or splenic lymphoma with villous lymphocytes
Hairy cell leukemia
Acute lymphoblastic leukemia
T-cell prolymphocytic leukemia
Large granular natural killer or T-cell leukemia

Patients may present with tumor cells immunophenotypically consistent with CLL but have predominately lymph node disease without a peripheral B-cell lymphocyte count of 5,000/μL despite bone marrow involvement. Although these patients are considered to have small lymphocytic lymphoma (SLL) and not true CLL by the NCI criteria, the most recent World Health Organization (WHO) classification[74] considers such SLL patients to have CLL, given the similar immunophenotypic features, genetic findings, natural history, and complications of these two diseases. The clinical management of SLL patients should be similar to CLL with respect to diagnostic testing and treatment. However, SLL patients may not be eligible for some clinical studies in CLL, if those trials follow NCI criteria and mandate a peripheral B-cell lymphocyte count of 5000/μL for study entry.

The recent increase in diagnostic blood testing for other B-cell lymphoid cancers has led to recognition of a precursor to CLL called monoclonal B-cell lymphocytosis (MBL). Patients with MBL have circulating peripheral B cells immunophenotypically consistent with CLL but do not have enlarged lymph nodes, a lymphocyte count greater than 5000/μL, or bone marrow lymphoid infiltration greater than 30%.[75] The frequency of MBL increases with age; 0.3% of patients under the age of 40 years have MBL compared to 2.1% of 40- to 60-year-old patients and 5.2% of 60- to 90-year-old patients.[76] The frequency of MBL in family members of patients with a first-degree relative with CLL is significantly higher in both young and older patients alike.[76–78] Similar to the relationship of MGUS and multiple myeloma, it appears that only a small proportion of patients with MBL develop overt CLL over time.[75,79,80] Prospective studies to investigate the natural history of isolated MBL will help elucidate the relationship of this diagnosis to CLL.

IMMUNOPHENOTYPIC, CLINICAL, AND LABORATORY FEATURES OF CLL

For many years, the diagnosis of CLL was made based on morphologic examination of the peripheral blood smear, which demonstrated mature lymphocytes with an abundance of smudge cells. Despite rigorous morphology, many diseases can mimic CLL in both appearance and clinical presentation, as summarized in Table 83–1, resulting in incorrect diagnoses. With the advent of new, more effective targeted therapies in CLL and other related diseases listed in Table 83–1, determining the correct diagnosis is of great importance. Flow cytometry, or immunophenotyping, has become a widely used diagnostic test that is currently performed in most reference pathology

laboratories, and the use of flow cytometry is now the standard approach to establish the diagnosis of CLL (Fig. 83–2, for example). The diagnosis of CLL relies on immunophenotypic confirmation, and flow cytometry should therefore be performed on all CLL patients at diagnosis. CLL cells have a relatively consistent immunophenotype, which differentiates CLL from mantle cell lymphoma, hairy cell leukemia, follicular center cell lymphoma, splenic lymphoma with villous lymphocytes, and other indolent B-cell malignancies. Specifically, CLL cells expresses a variety of B-cell markers, including dim sIg, CD19, dim CD20 and CD23, as well as the pan T-cell marker CD5. Kappa or lambda restriction is always present, establishing the presence of a clonal B-cell population, although sIg expression may be so dim that light chain restriction may be difficult to determine. In contrast, presence of CD10, FMC7, or CD79b (all typically absent on CLL cells) or bright expression of CD11c, CD20, or CD25 (all typically dim on CLL cells) suggests an alternative low-grade B-cell lymphoproliferative malignancy. Expression of CD5 without CD23 suggests mantle cell lymphoma, and FISH for t(11;14) should be performed to exclude mantle cell lymphoma. Some genetic subsets of CLL are predisposed to variant antigen expression, particularly patients with trisomy 12.[81,82] A scoring system based on antigen expression to definitely diagnose CLL has been proposed but is not widely used.[83] Repeating immunophenotyping after the initial diagnosis is not required unless there is a suspicion of transformation to a more aggressive histology or there is a need to assess bone marrow response, most notably the absence or presence of minimal residual disease, following treatment. Transformation of CLL (Fig. 83–3A–C) to either prolymphocytic leukemia (PLL) or large cell lymphoma (Richter transformation) is often associated with immunophenotypic drift, where CD5 is lost and FMC7 expression is acquired. Additionally, expression of CD20 and surface immunoglobulin typically becomes brighter in PLL or Richter transformation. Although the morphologic appearance of prolymphocytes or large cells in blood, bone marrow or lymph nodes is typically adequate to make the diagnosis of transformation, flow cytometry may be useful in cases where morphologic findings are less clear.

CLL patients often present with no symptoms, with the diagnosis being made as a consequence of asymptomatic enlarged lymph nodes or splenomegaly detected on physical exam or routine blood work done for another cause. Other patients present with symptoms of marrow replacement (fatigue, dyspnea or petechiae secondary to anemia and thrombocytopenia), symptomatic lymphadenopathy or hepatosplenomegaly, autoimmune complications (hemolytic anemia

When Do I Consider a Transplant Evaluation in Chronic Lymphocytic Leukemia?

With the introduction of nonmyeloablative stem cell transplant, the morbidity and mortality associated with this therapy in chronic lymphocytic leukemia (CLL) has decreased and this option thereby has been extended to young and older patients alike. Additionally, extended follow-up in several transplant series has suggested that prolonged remissions can occur with this treatment approach, potentially providing the only curative therapy option for this disease. In general, I do not consider detailed discussion of transplant or referral early in the disease. When patients become symptomatic and require therapy for their CLL, I also consider if they would qualify for transplant. Approximately 50% of patients with CLL are 75 years or younger, have acceptable end-organ function, and lack comorbidities when symptomatic disease develops. It is with this CLL patient group that a transplant consultation with HLA-tissue typing of patient and sibling is considered. For patients attaining a complete remission to initial combination chemotherapy, we would never consider a consolidative stem cell transplant. However, for those patients having only a partial response to combination therapy, remission duration is often short, and particularly in patients with high-risk genomic features such as del(17p13.1) and del(11q22.3), consolidation transplant in first partial remission might be considered. For all patients relapsing after first therapy, I strongly recommend transplant evaluation and pursuit of this option following second treatment unless a complete remission is obtained again. For patients attaining a complete remission both as initial and first relapse therapy, remission duration can be prolonged and transplant can be delayed, particularly in the absence of high-risk genomic features. Usually, patients referred for transplant beyond second-line therapy often do not eventually get to transplant treatment. Reasons for this include inability to cytoreduce for transplant, lack of time to identify unrelated donor, insurance approval delays following meeting criteria for eligibility for transplant and subsequent progression before approval can be obtained, and intervening complications of CLL or therapy that prevent moving forward with transplant. Therefore, if transplantation is to be considered for CLL patients, it should be pursued early in the course of disease.

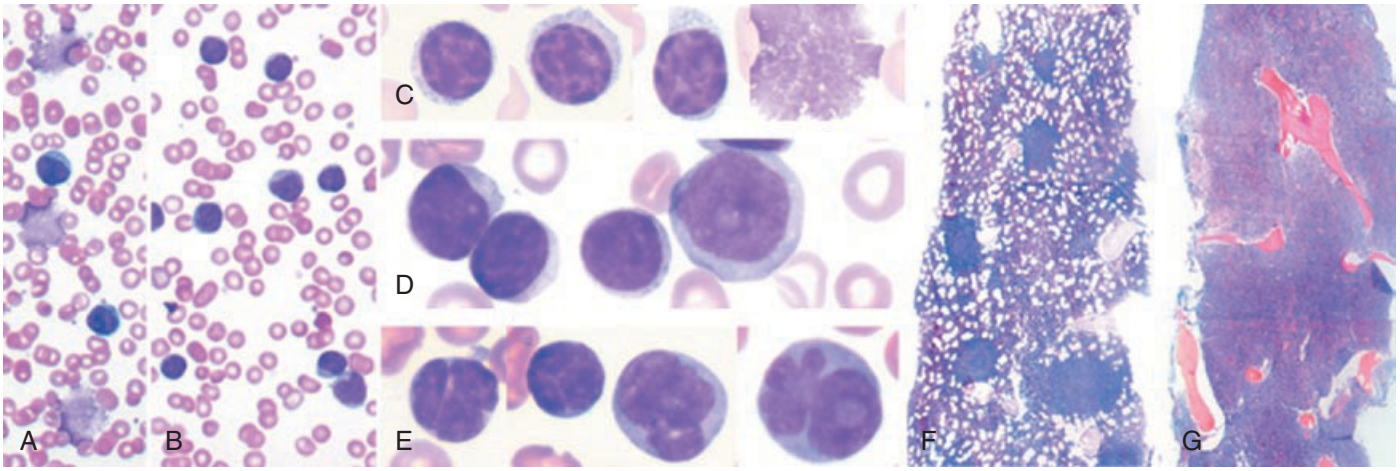

Figure 83–2 Chronic lymphocytic leukemia (**A**–**G**). Peripheral blood smear (**A**) typically shows lymphocytosis and increased smudge cells as a result of the fragility of the CLL cells (see also smudge cell in **C**, right side). These can be avoided by making a preparation of blood and bovine serum albumin (22%) at a ratio of 11 drops of blood and 1 drop of albumin before preparing the slide (**B**). Cytologic features of CLL cells differ. Classic cells have a small nucleus with a "soccer ball" chromatin pattern (**C**). Some cases have increased large cells, or prolymphocytes, with more open chromatin and prominent "punched-out" nucleoli (**D**; prolymphocyte, right side). Other cases, sometimes referred to as "atypical," can have clefted cells and large cells (**E**). The bone marrow can show nodular infiltrates of CLL cells (**F**), an interstitial infiltrate, or a diffuse infiltrate (**G**).

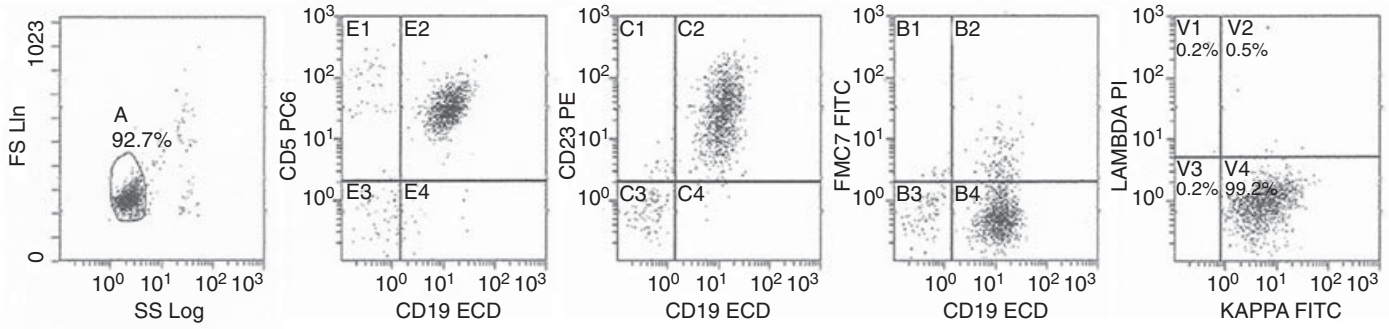

Figure 83–3 Flow immunophenotyping in chronic lymphocytic leukemia (CLL). Flow data in a typical case of CLL. The phenotype is CD19+ clonal B cells with Kappa light chain restriction (weak to moderately intense), with coexpression of CD5 and CD23, but lack of FMC-7. The cells were CD38-negative.

Table 83–2 Rai Staging System

Rai Stage at Diagnosis	Percent of Patients Never Requiring Chronic Lymphocytic Leukemia Therapy	Expected Survival in Months From Initial Diagnosis
0. Lymphocytosis >5 × 10^9/L only	59	150
1. Lymph node (LN) enlargement	21	101
2. Spleen/liver (S/L) enlargement ± LN	23	71
3. (Anemia with hemoglobin <11 g/dL) ± LN or S/L	5	19
4. (Thrombocytopenia <100 × 10^{12}/L ± LN or S/L)	0	19

or idiopathic thrombocytopenic purpura), or B-symptoms (fevers, night sweats, and weight loss). A small proportion of CLL patients will have pulmonary infiltrates at diagnosis that is representative of CLL involvement in some cases and active infection in others. Clearly, a wide spectrum of presentations exists for patients with CLL.

In addition to blood and bone marrow lymphocytosis, a few abnormal laboratory findings are commonly observed in CLL. Neutropenia, anemia, and thrombocytopenia can develop as a consequence of bone marrow infiltration or therapy administered to eliminate the leukemia. A positive direct antibody, or Coombs, test is observed in approximately 10% to 25% of CLL patients sometime during the course of the disease. Similarly, autoimmune thrombocytopenia or neutropenia may be present, although other causes such as marrow replacement or chemotherapy effect are much more common and should be excluded. Other nonhematologic autoimmune antibodies can rarely be present but do not appear to be more common than age-matched control patients without CLL.[84] Pure red cell aplasia can sometimes be observed with isolated anemia and absence of red cell precursor cells. Hypogammaglobulinemia is common in CLL and becomes more frequent and marked as the disease progresses. In contrast, hypercalcemia and markedly elevated LDH is not common in CLL and suggests Richter transformation.

STAGING AND PROGNOSTIC FACTORS IN CLL

Until recently patients with CLL have been staged utilizing either the Rai or Binet system.[85,86] Both of these discriminate CLL by the sites of disease and degree of cytopenias induced by leukemia marrow replacement. Patients can be categorized into three groups on the basis of these features. According to the modified Rai criteria, patients in the low-risk group (stage 0) have lymphocytosis without any other abnormality; patients in the intermediate-risk group (stages I and II) have, in addition to their lymphocytosis, enlarged lymph nodes and/or spleen or liver; and patients in the high-risk group have anemia (hemoglobin <11.0 g/dL) and/or thrombocytopenia (platelets <100 × 10^9/L). The median survival times for the Rai low-, intermediate-, and high-risk groups are similar to those of Binet stages A, B, and C: 12+, 8, and 2 years, respectively, as shown in Table 83–2.[85,86] For early-stage patients with CLL (Rai low and intermediate stage and Binet stage A and B), a significant range of time to developing symptoms of CLL exists. The lack of survival advantage with early treatment, the observation that a subset of CLL patients will never require therapy, and the varied natural history of the disease has driven research efforts in CLL to identify specific biologic or clinical prognostic factors that predict time to progression; several comprehensive reviews exist.[87–90]

Although lymphadenopathy is a common clinical feature of CLL and is incorporated into both major clinical staging systems, computed tomography (CT) scans are not standardly used to determine staging or to evaluate response to therapy according to NCI 96 criteria. However, several studies have recently examined whether the incorporation of CT scans in initial staging or response evaluation may affect the ability to predict disease progression and assessment of clinical response to therapy. A Spanish study prospectively performed abdominal CT scans on 140 consecutive patients who were diagnosed with Rai stage 0 CLL.[91] CT scans determined abnormal lymphadenopathy or splenomegaly in 27% of patients, and an abnormal CT scan correlated with 50% or more bone marrow infiltration, lymphocyte count of 30 × 10^9/L or greater, lymphocyte doubling time less than 12 months, and zeta-associated protein (ZAP)-70 expression or more. More importantly, patients with an abnormal CT scan were more likely to progress and require earlier therapy than patients with a normal CT scan (RR = 2.7; median TTP 3.5 years vs. not reached). However, no difference in 5-year OS was observed between the two groups.

The same group examined the role of CT scans in predicting response duration in 34 previously untreated CLL patients who received fludarabine, cyclophosphamide, and mitoxantrone (FCM) as initial therapy.[92] Sixty-four percent of the 69 patients treated with FCM achieved a complete response (CR), and 30% of the CR responders had residual abdominal lymphadenopathy by CT scans.

CR responders with an abnormal CT scan had a response duration (54% at 20 months) inferior to that of CR responders with a normal CT scan (95%) and similar to that of PR responders (42%). The effect of incorporating CT scans in response criteria is unclear; the limited studies in this area have presented conflicting data. The use of CT scans reduced the number of complete responders from 50 to 35 in a 375-patient German CLL Study Group phase III study of previously untreated CLL patients.[93] Similarly, CT scans were performed in 189 of 241 patients who received their initial therapy in a phase III study incorporating an investigational bcl-2 antisense molecule.[94] The addition of CT scans to NCI 96 response criteria reduced the percentage of patients achieving CR from 25% to 17% in the study arm and from 14% to 7% in the control arm. In contrast, a retrospective study of 82 patients who underwent pretherapy and posttherapy CT scans in three clinical trials at our institution concluded that CT scans did not improve the predictive power of existing NCI 96 response criteria, which do not use CT scans, in predicting progression-free survival (PFS) or overall survival (OS).[95] Thus, the use of CT scans in staging and response evaluation in CLL needs further study by well-designed, prospective clinical trials. However, CT scans should not be routinely incorporated in standard clinical use until their significance is evaluated by such trials. Although CT scans have been the focus of greatest debate, the use of positron emission tomography (PET) should also be briefly discussed. Specifically, PET scans may be useful in detecting Richter transformation (RT). In a single-institution study of 37 patients, PET scans identified 10 of 11 patients who had documented RT by tissue biopsy.[96] However, nine patients had false positive scans. Thus, PET scans appear to be sensitive for RT, with a high negative predictive value, but specificity is poor.

With recent advances in the molecular biology of CLL, some prognostic factors such as bone marrow infiltration pattern, which requires an invasive procedure at diagnosis, have not maintained their usefulness in predicting disease progression. Prognostic features outside of the traditional staging systems outlined above relative to daily practice are summarized below.

Thymidine Kinase Activity and β_2-Microglobulin

Thymidine kinase is an enzyme involved in the salvage pathway of DNA synthesis and correlates with proliferative activity. An elevated TKA has been observed to be predictive of early progression in a subgroup of untreated patients with smoldering CLL.[97] β_2-microglobulin (β_2M) is an extracellular protein component of the HLA Class I complex. β_2M has been shown to have significant prognostic relevance in lymphoma and multiple myeloma and correlates with disease burden in CLL. Hallek and colleagues examined 113 CLL and immunocytoma patients for β_2M levels and TKA and demonstrated that elevated TKA and β_2M both were independent predictors of shortened PFS.[98,99] Keating et al confirmed the prognostic value of β_2M in 622 patients, reporting that an elevated level was associated with a significantly shorter survival for both untreated and previously treated patients.[100] In this study, elevated β_2M was observed in patients with high tumor burden and extensive bone marrow infiltration. In addition to disease progression, both β_2M[101–103] and TKA[104] have been associated with short duration of remission and inferior survival following treatment.

IgV_H Mutational Status

Although the malignant cell of CLL morphologically resembles a mature lymphocyte, genetic, immunologic, and phenotypic studies suggest that this cell is better designated as either a pregerminal or postgerminal B cell. Somatic mutations in the first and second complementarity-determining regions (CDR1 and CDR2) of the IgV_H genes are thought to occur in the germinal centers. Examination of IgV_H genes in patient cells suggest that there may be two subsets of CLL: leukemias whose cell of origin has successfully traversed the germinal center, resulting in the mutated IgV_H phenotype, and leukemias that are derived from naïve B cells with the unmutated (germline) IgV_H sequence. Approximately 60% of CLL patients have cells with mutated IgV_H genes (less than 98% identity to germline), whereas the remaining patients have cells exhibiting unmutated IgV_H (98% or greater sequence identity with germline), typical of pregerminal B cells.[34,35] The prognostic significance of the absence of IgV_H gene mutations is substantial, with all studies uniformly noting an inferior survival and high predisposition to requiring early treatment in this patient subset.[34,35,105–109] A recent CLL Research Consortium study examined the impact of IgV_H mutation in 307 untreated CLL patients enrolled on a prospective tissue collection study. Fifty-three percent of these patients exhibited unmutated IgV_H genes, and this population had a significantly shorter median time to initial therapy (3.5 years) than those with mutated IgV_H (9.2 years, $P < 0.001$).[110]

Because of the difficulties in determining IgV_H gene mutational status, researchers have sought surrogate markers for this parameter. Correlation between the absence of IgV_H gene mutations and elevated expression of the cell surface molecule CD38 on CLL cells was noted in one such report.[34] In another work, ZAP-70 expression was shown to correlate with IgV_H gene mutational status.[111] ZAP-70 is a T-cell receptor associated tyrosine kinase that is aberrantly expressed in CLL cells, and ZAP-70 expression is generally found in patients with unmutated IgV_H but not in patients with mutated IgV_H.[111] These two associated biomarkers appear to tie directly to the difference in biology of CLL between these two genetic subtypes and are discussed independently. Other surrogate markers for CLL with unmutated IgV_H gene status have been reported, including methylation and subsequent silencing of *TWIST2*, a transcription factor that negatively regulates *p53*, is preferentially observed in IgV_H-mutated CLL cases.[71] Elevated levels of lipoprotein lipase and related genes[112–118] have been noted in patients with IgV_H-unmutated disease. Additionally, it has been reported that IgV_H-mutated CLL cells have long telomeres with low telomerase activity,[119–122] whereas IgV_H-unmutated patients have short telomeres with high telomerase activity. The extreme shortening of telomeres and elevated telomerase activity is associated with both genetic instability and disrupted apoptosis in other diseases.[123–125] Finally, distinct gene and miRNA expression profiles[69] have also been correlated with IgV_H gene mutational status.[111,126]

CD38 Expression

Retrospective studies have shown that CD38 is an independent prognostic marker in CLL, demonstrating that high CD38 expression is associated with both a shorter time from diagnosis to treatment and inferior survival.[34,105,127–138] CD38 functional studies using CD31 and plexin B1 transfected fibroblasts have provided a biologic explanation for this observation. CD38 interaction with its ligand CD31 in the presence of IL-2 results in upregulation of survival receptor CD100 exclusively on proliferating CLL cells. This occurs with concomitant downmodulation of CD72, a negative regulator of immune response. The interaction between CLL cells and transfected fibroblasts (CD38/CD31 and CD100/plexin B1) results in enhanced survival and growth of CLL cells. Furthermore, the presence of nurse-like cells in CLL patients expressing high levels of CD31 and plexin B1 corroborates the interplay of CD38 and CD31 and provides evidence of activation of circulating CD38-positive CLL cells.[139–141] This finding also may explain the aggressive nature of these CLL clones.

ZAP-70

ZAP-70 expression was identified as another surrogate marker for IgV_H gene mutational status by a cDNA microarray analysis of untreated CLL patients.[111] Multiple studies have subsequently confirmed this finding.[110,126,142–144] Functional studies in ZAP-70-positive cases have shown that on B-cell receptor ligation, increased

phosphorylation of cytosolic proteins (Syk, BLNK, PLCγ), calcium mobilization, and degradation of IκB leads to NF-κB target gene activation.[36,110,145,146] Despite the positive data with ZAP-70 as a prognostic factor, the reproducibility of this across laboratories has been problematic.[147,148] Inconsistent measurement of ZAP-70 may be the cause, as ZAP-70 is a labile protein and laboratories have employed different methods and reagents. Given the challenges of measuring ZAP-70 protein accurately, others have attempted to identify alternative markers or more stable readouts of ZAP-70 expression. For example, Corcoran and colleagues demonstrated that methylation of a specific CpG dinucleotide of the ZAP-70 gene correlated closely with expression of ZAP-70.[149] Overall, despite the apparent usefulness of ZAP70 in research laboratories for discriminating CLL patients at high risk for progression, this test currently is not useful for clinical practice.

Chromosomal Aberrations

Conventional metaphase cytogenetics can identify chromosomal aberrations in only 20% to 50% of cases, because of the low in vitro mitotic activity of CLL cells. Abnormalities noted in descending frequency of occurrence include trisomy 12, deletions at 13q14, structural aberrations of 14q32, and deletions of 11q, 17p, and 6q.[150] In addition, a complex karyotype (three or more abnormalities) occurs in approximately 15% of patients and predicts for rapid disease progression, Richter transformation, and inferior survival.[151–153] A recent study showed that the use of CD40L or combination of IL-2 and CpG stimulation revealed translocations in 33 of 96 patients (34%). These translocations were both balanced and unbalanced, occurring in 13q14, 11(q21q25), 14q32, or in regions also seen in lymphomas such as 1(p32p36), 1(q21q25), 2(p11p13), 6(p11p12), 6(p21p25), and 18q21.[65] These data define a new prognostic subgroup of patients with significantly shorter median time from diagnosis to requiring therapy (24 vs 106 months) and OS (94 vs 346 months) compared to those without translocations.[65] The frequency of these translocations in untreated patients was less common.[65] Although of interest, these findings require prospective validation before being used as a standard prognostic tool for CLL patients and may be more relevant for studies of clonal evolution from diagnosis.

Given the limitation of standard or stimulated karyotype analysis, at the present time interphase cytogenetics of known abnormalities by fluorescence in situ hybridization (FISH) is the state-of-the-art technique for accurately distinguishing genetic subtypes of CLL. The largest study of interphase cytogenetics resulted in improved sensitivity to detect partial trisomies (12q12, 3q27, 8q24), deletions (13q14, 11q22–23, 6q21, 6q27, 17p13), and translocations (band 14q32) in more than 80% of all cases.[65] In a large study of 325 patients by Dohner and colleagues,[156] a hierarchical model consisting of five genetic subgroups was constructed on the basis of regression analysis of CLL patients with chromosomal aberrations. The patients with a 17p deletion had the median survival time of 32 months and shortest treatment-free interval (TFI) of 9 months, whereas patients with 11q deletion followed closely with 79 months and 13 months, respectively.[156] The favorable 13q14 deletion group had a long TFI of 92 months and a median survival of 133 months, whereas the group without detectable chromosomal anomalies and those with trisomy 12 fell into the intermediate group with median survival of 111 and 114 months. Their TFI was 33 and 49 months, respectively. According to this pivotal study, CLL patients are prioritized in a hierarchical order (deletion 17p13 → deletion 11q22-q23 → trisomy 12 → no aberration → deletion 13q14).[156] The hierarchical model of cytogenetic abnormalities by FISH has been further confirmed by other studies relative to predicting disease progression. Of interest, patients with high-risk interphase cytogenetic abnormalities or other complex abnormalities are almost always found to have IgV_H-unmutated CLL.[136] The impact of high-risk interphase cytogenetics relative to disease progression, outside of its association with IgV_H-unmutated CLL, is yet unknown.

p53 Inactivation in CLL

p53 gene inactivation can occur through mutation or deletion of *p53* (primary) or mutation of other p53 regulatory factors (secondary). Mutations and/or deletions of *p53* are relatively uncommon (10%–20%) in CLL, compared to other tumor types,[136] but become more frequent as the disease progresses and predict an aggressive disease course, with rapid progression to time requiring therapy and inferior survival.[107,157,158] Indirect inactivation of p53 by mutation of *ATM* can also occur.[157] Indeed, examination of both primary p53 dysfunctions (ie, *p53* mutations) in the setting of other prognostic factors has demonstrated each of these to be important in predicting outcome and this represented 15% of the patient outcome.[157] Prospective validation of primary and secondary p53 inactivation will be required before this can be routinely implemented at diagnosis for routine risk stratification.

Preliminary Prospective Validation of New Biomarkers From the German CLL Study Group

The CLL-1 Study of the German CLL Study Group (GLLSG) is a randomized phase III study of early treatment with fludarabine versus observation in newly diagnosed CLL patients.[29] Risk of progression is determined on the basis of lymphocyte-doubling time, thymidine kinase, and diffuse bone marrow pattern. Differing from other early-intervention studies, patients with disease that meet some criteria of the NCI 96 criteria (ie, lymphocyte-doubling times <1 year) may enroll. Accompanying this study is the plan to assess interphase cytogenetics, IgV_H mutations, and β_2M level to determine their independent prognostic significance compared to other variables. If shown to be of prospective importance relative to predicting early treatment progression, these laboratory tests would be incorporated into subsequent risk stratification criteria. IgV_H-unmutated disease represented 41% of patients at diagnosis. Patients with IgV_H-unmutated disease assigned to observation had a median time to symptomatic disease of only 2 years. High-risk karyotypes were present in 15% of cases, with the great majority being IgV_H unmutated. A preliminary analysis of the first 340 patients randomized to observation suggested that IgV_H-unmutated disease, high-risk interphase cytogenetics, thymidine kinase, and lymphocyte-doubling time correlated with time to first treatment. Publication of these large prospective new prognostic factors will be important to determining the risk of CLL progression.

How Should Staging and Biomarkers Be Used for CLL in Year 2008?

Our understanding of the biology of CLL has improved dramatically and many relevant biomarkers are now becoming useful for predicting when CLL will clinically progress. However, no study to date has demonstrated that earlier treatment will alter the natural history of the patient in even the higher-risk groups with high progression rates. Therefore, at the present time the use of staging and predictive biomarkers should be used only to provide patients with information relative to the expected course of their disease. Outside of a clinical trial, these results should never be used to initiate therapy in patients with asymptomatic disease and no indication for treatment. Prior to performing predictive tests, a detailed discussion of how these tests will be used with the patient should occur and the option of not performing them should be provided. In a subset of patients, significant anxiety can be produced by identifying high-risk features for which intervention remains the only observation. Table 83–3 provides an example of the initial evaluation provided by our group when seeing a newly diagnosed patient. As lymphocyte-doubling time is a prognostic feature in the progression of CLL, our approach is to follow patients every 3 months during the first year and if little

Table 83–3 Evaluation of Chronic Lymphocytic Leukemia (CLL) Patients at Diagnosis

History
B-symptom and fatigue assessment
Infectious history assessment
Occupational assessment for chemical exposure
Familial history of CLL and lymphoproliferative disorders
Preventive interventions for infections and secondary cancers
Physical Exam
Laboratory Assessment
Complete blood count with differential
Morphology assessment of lymphocytes
Chemistry, LFT enzymes, LDH
Flow cytometry assessment to confirm immunophenotype of CLL
Serum immunoglobulins
Serum β_2M levels
Interphase cytogenetics for del(17p13.1), del(11q22.3), del(13q14), del(6q21), and trisomy 12
IgV_H mutational analysis
Stimulated metaphase karyotype (if available)
Selected Tests Under Certain Circumstances
Direct antiglobulin test (DAT), haptoglobin, reticulocyte count if anemia present
CT Scan if unexplained abdominal pain or enlargement present
PET Scan and/or biopsy if large nodal mass present
Bone marrow aspirate and biopsy if cytopenias present
Familial counseling if first-degree relative with CLL
Teaching
Varicella zoster identification instruction
Skin cancer identification
Disease education (Leukemia and Lymphoma Society, CLL Topics, ACOR)

Table 83–4 Modified Indications for Treatment of Chronic Lymphocytic Leukemia

Grade 2 or greater fatigue limiting life activities
B-symptoms persisting for 2 weeks or greater
Lymph nodes greater than 10 cm or progressively enlarging lymph nodes causing symptoms
Spleen or liver with progressive enlargement or causing symptoms
Anemia (Hemoglobin <11 g/dL) referable to CLL
Thrombocytopenia (Platelets $<100 \times 10^{12}$/L) referable to CLL
Autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura poorly responsive to traditional therapy
WBC $> 300 \times 10^9$/L on two occasions two weeks apart if no alternative comorbid diseases increase morbidity of Treatment
Severe paraneoplastic (insect hypersensitivity, vasculitis, myositis, etc) process related to CLL not responsive to traditional therapies

change in clinical or laboratory parameters occurs at this point, we extend this time period to every 6 months in the absence of new complaints.

INITIAL TREATMENT OF CLL

Initiation of Treatment of Newly Diagnosed or Previously Untreated Patients

Many patients are incidentally diagnosed with CLL on routine complete blood count (CBC) examination and are asymptomatic with a normal hemoglobin and platelet count at time of initial diagnosis. Expectant observation without therapy is the standard practice for such asymptomatic patients, and patients receive treatment only when their disease progresses. This practice is based on several studies that failed to show an improvement in OS when early therapeutic intervention with chlorambucil therapy was administered to asymptomatic patients.[159] A meta-analysis of 2048 patients in six trials demonstrated no difference in death rate between patients who were randomized to early therapy (42.6%) and those whose treatment was deferred (41.6%).[159] Thus, patients with asymptomatic or early-stage disease derive no therapeutic benefit from early alkylating agent therapy. However, in these studies chlorambucil was administered as initial therapy, and chlorambucil achieves CR in few patients. The past decade has seen the development of more effective treatment regimens combining monoclonal antibody therapy with purine analogs (chemoimmunotherapy), which are able to achieve a CR in a majority of previously untreated patients, and the increasing use of new molecular markers to risk-stratify newly diagnosed CLL patients. Furthermore, it is now well established that CLL undergoes genetic clonal evolution with time with greater frequency in IgV_H-unmutated CLL,[160] resulting in increasing resistance to therapy. Thus, the issue of early treatment needs to be reconsidered, particularly in patients with high-risk biological or molecular markers predicting a poor long-term prognosis. Ongoing efforts within the German CLL Study Group (GCLLSG) and several US cooperative groups will hopefully determine whether early intervention with modern chemoimmunotherapy regimens will improve long-term survival in patients with high-risk CLL.

To establish uniform clinical practice standards and ensure reproducible eligibility criteria for entrance into clinical studies, an NCI-sponsored working group on CLL established guidelines for initiation of treatment in 1996.[161] Indications to begin therapy included non-autoimmune cytopenias (Rai stage III and IV), bulky or symptomatic lymphadenopathy or hepatosplenomegaly, disease-related B symptoms or fatigue, extreme lymphocytosis (greater than 300×10^9/L) or a rapid lymphocyte-doubling time, and autoimmune hemolytic anemia or thrombocytopenia not controlled with steroids. It is imperative to determine if a patient's symptoms are due to CLL or a comorbid medical condition, because constitutional symptoms such as fatigue are nonspecific and can be due to many etiologies in elderly patients with comorbid illnesses. In addition to the official NCI 96 criteria for therapy, increasing frequency of infections and slowly progressive anemia are other indications that can aid the practicing physician in deciding when to initiate therapy in CLL. A summary of the NCI 96 guidelines for treatment is provided in Table 83–4 with some minimal modifications used by our group, and revised guidelines are under development at this time.

A useful paradigm for clinical practice is to institute treatment in CLL only for cytopenias or directly referable symptoms. When treatment is necessary, a variety of agents have been examined in clinical trials (outlined below). In addition, several retrospective[129,162–165] and prospective trials[93,166] recently demonstrated that some of the same prognostic features that predict time to progression and therapy may also predict the outcome of treatment. The role of these biomarkers in selecting the initial treatment for CLL is currently under study by several groups. In general, patients with del(17p13.1) and del(11q22.3) generally do not respond well to traditional therapy and should be considered for more aggressive interventions as part of initial therapy. Additionally, several studies have shown that CLL patients older than 70 or who have multiple comorbid illnesses do not tolerate certain more aggressive therapies,[102,167] and this needs to be factored into treatment algorithms. Below, we summarize the findings of clinical studies of different treatments for CLL; where such data exist, we integrate genomic biomarkers as well as clinical, including age and comorbid illnesses. Different therapies are outlined below with attention to details related to their initial use in previously untreated CLL.

As many of these regimens were also developed in relapsed CLL, these data are also reviewed and later referred to in the section Treatment of Patients with Relapsed CLL.

Cytotoxic Chemotherapy

Alkylating Agents

Chlorambucil and other alkylating agents served as first-line therapy for CLL for many decades, and chlorambucil is still given as first-line therapy for some patients, particularly older patients and patients who cannot tolerate purine analog therapy.[168] Chlorambucil is generally administered as a single pulse dose 40 mg/m^2 orally (PO) every 28 days, with or without concomitant steroid therapy.[169] Chlorambucil is typically given without steroid therapy, since the addition of steroids to alkylating agent therapy has not been shown to improve survival. Although a high-dose continuous dosing schedule of 15 mg PO daily has been evaluated in several large European studies and led to results superior to those of pulse therapy, high-dose therapy is associated with greater myelosuppression and frequently requires dose reduction, particularly in older or more fragile patients in whom chlorambucil is typically considered.[170] Although high-dose therapy may be more effective if maximal cytoreduction is desired, the less intensive pulse dosing schedule should generally be used outside the setting of a clinical study. Because most studies of alkylating agent therapy predated widespread use of cytogenetic and biological risk factors, data on the effect of biomarkers on response to chlorambucil are limited. However, the existing data indicate that patients with del(11q) or del(17p13.1) have a lower response rate and a shorter remission duration to chlorambucil, as compared to patients without these abonormalities.[171] The primary advantages of chlorambucil are its well-established toxicity profile and its low cost; its primary disadvantages are its low CR rate, even in previously untreated patients, and the very low possibility of developing myelodysplasia with extended therapy. Although not typically given as a single agent, its use should be considered in older patients and other patients who may not tolerate fludarabine or monoclonal antibody therapy.

Combination Chemotherapy With Alkylating Agents

A variety of trials combining alkylating agents and other cytotoxic agents have been performed. A phase III Eastern Cooperative Oncology Group (ECOG) study of chlorambucil and prednisone (CP), with or without vincristine (CVP), demonstrated no benefit in PFS for the CVP arm.[172] The French CLL group showed that a modified CHOP regimen (cyclophosphamide, adriamycin, vincristine, prednisone) was superior to CVP and achieved similar results as fludarabine monotherapy.[173,174] A meta-analysis compared alkylating agent-based combination regimens to a single-agent regimen based on an alkylating agent and demonstrated no survival benefit.[175] Given that alkylating agent-based combination regimens are associated with more toxicity and show no benefit over fludarabine-based therapy, our approach is to use the latter for most patients. Only in rare cases of de novo CLL do we consider alkylating agent-based combination therapy (ie, a young patient without comorbid illnesses who has fludarabine toxicity that prohibits further use, or a patient with renal failure who cannot receive fludarabine). In the relapse setting, although salvage lymphoma regimens such as CHOP-R, RICE, and ESHAP-R are used to treat CLL, clinical studies of these regimens in CLL are lacking and the utility of these regimens is undefined.

Purine Analogs

The introduction of purine analogs in the 1980s revolutionized CLL therapy, and fludarabine has demonstrated significant clinical efficacy in both relapsed and previously untreated CLL.[176–183] Pentostatin was the first nucleoside analog that demonstrated clinical activity in CLL and related B-cell lymphoproliferative disorders.[184] Phase II studies of pentostatin monotherapy in heavily pretreated patients showed modest activity, limiting further trials of single-agent pentostatin.[185,186] Given its more favorable myelosuppression profile, compared to other nucleoside analogs, pentostatin has been combined with other agents and shown favorable clinical activity and toxicity in selected populations.[187–189] Two other nucleoside analogs, fludarabine and cladribine, were subsequently found to be clinically active in CLL.[190–193] Phase II–III studies of cladribine monotherapy achieved similar clinical responses as alkylating agent-based treatments (reviewed in 194, 195) but were associated with more cytopenias and immune suppression. The Food and Drug Administration (FDA) approved fludarabine for the treatment of CLL, and thus most studies of purine analog-based therapy in CLL have focused on fludarabine. The remainder of this section will focus predominately on clinical trials of fludarabine.

Fludarabine was initially approved by the FDA for alkylating agent-resistant CLL in 1991 based on two phase II studies demonstrating a high response rate to fludarabine in this patient subset.[190,196] These two studies[190,196] prompted several additional trials of fludarabine as monotherapy in relapsed and previously untreated CLL. Following the observation of high response rates and a 33% CR rate in previously untreated CLL by Keating and colleagues,[197] several large prospective randomized studies in previously untreated CLL patients compared alkylating agent-based regimens to fludarabine. These studies collectively established fludarabine as an accepted standard first-line therapy for CLL based on improved response rates and PFS.[154,198,199] These studies are summarized in Table 83–5. A multicenter European study randomized 196 evaluable patients to fludarabine or cyclophosphamide, doxorubicin, and prednisone (CAP).[154] The overall response rate (ORR) favored fludarabine (60% vs 44%), and this benefit was observed in both relapsed ($n = 96$, 48% vs 27%) and previously untreated ($n = 100$, 71% vs 60%) patients, although the difference was not statistically significant in the untreated group. Fludarabine achieved a longer median duration of response than did CAP, with a tendency toward longer OS in previously untreated patients.[154] A randomized, multicenter American study confirmed these findings in 509 previously untreated CLL patients. Patients were randomized to receive fludarabine 25 mg/m^2 IV daily for 5 days every 28 days, chlorambucil 40 mg/m^2 PO every 28 days, or fludarabine 20 mg/m^2 daily for 5 days and chlorambucil 20 mg/m^2 PO every 28 days, for up to 12 cycles.[169] Patients who failed to respond or relapse were allowed to cross over to the other arm. The combination arm was closed because of excessive toxicity. Fludarabine achieved a superior CR rate, ORR, median duration of remission, and median duration of PFS (20%, 63%, 25 months, 20 months) than did chlorambucil (4%, 37%, 14 months, 14 months). However, there was no statistically significant difference in OS (66 vs 56 months), possibly because of the crossover design. A multicenter French study randomized 938 patients with previously untreated Binet stage B and C CLL to fludarabine, CHOP, or CAP. Although fludarabine achieved better response rates than CAP, overall survival (67–70 months) was identical in all three treatment groups.[199] Thus, single-agent fludarabine achieves superior response rates and duration of PFS than alkylating agent-based regimens. The impact of prognostic factors on response rates and duration of PFS to fludarabine was recently examined; patients with high-risk cytogenetic abnormalities including del(11q22.3) and del(17p13.1) have significantly shorter remission rate abnormalities in response to fludarabine-based therapy than patients with other cytogenetic abnormalities.[166]

Combining Fludarabine With Alkylating Agent Therapy

Fludarabine was combined with cyclophosphamide (Flu/Cy) in three randomized phase III studies (summarized in Table 83–5), based on two promising pilot studies in previously untreated CLL patients, with the goal of improving response rates and hopefully long-term

survival.[183,182] The GCLLSG randomized 375 previously untreated patients (age ≤65 years) to standard fludarabine or Flu/Cy (fludarabine 30 mg/m^2 IV and cyclophosphamide 250 mg/m^2 IV daily for 3 days) every 28 days for 6 cycles.[200] The ORR (94% vs 83%), CR rate (24% vs 7%), median PFS (48 vs 20 months), and duration of treatment-free survival (37 vs 25 months) all favored Flu/Cy, although there were more patients with cytopenias in the combination arm. Furthermore, no difference in OS was observed. EGOG randomized 278 patients to single fludarabine or fludarabine 25 mg/m^2 days 1 to 5, cyclophosphamide 600 mg/m^2 days 1, and G-CSF support every 28 days for 6 cycles.[201] Flu/Cy therapy achieved a superior ORR (74% vs 59%), rates of CR (23% vs 5%) and duration of PFS (32 vs 19 months), although no OS advantage was observed. Most recently, the United Kingdom LRF CLL4 study randomized 777 patients to oral chlorambucil, fludarabine or Flu/Cy.[202] Patients randomized to Flu/Cy enjoyed superior ORR, CR rates, and 5-year PFS rates (94%, 39%, and 33%) than did patients who received chlorambucil (72%, 7%, and 9%) or fludarabine (80%, 15%, and 14%).

Thus, three large, prospective, randomized, multicenter studies in the United States and Europe have clearly demonstrated that Flu/Cy therapy is associated with better response rates and duration of PFS than single-agent fludarabine. However, no OS advantage for upfront Flu/Cy has been observed to date. Although toxicity has generally been manageable, greater hematologic toxicity has been observed with Flu/Cy. Additionally, patients older than 65 or 70, who make up the majority of CLL patients receiving initial therapy in clinical practice, have either been excluded or minimally represented in these trials. Further studies are needed to determine if Flu/Cy is as well tolerated and active in older patients as it is in younger patients. Finally, of these patients long-term follow-up is required to determine the duration of remission, overall survival, and the incidence of potential late complications such as myelodysplasia to fully assess the utility of the Flu/Cy regimen. Examination of outcome by cytogenetic risk groups showed that patients with high-risk cytogenetic abnormalities including del(11q22.3) and del(17p13.1) had a significantly shorter remission than patients in the groups with good-risk or intermediate-risk cytogenetic findings.[166] Thus, the addition of alkylating agents to fludarabine does not appear to alter the poor prognosis associated with high-risk cytogenetic abnormalities.

Rituximab

Rituximab (Rituxan, IDEC-C2B8) is a chimeric murine monoclonal antibody that targets the CD20 antigen on the surface of normal and malignant B lymphocytes, and is the best studied and most widely used monoclonal antibody for the treatment of CLL and B-NHL. CD20, a calcium channel that interacts with the B-cell receptor complex, is an ideal target, because CD20 is expressed in 90% to 100% of CLL and B-NHL and is not internalized or shed. Rituximab induces antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC), activates caspase 3, and induces apoptosis in CLL and B-NHL cells.[203–206] Thus, multiple mechanisms of action likely contribute to rituximab's effectiveness in CLL.

In Phase I clinical studies in indolent B-NHL rituximab 375 mg/m^2 IV was administered weekly for 4 doses, although the dose and length of treatment were empirically determined. The pivotal phase II trial of rituximab was pursued in 166 patients with relapsed or refractory indolent B-NHL including SLL.[207] Although an ORR of 60% was achieved in indolent follicle center B-NHL, only 4 of 30 patients (13%) with SLL/CLL responded. Similarly, disappointing results were obtained in several other small studies enrolling 10 or fewer SLL/CLL patients each.[208–210] Two studies performed by the GCLLSG (n = 28 patients) and the Nordic Study Group (n = 24 patients) demonstrated an ORR of 25% and 35%, respectively, with short remission duration, as summarized in Table 83–6.[211,212]

Responses in each of these studies were predominately in the blood and nodal compartment with little improvement in marrow disease. In contrast, two trials in which higher doses of rituximab weekly (up to 2250 mg/m^2 per dose) or rituximab was administered thrice weekly to relapsed CLL patients showed an improved rate of response.[213–215] Benefit in these two trials was predominately in the blood and nodal disease, although response duration approached that achieved in follicular B-NHL in prior trials. Unfortunately, no patients with del(17p13.1) responded to rituximab administered thrice weekly, indicating that single agent rituximab is ineffective in this high-risk population.[216] Nonetheless, both dose escalation and thrice-weekly dosing improved response rates and established a role for single-agent rituximab in patients with relapsed CLL and provided support for the study of rituximab in combination with other agents in relapsed CLL.

Weekly single-agent rituximab demonstrated greater clinical efficacy when given to patients with previously untreated SLL/CLL (Table 83–7). Forty-four previously untreated patients with SLL/CLL received 4-weekly doses of rituximab 375 mg/m^2; the ORR after the first course of rituximab was 51% (CR 4%). Twenty-eight patients with stable or responsive disease received additional 4-week courses of rituximab every 6 months for up to 4 cycles. However, there was only a modest increase in ORR (58%) and CR rates (9%), and the median duration of PFS of 19 months was shorter than the 36- to 40-month median duration of PFS reported by the same investigators using the same regimen in previously untreated patients with follicle center B-NHL.[217] Nonetheless, this response duration compared favorably with the response duration achieved with fludarabine in the upfront setting, suggesting that rituximab is active and may have a role in the upfront therapy of SLL/CLL.

Rituximab is selective for the B-cell antigen CD20 and therefore has a relatively favorable toxicity profile. Toxicity associated with infusion of this agent commonly occurs with the first infusion of rituximab and may be greater in patients with CLL, compared to patients with NHL. These symptoms generally include fever, rigors, transient hypoxemia, dyspnea, and hypotension, which are partly due to an inflammatory cytokine release syndrome.[218] Although initial studies suggested that patients with high lymphocyte counts may be at greater risk of this cytokine release syndrome, subsequent larger studies failed to support this finding.[218,219] Tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6) levels peak 90 minutes after the start of rituximab infusion and are the likely source of the cytokine release syndrome. Although poorly understood, CLL patients with platelet counts less than 50×10^{12}/L may experience transient, severe thrombocytopenia associated with this infusional toxicity and may require platelet transfusions with the first 1 or 2 doses of rituximab. Patients with preexisting thrombocytopenia should therefore have a posttherapy platelet count after the first 1 or 2 doses of rituximab. Another uncommon, but potentially severe, toxicity is a tumor lysis syndrome, which is generally observed in patients with a high circulating peripheral lymphocyte count.[220,221] Such patients should receive prophylactic allopurinol, hydration, and careful observation, and inpatient monitoring and administration of rituximab can be considered for the highest-risk patients. Patients who develop tumor lysis syndrome following the first dose of rituximab can safely receive subsequent doses, especially after the number of circulating CLL cells is reduced.[220] Other rare toxicities with rituximab therapy include delayed neutropenia,[222–225] hepatitis B reactivation, skin toxicity, and interstitial pneumonitis. Patients with active hepatitis should be followed closely, and prophylactic antiviral therapy should be considered. Patients who develop profound neutropenia, pulmonary, or skin toxicity with rituximab should not be challenged with repeated dosing. In general, rituximab is a very well-tolerated therapy, making it ideal for use in combination with other agents in patients with CLL.

Rituximab Chemoimmunotherapy

Given its activity and toxicity profile, rituximab has been combined with cytotoxic chemotherapy in the treatment of CLL, and clinical trials have examined several such chemoimmunotherapy regimens.[226–230] Studies of chemoimmunotherapy in CLL have focused primarily on fludarabine-based combinations, because of the established role of fludarabine therapy in this disease.[231,232]

Fludarabine and Rituximab

The CALGB 9712 study randomized 104 previously untreated CLL patients to sequential or concurrent fludarabine and rituximab (FR) therapy.[232] Patients received standard fludarabine 25 mg/m^2 days 1 to 5 every 4 weeks for six cycles, with or without concurrent rituximab 375 mg/m^2 on day 1 of each cycle, with an additional dose on day 4 of cycle 1. Patients in both arms received rituximab 375 mg/m^2 weekly for four doses beginning 2 months after completion of fludarabine; thus, patients in the concurrent arm received 11 total doses of rituximab, compared to four in the sequential arm. Patients receiving concurrent FR therapy enjoyed a superior CR rate (47% vs 28%) and ORR (90% vs 77%) than patients in the sequential arm. The median duration of response was not reached at 23 months. The 104 patients in this study experienced an improved ORR rate (84% vs 63%), CR rate (38% vs 20%), 2-year PFS rate (67% vs 45%), and 2-year OS rate (93% vs 81%), as compared to 179 previously untreated patients who received single-agent fludarabine in the prior CALGB 9011 trial.[233] Retrospective analysis of prognostic cytogenetic abnormalities demonstrated that patients with del(11q22.3) and del(17p13.1) have a shorter duration of response to this regimen. Additionally, very few patients more than the age of 75 were treated

on this trial, making its relevance to elderly CLL patients uncertain.

A second multicenter European phase II study administered fludarabine 25 mg/m^2 days 1 to 5 every 4 weeks for six cycles, as well as rituximab 375 mg/m^2 on day 1 of cycles 3 to 6, to 31 evaluable CLL patients. The ORR and CR rate were 87% and 32%, respectively, with similar outcomes in previously treated (ORR 91%, CR rate 45%) and untreated patients (ORR 85%, CR rate 25%). Sixteen patients developed a total of 32 infections, and one patient died of cerebral hemorrhage resulting from prolonged thrombocytopenia.[234] The duration of PFS and the impact of age and prognostic factors were not reported with this trial.

Fludarabine, Cyclophosphamide, and Rituximab

The most active phase II results with chemoimmunotherapy have been achieved with a combination regimen of fludarabine, cyclophosphamide, and rituximab (FCR) in both previously treated and untreated CLL. One hundred seventy-seven evaluable patients with previously treated CLL received fludarabine 25 mg/m^2 and cyclophosphamide 250 mg/m^2 on days 2 to 4 of cycle 1 and on days 1 to 3 of cycles 2 to 6, in addition to rituximab 375 mg/m^2 on day 1 of cycle 1 and 500 mg/m^2 on day 1 of cycles 2 to 6.[235] An ORR of 73%, with a 25% CR rate and 16% nodular PR rate, was reported, and 12 of 37 patients (32%) in CR achieved molecular remission. The same authors administered FCR to 300 previously untreated CLL patients (Table 83–5); the ORR was 94%, with 72% of patients attaining a CR.[236] Remissions were durable, with the rates of 4-year relapse-free survival (RFS) and 4-year OS being 77% and 83%, respectively. The ability to achieve a remission with 1% or less residual CLL cells in the marrow as assessed by two-color flow cytometry significantly affected the duration of RFS and OS. Only 5 of 138 patients (4%) whose posttherapy bone marrow by immunophenotypic analysis demonstrated that 1% or less residual CLL cells relapsed, in contrast to 17 of 62 patients (27%) with more than 1% residual CLL cells by flow cytometry. Toxicity was acceptable, and infectious complications were manageable. A randomized phase III study comparing this regimen to fludarabine and cyclophosphamide in both previously treated and untreated CLL is currently ongoing. To date, data available from the phase II study outlined above suggests this regimen is not well tolerated by CLL patients older than 70 years of age. The impact of high-risk cytogenetic abnormalities on response to this regimen is also not certain.

Pentostatin, Cyclophosphamide, and Rituximab

Although the use of regimens such as FR and FCR to treat patients with have obtained excellent results, the median age of patients in these phase II studies was 63 and 58 years, respectively. In contrast, SEER data indicate that the median age of CLL patients at first treatment is 72 years. Thus, there are limited data on the toxicity profile and efficacy of chemoimmunotherapy regimens in patients more than 70 years of age. A recent phase II study of pentostatin, cyclophosphamide, and rituximab (PCR) in 64 patients with previously untreated CLL indicates that this regimen is effective and may be a particularly good choice for older patients.[237] The median age of participants in this trial was 62.5 years, and 71% of patients had unmutated IgV_H. Patients received pentostatin 2 mg/m^2 on day 1, cyclophosphamide 600 mg/m^2 on day 1, and rituximab 375 mg/m^2 on day 1 (100 mg/m^2 on day 1 and 375 mg/m^2 on days 3 and 5 of cycle 1) every 21 days for up to 6 cycles. Filgrastim was administered beginning on day 3. PCR was well tolerated and clinically active, with OR, CR, and nPR rates of 91%, 41%, and 22%, respectively, being reported. The duration of the median PFS was 33 months. The ability to achieve CR or nPR was not affected by any high-risk genetic or biological factor, with the exception that all three patients with del(17p13) failed to achieve CR or nPR. Patients aged 70 or more tolerated PCR as well as younger patients aged less than 70, with the only notable exception being that older patients required a dose delay of more than 1 week (28% vs 7%, $P = 0.03$). Grade 3 to 4 hematologic (61% vs 48%), infectious (6% vs 11%), and other nonhematologic toxicities (22% vs 28%) were similar in older and younger patients. The OR and CR rates were similar in patients aged 70 or more and those of age less than 70 (83% vs 93%, 39% vs 41%). EFS was identical for older and younger patients, with $P = 0.98$. Thus, the use of PCR should be particularly considered for previously untreated CLL patients aged 70 or more, who constitute approximately half of all patients requiring initial treatment of their CLL. Prophylactic antibiotics and G-CSF should be used as utilized in this study, in order to ensure the reproducibility of these results in CLL patients aged 70 or more.

What Is the Role of Rituximab in CLL?

Studies of rituximab to this point have demonstrated modest clinical activity in both previously untreated CLL patients using the weekly dosing schedule and in the relapsed state using more intensive dosing regimens. Rituximab does not have activity against CLL with del(17p13.1). For this reason, rituximab monotherapy is generally used in either of these settings only if more definitive therapy cannot be administered because of other comorbid conditions. Rituximab's greatest contribution is to combination therapy both in symptomatic, previously untreated CLL patients and relapsed patients receiving the FR, FCR, or PCR regimens. However, phase III studies demonstrating the clear benefit of such approach over traditional chemotherapy (FC) based treatments are required before this can be considered an established standard of care. To this point, no data exist for maintenance rituximab in CLL and this should not be considered out of the context of a clinical trial.

Alemtuzumab

Alemtuzumab (Campath-1H) is a humanized monoclonal antibody against CD52.[238–240] CD52 is a 21- to 28-kd cell-surface glycopeptide expressed on virtually all human lymphocytes, monocytes, and macrophages, a small subset of granulocytes, but not erythrocytes, platelets, or hematopoietic stem cells. CD52 is expressed on all CLL cells and indolent B-NHL cells.[241,242] Its physiological function remains unknown, but crosslinking of CD52 on B-cell and T-cell lymphoma cell lines inhibits their cell proliferation.[243] Alemtuzumab has been demonstrated to mediate apoptosis, CDC, and ADCC of CLL cells in vitro. CD52 is not shed, internalized, or modulated and is therefore an ideal antigen for targeted immunotherapy. However, the ubiquitous expression of CD52 on normal lymphocytes and monocytes is predictive of the increased neutropenia, lymphopenia, and infectious complications observed with alemtuzumab therapy.

Phase I studies of alemtuzumab has established a dose of 30 mg IV three times per week for 4 to 12 weeks. Alemtuzumab induced significantly more infusion-related toxicity than rituximab, but stepped up dosing diminished initial infusion-related toxicity and made administration of the antibody tolerable and feasible. Three milligrams is given on the first day, 10 mg on day 2, and 30 mg on day 3; after dose escalation, patients receive 30 mg thrice weekly. Several clinical studies have established a role for alemtuzumab in CLL, as summarized in Table 83–7.[244–248] In a multicenter European phase II study, alemtuzumab was administered 30 mg thrice weekly for up to 12 weeks to 29 recurrent and refractory CLL patients. The ORR was 42%, but only 1 patient (4%) achieved a CR.[248] Alemtuzumab cleared CLL cells from the peripheral blood in 97% of patients but was less effective at eliminating marrow (36%) or nodal disease (7%).

The pivotal CAM211 trial administered the same regimen of alemtuzumab therapy to 93 heavily pretreated, fludarabine-refractory CLL patients. The ORR was 33%, but only 2% of patients achieved a CR.[245] Median time to progression for responders was 9.5 months, with a median OS of 16 months for all patients and 32 months for responders. The median peripheral blood CLL count decreased by more than 99.9%, but the antibody was less effective against nodal

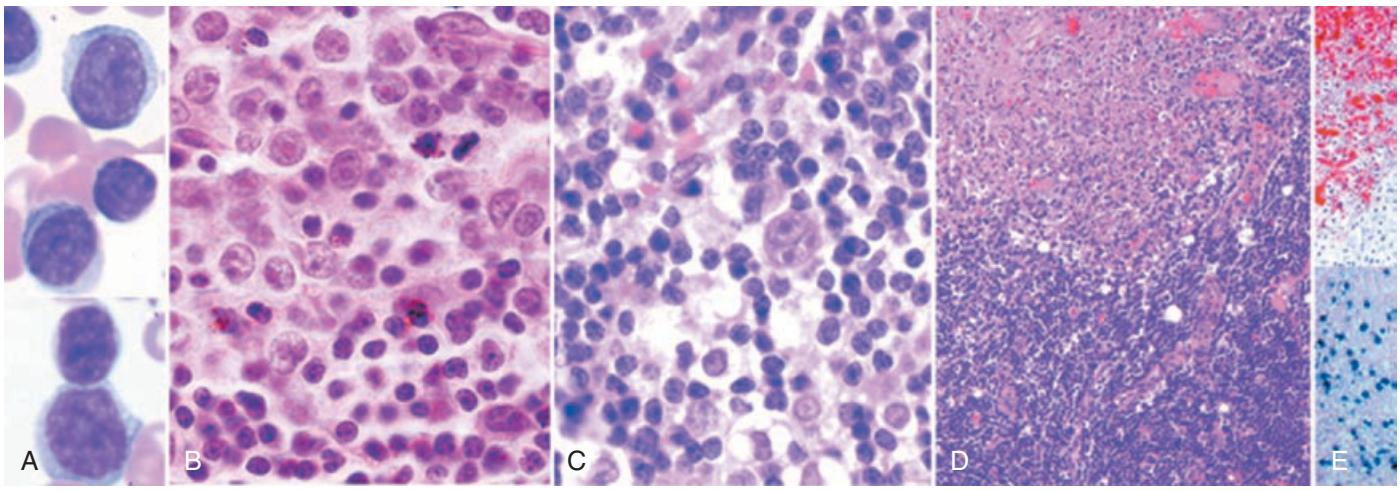

Figure 83–4 Transformation in chronic lymphocytic leukemia (CLL) (**A**–**E**). Some cases of CLL develop increasing numbers of prolymphocytes (**A**), and a "prolymphocytic transformation." A Richter transformation is to a large-cell lymphoma (**B**; large cells upper left, residual CLL lower right). Occasionally, cases can transform to Hodgkin lymphoma (ie, the Hodgkin variant of Richter) (**C**). With the use of fludarabine and other immunosuppressants, patient can also develop Epstein–Barr virus-related lymphadenopathies, or lymphadenopathies with large areas of necrosis due to herpes simplex virus. The case illustrated in **D** and **E** had both (**E**; upper panel shows an immunostain of HSV-1/2 and lower is EBER in situ hybridization).

disease, particularly in patients with bulky lymph nodes greater than 5 cm in diameter. Although 90% of patients with lymph nodes measuring less than or equal to 2 cm responded, with 64% achieving resolution of adenopathy, only 12% of patients with lymph nodes greater than 5 cm responded with no patients attaining resolution of their adenopathy. All patients were placed on prophylactic antibodies and antiviral agents, and treatment-related toxicity was manageable. Patients with a poor performance status did markedly worse than patients with no or minimal symptoms from their disease, likely owing to their reduced ability to tolerate the hematologic and infectious side effects of alemtuzumab, and no patients with ECOG performance status greater than 1 responded to therapy. The activity of alemtuzumab was later confirmed by a multiinstitutional, compassionate use study in 136 patients with fludarabine-refractory CLL.[249]

The German CLL Study Group has recently explored the use of subcutaneous (SC) alemtuzumab for patients with relapsed CLL in an attempt to diminish infusion-related toxicity associated with this regimen. This study administered alemtuzumab 3, 10, and 30 mg IV during week 1, followed by 30 mg SC thrice weekly for 4 to 12 weeks.[250] Forty-six heavily treated patients, with a median of 4 prior therapies, received a median of 838 mg (of the 1123 mg of the planned dose) of alemtuzumab. Despite less infusion-related toxicity, therapy was interrupted in 29 patients due to neutropenia (15), infection (8), or other cytopenias (3). Furthermore, treatment was discontinued early in 26 patients due to a lack of response (12), infection (4), or neutropenia (3). The ORR (36%), CR rate (2%), median duration of PFS (9.7 months), and median OS (13.1 months) were virtually identical to the results achieved with IV alemtuzumab in the CAM211 study. Additionally, the response rate was similar in patients with high-risk cytogenetic abnormalities with del(11q22.3) and del(17p13.1). Thus, SC administration of alemtuzumab appears to be as effective as IV dosing, with less infusion-related toxicity but significant hematologic and infectious toxicity.

Alemtuzumab's other distinguishing feature is its ability to eradicate CLL cells within the bone marrow and to achieve minimal residual disease (MRD) negativity. In a British study, alemtuzumab was administered at a dose of 30 mg IV thrice weekly for up to 16 weeks in (median 9 weeks) to 91 patients with relapsed CLL.[251] The ORR was 54% (CR 36%), and 18 patients had no evidence of disease as determined by flow-cytometric analysis. With a median follow-up of 36 months, the median treatment-free survival was significantly longer (not reached) in patients with no MRD in the bone marrow as compared to patients who achieved a CR but had MRD in the marrow (20 months) or MRD-positive PR (13 months). The 5-year OS was 84% for the 18 MRD-negative patients. However, this study also illustrated alemtuzumab's relatively poor activity as a single agent in patients with bulky nodal disease.[251] The ORR was 87% in 33 patients with no lymphadenopathy (CR 72%), compared to only 9% (CR 0%) in 11 patients with lymph nodes greater than 5 cm in size. As a result, the median OS was 30 months for patients whose largest lymph was equal to or less than 5 cm, compared to 9 months for patients with a lymph node greater than 5 cm. Thus, alemtuzumab's ability to eliminate MRD in the bone marrow translated into an improved long-term survival.

In a phase II clinical trial, alemtuzumab was administered at a dose of 30 mg SC three times per week for up to 18 weeks to 41 previously untreated patients with CLL. Except for transient grade 1–2 fever, adverse reactions after the first were minimal. The ORR was 81% on an intent-to-treat basis, and 87% of the 38 patients who received at least 2 weeks of treatment responded.[252] Alemtuzumab effectively cleared the peripheral blood (CR 95%) and bone marrow of evidence of disease (CR + nodular PR 66%) and was effective against the nodal disease (ORR 87%, CR 29%). Some patients who achieved a CR in the marrow required the full 18 weeks of therapy to do so, suggesting that prolonged administration was necessary to clear CLL cells from the marrow. The median time to treatment failure had not been reached at time of study report (18+ months). On the basis of these promising results in the upfront setting, the CAM307 study prospectively randomized 297 previously untreated CLL patients to oral chlorambucil 40 mg/m^2 every 4 weeks for 12 cycles or alemtuzumab 30 mg IV three times per week for up to 12 weeks. All patients on the alemtuzumab arm received prophylaxis for *Pneumocystis carinii* and varicella zoster. Alemtuzumab achieved a superior ORR (83% vs 55%), CR rate (22% vs 2%), and duration of PFS. Additionally, this trial prospectively demonstrated that patients with del(11q13.1) and del(17p13.1) had a superior response to alemtuzumab as compared to chlorambucil. The results of this study are still being analyzed for full publication.

Owing to the ubiquitous expression of CD52 on lymphocytes and monocytes, immunosuppression and infectious complications constitute the most concerning toxicity of alemtuzumab.[237,253,254] Although alemtuzumab also depletes B cells, CD8$^+$ T cells, natural killer (NK) cells, and monocytes, the antibody's most profound effect is its ablation of CD4$^+$ T lymphocytes.[255–257] This delayed recovery of CD4$^+$ T-lymphocytes has been observed by multiple investigators. The absolute CD4$^+$ T-cell count reached a nadir of 2/μL by week 4 and increased only to 84/μL by week 12 in the CAM211 trial.[245] Fur-

thermore, alemtuzumab depleted CD52+ myeloid peripheral blood dendritic cells, inhibiting the ability of peripheral blood mononuclear cells (PBMCs) to present antigen to purified CD4+ T lymphocytes.[258] This effect may explain the ability of alemtuzumab to prevent graft-versus-host disease (GVHD) following allogeneic stem cell transplantation.[259,260]

Given this prolonged immunosuppression, alemtuzumab should be administered carefully, particularly when the antibody is given in combination with other immunosuppressive agents such as fludarabine. Patients receiving alemtuzumab are at an increased risk for bacterial, fungal, viral, and other opportunistic infections as demonstrated by multiple clinical trials. For instance, 55% of patients in the CAM211 study developed infections (27% grade 3–4), and 13% experienced septicemia.[246] Patients receiving alemtuzumab must therefore be placed on appropriate prophylaxis for *P carinii* pneumonia and varicella zoster infection/reactivation. Additionally, cytomegalovirus (CMV) infection monitoring by PCR or hybrid capture assays should be performed regularly during and for at least 2 to 3 months after therapy with alemtuzumab. Patients who reactivate CMV should be treated appropriately. With these prophylactic measures, alemtuzumab can be administered safely and with acceptable infection-related morbidity in most patients.

Infusion-related toxicity is another event that occurs predominately with IV alemtuzumab. In the CAM211 study, infusion-related events occurred in 93% of patients, although the majority of reactions were grade 1 or 2. Rigors (90% overall, 14% grade 3), fever (85% overall, 17% grade 3, 3% grade 4), and nausea (53%) were the most common infusion-related toxicities.[245] Similar rates of developing rigors (71%), fevers (65%), and nausea (45%) were reported in the multicenter, compassionate use study, and almost all infusion-related toxicities were grade 1 or 2.[249] Most toxicity was observed with the first infusion.[246] This first-dose cytokine release syndrome involves TNF-α, IFN-γ, and IL-6.[260] TNF-α is the primary cytokine in this syndrome, with an increase of greater than 1000-fold in levels after alemtuzumab infusion.[261–263] Ligation of the low-affinity Fcδ receptor for IgG, FcδRIIIa, on NK cells resulted in release of TNF-α and may play a central role in inducing this infusional toxicity.[260] Corticosteroids may be administered if the infusion-related toxicity is severe, and side effects generally abate with steroid therapy.

The ubiquitous presence of CD52 on hematopoietic cells is predictive of the significant hematologic toxicity following alemtuzumab therapy. The multicenter, compassionate use study observed that 26% of the patients developed neutropenia (22% grade 3 or 4), 35% thrombocytopenia (23% grade 3 or 4), and 21% of the patients developed anemia (11% grade 3).[249] Many patients who develop cytopenias after alemtuzumab experience grade 3 or 4 toxicity, resulting in potentially severe infectious complications. Although infusion-related toxicity can cause discomfort to patients, hematologic toxicity and infectious complications are the most serious toxicities. These toxicities are clinically manageable with proper monitoring of peripheral blood counts, appropriate antibiotic prophylaxis, and routine CMV screening. Both G-CSF and GM-CSF should be avoided, as each may increase toxicity without improving granulocyte recovery.[262,264]

Chemoimmunotherapy With Alemtuzumab

Several groups have pursued adding alemtuzumab, similar to rituximab, either concurrently or sequentially with several chemotherapeutic agents for the treatment of previously treated or symptomatic untreated CLL patients. Results of these studies have not yet translated to a standard therapy used for the treatment of patients with CLL.

Fludarabine and Alemtuzumab

A small study of six CLL patients, refractory to fludarabine alone and alemtuzumab alone, suggested that such synergy may exist clinically. Fludarabine was given at a dose of 25 mg/m^2 IV for 3 to 5 days, and alemtuzumab was administered at 30 mg IV three times weekly for 8 to 16 weeks. Five patients responded, with 1 patient achieving CR; furthermore, MRD was undetectable using flow cytometric analysis in two patients. Patients received prophylaxis for PCP and VZV, and no serious adverse events were noted.[265] A German study confirmed these findings in a phase II study of 36 relapsed CLL patients who received fludarabine 30 mg/m^2 IV and alemtuzumab 30 mg IV for 3 days every 28 days for four to six cycles based on toxicity and response. The study achieved an ORR of 83%, with 30% CR; the median time to progression (TTP) was 13 months, and the median OS was 36 months. Although one heavily pretreated patient died of a fever of unknown origin, infection-related toxicity was tolerable. Median CD4 counts did not return to near normal for 14 to 18 months, so prolonged PCP and VZV prophylaxis should be considered.

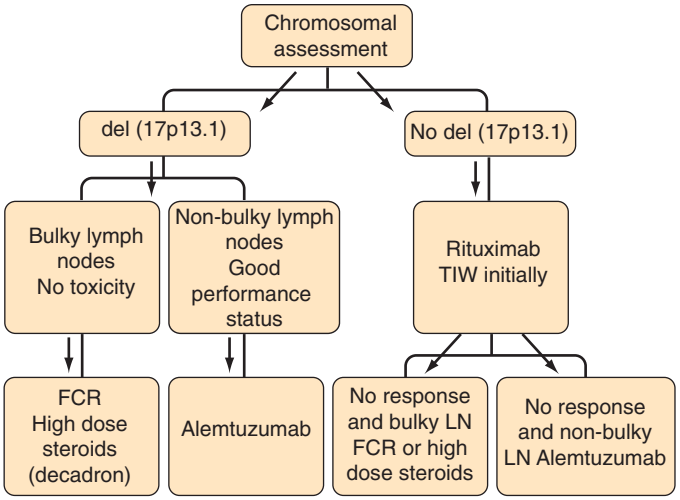

Figure 83–5 Algorithm to treatment approach to first relapsed chronic lymphocytic leukemia.

FCR + Alemtuzumab

Another phase II study added alemtuzumab to FCR, to determine if efficacy could be improved in previously treated CLL patients. Seventy-eight patients with relapsed CLL received fludarabine 25 mg/m^2 on days 2 to 4, cyclophosphamide 250 mg/m^2 on days 2 to 4, rituximab 375 mg/m^2 (cycle 1) or 500 mg/m^2 (cycles 2–6) on day 2, and alemtuzumab 30 mg IV on days 1, 3, and 5 every 28 days for up to six cycles.[266] Patients received pegfilgrastrim, as well as prophylaxis, for PCP pneumonia and CMV reactivation. Grade 3–4 neutropenia was seen in 89% of patients, and 59% developed grade 3–4 thrombocytopenia. The incidence of major infections (11%), minor infections (28%), and fever of unknown origin (36%) were similar to the same institution's historical experience with FCR in the relapsed setting. However, prophylactic valganciclovir was significantly more effective in preventing CMV reactivation (3 of 30 patients, 10%) than was prophylactic valacyclovir (25 of 48 patients, 52%). The ORR was 65%, with 24% of patients achieving CR. Median duration of PFS was 27 months for the 19 patients achieving CR, compared to only 10 months for the 32 patients attaining PR. Significantly better results were observed in patients who were sensitive to their last fludarabine regimen (ORR 74%, CR rate 36%), compared to patients refractory to fludarabine (ORR 49%, CR rate 6%). Given these promising results, a phase II study of CFAR in previously untreated patients is presently being conducted.

Alemtuzumab as Consolidation Therapy After Chemotherapy

Given the ability of alemtuzumab to clear bone marrow of CLL cells and to eliminate MRD, several investigators have examined the use

of alemtuzumab as consolidation therapy after initial induction therapy with fludarabine. In one report, alemtuzumab was administered at a dose of 10 or 30 mg IV thrice weekly for 4 weeks to 58 patients who had responded to their most recent therapy but still had residual disease.[267] The ORR was 53%, and the response rate was dose dependent; 65% of patients who received 30 mg responded as compared to 39% of patients who received 10 mg. Eleven of 29 patients (38%) achieved an MRD-negative marrow, and the TTP was not reached after a median follow-up of 24 months. In addition, the TTP was significantly longer in patients who had no marrow MRD after alemtuzumab consolidation. Similar findings were reported by the GCLLSG, which randomized 21 eligible patients, who had responded to fludarabine or Flu/Cy induction therapy but still had persistent disease, to observation ($n = 10$) or alemtuzumab 30 mg IV thrice weekly for up to 12 weeks ($n = 11$). The study was discontinued early as a result of increased toxicity in the alemtuzumab arm; 6 of 11 patients experienced grade 4 hematologic toxicity, and 7 of 11 patients developed grade 3 or 4 infectious complications, including 4 patients with CMV.[268] However, five of six evaluable patients had no MRD in the marrow with alemtuzumab consolidation. After a median follow-up of 48 months, the median PFS favored the alemtuzumab arm (not reached vs 20.6 months) with only 3 of 11 patients who received alemtuzumab relapsing.[269] On the basis of these promising results, the GCLLSG FLL2i study is currently evaluating the optimal dose and schedule of alemtuzumab consolidation after initial fludarabine-based therapy.

The administration of alemtuzumab subcutaneously (SC) has also been examined in the consolidation setting. The CALGB 19901 study administered fludarabine 25 mg/m^2 IV daily for 5 days every 28 days for six cycles, followed by alemtuzumab 30 mg subcutaneously thrice weekly for 6 weeks, to 28 patients (24 evaluable) with previously untreated CLL.[270] The ORR after fludarabine induction was only 36% (CR 4%), and 18 patients with stable or responsive disease went on to receive alemtuzumab. Twelve of these 18 patients responded, and 4 of 8 patients converted from a PR to a CR, for a final intent-to-treat ORR of 50% (CR 18%). Treatment was well tolerated, with only 3 of 18 patients reactivating CMV with alemtuzumab therapy. The CALGB 10101 study is currently examining a phase II regimen of concurrent fludarabine and rituximab for six cycles, followed by SC alemtuzumab for 6 weeks as consolidation therapy.

What Is Alemtuzumab's Role in CLL?

As a result of the ubiquitous expression of CD52 on lymphocytes and monocytes, alemtuzumab causes significantly more hematologic and immune toxicity than does rituximab, and careful monitoring of and prophylaxis for potential infections is required for any administration of alemtuzumab. Nonetheless, infectious complications are manageable with adequate antibiotic prophylaxis and careful monitoring for potential CMV reactivation. Infusion-related toxicity to intravenous administration of alemtuzumab is manageable with a stepped up dosing schedule, and infusion-related toxicity usually diminishes as therapy progresses. Alemtuzumab most effectively clears CLL cells from peripheral blood and bone marrow, but has limited activity against nodal disease, particularly bulky lymph nodes. Initial studies indicate that SC administration is as effective as IV dosing; although SC dosing markedly diminishes infusion toxicity, hematologic and immune side effects remain. Despite its limitations, alemtuzumab is the only approved therapy for CLL that has clinical activity in relapsed patients with del(17p). In addition, alemtuzumab is able to eliminate MRD from the bone marrow, thereby improving long-term OS. Thus, alemtuzumab has a role in the treatment of high-risk CLL, although it should always be used carefully. Current studies are focusing on the use of alemtuzumab in combination with fludarabine, such as the CFAR protocol at the MD Anderson Cancer Center, or as consolidation therapy after fludarabine induction (CALGB 10101 study). Until the toxicity and response data from such studies are published, the use of alemtuzumab in combination regimens should be reserved for clinical trials and should not be employed in standard clinical practice.

TREATMENT OF PATIENTS WITH RELAPSED CLL

The approach to reinitiating therapy for CLL patients who have relapsed after initial therapy is similar to that applied for initial therapy assessment. Patients need not receive therapy at the first sign of relapse. Rather, patients should have an indication for treatment, as discussed above. Patients should have repeat interphase cytogenetic analysis of the peripheral blood or bone marrow aspirate, as patients may acquire additional cytogenetic abnormalities most notably del(17p13.1) as their CLL becomes more advanced. The incidence of del(17p13.1) increases from 5% of patients at initial diagnosis to nearly half of heavily treated patients with advanced CLL, and acquisition of this abnormality has profound implications on treatment, as will be discussed below. IgV_H mutational analysis does not need to be performed if such information has been obtained previously, as a patient's IgV_H mutational status does not change with time. A bone marrow should be performed if cytopenias are present, to confirm that CLL is the cause and to exclude other potential causes of cytopenias such as transformed lymphoma, prolonged marrow toxicity from prior therapy, or development of treatment-related myelodysplasia. Patients should be treated according to the indications outlined in Table 83–4. An algorithm to our treatment approach to first relapsed CLL is summarized in Fig. 83–2. In general for the patient under the age of 70 who has experienced a good remission with initial therapy (>12 months), an FCR regimen preferably in combination with an investigational agent is suggested. If a complete remission is obtained in the absence of del(17p13.1) being present, our approach at this point is to observe. If a del(17p13.1) is present or a complete response to therapy is not obtained, we generally will consider a nonmyeloablative stem cell transplant. For patients relapsing who are 70 years or older, retreatment with the same therapy or an alternative antibody or investigational agent can be considered. In general, we do not administer FCR to this patient population owing to concerns of increasing toxicity.

Stem Cell Transplantation

For many years, autologous and allogeneic stem cell transplants (SCTs) were generally used for treatment of CLL late in the course of the disease. However, trials of SCTs have indicated that patients with multiply relapsed and chemotherapy-resistant disease are at highest risk for both relapse and treatment-related morbidity and mortality (TRM). Additionally, many patients with heavily treated CLL cannot be adequately cytoreduced or disease control cannot be maintained for a sufficient period of time to obtain insurance approval, producing a selection bias that often excludes patients with the most refractory or aggressive disease from actually receiving SCT. The recognition that patients with poor prognostic features such as del(11q22.3) and del(17p13.1) and patients who fail to achieve CR after receiving regimens such as FCR have a short remission duration to initial therapy has prompted many transplant centers to consider earlier application of SCT as therapy for CLL, including as consolidation treatment after induction therapy for the highest-risk patients. Referral of high-risk CLL patients at the time of initial treatment to an experienced transplant center for evaluation, potential tissue typing of the patient and his or her siblings, and initiation of an unrelated donor search (if needed) should be considered. Although historical data on autologous SCT is reviewed in this chapter, nonmyeloablative allogeneic SCT is the preferred modality for most patients requiring a transplant unless a suitable allogeneic donor is not available.

Autologous Stem Cell Therapy

Results of studies of high-dose therapy with autologous stem cell rescue, or autologous SCT, have varied considerably as a result of

patient selection and the variable use of stem cell purging. A British MRC study of autologous SCT in 65 patients attained a 5-year DFS and OS of 52% and 78%, respectively, and 16 of 20 evaluable patients achieved molecular remission.[271] In contrast, unmutated IgV_H remained an adverse prognostic factor despite autologous SCT in a retrospective German study of 58 CLL patients.[272] The median time to relapse was 37 months in the unmutated IgV_H group (n = 38), whereas only 1 of 20 mutated IgV_H patients relapsed 4 years after SCT. A retrospective case–control study matched 44 CLL patients who underwent autologous SCT with 44 similar CLL patients who did not.[272] Unmutated IgV_H was seen in 66% of patients in both cohorts. Median survival from diagnosis for unmutated IgV_H patients favored autologous SCT (139 months vs. 73 months; hazard ratio 0.31). Thus, although autologous SCT may benefit CLL patients with unmutated IgV_H, the results of autologous SCT in unmutated IgV_H patients is inferior to those achieved in mutated IgV_H patients.

The largest study of autologous SCT for CLL was performed by the Dana-Farber Cancer Institute in 137 patients, 90% of whom were IgV_H unmutated.[274] Patients received cyclophosphamide 120 mg/kg IV and 1400 cGy of total body irradiation (TBI), followed by infusion of anti-CD20-, anti-CD10-, and anti-B5-purged autologous bone marrow. The 100-day mortality was 4%, and 6-year PFS and OS were 30% and 58%, respectively. Thirteen patients (9%) developed myelodysplasia (MDS) at a median of 36 months after SCT.

Despite these promising results, autologous SCT for relapsed CLL is not routinely pursued. First, most CLL patients are poor candidates for autologous SCT because of bone marrow infiltration by CLL and contamination of the autologous stem cell product despite cytoreductive therapy.[275] Second, myelosuppression due to prior therapies such as fludarabine negatively affects autologous stem cell mobilization; in the MRC study, peripheral stem cell mobilization was unsuccessful in 33% of patients.[271] Third, secondary MDS or AML is a major concern, with 8% of patients in the MRC study and 9% in the Dana-Farber study developing MDS/AML.[271,274] Finally, no study has demonstrated a survival plateau for autologous SCT in CLL. Given these limitations, the major focus of clinical research in SCT for CLL has shifted to allogeneic SCT.

Myeloablative Allogeneic Stem Cell Therapy

Allogeneic SCT offers several theoretical advantages over autologous SCT in CLL. Contamination of the stem cell source and inadequate stem cell collection are not obstacles, and use of an allogeneic donor provides an immunologic graft-versus-leukemia (GVL) effect. Limited data suggest that TBI-containing conditioning regimens are superior to chemotherapy-only regimens in CLL transplant patients. A small study of 25 patients demonstrated a 100-day treatment-related mortality (TRM) of 57% in patients who received busulfan and cyclophosphamide (Bu/Cy; n = 7), compared to 17% for patients who received a TBI regimen (n = 18). Five-year actuarial survival was 56% for 14 patients transplanted with TBI regimens during 1992–1999.[276] A study of Cy/TBI in 28 CLL patients observed a 100-day TRM of 11%. Five-year PFS and OS were 78% and 78% for chemosensitive patients, compared to 26% and 31% for refractory patients.[277]

A retrospective EBMT study of 135 patients showed 54% 3-year OS and 40% 100-day TRM.[277] The IBMTR reported similar findings, with 45% 3-year OS and 30% 100-day TRM in 242 patients.[278] The high TRM may be explained in part by the late stage of the disease in many of these patients. Median time from diagnosis to SCT was 41 and 46 months in these two studies, and 37% of patients in the EBMT study were chemorefractory prior to transplant.[278,279] In a Canadian study of allogeneic SCT in 30 CLL patients, the 5-year EFS and OS were both 39%, with 48% OS for patients with sibling donors.[280] The role of unrelated donor allogeneic SCT was examined by a multicenter study in 38 patients, 92% of whom received TBI.[281] Five-year FFS and OS were 30% and 33%, and TRM was 38%. Although there are no prospective randomized studies, a retrospective comparison showed a 3-year DFS of 57% for allogeneic SCT, versus 24% for purged autologous SCT.[282] Finally, allogeneic SCT appears to overcome the adverse prognosis associated with an unmutated IgV_H; an analysis of 34 CLL patients who underwent SCT found that only 2 of 14 patients who received allogeneic SCT relapsed, compared to 13 of 20 patients who underwent autologous SCT.[283]

Thus, myeloablative allogeneic SCT may provide superior DFS to patients with CLL, as compared to autologous SCT. Although the 3-year DFS after allogeneic SCT is approximately 50%,[276–279,282] longer follow-up is needed to determine if the disease remissions are durable. However, this DFS advantage is offset by significantly higher TRM,[278,279] thus limiting the use of allogeneic SCT in CLL. Limited data indicate that Bu/Cy may be particularly toxic in this population; by contrast, TBI regimens have acceptable TRM.[276] To preserve the immunologic GVL effect while reducing TRM, the focus of clinical SCT research in CLL has turned to nonmyeloablative, or reduced-intensity, allogeneic SCT.

Nonmyeloablative Allogeneic Stem Cell Therapy

Ideally, the goal is to harness the GVL effect of allogeneic SCT for patients with CLL, while reducing TRM from acute GVHD, acute infection, and organ toxicity associated with myeloablative conditioning. Fludarabine, busulfan, and ATG were administered to 30 German CLL patients; the stem cell source was a matched related (n = 15) or unrelated (n = 15) donor.[284,285] Grade 2 to 4 acute GVHD was observed in 56% of patients, while 75% developed chronic GVHD.[285] Responses were seen in 93% of patients, with 40% achieving CR. Of note, it took up to 2 years for patients to achieve CR, suggesting a GVL effect. All patients achieved a molecular CR by PCR, but only six patients were in continued molecular CR after a median follow-up of 2 years. Two-year TRM, PFS, and OS were 15%, 67%, and 72%, respectively.[285]

The EBMT retrospectively examined 77 CLL patients who received a variety of nonmyeloablative conditioning regimens, following by allogeneic SCT.[286] The 1-year TRM was 18%, and the 2-year probability of relapse was 31%. Two-year DFS and OS were 56% and 72%, respectively. Nineteen patients received donor lymphocyte infusions (DLIs) for relapse or incomplete donor chimerism, but only seven responded to DLI (37%). Unfortunately, this study was complicated by the heterogeneity of conditioning regimens and the use of ATG or Campath-1H for T-cell depletion of the grafts in 40% of patients. A retrospective analysis of 73 CLL patients who underwent nonmyeloablative SCT and 82 patients who underwent myeloablative allogeneic SCT showed that the TRM was significantly reduced in the former group, with a hazard ratio of 0.4; however, there was no difference in EFS or OS between the two groups.[287]

Sixty-four patients received 200 cGy of TBI, with (n = 53) or without (n = 11) fludarabine, followed by an allogeneic SCT from a related (n = 44) or unrelated (n = 20) donor.[288] The 2-year DFS and OS were 52% and 60%, respectively, and the 2-year TRM was 22%. The incidence of relapse at 2 years was 26%, and the mortality due to relapse was 18%. Finally, a British study of 41 CLL patients who received fludarabine, melphalan, and alemtuzumab, followed by an allogeneic SCT from a related (n = 24) or unrelated (n = 17) donor observed a 2-year OS and TRM of 51% and 26%.[289] Eleven patients (27%) relapsed and received escalated donor lymphocyte infusions, but only three patients had a sustained response to DLI. Five patients (12%) have died of relapse.

Nonmyeloablative allogeneic SCT may be superior to autologous SCT in obtaining clinical and molecular remissions in high-risk CLL patients with unmutated IgV_H, due to a GVL effect. Seven of nine patients (78%) in a German study became negative by PCR for allele-specific IgV_H after d+100 post-SCT; attainment of molecular CR occurred after DLI or development of chronic GVHD.[290] In contrast, only 6 of 26 control CLL patients (23%) achieved a PCR-negative state after autologous SCT. Similar findings were reported by a

Spanish study of nonmyeloablative SCT in 30 CLL patients.[290] The 6-year EFS and OS were 92% and 90% patients with unmutated IgV_H or del(11q). Thus, an immunologic GVL effect appears to be important in CLL and may confer a long-term survival advantage for allogeneic over autologous SCT, given sufficient time.[291]

Investigational Agents Currently in Phase II–III Testing for Relapsed CLL

Although there are numerous therapeutic agents currently being tested in CLL, many likely will be ineffective. Attention is therefore directed toward agents that are currently in phase III registration studies based on preliminary efficacy in relapsed CLL.

HuMax CD20 (Ofatumumab)

HuMax CD20 (ofatumumab) is a fully humanized, high-affinity monoclonal antibody that targets a different epitope on CD20 molecule than rituximab. HuMax CD20 has higher affinity binding to CD20 and activates CDC more effectively than rituximab, suggesting that it may have more effective anti-tumor activity. Results of a phase I/II trial included 26 patients treated at the phase II dose and demonstrated an ORR of 46% (12 of 26 evaluable patients) with 1 nPR and 11 PR.[292] The median time to TTP was 161 days in responders, and median time to next CLL therapy was 366 days. The AUC of HuMax CD20 correlated with both TTP and time to next therapy, whereas clearance of ofatumumab (median 10 mL/h; range 3–42) correlated inversely with clinical outcome. Toxicity was predominately grade 1–2 infectious events in 48% of patients, although patient developed life-threatening interstitial pneumonitis. A phase III registration study of ofatumumab in patients with CLL resistant to alkylating agents, fludarabine, and alemtuzumab is ongoing. There are currently no data on the efficacy of HuMax CD20 in CLL patients with high-risk cytogenetic abnormalities.

Lumiliximab (IDEC-152)

CD23, a 45-kd low-affinity IgE receptor, is another potential target of monoclonal antibody therapy, as the antigen is expressed on almost all CLL cells. In vitro studies of a chimeric macaque-human anti-CD23 monoclonal antibody, Lumiliximab (IDEC-152), demonstrated that cross-linked lumiliximab was able to induce apoptosis in primary CLL cells, and that this apoptosis was enhanced by fludarabine and rituximab.[293] In an initial phase I study, 46 patients with relapsed CLL received lumiliximab 125–500 mg/m^2 IV weekly or thrice weekly for 4 weeks.[294] Toxicity was observed in 89% of patients, but only 15% developed grade 3 or 4 toxicity. A decrease in the degree of peripheral lymphocytosis was observed in 91% of patients, and 28% experienced more than a 50% reduction in their lymphocyte count. Reduction of nodal disease was seen in 52% of patients. A subsequent phase II study by the same investigators examined the combination of lumiliximab and FCR.[295] Thirty-one relapsed CLL patients received fludarabine 25 mg/m^2 and cyclophosphamide 250 mg/m^2 on days 2 to 4 of cycle 1 and on days 1 to 3 of cycles 2 to 6, rituximab 50 mg/m^2 and 325 mg/m^2 on days 1 and 3 of cycle 1 and 500 mg/m^2 on day 1 of cycles 2 to 6, and lumiliximab 50 mg/m^2 and 325 or 450 mg/m^2 on days 2 and 4 of cycle 1 and 375 or 500 mg/m^2 on day 1 of cycles 2 to 6, every 28 days for up to six cycles. Grade 3 or 4 toxicity, primarily hematologic, was observed in 65% of patients. The ORR was 71%, with 52% of patients attaining a CR. Patients with del(11q22.3) but not del(17p13.1) experienced high response rates and durable remissions to this therapy. On the basis of these promising results, a randomized phase III study comparing FCR alone to the combination of FCR and lumiliximab is under way.

Lenalidomide

Lenalidomide, or 3-(4-amino-1,3-dihydro-1-oxo-2*H*-isoindol-2-yl)-2,6-piperidinedione (Revlimid), is an immunomodulatory drug (IMiD) that is a more potent analog of thalidomide and targets the tumor microenvironment. At this time, the mechanism of action of this agent in CLL is uncertain. Lenalidomide 25 mg PO was given for 21 days every 28 days for up to 12 months to 45 patients with relapsed CLL.[296] A flare reaction was observed in 50% of patients (8% grade 3–4), and several patients discontinued therapy as a result of the flare reaction. The flare reaction clinically presents with sudden onset of tender enlargement of lymph nodes and/or spleen associated with fever and/or rash. Some patients can experience an increased white blood cell count. Low-dose prednisone, 20 mg daily, can alleviate the flare reaction. Hematologic toxicity associated with lenalidomide therapy was significant, with grade 3 to 4 neutropenia and thrombocytopenia occurring in 70% and 45% of patients, respectively, but only 5% of patients developed grade 3 to 4 infectious complications. The intent-to-treat ORR was 47%, with 9% patients achieving a CR. Lenalidomide was administered at a dose of 10 mg daily to 35 patients with relapsed CLL in one trial; dose escalation by 5 mg daily every 28 days was allowed, but median dose was 10 mg daily.[297] The ORR of the first 22 patients was 32%, with one patient achieving a CR. Nine additional patients had stable disease or experienced clinical benefit. In each of these two lenalidomide trials, a small number of responses were noted in CLL patients with del(11q22.3) and del(17p13.1) although data on their durability are not available. On the basis of these promising phase II clinical studies, a large, multicenter trial randomizing patients to low-dose (10 mg) or high-dose (25 mg) lenalidomide is currently under way in patients with relapsed and refractory CLL. Because of the potential for life-threatening tumor flair and other toxicity with lenalidomide, this agent should only be considered as part of a well-designed clinical trial despite its FDA approval for other indications (MDS and multiple myeloma).

Flavopiridol

Flavopiridol (alvocidib) is an *N*-methylpiperidinyl, chlorophenyl flavone that induces caspase 3-dependent apoptosis of primary CLL cells.[298] Caspase 3 acts distal to p53; thus, induction of apoptosis by flavopiridol is p53 independent.[299] Flavopiridol also induces profound reduction in Mcl-1 and XIAP expression in CLL cells in vitro.[300] Phase I clinical studies determined a safe, tolerable dose of 50 mg/m^2/day given by 72-hour continuous IV infusion (CIVI).[299] Unfortunately, phase II studies administering flavopiridol by 24- to 72-hour CIVI failed to show any clinical activity. Despite plasma flavopiridol concentrations of 200 to 400 nM, apoptosis was not seen in peripheral blood mononuclear cells of patients who received this CIVI schedule.[301,302] This lack of efficacy in CIVI dosing schedules was due to increased binding of flavopiridol to human serum proteins. Free flavopiridol concentration decreased from 63%–100% to 5%–8% if human plasma was used instead of fetal calf serum when performing in vitro studies, resulting in an increase in 1-hour and 24-hour LC_{50} values from 670 and 120 nM to 3510 and 470 nM, respectively.[302,303] Thus, CIVI dosing did not achieve pharmacologically effective drug concentrations, resulting in the lack of clinical responses.[301–303] Bolus dosing achieves the necessary LC_{50}; a phase II CALGB study giving flavopiridol 50 mg/m^2 by 1-hour IV bolus (IVB) for 3 consecutive days to 36 relapsed patients observed 4 PR (ORR 11%), and one patient experienced a tumor lysis syndrome (TLS).

Pharmacokinetic (PK) modeling indicated that a dosing schedule of a 30-min IVB followed by 4-hour CIVI would achieve a target $C_{4.5hr}$ of 1.5 *n*/4 and induce apoptosis of CLL cells in vivo. On the basis of this PK model, investigators conducted a phase I study of flavopiridol in patients with relapsed CLL.[304] The planned dose escalation was 30 to 80 mg/m^2 30-min IVB followed by 30–80 mg/m^2 4-hour CIVI weekly for 4 weeks, every 6 weeks for up to six

cycles. DLT was observed at dose level 2 (40 mg/m^2 30-min IVB + 40 mg/m^2 4-hour CIVI), with two of three patients developing grade 4 to 5 tumor lysis syndrome. Decreasing the dose to 30 mg/m^2 30-min IVB + 30 mg/m^2 4-hour CIVI, increased safety precautions, aggressive monitoring of serum potassium, and prompt intervention for hyperkalemia allowed safe administration of the drug. Subsequent cohorts in the phase I study demonstrated that the 4-hour CIVI could be safely escalated to 50 mg/m^2 after the initial treatment. This increase in the 4-hour CIVI dose from 30 to 50 mg/m^2 increased $C_{4.5hr}$ from 0.96 to 1.55 μM, with a concomitant increase in antitumor activity, as measured by a median rise in LDH. A tumor lysis syndrome requiring hemodialysis with first treatment dose was observed in 3% of patients with WBC less than 200 × 10^9/L, but 63% of patients with WBC counts of 200 × 10^9/L or more. Therefore, patients with extremely high peripheral lymphocyte counts should undergo cytoreduction before receiving flavopiridol. Nineteen of the first 42 patients in the phase I study responded (45%), including 5 of 12 patients (42%) with del(17p), 13 of 18 patients (72%) with del(11q), and 16 of 31 patients (51%) with bulky lymph nodes more than 5 cm in size.[305] The median duration of PFS was 12 months. Phase II studies are under way in CLL, as are clinical trials to examine flavopiridol as consolidation therapy for patients with MRD, as single-agent therapy for acute leukemias and lymphomas and as part of fludarabine-based combination regimens.

Other Agents in Clinical Trials for CLL

A variety of other therapeutic agents are currently in early phase I/II clinical trials for CLL or will be entering the clinic within the next year. Therapeutic antibodies or small modular immune pharmaceuticals (SMIP™) targeting surface antigens including CD40 (SGN40, HDC122), HLA-DR, CD19, CD20, and CD37 are under development. Additionally, therapeutic agents targeting signal transduction pathways (HSP-90 inhibitors, AKT inihibitors, PI3K-δ inhibitors, PKC-δ inhibitors, and PP2A activating agents) are in early clinical development. Finally, agents targeting epigenetic events (histone deacetylase inhibitors, hypomethylating agents, or miR-directed therapy), telomerase (GRN163), or innate immune activation (CpG oligonucleotides or IL-21) have promising preclinical data to support their ongoing early clinical investigation.

SPECIAL CONDITIONS IN CLL

Young Patients (Less Than 50 Years of Age) With CLL

As mentioned previously, CLL is a disease of the elderly, with only 10% of patients being under the age of 50 at diagnosis. Although CLL patients live for a prolonged period of time, young patients without comorbid illnesses have a great potential to have their life significantly shortened by the disease, irrespective of their cytogenetic abnormalities. Additionally, stress associated with job performance, insurance coverage maintenance, and disease-related symptoms are most significant in this age group. Special attention to psychosocial issues related to CLL should occur early in the course of the disease to allow patients to maintain or resume their normal life style as soon as possible. In the absence of impending need for therapy, our approach is generally not to empirically pursue HLA typing or examine transplant options prior to the development of symptomatic disease. Once therapy is initiated for this group of patients, consideration of aggressive intervention to promote prolonged remission duration is always a top priority. SCT is generally considered for patients in this age group with CLL with high risk cytogenetic abnormalities in first remission and for all patients who relapse after initial therapy unless high risk cytogenetic abnormalities are not present and a complete response is attained.

Patients With Fludarabine-Refractory CLL

Fludarabine-refractory CLL is generally considered to exist if a patient has not responded to a fludarabine-based therapy or relapses within 6 months of completing such a regimen. Several retrospective studies have documented a short survival (9 to 12 months) and particularly high frequency of both bacterial and opportunistic infections in this patient population.[306,307] New therapeutic agents such as alemtuzumab (currently approved for use in CLL) and new investigational agents (ofatumumab, lenalidomide, and flavopiridol) have been evaluated in this patient population. Although one group has advocated not pursuing nonmyeloablative allogeneic stem cell transplant until patients reach this state,[308] many patients have bulky lymph nodes or extensive bone marrow involvement that cannot be cleared with traditional or investigational therapies, making them a higher risk for treatment failure. Many patients also develop uncontrollable disease proliferation, Richter transformation, or infection that combined with insurance or regulatory delay prevents transition to this potentially curative intervention in a timely fashion. Therefore, although all patients under the age of 70 with fludarabine-refractory CLL should be considered for transplant, pursuit of this earlier following relapse is the approach used by our group. The complexities of complications, poor therapy options, and acute features of fludarabine-refractory CLL can put great strain on the patient, family members, and general hematologist alike. Referral of such patients to tertiary CLL centers for access to clinical trials and treatment of these specialized needs should be considered for patients with fludarabine-refractory CLL.

Richter Syndrome

Richter syndrome (RS) was described as the development of high-grade lymphoma in patients with CLL by Maurice Richter in 1928.[309] Over the years, the classification of RS has expanded to include lymphoid malignancies like Hodgkin disease, lymphoblastic lymphoma, prolymphocytic leukemia (PLL), and hairy cell leukemia (see Fig. 83–3A–C).[310] Incidence estimates range from 2.8 to 10.7%.[311,312] Recent studies have suggested that the development of RS may be related to the evolution of an abnormal clone unrelated to the underlying CLL clone.[313,314] Clearly identifiable risk factors for the development of RS are lacking, and its development has been shown to be independent of disease stage, duration of disease, type of therapy, or response to therapy.[310] However, the presence of diffuse lymphomatous involvement, advanced Rai stage, ZAP-70 expression, high LDH and β_2M levels may predict the development of RS.[315,316] The RS syndrome is characterized by sudden onset of B-symptoms (fever, night sweats, weight loss) and rapidly progressive lymphadenopathy at any anatomic site. Rarely the lymphomatous clone may arise from the bone or an extranodal site.[310] Laboratory abnormalities include anemia, neutropenia, and thrombocytopenia due to large-cell transformation in the bone marrow. A rapid increase in the serum LDH is seen in the majority of patients, with a significant proportion of patients also exhibiting paraproteinemia.[312] The diagnosis is generally made on examining the histology of a rapidly enlarging lymph node, which typically reveals large-cell lymphoma. Less commonly, the histology may be consistent with a high-grade small noncleaved cell lymphoma, lymphoblastic lymphoma, or hairy cell leukemia.[310] Even though a significant proportion of patients with advanced CLL and RS have abnormal cytogenetics, their prognostic significance has not been established.[317] Trisomy of chromosome 12 in the presence of a complex karyotype may have some correlation with aggressive disease,[318] although it is unlikely to be the only cytogenetic abnormality contributing to the lymphomatous transformation.[309] Historically, RS has been treated with regimens similar to those used for the treatment of large-cell lymphomas involving multiple agents like methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin, dexamethasone, cytarabine, and cisplatin (eg, MACOP-B, CHOP-B, DHAP, and VAD).[312,319] The best overall response rates of approximately 40% have been recently reported

with the CFA (cyclophosphamide, fludarabine, cytarabine) and HyperCVXD-R (fractionated cyclophosphamide, vincristine, liposomal daunorubicin, dexamethasone, and rituximab) regimens.[319–322] The duration of response and the overall survival rates are dismal, with most patients likely to die within 6 months of their diagnosis despite aggressive therapy.[311] Long-term remissions and survival have been reported in a few patients following allogeneic SCT but this approach is associated with an extremely high 30-day transplant-related mortality of around 38%.[323]

Like RS, prolymphocytic transformation (PT) occurs in less than 10% of patients with CLL.[324] PT is characterized by the appearance of large, immature prolymphocytes in the peripheral blood, which make up 10% to 50% of the peripheral circulating malignant lymphoid cells.[325] These patients may be older with advanced disease and have more pronounced lymphadenopathy and splenomegaly.[326] PT is associated with a poor outcome, with limited survival beyond 1 year.[327] Therapeutic options are limited, with patients typically responding poorly to chemotherapeutic agents, including nucleoside analogs.[328] Alemtuzumab has shown promising results in patients with T-PLL, a closely related disorder.[328] Allogeneic SCT may also be utilized as a potentially curative therapeutic option.

Secondary Malignancies in CLL

CLL is associated with an increased risk of secondary malignancies. These include not only hematologic malignancies like MDS and AML associated with the use of chemotherapeutic agents[329] but also solid tumors such as Kaposi sarcoma, malignant melanoma, and laryngeal and lung cancers.[330] The increased incidence of secondary malignancies may be attributable to multiple reasons, including the immune dysfunction associated with CLL, the frequent infectious complications, the carcinogenic side effects of the various chemotherapeutic agents, and the increased and close medical surveillance that patients with CLL receive from trained oncologists.[330,331]

Hypersensitivity in CLL to Mosquitoes and Insect Bites and Treatment

CLL patients commonly exhibit an exaggerated cutaneous response to insect bites. This was first reported by Robert Weed in 1965 who documented a hypersensitivity reaction to insect bites in 8 out of 97 patients with CLL over a 13-year period.[332] The reaction is characterized histologically by the presence of a dermal infiltrate comprising a mixed population of T and B cells, eosinophils, and eosinophilic granule protein.[333] The extent of eosinophilic degranulation may also correlate with the severity of symptoms[334] Clinically, these patients present with recurrent, painful, bullous eruptions that may be traced to an insect bite in some instances.[335] Identification and avoidance of known triggers may be useful in some cases, but most patients are unable to identify the inciting exposure.[333] Treatment with a short course of steroids is usually effective, but these patients frequently relapse and may require multiple courses of therapy. Dapsone and chlorambucil may also be useful in severe, recurrent cases.[333,335]

Other cutaneous conditions are also common in CLL patients, with up to 45% reporting some form of skin involvement.[336] This includes petechial, purpural or ecchymotic lesions related to thrombocytopenia, infectious eruptions like herpes simplex and zoster, and direct leukemic involvement in less than 10% of all patients with advanced disease.[336]

INFECTIONS IN PATIENTS WITH CLL

Infectious complications remain the leading cause of morbidity and mortality in patients with CLL. The incidence of infectious complications has been estimated to be as high as 80%[337,338] with a mortality of approximately 60%.[337,339] Various factors contribute to the increased incidence of infectious complications in CLL, the most important being progressive disease affecting host immunity through an impaired antibody response and hypogammaglobulinemia[340], weakened host cellular immune responses including impaired macrophage function[341], a decrease in T-regulatory cells[342], and finally the acquired defects after immunosuppressive chemotherapy.[306,343,344]

Recent studies have examined predictors of severe infections in patients with CLL. In their retrospective analysis of infection-related mortality in 280 patients, Francis and colleagues[345] identified advanced age, clinical Stage B or C disease, unmutated IgV_H, and positive CD38 status as independent predictors of both shorter time to first infection and infection-related mortality. Other risk factors that may also have an impact on development of infections include type of initial therapy and development of renal insufficiency.[345,346]

Historically, sinopulmonary infections from encapsulated bacteria like *Streptococcus pneumoniae* and *Haemophilus influenzae* have been the most common cause of infectious complications in patients with CLL.[347,348] With the recent use of more potent cytotoxic chemotherapy and the resultant profound myelosuppression, an increased frequency of severe pulmonary infections, bacteremia and gram negative infections has been reported.[337,349] Infections caused by atypical organisms like *Listeria monocytogenes*, *Nocardia* spp, *Mycobacterium* spp, and *Neisseria meningitidis* are relatively infrequent in patients who receive conventional chemotherapy.[350] Treatment for presumed infection can be initiated empirically in CLL patients who develop fever, since fever in CLL patients usually indicates an active infection.[350,351] Therapy should be tailored to the particular organ involved and the sensitivity of the organism. Prophylactic antibiotics can be initiated for debilitated patients with high-risk disease and significant immune dysfunction.

Viral infections are also commonly encountered in CLL patients (see Fig. 83–3D, E). Herpesvirus infections are especially common in patients treated with nucleoside analogs.[351,352] Chronic, indolent oropharyngeal and circumoral herpes simplex virus (HSV) outbreaks are more frequent than aggressive, disseminated visceral disease.[353] Reactivation of Epstein–Barr virus (EBV) has been implicated in some cases of Richter transformation.[354] Other viruses may cause severe systemic disease in patients with CLL. Varicella zoster virus (VZV) can cause herpes zoster, herpetic neuralgia, and rarely meningoencephalitis[306]; Parvovirus B19 can cause severe polyarthritis and pure red cell aplasia[355,356]; and JC polyoma virus has been implicated in the development of progressive multifocal leukoencephalopathy.[357,358] Management of these infections depends on early recognition of disseminated viral disease, timely initiation of antiviral therapy in cases of HSV and EBV, and a low threshold for the introduction of prophylactic acyclovir and supportive therapy. All patients should be provided instruction to identify the signs and symptoms of herpes virus infection at the time of diagnosis of CLL.

Fungal infections are not typically observed in CLL in the absence of treatment with corticosteroids or other immunosuppressive therapy for autoimmune complications arising from CLL. Cryptococcal meningitis, pneumonia, and fungemia are well recognized occurrences in patients with CLL and are associated with significant morbidity and mortality.[359] More cases of *P carinii* pneumonia, systemic candidiasis, and aspergillosis have been reported since the advent of combination nucleoside analog therapy with steroids.[337,360,361] Reactivation of parasitic infections including *Leishmania*[362] and *Strongyloides*[363] have also been reported. Treatment of the infection is dictated by the identification of the particular organism. Trimethoprim-sulfamethoxazole is routinely used as effective prophylaxis against *P carinii* infections, especially during and immediately after the use of nucleoside analogs.[346] Fungal prophylaxis with fluconazole may also be employed during protracted therapy with high dose steroids, although it should be noted that fluconazole will not cover organisms such as Aspergillus.

Prophylactic Strategies for Infections

Routine use of prophylactic antibiotics for CLL is generally not employed despite the higher frequency of infections observed in patients with this disease. Early recognition of signs and symptoms of infection and prompt initiation of empiric broad-spectrum antibiotics is probably a more feasible and cost-effective approach. When chemoimmunotherapy is used that includes a nucleoside analog or alemtuzumab therapy, prophylaxis for herpes simplex and varicella zoster should be used, particularly in older patients. Trimethoprim-sulfamethoxazole (or other alternative PCP prophylaxis) should also administered in this setting.[364,365]

Hypogammaglobulinemia is virtually always present in advanced CLL, and several studies have examined if IVIG replacement therapy can reduce the incidence and severity of infectious complications. Patients receiving IVIG in a double-blinded, placebo-controlled trial[366] experienced significantly fewer bacterial infections than the placebo group. The therapy was well tolerated with few adverse reactions, but there was no observed benefit in terms of preventing viral or fungal infections. However, other studies have shown an almost 50% reduction in the number of serious infections per year with IVIG infusions. Limited data support the use of IVIG at a higher dose of 600 mg/kg every 4 weeks to reduce the number and severity of respiratory infections.[367] However, the prohibitive cost of IVIG therapy and the fact that it has not been shown to prolong survival[368] argues against its empiric use in all patients. IVIG should be used judiciously and reserved for patients with advanced stage disease and recurrent infections. The usual dose used is 200 to 400 mg/kg every 4 to 6 weeks as needed, with the aim of keeping the trough serum IgG concentration greater than 500 mg/dL.

Among the strategies for preventing infection in this patient population is immunization. CLL patients however typically respond poorly to pneumococcal and influenza vaccines.[369,370] Advanced age, advanced disease stage, hypogammaglobulinemia, and low levels of soluble CD23 correlate with response to immunization.[371] Soluble CD23, a degradation product of membrane-bound CD23, is involved in several aspects of B-cell activation and proliferation and has a synergistic effect on histamine release. Histamine has a direct inhibitory effect on immunoglobulin production by B cells in vitro via histamine type-2 (H_2) receptors and also acts as an immune regulatory factor that can be modulated by H_2 receptor antagonists. Thus, responses to vaccines may be further enhanced by adjuvant treatment with H_2 blockers. Studies have shown that response to protein-conjugated vaccines may be enhanced by ranitidine in CLL patients to as much as 90%, compared to 43% in the control group.[372] Unfortunately, this response is not seen with polysaccharide vaccines. Recent studies have indicated that protein-conjugated vaccines may be more immunogenic, as shown by a more significant immune response to *Haemophilus influenzae* type b conjugate vaccine than to plain polysaccharide antigen.[373,374] In light of the paucity of data on an appropriate immunization schedule, we suggest a modified immunization plan based on the recommendations of the Advisory Committee on Immunization Practices.[375]

Growth factors such as granulocyte colony-stimulating factor (G-CSF) or granulocyte macrophage colony-stimulating factor (GM-CSF) can be used prophylactically in high-risk, severely neutropenic patients to shorten the duration and severity of neutropenia.[376]

AUTOIMMUNE COMPLICATIONS OF CLL

Patients with CLL have a greater predisposition to develop autoimmune hematologic complications, including autoimmune hemolytic anemia (AIHA), idiopathic thrombocytopenia purpura (ITP), and pure red cell aplasia. AIHA occurs in up to 37% of CLL patients at some time during the course of their disease. A small proportion (10%–15%) of patients may present with AIHA at diagnosis. AIHA can have a varied presentation, with patients developing signs of anemia, including weakness, lethargy, dyspnea on exertion, and dizziness over a period of months. Examination may reveal pallor, jaundice, hepatosplenomegaly and lymphadenopathy. Hemolysis can cause mild to moderate indirect hyperbilirubinemia, elevated LDH levels, and hemoglobinuria. The direct antiglobulin Coombs test is positive in up to 74% of patients with CLL,[377] but not all patients develop hemolysis. Most of the antibodies produced are warm reactive,[84] but patients can occasionally present with cold agglutination syndrome.[378] The antibodies are mostly polyclonal and usually a product of normal B cells rather than the leukemic clone.[379,380]

In contrast to the high frequency of AIHA in CLL, ITP or ITP and AIHA or Evan syndrome occurs less frequently in CLL. These events can occur throughout the entire course of CLL and is much more difficult to diagnose because of the absence of multiple implicating laboratory features as seen with autoimmune hemolytic anemia.

Given the small number of patients with AIHA, there are no data from controlled trials to guide the management of AIHA. Glucocorticoids have been used since 1940s[381] and are considered the first line of therapy. Most patients will respond to prednisone at a dose of 1 mg/kg for 10 to 14 days, followed by a slow taper over 2 to 3 months depending on the extent of hemolysis. Overall response rates of up to 90%, with 65% complete responses, have been reported with the use of steroids.[382] Unfortunately, approximately 60% of patients relapse when steroid therapy is stopped. IVIG, the next line of treatment, induces responses in 40% of patients.[382,383] Cyclosporine A (CSA) has been used for refractory AIHA at a dose of 5 to 8 mg/kg/day given in divided doses twice daily. The dose should be adjusted to maintain a serum level of around 100 to 150 μg/dL.[384–386] Rituximab has been used as treatment for AIHA with some success,[387] and studies are now examining the impact of rituximab in further reducing the incidence of AIHA when combined with conventional therapy.[388] Similarly, alemtuzumab has been used in combination with steroids or CSA or treatment of AIHA.[389–391] Alemtuzumab can also be effective as a steroid sparing agent.[390] Other treatment modalities include splenectomy[392,393] or splenic irradiation, alkylating agents, danazol, plasma exchange, immunoabsorption as an adjunct to plasma exchange,[394] and vincristine-loaded platelets.[395] Treatment of the underlying CLL is generally required for long-term control of autoimmune cytopenias. However, our practice is to first control the autoimmune process with steroids or other therapies before considering treatment of the underlying CLL. Supportive therapy with periodic red cell transfusions is also important in the management of AIHA.

There are limited data on the routine use of erythropoiesis-stimulating agents (ESA) in patients with Coombs negative anemia.[396,397] These agents are most effective in patients with low levels of endogenous erythropoietin and may improve the quality of life and reduce the frequency of transfusions in this subset of patients. However, given the recent data on the increased risk of thromboembolic events and higher sudden death rates in patients treated with these agents,[398–400] judicious use is recommended. ESAs are never recommended when rapid correction of hemoglobin is required.

Pure red cell aplasia (PRCA) is a relatively rare T-cell–dependent complication associated with CLL, but an incidence as high as 6% has been reported.[401] PRCA was first described by Dameshek and colleagues in 1967.[402] It is characterized by a hypoproliferative anemia that can be detected even in early-stage CLL and is thought to be caused by cytotoxic effects of suppressor T cells on erythroid progenitor cells.[403] Higher number of these CD3, CD8, and CD57 coexpressing cells have been shown to gradually accumulate in the bone marrow of patients with PRCA.[401] Abeloff and Waterbury described the first remission of PRCA to cyclophosphamide therapy in 1974,[404] and Chikkappa and colleagues described the first case of response to CSA.[405] Subsequent larger studies have shown a response rate as high as 63% with 300 mg daily of oral CSA.[385] Mild reversible nephrotoxicity may warrant dose adjustment in some patients. Most patients exhibit a response by having reticulocytosis within the first 10 to 14 days, but maximal response may occur an average of 10 weeks after the start of therapy. However, steroid therapy at a dose of 1 mg/kg/day of prednisone remains the first line of treatment.[382] If a response is not obtained in 4 weeks, CSA should be added to the regimen.[382,386]

Other agents that have shown promising activity in treating PRCA include rituximab,[387] IVIG,[406] alemtuzumab,[407] and antithymocyte globulin.[408] Packed red cell transfusions are usually indicated in patients who are clinically symptomatic from severe anemia.

A number of other complications, most of which are autoimmune in nature, have been reported in patients with CLL. These complications include paraneoplastic pemphigus,[409] angioedema due to acquired C1-inhibitor deficiency,[410] and nephrotic syndrome.[411] As a result of autoimmune involvement of various organs, patients with CLL may have abnormal serum chemistry profiles and liver function tests.

CONCLUSIONS

Advances in the molecular biology of CLL over the past two decades have translated into new diagnostic tests that allow better assessment of initial prognosis and also to assign treatment. Additionally, multiple new therapies have come forward and progress is being made to extend remission duration and improve quality of life of CLL patients. Additionally, medications and interventions to support complications that arise from CLL have also been introduced. Overall, the future for patients with CLL remains brighter based on these past efforts and likely will improve further with continued laboratory and clinical research ongoing in this disease.

CHAPTER 84

HAIRY CELL LEUKEMIA

Anaadriana Zakarija, LoAnn C. Peterson, and Martin S. Tallman

INTRODUCTION

Hairy cell leukemia (HCL) is an uncommon chronic lymphoproliferative disorder initially described by Bouroncle and colleagues in 1958.[1] Although the cause remains unknown, the morphologic findings, clinical manifestations, and pathologic features have been well described over the past 50 years. HCL is characterized by splenomegaly, pancytopenia, and infiltration of the bone marrow with lymphocytes that have irregular cytoplasmic projections when identified in the peripheral blood (Fig. 84–1).[2,3] The disease is known to be a clonal B-cell malignancy as determined by heavy-chain immunoglobulin gene rearrangements.[4–6] Hairy cells exhibit an immunophenotype of mature B cells with expression of B-cell–associated surface antigens and monoclonal surface immunoglobulin.[7,8] Although many patients have few symptoms at diagnosis, others have life-threatening pancytopenia, symptomatic splenomegaly, or constitutional symptoms requiring treatment.[9,10]

Splenectomy, the treatment of choice for many years, leads to normalization of the peripheral blood counts in approximately one-half of all patients.[11–14] Interferon-α was first introduced for the treatment of patients with HCL in 1984,[15] and although a high overall response rate is achieved, most responses are partial.[14–21] Patients invariably relapse when the drug is discontinued. The most remarkable progress has occurred with the introduction of the two purine analogs, 2′-deoxycoformycin (2′-DCF)[22,33] and 2-chlorodeoxyadenosine (2-CdA).[24,34–44] Most patients with previously treated or untreated HCL achieve durable complete remission (CR) with either of these agents. The purine analogs appear to have changed the natural history of this disease.

EPIDEMIOLOGY

In the United States, HCL represents 2% of adult leukemias; approximately 600 to 800 new patients are diagnosed each year.[45,46] Although there have been several reports of familial HCL, there is no known genetic predisposition.[47–53] The median age of diagnosis is 52 years, and the disease occurs in men more often than in women by a ratio of approximately 4 to 1.[54] Although the incidence is similar in the United States and Great Britain,[45,46] classical HCL is rare in Japan, where a distinct variant form has been described.[55–57]

ETIOLOGY AND PATHOGENESIS

The cause of HCL is not known. Although some studies have suggested that exposure to benzene,[58,59] organophosphorus insecticides,[60] or other solvents[61] may be associated with development of the disease, this association has not been confirmed by other reports.[62] Exposure to radiation,[63] agricultural chemicals,[59] or wood dust[46] and a previous history of infectious mononucleosis[61] have also been suggested etiologies, but a causal relationship has not been firmly established.

Cyclin D1, an important cell cycle regulator, may play a role in the molecular pathogenesis of HCL. Overexpression of the cyclin D1 protein has been described in HCL patients.[64,65] Unlike mantle cell lymphoma, 11q13 rearrangements are not detected in most cases, suggesting other mechanisms of gene deregulation.[65]

CLINICAL PRESENTATION

The diagnosis is usually readily apparent in a middle-aged man who presents with splenomegaly, pancytopenia, and circulating hairy cells (Table 84–1). The initial evaluation of a patient with HCL should include a history and physical examination, a complete blood cell count with a differential cell count, review of the peripheral blood smear, routine serum electrolyte determinations, levels of blood urea nitrogen and creatinine, assays of hepatic transaminases, a bone marrow aspirate and trephine biopsy, and immunophenotyping of peripheral blood or bone marrow aspirate by flow cytometry (Table 84–2).

At the time of diagnosis, most patients present with symptoms related to anemia, neutropenia, thrombocytopenia, or splenomegaly. Approximately 25% of patients present with fatigue or weakness, 25% with infection, and 25% because of the incidental discovery of splenomegaly or an abnormal peripheral blood count.[54]

Patients usually appear well at the time of diagnosis. The most common and almost always sole physical finding is palpable splenomegaly, occurring in approximately 80% of patients.[3,54] The spleen is palpable 5 cm below the left costal margin in approximately 60% of patients. Hepatomegaly occurs in approximately 20% of patients. Unlike many other lymphoproliferative disorders, peripheral adenopathy is uncommon, with less than 10% of patients presenting with peripheral nodes larger than 2 cm in diameter. Although adenopathy is not common at diagnosis, internal adenopathy may develop after a prolonged disease course[66,67] and is present in 75% of patients at autopsy.[68] The characteristic distribution of disease in HCL probably results from the expression of the integrin receptor $\alpha_4\beta_1$ by the hairy cells and its interaction with the vascular adhesion molecule–1 (VCAM-1) found on splenic and hepatic endothelia, bone marrow, and splenic stroma.[69]

Patients with HCL are susceptible to gram-positive and gram-negative bacterial infections,[70] but they are also susceptible to atypical mycobacterial infections,[71] particularly *Mycobacterium kansasii*, and invasive fungal infections.[70] Other diseases of opportunistic infections that have been reported include Legionnaires disease,[72] toxoplasmosis,[73] and *Listeria monocytogenes* infection.[74] Infection in HCL may be attributable in part to granulocytopenia, monocytopenia, poor granulocyte reserve and abnormal mobilization,[75] T-cell dysfunction,[76] and decreased numbers of dendritic cells and antigen-presenting cells.[77]

Patients with HCL may have associated systemic immunologic disorders,[78] including scleroderma and polymyositis[79] and polyarteritis nodosa.[80] HCL has been associated with other cutaneous lesions such as erythematous maculopapules[81] and pyoderma gangrenosum.[82,83] An associated coagulopathy manifested by factor VIII antibodies has been reported.[84] Osseous involvement has also been described, primarily manifesting as lytic lesions in the axial skeleton, usually the proximal femur.[85,86] Rarely, osteolytic lesions may be associated with paraproteinemia.[87] A rare case of HCL occurring with systemic mast cell disease has been reported.[88]

LABORATORY EVALUATION

Pancytopenia is present in approximately 50% of patients with HCL at diagnosis, whereas most other patients present with suppression of

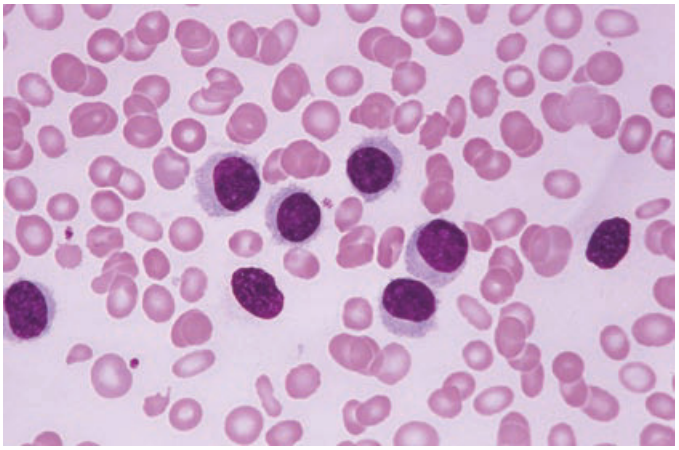

Figure 84–1 Peripheral blood smear from a patient with hairy cell leukemia. The patient was unusual in that he presented with a marked leukocytosis. The hemoglobin level and platelet count were reduced. The nuclei of the hairy cells are eccentrically located and exhibit a reticular chromatin. The cytoplasmic borders are irregular, with fine, hairlike projections (Wright-Giemsa stain, 1000×).

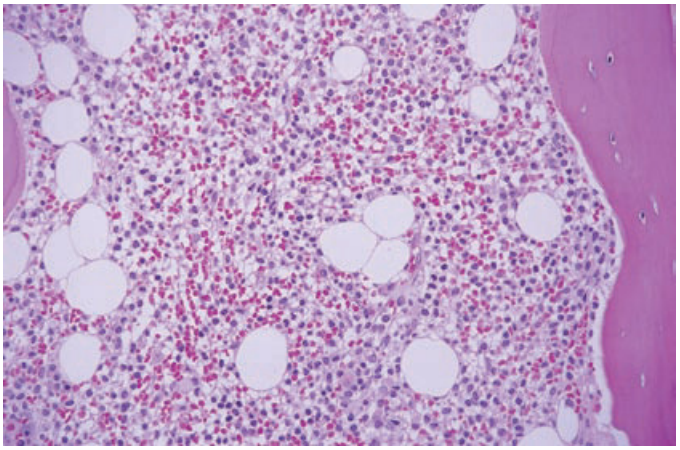

Figure 84–2 Bone marrow trephine biopsy section from a patient with hairy cell leukemia. The bone marrow is hypercellular with a diffuse infiltration by hairy cells. The hairy cell nuclei are widely spaced, separated from each other by a pale, lightly eosinophilic cytoplasm. Many extravasated red blood cells are present between the hairy cells (hematoxylin and eosin stain, 630×).

Table 84–1 Classic Presentation of a Patient with Hairy Cell Leukemia

Middle-aged man
Splenomegaly, often more than 5 cm below the left costal margin
Pancytopenia
Bone marrow usually cannot be aspirated ("dry tap")
Bone marrow trephine biopsy showing mononuclear cells separated by clear cytoplasm

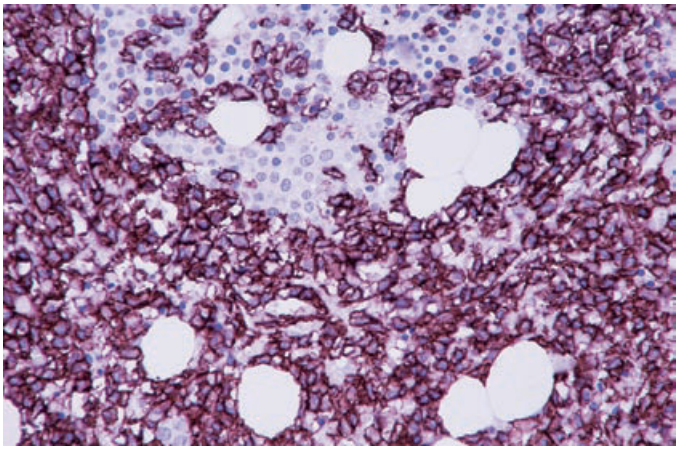

Figure 84–3 The hairy cells in the hypercellular bone marrow biopsy shown in Fig. 80–2 are accentuated by immunostaining for the B-cell antigen CD20. Residual erythroid and myeloid precursors are negative for CD20 (immunohistochemical stain for CD20, 400×).

only one or two cell lines.[3,54] Most patients with HCL present with leukopenia, although 10% to 20% of patients exhibit a leukemic phase with a white blood cell count higher than 10 to 20 × 10^9/L. Monocytopenia is a common, but often overlooked, finding and may be a helpful clue to the diagnosis.[1,3,54] Other laboratory findings include abnormal levels of hepatic transaminases (19%), azotemia (27%), and hypergammaglobulinemia (18%), which is rarely monoclonal.[3,87,89] Hypogammaglobulinemia is uncommon.

Hairy cells can be identified in Wright-stained peripheral blood smears from most patients with HCL. The number of circulating hairy cells varies, but is usually low. In some patients, hairy cells can be found only after a prolonged search. Bone marrow often cannot be aspirated, resulting in a so-called dry tap. However, when bone marrow aspiration is successful, hairy cells similar to those in the blood are present.

The morphologic features of hairy cells are characteristic (see Fig. 84–1). The neoplastic cells are approximately one to two times the size of a small lymphocyte. The nuclei are usually round, oval, indented, or monocytoid; rarely, they appear convoluted.[90] The nuclei are located in a central or eccentric position. The chromatin pattern is reticular or netlike in appearance; nucleoli are indistinct or absent. The amount of pale blue-gray cytoplasm varies. The cytoplasmic borders are irregular, with fine, hairlike projections or ruffled borders. Occasionally, cytoplasmic granules are present. Rarely, the cytoplasm exhibits rod-shaped inclusions that correspond to ribosomal lamellar complexes, which are observed ultrastructurally in approximately 40% of cases.[91]

Examination of the bone marrow trephine biopsy plays a critical role in the diagnosis of HCL because of its characteristic histopathologic appearance (Figs. 84–2 and 84–3).[92–95] The bone marrow is hypercellular in most patients. Hairy cell infiltration may be diffuse, patchy, or interstitial. In patients with diffuse involvement, large areas of the bone marrow are replaced by hairy cells, with complete effacement of the bone marrow in some patients. With patchy infiltration, subtle, small clusters of hairy cells are present focally or throughout the bone marrow. The hairy cells do not form well-defined, discrete aggregates; instead, they merge almost imperceptibly with the surrounding normal hematopoietic tissue. In the interstitial pattern of involvement, variable numbers of hairy cells infiltrate

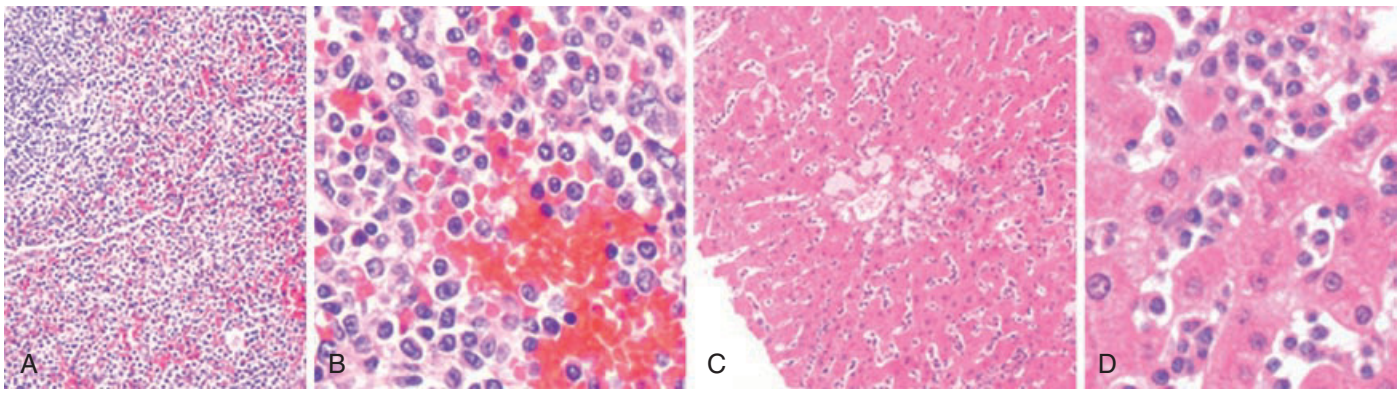

Figure 84–4 Spleen and liver in hairy cell leukemia (**A**–**D**). The spleen (**A**, **B**) shows a massive and diffuse infiltrate in the red pulp and depletion of the white pulp. The infiltrate is associated with hemorrhage, which results in red blood cell "lakes" (**B**, *lower right*). The liver (**C**, **D**) is frequently involved and the pattern of infiltration is predominantly sinusoidal.

between normal hematopoietic cells and fat, with preservation of the overall bone marrow architecture. The hairy cell nuclei are usually round, oval, or indented and are widely separated from each other by abundant, clear or lightly eosinophilic cytoplasm; rarely, the cells are convoluted or spindle shaped. The nuclear chromatin is lightly condensed, nucleoli are small and inconspicuous, and mitotic figures are rare. Extravasated red blood cells are frequently seen, and blood lakes, similar to those observed in the spleen, may also be present. Mast cells are often numerous. Reticulin stains of the bone marrow trephine biopsy in HCL almost always show a moderate to marked increase in reticulin fibers.

Residual hematopoietic cells are usually decreased in HCL; granulocytes are typically more severely reduced than erythroid precursors and megakaryocytes. Approximately 10% to 20% of patients exhibit a hypocellular bone marrow. The hypocellularity may be severe, with small numbers of hairy cells infiltrating around fat cells.[96] The morphology of these latter cases strongly resembles aplastic anemia.

Cytochemical or immunohistochemical demonstration of tartrate-resistant acid phosphate (TRAP) activity can aid in the diagnosis of HCL.[97] TRAP-positive cells are found in almost all cases of HCL at diagnosis, although the percentage of positive cells varies greatly among patients. TRAP positivity is not specific for HCL since a wide variety of other hematopoietic malignancies, including prolymphocytic leukemia, Sézary syndrome, and adult T-cell leukemia/lymphoma, may rarely show positive reactions. The introduction of immunophenotyping for the diagnosis of chronic lymphoproliferative disorders has made reliance on the TRAP stain much less important than it was historically.

Flow cytometric immunophenotyping is an important part of the diagnostic evaluation to identify the characteristic immunophenotypic profile of HCL and to distinguish it from other lymphoproliferative disorders. Because hairy cells exhibit distinctive light scatter pattern and a characteristic immunophenotype, they can be identified even in very low levels (<1% of lymphocytes) in the peripheral blood or bone marrow aspirate.[98] This property is useful at the time of diagnosis and after therapy to assess the blood and marrow for residual disease.[99]

Hairy cells strongly express CD45, seen as a bright signal, with increased forward and side scatter. They exhibit a mature B-cell phenotype and typically express one or more heavy chains and monotypic light chains. The heavy chain type is usually IgG, occurring alone or in combination with other types of heavy chains. The number of cases expressing κ or λ light chains is approximately equal. Surface immunoglobulin is expressed as moderate to bright intensity. Hairy cells strongly express pan-B-cell antigens, including CD19, CD20, CD22, and CD79b. They are usually negative for CD5, CD10, and CD23, but they strongly express CD11c, CD25, and FMC7. CD103, an antigen expressed on mucosal T cells and some activated T cells, is expressed in most cases of HCL.[98,100] Atypical immunophenotype with typical morphologic findings can be found in approximately 35% of patients including $CD23^+$ in 17%, and all such patients appear to respond well to purine analogs.[101]

Several B-cell–associated antibodies, including CD20, CD79a, and DBA.44, react with hairy cells in fixed, routinely processed tissue sections. None is specific for HCL, but these antibodies are useful in documenting the B-cell nature of the infiltrate and highlighting the extent of bone marrow infiltration at the time of diagnosis and after therapy.[102–105]

Splenic involvement in HCL is characterized by diffuse infiltration of the red pulp cords and sinuses, with atrophy or replacement of the white pulp (see Fig. 84–4A,B). Blood-filled sinuses lined by hairy cells are often a prominent, but not pathognomonic finding in the spleen; they have been referred to as *pseudosinuses*.[106] The liver shows sinusoidal and portal infiltration by hairy cells (see Fig. 84–4C,D). Involved lymph nodes commonly exhibit partial effacement, with hairy cells infiltrating the paracortex and medulla in a leukemic pattern. The leukemic cells often surround residual lymphoid follicles and extend through the capsule.

Clonal cytogenetic abnormalities are present in approximately two-thirds of patients with HCL. Chromosomes 1, 2, 5, 6, 11, 14, 19, and 20 are most frequently involved. Chromosome 5 is altered in 40% of patients, most commonly as trisomy 5, pericentric inversions, and interstitial deletions involving band 5q13.[107–109]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of HCL includes other small B-cell lymphoproliferative disorders associated with splenomegaly, such as prolymphocytic leukemia, splenic marginal zone lymphoma (ie, splenic lymphoma with villous lymphocytes), and HCL variant (Table 84–3 and Fig. 84–5). Patients with prolymphocytic leukemia typically present with splenomegaly, but this disorder can usually be readily

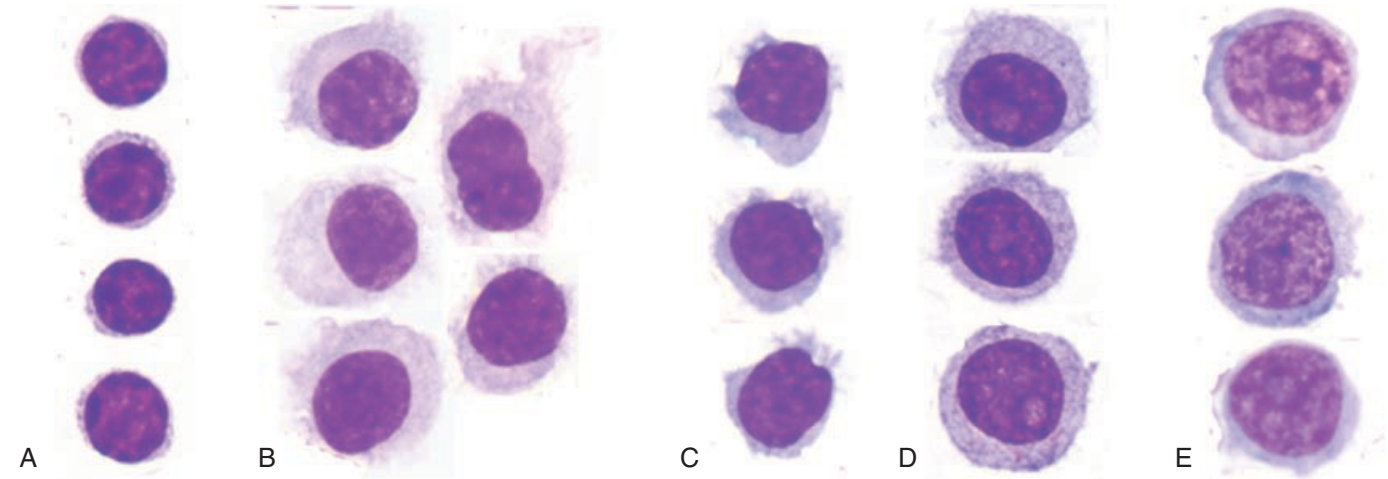

Figure 84–5 Cytologic features of hairy cells in comparison to other lymphoid leukemias to be considered in the differential diagnosis (**A–F**). Chronic lymphocytic leukemia cells (**A**), for comparison. Note small size, block-like, chromatin and scant cytoplasm. Hairy cells (**B**) have a larger nucleus, which is sometimes oval, reniform, or dumbbell-shaped, with more open chromatin and abundant pale cytoplasm with fuzzy edges. Splenic marginal zone lymphoma cells (ie, splenic lymphoma with villous lymphocytes) (**C**) are smaller and have more condensed and more blue cytoplasm with polar projections. Cell of the prolymphocytic variant of hairy cell leukemia (**D**) resemble hairy cells, although the nucleus is more condensed and nucleoli are present. Prolymphocytes (**F**) are large and have an open nuclear chromatin and prominent "punched-out" nucleoli.

distinguished from HCL by the marked elevation of the white blood cell count, the morphology of the prolymphocytes, and an immunophenotypic profile different from that of HCL.[110–113] Splenic marginal zone lymphoma exhibits some clinical and morphologic features similar to HCL, but the cells usually do not exhibit TRAP positivity, the bone marrow infiltrates are sharply demarcated, and the immunophenotypic profile differs from that of HCL, including no expression of CD103.[114–117] HCL variant exhibits morphologic features intermediate between hairy cells and prolymphocytes. HCL variant is associated with leukocytosis, lack of monocytopenia, and absence of CD25 expression.[118–122] Infiltrates of systemic mastocytosis in the bone marrow may closely resemble HCL. Immunohistochemical studies show the mast cells, unlike hairy cells, to be negative for B-cell markers and positive for tryptase.[123]

TREATMENT

Indications

HCL usually has an indolent course, with some patients surviving 10 years without requiring therapy.[124] In most patients, progressive disease eventually leads to complications resulting from anemia, bleeding, splenomegaly, or recurrent infections. Therapy is indicated when the patient has significant cytopenias, symptomatic organomegaly or adenopathy, or infections or constitutional symptoms such as fever, night sweats, or fatigue. Typical blood counts that warrant treatment include an absolute neutrophil count less than 1000/μL, a hemoglobin concentration less than 11.0 g/dL, or a platelet count less than 100,000/μL.

Role of Splenectomy

Splenectomy was the first effective therapy for HCL and remained the initial treatment of choice until the introduction of interferon and then the purine analogs.[11–14] Although splenectomy does not produce morphologic remissions in the bone marrow, all three cell lines return to normal in approximately 40% to 70% of patients.[14,125] This response is maintained for a median of 20 months in approximately two-thirds of patients, and the overall 5-year survival rate is approximately 70%.[125] There appears to be no correlation between spleen size and response to splenectomy. There may be a role for splenectomy in rare, selected patients for diagnostic reasons, in cases of splenic rupture, or when thrombocytopenia and a significant bleeding diathesis exist, because splenectomy can lead to a rapid rise in the platelet count. However, there has been little or no role for splenectomy since the introduction of the purine analogs.

Chemotherapeutic Approaches

Cytotoxic chemotherapy was used before the advent of more effective therapies in the early 1980s. A variety of agents, including anthracyclines,[126] alkylating agents (eg, chlorambucil),[127] and high-dose methotrexate,[128] demonstrated some efficacy. Combination chemotherapy, such as the CHOP regimen, was reported to produce long-lasting normalization of peripheral blood counts.[129] There is also a report in the literature of a successful syngeneic (identical twin) bone marrow transplantation in which the patient remained free of disease at least 15 years after the procedure.[124] HCL is sensitive to chemotherapy, but treatment is associated with significant myelosuppression and toxicity. Conventional chemotherapy is now only of historic interest.

Interferon

Interferon was first reported to be an effective therapy for patients with HCL in 1984.[15] Since then, numerous large studies have confirmed its activity.[15–21] The precise mechanism of action of interferon is unknown, but it may result from the reduced production of cytokines such as granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3), and interleukin-6 (IL-6), perhaps related to the characteristic monocytopenia associated with interferon treatment.[130] Some work suggests that interferon-α results in apoptotic death of hairy cells, mediated by tumor necrosis factor-α.[131] Despite a high overall response rate of 75% to 90%, most patients achieve only partial remission (PR, defined as normalization of all peripheral blood cell counts).[18,19] Interferon is commonly administered subcutaneously at a dose of 2 million international units/m^2 three times each week for 12 to 18 months. During the first 2 months of treatment, the white blood cell count and hemoglobin level are often decreased, occasionally necessitating transfusion. The numbers of platelets normalize first in responding patients, followed by the hemoglobin con-

centration and the white blood cell count. An absolute neutrophil count greater than 1500/μL is achieved after a median of 5 months of therapy.

Common toxicities include flu-like symptoms, anorexia and fatigue, nausea and vomiting, diarrhea, dry skin, peripheral neuropathies, and central nervous system dysfunction. The latter usually manifests as depression or memory loss. Elevated levels of hepatic transaminases are the most common clinical abnormality other than myelosuppression. The median failure-free survival after discontinuing interferon ranges from 6 to 25 months in different series.[18–20,132] Patients with more than 30% hairy cells in the marrow or a platelet count of less than 160,000/μL at the end of treatment are at higher risk for early relapse.[18–20] Patients whose cells express the CD5 antigen appear to respond poorly to interferon.[133] One report suggests that patients can be maintained on long-term interferon at a dose of 3 million units administered subcutaneously and given three times each week with minimal toxicity. Sixty percent of patients sustain their initial response for a median of 5 years, 9% discontinue therapy early because of unexpected neurologic toxicity, and only 13% stop therapy because of progressive disease.[21] In summary, treatment of HCL with interferon is effective, resulting in normalization of the peripheral blood counts in most patients. However, CRs are uncommon, and failure-free survival is usually short after discontinuation of treatment (see box). The purine analogs have completely supplanted interferon except is very rare and unusual circumstances.

Management of Hairy Cell Leukemia

For patients with newly diagnosed hairy cell leukemia (HCL) who require treatment (absolute neutrophil count <1000/μL, or hemoglobin concentration <11.0 g/dL, or platelet count <100,000/μL or symptomatic organomegaly), we administer 2-chlorodeoxyadenosine (2-CdA) at a dose of 0.1 mg/kg/day by continuous intravenous infusion for 7 days as an outpatient procedure by portable pump using a midline percutaneous intravenous central catheter. Other schedules such as a 2-hour daily infusion for 5 days may be equally effective.[134] If fever of 100.5°F or higher develops while the patient is neutropenic, blood is drawn for cultures, urine culture and chest radiography are done, and oral ciprofloxacin (750 mg taken orally twice daily) or another antibiotic of similar spectrum of coverage is administered. If cultures are sterile at 24 to 48 hours, naproxen (250 mg taken orally twice daily) is added for 2 to 4 days. Treatment with 2-CdA is not discontinued. Hematopoietic growth factors are not routinely given. The platelet count is usually the first cell line to recover (within 2–4 weeks), followed by the white blood cell count and then the hemoglobin concentration. We repeat the bone marrow examination at 3 months to assess remission status. We do not administer a second cycle of 2-CdA for patients with minimal residual disease. Recent data suggest that the anti-CD20 monoclonal antibody rituximab (Rituxan) may be effective in eradicating minimal residual disease, but the benefit with respect to overall survival is not determined.[135]

Both 2′-DCF and 2-CdA are effective therapies for newly diagnosed patients with HCL. In a long-term follow-up retrospective report, CR rates (81% and 82%, respectively) and overall survival rates at 10 years (96% and 100%, respectively) were the same. With both purine analogs, relapses continue to occur.[136]

For patients with relapsed HCL who have been previously treated with splenectomy, interferon, or 2′-deoxycoformycin (2′-DCF), we administer a cycle of 2-CdA as described previously. For patients who relapse after a single cycle of 2-CdA, we administer a second cycle of 2-CdA. For patients with relapsed HCL previously treated with at least two prior cycles of 2-CdA, we consider BL22 or rituximab. 2′-DCF is considered depending on the availability or response to either BL22 or rituximab.

Food and Drug Administration–Approved Treatments for Hairy Cell Leukemia

Interferon-α: 2×10^6 international units/m^2 administered subcutaneously three times each week for 12 to 18 months

2′-Deoxycoformycin (2′-DCF, Pentostatin): 4 mg/m^2 given intravenously every 2 weeks until remission (usually 3 to 6 months)

2-Chlorodeoxyadenosine (2-CdA, cladribine, Leustatin): a single cycle, with 0.1 mg/kg/day given as a continuous infusion for 7 days

Purine Analog Therapy

Twenty-five years ago, Giblett and colleagues[137] observed that 30% of children with severe combined immunodeficiency syndrome lacked the enzyme adenosine deaminase (ADA). It appeared that the accumulation of the triphosphorylated form of deoxyadenosine was responsible for the absence of lymphocyte development.[138] The deliberate inhibition of ADA became a potentially useful antileukemic strategy. The methods to accomplish this include agents to bind irreversibly to ADA or resist the action of the enzyme. These agents affect dividing and nondividing cells.[139] After purine analog therapy, accumulation of deoxyadenosine triphosphates leads to DNA strand breaks and inhibition of DNA repair, which ultimately results in cell apoptosis.

2′-Deoxycoformycin

The first agent found to induce a significant number of CRs in patients with HCL was 2′-DCF.[22,140] This drug binds to ADA, resulting in irreversible inhibition of the enzyme,[141] which is found in all lymphoid cells and is important in purine metabolism. In most studies, CR is defined by disappearance of hairy cells in the blood and bone marrow; complete normalization of peripheral counts (hemoglobin concentration >12.0 g/L, platelets $>100 \times 10^9$/L, and absolute neutrophil count $>1.5 \times 10^9$/L); and resolution of splenomegaly and lymphadenopathy. A PR requires normalization of blood counts, more than 50% reduction in hairy cells in the bone marrow, and greater than 50% reduction in splenomegaly.

Several studies have demonstrated the efficacy of 2′-DCF in patients with HCL (Table 84–4).[23–33] A large, prospective, randomized study showed that the CR rate and relapse-free survival rate are significantly better with 2′-DCF than with interferon.[31] Various dosing schedules were used in early studies, but the current convention is 4 mg/m^2 given by intravenous infusion every 2 weeks until a maximum response is achieved. The median number of cycles required by patients until best response has been 6 to 12 cycles.[24,27,29,33] In one of the earlier studies conducted by the Eastern Cooperative Oncology Group, most patients achieved a maximal response within the first 6 months.[27] Therapy is relatively well tolerated; neutropenia, fever, and infections are the most common toxicities.[25,27,32] One of the largest published series with long-term follow-up was reported by the Southwest Oncology Group.[25] A total of 241 patients received 2′-DCF in a phase III trial comparing interferon with 2′-DCF; 154 were randomized to 2′-DCF initially, and 87 crossed over after failing interferon therapy. Seventy-two percent of patients achieved a CR with 2′-DCF. Long-term survival was not statistically different based on initial treatment; in both groups, the overall survival rate was 90% at 5 years and 81% at 10 years (Fig. 84–6). With longer follow-up, it has become obvious that 2′-DCF is not curative in all patients, and the relapse incidence continues to increase. Studies with follow-up longer than 5 years after treatment report relapses in 15% to 48% of patients.[23–25,30]

Patients were stratified by treatment upfront or after failure on interferon. *(Data from Flinn IW, Kopecky KJ, Foucar MK, et al: Long-term follow-up of remission duration, mortality, and second malignancies in hairy cell leukemia patients treated with pentostatin. Blood 96:2981, 2000.)*

2-Chlorodeoxyadenosine

2-CdA is a purine analog that is resistant to the action of ADA. This agent accumulates in the lymphoid cells, presumably because they are rich in the enzyme deoxycytidine kinase.[141] This enzyme phosphorylates 2-CdA to the active 5′-triphosphate form, creating a deoxynucleotide that cannot readily exit the cell. This compound inhibits ribonucleotide reductase, which results in decreased synthesis of deoxynucleotides. DNA synthesis and repair are impaired.

2-CdA was first reported to be effective for HCL by Piro and colleagues in 1990.[34] Twelve patients were treated with a single cycle of 2-CdA at a dose of 0.1 mg/kg/day by continuous infusion for 7 days, and a pathologic CR was obtained in 11 of the 12 patients within 8 weeks of treatment. Subsequent studies have shown similar efficacy with the same dosing schedule (Table 84–5).[24,34–44] Clear orders for the 7-day infusion pump are critical because poor response to therapy has been attributed to underdosing of drug when 1 day's dose was administered over 7 days.[142] Alternative dosing schedules and routes have been reported with good results (Table 84–6).[143–146] In the study conducted by Von Rohr and colleagues,[146] 2-CdA was administered by subcutaneous bolus injection of 0.14 mg/kg/day for 5 days to 62 patients. The results were similar to those of previous studies, with 76% of patients achieving CRs and an overall response rate of 97%.

The most common toxicities in patients treated with 2-CdA are neutropenia and fever. Saven and colleagues[38] at the Scripps Clinic reported the largest collection of patients treated with 2-CdA. Among 349 patients who received a single cycle of 2-CdA, 87% had grade 3 or 4 neutropenia, 42% had neutropenic fever, but only 13% had documented infections, none of which was an opportunistic infection. Most of the fevers seen with administration of 2-CdA do not reflect infection but are probably caused by the release of cytokines. Because of the high incidence of neutropenic fever, Saven and colleagues[147] conducted a prospective trial on the effect of filgrastim in 35 patients treated with 2-CdA. Filgrastim was administered on days −3 through −1 and again after completion of 2-CdA until the absolute neutrophil count was more than 2×10^9/L on 2 consecutive days. When compared with historical controls, the filgrastim-treated group achieved an absolute neutrophil count greater than 1.0×10^9/L more rapidly than controls (9 vs 22 days). Despite this effect, the incidence of fever and rate of admission to the hospital were not different in the two groups, and routine use of prophylactic filgrastim therefore is not indicated for these patients.

Although responses are excellent with 2-CdA, they are not sustained in all patients. Follow-up after 2-CdA has been shorter than after 2′-DCF treatment, but the experience is similar—relapses have appeared with longer follow-up (Table 84–5). Several studies have reported quite long follow-up. After a median follow-up of 108 months, Goodman and colleagues reported that 37% of patients relapsed, with a median time to relapse of 42 months.[39] Initial PR was associated with a shorter duration of remission (Fig. 84–7). The response to retreatment remained very good; 79% of relapsed patients were retreated with 2-CdA. The overall response was 92%, including 75% with CRs.[39] Jehn and coworkers reported that among 44 consecutive patients, after a median follow-up of 8.5 years, the disease-free survival was 36% at 12 years with an overall survival or 79%.[148] At Northwestern University, among 86 consecutive patients treated with a single cycle of 2-CdA, the progression-free survival after 12 years was 54% with an overall survival after 12 years of 87%.[149] Results of one retrospective study suggested that the durability of response is greater with 2′-DCF than with 2-CdA; at 45 months of follow-up for each, the relapse rates were 9.7% and 29%, respec-

tively.[24] There are no randomized trials comparing the two agents that could answer this question. No plateau has been reached with either agent, and relapses continue to occur after initial treatment.

Immunosuppression with Purine Analogs

Both 2′-DCF and 2-CdA are associated with prolonged immunosuppression.[41,150–154] With 2′-DCF, a decrease in the total lymphocyte count occurs, with a greater reduction in T cells than B cells or natural killer (NK) cells.[153] The levels of $CD4^+$ and $CD8^+$ cells decrease to less than 200 cells/μL for at least 6 months after 2′-DCF treatment is discontinued. In a series of 15 patients treated with 2′-DCF with a long follow-up period, the median time to recovery of $CD4^+$ lymphocyte counts to normal was 54 months.[152] Treatment with 2-CdA induces similar suppression of $CD4^+$ lymphocyte counts.[35] The median time to recovery of $CD4^+$ lymphocyte counts to normal levels after 2-CdA was 40 months. Treatment with 2-CdA affects two distinct subsets of $CD4^+$ T cells. The $CD4^+CD45RA^+$ subset is significantly reduced for up to 5 years, but the $CD4^+CD45RO^+$ T cells, which secrete cytokines and enhance B-cell function, are not suppressed.[153] Recovery of CD8 and NK cells is more rapid; they normalize within 3 months of treatment with 2-CdA. This may explain why opportunistic infections, other than an occasional case of herpes zoster, are uncommon.[33,38,41,155]

Prognosis

Purine analog therapy has significantly changed the outcome of patients with HCL, who now have excellent long-term survival rates. Before the advent of interferon therapy, survival at 4 years was reported to be 68%.[156] With the use of purine analogs, durable remissions are attained, and even after relapse, retreatment produces good responses. The 5-year survival rates are more than 85%.[24,25,29,33,38,39] Flinn and coworkers[25] reported long-term results for 241 patients treated with 2′-DCF, and the overall survival rate was 90% at 5 years and 81% at 10 years (Fig. 84–7). The leading causes of death were second malignancies and infections. Only 2 of 40 deaths were attributable to HCL. Two hundred nine patients treated at the Scripps clinic with 2-CdA have been followed for at least 7 years.[39] The overall survival rate at 9 years is 97% (Fig. 84–7). Because of the indolent natural history of this disease, very long follow-up of patients treated with either purine analog will be required to determine whether one of the agents offers a substantially longer remission duration or overall survival. However, it seems unlikely that such a prospective, randomized comparison between 2-CdA and 2′-DCF

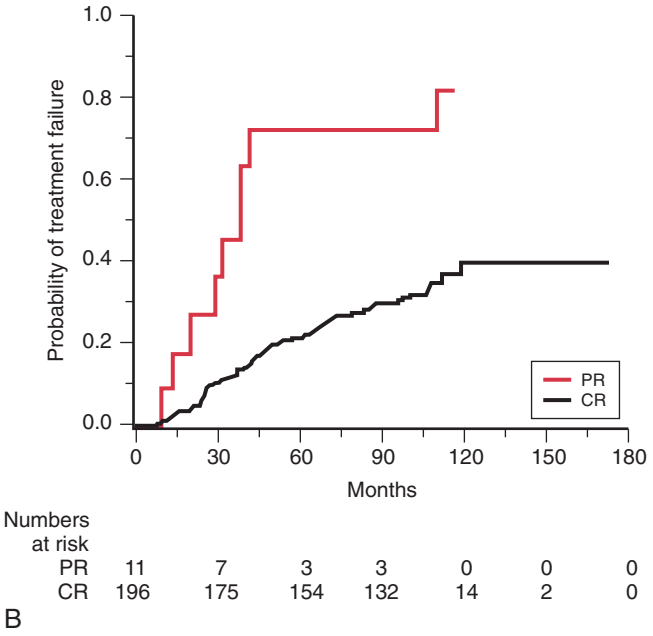

Figure 84–7 **A**, Kaplan–Meier survival curves for 209 patients with hairy cell leukemia (HCL) treated with 2-chlorodeoxyadenosine (2-CdA) and followed for at least 7 years. **B**, Time to treatment failure of 207 patients with HCL after the first course of 2-CdA, stratified by response to first course of therapy. will ever be conducted because the CR rates with each agent are so high, and many years and resources would be required to detect even small differences.

EVALUATION OF MINIMAL RESIDUAL DISEASE

The remarkable activity of the purine analogs has led to the examination of posttreatment bone marrow biopsies to detect minimal residual disease (MRD) in patients otherwise in CR. Immunohistochemistry using anti-CD20, DBA.44, and anti-CD45RO antibodies in paraffin-embedded biopsy specimens has been used most frequently.[102–105,155–158] Techniques for MRD detection include flow cytometric immunophenotyping or consensus primer polymerase

Light lines represent 95% confidence limits. *(Data from Chadha P, Rademaker AW, Mendiratta P, et al: Treatment of hairy cell leukemia with 2-chlorodeoxyadenosine (2-CdA): Long-term follow-up of the Northwestern University experience. Blood 106:241, 2005.)*

chain reaction (PCR).[99] Depending on the criteria used, 13% to 51% of patients in apparent CR have evidence of MRD.[102–105,158] There has not been a statistically significant difference in the incidence of MRD between patients treated with 2′-DCF or 2-CdA.[159] The presence of MRD appears to predict relapse.[104,158] In one study evaluating MRD in 66 patients, 50% of those with MRD relapsed, whereas only 6% of patients without MRD relapsed.[158] There is no evidence to support the treatment of MRD.

TREATMENT OF RELAPSE

Relapse is often detected on bone marrow biopsy alone, and immediate retreatment is not necessary. In the study by Kraut and colleagues,[30] relapse was detected at a median of 30 months from achievement of remission with 2′-DCF, but retreatment was initiated at a median of 60 months after first remission. Five of seven patients retreated with purine analogs attained CRs. Patients with an initial response to 2-CdA also respond well to retreatment with a purine analog. In the Scripps Clinic series, 76 of 207 patients relapsed; 79% were retreated with 2-CdA. The overall response was 92%, including 75% with a CR.[39] The median duration of the second response was 35 months, which is comparable to the 42-month duration of first response. Responses continue to be seen even with a third cycle of 2-CdA in 80% of retreated patients. Patients who relapse after purine analog therapy should be retreated with 2-CdA or 2′-DCF. An alternative in relapsed or refractory cases includes enrollment in a clinical trial with newer therapies (discussed later under Monoclonal Antibody Therapies). The outcome of patients who relapsed after 2-CdA and receive other therapies or are observed is very favorable (Fig. 84–8).

RISK OF SECOND MALIGNANCIES

An association has been noticed between HCL and second malignancies, although the link is controversial. Malignancies that have been observed in HCL patients include melanoma, prostate cancer, gastrointestinal cancers, non-Hodgkin's lymphoma, and nonmelanomatous skin cancers. It is not clear whether HCL itself

increases risk or whether the type of therapy plays a role. Kampmeier and colleagues[160] reported a significantly increased incidence of second malignancies in HCL patients treated with interferon. The British Columbia Cancer Agency reported a 20-year follow-up of 117 patients—31% developed a second malignancy, 30% of which were diagnosed before the diagnosis of HCL.[161] The risk was elevated regardless of the type of therapy. However, this association has not been uniformly observed.[159,162] Kurzrock and colleagues[163] reported no excess of second malignancies among 350 patients treated with interferon, 2-CdA, or 2′-DCF.

Immunosuppression due to the purine analogs may play a role in the increased malignancy incidence, but the evidence is not clear. Long-term follow-up studies of patients treated with 2′-DCF have not demonstrated a statistically significant increased risk of second malignancies.[23,25] However, other studies have suggested that treatment with 2-CdA is associated with an increased cancer risk.[38,39,164] In Saven's review of the Scripps Clinic experience with 349 patients, 8% of patients had a second malignancy that developed at a median of 62 months after the diagnosis of HCL and 21 months after treatment with 2-CdA.[38] Eleven percent of the patients in this study had a diagnosis of malignancy before the diagnosis of HCL. It is still not clear whether therapy increases risk; HCL itself may have an inherent predisposition to malignancy. Continued observation will be necessary to address this question.

MONOCLONAL ANTIBODY THERAPIES

The anti-CD20 monoclonal antibody rituximab has been tested in patients with HCL refractory to other treatments.[165,166] Hagberg and associates[167] treated 11 patients with rituximab and reported an overall response rate of 64% (Table 84–7). The median duration of response in this group was 14 months. The largest published report[168] describes 24 patients treated with 4 weekly doses of rituximab. All the patients had relapsed after prior treatment with 2-CdA, and the median time since treatment was 73 months. Thirteen percent of patients had CRs, and 13% had PRs, for an overall response rate of 26%. One-third of responders relapsed after a median follow-up of 14.6 months. It appears that rituximab has activity in some patients with HCL.

CD25, also known as Tac, is the α subunit of the IL-2R and is expressed in 80% of patients with HCL.[169] LMB-2, anti-Tac(Fv)-PE38, is an immunotoxin that contains the variable heavy domain of anti-Tac fused to the amino terminus of a 38-kd truncated form of the *Pseudomonas* exotoxin.[169] It has demonstrated some efficacy in patients with $CD25^+$ hematologic malignancies. After binding to CD25, the compound is internalized and leads to apoptotic cell death. Of four patients who were refractory to standard therapies, including 2-CDA and interferon, all had a response to LMB-2, with one CR.[170] This treatment is well tolerated and appears to have no hematologic toxicity. Larger studies need to be conducted to better determine the safety and efficacy of this treatment.

Another promising immunotoxin under investigation is BL22, a recombinant immunotoxin containing anti-CD22 monoclonal antibody and PE38, the *Pseudomonas* exotoxin. CD22 is expressed by normal B cells and B-cell leukemias and lymphomas, including HCL, but it is not found on stem cells.[171] Kreitman and coworkers updated their original study[172] and presented the results of 23 HCL patients treated with BL22.[173] The overall response was 83%, with 65% of patients attaining CRs. Of the complete responders, only one had MRD determined by immunohistochemistry of the bone marrow, and none had MRD when peripheral blood was tested by PCR. The median follow-up was 12 months, and in four patients who relapsed, retreatment resulted in CRs in three. This therapy appears to be well tolerated, although two patients did have a reversible hemolytic-uremic syndrome. No other hematologic toxicity or decrease in T-cell count was observed. This is the first therapy since the purine analogs to produce a high rate of CR.

These newer therapies have efficacy in patients who are resistant or refractory to the purine analogs and therefore offer another option for therapy. The durability of effect remains to be determined in larger studies with longer follow-up.

HA22 is a second-generation recombinant immunotoxin that differs from BL22 by three animo acids, which results in increased binding of the immunotoxin to CD22.[174] Preliminary in vitro studies suggest that this agent has better cytotoxic activity in B-cell cell lines and in leukemic cells from patients with HCL.[175] Clinical studies are under way.

CHAPTER 85

CUTANEOUS T-CELL LYMPHOMAS

Timothy M. Kuzel, Joan Guitart, and Steven T. Rosen

The T-cell non-Hodgkin lymphomas include a wide variety of clinical disorders with different prognoses. The Revised European-American Lymphoma (REAL) classification system[1] suggests that more than 10 discrete clinicopathologic entities can be considered part of this family. This chapter focuses on the disorders that would be encompassed by the diagnosis cutaneous T-cell lymphoma (CTCL) (Table 85–1). The most common subtypes of cutaneous T-cell lymphomas are the epidermotropic variants mycosis fungoides (MF) and the related leukemic variant, Sézary syndrome (SS). Most of this chapter focuses on the approach to these more common disorders, although features that allow the clinician to exclude the distinct variants are also described.

EPIDEMIOLOGY

MF and SS are the most common primary lymphomas involving the skin.[2,3] Data collected from the Surveillance, Epidemiology, and End Results (SEER) program showed a rapidly increasing incidence from 0.2 cases per 100,000 people in 1973 to 0.4 cases per 100,000 people in 1984. This corresponds to approximately 1000 new cases each year in the United States. Whether this represented a true increase in incidence or was attributable to a better awareness and therefore more frequent recognition of this disease has not been resolved. Since that time, the incidence rate of CTCL has stabilized at 0.36 cases per 100,000 persons, and the mortality rate has declined. The incidence of MF/SS increases with advancing age, as does the incidence of non-Hodgkin lymphomas in general. The average age at presentation is approximately 50 years. Although very young patients have been reported, most patients are at least 30 years of age.[4,5] MF/SS is seen in all racial groups. There is a 1.6:1 ratio of black people to white people and a 2.2:1 ratio of men to women with this disorder. MF is less common in the Asian population. Clusters of cases of MF/SS within families have been reported.[6] An association with histocompatibility antigens AW31, AW32, B8, BW35, and DR5 has been described.[7] However, a solid genetic predisposition or inherited genetic defect has not been demonstrated.

BIOLOGY AND MOLECULAR ASPECTS

The T lymphocyte is central to the body's ability to mount an immune response and is the precursor of neoplastic cells in MF/SS. These cells spontaneously form rosettes with sheep red blood cells. Sézary cells respond to phytohemagglutinin and perform T-cell immunoregulatory functions similar to normal lymphocytes.[8,9] The clonal nature of CTCL can be demonstrated by Southern blotting or polymerase chain reaction (PCR) methods of analysis of the T-cell receptor.

The development of monoclonal antibodies directed against specific cluster of differentiation (CD) antigens has allowed for more precise identification of surface markers on the malignant cell.[10] Most cases of MF and SS are of the helper T memory or effector subset with a $CD4^+CD45RO^+$ phenotype. In most instances, the cells express the pan–T-cell antigens CD2 (the sheep erythrocyte receptor), CD3, and CD5. Early T cells may also express CD7 on their cell surface. This marker is frequently deleted in MF/SS but may also be deleted in benign dermatoses and inflammatory skin lesions. Additionally, CD26 is often deleted in cases of MF and SS. Flow cytometry provides a sensitive method for detecting early peripheral blood involvement in patients by detection of a $CD4^+$, $CD26^-$ population. Occasional cases expressing the suppressor $CD8^+$ phenotype have been described. Low expression of the α-chain component of the interleukin-2 receptor (CD25) is detected with heterogenous expression on the malignant cells in less than half of the patients. The implication of this finding is of uncertain significance, as both activated T cells and immunoregulatory T cells can express CD25.

Cytogenetic analyses have demonstrated numerical and structural chromosomal abnormalities in MF/SS[11] although usually in advanced-stage disease. Hyperdiploidy and complex karyotypes are common. Nonrandom deletions of chromosomes 1, 6, 8, 10, and 17 have been reported with gains in chromosome 17q and 4p occurring in more than 25% of cases. Regions of the genome that include genes encoding the T-cell receptor do not appear to be involved, suggesting that the genetic basis for malignant transformation in MF/SS appears to be different from that involved in other T-cell malignant disorders.

Modest data exist on the aberrant expression of oncogenes and suppressor genes in MF/SS. Loss of heterozygosity (LOH) is identified in 30% to 60% of patients, commonly at 9p 10q, 1p, and 17p. LOH in early stages is associated with a threefold increase in mortality.[12] Mutant forms of the P53 tumor suppressor gene are observed rarely, usually in tumor-stage and large cell transformation of MF.[13] LYT-10, a member of the NF-κB family of transcription factors associated with translocations in lymphoid malignancies, is rearranged in a small proportion of cases.[14] However, *BCL2,* a gene whose rearrangement is characteristic of follicular B-cell lymphomas and which slows programmed cell death, is overexpressed in MF. Constitutive phosphorylation of STAT3 (a member of the transcription factor family that contributes to the diversity of cytokine responses) has been reported and suggests these malignant T cells are activated.[10,15] Altered expression or release of select cytokines or their receptors including IL-1, IL-2R, IL-4, IL-5, IL-6, IL-7, IL-8, IL-12, and TGF-β receptor II has been noted.[16] IL-7 and IL-15 have been identified as growth factors for MF/SS and shown to regulate expression of the *BCL2* and *MYB* oncogenes and stimulate DNA binding of stat proteins.[17,18]

ETIOLOGY AND PATHOGENESIS

The cause of MF/SS remains unknown. It is considered to be a sporadic disease without compelling evidence of transmissibility. Several viruses have been implicated in the pathogenesis of MF/SS, including human T-cell lymphotropic virus types 1 and 2, herpes simplex virus, herpesvirus-6, and the Epstein–Barr virus. However, a viral cause of MF/SS has not been proved, and no epidemiologic evidence supports these hypotheses.

Investigators have suggested that prolonged exposure to contact allergens may lead to enhanced immune responses leading directly or indirectly to the development of MF/SS. Sézary cells respond in vitro to superantigenic exotoxins, and colonization by *Staphylococcus aureus* may influence disease activity.[19] Several reports suggested that exposure to metals or their salts, pesticides or herbicides, and organic sol-

vents (halogenated or aromatic hydrocarbons) could be related to the development of MF/SS.[20] However, two well-designed case-control studies have failed to support these observations.[21,22]

Various theories have been advanced to explain the epidermotropism of malignant T cells in MF/SS. Organ-specific affinity to skin and other organs has been recognized in subsets of normal T cells. Homing of CTCL cells to the skin is probably mediated by more than one adhesion receptor mechanism. CTCL cells express cutaneous lymphocyte antigen (CLA), a skin homing receptor that interacts with e-selectin expressed on dermal venules.[10,23,24] Furthermore, the CLA+ T-lymphocytes also typically express the CC-chemokine receptor 4 which binds to chemokines produced in the skin, such as the CC-chemokine ligands 17 and 22. Peripheral blood mononuclear cells bind to cultured keratinocytes exposed to interferon-γ. The MHC II proteins, along with intercellular adhesion molecule 1 (ICAM-1) present on keratinocytes, attract and bind lymphocytes. Additional chemokine receptors, such as CXC-chemokine receptors 3 and 4, as well as unique integrins, have been shown to have corresponding ligands or integrin receptors on dermal Langerhans cells, suggesting a relationship between the malignant T cells and host immune cells.

An additional feature of MF/SS cells is the production of a cytokine profile consistent with T-helper-2 type cells (T_H2).[25] The T_H2 cells produce IL-4, IL-5, and IL-6 and they are inhibited by interferon-γ. The T_H2 cells are critical for stimulating antibody and eosinophil-mediated responses. Hypergammaglobulinemia and eosinophilia are often seen in advanced cases of MF/SS and are consistent with a T_H2 profile. Stimulation of T_H2 cells inhibits the T_H1 subpopulation of lymphocytes involved in cell-mediated immunity. A cause as well as a consequence of the progression of MF/SS is immune suppression as a result of depletion of this T-cell subset. The T_H2 cytokine profile may explain the decrease in tumor infiltrating lymphocytes during tumor progression. In addition to the effect of cytokines secreted by the neoplastic cells, it has been shown that the malignant $CD4^+$ cells express antigens (eg, FAS ligand) that may directly mediate elimination of the $CD8^+$ infiltrating lymphocytes by induction of apoptosis.[26]

CLINICAL PRESENTATION

Alibert reported the first case of MF in 1806.[27] His patient developed a skin eruption that progressed into mushroom-like tumors, prompting the term mycosis fungoides. Later in the nineteenth century, Bazin defined the three classic cutaneous phases (patch, plaque, and tumor stage) of the disease.[28] The recognition of the clinical triad of intensely pruritic erythroderma, lymphadenopathy, and abnormal hyperconvoluted cells in the peripheral blood led to the description of SS.[29]

More than 50% of CTCL patients have MF. The initial course of patients with MF is usually indolent. Most patients give a history of antecedent skin lesions, usually nonspecific erythematous patches that can mimic eczema or psoriasis. In many cases, there is an orderly progression from limited patches to more generalized patches, plaques, tumors, and nodal or visceral involvement. The characteristic patch lesion is typically poorly demarcated, lightly erythematous, with a predilection for sun-protected areas, such as the lower abdomen or buttocks (Fig. 85–1). Plaque lesions are more indurated, have well-demarcated margins, and some scaling (Fig. 85–2). Plaques can arise from patch lesions or previously uninvolved areas of skin. Tumor lesions tend to be later lesions, frequently associated with previous patches or plaques, and often represent advanced disease, with histologic evidence and large cell transformation. They can be located on any part of the body. Ulceration of these lesions is common and secondary infection is a major cause of morbidity (Fig. 85–3). Tumors may be the initial presentation in a small percentage of patients (D'emblée presentation, Videl and Brocg, 1889).

SS patients present with generalized desquamative erythroderma, pruritus, and circulating malignant cells. Peripheral blood usually shows a significant number or percentage of hyperconvoluted atypical lymphocytes (Fig. 85–4). Approximately 5% to 10% of all newly reported cases of CTCL are SS. In its most advanced form, patients with SS suffer from alopecia, ectropion, leonine facies, hyperkeratosis, nail dystrophy, fissuring of the palms and soles, and severe pruritus and cutaneous pain. Many other entities can clinically mimic this disease including drug eruptions, atopic dermatitis, contact dermatitis, and erythrodermic psoriasis.

A number of variant presentations of CTCL have been described. The following sections discuss variants of CTCL.

CLONAL DERMATITIS

Clonal dermatitis is a term introduced by Wood and colleagues[30] that included a variety of lymphocyte-rich dermatoses, often characterized by clonal T-lymphocyte proliferations. Clinically they exhibit a myriad of cutaneous presentations from poikiloderma (atrophic patches) to hyperpigmented areas resembling pigmented purpuric dermatosis.

Figure 85–1 Erythematous and scaly patch lesion of mycosis fungoides.

Figure 85–2 Plaque lesion of cutaneous T-cell lymphoma.

LARGE PLAQUE PARAPSORIASIS

Large plaque parapsoriasis is the classic premalignant lesion of MF. It most commonly consists of a few scattered, erythematous to brown plaques that are usually greater than 6 cm in size.[31] There is a predilection for the buttocks and intertriginous areas. Histologic examination shows a superficial lymphocytic infiltrate with minimal nuclear atypia. Epidermotropism is scant or absent and dermal fibrosis correlates with the chronicity of the process. Plaques can persist for decades before a frank evolution to MF occurs. Approximately 10% to 30% of patients ultimately develop an overt malignant transformation.

FOLLICULAR MUCINOSIS

Follicular mucinosis manifests with grouped erythematous follicular papules or boggy or indurated nodular plaques, notably devoid of hair (Fig. 85–5).[32] There is a predilection for the head and neck area, especially the forehead, which has the highest density of pilosebaceous units. Histopathologic evaluation reveals cells in sebaceous glands often associated with destruction of hair follicle structures due to infiltration by a T-lymphocytic process. This condition may be idiopathic or associated with MF. Even idiopathic cases can be associated with clonal T-lymphocytic infiltration.[33] In general, patients older than 40 with a more generalized cutaneous involvement and a chronic course are more likely to develop associated MF. No cases of MF have been reported in children with alopecia mucinosa, although few reports of Hodgkin disease have been reported in children with

Figure 85–3 Ulcerated tumors arising from mycosis fungoides plaques.

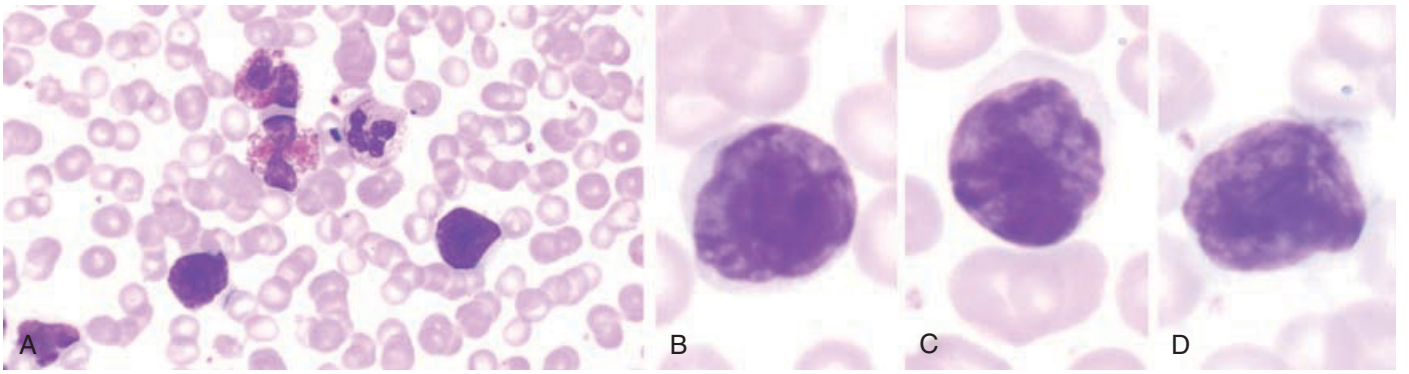

Figure 85–4 Sézary Cells **A–D**. Peripheral smear (**A**) with Sézary cells associated with eosinophilia. Note the cerebriform nuclei with fine chromatin (**B**, **C**, **D**). The hyperconvoluted nature of the nuclei is evident as complex nuclear folds seen through the chromatin.

Figure 85–5 Follicular mucinosis showing a patch of alopecia with follicular prominence.

follicular mucinosis.[34] Patients with mycosis fungoides and follicular mucinosis are reported to have a worse prognosis, stage for stage, which may be caused by inability of topical treatment to penetrate to the deeper layers of the process.[35]

LYMPHOMATOID PAPULOSIS

Lymphomatoid papulosis is characterized by recurrent crops of self-healing, red-brown, centrally necrotic, asymptomatic papules and nodules (Fig. 85–6).[36] This entity represents 10% to 15% of all CTCL cases. Patients may have a few lesions or more than 100 at a time. Histologic evaluation reveals an atypical $CD4^+$ lymphocytic infiltrate with a variable mixed inflammatory infiltrate (Fig. 85–7). These may be primarily small cerebriform cells similar to those seen in MF (type B) but most often there are larger $CD30^+$ cells with prominent nucleoli resembling Reed–Sternberg cells (type A). A third variety of lymphomatoid papulosis (type C) with sheets of anaplastic large cells resembling $CD30^+$ large cell lymphoma has also been reported.[37] T-cell receptor gene rearrangement studies demonstrate a clonal origin. Although the typical course is usually indolent, spanning decades, approximately 15% of patients develop MF, Hodgkin, or non-Hodgkin lymphoma during their lifetime.[38] A direct link between lymphomatoid papulosis, CTCL, and Hodgkin disease was demonstrated in a patient with the three lymphoproliferative disorders arising from a common T-cell clone as shown by TCR gene studies.[39]

PAGETOID RETICULOSIS

Pagetoid reticulosis (ie, Woringer–Kolopp disease) is a rare condition affecting young adults. It typically manifests with a solitary, hyperkeratotic, often-verrucous plaque on the lower limb.[40] Biopsies show atypical cerebriform lymphocytes with a perinuclear halo almost exclusively localized within the intraepidermal compartment.[41] Extracutaneous dissemination is exceedingly rare. Most cases have a $CD8^+$ phenotype, although $CD4^+$ cases or double-negative ($CD4^-$/CD8) cases have been reported. Frequently the tumor cells express CD30, but T-cell receptor gene rearrangement studies are often negative. Whether pagetoid reticulosis should be considered a localized form of MF or a reactive pseudomalignant process is debatable. Although most cases have an indolent protracted course, generalized and sometimes aggressive variants have been reported.[42]

GRANULOMATOUS SLACK SKIN

In granulomatous slack-skin syndrome, an extremely rare disorder, clonal $CD4^+$ T cells elicit a reactive granulomatous response that destroys the elastic fibers, rendering skin slack, fibrotic, and inelastic (Fig. 85–8).[43] Changes characteristic of MF are often found within the epidermis and papillary dermis, and the reticular dermis contains numerous histiocytes with multinucleated giant cells and elastophagocytosis. Some patients with granulomatous MF do not have destruction of the elastic fibers with slack-skin changes. The differential diagnosis for such cases includes sarcoidosis and tuberculoid leprosy.

LABORATORY EVALUATION

The gold standard in the diagnosis of MF/SS is light microscopic examination of a skin biopsy. Characteristic findings include a band-like infiltrate involving the papillary dermis containing small, medium-sized, and occasionally large mononuclear cells with hyperchromatic, hyperconvoluted (cerebriform) nuclei and variable numbers of admixed inflammatory cells often expanding into adnexal structures (hair follicles and sweat glands).[16,44] Epidermal exocytosis of single or small clusters of neoplastic cells is a characteristic finding (Fig. 85–9 A,C,D). The presence of Pautrier's microabscesses defined as four or more atypical lymphocytes arranged in an aggregate in the epidermis is classic, but is seen only in a minority of cases. Tumor-stage lesions demonstrate a more diffuse, superficial and deep, dermal infiltrate with fewer reactive cells and an absence of epidermotropism (Fig. 85–9 B,E,F)). The malignant T-cell clone often evolves into

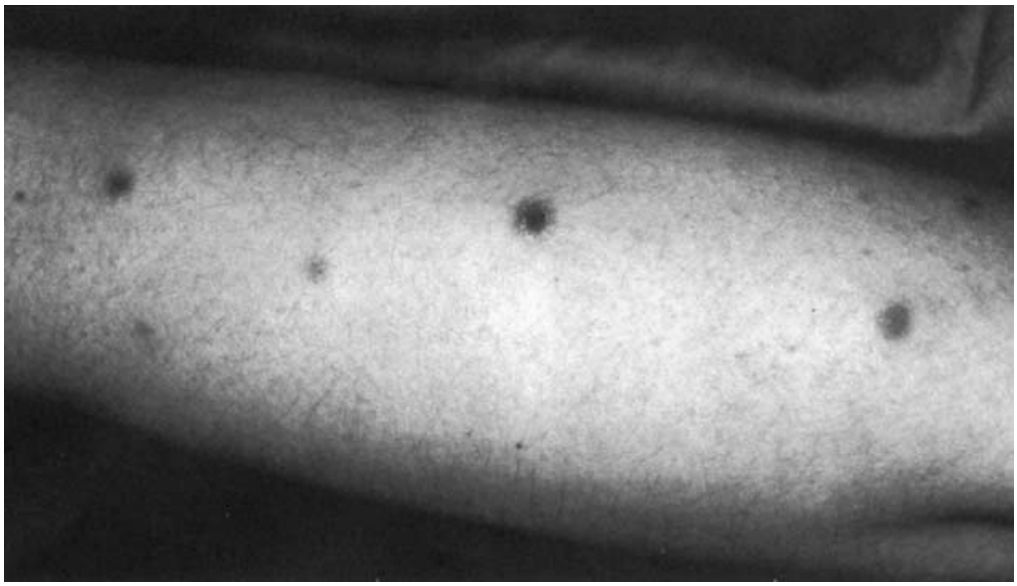

Figure 85–6 Lesions of lymphomatoid papulosis appear in crops and consist of ulcerated papules and scars.

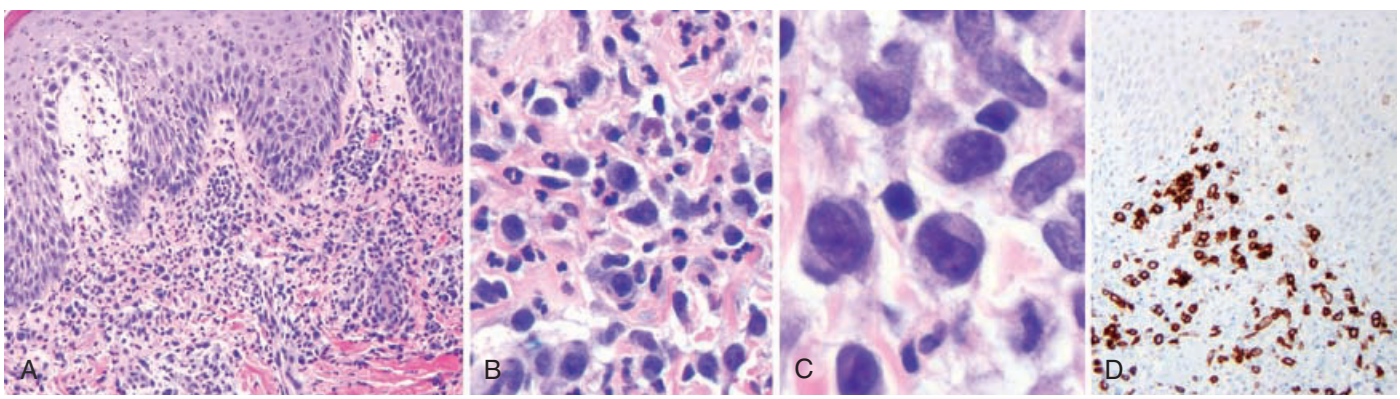

Figure 85–7 Lymphomatoid papulosis (**A**–**D**). Low power (**A**) shows a moderately dense dermal infiltrate of lymphoid cells admixed with inflammatory cells including neutrophils and eosinophils (**B**). The lymphoid cells are varied but include atypical large forms (**C**), which are brightly positive for CD30 (**D**). *(Case courtesy of Drs.Vesna Petrovic-Rosic and Mark Racz, University of Chicago.)*

Figure 85–8 Lesions of granulomatous slack skin with destruction of the dermal elasticity.

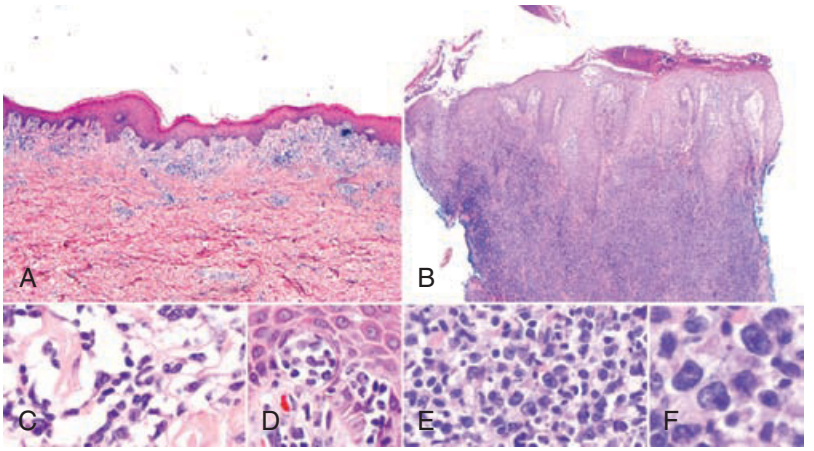

Figure 85–9 Mycosis fungoides, plaque-stage and transformed tumor-stage (**A–F**). Plaque stage (**A**, **C**, and **D**) demonstrates a band-like infiltrate (**A**, **C**) with some epidermotropism in the form of Pautrier micro-abscesses (**D**). In the tumor stage (**B**, **E**, **F**), there is a deep and dense infiltrate without significant epidermotropism. The cells are mostly large and atypical (**E**, **F**) and CD30+ (not shown). *(Case courtesy of Drs. Vesna Petrovic-Rosic and Robert Chen, University of Chicago.)*

large cell morphology during tumor progression, although rare cases show large cell morphology from the early patch lesions.[45] The presence of large cells in a skin lesion should be distinguished from "large cell transformation," which displays rapid skin, node, and visceral progression, is refractory to treatment, and is associated with poor survival. The histologic features in SS may be similar to those of MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may be absent.

Lymph node involvement initially involves the paracortical regions. Progression is associated with small to large clusters of atypical cells with preserved nodal architecture, followed by partial or total effacement of the node by neoplastic cells. Visceral involvement is a late clinical feature. Peripheral blood involvement can be demonstrated in all stages of skin disease, although it is most prevalent in patients with tumor or erythrodermic presentations. Patients with SS may have circulating neoplastic cells but can be lymphopenic. Bone marrow involvement can often be demonstrated in patients with SS or advanced tumor- or plaque-stage MF, but rarely influences management outside an investigational setting. We do not recommend a staging bone marrow aspirate and biopsy.

The malignant cells are typically $CD3^+$, $CD4^+$, $CD45RO^+$, $CD8^-$, and $CD30^-$ by immunohistochemistry. CD7 is often deleted from the early stages. More aggressive variants and advanced CTCL may have multiple pan–T-cell antigen deletions, especially CD2, CD5, and even CD4. T-cell receptor genes are clonally rearranged, and can be demonstrated in most cases by Southern blotting or polymerase chain reaction (PCR) assays when a sufficient malignant infiltrate exists.

Analysis of peripheral blood may reveal an elevated LDH (lactate dehydrogenase) in a small percentage of patients with bulky advanced disease. Eosinophilia and hypergammaglobulinemia are not uncommon is SS patients. A limited number of patients have an associated monoclonal gammopathy. Elevated serum β_2–microglobulin and IL-2 receptor levels have also occurred in advanced cases.

Imaging studies for classic MF/SS are generally of modest utility. CT scans of the chest, abdomen, or pelvis should be reserved for patients with SS, nodal involvement, or CTCL variants. In an investigational setting, electron microscopy, cytogenetics, and molecular analyses have shown that a higher percentage of patients have occult involvement of internal organs.

DIFFERENTIAL DIAGNOSIS

Primary CTCL represents a heterogeneous group of disorders with considerable variability in histology, phenotype, and prognosis. The Kiel Classification, Working Formulation, and the Revised European-American Lymphoma (REAL) classification system were developed for non-Hodgkin lymphomas and are not designed to provide an adequate characterization of the spectrum of CTCL. To address the deficiencies of the previously proposed systems a more clinically useful classification has been developed by the European Organization for Research and Treatment of Cancer (EORTC).[3] The World Health Organization has proposed a new classification with nearly 90% concordance with the EORTC classification (see Table 85–1). A number of other disorders in which malignant T cells infiltrate the skin should be distinguished from MF/SS. These disorders are discussed in the following sections.

CD30-POSITIVE CUTANEOUS LARGE T-CELL LYMPHOMA

Primary cutaneous $CD30^+$ large cell lymphoma ($CD30^+$LCL) typically occurs in adults presenting with solitary or localized (ulcerating) nodules or tumors (Fig. 85–10).[46] Regional lymph node involvement is seen in 25% of patients at presentation. These primary cutaneous $CD30^+$ LCLs are probably closely related to lymphomatoid papulosis, regressing atypical histiocytosis, and primary cutaneous Hodgkin disease. The tumor has a favorable prognosis and often complete or partial spontaneous regression occurs. This is in contrast to primary noncutaneous $CD30^+$ LCL, which can be seen in children or adults and which carries a poor prognosis.[47] These primary cutaneous lesions, in contradistinction from the nodal or pediatric cases, have been shown to rarely have the chromosomal translocation t(2:gene 5) associated with overexpression of the anaplastic lymphoma kinase (ALK negative). Histopathology consists of diffuse nonepidermotropic infiltrates with cohesive sheets of large $CD30^+$ tumor cells (Fig. 85–11). In most instances, the tumor cells have an anaplastic morphology, showing round, oval, or irregularly shaped nuclei; prominent (eosinophilic) nucleoli; and abundant cytoplasm. Less commonly, the neoplastic cells have a pleomorphic or immunoblastic appearance. Reactive lymphocytes are often present, but infiltrating eosinophils are often less conspicuous. The immunophenotype of this disorder is characteristically $CD4^+$, with more than 75% of neoplastic cells expressing CD30. In contrast to the poor outcome of MF that has transformed to a $CD30^+$ large cell variant, primary $CD30^+$ cutaneous large T-cell lymphomas are associated with an excellent prognosis. Radiotherapy is the preferred treatment for solitary or localized disease, with combination chemotherapy reserved for patients with generalized skin lesions or extracutaneous dissemination. Surgical excision may be adequate in many cases. In advanced cases, 5-year survival exceeds 30%.

CD30-NEGATIVE CUTANEOUS LARGE T-CELL LYMPHOMA

These lymphomas tend to have an aggressive clinical course. Patients present with localized or generalized plaques, nodules, or tumors.[48]

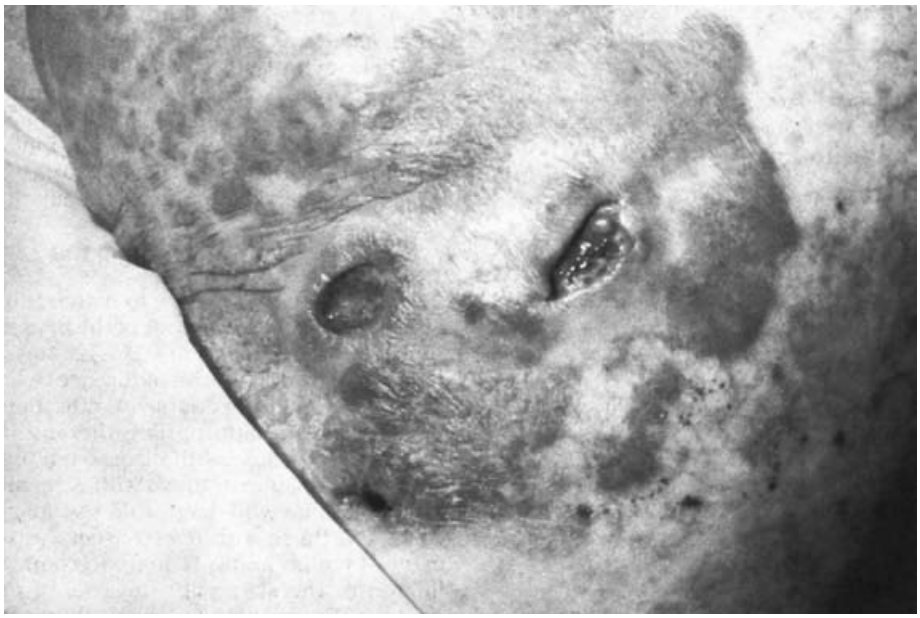

Figure 85–10 Lesions of CD30+ large cell lymphoma with ulceration.

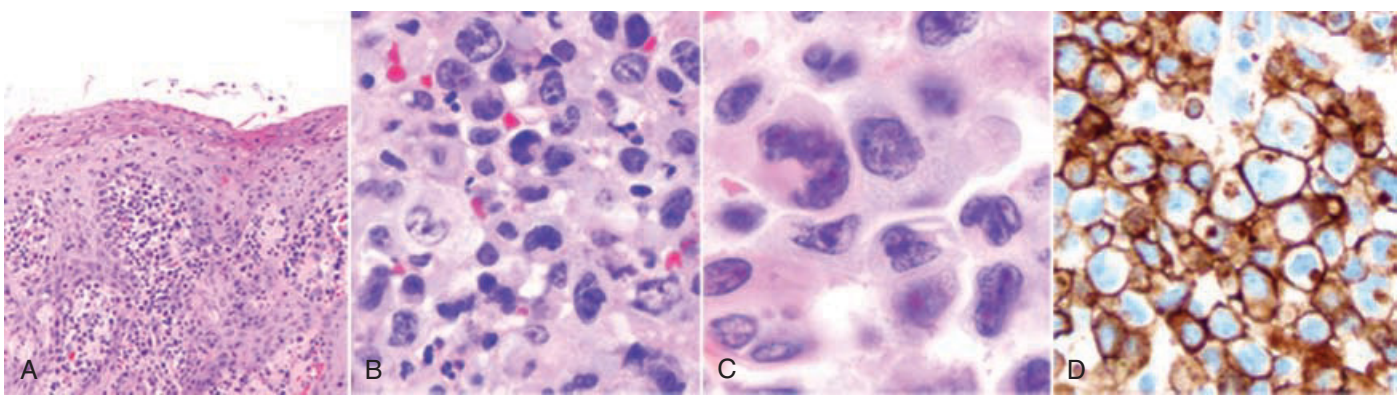

Figure 85–11 Cutaneous anaplastic large cell lymphoma (**A**–**D**). Sheets of tumor cells are present in the dermis (**A**) and are associated with marked pseudoepitheliomatous hyperplasia. The cells are quite varied and bizarre (**B**) and frequently show abnormal "embryoid" shapes (**C**) constituting the so-called hallmark cells. There is bright staining with CD30 (**D**). ALK-staining (not shown) is typically negative.

Histopathology demonstrates that infiltrates are nonepidermotropic with variable numbers of medium-sized to large pleomorphic T cells with or without cerebriform nuclei, and immunoblasts. The tumor cells are $CD4^+$ with CD30 staining negative or restricted to a few scattered tumor cells. Multiagent chemotherapy is used in most instances, with radiation therapy reserved for patients with localized disease. The 5-year survival rate is less than 20%.

PLEOMORPHIC SMALL OR MEDIUM-SIZED CUTANEOUS T-CELL LYMPHOMA

This is an uncommon entity. Patients typically present with red-purplish nodules or tumors. Histopathology shows a dense, diffuse, or nodular infiltrate with small or medium-sized pleomorphic neoplastic cells within the dermis, often with extension into the subcutis.[49] The neoplastic cells are of the helper phenotype and do not express CD30. Localized disease is typically treated with radiation therapy. Prognosis for these patients is good in our experience, with rare progression to more aggressive clinical behavior. Patients with more generalized disease have been treated with regimens used for indolent non-Hodgkin lymphomas. Five-year survival rates exceed 60%.

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

Subcutaneous panniculitis-like T-cell lymphoma is a rare entity. Patients present with subcutaneous nodules and plaques.[50,51] Systemic symptoms are common, including fevers, fatigue, and anorexia. Histopathology reveals a subcutaneous infiltrate with pleomorphic T cells of variable size, mixed with benign macrophages. Tumor cell necrosis, karyorrhexis, and erythrophagocytosis are common findings. Differential diagnosis includes the frequently fatal but non-neoplastic cytophagic histiocytic panniculitis. Neoplastic infiltration of deep blood vessels can be noted in some cases.[52] Immunophenotyping reveals postthymic T-cell markers with $CD4^+$ and $CD8^+$ subtypes. T-cell γ/δ gene rearrangement may be present in some cases, (typically those with a cytotoxic T-cell phenotype $CD8^+$). The prognosis is in general poor despite aggressive chemotherapy, especially when the disorder manifests concurrent with a hemophagocytic syn-

drome (fevers, cytopenias). Cases in which the panniculitic findings coexist with lupus erythematosus may behave in a clinically indolent fashion, however.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis is a rare multiorgan disease of the lungs, nasopharynx, joints, and peripheral and central nervous systems.[53] Cutaneous involvement occurs in 25% to 50% of patients. Though nodules are most common, some patients have nonspecific macules, papules, or ulceration. Histologic evaluation reveals an angiocentric, polymorphous infiltrate of atypical lymphocytes and histiocytes surrounding and invading blood vessels within the dermis. Molecular and immunologic studies suggest a mature clonal helper T-cell process. However, reports have suggested a massive reactive T-cell infiltrate driven by a small number of clonal B cells.[54]

Epstein–Barr virus DNA sequences are frequently present, and their role in the pathogenesis of this disorder is being explored. Though the clinical course is variable, the prognosis for patients with diffuse pulmonary involvement or the appearance of high-grade lymphoma is poor, with a median survival of less than 2 years. Treatment that depends on histologic findings and extent and location of disease may include corticosteroids, radiotherapy, and chemotherapy. Interferon has shown significant activity against this disease.[55]

ADULT T-CELL LEUKEMIA AND LYMPHOMA

Adult T-cell leukemia and lymphoma (ATLL) is in most instances a rapidly progressive T-cell neoplasm expressing a helper phenotype.[56,57] It is endemic in southern Japan and the Caribbean islands and is associated with the retrovirus HTLV-1. However, most HTLV-l–infected patients remain asymptomatic and only 2% to 4% develop ATLL. The clinical presentation is polymorphous and can resemble MF or SS. Cutaneous lesions are variable, ranging from a rash simulating a viral exanthem, to annular lesions resembling erythema multiforme, to large tumors and plaques similar to MF (Fig. 85–12). Advanced stages of the disease, which affects a younger population than seen with MF, are characterized by visceral involvement, immunodeficiency, elevated LDH, and hypercalcemia. Malignant lymphocytes often have convoluted or multilobed nuclei and can be detected in the peripheral blood in 75% of patients. The neoplastic T cells express high levels of the IL-2 receptor (CD25). For purposes of treatment and prognosis, it is wise to view ATLL as a spectrum with two subgroups, acute and all others, with treatment, though inadequate, reserved for those with acute ATLL. Therapeutic options include multiagent chemotherapy and antibody or recombinant toxins directed against the IL-2 receptor. Patients with acute ATLL have poor survival rates, with a median duration of 4 to 6 months. Patients whose disease is not "acute" are considered to have "smoldering" disease and have lesions that may wax and wane in size and shape despite treatment.

PROGNOSIS

The goals of treatment in MF are the relief of symptoms with improved quality of life generally through prevention or delay in development of advanced skin disease, and improvement in cosmetics. Despite some uncontrolled clinical trial results that have been reported to suggest "cures" in this disease, the general perception remains that this disease is not curable with standard therapies available today. The disease behaves similarly to other low-grade lymphomas, with periods of remission gradually becoming shorter with subsequent therapeutic interventions. Unlike B-cell low-grade lymphomas, however, advanced-stage MF is associated with a relatively short median life expectancy. Patients with significant nodal involvement (LN3 or LN4) or extensive skin involvement (T4) have median life expectancies of 30 to 55 months.[58,59] A driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor prognosis patients. No clinical trial has determined that aggressive early therapy is better than sequential palliative approaches or investigational approaches,[60] and new treatments continue to be developed and tested for these patients.

Figure 85–12 Skin lesions in adult T-cell lymphoma/leukemia syndrome.

Techniques such as flow cytometry, cytogenetic analysis, and determination of nuclear contour indices are specialized methods, which may also improve diagnostic and prognostic specificity. Flow cytometry and cytogenetic analysis are complementary techniques. Flow cytometry allows the detection of cell populations with the normal (diploid) number of chromosomes versus abnormal (aneuploid) numbers, and cytogenetic analysis precisely identifies the individual chromosomal structure and number. Bunn and coworkers[61] demonstrated that this can be important prognostically in MF/SS, as the presence of aneuploidy during the clinical course was associated with more aggressive behavior of the disease. Hyperdiploid cell clones were demonstrated in patients with large-cell histology, aggressive disease, and shortened survival time. Specific chromosomal deletions also have an effect on prognosis.[62]

The nuclear contour index has been used by several groups in an effort to separate "benign" cutaneous lymphocytic disorders, such as lymphomatoid papulosis and pityriasis lichenoides, from MF/SS.[63,64] Electron microscopy allows the calculation of a value based on the degree of nuclear folding; this nuclear contour index is significantly greater in patients with MF than in other benign conditions.

The density of epidermal Langerhans cells in biopsy samples, as determined by immunoperoxidase stains, has been identified as a prognostic feature.[65] Epidermal Langerhans cells are necessary for antigen recognition and processing in the normal immune response. Patients with Langerhans cell densities greater than 90 cells per square millimeter had a significantly reduced risk of death from MF/SS compared with those with lower densities. There was no prognostic significance identified for the presence or absence of CD30-positive cells. It has been noted that the presence of cytotoxic $CD8^+$ T lymphocytes in the skin infiltrate is associated with a better prognosis.[66]

Occasionally patients may develop a more clinically aggressive lymphoma concurrent with a change in the histologic appearance of the neoplastic cells and the pace of their disease. This progression from typical small, convoluted lymphocytes to larger lymphocytes, such as those associated with large-cell lymphoma, has been documented.[67,68] Whether this conversion is secondary to prior therapeutic modalities used remains uncertain.

The gold standard for the diagnosis of mycosis fungoides is still routine histopathology with adequate clinical correlation. Early lesions of MF are frequently accompanied by heavy infiltrates of benign reactive T cells, hampering the detection of abnormal T-cell clones by any laboratory method. Hence most adjuvant laboratory methods are not helpful at the precise time when they are most needed.

In 1979, the staging committee at an international workshop on MF proposed a staging system based on the international tumor-node-metastasis (TNM) system (Table 85–2).[69] This classification was based on the evaluation of 347 patients and a multivariate analysis of potential prognostic factors. This group identified several independent prognostic factors: extent of skin disease at diagnosis (T), type of lymph node (N) involvement, presence or absence of peripheral blood (PB) involvement, and presence or absence of visceral (M) involvement. The group also translated this staging into a recommended clinical staging system (see Table 85–2).

Investigators at the National Cancer Institute retrospectively analyzed 152 patients who underwent uniform pathologic staging.[70] They were able to identify three distinct prognostic groups. Good-risk patients had plaque-only skin disease without lymph node, blood, or visceral involvement, and a median survival of more than 12 years. Less than 10% of patients with stage 1A (limited patch) and less than 30% with stage 1B (extensive patch or plaque) progress to more advanced disease. Intermediate-risk patients had skin tumors, erythroderma, or plaque disease with lymph node or blood involvement (but no visceral disease) and a median survival of 5 years. Poor-risk patients had visceral disease or complete effacement of lymph nodes by lymphoma, and a median survival of 2.5 years.

Table 85–2 TNM Staging System for Cutaneous T-Cell Lymphomas

Classification	Description
T	Skin
T0	Clinically or histopathologically suspicious lesions
T1	Limited plaques, papules, or eczematous patches covering 10% of the skin surface
T2	Generalized plaques, papules, or erythematous patches covering 10% of the skin surface
T3	Tumors (one or more)
T4	Generalized erythroderma
	Pathology of T1–4 is diagnostic of a cutaneous T-cell lymphoma. When more than one T stage exists, both are recorded and highest is used for staging. Record other features if appropriate (eg, ulcers, poikiloderma, scale)
N	Lymph nodes
N0	No clinically abnormal peripheral lymph nodes
N1	Clinically abnormal peripheral lymph nodes (record number of sites)
NP0	Biopsy performed, not cutaneous T-cell lymphoma (CTCL)
NP1	Biopsy performed, CTCL
PB	Peripheral blood
PB0 (≤5%)	Atypical circulating cells not present
PB1	Atypical circulating cells not present (>5%), record total white blood cell count, total lymphocyte count, and percentage of abnormal cells
M	Visceral organs
M0	No visceral organ involvement
M1	Visceral involvement (must have pathologic confirmation), record organ involved
Staging	
Stage Ia	T1, N0 NP0, M0
Stage Ib	T2, N0 NP0, M0
Stage IIa	T1-2, N1 NP0, M0
Stage IIb	T3, N0 NP0, M0
Stage III	T4, N0 NP0, M0
Stage IVa	T1-4, N0,1 NP1, M0
Stage IVb	T1-4, N0,1 NP0,1, M1

THERAPY

Therapy can be conveniently divided into two approaches: *topical* (skin directed), such as psoralens with ultraviolet light A (PUVA), topical chemotherapy application (nitrogen mustard or carmustine), and total skin electron beam radiotherapy, and *systemic* (skin and viscera directed), such as interferons, oral or parenteral chemotherapy, photopheresis, oral retinoids, and investigational new compounds (Table 85–3). No studies have demonstrated that one topical therapy is more effective than another, and patient and investigator preference remains the most important discriminating factor governing choice. However, as the biology of the neoplastic cell has become better understood,[71] it is clear that some therapies may actually have topical and systemic effects through alterations in the body's cytokine milieu and ability to mount a host response against the neoplastic cell.[72] Investigational approaches combining therapies remain active research strategies. The following sections detail the individual treatment options and discuss the mechanisms of action, rationale for use, and outcomes.

PHOTOTHERAPY

8-Methoxypsoralen (8-MOP) is a member of a family of photoactivated compounds (furocoumarin derivatives), which may inhibit DNA and RNA synthesis through formation of mono- or bifunctional thymine adducts, gene mutations, or sister chromatid exchanges.[73,74] The cross strand formed between DNA strands results in a halt in cell division as well as oxidative damage of cytoplasmic organelles and cell membranes. These drugs are only active if the tissue containing the psoralen compound is exposed to ultraviolet A rays (UVA). The mechanism of cell cytotoxicity for many cancer therapies involves the induction of apoptosis. Yoo and associates[75] demonstrated that peripheral blood mononuclear cells from Sézary syndrome patients and controls exposed in vitro to PUVA undergo apoptosis. This finding was confirmed with light microscopy, flow cytometry, and electron microscopy, and by gel electrophoresis.

Table 85–3 Therapeutic Options for Mycosis Fungoides

Topical Therapy
Ultraviolet light A with psoralen (PUVA)
Ultraviolet light B (UVB)
Total-skin electron beam radiation
Topical chemotherapy
Topical retinoids
Systemic Therapy
Photophoresis
Interferon-α
Single-agent chemotherapy
Combination chemotherapy
Oral retinoids
Investigational agents

Unfortunately, normal and neoplastic lymphocytes were equally sensitive to the apoptosis induction with PUVA (as opposed to with psoralen alone). However, macrophages appeared to be resistant to apoptosis induction and phagocytized apoptotic lymphocytes (but not nonapoptotic lymphocytes). Apoptosis induction may be the ultimate end point yielding benefit, but an immunologic effect due to monocyte phagocytosis and antigen presentation resulting from effector cells may also be present.

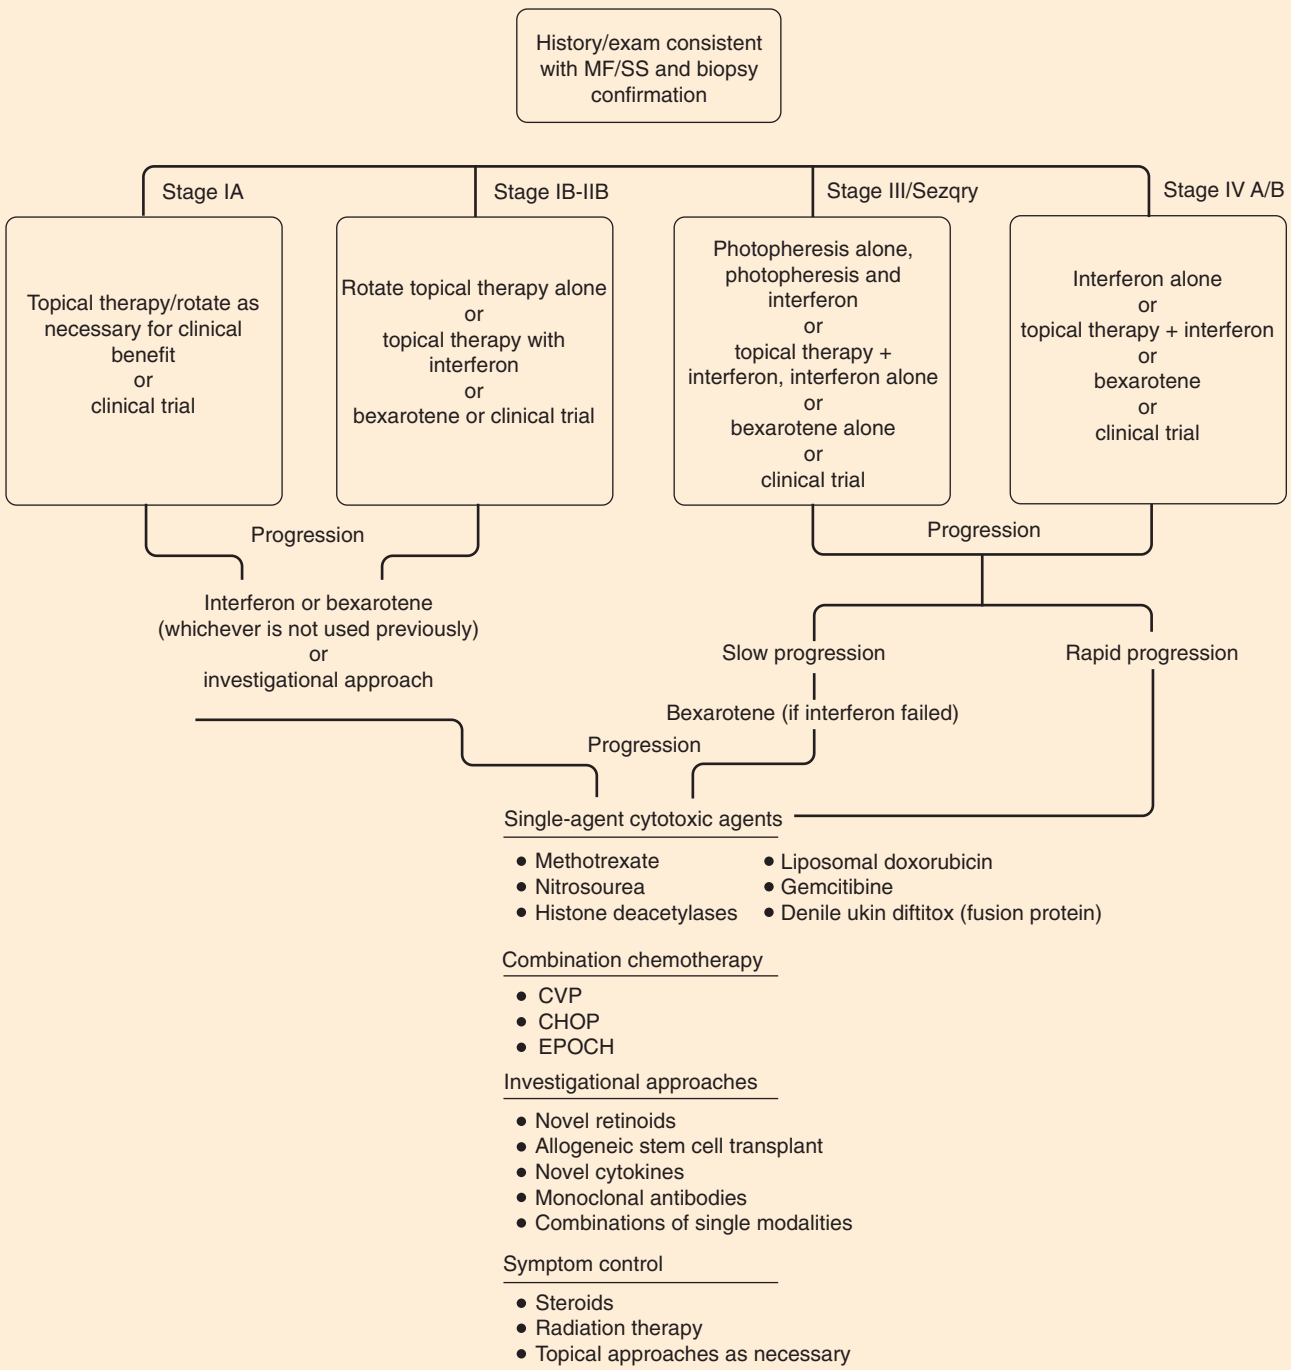
Photochemotherapy units with UVA lamps emit a continuous spectrum of long UVA in the range of 320 to 400 nm with peak emission between 350 and 380 nm. Initial exposure times of patients to high-output UVA are based on the degree of pigmentation before therapy, history of ability to tan, and the output of the photochemotherapy units. Exposure times are increased with each treatment depending on the patient's response, and evidence of erythema. The initial UVA dose is between 0.5 and 2.0 J/cm^2 and can be increased by approximately 0.5 J/cm^2 per treatment as tolerated. The psoralen compound is ingested 2 hours before the UVA exposure. Topical psoralen protocols are also available. UV light-blocking glasses should be worn for 24 hours after administration of 8-MOP. Therapy is typically given three times weekly until complete clearing occurs. The frequency of treatments can then be reduced, but some maintenance therapy (once every 2–4 weeks) may prolong the duration of remission. As new data emerge regarding the long-term risks of second skin malignancies after PUVA, the advisability of this maintenance therapy recommendation has been questioned.

Initial trials using PUVA noted benefit in psoriasis patients.[76] Several clinical trials with PUVA for patients with MF soon followed.[77] These studies all demonstrated high rates of remission induction in the early stage (patch or plaque stage of disease). The Scandinavian study group reported a 58% complete remission rate for these patients within 4 to 12 months of initiation of therapy.[78] Maintenance therapy allowed remission duration of up to 53 months. In these early studies, the same group also reported a surprisingly high rate of objective remission induction in tumor-stage patients of 83%.[79] In a large series, 82 patients were followed for a median of 43 months.[80] An objective response rate was observed in 95% of patients, with a 65% complete clearance rate. Ninety percent of these patients had early-stage disease (stage IA–IIA). A single patient with tumor-stage disease attained a short remission with PUVA alone. Two of six patients with generalized erythroderma cleared completely (no evidence of circulating neoplastic lymphocytes). Given the difficulty in treating advanced-stage patients with PUVA alone, we usually restrict PUVA therapy to patients with stage IA–IIA disease (see Table 85–2), monitoring patients with tumor disease closely for progression.

Side effects with PUVA are quite tolerable. Nausea or vomiting due to psoralen ingestion is observed occasionally, and erythema, pruritus, and chronic dry skin are effects of the UVA light damage to the skin. Long-term PUVA exposure has been associated with a number of late effects. These include dry skin, lichenification, keratosis, and rarely amyloid deposition in the skin.[81] Most important is the late development of iatrogenic (basal and squamous) carcinomas,[82] secondary malignant melanomas of the skin,[83] and rarely cataract formation. Because the cumulative dose of PUVA is correlated with the risks of second skin neoplasms, routine use of maintenance therapy may be less desirable, especially for patients with an excellent prognosis (stage IA). Despite these problems, the long remissions induced, the ease of administration, and the lack of interactions with other therapeutic modalities make PUVA an attractive early intervention.

Narrow-band UVB light (wavelength of 311 nm) is emerging as a valid alternative to PUVA for patients with limited patch or plaque disease. Although probably not as effective as PUVA, initial studies reported response rates near 70%.[84] The advantages of narrow-band UVB are that oral psoralen is not required and there may be less of a photocarcinogenic effect. The role for maintenance therapy has not been established.

UVA-1 is a new modality of phototherapy that uses high-energy UVA-1 (340–400 nm) output, which penetrates deep into the dermis. Resolution of tumor lesions has even been reported using this new therapeutic approach.[85] However, the reduction in circulating CD4$^+$ cells raises the possibility that chronic use of this modality could be immunosuppressive.



RADIATION THERAPY

The non-Hodgkin lymphomas in general, and the CTCL in particular, have been shown to be radiosensitive.[86] External-beam radiation has been shown to adequately control local areas of otherwise resistant MF, or provide palliation in cases of bulky tumor lesions.[87,88] Unfortunately, the cumulative dosage that can be given to patients over time is limited owing to normal organ toxicity. Side effects consisting of leukopenia, thrombocytopenia, and radiation dermatitis may prevent long-term therapy with other agents. Newer techniques involving total nodal irradiation, fractionated total-body irradiation, or hemibody irradiation may have a role to play in the development of multimodality approaches to this disease.

The limitations of external beam radiation led to increasing use of electron beam radiotherapy for cases of MF confined to the skin. Linear accelerator-generated electron beams are scattered by a penetrable plate placed at the collimator site. The energy of the electrons is reduced to 4 to 7 MeV and allows adequate field distribution. Because of this low energy level, the beam only penetrates the surface several millimeters to 1 cm into the dermis. Patients may be treated using six-field or rotational treatments.[89,90] The total skin surface can be treated without significant internal organ toxicity. Most patients are able to tolerate total doses of approximately 3000 to 3600 cGy over an 8- to 10-week period.[90]

An excellent review[91] compared results of external beam therapy at Stanford University with those achieved in Hamilton, Ontario. The results cited in this paper reflect the extensive expertise of both centers in the delivery of this therapy, and may not be applicable to centers with much less frequent use of the technique. For patients with stage IA–IIA (see Table 85–2), almost 65% to 95% of patients achieved a complete remission. Treatment delivered without adjuvant therapies is associated with a relatively high rate of relapse in patients of all stages except stage IA. Ten-year relapse-free survival rates at the two centers range from 33% to 52% for this good-prognosis group. However, for stage IB and worse disease, 10-year unmaintained remission rates are only 16% or less. Higher-risk patients may be "induced" with external beam radiation and then placed on topical chemotherapy or systemic treatments such as extracorporeal photopheresis for "maintenance." Still the benefits of therapy may extend beyond crude estimates of relapse rates or survival. Patients with tumor lesions, generalized erythroderma, peripheral blood or nodal involvement, and even visceral spread can be successfully palliated with electron beam radiation therapy, as well. Side effects, however, can be occasionally extreme, including scaling, dryness of skin, erythema, extremity edema, telangiectasia formation,

Algorithm for Care of Patients with Mycosis Fungoides or Sézary Syndrome

skin ulceration, and hair or sweat gland loss (usually transient but occasionally permanent). Careful radiation dosimetric techniques are required to ensure adequate skin treatment without excessive normal organ toxicity.[90] We do not use electron beam radiotherapy early in the disease because other topical therapies have been developed that yield similar response rates with less potential toxicity. The long duration of remissions observed in patients with stage IA disease does not equate with cure, as their life expectancy is essentially the same as age-matched controls, and these patients may simply have indolent biology. One group has reported their experience with multiple courses of therapy.[92] They re-treated 15 patients with relapsed MF a mean of 41 months after the initial course of electron beam therapy. All patients had received intervening therapies for disease control. Eleven of the 15 had a complete remission with their first cycle of radiation. The second course achieved six complete remissions and nine partial remissions. The median duration of initial complete remission was 11 months. The median duration of complete remission to the second course of therapy was only 3 months, suggesting radioresistance had developed between the first and second cycles in many patients. In general, toxicity was thought to be tolerable.

TOPICAL DRUG THERAPY

The earliest therapies for MF focused on treatment of the skin disease. Patients have long been known to benefit from the application of topical steroids. Zackheim and colleagues[93] reported a 63% complete response rate with twice-daily applications in stage T1 patients but only a 25% complete response rate in stage T2 patients. Novel approaches by dermatologists to apply chemotherapy topically to avoid systemic therapy complications have also been devised. Mechlorethamine hydrochloride was the first topical agent evaluated to demonstrate efficacy in MF.[94] The solution used for topical application contains 10 to 20 mg of mechlorethamine dissolved in 50 to 100 mL of tap water (no vesicant activity at this low concentration). Although several methods may be used for administration, self-administration at home to the entire skin surface is preferred. The concentration may need to be varied depending on patient tolerance and sensitivity.[95] The time to initial response is usually short, approximately 1 to 2 weeks, but long-term application is usually required to obtain the maximum response.

Several large studies have been completed demonstrating the benefit of mechlorethamine, especially in early-stage disease.[96,97] One by Vonderheid and coworkers[96] reported their experience with topical mechlorethamine and found that it compared favorably with electron beam treatment results. Complete remissions were seen in 80%, 68%, and 61% of patients with limited plaque, extensive plaque, and tumor lesions, respectively. The corresponding median duration of remissions was in excess of 15, 5, and 12 months, respectively. It is difficult to draw definite conclusions from these data, as many patients included in the analysis also received intravenous mechlorethamine or methotrexate, and some may have received radiation therapy. Several patients have relapsed as long as 8 years after the completion of therapy, suggesting that follow-up times must be long to compare various topical therapies for early-stage disease. Hoppe and associates[97] confirmed these findings using an ointment-based (Aquaphor or polyethylene glycol) topical mechlorethamine, which may be associated with a lower incidence of cutaneous sensitivity.

For early-stage disease, topical mechlorethamine offers an efficient, convenient (outpatient treatment), and relatively inexpensive treatment option. Side effects consist of delayed hypersensitivity in approximately 35% of patients, although ointment-based solutions appeared to offer a reduced risk of allergic contact dermatitis. Once hypersensitivity develops, patients can be desensitized by injecting minute daily doses of mechlorethamine over a period of several weeks.[98] This should only be done in a medical setting with appropriate anaphylaxis precautions observed. Other investigators had difficulty replicating the results using this risky procedure, and topical desensitization has become much more common. Constantine and colleagues propose that therapy should be transiently discontinued until clearance of the allergic dermatitis is achieved (using topical steroids if necessary).[99] Then 0.01 to 0.1 mg per 100 mL of the drug should be applied daily for 1 week. If this dilution is tolerated, the dosage is doubled weekly until the dose achieved is often identical to the initial concentration that induced the hypersensitivity.

Some clinicians, however, believe that a mild hypersensitivity reaction may have beneficial antitumor effects. Ratner and coworkers previously demonstrated that plaque lesions of MF cleared when exposed to topical doses of 2,4-dinitrochlorobenzene, a known universal inducer of delayed hypersensitivity responses.[100] Anergic individuals failed to improve. Other known sensitizing agents yielded similar but less dramatic responses. Some hypersensitivity may be beneficial; the generalized erythroderma and pruritus are usually poorly tolerated when severe, however, and some alteration in therapy is required.

There has been an increased risk of secondary skin cancers in patients receiving long-term mechlorethamine. Of recent concern is the safety of family members or health care workers secondarily exposed to the topical solutions. Home treatment with topical mechlorethamine has been shown to result in aerosolized drug levels, which may result in mucous membrane or ocular irritation.[101] However, we are unaware of any documented adverse outcomes, and believe this to be a theoretical concern more than a practical one.

Several other topical agents have been tested and shown to be of benefit in the treatment of MF, including, cytarabine, dianhydrogalactitol, dacarbazine, guanazole, teniposide, hydroxyurea, thiotepa, and methotrexate.[102] However, topical carmustine is the only agent that has demonstrated clinical use.[103] A stock solution is created with 300 mg carmustine in 150 mL of 95% ethanol (sufficient for 30 days of treatment). The patient then adds 5 mL of the 0.2% stock solution to 60 mL of room-temperature tap water. This solution can then be applied to the general body surface, with the exception of the head, genitals, palms, soles, and intertriginous zones, unless involved by disease. Applications occur daily for 2 to 6 months, if necessary. Brief exposures to double-dose solution can be tried for resistant disease.

Results in 188 patients with patch or plaque disease demonstrate efficacy similar to that of topical mechlorethamine.[103] For limited patch disease, there was a failure-free rate of 90% at 3 years. For more extensive patch-stage disease the freedom from treatment failure rate at 3 years was 62%. Some patients have been managed as long as 10 years with the topical carmustine. Side effects of contact dermatitis are less frequent with this agent, but systemic side effects, mainly leukopenia, are more common. This drug may be helpful for the treatment of patients who do not tolerate topical mechlorethamine, as there is no cross-sensitivity.

Hamminga and associates[104] performed one of the few prospective trials comparing total-skin electron beam radiation to topical mechlorethamine. A total of 42 patients with MF localized to the skin (no documented nodal or visceral involvement) were treated. Patients were not randomized to their treatment; rather, the physician based the decision on patient health, availability of the linear accelerator, and the distance the patient lived from the clinic. In patients with minimal skin disease, no difference in outcome was observed. In more advanced skin disease, a trend toward superior initial response was seen with electron beam therapy, but there was a high relapse rate in those patients, necessitating subsequent therapy.

SYSTEMIC CHEMOTHERAPY

This chapter includes information on the therapeutic options for treatment of patients with MF or SS. The sheer number of interventions creates a unique dilemma for practitioners caring for these patients: how to prioritize the treatments to maximize therapeutic benefit while minimizing the impact on quality of life. Almost all established chemotherapy agents cause significant acute toxicity, such as myelosuppression (exacerbating the risk of infection in this challenged population), or chronic toxicity, such as development of second malignancies (especially important to consider for patients with an expected long life span). It has been our philosophy that systemic chemotherapy should be reserved for those patients with relapsed or refractory disease after topical interventions; or for those patients with advanced nodal or visceral disease at presentation. Many of the patients we treat with chemotherapy have also previously been treated with cytokine-based or other nontraditional chemotherapeutic agents before our consideration of systemic chemotherapy. With that in mind, a number of trials have been published, reporting results using agents developed many years ago for other indications but still in use for the treatment of MF/SS today, as well as new agents being increasingly studied for specific efficacy in MF/SS based on molecular or proteonomic rationale. An example of such a family of agents is the histone deacetylase (HDAC) inhibitors. Vorinostat (aka SAHA) has recently been approved by the FDA for the treatment of the cutaneous manifestations of CTCL in patients in whom bexarotene (see Retinoids below) has failed,[105–108] and a related HDAC inhibitor depsipeptide (aka FR901228) is in late phase testing. These agents increase acetylation of histones and other nuclear factors, and alter the expression of a number of genes, including some that control growth and differentiation. Vorinostat 400 mg daily orally was tested in an open-label trial of 74 patients who had

progressed on at least two prior systemic therapies. The objective response rate was 29.5%, with 1 complete and 18 partial responses. Common adverse events included diarrhea (49%) and fatigue (46%). Grade III events were less common but included fatigue (5%), deep venous thromboses/pulmonary emboli (5%), and thrombocytopenia (4%).

Reports from the National Cancer Institute with depsipeptide, another histone deacetylase inhibitor, have provided confirmatory results of the use of this class of agent for the treatment of patients with T-cell lymphomas including some with MF/SS.[109,110] In these reports of several phase I and phase II trials, 10 of 20 patients with MF/SS appeared to have had a partial response. Toxicity to depsipeptide has included alterations in the electrocardiogram that could potentially predispose to arrhythmias, and treatment of patients has required ongoing telemetry monitoring in some trials, but no evidence for acute or chronic impairment in cardiac function has been noted. Vorinostat demonstrated drug-related grade I ECG changes in five patients and grade II in one patient.

Unfortunately, depsipeptide has been shown to be a substrate for the multidrug resistance (MDR) protein (a *p*-glycoprotein) and upregulates the expression of MDR1. Preliminary molecular analysis confirmed the upregulation of MDR1. Several patients demonstrated increased surface expression of the CD-25 component of the high-affinity interleukin-2 receptor after treatment. This protein is a target for denileukin diftitox, discussed elsewhere in this chapter as a therapy for MF, suggesting strategies for combination approaches could be devised to enhance responses to both agents.

Older agents studied previously include alkylating agents like chlorambucil or cisplatin, the microtubule inhibitors etoposide, vincristine, and vinblastine, or the antitumor antibiotics, like bleomycin and doxorubicin.[111–114] In general, the response rates are modest and duration of response typically less than 6 months.

McDonald and Bertino[115] reported particularly good results with the antimetabolite methotrexate administered intravenously followed by oral citrovorum factor. Patients received 1 to 5 mg/kg of intravenous methotrexate every 5 days. If a patient tolerated the lowest dose, each subsequent dose was escalated. After 5 intravenous doses, patients were switched to oral methotrexate (25–50 mg) with oral citrovorum as weekly maintenance. All 11 patients achieved "good" or better clearing (>60%) for a median duration of 24 months. Mucositis and skin ulcerations were the most significant toxicity witnessed. Myelosuppression was mild in general. The related compound, trimetrexate, also was effective in treating CTCL.[116]

Subsequently, the benefits of adding 5-fluorouracil to the methotrexate-based regimen, exploiting the synergy between these agents, were evaluated.[117] The methotrexate was administered as a 24-hour continuous infusion at 60 mg/m^2. Immediately after this infusion, 5-flourouracil (20 mg/kg each 24 hours) was continuously infused for 36 to 48 hours. Oral citrovorum factor (10 mg/m^2) was administered intravenously 6 hours after cessation of the methotrexate infusion and then orally for five additional doses. The methotrexate dose was escalated to a maximum of 120 mg/m^2, as allowed by toxicity and response. Ten patients were treated for an average duration of 33 months (range, 3 to 78 months). The number of cycles administered ranged from 5 to 45. All patients achieved a partial remission. Initial cycles were given every 5 to 8 days. Once a good response was achieved, cycles were administered every 3 months as maintenance. Other groups anecdotally reported success with low doses of oral methotrexate. In general these regimens appear to be fairly well tolerated.

The purine antimetabolites have been shown to be active in the treatment of MF/SS. These compounds do not have a single mechanism of action, but all ultimately interfere with intracellular regulation of deoxyribonucleotide pools and this imbalance partially explains the cytotoxicity. This family of drugs includes 2-deoxycoformycin (DCF), fludarabine phosphate, and 2-chlorodeoxyadenosine (2-CdA).[118]

DCF is a transition state inhibitor of adenosine deaminase. Inhibition of this enzyme, necessary for the conversion of adenosine to inosine, results in accumulation of 2-deoxy-ATP and subsequent inhibition of the enzyme ribonucleotide diphosphate reductase necessary for DNA synthesis in dividing cells. DCF is also effective against cells in the resting state, where ribonucleotide diphosphate reductase levels are barely detectable. It has been shown that deoxy-ATP accumulation in resting lymphocytes results in increased DNA strand breaks over time; this results in the activation of Ca^{2+}/Mg^{2+}-dependent endonuclease that produces double-stranded DNA strand breaks at internucleosomal regions, and also activation of a poly-ADP-ribose polymerase that consumes NAD and adenosine triphosphate. These perturbations lead to apoptotic cell death.

Fludarabine phosphate represents the fluorinated derivative of ara-A. This compound was known to retain cytotoxic action against leukemias, and was resistant to degradation by adenosine deaminase. Solubility was poor, however, unless the 5′-monophosphate derivative was used; hence fludarabine monophosphate is the 5′-monophosphate form of F-ara-A. Similar to the mechanism of action of cytarabine or ara-A, fludarabine phosphate requires phosphorylation by deoxycytidine kinase to the active triphosphate metabolite F-ara-ATP. Again, this triphosphate derivative inhibits ribonucleotide reductase, resulting in nucleotide pool imbalances, which prevent DNA repair, and ultimately cause apoptosis.

2-CdA represents another chemical modification of deoxyadenosine, which renders the drug resistant to adenosine deaminase. After activation by deoxycytidine kinase, the triphosphate derivative similarly inhibits ribonucleotide reductase, and accumulates intracellularly perturbing the deoxyribonucleotide pool balance, resulting in DNA damage and cell death.

Enzymes such as cytoplasmic 5′-nucleotidase catalyze the degradation of the active triphosphate derivatives discussed earlier. Cells with relatively greater levels of the activation enzymes versus degradation enzymes were identified as likely clinical targets. Lymphoid disorders make good targets for these agents because they contain high levels of deoxycytidine kinase and low levels of 5′-nucleotidase and depend on polymerase-α for DNA repair. Because it was known that T-lymphoblastoid cell lines were most sensitive to these drugs, it was thought that T-lymphocyte disorders would be sensitive in vivo to these agents.

A number of studies treating patients with MF/SS have been performed with these drugs. Table 85–4 shows the results in these studies. Four studies used DCF as a single agent at doses ranging from 3.75 to 10 mg/m^2 daily for three doses every 21 to 28 days.[119–122] Twenty-five patients with MF/SS were included in the first three studies[119–121]; overall, 3 complete responses (12%) and 12 partial responses (48%) were documented. The fourth study represents the largest phase II experience reported to DCF for the treatment of MF/SS and other cutaneous T-cell lymphomas.[122] Twenty-seven eligible patients were treated for 3 consecutive days at 3.75 mg/m^2/day. Essentially, 80% of the doses in the trial were delivered at 3.75 or 5.0 mg/m^2/day. Twenty-one of 24 response-evaluable patients had

Table 85–4 Response Rates Observed in Clinical Trials with Purine Antimetabolite Agents

Drug	Overall Response Rate	Reference
DCF	66%	119
DCF	100%	120
DCF	54%	121
DCF	66%	122
Fludarabine	18%	123
2-CdA	28%	124
2-CdA	38%	125
2-CdA	18%	126
2-CdA	100%	127

DCF, deoxycoformycin; 2-CdA, 2-chlorodeoxyadenosine.

SS (14 patients), tumor-stage MF (6 patients), or large cell transformation of MF (1 patient). Patients had failed a median of three prior treatments before enrollment. The overall response rate for patients with MF/SS was 66% (five complete and nine partial responses). Most responses were short-lived as the median duration of response in patients with tumor-stage disease was 2 months (range, 1–2 months), and the median duration of response in erythrodermic disease was 3.5 months (no range given, but 2 patients had responses of at least 17 months).

The use of fludarabine for the treatment of MF/SS has also been assessed in a single, large phase II trial by von Hoff and colleagues.[123] They treated 33 patients who were good risks (ie, no prior systemic therapy) or poor risks (ie, prior systemic therapy) with fludarabine alone at doses of 25 or 18 mg/m^2 for the two groups, respectively. One complete response and five partial responses were obtained for an overall response rate of 18%.

2-CdA has been evaluated as a single agent for the treatment of MF/SS. We have treated 21 patients who had failed at least one prior therapy.[124] There were three complete and three partial responses (overall response rate of 28%). The median duration of response in this heavily pretreated group, however, was only 4 months. Three other groups have also reported results in small numbers of patients in the treatment of MF.[125–127] A total of 21 patients were reported when the studies are taken together. Seven patients achieved responses, giving an overall objective response rate of 33%, remarkably similar to results from our large, single-institution study.

The similarity in mechanism of action of these compounds would suggest that toxicity associated with the various compounds would be similar. This has definitely not been the case, however. There are distinct differences in the spectrum of acute and chronic toxicities with these agents. DCF and fludarabine are associated with higher rates of nausea or vomiting and alopecia than commonly associated with 2-CdA. The most significant toxicity with DCF and fludarabine, however, are neurotoxicity and immunosuppression. Approximately 15% of patients developed sepsis, and 10% developed an opportunistic infection, such as disseminated toxoplasmosis, cytomegaloviral infection, *Pneumocystis carinii* pneumonia, atypical mycobacterial infection, and fungemia in studies with these drugs. Another 15% developed severe neurotoxicity in the form of confusion, motor weakness, paresthesias, and central nervous system demyelination. Treatment with 2-CdA is extremely well tolerated acutely, but may result in somewhat greater myelosuppression than the other agents. This myelosuppression may even be more significant when the agent is used to treat T-lymphocyte disorders compared with B-cell diseases. In the study by Betticher and coworkers,[127] significant decrements in neutrophils and lymphocyte populations occurred in 46% and 41%, respectively. In our study of 2-CdA, we reduced the days of therapy delivered by continuous infusion to 5 days from the usual 7 because of a perception that the toxicity, primarily prolonged thrombocytopenia, was unacceptable. These results suggest that patients treated with these agents should be carefully evaluated for infectious complications, especially opportunistic infections, and that prophylactic therapy should be considered during and after therapy if significant immunosuppression is documented. Additionally, one should carefully consider the value of continuing to administer cycles of therapy if there is no evidence of further improvement in clinical response, because of the risk of suddenly developing prolonged cytopenias that may limit future therapeutic approaches. In general it is not apparent that one purine antimetabolite is dramatically better for this indication from these studies, although DCF has a slightly higher overall response rate. It has been observed repeatedly in these studies that occasional patients with SS may have striking and durable responses to treatment, but ideally other agents emerging may allow for higher response rates with less toxicity in this population.

Combination chemotherapy has often been employed for patients with advanced disease at presentation or with progression. Usually alkylator agents are used, in combination with doxorubicin, or vinca alkaloids.[128,129] Response rates of 80% to 100% have been achieved, with longer durations of remission than observed with single agent therapy. There have been no trials comparing different aggressive combination regimes. High response rates with perhaps less toxicity have been observed in treating other non-Hodgkin lymphomas using infusional combination regimens such as etoposide, vincristine, doxorubicin, cyclophosphamide, and prednisone (EPOCH regimen). A trial in CTCL suggested comparable activity to a bolus schedule, with greater risk of febrile neutropenia and bacteremia associated with indwelling catheters required for the infusion.[130]

It is our philosophy that this disease behaves similarly to other low-grade lymphomas (ie, B-cell type), with periods of remission becoming shorter with subsequent therapeutic interventions. However, as noted, advanced-stage MF is associated with a relatively short median life expectancy. Patients with significant nodal involvement or extensive skin disease (T4 in particular) have median life expectancies of 30 to 55 months.[58] A driving force in the development of treatments for this disease is the goal of altering the natural history for this group of poor prognosis patients, or for delaying the development of poor prognosis disease. There is no clinical trial of any modality that has demonstrated a survival benefit compared with a control group. Kaye and associates demonstrated more than a decade ago that combination chemotherapy (and total skin electron beam radiation therapy) did not provide better survival or even clinically significant delays in time to recurrence for patients compared with standard palliative, less aggressive therapies.[60] New drugs or approaches are still being developed with the goal of altering the disease state in poor-prognosis patients.

Because of the pressing need to identify new strategies to provide more durable remissions or even curative therapy for advanced CTCL, new drugs continue to be tested. On the basis of the clinical evidence of possible activity in early-phase testing, several drugs have been evaluated. In a phase II trial of 44 patients with relapsed MF or peripheral T-cell lymphoma (unspecified), gemcitabine was administered at 1200 mg/m^2 over 30 minutes on 3 weekly administrations every 28 days.[131] There were 5 (11.5%) complete remissions and 26 (59%) partial responses (overall response rate 70.5%). The median duration of response ranged from 15 months for complete responders to 10 months for those patients with partial response. There appeared to be no difference in response type between patients with MF or peripheral T-cell lymphomas. In a second trial at the MD Anderson Cancer Center with gemcitabine administered similarly but at a dose of 1000 mg/m^2, investigators found a 68% overall response rate (17/25), with two patients developing a complete remission.[132] Toxicity included myelosuppression in the majority of patients and development of a hemolytic-uremic syndrome in two elderly patients. Most recently gemcitabine was studied as a first-line systemic treatment in 27 patients with stage T3 or T4 MF/SS.[133] The overall response rate was 70% (19/27), with six complete remissions. The median time to progression was 10 months. Toxicity was generally mild.

The campothecins are a family of compounds that inhibit topoisomerase I, an enzyme required for unwinding strands of DNA for transcription and replication. In early phase studies it was recognized that the administration of 9-aminocampothecin (9-AC) by continuous infusion to maintain a drug concentration above a threshold level coupled with duration of exposure was important to ensure adequate inhibition of the target enzyme. In these studies at appropriate concentrations, activity was identified in non-Hodgkin lymphomas,[134] and it was therefore appropriate to study in MF/SS. We undertook a trial of infused 9-AC in patients with MF/SS.[135] The trial was prematurely closed after 12 patients received 30 cycles. There were two partial responses (17%) in a heavily pretreated population of patients; however, 6 of the 12 patients (50%) developed indwelling catheter infections, and 3 patients died 4 to 8 weeks after the last dose of 9-AC. The toxicity was deemed too excessive to justify this dose, route, and schedule of administration. This study nicely demonstrates the hazards of chemotherapy in this patient population, including the underlying risk of infection and the relative contraindication to indwelling catheters (hence a bias toward agents administered with short infusions through peripheral catheters, or oral agents, and the importance of prophylactic antibiotics if excessive invasive procedures are anticipated).

Another drug empirically tested for the treatment of MF/SS is pegylated doxorubicin based on the historic activity of doxorubicin against non-Hodgkin lymphomas. The process of encapsulating the doxorubicin in pegylated liposomes creates stable, long circulating carriers of the drug that results in greater tumor cell uptake versus normal cell uptake. This may reduce normal cardiotoxicity and myelosuppression. The drug is approved for use against Kaposi sarcoma but has been evaluated in a small group of patients with MF from Europe. Six patients in this pilot study received pegylated liposomal doxorubicin at 20 mg/m^2 every 4 weeks.[136] Four patients achieved a complete remission and one other patient achieved a partial remission. The overall response rate was 83%. The median duration of response was not reported. Grade III adverse events were few and included one patient with lymphopenia and two with anemia. No other severe adverse effects were noted. A larger retrospective multicenter report of this agent administered intravenously at 20 to 40 mg/m^2 every 2 to 3 weeks in 34 patients has also been conducted.[137] Overall, 15 patients achieved a complete remission and 15 achieved a partial remission (response rate of 88%), with event-free survival of 12 months. Toxicity was similarly manageable.

The ability to biopsy skin lesions for studies of tumor cells in MF/SS has resulted in this disease being a favored setting for the evaluation of candidate therapeutic agents and exploration of rational therapeutic development. The knowledge gained regarding the human genome and the new studies of proteonomics are increasingly allowing investigators to test new drugs at appropriate dosages, by correct schedule of administration, and to generate, prove, or refute hypotheses regarding mechanism of action or resistance. A number of studies of such agents have recently been completed and may lead to further drug testing in search of enhanced therapeutic activity in MF or perhaps achieve cure of MF.

An example of such an achievement has been the work with temozolomide for the treatment of MF/SS. This agent is an oral imidazotetrazine that has shown activity in solid tumors, such as brain tumors and melanoma. It has been determined that mechanisms of resistance to this agent include expression of high levels of the scavenger protein O^6-alkylguanine DNA alkyl transferase (AGT) in tumor cells. This protein is implicated in the recognition and repair of alkylator-induced DNA damage introduced by chloroethylnitrosourea (eg, *bis*-chloroethylnitrosourea or BCNU) or methylating agents (temozolomide).[138] The presence of the AGT protein imparts resistance by removing toxic lesions formed at the O^6 position of guanine. Chloroethylnitrosourea cross-links are prevented from forming by the removal of the chlorethyl lesion from the O^6 position before rearrangement or by the reaction with the intermediate, 1,O^6-ethanoguanine, to form a cross-link between DNA and the repair protein. The AGT protein is inactivated in the process.[139] Studies evaluating AGT levels in patients with brain tumors receiving BCNU therapy support the role of AGT in resistance to chlorethylating and methylating agents. Retrospective and prospective human studies have demonstrated a correlation between AGT concentration and clinical outcome after treatment with BCNU.[140]

Because of the unique sensitivity of MF to topical BCNU, we were interested in exploring levels of AGT in a variety of patients with various stages of MF/SS. Patients with patch or plaque lesions expressed low levels of the AGT protein compared with a number of controls with reactive dermatitis, and the level of AGT increased correlating with the stage of the patient (ie, patients with malignant lymphocytes harvested from peripheral blood or involved lymph nodes had higher levels of AGT than patch or plaque lesions).[141] Given this data, we initiated a prospective trial of temozolomide in relapsed patients with MF/SS, correlating response to levels of AGT and other known resistance proteins (such as the family DNA mismatch repair proteins).

We reported a preliminary evaluation of the trial.[142] Twenty-two patients had been treated with relapsed stage Ib–IVa disease. All patients had tumor sampled before treatment for assessment of the biologically important resistance proteins. At the time of the presentation, 5 of 19 evaluable patients had achieved a response (26% overall response rate). Preliminary analysis of the resistance proteins suggest that the optimal phenotype, which predicts for good response to therapy, would be low levels of AGT combined with normal levels of several DNA mismatch repair proteins. Interestingly, hypermethylation of these DNA repair proteins has been reported resulting in silencing of the genes, and correlating with lack of the proteins by immunohistochemical techniques in patients with MF.[143] This hypermethylation may be more prevalent in more advanced tumor lesions, and suggests that a propensity for mutations may precede clinical progression. It also suggests that patients might benefit from treatment with demethylating agent in combination with temozolomide. More patients continue to accrue to this trial, and further analysis of pretreatment tumor specimens is ongoing to provide more robust data for assessment of this agent in this disease.

STEM CELL TRANSPLANTATION

The natural evolution of the use of chemotherapy for this disease has been to use dose-intensified approaches with hematopoietic reconstruction with autologous[144] or allogeneic bone marrow.[145] There are few reports in the literature of such treatment programs. Of a total of nine patients (of whom we are aware) who received high-dose chemotherapy with or without total-body irradiation and autologous bone marrow transplants, only two had reasonable disease-free intervals (>12 months).

Given the propensity of Sézary cells to be detectable despite a lack of clinical evidence even in early-stage disease if sophisticated molecular techniques are used, it is likely that reinfusion of neoplastic cells may occur with autologous bone marrow transplantation. The lack of benefit in low-grade B-cell lymphomas for autologous bone marrow transplantation similarly suggests that this approach will not benefit patients. Allogeneic bone marrow transplantation has been presumably curative in small percentages of patients with low-grade B-cell lymphomas, and this approach should be investigated in the small subset of young patients with HLA identical siblings who have poor-prognosis disease and have demonstrated relapse or resistance to interferons and topical therapies. A single patient treated with cyclophosphamide and total-body irradiation was reported to achieve complete remission after allogeneic stem cell transplantation, but relapse occurred by day 70, necessitating additional therapy.[146] The patient remained in complete remission and alive at least 6 years after the transplantation. In light of this, we have begun to explore this approach in patients with MF/SS who are young and have matched donors available.[105] We have used marrow-derived stem cells enriched with peripheral blood-derived stem cells or peripheral blood stem cells only. In appropriate patients, this approach should continue to be explored, and older patients may benefit from strategies involving the use of so-called "mini-allogeneic" transplants that involve less myeloablative preparative regimens, and rely on the effects of the donor marrow to create a graft-versus-lymphoma effect for disease control. Recently, Molina and coworkers have reported promising data utilizing allogenic hematopoietic stem cell transplantation for patients with refractory Sézary syndrome and mycosis fungoides.[147] Each of the seven patients treated had failed a median of seven therapies. Although one patient received a myeloablative conditioning regimen, five received a reduced-intensity regimen consisting of fludarabine and melphalan. Each of the patients achieved a clinical remission and resolution of molecular and cytogenetic evidence of the disease. After a median follow-up of 56 months, six of the eight patients were alive and free of evidence of lymphoma. The two other patients died of transplant-related complications. This small study provides impetus to further development of allogeneic transplantation strategies for the treatment of advanced CTCL refractory to standard therapies. The breakthroughs in technology and basic understanding of the cell biology in patients with MF/SS suggest that chemotherapy will be a component of treatment for patients with this disease, joining the retinoids, cytokines, and targeted approaches.

PHOTOPHERESIS

An adaptation of the use of psoralen with UVA light called extracorporeal photopheresis (ECP) has been described by Edelson and associates.[148] Patients ingest 0.6 mg/kg of oral 8-methoxypsoralen before a treatment. The treatment consists of routine leukapheresis with isolation of the mononuclear cell fraction. The cells are then exposed to UVA light ex vivo within a special chamber inside the pheresis device. In the initial report, Edelson and colleagues documented an 88.5% loss of lymphocyte viability compared with control patients treated with drug alone. Overall, 64% of patients responded to therapy, with the best results in those with generalized erythroderma and, presumably, higher circulating Sézary cell levels. The mechanism is not thought to be directly cytotoxic, but rather to induce a host immune response to the reinfused altered Sézary cells possibly through activation of circulating dendritic cells.[149] This theory would explain the findings of some investigators that patients without leukemic involvement do poorly with this therapy. This treatment modality has given best results in SS patients with erythroderma of short duration and with adequate $CD8^+$ blood counts.

Several other groups have reported their experiences with photopheresis.[150,151] When the data are analyzed on an intent-to-treat basis, overall response rates of 36% to 52% are observed. Only 12% to 18% achieve complete remissions using this therapy. These investigators attempted to wean patients from therapy as clearing of lesions was documented. Ultimately, most responders developed recurrent disease. Many trials are underway combining ECP with other active modalities.

Toxicity is mild and includes occasional nausea, erythematous flares, and temperature elevations. Patients may develop hypotension during leukapheresis, which usually responds to saline infusions.

INTERFERONS

The most active agent for the treatment of MF is interferon-α.[152–156] Dosages and routes of administration have differed among studies. Initially, high-dose interferon was used, with maximum doses of 36 to 50 million IU. Bunn and colleagues[152,153] and Olsen and coworkers[153] independently demonstrated complete response rates of 10% to 27% in heavily pretreated patients. The duration of response was only 5.5 months. Later trials of untreated patients with doses of 3 to 18 million IU given subcutaneously daily have demonstrated response rates of 80% to 92%. From all these studies, it appears that a reasonable and tolerable single-agent dose is 12 million IU/m^2 administered subcutaneously daily. We recommend starting at 3 million IU and gradually increasing as treatment is tolerated by the patient.

In a single trial, the results of treatment of 16 refractory CTCL patients with interferon-γ were reported.[157] Five patients experienced partial responses (response rate 31%) with a median duration of 10 months (range, 3 to 32+ months).

Side effects of all interferons are dose-dependent. Most common adverse effects are constitutional symptoms consisting of fever, chills, myalgias, malaise, and anorexia. Rarely, cytopenias, elevations of liver function tests, renal dysfunction, cardiac dysfunction, or changes in mental status can be seen. Patients need to be monitored closely while on interferon.

RETINOIDS

Vitamin A and its natural and synthetic analogs are known as retinoids. These compounds have diverse biologic effects, influencing differentiation and proliferation of a number of structures during development.[158] Additionally, some compounds have been shown to influence immune function.[159,160] Clinically, a number of approved formulations have demonstrated efficacy in MF and SS.

Many of the trials of retinoids for MF/SS were performed decades ago with limited patient numbers. Treatment with isotretinoin (13-*cis*-retinoic acid), a nonaromatic retinoid, has been associated with clinical benefit in a number of trials. Overall objective responses have been described in 33 of 56 patients treated in three clinical trials.[161–163] A monoaromatic retinoid compound, etretinate, did not achieve similar results when tested as monotherapy for MF in several trials[164–170] but did show efficacy in a trial for the treatment of parapsoriasis en plaque.[166] A polyaromatic retinoid demonstrated efficacy in a small trial. Objective responses were observed in three of six patients (one complete and two partial responses).

There has been a resurgence of interest in retinoids for the treatment of hematologic malignancies with the approval of all-trans retinoic acid (ATRA) for acute promyelocytic leukemia. The mechanism of biologic effect for retinoids is better understood given the advances in basic sciences over the past decades. ATRA has been studied in 33 patients with relapsed MF who had not had prior exposure to oral retinoids.[167] Patients received 45 mg/m^2 daily in two divided doses for up to 2 years. In 29 evaluable patients, 5 responses were observed (1 complete, 4 partial) for an objective response rate of 17% with a median duration of response of 4.5 months. Another seven patients (24%) had stable disease. The most common toxicities included headache (37%) and mucous membrane dryness (80%). Only one patient experienced severe elevation of lipids. ATRA works through binding to specific retinoic acid receptors (RAR family α, β, and γ) that then bind to retinoic acid response elements located upstream of gene promoters, providing transcriptional control of proteins.

A second family of receptors, the retinoid X family of receptors (RXR), has been identified.[167,168] Bexarotene is a synthetic retinoid that selectively binds this family of receptors. Unfortunately, as is the case with the retinoids that bind the RAR family of receptors, it is not known ultimately which gene's expression is altered to provide the clinical benefits observed. This compound has been tested in separate trials of early- and advanced-stage patients. At the 300 mg/m^2 dosage daily (recommended dose by U.S. Food and Drug Administration), 54% of the 94 advanced-stage patients in an open-label phase II study responded to therapy (2% clinical complete response).[167] The median duration of response was 299 days. The early disease trial showed similar response rates. The toxicity spectrum is somewhat different from the RAR-specific retinoids, including more frequent severe elevations of lipids (although rarely associated with pancreatitis), hypothyroidism, and less frequent headaches and dry mucous membranes. The compound can also be used topically. A phase I/II trial of the topical bexarotene demonstrated a 63% response rate (clinical complete response 21%) in mostly early-stage patients with lesional application.[168] Toxicity was mostly local irritation with erythema.

The favorable toxicity profile has led to a number of combination modality trials using retinoids. Some of these small trials have combined retinoids with interferon-α and have reported response rates of 40% to 50%. Combinations of retinoids with PUVA have been suggested to result in clinical benefit in less time with less exposure to ultraviolet radiation. These experiences have been generally limited and often uncontrolled, making definitive conclusions impossible. Larger randomized trials would be needed to determine if routine use of such combinations should be undertaken off of an investigational trial except in rare cases.

FUSION PROTEIN-TARGETED THERAPIES

Targeted therapy has become a reality for the treatment of many types of cancer, including MF/SS. Although the most common approach has been with the use of antibodies that target antigens on the tumor cell surface (eg, rituximab), another class of compounds known as recombinant fusion proteins have been developed, the prototype being denileukin diftitox, for the treatment of CTCL.

Denileukin diftitox is a single-chain protein in which the receptor-binding domain of native diphtheria toxin is replaced by the sequences encoding the interleukin-2 (IL-2) gene.[169] Once this molecule binds to the high-affinity IL-2 receptor, the fusion toxin is internalized by receptor-mediated endocytosis and is proteolytically cleaved within endosomes to liberate the free adenosine diphosphate

(ADP)-ribosyl transferase activity of diphtheria toxin into the cytosol, where it then inhibits protein synthesis.[170,171]

In early phase I studies with denileukin diftitox, the response rate of CTCL patients who demonstrated at least 20% expression of the IL-2 receptor was 30%.[172] A phase III study comparing various dose levels of denileukin diftitox demonstrated a similar response rate, but there was significant toxicity that led to a high drop-out rate (constitutional symptoms, infusion reactions such as hypotension, chest pain or dyspnea, and a vascular leak syndrome).[173]

Because of the toxicity spectrum, we limit the use of this agent to patients who have failed several systemic agents previously, and have more threatening disease such as the presence of skin tumor lesions or nodal involvement. It is important to note that the pivotal trials did not allow concomitant use of corticosteroids to prevent nausea and infusion reactions. Subsequently, a retrospective case review of patients pretreated with corticosteroids suggested a more favorable toxicity profile, and a response rate of nearly 60%.[174] The nature of the trial limits the conclusions to be drawn, but suggests that aggressive pretreatment can make this drug a useful addition to patients with advanced relapsed mycosis fungoides.

INVESTIGATIONAL APPROACHES

Because of the chronic relapsing nature of MF, new therapies with different mechanisms of action are needed to circumvent tumor resistance. A variety of such approaches are under investigation. These include the use of existing or newly developed retinoid compounds or combinations of retinoids with other agents.[175] Other combination modalities under study include retinoids, interferons, and chemotherapy or radiation therapy[176] and total-skin electron beam radiotherapy followed by photopheresis or chemotherapy.[177] Given the lack of benefits of combination chemotherapy and radiotherapy previously, the role of such approaches should remain investigational. Another less toxic combination approach has been the simultaneous administration of interferon and phototherapy.[178] An overall response rate of 92% has been observed with this combination in all stages of patients, many of whom had been previously treated with other therapies.

Another approach to the therapy of this disease has involved new drugs to exploit the biology of these neoplastic cells. Targeted therapies against unique tumor antigens continue to be tested, such as the monoclonal antibody, Campath-1H. Knowledge of the unique cytokine milieu associated with these neoplastic T cells has led to trials testing cytokines that may inhibit the growth of these cells, such as IL-12[178] or IL-2.[179] Vaccine approaches may be practical. As molecular knowledge continues to expand regarding the biology of MF/SS, specific agents can be developed and tested. For example, data demonstrating that the activation of NF-κB in CTCL cell lines predisposes to resistance to apoptosis were cited above. Specific inhibitors of NF-κB or proteosome inhibitors that result in NF-κB inhibition may result in clinical benefits.[180]

Significant amounts of basic and practical research have been performed in an attempt to control this disease, and future treatment approaches will likely depend on further understanding of the molecular and genetic bases of these disorders. We hope that one of the strategies under development or study will lead to treatments that can control the disease and symptomatic effects or even cure this neoplasm.

CHAPTER 86

AIDS-RELATED LYMPHOMAS

David T. Scadden

Non-Hodgkin lymphoma (NHL) is the most lethal complication of human immunodeficiency virus (HIV) infection. It was noted to be associated with HIV infection early in the epidemic and was added to the list of complications defining the acquired immunodeficiency syndrome (AIDS) in 1987.[1–9] The clinical landscape of HIV infection has changed since the introduction of highly active antiretroviral therapy (HAART) accompanied by modifications in both the understanding and treatment of AIDS-related lymphomas. This chapter covers current background information, evolving concepts in pathophysiology, treatment guidelines, and prospects for future development in AIDS-related lymphoma (ARL).

Lymphoid proliferation is common among many different types of immunodeficiencies. Congenital abnormalities of lymphocyte function, such as Wiskott-Aldrich syndrome, or immunosuppressive therapy employed in the setting of organ transplantation have long been known to predispose patients to developing often fatal lymphoproliferative disease. The incidence of NHL following organ transplant is related to the severity of the immunosuppressive regimen used and is more common in multiorgan transplants for that reason. Although the depth of immunosuppression enhances the likelihood of developing lymphoma, immune stimulation may also participate in the lymphomagenic process. This is supported by the association of lymphoma with autoimmune diseases considered reflective of excessive immune activation, such as sicca syndrome (Table 86–1).[10–19]

Despite a common association of immunodeficiency with lymphoma, HIV-1–induced immunosuppression and resultant lymphoma do have distinctive features. For example, the relatively high incidence of a polyclonal, prodromal phase in posttransplant patients appears to be relatively infrequent in ARL, although the issue remains controversial.[20] Epstein-Barr virus (EBV) is virtually uniformly present in the posttransplant lymphomas, whereas it is present only in approximately half of ARLs. Translocations of *c-MYC* are generally not seen in the posttransplant setting but are common in ARL. The small noncleaved cell- or Burkitt-like lymphoma seen in ARL is not an entity among the other immunodeficiency lymphomas. It is extremely rare in the posttransplant patient, strongly suggestive of unique pathophysiologic characteristics in the setting of AIDS.

The heterogeneity of lymphomas within the HIV-infected population emphasizes the complexity of tumor development. A range of different mechanisms have been evoked, including abnormal B-cell activation, excessive cytokine stimulation, altered microenvironment preferentially supporting lymphomatous cells, the predisposition to the persistence of specific chromosomal abnormalities, and perhaps most important, the inadequate immunologic control of persistent viral infections with transforming potential. Understanding how these factors can result in the manifestation of malignancy offers the potential for unraveling how immunologic function interfaces with immunologic malignancy with implications extending beyond that of the AIDS epidemic.

EPIDEMIOLOGY

An increased incidence of NHL was first noted among middle-aged unmarried men in the San Francisco area in 1984 and, with the first redefinition of the syndrome by the Centers for Disease Control and Prevention (CDC), became a criterion for defining an AIDS-related illness. This association has been reaffirmed in other epidemiologic series and includes individuals from virtually every risk group for HIV infection. Unlike the other major neoplastic complication of AIDS, Kaposi sarcoma (KS), NHL is fairly uniform across the spectrum of HIV-infected individuals.[21,22] There is a slight increase in incidence noted among hemophiliacs[21–23] that has provided an intriguing link and potential window on other contributing cofactors, but this remains simply a statistical observation at this time. Lower incidences of lymphoma among intravenous (IV) drug abusers in some series probably reflects the early death of such patients from other opportunistic diseases as well as issues related to their overall care, rather than a true biologic difference. Distinct risk appears to be biologically determined in genotypes of chemokines and their receptors. It has been noted that the presence of an inactivating mutation in the CCR5 chemokine receptor (CCR5 del32) can substantially reduce the risk of susceptibility to HIV infection and its complications. These are data indicating that heterozygosity for this gene may also affect risk for NHL in HIV disease.[24] This same study noted that polymorphisms in the noncoding region of the chemokine SDF1 (SDF103'A) was associated with an approximate increased risk for ARL of twofold for heterozygotes and fourfold for homozygotes. The variable frequency of this genotype in racial groups was thought to contribute to the higher incidence of ARL in whites in the United States.

The overall incidence of NHL in HIV-infected individuals has been variably estimated between 1.6% and 6% per year.[25–27] The discrepancy in estimates can be related to inclusion of postmortem diagnoses in the series with high estimates. The incidence of lymphoma increases with worsening immunosuppression and most often is seen in patients with long-standing HIV infection. However, lymphoma can be the presenting symptom of HIV, and consideration should be given to this possibility in patients with aggressive lymphomas. Concerns have been voiced that antiretroviral therapy can predispose to the development of lymphoma because of the potential effect of nucleoside analogs on cellular DNA synthesis. However, subsequent studies have failed to note any association and discount the notion that retroviral therapy should be withheld out of concern about induction of lymphoma.[28]

Projected increases in the incidence of NHL in AIDS as other opportunistic disease has been better controlled,[29] have not materialized. Indeed, it is now clear that the risk for lymphoma is reduced among patients treated with HAART for HIV. This effect is uneven across the types of lymphoma. For example, primary CNS lymphoma is an agonal manifestation of HIV disease and has dramatically dropped in incidence among those patients with access to antiretrovirals. A decline in incidence of systemic lymphomas is less dramatic but is estimated to be twofold to sevenfold decreased since the introduction of HAART.[30–33] In an observational cohort study of 8500 HIV-infected individuals in Europe, the reduction was apparent across all lymphoma subtypes.[34] In contrast, an international cohort study found that the decline was disproportionately great in immunoblastic and primary CNS lymphoma, the subtypes most often associated with EBV. Therefore, antiviral immunity is likely a host factor influencing the risk for ARL development, but the issue involves a more complex array of pathophysiologic processes (Fig. 86–1).

Table 86–1 Magnitude of Relative Risk of Lymphoma*

High (RR > 15)	Intermediate (RR > 2)	Low (RR ≤ 2)
Multiple transplants	Sibling transplant	Splenectomy
Cadaver transplant	Mild sicca syndrome	Sarcoidosis
Severe Sicca syndrome	Nontropical sprue	Hyperimmunization
Wiskott-Aldrich syndrome	Crohn disease	Asthma
Ataxia telangiectasia	Short-term HIV infection	Hansen disease
Long-term HIV infection	Rheumatoid arthritis	Cytotoxic drug prescription
		Systemic lupus erythematosus

HIV, human immunodeficiency virus; RR, relative risk.
*Risk of lymphoma in patients with the condition relative to a risk of 1.0 compared with individuals without the condition.

PATHOPHYSIOLOGY

The epidemiology of NHL is generally changing within the United States, with an increased incidence noted particularly among men. The bases for this change are poorly understood, but a contributing factor is the HIV epidemic and ARL. The epidemiology of ARL is influenced by HIV treatment and coincident associated viruses, such as EBV and the KS herpesvirus (KSHV), also known as human herpesvirus type 8 (HHV-8). There are likely other, yet undetected cofactors that account for some of the other subsets of this disease. In particular, the Burkitt or Burkitt-like lymphomas uniquely seen in AIDS and not in other immunodeficiency states represent a subset likely to yield novel insight into factors contributing to ARL.

HIV-1 itself rarely participates directly in the malignant process, but rather provides the background of immunodeficiency within which lymphomas might arise. However, rare tumors have been associated with a direct effect of HIV among the small minority of lymphomas seen in AIDS that are of T-cell origin. Molecular analysis of some of these cases has indicated that HIV was either integrated in the T cells or highly expressed in tumor-associated macrophages. The site of HIV integration into the host genome was evaluated and found to be in a common site upstream of the protooncogene, *c-fes*.[34] Aside from these relatively uncommon tumors, the transformed cells do not contain HIV-1 DNA. Rather, other mechanisms of lymphomagenesis predominate.

Potential contributing underlying abnormalities include most prominently:

1. Inadequate immunologic control of persistent viruses with transforming capability.
2. Alteration in the regulatory environment for lymphoid growth control.
3. Accumulation of genetic abnormalities in frequently activated B cells.

The issue of participating secondary infectious processes in ARL is generally supported by the spectrum of AIDS malignancies (Table 86–2). Tumors with definite or probable increased frequency in HIV disease are notable for the relatively small number of tumor types seen. Unlike tumors outside the setting of HIV disease, where a broad spectrum of epithelial neoplasms occur, the spectrum of malignancy is narrow. Unifying most of these diseases is an association with underlying infectious agents. The herpes virus KSHV is associated with both KS and a subset of NHL.[35] The squamous cell neoplasia of the uterine cervix in HIV-infected women, of the anus of homosexual men, and of the conjunctiva in individuals in Africa is associated with the human papillomavirus.[36–42] EBV is a well-known participant in a subset of lymphomas, as well as the leiomyosarcoma seen in children,[43] and in the Hodgkin lymphoma seen in the setting of HIV.[44] Therefore, viral pathogens are strongly related to the development of neoplastic complications. The specific mechanisms participating in transforming events are in the process of further evaluation. These offer the potential for novel types of therapeutic intervention, and the viral antigens associated with them offer possible immunotherapeutic targets.

The EBV genome has been reported to be present in 33% to 67% of ARLs, as opposed to 5% of high-grade lymphomas outside the setting of HIV.[45] The frequency varies depending on the cell type involved. The EBV genome is present in virtually all immunoblastic tumors of the CNS, whereas only 20% to 34% of the Burkitt-like tumors contain EBV.[46,47] Oral-cavity ARLs with T-cell markers[48] and plasmablastic lymphomas in the oral cavity[49] all appear to contain the EBV. Leiomyosarcomas occurring in children with HIV disease, but not in adults, also uniformly contain EBV within the tumor cells.[46]

EBV is thought to infect cells and induce their altered proliferation by expression of virus genes that are part of the latent (as opposed to lytic) virus phase. The pattern of EBV gene expression varies with the clinical and pathologic setting. In most patients with primary CNS lymphoma, the EBV latent gene expression pattern is identical to that of posttransplant lymphoproliferative disease, including Epstein-Barr nuclear antigen (EBNA)-2 through EBNA-5 and latent membrane protein (LMP)-1 and LMP-2.[50,51] In Burkitt lymphoma (BL), only EBNA-1 is usually detectable.[50,51–54] For some systemic ARLs, a unique combination of EBNA-1 and LMP-1 expression has been reported.[55] Molecular analysis of EBV latent genes has indicated that EBNA-1 is important for transformation because of its effects on transcription and maintenance of the EBV episome. LMP-1 is essential for primary B-cell transformation and for transforming effects on nonlymphoid cells.[56–58] LMP-1 interacts with the signaling pathway used by the tumor necrosis factor receptor family of genes through very specific molecular interactions at its carboxyl terminus.[56–59] Several mutations have been noted within the LMP-1 portion of the EBV genome, and some data have supported the possibility that these variants are associated with ARL or HIV-related Hodgkin lymphoma.[60–63] However, controversy on this continues, as some studies have indicated that LMP-1 mutations occur with similar frequency in patients with lymphoproliferative disease and in unaffected individuals.[61] The relationship of EBV to transformation is clear, but why certain individuals are more predisposed to develop lymphoma is still unknown. Molecular evolution of the virus within the host remains a tenable, but unproved, hypothesis.

An alternative possibility is that some individuals will selectively lose their immunologic reactivity to EBV or other transforming viruses. Many immunologically recognized antigens within the EBV genome have been characterized as being targets for cytotoxic T lymphocytes (CTLs).[64] These may be masked by direct effects of EBV EBNA-1 on antigen presentation through altered antigen-processing pathways[43,65,66] or through deletion of reactive CTL clones during the course of progressive immunodeficiency. Alteration of the T-cell receptor repertoire is a well-documented phenomenon in AIDS and may result in nonhomogeneous losses of reactivity to specific foreign or tumor antigens.[67] This phenomenon suggests the potential for clonal repletion as a strategy for intervention and, indeed, such an approach has been successfully demonstrated in posttransplant patients with EBV lymphoproliferation.[68–70] Adoptive transfer of T cells is complicated outside the transplant setting, however, and, therefore, reconstituting EBV immunity in HIV disease is currently left to the gradual immune regeneration following HAART. Whether this can have a therapeutic effect for EBV-related ARL is unclear, but the documentation of long-term survivors of primary CNS lymphoma in AIDS following radiation and HAART is suggestive.

The vigor of immunologic response may also be affected by oncovirus gene products. In particular, an EBV gene (BCRF-1) has homology with human interleukin 10 (IL-10) and mimics IL-10 function.[71–73] IL-10 has been noted to inhibit interferon gamma and interleukin 2 (IL-2) elaboration by T-helper cell type 1 (Th1), cells important in activating and sustaining an immunologic response.[72] Cell lines and primary tumors isolated from patients with AIDS lymphoma produce a high level of IL-10, and elevated circulating levels of IL-10 in mouse models of AIDS lymphoma have been well documented.[71,73–76] Other cytokine-related effects include the production of CD40 (a B-cell proliferation signal) by HIV-infected bone marrow endothelial cells[77] and interleukin 6 (IL-6) production by HIV-infected macrophages or by KSHV-infected cells.[78,79] Increased IL-6 levels have been noted to correlate with malignancy and increased serum CD23 (a marker of activation) to precede it.[80,81] Dysregulation of cytokines further induces alterations in B-cell biology contributing to a hyperproliferative state.

Another viral pathogen that contributes to ARL is the most recently described member of the γ-herpesvirus family, KSHV. This virus was originally identified by comparative analysis of the DNA content from KS tissue versus uninvolved tissue.[82] This genetic approach to pathogen identification revealed a virus that has now been shown convincingly to be associated with KS, but also with a subset of ARLs, Castleman disease, and perhaps plasma cell dyscrasias.[33,35,83,84] The lymphomas are generally restricted to body cavities without tumor masses and are called primary effusion lymphomas (PELs). Features of this clinicopathologic entity are discussed further in a separate section, but features of this virus are extremely interesting from the pathophysiologic perspective.

KSHV is known to be capable of infecting primary B cells[85] and is uniformly found in the transformed B cells of PELs. Mechanisms by which this virus participates in the malignant process remain speculative because in-vitro infection with KSHV does not result in B-cell transformation. However, a number of components of the KSHV genome suggest the potential for this virus to alter B-cell physiology. These include a constitutively active chemokine receptor that causes cell lines to have enhanced malignant potential when transfected, a physiologically active cyclin-D homologue, a viral IL-6 with potent biologic activity, a B cell lymphoma (BCL)-2 homologue, and CC chemokine homologues.[79,84,85–90] This constellation of different immunoregulatory proteins is highly suggestive of direct mechanisms by which the virus can perturb cell functions, but the details have not yet been clarified. Activation of STAT3 has been noted in KSHV primary effusion cells, but its relationship to KSHV is not known.[91] However, interruption of STAT3 signaling efficiently induces PEL apoptosis mediated by reduced expression of the anti-apoptotic gene, survivin. Therefore, targeting this pathway may have therapeutic significance for controlling KSHV-related lymphoma. Another approach would be through immunologic response to KSHV. The nature of the response is not well understood because in-vivo reactivity appears to be at very low levels even in immunocompetent individuals. Although T-cell targets of KSHV have been defined,[92,93] the virus also encodes proteins capable of hiding infected cells from either CTL or natural killer cell attack.[93–96] The strong association of KS with immunodeficiency and the response of this tumor to immune regeneration indicates the role of immune control, but the specific details of this response, whether it can be enhanced with vaccine, and whether it participates in control of lymphoma outgrowth, remain undefined.

Many ARLs do not evidence either EBV or KSHV infection. Although it has been hypothesized that these may represent cells transformed by still-unknown infectious agents, a number of potential etiologies remain. These include the proliferative drive provided by EBV- or HIV-induced cytokine alterations as noted previously. In addition, a gross dysregulation of B-cell biology is evident early on in HIV disease, regardless of the subsequent development of lymphoma.[97] This includes the presence of hypergammaglobulinemia, which is perhaps the most common serologic abnormality among HIV-infected individuals.[98,99] As patients progress in HIV disease, lymphadenopathy with follicular hyperplasia is common and is similarly reflective of disordered regulation of the B-cell lineage.[100,101] It has been postulated that a portion of the HIV envelope may be capable of inducing T-cell–mediated B-cell activation.[102,103] This may result in particular outgrowth of HIV-specific B cells. With chronic stimulation, transformation can occur, and sporadic multiple myeloma with HIV specificity has been reported.[104–106] Characterization of the variable chain repertoire of immunoglobulins produced by B cells in patients with HIV disease has indicated that preferential use of the variable heavy chain (VH) subsets occurs early in HIV infection[107] and in ARL tumors.[108] These findings suggest that there may be an antigen-driven expansion of selected B-cell clones that can provide the mitogenetic background for mutagenesis to result in malignancy.

Many specific genetic mutations have been observed in ARL and are associated with specific tumor types.[109–111] That is, tumors of small cell, Burkitt, or Burkitt-like histology uniformly exhibit *c-MYC* gene rearrangements, have *p53* gene mutations in approximately 50% of tumors, and do not exhibit *BCL6* rearrangements.[112–116] This is in contrast with large cell lymphomas, among which approximately one-third demonstrates *BCL6* rearrangement, 40% *c-MYC,* and 25% to 40% of *p53* mutations.[116,117] The *c-MYC* rearrangement that is found most often juxtaposes *c-MYC* with the immunoglobulin heavy

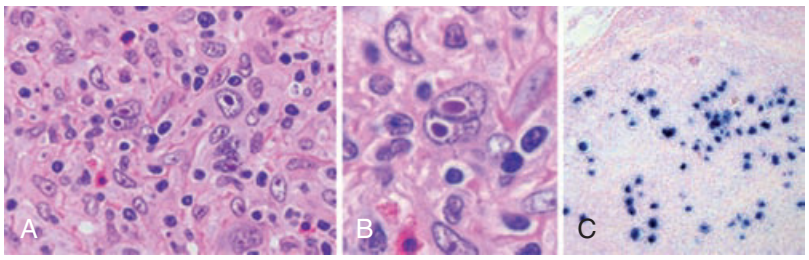

Figure 86–2 AIDS-Related Hodgkin Lymphoma. Hodgkin lymphoma (**A, B, C**): Hodgkin lymphoma of the mixed cellularity type in an HIV-positive patient (**A**) These cases commonly have some depletion of lymphocytes in the background, and increased numbers Hodgkin and Reed-Sternberg cells (**B**). Epstein Barr Virus mRNA (EBER) can usually be detected by in-situ hybridization (**C**).

chain switch region.[114,118–121] The involvement of this region suggests that the transforming event has occurred in a B cell that is undergoing transition between heavy chain isotopes: phenomena occurring at a relatively late stage in B-cell ontogeny.[22,102,103,112,113,115,122–124] The malignant cell, therefore, appears to be a relatively mature B lymphocyte. In ARL, *c-MYC* rearrangement and EBV infection are not necessarily present in association with one another.[112–115] Similarly, *BCL6* rearrangements are variably associated with the presence of EBV. It is of interest that no coincident *c-MYC* and *BCL6* rearrangements have been detected.[125] A characteristic of B cells is the ongoing mutation of the immunoglobulin locus to potentially enhance immunoglobulin affinity for antigens. This process, called *somatic hypermutation*, can target genes besides the immunoglobulin genes such as *BCL6*. Not usually seen, however, and what has now been identified in ARL is mutation in the *PIM-1* or *c-MYC* loci, genes associated with lymphoma. Somatic hypermutation may, therefore, play a role in lymphomagenesis in AIDS. Molecular abnormalities associated with low-grade lymphomas (such as the 11 : 14 rearrangement) are generally not seen in ARL.

CLINICAL MANIFESTATIONS

ARLs are generally extremely aggressive, high-grade lymphomas of B-cell origin. However, the spectrum of lymphoproliferative disease is broad and is continuing to expand. T-cell malignancies have been reported, including large granular lymphocyte disease, large-cell or anaplastic T-cell lymphoma, Sézary syndrome, and angiocentric T-cell proliferation.[106,126–133] Virus infection with human T-cell leukemia-lymphoma virus (HTLV)-1 has been noted in some cases of T-cell malignancy with coincident HIV infection.[134] In addition, HIV itself has been noted to be integrated in some of these lymphomas,[34,133] as previously discussed. Oropharyngeal T-cell lymphoma has been described in AIDS patients and is associated with the presence of EBV in the tumor cells.[48]

Castleman disease or angiofollicular lymph node hyperplasia has been reported in patients with advanced HIV disease.[35] This is typically a multicentric variant of Castleman disease that is associated with fever, peripheral adenopathy, weight loss, hepatosplenomegaly, pulmonary symptoms, and anemia or pancytopenia. Both the hyalin-vascular and plasma-cell subtypes of multicentric Castleman disease have been reported in AIDS patients. There is a very high association of this process with the presence of KSHV in the involved nodes and a high prevalence of coincident or subsequent KS.[35,84,135,136] This lymphoproliferative process is often aggressive with poor outcome, although responses to chemotherapy have been reported.[35] Anti-CD20 antibody therapy may be active in the treatment of Castleman disease, and initiation of HAART can influence the outcome.[125,137]

Plasma cell disorders appear to be increased in the setting of HIV infection. Plasmablastic lymphomas of the oral cavity have been described[138] as a relatively uncommon neoplasm, notable for the frequent absence of typical lymphoid markers such as CD45 (leukocyte common antigen) or CD20. Extramedullary plasmacytomas have been reported, as well as overt multiple myeloma.[139,140] The clinical course of these disorders is highly variable, and the clinical approach should be based on standard guidelines for these diseases outside the context of HIV infection.

Hodgkin Lymphoma

The incidence of Hodgkin lymphoma in patients with HIV infection has been variably reported, but an excess above the general age-matched population is evident and estimated to be 2.5- to 8.5-fold in magnitude.[141–143] The clinical presentation in the setting of HIV infection is often distinct in that the clinical stage is more advanced and the mixed cellularity subtype more common.[5,128,144–151] Stage III to IV disease at presentation has been noted in more than 80% of HIV-seropositive patients.[146] Extranodal disease is also more common in HIV-seropositive patients, with one series reporting a frequency of 63% compared with 29% in seronegative patients.[150] In addition, histopathologic features of Hodgkin lymphoma in AIDS are different both in the frequency of mixed cellularity and the presence of EBV (Fig. 86–2). Virtually all tumors have detectable EBV and express LMP-1.[152] A high frequency of LMP-1 molecular abnormalities has also been noted in patients with AIDS compared with patients with Hodgkin lymphoma who do not have AIDS.[152]

The clinical approach to patients with Hodgkin lymphoma in the setting of HIV infection is similar to that in other contexts with standard staging methods. Treatment strategies should be applied as appropriate for stage, similar to guidelines outside the setting of HIV infection. However, the underlying level of immunosuppression and overall performance status of the patient must be considered. A higher incidence of treatment complications can be expected if the patient has very advanced AIDS, and appropriate prophylaxis for *Pneumocystis carinii* should be undertaken. However, cure of Hodgkin lymphoma has been well demonstrated in the setting of HIV infection, and dose attenuation should be contemplated only in those patients with advanced AIDS or those who have demonstrated intolerance to the standard dose regimens.

Non-Hodgkin Lymphoma

Most lymphomas that occur in the context of HIV are of B-cell origin and are typically aggressive, high-grade malignancies (Fig. 86–3). The lymphomas can basically be broken down into two major subcategories: primary CNS lymphoma and systemic lymphoma that may or may not include CNS involvement. In the systemic disease category, a subset of patients have the primary effusion lymphoma (PEL) mentioned previously (Table 86–3) or the plasmablastic lymphoma of the oral cavity. Both these latter tumors are uncommon outside the setting of HIV disease.

These primary effusion lymphomas or body-cavity lymphomas are generally present in body fluids without associated tumor masses.[33,153] They have a common immunophenotype in that markers of B or T cells are generally absent from the cell surface, but evidence for

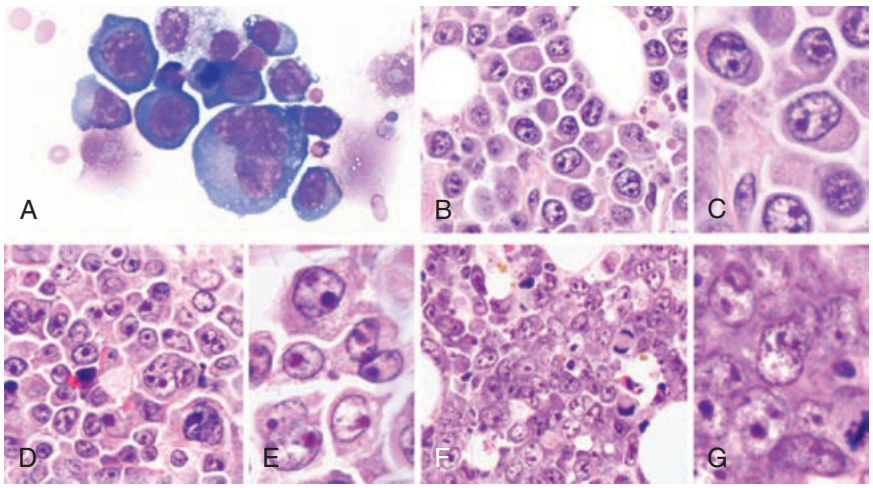

Figure 86–3 AIDS-Related Non-Hodgkin Lymphoma. Pleural effusion lymphoma (**A**), primary effusion lymphoma (PEL), or body cavity lymphomas are diagnosed by examination of the fluid on cytospin preparations and by flow cytometric and genetic studies. On the cytospin preparation the cells are large and frequently include multinucleated forms. Flow cytometric studies can be difficult to interpret as the cells lack B markers and surface immunoglobulin, but clonality can be detected by immunoglobulin gene rearrangement analysis. Plasmablastic lymphoma (**B, C**): Plasmablastic lymphomas occur in the oral cavity but can present elsewhere. They are comprised of large plasmablastic cells with eccentric nuclei and amphophilic cytoplasm. These are usually CD45- and CD20-negative but express CD138 and MUM1. Large B-cell lymphoma (**D, E**): These lymphomas resemble large B-cell lymphoma in the non-AIDS setting. Frequently they have an activated B-cell phenotype. Burkitt lymphoma (**F, G**): In AIDS patients Burkitt lymphoma sometimes has atypical morphology with plasmacytic features or more irregular nuclei than usually seen (**G**). These cases are considered variant Burkitt lymphoma. The case depicted had the typical t(8;14) associated with *c-MYC* rearrangement.

immunoglobulin gene rearrangement by analysis of tumor DNA indicates that they are of B-cell origin. Gene-profile analysis has indicated that these tumors are not of germinal center or mature B-cell origin, but rather resemble immunoblasts and plasma cells and have, therefore, been considered of "plasmablast" origin.[143,154] These tumors are uniformly associated with the presence of the KSHV genome in the tumor cells. Although many also contain EBV, this finding is less uniform.[109,110] Seroepidemiologic data regarding this virus are still limited, but it is clear that the virus can be found in abundance in saliva.[154,155] Transmission is associated with sexual activity, but nonsexual transmission to young children in endemic areas is also common.[155,156]

The virus is found in subsets of the North American population with estimates ranging from 5% to 20%.[157,158] Other areas associated with the higher frequency of KS, such as the Mediterranean basin and Central Africa, have been noted to have far higher frequencies of seropositivity for KSHV.[157] Patients with PEL often have advanced immunosuppression and present with rapidly evolving pleural or pericardial effusions or ascites. The bowel can be involved,[159] and some patients will show dissemination to bone marrow and blood. This tumor generally behaves very aggressively, and the outlook with current approaches is unfavorable.

The most common histologic types of NHLs in AIDS are those also seen outside the setting of HIV disease. Among these, diffuse large B-cell lymphoma is the most common, followed by Burkitt or Burkitt-like lymphoma. Mucosa-associated lymphoid tissue lymphomas have been reported but are rare. Low-grade B-cell malignancies are a distinct minority among HIV-infected patients. Such tumors can occur but with a frequency approximately comparable with the background for the population.

Like high-grade malignancies outside the setting of HIV disease, ARL often involves sites outside the confines of the lymphatic system (Table 86–4). Extranodal disease has been estimated to occur in up to 95% of patients with ARL, with extranodal tissue frequently the source of diagnosis.[3,5,7,113,160–173] Disease that is exclusively outside the lymphatic system has been reported in up to 56% of patients.[173]

The frequency of extranodal disease emphasizes the necessity of exercising particular vigilance in evaluating these patients. Unusual symptoms must be assessed with attention to possible direct tumor involvement as the cause. ARL can also mask or be confused with other opportunistic disease. In particular, the constitutional symptoms accompanying either infection or lymphoma should be assessed for both. In addition, lymphadenopathy occurs frequently in the course of HIV infection and is often simply evidence of hyperproliferation without transformation. A high index of suspicion must be maintained, particularly for those patients who have coincident B symptoms or who have rapidly progressive asymmetric lymphadenopathy.

Sites of extratumor involvement are favored by particular histologic subtypes. For example, the small, noncleaved cell histology often favors bone marrow or meninges. In contrast, immunoblastic histology often favors the gastrointestinal (GI) tract and brain parenchyma. The most common extranodal sites of involvement are the bone marrow in approximately 25% of patients, CNS in 23%, GI tract in 15%, and liver in 13%.[4,5,7,8,113–115,160–162,164–174]

Although approximately 15% to 25% of patients will present with stage I or II disease (see Table 86–4), the sites of involvement are often extranodal. If local therapies are undertaken, it is highly likely that patients will relapse at remote sites, and, therefore, systemic therapy is generally favored, regardless of the stage at presentation.

DIAGNOSIS AND PROGNOSIS

Staging of patients with systemic ARL includes tests performed in other lymphoma populations, such as computed tomography (CT) scans of the chest, abdomen, and pelvis; bone marrow biopsy; and, if bulky mediastinal or abdominal disease is present, positron emission tomography (PET), or gallium-67 scanning. In addition, the frequency of involvement of the CNS supports the use of both

radiographic imaging and cerebrospinal fluid (CSF) sampling at the time of initial staging.[162]

Patients who present with constitutional or B symptoms and a low CD4 count should have a thorough microbiologic workup to address the possibility of coincident opportunistic infections. This should include isolator cultures of the blood for mycobacteria, serologic assays for cryptococcal antigen, cytomegalovirus antigen, toxoplasmosis antibody, induced sputum for *P. carinii*, and routine blood culture.

The prognostic indicator that has been most predictive in patients not on HAART with ARL is the stage of immunodeficiency as reflected by the CD4 count at the time of diagnosis. CD4 cells of less than 100 cells/cm^3 are associated with a shorter survival in several series. In addition, previous AIDS-defining diagnoses, the Karnofsky performance score, and the presence of extranodal disease have been regarded as indicators of outcome.[150,167,175–177] More recent studies evaluating patients after the introduction of HAART have indicated that the parameters of HIV infection and immunodeficiency have largely been supplanted by features common to lymphomas outside the setting of HIV disease. The International Prognostic Index (IPI) score has been shown to be highly predictive of risk in ARL, although CD4 count has not always been found to be relevant.[178,179] There are several molecular features of large cell lymphomas that have been associated with prognosis, including the overexpression of BCL2[116] and markers of a post-germinal center cell of origin; both of these are unfavorable when present. Post-germinal center markers predicting poorer outcome include MUM1/IRF4 and/or CD138/Syn-1 and the absence of CD10 or BCL-6.[180] The analysis of ARL since the advent of HAART has indicated that the molecular features of this disease are changing and that tumors in the post-HAART era bear the more favorable indications of a germinal center tumor (the expression of CD10 or *BCL6* rearrangement) and do not overexpress BCL2. Thus, the frequency of ARL is diminished with the use of HAART, and the virility of the tumor may be lessened; however, overexpression of *p53* (generally a poor prognostic indicator) is not decreased in frequency.

Other molecular features that have been associated with outcome include polyclonality, which in one study was associated with a more positive outcome.[175] This feature was particularly favorable if tumors were EBV negative and the CD4 counts more than 200 cells/cm^3. Of note, histology has generally not been predictive.[180,181] The presence of the Burkitt or Burkitt-like subtype generally thought to bode poorly outside HIV disease has generally not been a feature affecting outcome. Whether this will change in the era when patients are overall doing better with HAART is still to be determined.

The presence of PEL has generally been associated with a very poor outcome; however, the compiled number of cases with this syndrome remains relatively limited.[153]

TREATMENT

Treatment of patients with ARL should include several components that distinguish this patient population from others. These include the use of prophylaxis for *P. carinii* pneumonia at initiation of chemotherapy. This practice is generally applied because of the high potential risk during treatment-induced exacerbation of immunosuppression. The high incidence of CNS involvement in a series reported early in the epidemic[164] has led to a controversy as to whether or not CNS prophylaxis should be provided for all patients. There are no definitive data on this point, but with use of CNS prophylaxis, the previously observed frequency of CSF relapse has been diminished.[182] No clinical standard can be said to have been defined, although many centers including our own administer either cytosine arabinoside (ara-C) or methotrexate weekly for 4 weeks by intrathecal injection to at least those patients with Burkitt histology, bone marrow involvement, testis involvement, or perinasal sinus disease. In addition, EBV present in the primary tumor has been identified as a risk factor for CNS involvement and can be useful in factoring the relative risk for individual patients.[181,183]

A concern regarding myelotoxicity has led many investigators to use growth factors prophylactically. Bone marrow dysfunction is a common feature of advanced HIV disease, and those patients who present with cytopenias at diagnosis are reasonable candidates for prophylactic growth factor use. A small, randomized, prospective trial in patients receiving a cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (CHOP) regimen indicated that patients who received granulocyte-macrophage colony-stimulating

factor (GM-CSF) had statistically significantly reduced instances of fever and neutropenia and fewer days of hospitalization than patients who received chemotherapy without growth factor support.[169]

The use of antiretroviral therapy in conjunction with chemotherapy remains controversial. Earlier in the epidemic when zidovudine (AZT) was essentially the only retroviral agent available, the myelotoxic effects of this medication generally precluded its use. Most reports of treatment in patients with ARL are patients who have not received concurrent antiretroviral therapy. A study by Levine and colleagues[177,184] assessed whether or not antiretroviral dideoxycytidine (DDC) could be given concurrently with modified methotrexate, bleomycin, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), dexamethasone (m-BACOD) chemotherapy and did not note any enhanced toxicity. In particular, neurotoxicity was not worsened, and a favorable effect on HIV p24 antigen levels was noted. Other studies have taken one of two approaches: Either dictate the antiretroviral regimen and study the pharmacokinetics, or preclude antiretrovirals and measure the immunologic and virologic consequences. Both approaches are supported by study data. A study by the AIDS Malignancy Consortium documented that CHOP could be given in conjunction with stavudine, lamivudine, and indinavir with no unexpected or unusually severe toxicities.[183,185] The pharmacokinetic data indicated an approximate doubling of the cyclophosphamide clearance time, but this was without clinical correlate and levels of doxorubicin, and indinavir metabolites were unaffected. The U.S. National Cancer Institute took the alternative approach, stopping all antiretroviral drugs or not starting them for those with newly diagnosed HIV. With the use of a continuous infusion regiment, dose-modified etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, fluoxymesterone (Halotestin) (EPOCH), these authors noted reductions in CD4 not unlike what others have seen when chemotherapy was given and antivirals continued. HIV plasma levels did increase in those stopping anti-HIV medications, but both the CD4 and HIV RNA levels improved to at least baseline once the antiretrovirals were resumed after antitumor therapy was completed.[116] This approach can, therefore, be reasonable for patients willing to accept it. For many, the concept of withholding medications they view as lifesaving is simply a nonstarter. In such cases, very few drug-drug interactions have been reported. It should be noted that the P450 effects of the non-nucleoside reverse transcriptase inhibitors can be particularly potent. Drug-drug combinations must always be vigilantly assessed when combining antiretroviral and antitumor chemotherapies. Because HIV levels are generally a risk in the context of chronicity, it should also be noted that antitumor chemotherapy against these imminently life-threatening lymphomas should not be compromised to accommodate antiretroviral therapy. If antiretrovirals are to be given, they should be used at doses that maximally suppress the virus, because submaximal suppression may permit the emergence of resistant strains of the virus.

Selecting treatment for lymphoma is largely dictated by the patient's overall clinical status. Until the availability of HAART, a fair amount of skepticism existed as to whether a curative approach should be undertaken in ARL patients because they all had what was considered a uniformly fatal underlying disease-AIDS. However, with the optimism surrounding the developments in anti-HIV therapy, it is now clear that a curative approach should be undertaken except under usual circumstances. For those patients who have far-advanced AIDS, are refractory to antiretroviral therapy, and have poor performance status, a palliative approach might be appropriate. No specific guidelines in this situation can be provided except that careful consideration should be given to patients' history of antiretroviral therapy, their history of HIV-related complications, their current CD4 count, their HIV RNA levels, and, most important, their wishes regarding the level of aggressiveness of care.

Full-dose chemotherapy of regimens established in the non-HIV setting is now standard. CHOP is a mainstay and the generally standard approach. The responses to this regimen are comparable to those seen outside the context of the HIV epidemic. Efforts to improve on standard CHOP include studies of adding rituximab (a humanized anti-CD20 antibody) to CHOP similar to that found useful in the context of large-cell lymphoma outside the context of HIV. A randomized trial comparing this regimen with CHOP alone demonstrated that there was not an overall benefit of adding rituximab (Rituxan) in either complete response rate, progression-free survival or overall survival. Instead, an increased incidence of fatal infections was noted, particularly among those with fewer than 50 $CD4^+$ cells/mm^3.[186] Increased infections were seen in another report of patients receiving rituximab (Rituxan) with an infusional regimen,[187] although a phase II trial of CHOP-rituximab (Rituxan)saw no significant infections, yet strikingly good remission and overall 2-year survival outcomes (77% and 75% respectively).[188] Therefore, it remains ambiguous as to whether rituximab (Rituxan) adds benefit in this patient group. If CHOP-rituximab (Rituxan)is contemplated, additional antimicrobial prophylaxis should be considered.

An alternative to CHOP has been proposed by Little and colleagues[116] at the U.S. National Cancer Institute using a dose-modified continuous infusion regimen, dose-adjusted EPOCH. This approach has resulted in remarkably high levels of response (complete remission in 74%) and durability of response (Fig. 82–4). At 53 months, the disease-free survival was 92%, and overall survival, 60%. The activity of this regimen may in part be caused by the high proliferative nature of ARL. The tolerability of the regimen has been good, and it is now being tested in larger consortia to evaluate whether it should become the new standard of care. This regimen involves continuous infusions of etoposide (50 mg/m^2/day for 96 hours), doxorubicin

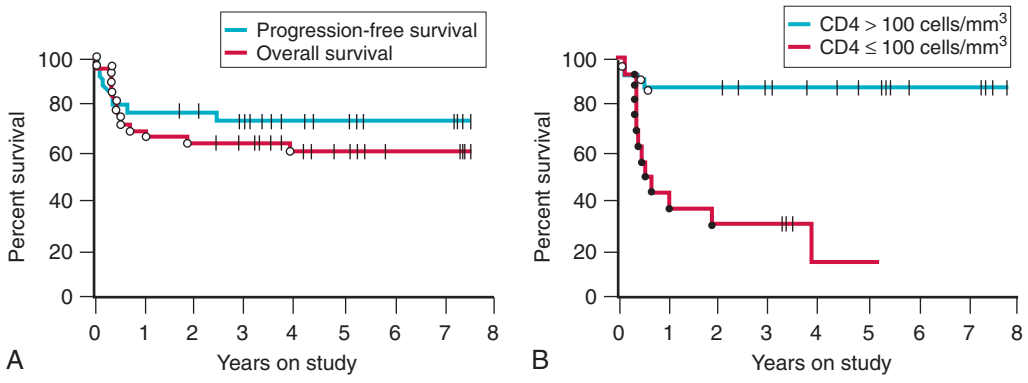

Figure 86–4 Kaplan-Meier survival curves of acquired immunodeficiency syndrome (AIDS)-related lymphoma patients treated with dose-adjusted etoposide, prednisone, vincristine (Oncovin), cyclophosphamide, fluoxymesterone (Halotestin) (EPOCH). (Data from Little RF, et al: Highly effective treatment of acquired immunodeficiency syndrome-related lymphoma with dose-adjusted EPOCH: Impact of antiretroviral therapy suspension and tumor biology. Blood 101:4653, 2003.)

(10 mg/m^2/day for 96 hours) vincristine (0.4 mg/m^2/day for 96 hours), bolus infusion of dose adjusted cyclophosphamide on day 5 (375 mg/m^2 if CD4 > 100 cells/mm^3; 187 mg/m^2 if CD4 < 100 cells/mm^3 on the first cycle; thereafter, increase by 187 mg/m^2 if nadir absolute neutrophil count [ANC] > 500 cells/mm^3 or decrease by 187 mg/m^2 if ANC < 500 cells/mm^3 or platelets <25,000 cells/mm^3). Prednisone is given at 60 mg/m^2 daily days 1 through 5, and filgrastim is given at 5 μg/kg/day, beginning day 6, until the ANC exceeds 5000 cells/mm^3. The cycle is repeated every 21 days or when the ANC exceeds 1000 cells/mm^3 and platelets exceed 50,000 cells/mm^3.

Efforts in Europe have similarly focused on alternative approaches such as cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) plus rituximab (Rituxan), and chemotherapy-intensive regimens have been assessed. In a 140-patient study conducted by a French-Italian Cooperative Group using the LNH84 regimen, 65% of patients achieved a complete remission with a relatively low relapse rate of 24%.[186] In a followup study, patients who had CD4 counts of >100 cells/mm^3, no prior AIDS-defining illnesses, and good performance status were enrolled. The patients were randomized to receive either CHOP chemotherapy, or ACVB (doxorubicin [Adriamycin] 75 mg/m^2 day 1, cyclophosphamide 1.2 g/m^2 day 1, vindesine 2 mg/m^2 day 1, bleomycin 10 mg days 1 through 5, prednisolone 60 mg days 1 through 5) with granulocyte colony-stimulating factor (GCSF) support. More severe toxicity in the ACVB arm, but a higher response rate, has been reported.[187] Further analysis of these data is required before firm conclusions can be drawn. However, the potential for dose-intensive regimens for patients in this population with good prognostic factors is suggested and should be further explored.

Other continuous infusion regimens have been assessed for patients as first-line therapy. The CDE regimen (cyclophosphamide 800 mg/m^2, doxorubicin 50 mg/m^2, etoposide 240 mg/m^2, all over 4 days) to which dideoxyinosine (ddI) was added, resulted in a complete response rate of 58%, with a median response duration exceeding 18 months.[188] Although controversy remains regarding the optimal strategy for treating patients who present with AIDS-related lymphoma, each of the trials indicates the potential for durable response. These data emphasize the need to approach patients with otherwise good prognostic features in a manner focused to maximize cure. However, the fraction of patients failing to respond continues to remain high and the frequency of relapse significant. Because the use of HAART has resulted in more patients tolerating anticancer chemotherapy, autologous transplant protocols have been initiated. Several studies have indicated that this approach is tolerated, results in rapid engraftment, and can result in long-term tumor control.[189–191] Multicenter trials to test this approach also indicate favorable outcomes. The long-term results of this approach are beginning to be available and indicate that autologous stem cell transplantation may be curative. In at least one study of 20 patients the progression-free survival rate is at 85% with a median followup of 32 months.[192] Therefore, intensive chemotherapy with stem cell rescue is a reasonable approach to this patient population. Whether allogenic transplant will prove useful remains to be determined. Overall, however, the approach to patients with ARL now overlaps with lymphoma patients outside the setting of HIV infection.

This is also evident in the treatment of patients with Burkitt histology ARL. Earlier in the epidemic these patients received the therapy of other ARL because of concerns for poor tolerance. Although the introduction of HAART was shown by one study to improve the survival of patients with diffuse large cell lymphoma (DLCL) histology (median survival 8.3 months to 43.2 months), those with Burkitt lymphoma (BL) did not enjoy a similar outcome (median survival 6.4 months to 5.7 months in HAART era).[178] These data suggested that chemotherapy needed to be modified for BL histology, and it was noted that HIV-positive patients with BL could tolerate more intensive chemotherapy regimens.[193,194] In a retrospective analysis of patients with BL histology treated with either standard regimens or a more intensive regimen (similar to what this group uses for acute lymphocytic leukemia), those who received the intensive therapy had a better complete response rate and 1-year survival (65% vs. 44%).[195] Patients with HIV infection and BL should be considered for standard BL treatment approaches.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Patients with HIV presenting with a mass lesion of the brain raise a number of diagnostic possibilities. Abscesses (toxoplasma, mycobacterial, or bacterial) or progressive multifocal leukoencephalopathy must be considered in addition to primary CNS lymphoma.[196–202] Criteria for distinguishing between these entities are not definitive without tissue sampling. However, for those patients in whom biopsy is either impossible or refused, certain parameters can raise or lower the likelihood of a lymphoma diagnosis. Perhaps the most important among these is CSF for EBV. The patient's toxoplasmosis serologic status and knowledge of whether the patient has been using trimethoprim-sulfamethoxazole as *P. carinii* pneumonia prophylaxis can also be extremely informative. The latter is highly effective for toxoplasma, and this, coupled with a negative toxoplasma titer, is strong evidence against toxoplasmosis. More commonly, patients have had previous toxoplasma exposure and have an immunoglobulin (Ig)G titer to this agent; differentiating an IgG versus IgM response can weigh the relative likelihood of an acute process. In addition, cultures for mycobacterium, fungus, and serum assay for cryptococcal antigen can be helpful in defining the nature of the CNS process. Some radiographic criteria have been described as being more suggestive of AIDS-lymphoma than toxoplasma brain abscess. These include large size (>2 cm), central location, and lack of multifocality.[174,198] Lymphoma can cross the midline, but this is extremely rare in the case of infectious causes.

Data in toxoplasma seronegative patients suggest that the presence of EBV detected by polymerase chain reaction strongly correlates with the presence of EBV-related disease (lymphoma) in the CNS.[197,199–201] In some centers, it has now become acceptable to use positive DNA polymerase chain reaction with radiographic imaging (often including thallium or PET scanning) to begin empirical therapy for lymphoma. In those patients in whom ambiguity remains, but biopsy is not possible, it is reasonable to begin an empirical trial of antibiotic therapy (sulfadiazine or clindamycin and pyrimethamine) directed against toxoplasmosis. In those patients who worsen after day 5 or fail to improve after 14 days, there is a higher likelihood that the disease not caused by toxoplasmosis.[202]

The clinical presentation of patients with primary CNS lymphoma can be extremely variable and quite subtle. This is a disease most common in late-stage AIDS, and in that patient population a high level of vigilance must be maintained for patients who present with neurologic or psychologic symptoms. Treatment of primary CNS ARL has generally been restricted to radiation therapy and steroids. The response rate to radiotherapy is high (60% to 79%), but durable remissions are relatively uncommon.[174,203–206] Patients' prognoses have often been limited by other opportunistic disease. It may be possible now with improved supportive care to better define the usefulness of other regimens in this patient population. A recent clinical trial evaluating the combination of systemic chemotherapy with radiation therapy failed to demonstrate any benefit to offset the toxicity of the chemotherapy. However, small studies with high-dose methotrexate have been encouraging.[207] In addition, combining antiviral agents ganciclovir and intravenous zidovudine with interferon has been reported as active against this disease and is now being systematically studied.[196]

Because this disease represents a failure of anti-EBV immunity and is generally seen only in advance AIDS, it is important to consider attempts to improve immune function as part of the therapy. That is, for patients who present with this lymphoma and are either not on HAART or receiving a suboptimal regimen, efforts should be made to maximally suppress HIV by medications in addition to the antitumor therapy. In such settings, there are a number of reports of patients with long-term control of the lymphoma despite having received radiation therapy alone. However, it cannot be considered sufficient to use HAART as therapy for this lymphoma.

Overall, primary CNS ARL remains a devastating and poorly treated problem. It is important that new approaches be critically evaluated, and enrollment of patients in clinical trials is strongly encouraged. If no trial is available, the approach must be clearly tailored to the overall status of the patient. Frank discussion of the generally poor prognosis (historically 2 to 5 months) in patients with end-stage AIDS should be a part of establishing a treatment plan. In patients with advanced AIDS who have failed HAART, palliative measures, such as steroids or pain medications alone, may be appropriate.

CONTROVERSY AND FUTURE DIRECTIONS

A number of areas within the context of ARL remain to be fully defined. The need for better understanding of the basis for lymphomagenesis is particularly acute in AIDS because of the potential for novel underlying infectious cofactors that can serve as therapeutic targets. Recent identification of KSHV and its clear relationship with a small subset of these tumors has provided a compelling example of this and represents considerable opportunity for new therapeutic interventions. The presence of multiple viruses now identified in ARL raises the question of what role there might be for specific antiviral medications or immunization. Why some patients develop malignancy whereas others with EBV or KSHV remain tumor-free is a puzzle rich with possibilities. Unraveling such issues will potentially point to mechanisms of screening and subsequent intervention. The molecular biologic basis of cell transformation by infectious cofactors is also a highly appealing area for investigation with potential targets for the small molecule or structurally designed pharmacologic agents currently under vigorous study by the pharmaceutical industry.

More extensive clinical investigation into the immunologic, cytokine, and viral profiles of select patient populations or in animal models with EBV-like disease[208] will likely provide significant insights into the pathology of ARL. Looking for potential interactions of virus and host by intensive laboratory study and genetic profiling may identify patients with high risk for ARL development and provide surrogate markers for early intervention.

Issues specifically related to therapy of ARL include which patients need CNS prophylaxis and what the role is for intensive retroviral therapy during ARL chemotherapy. Pursuing therapeutic trials testing agents such as additional monoclonal antibodies directed against lymphoma cells and novel infusion regimens is important. Augmentation of immunologic reactivity is compelling in a disease arising from an immunologic incompetent background; however, the specific nature of the intervention is yet to be defined. The use of specific cell-based approaches to therapy in this setting are based on the striking success of adoptively transferred lymphocytes in patients with EBV lymphoproliferative disease in the transplant setting.[69,70] Attempts employing similar approaches or efforts to immunize against tumor-related antigens in patients with ARL are planned and can offer alternative approaches to those patients refractory to standard cytotoxic agents. The potential of supplementing chemotherapy with biologically directed therapies is a focus of clinical investigation in ARL, and, if fruitful, might provide benefit not just for patients with ARL but also for non–HIV-infected lymphoma patients. The interplay between immune function and lymphomagenesis is an issue best demonstrated by ARL. Unraveling the details of this relationship will provide principles applicable well outside the scope of the AIDS epidemic.

Preferred Approach

Patients who present with NHL in the setting of AIDS should be assessed with a standard complete blood cell count and chemistry panel to which should be added a lymphocyte subset analysis and plasma HIV RNA. Patients who have "B" symptoms and a CD4 count of fewer than 200 cells/cm^3 should also have blood cultures and blood isolator tubes sent. A cytomegalovirus serum titer, toxoplasmosis titer, and cryptococcal antigen are also indicated as is sputum analysis for *P. carinii* pneumonia. Imaging studies for evaluation of the extent of lymphoma should be completed in the manner employed outside the setting of HIV disease. However, we also recommend imaging of the CNS and sampling of the CSF. Bone marrow aspiration biopsy should be obtained and special stains and cultures performed to exclude opportunistic infections.

For those patients who have a small, noncleaved, or Burkitt-like histology, paranasal involvement, bone marrow involvement, or testicular involvement, I prefer the administration of intrathecal arabinoside (ara-C) at 50 mg weekly for 4 weeks. This should be started at the initiation of chemotherapy. Chemotherapy, in patients for whom a protocol is not available or practical, is generally standard CHOP, unless patients have advanced AIDS or poor bone marrow reserve. In such cases, a modified or half-dose regimen can be justified, and is often quite effective. For patients with Burkitt histology, a Burkitt protocol should be used.

If patients have active involvement of the meninges, twice weekly ara-C is used until clearing of the CSF of lymphoma cells is achieved, and ara-C is administered monthly for 3 months. Whole-brain radiation is also added.

With relapse, there are no standard regimens available. I commonly use the EPOCH regimen, but encourage consideration of investigational protocols for such patients.

Patients who present with primary CNS lymphoma should receive dexamethasone (Decadron) 4 mg, four times daily until improvement of symptoms, and then the dose should be gradually reduced during a course of CNS radiation therapy. Steroids should be tapered as rapidly as tolerated to avoid the complications of prolonged immunosuppression. All such patients should receive antiretroviral therapy.

In general, all patients undergoing treatment for systemic NHL should have prophylaxis for *P. carinii* pneumonia. I prefer trimethoprim-sulfamethoxazole when tolerated. My policy regarding antiretroviral therapy is to use standard regimens avoiding those likely to affect myelosuppression (AZT) or drug metabolism. Alterations in drug metabolism are more likely to be encountered with the use of ritonavir or the non-nucleoside reverse transcriptase inhibitors delavirdine or nevirapine, and these should, therefore, be used with caution. Growth factor support is often required because of poor marrow reserve in patients with AIDS, but is often not needed in patients responding to HAART.

CHAPTER 87

MULTIPLE MYELOMA

Guido Tricot

Multiple myeloma (MM) is a prototype of a differentiated clonal B-cell tumor usually comprising slowly proliferating plasma cells. The disease is mainly contained within the bone marrow. The disorder is frequently accompanied by monoclonal (M) protein production and either diffuse osteoporosis or lytic bone lesions (Fig. 87–1). MM accounts for approximately 1% of all malignant diseases and 10% of hematologic malignancies. The annual incidence of myeloma is three to four per 100,000. An estimated 14,000 new cases of myeloma are diagnosed each year in the United States, and approximately 13,000 patients die of myeloma each year. A distinct feature of myeloma is the late age of onset. The median age at diagnosis for myeloma patients is approximately 69 years for men and 71 years for women; less than 5% of patients are younger than 40 years. Although myeloma can occur in people younger than 30 years, the diagnosis should be considered only after careful evaluation of all data and when other causes of monoclonal gammopathy or lytic lesions, such as a non-Hodgkin lymphoma or metastatic malignancy, have been ruled out. An excessive incidence of MM is observed among blacks and males. The incidence of myeloma in black males is approximately nine per 100,000 per year compared with six per 100,000 persons per year in black females. The incidence in white males is four per 100,000 persons per year and in white females is three per 100,000 persons per year.[1] Other ethnic groups, including Hawaiians, female Hispanics, female American Indians from New Mexico, and Alaskan Natives, also experience high myeloma rates compared with U.S. whites from the same geographic region. The Asian population has a lower incidence of myeloma compared with their white counterparts. Whereas the mortality rate for most other malignancies has slowly decreased during the past 30 years, it has increased for patients afflicted with MM and non-Hodgkin lymphoma. This finding is mainly due to the increased frequency of diagnosis in men and women aged 85 years and older. Compared with 1968 to 1990, the mortality rate due to myeloma in men and women 85 years and older has increased by approximately 45%.

ETIOLOGY

The cause of MM is largely unknown. Genetic predisposition and environmental factors likely are involved. The genetic susceptibility probably is related to the method by which individuals deal with environmental toxins and antigen exposure. A large individual variation in activity along xenobiotic metabolic pathways has been implicated in the susceptibility to childhood acute lymphoblastic leukemia.[2,3] Several of these participating enzymes metabolize environmental carcinogens. Multiple variants in genes coding for detoxification and DNA repair enzymes have been described.[4,5] Although more than 99% of human DNA sequences are the same for all individuals, variations in DNA sequence in the remaining less than 1% can have a major impact on how humans respond to environmental insults. Single nucleotide polymorphisms are the most frequent forms of DNA variation and disease-causing gene mutations.

Environmental and occupational exposures have been implicated in the etiology of myeloma. Exposure to ionizing radiation is the most convincing risk factor for MM. MM occurred after a long latent period in atomic bomb survivors exposed to high-dose radiation.[6] Studies performed on radiologists also suggest a link with long-term exposure to low-dose radiation. Several studies have indicated an increased risk of MM mortality among workers in the nuclear industry,[7–10] whereas other studies failed to show such a correlation.[11] Most excesses of MM mortality rates correlate with exposure to radiation between 10 to 15 years before diagnosis.[8,10] The role of occupational exposures to the risk of MM development remains unclear. Most occupational associations with myeloma have been related to agriculture and include dusty occupations and exposure to grain dusts, aflatoxins, and engine exhausts from farm equipment.[12–14] A 2.5-fold increased risk of development of MM has been observed with pesticide use.[15]

Exposure to various metals have been linked to myeloma. A significant risk of myeloma has been found among smelter, metallurgy,[16] and sheet metal workers.[17] An increased mortality rate due to MM was seen in workers in a Canadian nickel refinery.[18]

Benzene has been suggested as a possible etiologic agent of MM because its metabolites are known bone marrow toxins.[19,20] Epidemiologic studies correlating MM with employment as a beautician or cosmetologist have reported both positive[21,22] and negative associations.[23] Medications such as propoxyphene, phenytoin, phenobarbital, diazepam, propranolol, ibuprofen, diet drugs, stimulants, and laxatives have been implicated in an increased risk for developing MM.[24,25] MM has not been found to be strongly related to either cigarette smoking or alcohol consumption.

Familial occurrence of myeloma is well established.[26,27]

PATHOGENESIS

Normal B-Cell Development

B-cell development[28,29] occurs initially in the bone marrow and subsequently in lymphoid tissues. Terminal B-cell differentiation takes place in the bone marrow. In the bone marrow, hematopoietic progenitor cells differentiate into the earliest identifiable cell type committed to the B lineage, the *pro-B cell.* This cell undergoes rearrangement of its immunoglobulin (Ig) heavy chain genes and is called a *pre-B cell.* It is characterized by the presence of cytoplasmic μ chains. Subsequent rearrangement of the light chain enables the cell to express surface IgM and the cell becomes an *immature B lymphocyte.* These cells leave the bone marrow and, on entering the peripheral blood, start to express surface IgD and are called *virgin B cells.* They are arrested in the G_0 phase of the cell cycle. These virgin B cells enter the lymphoid tissue, where they are exposed to antigen-presenting cells, become activated, and differentiate into *short-lived low-affinity plasma* cells or *memory B cells.* These memory B cells travel from the extrafollicular area of the lymph node to the primary follicles, where they are confronted with an antigen, presented by follicular dendritic cells, resulting in the development of a secondary response. At this stage, primary follicles change into secondary follicles containing germinal centers. Through activation by an antigen, memory B cells differentiate into *centroblasts*, resulting in Ig isotype switching and somatic mutations in the variable region of the Ig with the generation of high-affinity antibodies. Centroblasts then progress to the *centrocyte* stage and reexpress surface Ig. The centrocytes with high-affinity antibodies differentiate into either memory B cells or *plasmablasts*, which subsequently move to the bone marrow and ter-

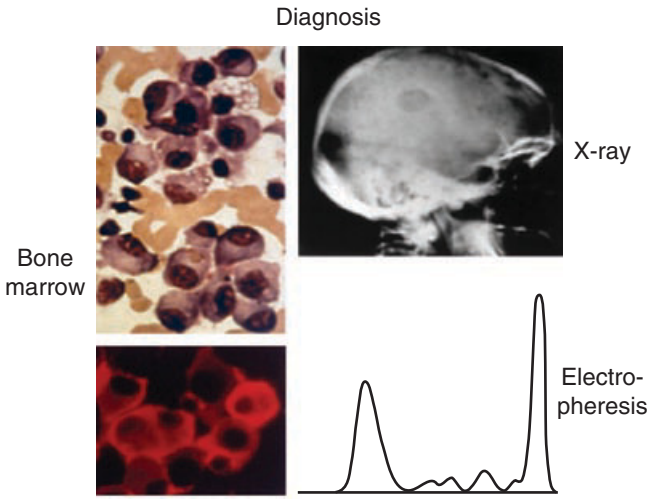

Figure 87–1 Common diagnostic features in multiple myeloma: light chain–restricted plasma cells in a bone marrow aspirate; multiple lytic lesions in a skull radiograph; large monoclonal spike in the γ-globulin area in serum electrophoresis.

minally differentiate to *plasma cells*. These bone marrow plasma cells produce most of serum Igs and have a lifespan of approximately 1 month.

Three distinct gene segments, the variable (V_H), diversity (D_H), and joining region (J_H) genes, encode the variable region of the heavy chain, whereas two segments, variable (V_κ or V_λ) and joining (J_κ or J_λ) region genes, encode the variable fraction of the light chain. The Ig heavy chain (IgH) locus on chromosome 14q32 contains an estimated 100 to 150 V_H genes, 30 D_H, and 6 J_H gene segments. Because some of the V_H genes are nearly identical, 60 to 70 V_H genes likely are available for rearrangement. These 60 to 70 genes belong to seven families (V_H1 to V_H7) whose members have more than 80% sequence homology. Of the 75 known V_κ sequences, only 36 are potentially functional, and of the 36 known V_λ sequences, only 24 are functional. Rearrangement of V gene segments is dependent on the protein products of the recombinase-activating genes RAG-1 and RAG-2. Recombination of V genes starts in lymphoid progenitors within the IgH locus of either the maternal or paternal chromosome 14. If the initial VDJ rearrangement yields a sequence that cannot be translated, then rearrangement of the IgH locus proceeds on the other allele. The presence on the B-cell surface of a fully assembled μ heavy-chain rearrangement begins when one of the V_κ genes rearranges to one of the J_κ genes. If κ light-chain rearrangement is unsuccessful on both alleles, by default λ light chains subsequently rearrange.

Ig heavy and light chains each contain three hypervariable segments (complementarity-determining regions [CDRs]), which are the areas of the Ig in direct contact with the antigen. In a process of trial and error, Igs increase their affinity for an antigen by a series of somatic mutations. CDR3 is the most variable portion of the Ig molecule because it not only contains somatic mutations, as is the case for CDR1 and CDR2, but it also encompasses the 3′ end of V_H, all of D_H, and the 5′ end of J_H. Therefore, it is an ideal marker for detecting a very small population of the malignant myeloma clone within a larger population of normal cells.

Myeloma Stem Cell

The origin of malignant plasma cell remains a mystery. Although the predominant cell in MM is the plasma cell, accumulating data show that other lymphoid cell types are involved in the malignant process. A significant number of peripheral blood lymphocytes bear the unique paraprotein idiotype found in plasma cells[30–33] and have clonal Ig gene rearrangements identical to those seen in bone marrow plasma cells.[34,35] These data strongly suggest the existence of a precursor compartment, which may contain the myeloma stem cell. Killing all myeloma stem cells will be required to completely eradicate the disease. However, in most cancers enough plasticity is present to allow more mature-appearing cells to again assume the characteristics of tumor stem cells. Little is known about the characteristics of the myeloma stem cell. It has been proposed that such a stem cell is $CD138^-$ and $CD20^+$, based on the observation that this subpopulation derived from either myeloma cell lines or primary myeloma has a greater clonogenic potential.[36] Cloning and sequencing of V_H genes in myeloma show multiple somatic mutations, characteristic of an antigen-driven process with no further intraclonal diversity with disease progression,[37,38] strongly implying that malignant clone in MM evolves from a cell in late B-cell development, which has traversed the germinal center and has been extensively exposed to an antigen.[28,38] Therefore, the cell of origin for myeloma most likely is either a memory B cell or a plasmablast. That myeloma arises in the lymph node remains somewhat counterintuitive because lymphadenopathy is not a hallmark of MM. During migration of the B cell through the germinal center, multiple DNA breaks occur at the level of the gene coding for the heavy chains of the Ig (14q32). These breaks are the consequence of VDJ rearrangements. It is also clear that somatic mutations are associated with DNA breaks. In addition, while and after the antigen-primed B cell leaves the germinal center, additional DNA breaks occur when the Ig isotype switches from IgM to either IgA or IgG. These DNA breaks lead to genetic instability and an increased chance of chromosome translocations involving 14q32.

Once malignant precursor cells leave the lymph node and enter the peripheral blood circulation, they acquire adhesion molecules and home to the bone marrow environment. Homing to the bone marrow is the consequence of the presence on the plasma cell membrane of the chemokine receptor CXCR4. The ligand for CXCR4 is CXCL12 or stroma-derived factor (SDF)-1.[39–41] Remember that hematopoietic stem cells are attracted to the bone marrow microenvironment through the same mechanism of CXCR4 expression on their cell surface. This explains why myeloma cells usually are found only in bone marrow areas, where normal hematopoiesis occurs. In addition, myeloma cells are attracted to CCL1, which is secreted by myeloma cells; this explains why myeloma cells have the tendency to form small or larger nodules.[42] The larger nodules cause the typical osteolytic lesions seen on metastatic bone survey, magnetic resonance imaging (MRI) or positron emission tomography (PET) scan. Like myeloma cells, osteoclasts are attracted to sources of CXCL12 (SDF-1). Myeloma cells are able to attract osteoclasts precursors directly via the secretion of CCL3 or macrophage inflammatory protein 1α (MIP-1α).[42]

ROLE OF THE MICROENVIRONMENT IN MULTIPLE MYELOMA

MM cells adhere to bone marrow stromal cells. The myeloma cells interact with the bone marrow stromal cells through multiple adhesion molecules. These include CD56/CD56; syndecan-1 (CD138)/collagen; intercellular adhesion molecule (ICAM)-1/leukocyte function-associated antigen (LFA)-1; CD49d/vascular cellular adhesion molecule (VCAM)-1 or fibronectin; and CD38/CD31. CD49d/VCAM-1 likely is the major pathway capable of providing effective capture of myeloma cells within the bone marrow, as has also been demonstrated for hematopoietic stem cells.[43] These adhesion molecules not only are important for binding myeloma cells to stroma, but they also cause homotypic aggregation of myeloma cells in concert with CCL1, which is secreted by myeloma cells. Interaction of myeloma cells with stromal cells leads to bone destruction as well as survival, proliferation, drug resistance, and genetic instability of myeloma cells.

Bone Destruction

Bone destruction is a prominent clinical feature of almost all patients with MM. It is responsible for many of the most debilitating clinical features of the disease, such as pain, fractures, and hypercalcemia. When myeloma cells adhere to the bone marrow stroma, stromal cells produce cytokines and inflammatory proteins such as interleukin (IL)-6,[44] IL-1,[45] tumor necrosis factor (TNF),[46] IL-11,[47] and MIP-1α.[48] In addition, myeloma cells secrete hepatocyte growth factor (HGF)[49] and parathyroid hormone-related peptide.[50] All of these factors, called osteoclast-activating factors (OAFs), cause local expression on stromal cells of receptor activator of nuclear factor (NF)-κB ligand (RANKL), also called TNF-related activation-induced cytokine (TRANCE). RANKL is a member of the TNF gene family. It activates c-Jun terminal kinase and signals through NF-κB.[51] The gene for RANKL has been mapped to chromosome 13q14. OAFs induce osteoclast formation indirectly by stimulating marrow stromal cells to express increased levels of RANKL on their surface. RANKL binds to the RANK receptor on osteoclast precursors and induces osteoclast differentiation and maturation. Osteoclasts are derived from monocytes/macrophage precursor cells. Osteoclastogenesis is induced by macrophage colony-stimulating factor 1 in combination with RANKL or TNF-α and is completely inhibited by the addition of granulocyte–macrophage colony-stimulating factor or IL-3 at the early stages of differentiation.[52] The absence of RANKL expression in mice results in severe osteopetrosis and absence of osteoclasts.[53] In contrast, overexpression of RANKL in mice induces severe osteoporosis. RANKL activity can be blocked by the naturally occurring decoy receptor osteoprotegerin (OPG), which is a member of the TNF receptor superfamily. Most cell types produce OPG. However, OPG is not a specific receptor for RANKL. It also binds TNF-related apoptosis-inducing ligand (TRAIL). Overexpression of OPG results in severe osteopetrosis, whereas absence of OPG induces osteopenia.[54] In patients with MM, OPG levels are reduced,[55,56] with an inverse correlation between OPG levels and the degree of skeletal destruction in myeloma. Myeloma cells bind, internalize, and degrade OPG.[57] The process of degradation by myeloma cells of OPG is dependent on interaction with heparan sulfates on myeloma cells. OPG has a highly basic heparan-binding domain, making interactions with heparin and heparan sulfates possible. One feature of normal and malignant plasma cells is abundant expression of syndecan-1, which is a transmembrane proteoglycan having heparan sulfate side chains.[58]

The ultimate result is a major imbalance between RANKL, the activity of which is highly increased, and OPG, the activity of which is drastically decreased. This situation switches the balance completely in the direction of bone destruction.[59] The bony matrix is a rich source of all types of cytokines, such as insulinlike growth factor (IGF), IL-6, and basic fibroblastic growth factor, which stimulate the survival and growth of myeloma cells and result in the release from the myeloma cells of OAFs such as parathyroid hormone-related peptide and MIP-1α. More myeloma cell growth will result in more release of OAFs, which will cause more production of RANKL. This becomes a vicious cycle where growth of myeloma cells leads to more bone destruction, and more bone destruction leads to more growth of myeloma cells. This cycle can be effectively blocked by administration of bisphosphonates[60] or OPG.[61] Treatment of myeloma in the SCID-hu hosts with an inhibitor of osteoclast activity (*pamidronate* or zoledronate) or with a specific inhibitor of RANKL halts myeloma-induced bone resorption but also results in inhibition of myeloma cell growth and survival.[62] Evidence has shown that MIP-1α and MIP-1β are major OAFs produced by myeloma cells.[63] Stromal cells express the receptor for MIP-1α and MIP-1β, called CCR5. Whether myeloma cells actually express RANKL is a matter of debate.[59,64] A schematic representation of bone destruction in myeloma is shown in Fig. 87–2. MIP-1α is abnormally regulated in myeloma due to imbalanced expression of acute myeloid leukemia (AML)-1A and AML-1B.[65] IL-3 also is induced by this imbalanced expression. Increased IL-3 levels in the microenvironment can increase bone destruction and myeloma cell growth.[66]

The method by which bone destruction occurs in myeloma is reasonably well known, but the reason why increased bone destruction does not result in increased bone formation as in most other malignancies involving the bone remains largely unknown. Although an increased number of osteoblasts is present in the earlier stages of myeloma, osteoblasts undergo apoptosis and ultimately almost completely disappear with progression of disease.[67] The canonical Wnt/

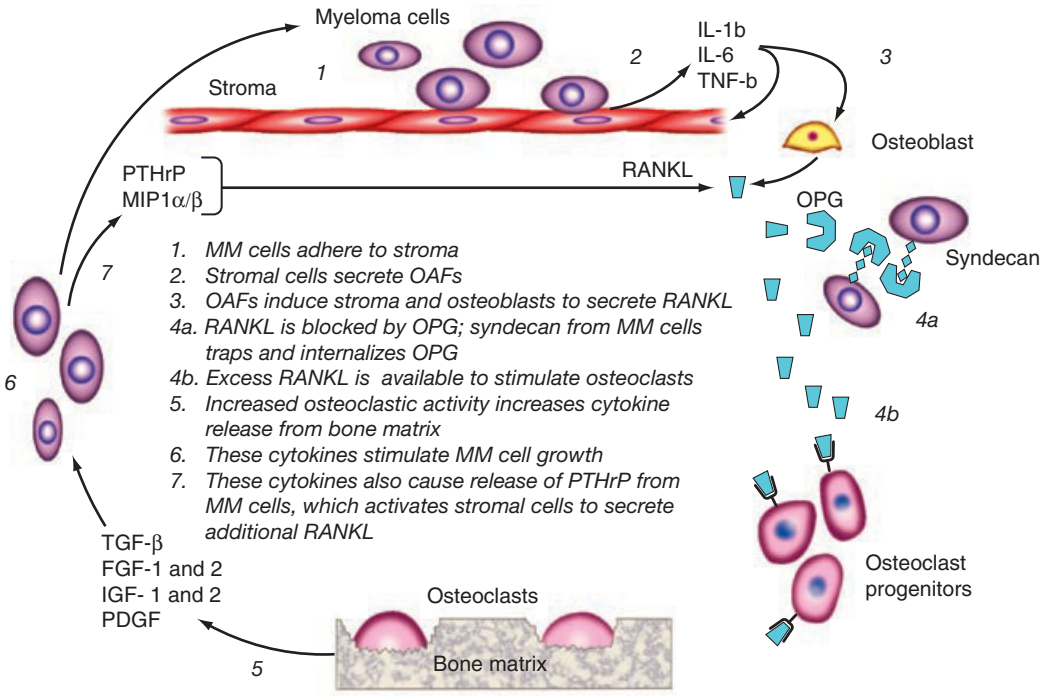

Figure 87–2 Bone destruction in multiple myeloma. *(From Tricot G: New insights into the role of microenvironment in multiple myeloma. Lancet 355:248, 2000.)*

β-catenin signaling pathway plays an important role in bone formation during embryonic development by differentiation of osteoblasts from precursor cells through direct regulation of the *Runx2* gene.[68,69] Wnt signaling also negatively regulates osteoclasts formation through transcriptional repression of *RANKL*.[70] Dkk1 (Dickkopf-1) is a Wnt antagonist that negatively regulates osteoblast differentiation and bone formation.[71] Our group has shown that Dkk1 is produced by myeloma cells and is associated with the presence of myeloma bone lesions.[72] Other potential osteoblast inhibitors are secreted Frizzled-related protein 2 (sFRP-2) and IL-7.[73,74]

Growth and Survival of Myeloma Cells

Myeloma cells in the early stages of the disease are completely dependent for their survival and growth on the bone marrow microenvironment. The myeloma cell has multiple receptors on its membrane, the ligands of which are present in the microenvironment. Important receptors are the IL-6 receptor, IL-15 receptor, IGF receptor, β_1 integrins (very late antigen [VLA]-4 and VLA-5), CD38, and CD40. The ligands for β_1 integrins are fibronectin and VCAM. The ligand for C38 is CD31. Activation of these multiple receptors by their ligand results in activation of four major pathways: STAT3, Ras, Akt, and NF-κB (Fig. 87–3). STAT3 is activated by IL-6 and IL-15. It results in upregulation of the antiapoptotic factors Bcl-X_L and myeloid leukemia cell (Mcl)-1 as well as the cell cycle regulatory protein p21.[75] Activation of STAT3 is responsible for the increased level of C-reactive protein (CRP), which is frequently seen in MM and has been associated with a poor prognosis. In addition, STAT3 increases transcription of c-myc.

The Ras pathway is activated by IGF and IL-6. It results in upregulation of myc and cyclin D, and it activates the NF-κB pathway. In addition, the Ras pathway plays an important role in downregulation of the CDK inhibitor p27.[76]

The Akt pathway is activated by IL-6 and IGF and acts downstream of the phosphatidylinositol 3-kinase (PI3K). The PI3K/Akt signaling pathway is constitutively activated in MM.[77] Constitutively active Akt rescues myeloma cells from PTEN-mediated apoptosis. Akt activation results in inactivation through phosphorylation of BAD, which is a proapoptopic member of the Bcl-2 family of proteins and promotes cell death by forming a nonfunctional heterodimer with the survival factor Bcl-X_L. Phosphorylation of BAD by Akt prevents such interaction and restores Bcl-X_L antiapoptotic function. Akt phosphorylates FKHR, a member of the Forkhead family of transcription factors. Phosphorylation of FKHR prevents its nuclear translocation and activation of the Forkhead gene targets, which include several proapoptotic proteins, such as Fas ligand. Akt also activates the NF-κB pathway by phosphorylation and activation of I-κB kinase (IKK), a kinase that induces degradation of NF-κB inhibitors I-κB. Akt phosphorylates Mdm2. Phosphorylated Mdm2 translocates more efficiently to the nucleus, where it combines with wild-type p53, resulting in enhanced p53 degradation. Akt negatively influences the expression of p27, a cell cycle inhibitor. The proliferative effect of Akt activation is associated with MEK/MAPK signaling cross-talk.[78,79]

NF-κB, the fourth pathway, is activated by ligation of CD38 and CD40 but also by the Ras and Akt pathways. Activation on NF-κB results in increased telomerase activity,[80] upregulating the proangiogenic factors basic fibroblastic growth factor, vascular endothelial growth factor (VEGF), and IL-8,[81] the antiapoptotic factors A-1, Bcl-2, and Bcl-X_L,[82,83] and the inhibitors of apoptosis proteins IAP-1, IAP-2,[84] and IEX-1.[85] In addition, NF-κB is directly involved in cell cycle progression through transcriptional activation of cyclin D1; the c-*myc* protooncogene promoter contains two NF-κB binding sides.[86]

The effects of Notch signaling are pleiotropic and depend on the cell type and its interaction with the microenvironment. Notch activation may promote or inhibit differentiation, increase proliferation or trigger cell cycle arrest, induce apoptosis, or protect cells from apoptosis.[87] Jundt et al.[88] reported that Jagged1-induced Notch signaling drove proliferation of myeloma cells, whereas Nefedova et al.[89] showed that activation of Notch1 resulted in protection of myeloma cells from melphalan and mitoxantrone-induced apoptosis by upregulation of p21, resulting in cell cycle arrest. These seemingly contradictory findings can be explained by the pleiotropic activity of Notch. In the presence of stimulating signals, Notch may cause proliferation, whereas in the presence of toxic agents, Notch may cause cell cycle arrest to protect myeloma cells from apoptosis.[87] Finally, Notch promotes osteoblastic cell differentiation of multipotent mesenchymal cells.[90]

The result of activation of the different pathways is increased proliferation, increased antiapoptotic activity, and increased angiogenic activity. Figure 87–3 clearly shows the tremendous redundancy in activation of the end targets. Therefore, blocking a single pathway is unlikely to have a major lasting effect on the growth of myeloma cells. Although all of these pathways have been shown to be active either in myeloma cell lines or in fresh myeloma cells, whether all these pathways are active all the time and which of these pathways is the most important are not clear. High interpatient variability is likely.

Drug Resistance in Multiple Myeloma

In contrast to what is generally accepted, drug resistance in the early stages of the disease is mainly induced by the microenvironment and by epigenetic changes.[91] This type of resistance can be overcome by high-dose chemotherapy. However, in the end stages of disease, drug resistance is determined by major genetic alterations. The existence of cell adhesion-mediated drug resistance in myeloma has been well demonstrated.[92] The human myeloma cell line 8226, which expresses CD49d (VLA-4), is resistant to the apoptotic effect of doxorubicin and melphalan when preadhered to fibronectin but not when the same cells are grown in suspension. Adhesion of myeloma cells to the stroma induces upregulation of p27, resulting in a decrease of cells in the S phase. Evidence also indicates that Notch signaling protects myeloma cells from the apoptotic effects of chemotherapy.[89] The importance of the microenvironment in drug resistance was also shown by using a human B-cell lymphoma line.[82] After treatment with etoposide, more than 80% of the cells in culture died as a result of apoptosis. When the microenvironment was artificially recreated by ligating VLA-4 with VCAM-1, CD40 with an anti-CD40 antibody, and IL-4 receptor with IL-4, less than 25% of the cells died.

Most myeloma cells are in the G_1 phase of the cell cycle. These cells are very poor targets for chemotherapy because they have ample time to repair any DNA damage caused by alkylating agents before they proceed to the next cell division. In addition, the concept of cancer stem cells is gaining popularity. This concept assumes that a small compartment of malignant cells are noncycling and have excellent detoxification systems, making those cells particularly resistant to chemotherapy.[93] The different mechanisms of drug resistance are outlined in Fig. 87–3.

The major mechanism of resistance to melphalan, at least in advanced myeloma, is related to increased DNA interstrand cross-link repair.[94] Although similar levels of DNA interstrand cross-linking were observed in cells from both melphalan-naive and melphalan-treated patients, marked differences in repair were noted. Myeloma cells from melphalan-naive patients showed no DNA repair, whereas myeloma cells from melphalan-treated patients exhibited between 42% and 100% repair at 40 hours. Enhanced DNA repair in myeloma occurs via the Fanconi anemia/BRCA pathway (Fig. 87–4).[95]

Genetic Instability

B cells are inherently less stable because they undergo multiple DNA breaks to accommodate for VDJ rearrangements, somatic mutations, and isotype switching. In addition, upregulation of many antiapoptotic factors makes it possible for cells that have acquired a tremendous amount of genetic changes to survive, which would not be

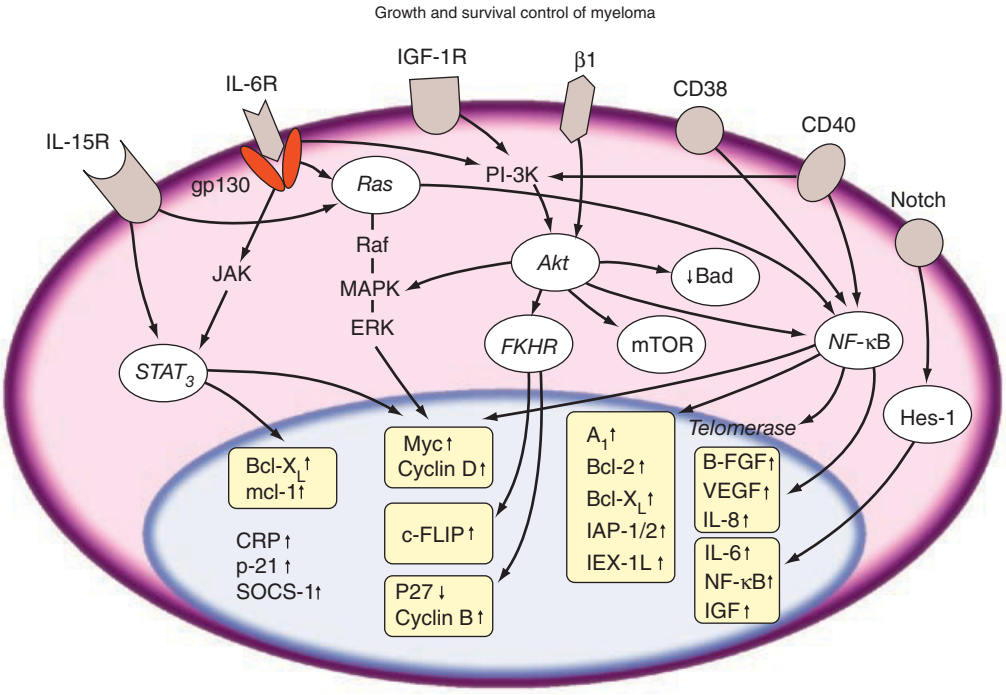

Figure 87–3 Growth and survival control of myeloma.

possible in the absence of these antiapoptotic factors. This is reflected in the complex karyotypes observed in myeloma that are reminiscent of solid tumor karyotypes rather than those seen in hematologic malignancies.

Multiple Myeloma is a Multistep Transformation Process

As is the case for chronic lymphocytic leukemia, low-grade non-Hodgkin lymphoma, chronic myeloid leukemia, and the myelodysplastic syndromes (MDS), myeloma evolves from a relatively benign process to a highly malignant transformed phase ("malignant myeloma"). The initial stage is an *indolent phase* (monoclonal gammopathy of undetermined significance [MGUS], smoldering myeloma or myeloma stage IA with stable disease, and no evidence of end-organ damage). In this phase of the disease, patients do not require any cytotoxic treatment. The growth and death rates of myeloma cells are approximately equivalent.

The second phase is the *overt phase* of myeloma, with either progressive increase in myeloma protein or the appearance of end-organ damage. In this phase, the disease is completely dependent on the bone marrow stroma for survival and growth, and it is chemosensitive. This is the optimal phase to treat patients effectively.

In the *aggressive terminal phase*, the myeloma cells become independent of the bone marrow stroma. Increased proliferation is evidenced by an increase in plasma cell labeling index (PCLI), usually to more than 1%, and in the level of lactate dehydrogenase (LDH). The bone marrow morphology is much more aggressive, having the appearance of plasmablasts. Conventional cytogenetics reveal abnormalities in most patients, who frequently also have manifestations of extramedullary disease. A PET scan probably is the best test for evaluating the presence of extramedullary disease. In this stage of the disease, the myeloma has become virtually resistant to chemotherapy due to acquisition of multiple genetic changes. Although the disease can be temporarily controlled with chemotherapy, consisting of a combination of alkylating and cell cycle-specific agents, responses are generally short lived and survival is generally poor, even with high-dose chemotherapy and autotransplants (Fig. 87–5).

ROLE OF CYTOKINES IN MYELOMA

Interleukin 6

IL-6 has always been considered the most important cytokine in myeloma. However, other cytokines are equally, if not more, important in the survival and growth of myeloma. IL-6 is essential for the proliferation of normal plasmablastic cells and for the terminal differentiation of plasmablast to nondividing plasma cells. Terminally differentiated plasma cells produce a large amount of Ig (>600 pg/cell in 24 hours).[96] In MM, IL-6 is mainly a survival factor[97] and does not induce terminal differentiation. It promotes survival through upregulation of many antiapoptotic factors (see Fig. 87–3) but also through inhibition of the JNK/SAPK pathway, resulting in inhibition of Fas-induced apoptosis.[98,99] IL-6 prevents dexamethasone-induced myeloma cell death.[100,101] IL-6 is also a growth factor for myeloma,[96] among other mechanisms through phosphorylation of the retinoblastoma (Rb) protein.[102] The major source of IL-6 production is the bone marrow stroma[103,104] although myeloma cells also produce IL-6 but to a much lesser extent.[105,106] Support for the role of IL-6 in the survival and growth of myeloma cells has been provided by the clinical application of anti–IL-6 monoclonal antibodies and IL-6 receptor antagonists.[107,108] Other cytokines using the same signal transducer (gp130) as IL-6, such as ciliary neurotropic factor, IL-11, leukemia inhibitory factor, and oncostatin M, stimulate the growth of myeloma cells.[109] Using the U-266 myeloma cell line, only the $CD45^+$ fraction shows proliferative advantage after IL-6 stimulation. IL-6 stimulation results in gradual conversion of $CD45^-$ cells to $CD45^+$ cells, whereas withdrawal of IL-6 leads to gradual loss of CD45 expression, indicating that CD45 expression can be induced by IL-6. IL-6 transgenic mice develop a progressive kidney pathology that starts with membranous glomerulonephritis, followed by focal glomerulosclerosis and finally extensive tubular damage, as observed in patients with myeloma kidney.[110] IL-6 prevents differentiation of monocytes to macrophages and dendritic cells,[111] which are functionally defective in MM.[112] Additionally, IL-6 promotes increased coagulation without affecting fibrinolysis. During pregnancy and in women after menopause, IL-6 levels rise significantly. Both of these conditions are associated with an increased risk of thrombosis. IL-6 induces a prothrombotic state by increasing expression of tissue factor, fibrinogen, factor VIII, and von Willebrand factor; activation of endothelial cells; and platelet production. It also reduces levels of inhibitors of hemostasis, such as antithrombin III and protein S.[113]

Insulinlike Growth Factors

IGFs constitute a family of peptides capable of stimulating various cellular responses, including cell proliferation and differentiation. Both IGF-1 and IGF-2 are mitogenic factors secreted by malignant cells. A steadily increasing number of IGF-binding proteins (IGF-BPs) and IGF-BP–related proteins are part of the IGF system. These IGF-BPs can either enhance or inhibit IGF-mediated effects. There is a specific receptor for IGF-1 and IGF-2.[114] IGF-1 is a growth and survival factor for human myeloma cell lines.[115] The presence of an IGF-1 receptor is an absolute requirement for the establishment and maintenance of the transformed phenotype of many malignancies[116] and was found to be expressed in seven of the eight myeloma cell lines examined. Activation of the IGF-1 receptor leads to activation of PI3K, which activates the Akt pathway and leads to inhibition of apoptosis. A second pathway activated by the IGF-1 receptor is the mitogen-activated protein kinase (MAPK) pathway, which leads to proliferation of myeloma cells.[117,118] IGF-1 has also been shown to be a chemoattractant for myeloma cells.[119] In colon cancer, IGF-1 regulates VEGF and angiogenesis.[120]

Interleukin 15

IL-15 induces proliferation and promotes cell survival of T cells, B cells, natural killer cells, and neutrophils. Constitutive expression of a functional IL-15 receptor was shown in all of the six myeloma cell lines and in the primary myeloma cells of 14 of 14 patients.[121] IL-15 transcripts were found in all six myeloma cell lines and IL-15 protein in four of the six cell lines. IL-15 transcripts were also found in eight of the 14 primary myeloma samples. This finding suggests the existence of an autocrine IL-15 loop. In addition to the autocrine loop is a paracrine loop, as IL-15 is released from the bone marrow microenvironment. Blocking IL-15 in myeloma cell lines increases the rate of spontaneous apoptosis. Furthermore, IL-15 lowers the responsiveness to Fas-induced apoptosis and to cytotoxic treatment with vincristine and doxorubicin but not with dexamethasone. In addition to preventing apoptosis of myeloma cells, IL-15 induced proliferation in four of the six primary myeloma samples.[122]

Interleukin 10

IL-10 is a potent inducer of Ig secretion by normal plasma cells. IL-10 does not induce differentiation or increased Ig synthesis in myeloma cells. However, it stimulates proliferation of primary myeloma cells and myeloma cell lines.[123] The proliferative activity of IL-10 can be abrogated by antibodies to the gp130 transducer. IL-10 induces the production of oncostatin M in myeloma cells as well as the expression of the leukemia inhibitory factor receptor and the IL-11 receptor[124] and therefore is an indirect stimulator of myeloma cell growth.

Hepatocyte Growth Factor

HGF is a cytokine that promotes formation of osteoclasts from hematopoietic precursor cells, attracts osteoclasts to sides of bone marrow resorption, and increases the level of bone resorption when in coculture with osteoblasts. The HGF receptor c-Met is expressed by the bone-forming osteoblasts and the bone-resorbing osteoclasts. HGF stimulates the growth of both cell types.[125] HGF and its receptor c-Met are expressed by the U-266 myeloma cell line. c-Met proteins were detected by enzyme-linked immunosorbent assay and Western blot analysis in highly purified primary myeloma cells.[49] The mean serum level of HGF in myeloma patients at diagnosis was more than fourfold higher than the mean level in controls. Activation of c-Met favors cell invasion, migration, and proliferation, all of which are essential in myeloma tumor progression.

Transforming Growth Factor β

Transforming growth factor (TGF)-β has pleiotropic biologic effects, including suppression of hematopoiesis by antagonizing stem cell factor as well as inhibition of wound healing and immune response. It suppresses B-cell proliferation and Ig production. In myeloma, TGF-β is produced by bone marrow stroma cells and myeloma cells. It triggers IL-6 secretion by both types of cells. It causes tumor cell proliferation indirectly, probably by upregulation of IL-6 secretion.[126] In myeloma, the Rb protein is constitutively phosphorylated. TGF-β does not alter or increase phosphorylation of Rb protein. TGF-β probably is the major factor causing suppression of normal plasma cells resulting in low levels of uninvolved Igs in patients with myeloma.

Tumor Necrosis Factor α

TNF-α is a potent mediator of inflammation and bone resorption. It induces expression of NF-κB and adhesion molecules[127] but only modestly triggers proliferation of myeloma cells. It markedly upregulates secretion of IL-6 and expression of CD11a (LFA-1), CD54 (ICAM-1), CD106, and CD49d (VLA-4).[128] The proteosome inhibitor PS-341 and thalidomide abrogate TNF-α–induced NF-κB activation as well as induction of the adhesion molecules, resulting in decreased adhesion of myeloma cells to the bone marrow stroma.

Vascular Endothelial Growth Factor

VEGF is produced by myeloma cells and bone marrow stromal cells and probably is the major factor explaining increased angiogenesis in myeloma. In human myeloma cells VEGF is upregulated by IL-6 and CD40 activation.[129,130] It promotes migration and, to a lesser extent, proliferation of myeloma cells.[131]

CYTOGENETICS IN MULTIPLE MYELOMA

Cytogenetic information obtained by conventional techniques is limited in MM because it is a malignancy composed mainly of more differentiated B cells with low proliferative activity. Abnormal karyotypes are observed in only 30% to 50% of cases.[132–134] Typically, previously treated and relapsed patients have a higher frequency of chromosome abnormalities compared with newly diagnosed patients. This finding reflects the more proliferative nature of myeloma in its advanced stages. The presence of abnormal cytogenetics by conventional karyotyping has been associated with an inferior outcome.[132,133,135] Flow cytometry-derived aneuploidy data and fluorescent in situ hybridization (FISH) analysis indicate the presence of cytogenetic abnormalities in at least 90% of myeloma patients. Therefore, most of the normal karyotypes in myeloma patients are derived from normal hematopoietic cells and not from the myeloma clone. Even at the stage of MGUS, flow cytometry and FISH analysis demonstrate aneuploidy or cytogenetic abnormalities in at least 50% of patients.[136–138] Approximately 65% of myeloma patients with abnormal cytogenetics have a hyperdiploid karyotype. Pseudodiploid and hypodiploid karyotypes are found in approximately 15% and 20% of patients, respectively. The most common abnormalities are gains of the whole chromosomes 3, 5, 7, 9, 11, 15, and 19. Every single chromosome potentially can be involved in deletions, gains, additions, or translocations in MM (Fig. 87–6).

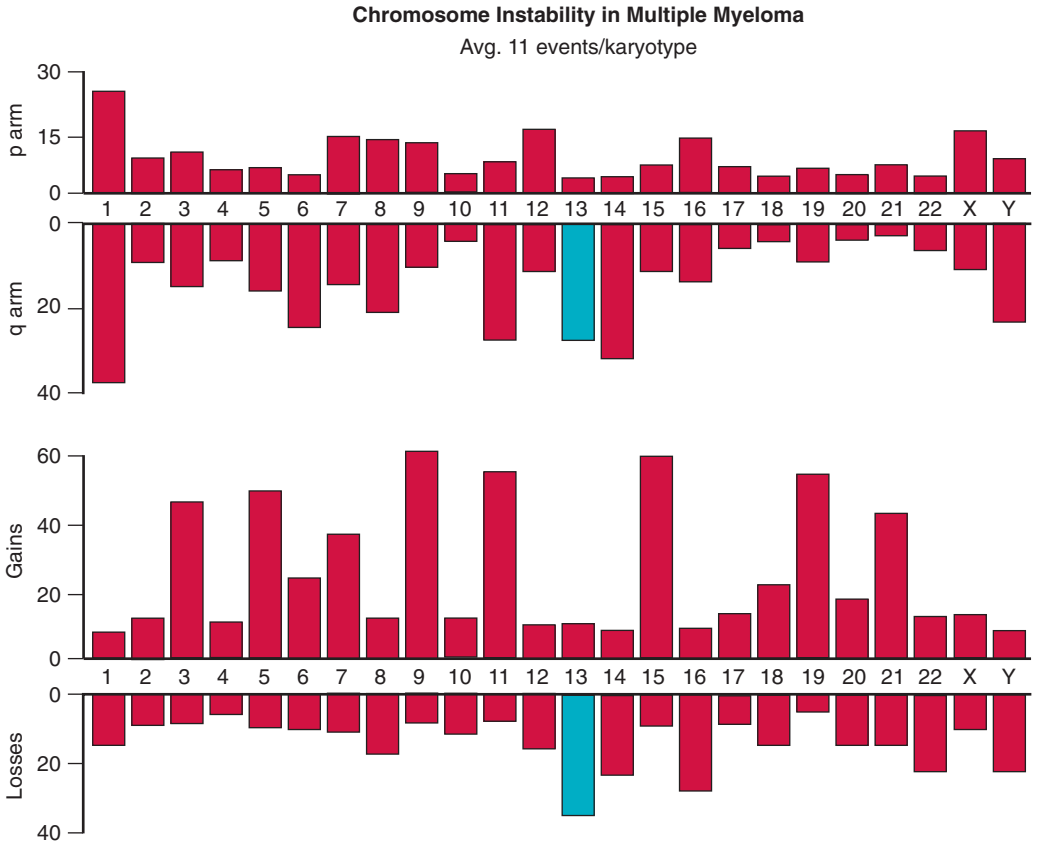

Figure 87–6 Chromosome instability in multiple myeloma.

Importance of Translocations Involving Chromosome 14q32

Chromosome 14q32 translocations involving IgH probably are an early important event in the pathogenesis of myeloma.[139] Multiple translocation partners have been identified for 14q32, several of which cannot be detected by conventional cytogenetics because they are located in telomeric positions. By interphase FISH analysis, IgH translocations are found in approximately 47% of MGUS patients, in 60% to 70% of patients with intramedullary MM, and in more than 80% of patients with primary or secondary plasma cell leukemia.[140,141] Translocations involving the λ light chain on chromosome 22 are present in approximately 17% of advanced and intramedullary myelomas. Translocations involving the κ light-chain gene on chromosome 2 are rare. The major recurrent translocation partners involving 14q32 are 4p16, 6p21, 11q13, and 16q23. Using FISH analysis, the t(11;14)(q13;32) translocation is present in approximately 15% to 20% of myeloma patients.[142,143] The breakpoint on 14q32 is located within the IgH or the switch region, compatible with the translocations caused by either somatic hypermutation or switch recombination. This is in contrast to mantle cell lymphoma, where the IgH breakpoints occur near the site targeted by VDJ recombination.[144] On 11q13, the breakpoints in myeloma are dispersed over a 330-kb region, centromeric to cyclin D1. Because of this translocation, cyclin D1 is juxtaposed to the powerful IgH 3′ enhancer on 14q32, leading to overexpression of cyclin D1. The t(11;14) translocation is also common in MGUS and primary systemic amyloidosis.[145] When detected by conventional cytogenetics, the t(11;14) translocation was associated with a poor prognosis.[146,147] However, when the t(11;14) translocation was identified by FISH, no inferior outcome was found.[148,149] Patients with the t(11:14) translocation are more likely to have lymphoplasmacytic morphology and a pseudodiploid karyotype. The labeling index usually is low.

Using FISH-based techniques, the t(4;14)(p16;q32) translocation was found in approximately 15% of MM patients.[142,150] This translocation is undetectable by conventional karyotyping because of its telomeric location. On chromosome 4p16, the breakpoints occur within the 5′ exon of the MMSET gene. The hybrid transcripts between IgH and MMSET gene are easily detected using reverse transcriptase polymerase chain reaction. The breakpoint on chromosome 4 occurs 50 to 100 kb centromeric to the fibroblast growth factor receptor 3 (*FGFR3*) gene. FGFR3 is one of the four high-affinity tyrosine kinase receptors for FGF. This receptor is not expressed in normal plasma cells. Signaling through FGFR results in phosphorylation of STAT3 and activation of the MAPK pathway. FGFR signaling can substitute for IL-6 with respect to the growth and survival of myeloma cells, and inhibition of FGFR signaling results in apoptosis.[151] FGFR3 may constitute a potential target for experimental therapies in patients with the t(4;14) translocation. Approximately one third of the myeloma cell lines with t(4:14) have activating mutations involving FGFR3. Patients who do not have activating FGFR3 mutations may have mutations of Ras.[152] A strong association between the t(4;14) translocation and chromosome 13/hypodiploidy has been observed, and t(4;14) has been associated with a poor prognosis.[153,154] Whether t(4;14) is present in stable MGUS patients is unclear.

Using FISH techniques, the t(14;16)(q32;q23) translocation has been identified in 5% to 10% of patients with MM. It leads to dysregulation of the c-*maf* protooncogene. c-Maf is a basic zipper transcription factor belonging to the AP1 superfamily and is widely expressed not only in embryonic but also in adult tissues. It is involved in the transcription of IL-6. Unexpectedly, *c-maf* expression was also observed in myeloma cell lines lacking the *c-maf* translocation.[155] Using gene expression profiling, three *c-maf* target genes were identified: cyclin D2, integrin β_7, and CCR1. c-Maf transactivates the cyclin D2 promotor and enhances myeloma proliferation. Increased levels of integrin β_7 enhance adhesion of myeloma cells to bone marrow stroma and increase production of VEGF. CCR1 is the receptor for MIP-1α and increases the chemotaxis of myeloma cells.[155] Patients with this translocation have a poor prognosis, at least with conventional chemotherapy.[156]

The t(14;20)(q32;q11) translocation results in aberrant expression of MafB, another basic transcription factor, and is present in fewer than 5% of newly diagnosed myeloma patients.[156,157] It appears to be associated with poor outcome.

The t(6;14)(p21;32) translocation results in dysregulation of cyclin D3 and has been identified in 4% of patients using metaphase chromosome analysis and in 6% of patients using gene expression profiling.[158] In approximately 20% to 25% of myeloma patients, either cyclin D1 or cyclin D3 is involved in translocations, highlighting the importance of this pathway.

The t(6;14)(p25;q32) translocation occurs downstream of the *IRF-4* gene, a member of the interferon regulatory factor family. The exact incidence of this translocation in patients with myeloma and its role in pathogenesis of myeloma are unclear. This translocation is found in approximately 18% of myeloma cell lines.[159]

The t(8;14)(q24;q32) translocation involves the protooncogene c-*myc*. This classic translocation for Burkitt lymphoma occurs very rarely in myeloma and mostly in the advanced stages of the disease.

The t(9;14)(p13;q32) translocation has been found in rare patients with myeloma. This translocation dysregulates the *PAX-5* gene at 9p13 and is seen more frequently in lymphoplasmacytoid lymphoma.[160]

Deletion 13q14 (Δ13)

By conventional cytogenetics, deletion of chromosome 13 has been detected in approximately 15% to 20% of the patients. Using interphase FISH, deletions have been detected in 50% of the patients.[161] Using 11 probes spanning the entire long arm, chromosome 13 deletions have been found in up to 86% of patients.[162] A 13q deletion by FISH is also found in 50% of patients with MGUS.[163,164] In contrast to MM, however, the 13q14 abnormality in MGUS may be restricted to a small subpopulation of cells, probably indicating that it is a secondary genetic event occurring after clonal expansion. The finding of 13q abnormalities with conventional karyotyping has been associated with poor outcomes in patients treated with either conventional chemotherapy[165] or tandem transplants.[146,166] The presence of 13q deletion as assessed by FISH studies has been associated with a poor outcome.[167] The poor prognosis in these patients probably is entirely related to the one third of patients who have a 13q deletion by conventional cytogenetics (Fig. 87–7). Chromosome 13q abnormalities are common in chronic lymphocytic leukemia but do not confer an adverse prognosis. Monoallelic deletion of the *Rb* gene, present in approximately 50% of the myeloma patients, does not seem to affect Rb protein expression. A high incidence of 13q deletions has been reported in patients with MM and a history of MGUS, suggesting that it may be involved in the transformation of MGUS into myeloma.[163] As mentioned earlier, there is an association between 13q deletions and t(4;14). Chromosome 13 deletion can be detected by gene expression profiling.[168] *IGF1R* is overexpressed in patients with deletion 13 by FISH.[168] Because myeloma cells express *IGF1*, this may represent an autocrine growth signal loop in this type of myeloma.

Hypodiploidy

Hypodiploidy in myeloma initially was detected by DNA content[138] but when detected by conventional karyotyping was found to have a negative impact on survival.[169] It often is associated with deletion of chromosome 13. French investigators suggested that hypodiploidy, and not the 13q deletion, was the major negative prognostic factor in MM. A subsequent analysis of hypodiploidy and the deletion of chromosome 13 in 1000 patients showed that both abnormalities are independently associated with poor prognoses.[170]

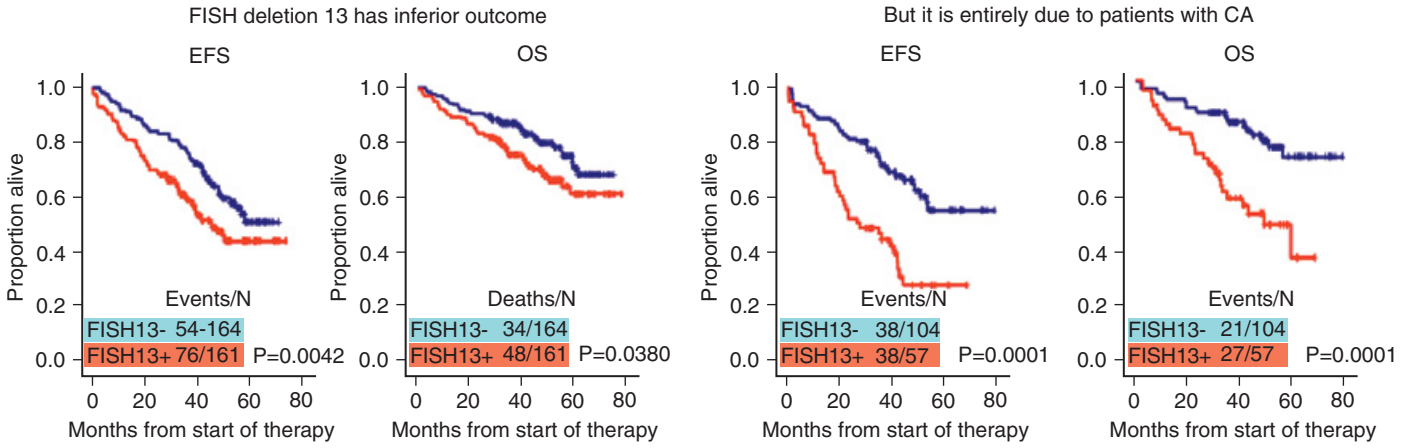

Figure 87–7 Fluorescent in situ hybridization deletion 13 (FISH 13+) occurs in approximately 50% of myeloma patients, whereas deletion of chromosome 13 by metaphase cytogenetics is seen in approximately 17% of patients. Although event-free survival (EFS) and overall survival (OS) of myeloma patients with FISH deletion, the difference in outcome is entirely due to the poor prognosis of patients who in addition to FISH deletion 13 have abnormal metaphase cytogenetics (CA). *(From Zhan F, Sawyer J, Tricot G: The role of cytogenetics in myeloma. Leukemia 20:1484, 2006.)*

Gene Expression Profiling

Metaphase and FISH chromosomal analysis are relatively crude methods for assessing DNA damage. Gene expression profiling permits quantitation of RNA expression of more than 30,000 genes, many related to important cancer features such as proliferation, apoptosis, DNA repair, and drug resistance. Based on unsupervised hierarchical clustering of highly purified plasma cells of newly diagnosed myeloma patients, seven subgroups were identified, related to either spiked gene expression as a consequence of translocations involving 14q32 or hyperdiploidy or a proliferative signature.[171] In addition to its biologic significance, the seven-group gene model had major prognostic implications, with an inferior outcome seen in patients with a proliferative signature and translocations involving *MMSET*, that is, t(4;14) or c-*maf;* t(14;16) or MafB; t(14;20). In an effort to identify gene expression patterns linked to an aggressive disease course, a model was created that included 70 genes with either very high (quartile 4) or very low expression (quartile 1) and correlating with outcome.[172] It was remarkable that 30% of these genes mapped to chromosome 1. One of these genes, *CKS1B*, maps to chromosome 1q21, which often shows gains based on comparative genomic hybridization[173] CKS1B is an essential cofactor of the SCF (Skp1-Cullin1-F-box protein) ubiquitin ligase complex that regulates p27 ubiquitination and degradation. Amplification of 1q21 (three or more signals) can be assessed by FISH. Patients with amplification of 1q21 have an inferior 5-year event-free survival (EFS) and overall survival (OS).[174] A combination of metaphase cytogenetic abnormalities and either *CKS1B* by gene array or amplification of 1q21 by FISH, after exclusion of cases with t(11;14), identifies most patients with a poor prognosis even after tandem transplants.[175] A poor prognosis was seen in all stages of the International Staging System.

Oncogenes/Suppressor Genes in Myeloma

Dysregulation of oncogenes and suppressor genes that control cellular proliferation, survival, and apoptosis contribute to the pathogenesis of most malignancies, including MM.

Loss of Function of Suppressor Genes

The *p15* and *p16* genes often are hypermethylated in MM and, therefore, deactivated,[176,177] even more frequently in advanced disease.[178,179] Whether hypermethylation of these genes is an early immortalization event in MGUS[180] or appears during progression of the myeloma is unclear.[181]

Levels of p21 and p27 protein are increased in patients with myeloma, probably as a consequence of the constitutively activated STAT3 pathway. They protect myeloma cells from apoptosis by inducing cell cycle arrest and allow subsequent DNA repair. Upregulation of expression of these gene products probably is a major factor in inducing resistance to chemotherapy and radiation therapy. Degradation of p27 occurs in the proteasome complex and is inhibited by bortezomib.

SOCS1 and *SHP1* are often hypermethylated in myeloma.[182] Suppressor of cytokine secretion (SOCS) members are induced by cytokines and are negative regulators of cytokine signaling. SHP1 is a tyrosine phosphatase. Both negatively regulate the Jak/STAT signaling pathway.

Death-associated protein (DAP) kinase promoter is hypermethylated in two thirds of primary myeloma samples.[183] DAP kinase is a cytoskeletal-associated serine/threonine kinase with death-inducing properties. Because myeloma in the early stages is a disease with very slow growth, hypermethylation of this gene may be critical in the induction and maintenance of tumor cells.

ras Oncogenes

The frequency of *ras* mutations in newly diagnosed patients with MM is approximately 40%[184] and increases significantly with disease progression. Mutations are present in most patients with terminal disease or plasma cell leukemia.[185,186] The most frequent mutation seems to be in N-*ras* at codon 61. Activating mutations of *ras* likely result in independence of myeloma cells from external cytokines such as IL-6 and IGF. It probably is one of the first mechanisms myeloma cells acquire in becoming stroma independent. Transduction of the IL-6–dependent cell line ANBL-6 with mutant *ras* makes this cell line IL 6 independent.[187]

More recently, N-*ras* mutations at codon 61 have been detected in plasma cells of all 34 myeloma patients examined, suggesting that mutational activation of N-*ras* is a mandatory event in the pathogenesis of MM.[188] *ras* Mutations are not evenly distributed among different molecular subclasses. A higher frequency of *ras* mutations is seen in patients expressing high levels of cyclin D1, whereas a low frequency of such mutations is seen in patients with t(4;14).[189] Surprisingly, in patients with paired samples of intramedullary and extramedullary myeloma, *ras* mutations were found only in the extramedullary plasmacytomas, suggesting a role of *ras*

mutations in the transition from intramedullary to extramedullary tumor.[188] Myeloma cells containing *ras* mutations upregulate cyclooxygenase (COX)-2 expression, which results in increased binding to extracellular matrix proteins and chemotherapeutic drug resistance.[190]

Bcl-2 Family in Multiple Myeloma

The *bcl-2* protooncogene initially was identified through t(14;18) present in 85% of low-grade follicular non-Hodgkin lymphomas.[191] Bcl-2 prevents apoptosis induced by a variety of agents, such as glucocorticoids, cytotoxic agents, cytokine deprivation, and radiation. High expression of *bcl-2* probably has a negative effect on cell proliferation. Multiple *bcl-2*–related genes have been identified based on their amino acid homology to *bcl-2.* They include positive and negative regulators of apoptosis, such as Bax, Bcl-X_L, Bcl-X_s, Mcl-1, and A-1. These proteins localize to the outer membrane of the mitochondria. Bax initiates an increase in permeability of the outer mitochondrial membrane leading to cytosolic release of cytochrome C. An activation complex consisting of cytochrome C, apoptotic protease activating factor 1, and deoxyadenosine triphosphate triggers activation of caspases, which in turn effects cell demise. Antiapoptotic members of the Bcl-2 family prevent this increase in permeability of the outer mitochondrial membranes by associating with Bax. Smac/diablo is another apoptogenic protein released from the mitochondria that can induce activation of caspases and lead to cell death. Smac binds to IAPs, overcoming their inhibitory influence on various caspases.[192] Levels of Bcl-2 in myeloma usually are increased and contribute to the resistance of myeloma cells to chemotherapy. It has also been suggested that Bcl-2 expression is upregulated after exposure to chemotherapeutic agents.[193] Most myeloma cells show overexpression of Bcl-X_L and Mcl-1.[194] There seems to be a good correlation between the expression of the latter two gene products. Their expression is tightly regulated by IL-6. It appears that Mcl-1 rather than Bcl-2 or Bcl-X_L is essential to survival of myeloma cells, based on antisense strategies. Antisense oligonucleotides against Mcl-1 trigger an important decrease of viability in myeloma cell lines and in primary myeloma cells, whereas neither Bcl-2 nor Bcl-X_L antisense affected the viability of myeloma cells.[195]

Retinoblastoma Gene in Multiple Myeloma

The *Rb* tumor suppressor gene is located on chromosome 13q14 and codes for a nuclear phosphoprotein that suppresses the G_1 to S transition of the cell cycle by inhibiting E2F-mediated transactivation of a variety of genes involved in initiating DNA synthesis, such as *myc*, dihydrofolate reductase, and thymidine kinase. Hypophosphorylated or dephosphorylated Rb protein binds E2F and prevents its activity. Mutations of the *Rb* gene or protein contribute to cellular transformation in many types of malignancies. Elimination or deactivation of both *Rb* gene copies is required for manifestation of a tumorigenic phenotype. Several independent studies have concluded that *Rb* gene deletion is frequent in myeloma.[196,197] However, biallelic deletion of *Rb* is infrequent.[198] Monoallelic deletion of *Rb* does not appear to modulate expression of the Rb protein. Evidence indicates that IL-6 promotes MM cell growth through phosphorylation of the Rb protein.[102,199] Whether *Rb* deletion plays any role in myeloma transformation is unclear.

p53 Mutations

The p53 protein plays a central role in modulating cellular responses to cytotoxic agents by contributing to cell cycle arrest and programmed cell death. Loss of *p53* function usually is accomplished through mutations and leads to inappropriate cell growth, increased cell survival, and genetic instability. *p53* gene mutations are observed in approximately 50% of malignancies. They occur relatively early in the disease in cancers of the skin, lung, and head and neck. Of note, development of these tumors is associated with exposure to known environmental carcinogens. The presence of specific *p53* mutations in tumors now is being used to identify environmental carcinogens as a cause of a particular type of tumor. The presence of *p53* mutations has been associated with resistance to therapy and shortened survival in acute myeloid leukemia, MDS, and chronic myeloid leukemia. The prognostic significance of *p53* mutations in these malignancies may be due to a reduced ability to initiate program cell death following cytotoxic therapy. For *p53* to be active, it may require the cooperation of closely related proteins, such as p63 and p73.[200] In undamaged cells, p53 is highly unstable, with a half-life measured in minutes. The instability of p53 depends on Mdm2. Mdm2 binds to the amino terminus of p53 and targets it for ubiquitination and degradation. Preventing the interaction of p53 with Mdm2 is sufficient to promote the stabilization of p53. Mdm2 protein facilitates G_1 to S phase transition by activating E2F-1 and enhances cell survival by suppressing wild-type p53. Mdm2 is strongly and constitutively expressed in MM cell lines and in plasma cell leukemia cells.[201] Mdm2 enhances cell cycle progression in myeloma cells by downregulating cell cycle inhibitory proteins such as p21. p53 may be involved in transcriptional repression of the IL-6 gene during cellular differentiation and oncogenesis.[202] *p53* mutations are very uncommon in myeloma and usually are associated with the end-stages of the disease,[185,203] explaining the common occurrence of *p53* mutations in human myeloma cell lines, which are derived from end-stage patients.[204] The overall incidence of *p53* mutations probably is not more than 8% to 10%.[205] This is confirmed by the very low incidence of p53 antibodies in MM.[206] In contrast, the presence of *p53* gene deletion as measured by FISH, and which usually is monoallelic, has been detected in 10% to 33% of myeloma patients; it usually is caused by an interstitial deletion of 17p.[207] *p53* gene deletion has been associated with stage III disease and significantly shorter survival times compared with patients without the deletion.[207,208]

c-myc in Myeloma

The c-Myc protein is a nuclear phosphoprotein with DNA-binding properties. c-Myc heterodimerizes with max, a protein that cooperates with c-myc to bind specifically to core DNA sequences. c-myc participates in the regulation of gene transcription of normal and neoplastic cells. It plays a role in controlling proliferation, differentiation, and apoptosis. The classic translocations t(8;14), t(2;8), or t(8;22) juxtaposing c-myc and the IgH or Ig light-chain locus are the hallmark of Burkitt lymphoma. Although such translocations also occur in murine plasmacytomas induced by pristine, in human myeloma, the classic t(8;14) occurs in less than 5% of cases.

Transcription of c-myc in the normal plasma cells is repressed by blimp-1, an inducer of terminal B-cell differentiation. However,[209] in human MM, elevated myc expression was found in approximately 25% of myeloma patients.[210] In a subsequent study, c-*myc* gene transcripts were detected in 92% of cases (12 out of 13) with no correlation to proliferative activity, as measured by KI-67, but correlating with the extent of bone marrow plasmacytosis and percentage of plasmablasts.[211] It was shown that c-myc abrogates p53-induced G1 arrest by interfering with the inhibitory action of p21.[212] In the absence of growth factors, c-myc is an important inducer of apoptosis. Induction of apoptosis by c-myc can be counteracted by bcl-2 expression.[213] c-*myc* and cyclin D3 genes are independent targets for glucocorticoid inhibition of lymphoid cell proliferation.[214] Using FISH analysis, c-myc rearrangements have been detected in approximately 15% of myeloma patients and 55% of myeloma cell lines.[215] These translocations are often complex, frequently do not involve the IgH locus, and are typically not expressed in all the myeloma cells, suggesting that c-myc rearrangements occur late in myeloma development.

Fas Gene in Myeloma

The Fas antigen, CD95, is a transmembrane protein that induces apoptosis when engaged by Fas ligand. Point mutations of the *Fas* gene have been identified in 10% of primary myeloma samples (4/48) leading to blocking apoptosis by the Fas ligand.[216] All of the mutations identified were located in the cytoplasmic region of the Fas antigen, known to be involved in transduction of apoptotic signals. In addition, it has been shown that β_1-integrin–mediated adhesion (VLA-4) to fibronectin inhibits Fas-induced caspase 8 activation. This adhesion-dependent inhibition of Fas-mediated apoptosis correlates with enhanced c-*fas*–associated death domainlike IL-1–converting enzymelike inhibitory protein (cFLIP).[217] Expression of the Fas antigen was found in 7 of 11 primary myeloma samples. Remarkably, Fas ligand was found in all five cases with high serum LDH.[218] Myeloma cells upregulate Fas ligand,[219] leading to erythroblast apoptosis, partly explaining the anemia observed in myeloma.

TNF-Related Apoptosis-Inducing Ligand

TRAIL induces apoptosis of primary myeloma cells and of the majority of myeloma cell lines, both sensitive and resistant to dexamethasone, doxorubicin, or melphalan, and overcomes the survival effect of IL-6 on myeloma cells. It induces apoptosis of myeloma cells by interacting with a complex system of cell surface receptors, including the death signal-transducing receptors DR4 and DR5. In contrast, death receptors DR1 and DR2 lack a functional death domain and cannot transduce a proapoptotic signal and therefore are considered decoy receptors. Both NF-κB inhibitors and proteosome inhibitor PS-341 enhance the proapoptotic activity of TRAIL. TRAIL activates caspase 8 in TRAIL-sensitive myeloma cells. Sensitivity in TRAIL-resistant myeloma cells is restored by cycloheximide and the protein kinase C inhibitor bisindolylmaleimide, which lowers cFLIP and the cellular inhibitor of apoptosis protein 2.[220]

CLINICAL MANIFESTATIONS

The clinical manifestations of MM are the direct consequence of marrow infiltration by plasma cells, production of monoclonal protein in blood or urine, and immune deficiency (Fig. 87–8).

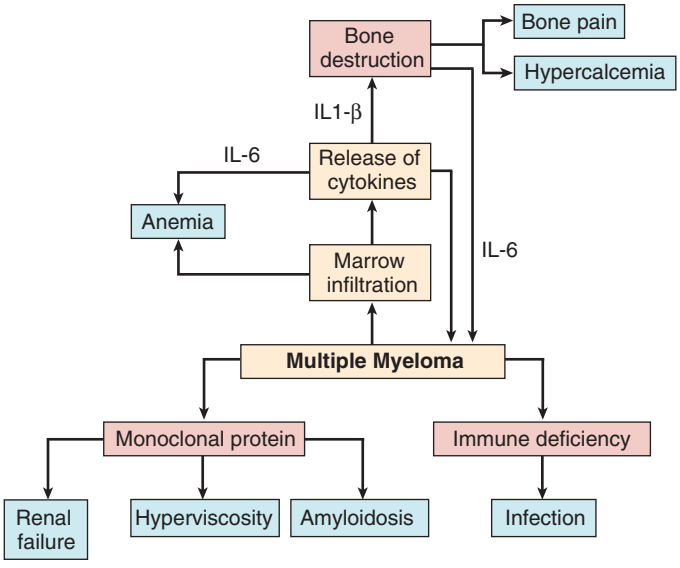

Figure 87–8 Major clinical and laboratory features of multiple myeloma.

Bone Pain

Bone pain, typically in the back (spine) or chest (ribs) and less often in the extremities, is present at diagnosis in more than two thirds of patients. The pain usually is aggravated by movement. The patient's height may be reduced by several inches because of collapse of one or more vertebral bodies.[221] Sudden onset of back pain in an individual older than 40 years, especially if the complaint is new for the patient, is sufficient to suspect the diagnosis of myeloma and should lead to a proper workup for the disease.

Renal Insufficiency

The two major causes of renal insufficiency in MM are myeloma kidney and hypercalcemia. Myeloma kidney is characterized by the presence of large, waxy, laminated casts in the distal and collecting tubules. The casts are composed mainly of precipitated monoclonal light chains and are surrounded by multinucleated syncytial epithelial cells (giant cells). The casts result in dilation and atrophy of the renal tubules. Eventually the entire nephron becomes nonfunctional, and interstitial fibrosis may occur.[222] The extent of cast formation correlates directly with the amount of free urinary light chains, but the actual mechanism of nephrotoxicity from Bence Jones proteinuria is unknown, although dehydration, associated with hypercalcemia, or radiographic contrast medium studies may precipitate myeloma kidney. Myeloma kidney is more often encountered with λ light chains.

The second most common course of renal insufficiency is hypercalcemia, resulting in hypercalciuria and osmotic diuresis, leading to volume depletion and prerenal kidney failure. Hypercalcemia also may cause calcium deposits, leading to interstitial nephritis. Hyperuricemia as well as nonsteroidal antiinflammatory drugs reduce blood flow to the glomeruli and may promote the development of renal failure. Patients with myeloma are highly sensitive to nephrotoxic medications, such as aminoglycosides, cisplatin, amphotericin B, and cyclosporine A. Plasma cell-derived (light-chain associated [AL]) amyloidosis of the kidney in myeloma patients is associated with minimal light-chain proteinuria and usually presents as nephrotic syndrome, but it can lead to renal failure with time (see Chapter 89). Probably underestimated as a cause of renal failure is Ig light-chain deposition disease, which is commonly associated with κ light-chain myeloma proteins, in which monoclonal light chains are deposited in renal glomeruli. Urinary total protein and M protein usually are minimal. The histopathologic picture resembles nodular glomerulosclerosis, but electron microscopy reveals granular, electron-dense deposits representing light chains. Myeloma involvement of the kidneys is uncommon but should be suspected in patients who have renal enlargement that is not caused by amyloidosis. IL-6 may contribute to renal failure.[110]

Bisphosphonates, especially infused over a short period, eventually may lead to renal insufficiency, usually preceded by nonspecific proteinuria in case of pamidronate but not commonly in the case of zoledronate.

Hypercalcemia

Some patients with myeloma have paraproteins that avidly bind calcium, resulting in spurious hypercalcemia. The best solution to this problem involves measuring the ionized serum calcium level. Hypercalcemia occurs in 30% to 40% of patients with MM and usually is associated with a large disease burden. Hypercalcemia is the presenting finding in 15% to 30% of patients and leads to lethargy, polyuria, polydipsia, constipation, nausea, and vomiting.[223] Levels of total serum calcium should be adjusted for serum protein concentrations, especially albumin. Pronounced hypoalbuminemia, caused by an increased level of IL-6, poor food intake, or urinary loss in the case of concomitant amyloidosis, can mask frank hypercalcemia unless an ionized serum calcium level is measured.

Neurologic Symptoms

Neurologic symptoms usually are the result of compression by a soft-tissue plasmocytoma or bone fragments of a vertebral body on the spinal cord or on a nerve. The pain usually is in the thoracic or lumbosacral area. Compression of the spinal cord must be considered an oncologic emergency requiring prompt intervention. It is best diagnosed by MRI. In addition to back pain with radicular features, weakness or paralysis of the lower extremities and bowel or bladder incontinence may occur. Peripheral neuropathy is uncommon in MM and almost always is associated with amyloidosis. It is seen in osteosclerotic myeloma and sometimes is part of the polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes (POEMS) syndrome. Intracranial plasmacytomas usually represent extensions of myelomatous lesions of the skull and may lead to cranial nerve deficits or, more infrequently, leptomeningeal infiltration (usually seen only in the terminal phases of the disease). Peripheral neuropathy, mainly sensory (numbness and paresthesias), is a common side effect of thalidomide and, to a lesser extent, bortezomib therapy.

Hyperviscosity

In contrast to Waldenström macroglobulinemia, hyperviscosity is rare in MM, occurring in less than 10% of patients. Because of a greater tendency for IgA to form polymers, patients with IgA myeloma more often have features of hyperviscosity, resulting in circulatory problems and leading to cerebral, pulmonary, and renal manifestations. Hyperviscosity often is associated with bleeding. Among patients with IgG myeloma, those with the IgG3 subclass are most likely to develop hyperviscosity. The diagnosis of hyperviscosity can be made by measuring serum viscosity or by funduscopic examination showing slow blood flow in blood vessels that often are distorted. Hyperviscosity can give the clinical and radiologic pictures of pulmonary edema and will worsen only if treated with diuretics. Plasmapheresis is the appropriate treatment of the condition.

Amyloidosis

Amyloidosis is a clinical syndrome that results from extramedullary deposition of insoluble fibrillar protein. A diagnosis of MM can be made in 20% of patients with AL amyloidosis.[221] Approximately 3% of patients with newly diagnosed MM have overt amyloidosis,[224] but the frequency of asymptomatic amyloidosis in myeloma, as diagnosed by subcutaneous fat aspiration and rectal and bone marrow biopsies, is much higher (35%).[225] The most common clinical manifestations are carpal tunnel syndrome or generalized edema due to nephrotic syndrome. Less common manifestations are cardiomyopathy, macroglossia, and extensive bruising around the eyelids. The presence of symptomatic amyloidosis in patients with MM adds to morbidity rates and has an adverse effect on survival.[224] When treated with conventional chemotherapy, the median survival duration of patients with myeloma and amyloidosis is approximately 12 months.[224] More encouraging results have been obtained with high-dose melphalan and stem cell support.[226]

Infections

Patients with MM have an increased susceptibility to develop infections because of the associated hypogammaglobulinemia. Myeloma patients are not able to mount a vigorous primary immune response and have an impaired secondary antibody response to antigens. Defects of T cells, natural killer cells, and monocytes may accelerate and contribute to humoral deficiency. The additional immunosuppressive effect of chemotherapy, especially with corticosteroids, further increases the infection risk. The average MM patient will suffer from 0.5 to 1.5 infections per year, with the highest frequency during the first 2 months of treatment. Polysaccharide-encapsulated organisms, especially *Streptococcus pneumoniae* and *Haemophilus influenzae*, initially were identified as the major causes of infection. However, now it is clear that enteric gram-negative bacilli are the most common isolates, accounting for approximately 60%; encapsulated organisms represent less than 25% of blood culture isolates. Oral thrush is the only fungal infection of significance. Other organisms, such as anaerobes, *Mycobacterium tuberculosis*, herpes simplex, cytomegalovirus, and varicella zoster, are uncommon unless patients have received transplantation. Early diagnosis and prompt initiation of broad-spectrum antibiotic therapy are critical in patients with MM. Third-generation cephalosporins or extended-spectrum penicillins are used most frequently. Infection prophylaxis with trimethoprim-sulfamethoxazole is effective in decreasing the incidence of infectious complications during the first few months of initial standard-dose chemotherapy.[227] Vaccination against influenza in patients with MM is safe and may have significant benefits.[228]

Extramedullary Disease

Extramedullary plasmacytomas have been found in the lymph nodes, skin, liver, and spleen and occasionally in the kidneys, breast, testis, and meninges. The finding usually is associated with high serum LDH levels and plasmablastic morphology (end-stage myeloma). Patients usually have poor outcomes even with more aggressive treatment approaches.

Bleeding and Anemia

Bleeding problems occur in 15% of IgG myelomas and 30% of IgA myelomas and may be due to platelet dysfunction or acquired coagulopathy. Thrombocytopenia, even with extensive bone marrow involvement, is rare in the early phases of the disease. The preserved platelet count might be related to increased IL-6 levels, which promote megakaryocyte maturation. Anemia, which is present in two thirds of myeloma patients, is the consequence of increased IL-6 production by the microenvironment, MIP-1α secretion by myeloma cells, and Fas ligand expression on their membranes, inducing apoptosis of red cell precursors. It may be spuriously aggravated by expansion of plasma volume due to large amounts of circulating Igs. Serum erythropoietin levels are low relative to the degree of anemia, a finding that probably is due to abundant production of cytokines such as IL-1β and TNF-β. Routine use of erythropoietin should be encouraged in cases of anemia.

LABORATORY EVALUATION

The *bone marrow* is involved with an excess of plasma cells (>5%) in approximately 90% of cases (Figs. 87–9 and 87–10). The mean percentage of plasma cells at diagnosis is 30%.[229] Only scattered nodular infiltration of the bone marrow is found in less than 5% of cases.

A *monoclonal protein* (M protein) is evidenced on serum protein electrophoresis as a spike or localized band in the β- or γ-globulin region in 80% of patients; approximately 10% have hypogammaglobulinemia, and 10% have a normal-appearing pattern. The more sensitive immunoelectrophoresis and immunofixation reveals an M protein in the serum in more than 90% of patients and in the urine in 80%. With these sensitive techniques, an M protein in serum or urine is found in 99% of cases.[221] Approximately 55% of patients have an IgG isotype, 25% have IgA, 1% have IgD, 1% have IgM, and approximately 20% have only light-chain secretion with a κ/λ ratio of 2:1.[230] In heavy-chain disease, a localized band is often not seen, and either immunoelectrophoresis or immunofixation is required for identification of an M protein.

Other laboratory manifestations of MM include increased erythrocyte sedimentation rate in patients with a significant M protein in the serum, elevated creatinine in approximately half of cases, and a

decreased albumin level, which usually is associated with increased IL-6 activity.

A relatively new test that has rapidly gained importance measures the concentration of serum Ig free light chains. Serum concentrations of free light chains are dependent upon the balance of production by plasma cells and renal function. In cases of increased polyclonal Ig production or renal failure, both κ and λ concentrations can increase considerably, but the κ/λ ratio remains unchanged. Approximately 20% of myeloma patients have either nonsecretory or light-chain only disease. The majority of those patients have abnormal free light-chain concentrations. Among patients with a clear serum M protein, 95% have abnormal free light-chain concentrations.[231] The serum free light-chain concentration and serum M protein level do not correlate. In general, the larger the imbalance between light- and heavy-chain production, the more aggressive the myeloma, although there are exceptions. The half-life of free light chains is short (2–6 hours), compared to more than 20 days for intact IgG. Therefore, responses to therapy will be noted much more rapidly by following free light-chain concentrations than serum M protein.[232] Serum free light-chain concentrations are below the sensitivity of serum protein electrophoresis, although occasional patients have a persistent serum M protein and normal free-light concentrations and ratio. Regular followup of free light chains is a good method for detecting early myeloma relapse. Serum free light-chain concentrations are important in assessing hematologic responses in patients with AL amyloidosis and in predicting survival after therapy.[233]

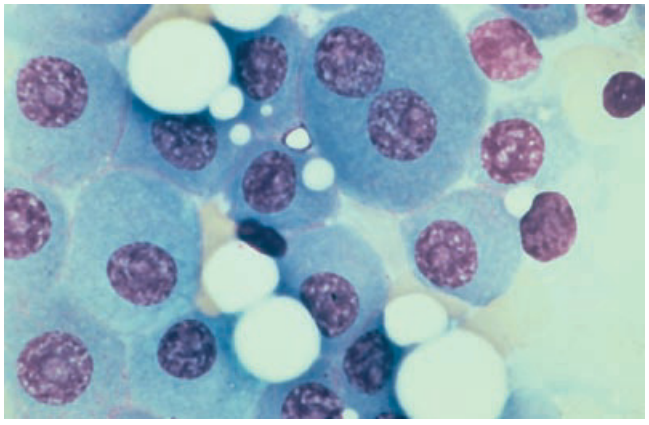

Figure 87–9 Bone marrow is invaded by plasma cells, which are more immature than normal plasma cells, as evidenced by a more delicate chromatin structure and the presence of a nucleolus in some of the cells.

DIAGNOSIS

Minimal criteria for diagnosis of overt myeloma include the presence of at least 10% abnormal plasma cells in the bone marrow or histologic proof of a plasmacytoma and at least one of the following abnormalities: serum M protein (usually >3 g/dL), M protein in the urine (usually >1 g/dL), or osteolytic lesions.[234]

If the diagnosis of MM is suspected, the physician should obtain, in addition to a complete history and physical examination, the following tests: complete blood count with differential, electrolytes, blood urea nitrogen, creatinine, calcium, phosphorus, uric acid, LDH, alkaline phosphatase, serum protein electrophoresis, quantitative Igs, serum immunoelectrophoresis, β_2 microglobulin (β_2M),

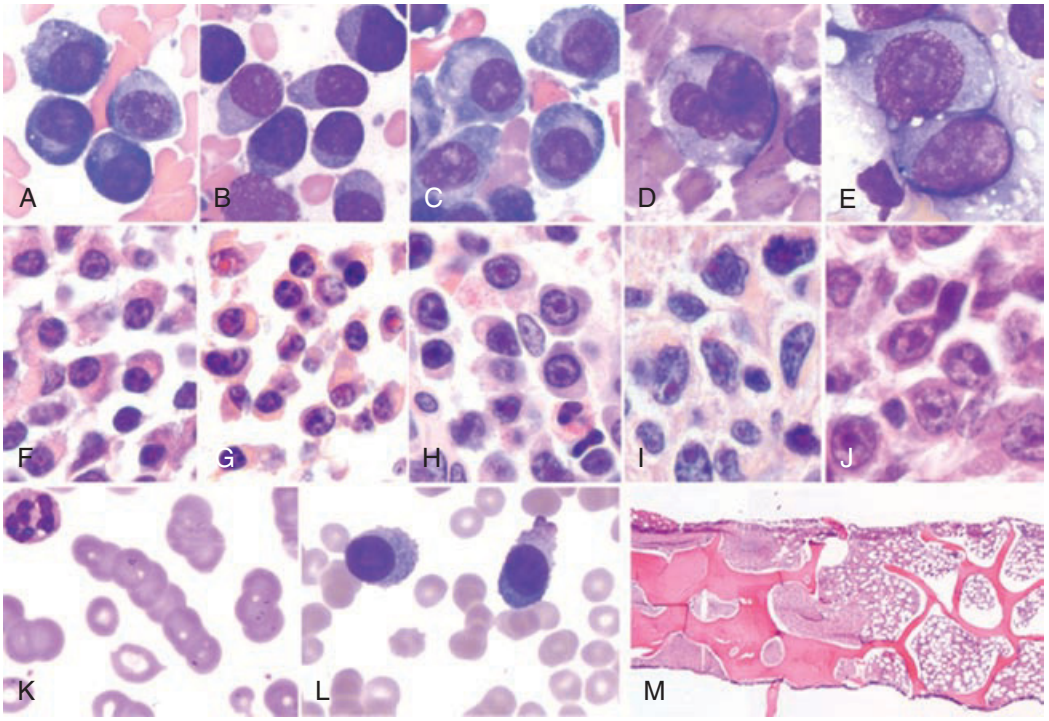

Figure 87–10 Multiple myeloma. **A–J,** Morphologic spectrum of myeloma. Multiple myeloma exhibits a wide cytologic and morphologic spectrum in the bone marrow aspirate and biopsy. **A, F,** The typical type has fairly mature appearing plasma cells with eccentric nuclei and cytoplasmic hofs. **B, G,** A lymphocytelike type has less abundant cytoplasm. **C, H,** A dyssynchronous type C, H) has mature chromatin but prominent nucleoli. **D, I,** An anaplastic type has highly irregular plasma cells that on the aspirate sometimes resembles monocytes **(D).** This type can present a diagnostic challenge if myeloma is not suspected. **E, J,** The plasmablastic type can be difficult to distinguish morphologically from immunoblastic lymphoma. **K,** Rouleau formation. The red cells resemble a stack of coins. **L,** Plasma cell leukemia. A diagnosis can be made when circulating plasma cells are greater than 2×10^9/L or when they account for greater than 20% of circulating leukocytes. **M,** Osteosclerotic myeloma. The left side of the illustration shows bone sclerosis and the marrow cavity replaced by myeloma. This patient had the polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes (POEMS) syndrome.

CRP, free light chains, radiographic survey of the bones, and bone marrow aspirate and biopsy, preferentially with PCLI and cytogenetics, and either MRI with T1 and short T1 inversion recovery images or PET/CT scan. In case of a solitary plasmacytoma, MRI of the head, spine, pelvis, shoulders, and sternum or PET/CT scan are indicated to better evaluate the extent of disease. In case of severe back pain, MRI of the spine is performed to exclude cord compression. If extramedullary disease is suspected, PET/CT scan is the preferred test.

DIFFERENTIAL DIAGNOSIS

In patients with monoclonal gammopathies associated with borderline bone marrow plasmacytosis, connective tissue diseases, chronic infections, carcinoma, and lymphoma should be excluded. In most patients, however, the diagnosis of MM is readily established. It is important to distinguish myeloma from MGUS, solitary plasmacytoma of the bone, and amyloidosis. Imaging tests such as MRI and PET/CT scan, free light chains, cytogenetics, and PCLI will help in the differential diagnosis.

Monoclonal Gammopathy of Undetermined Significance

MGUS is characterized by the presence of a serum M protein concentration usually less than 3 g/dL, less than 10% plasma cells in the bone marrow, no or only small amounts of Bence Jones protein in the urine, absence of lytic lesions or focal lesions due to myeloma cells on MRI and PET/CT scan, anemia, hypercalcemia, cytogenetic abnormalities with conventional karyotyping and renal insufficiency, and, most importantly, the presence of a stable M protein.[23] MGUS is found in approximately 3% of individuals older than 70 years. Of all patients with monoclonal gammopathies, 62% have MGUS.[235] Most patients with MGUS die of unrelated causes (52%), whereas 22% have either no substantial increase in M protein or an increase in M protein without any symptoms, and 11% progress to MM.[235] The median interval from recognition of the M protein to the diagnosis of MM is 10 years (range 2–29 years). Currently, no single test can distinguish MGUS from MM. In MGUS, PCLI is low (<0.2%), and β_2M and CRP levels are normal.[138] Fifty percent of patients with MGUS have an abnormal DNA content either by flow cytometric analysis[138] or FISH.[136] On gene expression profiling, plasma cells from patients with MGUS cluster with myeloma patients and separate from normal bone marrow cells.[236] The clinical and laboratory features of patients with MGUS with chromosomal abnormalities on FISH analysis are indistinguishable from those without.

Smoldering Myeloma

Patients with smoldering disease have a serum monoclonal component greater than 3 g/dL but usually less than 4.5 g/dL and more than 10% marrow plasmacytosis. However, they have no end-organ damage, exemplified by normal renal function and calcium levels, very mild (if any) anemia, and no lytic bone lesions on skeletal survey or CT scan. PCLI is invariably low, and conventional cytogenetic analysis is normal. Patients with smoldering myeloma may have decreased uninvolved Ig levels and a small amount of Bence Jones proteinuria.[237,238] The median time to progression to active myeloma is 26 months, with shorter times observed in patients with higher levels of monoclonal protein and Bence Jones proteinuria. Response rates and survival times after initiation of treatment are similar despite the different times to progression. Participation of patients with smoldering myeloma in clinical trials evaluating the impact of various interventions on the time to disease progression is strongly encouraged.

Solitary Plasmacytoma of the Bone

Solitary plasmacytoma of bone is uncommon; it is present in 3% to 5% of patients with plasma cell dyscrasias. The most common symptom at diagnosis is pain. The median patient age is one decade younger than that in MM.[235]

The diagnosis is based on histologic evidence of a tumor consisting of light chain–restricted plasma cells with no other lesions on skeletal survey, MRI, or PET/CT scan, a normal bone marrow without clear excess of light chain–restricted plasma cells, and absence of an M protein in blood and urine; or, if M protein is present, therapy for the solitary lesion should result in disappearance of the M protein, which may take up to 6 months. The uninvolved Igs may be normal, and no evidence of anemia or hypercalcemia is seen. Overt MM develops in approximately 50% of patients, with evidence of progressive disease within 3 years in two thirds of patients. The 5- and 10-year survival rates are 74% and 45%, respectively.[235] Tumoricidal radiotherapy with 4000 to 5000 cGy has been considered the treatment of choice. However, such doses given to a large part of the spine or pelvis may hamper attempts to collect adequate numbers of stem cells for autotransplantation. Common findings after tumoricidal radiotherapy are continuing increased uptake on PET scan and abnormal cytogenetics of the solitary plasmacytoma.

Extramedullary Plasmacytoma

Isolated extramedullary (soft-tissue) plasmacytomata occurs more frequently in the respiratory sinuses, nasopharynx, larynx, and gastrointestinal tract.[239] The diagnosis is established by detection of monoclonal plasma cells in an involved organ biopsy in the absence of other disease manifestations. The treatment of choice is local radiotherapy, which in cases of head and neck lesions should encompass the adjacent lymph nodes. Approximately 70% of patients with extramedullary plasmacytoma remain free of disease at 10 years and less than 30% develop frank myeloma or multiple extramedullary tumors.[240]

Amyloidosis

Plasma cell-derived amyloidosis can occur in the context of MM but without overt myeloma. Primary amyloidosis and amyloidosis associated with myeloma have the same underlying pathologic process whereby excessive amounts of the Ig produced by a single clone of B cells are deposited in tissues in a manner and quality sufficient to compromise organ function. In primary amyloidosis, there is a minimal or no clinically detectable increase in plasma cells and no other manifestations of myeloma, such as anemia, hypercalcemia, and bone lesions. The diagnosis of amyloidosis is made by staining tissue with Congo red with resulting classic apple-green birefringence when viewed under polarized light, immunofluorescent staining for light and heavy chains, and electron microscopy.[222] Serum free light chains are important in establishing the diagnosis of primary amyloidosis.[233]

POEMS Syndrome

The POEMS syndrome is poorly understood. Other important features not represented in the acronym include sclerotic bone lesions (see Fig. 87–10 *M*), Castleman disease, thrombocytosis, pleural effusion, edema, and ascites. The dominant clinical feature is a sensorimotor demyelinating polyneuropathy, presumably due to the toxic effects of the secreted monoclonal Ig. Endocrine abnormalities (hypogonadism, hypothyroidism, primary adrenal dysfunction, diabetes mellitus) and skin changes (hyperpigmentation, acrocyanosis, hypertrichosis, multiple hemangiomata) were reported in approximately two thirds of 99 patients included in the largest, published series from the Mayo Clinic.[241] The amount of M protein (possible subtype in

all cases in this series) was relatively small (median serum M spike of 1.1 g/dL). These patients have minimal bone marrow plasmacytosis (except in areas of sclerotic bone disease) and normal renal function and calcium levels. Cytokines appear important in the disease pathogenesis. IL-1β, IL-6, and TNF-α levels are elevated; more recently, VEGF has been implicated as having a potentially pathogenetic role. Chemotherapy, not including potentially neurotoxic agents, and aggressive local measures (surgery or radiotherapy) to alleviate the bone manifestations are indicated. High-dose treatment (HDT) with stem cell support has been found effective, especially in patients with rapidly progressive polyneuropathy, but is associated with significant morbidity.[242] The overall median survival duration in the Mayo Clinic series was 165 months.[241] Survival was adversely affected by the presence of clubbing and extravascular fluid overload. Responding patients had superior survival times. Infections and cardiorespiratory failure were the most common causes of death; no patient died of progression to frank myeloma.

Plasma Cell Leukemia

Although detection of circulating plasma cells in the peripheral blood by flow cytometry is not rare, the term *plasma cell leukemia* (PCL) is used when the absolute plasma cell count is greater than 2×10^9/L or the relative number is greater than 20% of the peripheral white cells (see Fig. 87–10 *L*). PCL may be de novo, when the patient is originally diagnosed in the leukemic phase, or secondary, when a patient with previously recognized myeloma undergoes leukemic transformation. Fewer than 5% of newly diagnosed MM patients present with PCL. These patients tend to have higher tumor burdens (compared with MM patients) and higher incidences of extramedullary involvement and thrombocytopenia. Elevated LDH and β_2M levels, higher proliferative potentials (expressed by percentage of plasma cells in S phase), and hypodiploidy are observed more frequently in PCL than MM.[243,244] In one series, 11 of 13 patients with PCL analyzed by FISH had monosomy of chromosome 13,[243] OS was much worse in PCL (8 months) versus MM (36 months), but it was significantly better in PCL patients treated with more aggressive chemotherapy than in those treated with melphalan plus prednisone (MP). The higher incidence of monosomy 13 in PCL patients was confirmed in another study.[141] Timely application of HDT is indicated in de novo PCL. Patients with secondary PCL usually are refractory to chemotherapy and have a poor survival compared to patients with primary PCL (median <2 months).[245]

PROGNOSTIC FACTORS

MM is a highly heterogeneous disease, with survival ranging from a few months to several years. The median survival achieved with standard treatment is approximately 3 years; a small percentage (5%) of patients survive more than 10 years.

Attempts to better identify subgroups of patients with distinct outcomes has led to the recognition of various prognostic factors. The serum level of β_2M is one of the most important prognostic factors in myeloma. β_2M is a small protein that associates with human leukocyte antigen class I and normally is excreted by the kidneys. It reflects tumor load and renal function; however, it predicts survival irrespective of renal function and Durie-Salmon stage.[246] The exact underlying biologic significance of β_2M is unknown; possible interactions with drug resistance pathways may exist. The best cutoff level at diagnosis is 6 mg/L.[246,247] Levels of β_2M may increase during treatment with interferon-α. The significance of β_2M as prognostic factor has been confirmed in HDT trials; the best cutoff level before autologous stem cell transplant is 2.5 mg/L.[248]

Serum concentrations of CRP, as a surrogate marker of IL-6 activity, is a prognostic factor independent of β_2M. Combining the two parameters stratifies patients into three groups with distinct prognoses when treated with standard therapy: a low-risk group with CRP and β_2M less than 6 mg/L, an intermediate-risk group with either CRP or β_2M of 6 mg/L or more, and a high-risk group with CRP and β_2M of 6 mg/L or more. The median survival duration in the three groups was 54, 27, and 6 months, respectively.[249] Given that any inflammation or infection can cause significant elevations of CRP, its prognostic value is relevant only in the absence of other possible causes for elevated CRP.

The *Durie-Salmon staging* system is based on a combination of factors that correlate with myeloma burden and renal function.[250] Patients with low tumor mass and a serum creatinine concentration less than 2 mg/dL have a median survival of approximately 5 years, whereas patients with high tumor burdens and renal insufficiencies have a median survival of 15 months. This staging system has allowed more uniform subgrouping of myeloma patients and, therefore, probably a more accurate interpretation of clinical trials. However, it has significant shortcomings in categorizing lytic bone lesions and does not take into consideration important characteristics such as the proliferative rate of the disease and the patient's response to treatment.

The *International Staging System*, which was introduced in 2005, is based on clinical and laboratory data gathered on 10,750 myeloma patients.[251] Serum β_2M, albumin, platelet count, creatinine level, and age were powerful predictors of survival. A combination of β_2M and albumin provides a simple and powerful staging system. Stage 1 is defined as β_2M less than 3.5 mg/L and albumin at least 3.5 g/dL. Median survival of stage 1 patients is 62 months. Stage 3 is defined as β_2M of 5.5 mg/L or higher. Median survival of stage 3 patients is 29 months. Stage 2 is defined as neither stage 1 or 3. Median survival of stage 2 patients is 44 months. It now is widely used as a prognostic parameter. However, it does not include genetic information gained from FISH analysis, metaphase cytogenetics, or gene expression profiling.

The *PCLI* reflects the proliferative capacity of malignant cells. In the presence of PCLI, CRP level does not provide additional prognostic information.[252,253] The combination of β_2M and PCLI allows identification of distinct subgroups regarding the prognosis. Median survival time is 17 months when both markers are elevated compared with 71 months when both markers are low.[254] Although clinical and biologic parameters such as β_2M and PCLI are quantitative and reproducible and are very useful indicators of outcome in patients receiving standard treatment, they do not address the fundamental genetic abnormalities involved in myeloma.

Angiogenesis (new blood vessel formation driven by increasing growth of malignant cells) appears to be important not only in solid tumors but also in hematologic malignancies. Both angiogenesis and expression by plasma cells of various adhesion molecules such as LFA-1, VLA-4, leukocyte adhesion molecule 1, and CD44 are markedly increased in patients with active MM (vs patients with nonactive MM and MGUS).[255] A positive correlation was found between bone marrow angiogenesis (evaluated as microvessel density) and tumor proliferation (evaluated by PCLI) in patients with MGUS, and active and nonactive MM. The combination of vessel density (high, if >2% of bone marrow microvessel area) and PCLI (high, if >1%) appropriately grouped more than 85% of MM patients between rapidly and slowly progressive disease.[256] Significantly increased microvessel densities in biopsy samples from patients with deletion of chromosome 13 have been reported.[257] Myeloma patients with low microvessel densities as assessed by immunostaining of bone marrow biopsies with anti-CD34 monoclonal antibodies survived longer than did patients with higher densities (independent prognostic factor).[258]

Plasmablastic myeloma occurs in approximately 8% of newly diagnosed patients and is considered to be present when at least 2% of the bone marrow plasma cell population consists of plasmablasts.[259] A *plasma cell* is defined as a plasmablast when it has a large nuclear size (>10 μm) or large nucleolus (>2 μm), fine reticular nuclear chromatin pattern with minimal or no clumping, and cytoplasm composing less than half the nuclear area.[260] Using these morphologic criteria, plasmablastic morphology was identified as an independent adverse prognostic factor in a large study of 453 newly diagnosed patients.[259] Median OS time was 1.9 years in patients with plasmablastic morphology versus 3.7 years in patients with nonplasmablastic morphol-

ogy. The significance of plasmablastic morphology was confirmed in the posttransplant setting in patients treated for relapsed or refractory myeloma.[261]

The detection of *circulating plasma cells* is associated with a poor prognosis. In a study from the Mayo Clinic, the median number of circulating monoclonal plasma cells (quantified by the presence of cytoplasmic Ig staining) was 6% of mononuclear cells.[262] Fifty-seven percent of patients had a high count (>4%). OS times were poorer among patients with high than in those with low counts (2.4 vs 4.4 years, respectively; $P < 0.001$). The presence of circulating plasma cells also predicts shorter time to progression from smoldering to active myeloma.[263]

Syndecan-1 (CD138) is a transmembrane heparan sulfate-bearing proteoglycan expressed on the surface of and actively shed by myeloma cells. Through its ability to bind to various growth factors and to mediate cell attachment to extracellular matrix, it may promote myeloma growth in vivo. It appears that the molecule in its soluble form may stimulate tumor growth and survival more effectively than in its membrane-bound form.[264] In an analysis of 138 myeloma patients, serum syndecan-1 levels emerged as an independent prognostic parameter. Patients with high soluble syndecan-1 levels had a median survival period of 20 months versus 44 months in patients with low levels.[265] Confirmatory clinical studies and further elucidation of the biologic activities of the molecule are needed.

The significance of high *serum LDH* levels (in the absence of any other cause, such as liver disease or hemolytic anemia) in predicting poor prognosis in MM has long been recognized.[266] Although rarely observed in the early phase of disease, marked elevations of LDH were detected in up to 20% of patients with disease progressing after vincristine, Adriamycin (doxorubicin), and dexamethasone (VAD) chemotherapy. High LDH levels were associated with hypercalcemia, elevated serum β_2M levels, extramedullary manifestations, plasmablastic morphology, and short OS duration, despite marked (usually very transient) antitumor responses to HDT. The same poor prognosis was noted in patients with initially normal LDH levels in whom marked LDH increments were induced by HDT, presumably resulting from tumor lysis syndrome as an indicator of rapidly proliferative myeloma.[266] This observation was confirmed in a small study of MM patients who developed tumor lysis syndrome after effective chemotherapy (usually HDT). Despite significant cytoreduction achieved immediately after treatment, the survival of this group of patients was extremely short. Close correlations with PCLI and plasmablastic morphology were confirmed in this study.[267] Elevated serum LDH levels at diagnosis also emerged as a significant prognostic factor in an analysis of 155 newly diagnosed patients who received at least one course of HDT with autologous stem cell transplantation (ASCT), irrespective of deletion of chromosome 13. The combined use of Δ13/LDH levels identified subgroups with distinct prognosis (Fig. 87–11). The median OS for patients with no Δ13/normal (<190 μ/L) LDH was 9.5 years (vs 4.7 and 4.1 years for the groups with no Δ13/high LDH and with Δ13/normal LDH, respectively).

Involvement of the central nervous system by MM, as defined by detection of malignant plasma cells in the cerebrospinal fluid in the presence of suggestive symptoms (elevated intracranial pressure, motor or sensory impairment, cranial nerve pulses), is considered extremely rare; the overall incidence is approximately 1.5% to 2%.[268] Almost all patients have cerebrospinal fluid pleocytosis and elevated protein levels. Brain MRI scans are invariably abnormal, with frequent observation of leptomeningeal enhancement. Central nervous system involvement is strongly associated with unfavorable cytogenetic abnormalities (especially translocations and deletion of the chromosome 13), high tumor mass, plasmablastic morphology, additional extramedullary myeloma manifestations, and circulating plasma cells. Despite intensive local (intrathecal chemotherapy and craniospinal irradiation) and systemic treatment, the prognosis of central nervous system myeloma is extremely poor, probably reflecting the aggressive features of the underlying systemic disease.

The role of *cytogenetics* and *gene expression profiling* as a prognostic marker has been outlined above.

THERAPY

Standard-Dose Treatment

Effective treatment of MM became available in the early 1960s when melphalan was introduced. The most commonly used standard treatment is the combination of melphalan and prednisone (MP).[269] A reasonable schedule is concomitant administration of oral melphalan 8 to 10 mg/day and prednisone 60 to 100 mg/day for 7 days, with courses repeated every 4 to 6 weeks. Unless rapid disease progression is documented, treatment should continue for at least 1 year, because responses may be delayed. Due to the erratic absorption of oral melphalan, leukocyte and platelet counts must be checked frequently after initiation of treatment, and the dose of melphalan (in the subsequent courses) should be modified, targeting nadir (days 14–21 of the cycle) absolute neutrophil count and platelet count of approximately 1 and 100 × 10^9/L, respectively.[270] Because similar hemato-

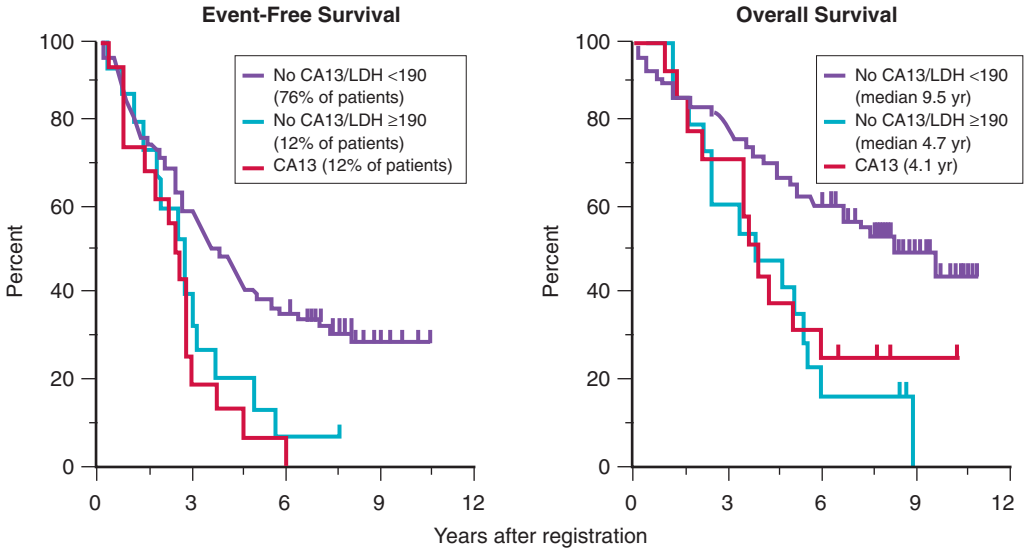

Figure 87–11 Event-free survival and overall survival based on serum lactate dehydrogenase levels at diagnosis and Δ13 in a group of 155 newly diagnosed myeloma patients treated with high-dose treatment. CA, cytogenetic abnormalities. *(From Fassas A, van Rhee F, Tricot G: Predicting long-term survival in multiple myeloma patients following autotransplants. Leuk Lymphoma 44:749, 2003.)*

logic toxicities are observed in responders and nonresponders, resistance is more likely due to inherent disease features, regardless of absorption.[271] This is further supported by the fact that response is not affected by the route of administration, that is, intravenous low-dose versus oral melphalan.[272]

The overall objective response rate (>50% reduction in paraprotein levels) to MP is approximately 50% to 60%, with a median survival of 24 to 30 months.[273] Responding patients enjoy longer survival than do nonresponders (43 vs 19 months); no survival advantage exists for complete versus partial responders.[274,275] Most responders attain a plateau phase during which the malignant clone appears to be dormant. The duration of the plateau phase is variable; the longer the plateau, the longer the median OS period.[276]

Observations that human and mouse plasmacytomata that are resistant to melphalan retained chemosensitivity to cyclophosphamide[276,277] prompted the design of various combination regimens. Vincristine, bis-chloroethyl-nitrosourea (BCNU), cyclophosphamide, and doxorubicin were used in different combinations along with melphalan and steroids. In a large meta-analysis of more than 6500 patients treated with either MP or combination regimens,[278] no survival advantage was detected for the combination chemotherapy, despite the statistically significant superior response rate (60% for the combination vs 53% for MP; $P < 0.00001$), suggesting that minor increases in dose intensity do not affect disease outcome.

In an effort to overcome the problems with the low proliferative rate of myeloma, the combination of vincristine and doxorubicin given as 96-hour continuous intravenous infusion along with three 4-day pulses of oral dexamethasone at 40 mg/day (VAD regimen) was introduced and was found to produce rapid and marked cytoreduction (>50% decrease in paraprotein levels) in at least 50% of patients who relapsed after treatment with MP.[279] Furthermore, near-maximum response occurs after two to three cycles of treatment.[279] When used up front (in previously untreated patients), it produces a response rate of approximately 50% to 60%; however, survival durations achieved with VAD last no longer when compared with MP.[280] VAD can be used safely in patients with renal insufficiency, and, in contrast to melphalan and BCNU, it is not stem cell toxic. However, it requires the insertion of a central venous catheter, potentially leading to a higher incidence of infection or thrombosis, and in rare cases leads to extravasation of the chemotherapeutic agents. Concomitant administration of prophylaxis against *Pneumocystis carinii* pneumonia as well as against viral and fungal infections is strongly recommended. Because the activity of the VAD regimen is almost entirely due to high-dose dexamethasone,[281] its failure to significantly affect survival is not surprising. Probably only mature plasma cells are killed by dexamethasone, whereas the immature, clonogenic myeloma compartment can be rescued from dexamethasone-induced apoptosis by IL-6. Actually, an increase in clonogenic myeloma cells has been observed after treatment with VAD.[282]

Newer Agents

Thalidomide

The observation that increased neovascularization occurs in bone marrow biopsies from myeloma patients and is prognostically relevant prompted the evaluation of thalidomide (at the time, the only drug available with major antiangiogenic activity) in patients with relapsed and refractory disease by the Arkansas group. In a landmark study, 90% of the 84 study patients had relapsing disease after at least one course of HDT. Thalidomide dose was escalated (from a starting dose of 200 mg/day) to a maximum of 800 mg/day. The overall response rate (>50% reduction in monoclonal component) was 32%, with a median time to response of 1 month. The median duration of response was approximately 15 months. No correlation was seen between response rate and microvessel density in the bone marrow biopsies.[283] An update of 169 myeloma patients demonstrated 2-year EFS of 20% and OS rate of 48%. Absence of cytogenetic abnormalities, low β_2M levels, and low PCLI, the same factors that predict outcome with cytotoxic therapy, were associated with superior survival as well as higher cumulative thalidomide dose.[284] Similar response rates, response durations, and survival times were reported by the Mayo Clinic group.[285] Thalidomide has also been used for treatment of indolent/smoldering myeloma.[286] Thalidomide with pulse dexamethasone yielded a 70% response rate in the remission induction phase of patients with newly diagnosed active disease.[287,288]

In a retrospective matched case-control analysis of 200 patients treated with either thalidomide/dexamethasone or VAD in preparation for autologous transplantation, thalidomide/dexamethasone resulted in a significantly higher response rate of 76% versus 52% ($P < 0.001$), with comparable numbers of patients in both groups proceeding to transplantation and no significant differences in quantity of stem cell collection.[289] Deep vein thrombosis was more frequent in the thalidomide/dexamethasone arm, whereas neutropenia was more often observed in the VAD arm. In a randomized phase III clinical trial of thalidomide plus dexamethasone compared with dexamethasone alone in newly diagnosed patients, entire study group included 207 newly diagnosed patients, the response rate to thalidomide and dexamethasone was significantly higher (63% vs 41%), but grade 3 or greater deep vein thrombosis, rash, bradycardia, neuropathy, and any grade 4 and 5 toxicity in the first 4 months were significantly higher in the thalidomide/dexamethasone arm.[290] The authors concluded that the higher response rate with this regimen must be balanced against its greater toxicity. The combination of thalidomide with dexamethasone normalizes abnormal bone remodeling through a reduction in the soluble RANKL (sRANKL)/OPG ratio.[291] Thalidomide markedly downregulates angiogenic genes in endothelial cells of active, but not of nonactive, myeloma.[292] The appropriate dose of thalidomide in myeloma is unknown. Most of its side effects (somnolence, constipation, fatigue, tremor, bradycardia, edema, neuropathy, rash) can be managed by reducing the dose. Hypothyroidism frequently complicates its use and requires thyroid hormone replacement.[293] An increased incidence of deep vein thrombosis from 5% when used as a single agent up to 25% to 30% when thalidomide is given concurrently with cytotoxic chemotherapy (especially doxorubicin-containing regimens) is observed.[294] Use of low-molecular-weight heparin can mostly prevent this risk.[295] Arterial thromboses are seen with thalidomide.[296] In one study focused on neuropathy in myeloma patients treated with thalidomide who had undergone serial nerve electrophysiologic studies, 39% already had some abnormalities at baseline on electrophysiologic studies. The study showed that the majority of patients will develop neuropathy given sufficient length of treatment with thalidomide. The actuarial incidence of neuropathy increased from 38% at 6 months to 73% at 12 months. Serial electrophysiologic studies did not reliably predict the imminent development of clinical neuropathy. To minimize the risk of neuropathy, thalidomide therapy should be limited to less than 6 months.[297] The mechanism of action of thalidomide is unclear. In addition to its antiangiogenic properties, thalidomide has potent immunomodulatory effects (induction of secretion of interferon-γ and IL-2 by cytotoxic T cells,[298] inhibition of TNF-α,[299] IL-6, and VEGF production in the bone marrow milieu, modulation of expression of several cell surface adhesion molecules,[300] inhibition of the transcription factor NF-κB[301]) and targets the cross-talk between malignant cells and stromal cells in the bone marrow microenvironment, thereby overcoming drug resistance.

Thalidomide has been combined with noncytotoxic and cytotoxic therapy. In a multicenter phase II trial, thalidomide up to 800 mg was combined with celecoxib 400 mg bid. Cyclooxygenase 2 inhibitors suppress angiogenesis and induce apoptosis and hematogenic metastases. Cyclooxygenase 2 is overexpressed in myeloma cell lines and primary myeloma cells.[302,303] Among 66 previously treated patients enrolled in the phase II study, the overall response rate was 42% and the median time to progression was 6.8 months. Because of fluid retention and decreased renal function, celecoxib was discontinued in 57% of patients.[304] More than 250 elderly patients (age 60–85 years) with newly diagnosed myeloma were randomly assigned to MP with or without thalidomide for six 4-week cycles.[305] In this

study, patients in the thalidomide arm had a higher response rate than did those in the nonthalidomide arm (76% vs 48%), with complete remission (CR) and near-CR rates of 28% and 7%. The 2-year EFS was 54% vs 27% (thalidomide vs nonthalidomide; $P = 0.0006$). Grade 3 or 4 adverse events were 48% in the thalidomide arm versus 25% in the nonthalidomide arm ($P = 0.0002$). Low-dose molecular heparin reduced the risk of thromboembolic complications from 20% to 3%. In another phase II trial, thalidomide and dexamethasone were combined with pegylated liposomal doxorubicin (ThaDD) for treatment of 50 newly diagnosed patients older than 65 years.[306] CR was achieved in 34%, near-CR in 7%, and very good partial response in another 10%; 30% attained a partial remission (PR). Time to progression, EFS, and OS at 3 years were 60%, 57%, and 74%, respectively. Grade 3 to 4 infections and thromboembolic events were 22% and 14%, respectively. Thalidomide/dexamethasone has been combined with 4 days of continuous infusions of cisplatin, doxorubicin, cyclophosphamide, and etoposide in the DT-PACE regimen. Response to two cycles of this regimen was evaluated in 236 patients, of whom 63% had progressive myeloma on standard chemotherapy and 23% had chromosome 13 abnormalities by metaphase cytogenetics. Thirty-two percent achieved PR and 16% CR or near-CR. Excellent responses were also seen in patients with high LDH and chromosome 13 abnormalities. Patients who received two cycles of this regimen at 100% dose had a 49% partial response rate and a 27% CR and near-CR rate.[307]

Thalidomide has been given posttransplantation. Two months after transplantation, 597 patients younger than 65 years were randomly assigned to receive no maintenance (arm A), pamidronate (arm B), or pamidronate plus thalidomide (arm C).[308] A complete or very good partial response was achieved in 55% of patients in arm A, 57% in arm B, and 67% in arm C ($P = 0.03$). The 3-year postrandomization EFS was 36% in arm A, 37% in arm B, and 52% in arm C ($P = 0.009$). The 4-year postdiagnosis survival was 77% in arm A, 74% in arm B, and 87% in arm C ($P < 0.04$).

Lenalidomide

Lenalidomide is a thalidomide derivative. Its immunomodulatory effects include growth arrest or apoptosis of drug-resistant myeloma cell lines, abrogation of adhesion of myeloma cells to bone marrow stromal cells, and modulation of cytokines that promote growth, survival, and drug resistance of myeloma cells. It is nonteratogenic in rabbits and has a toxicity profile different from thalidomide.[309] Lenalidomide activates natural killer and natural T cells.[310,311] In a phase I dose escalation study of 27 patients, the majority of whom had received a prior transplant and thalidomide, grade 3 myelosuppression developed in all patients treated with lenalidomide 50 mg/day. Therefore, 25 mg/day was considered the maximum tolerated dose. Importantly, no significant somnolence, constipation, or neuropathy was observed.[312] In a multicenter double-blind phase III trial, 354 patients with relapsed or refractory myeloma were randomized to dexamethasone pulsing every 4 weeks with or without lenalidomide 25 mg/day on days 1 to 21. The overall response rate was greater in the lenalidomide/dexamethasone arm (59% vs 21%; $P < 0.001$). Complete responses were observe in 13% of patients in the lenalidomide/dexamethasone group versus < 1% in the dexamethasone arm. Median time to progression was 11 months in the study group versus 4.7 months in the control group. Grade 3 to 4 neutropenia (24% vs 3.5%) and thromboembolic events (15% vs 3.5%) were more frequent in the study group.[313] In a multicenter randomized phase II study of relapsed refractory myeloma, two different dose regimens of lenalidomide were evaluated. Seventy patients received either lenalidomide 30 mg once per day or lenalidomide 15 mg twice per day for 21 days of every 28-day cycle. After two cycles, dexamethasone was added for patients with progressive or stable disease. Myelosuppression was more common in the group that received 15 mg twice per day (41% vs 13%; $P = 0.03$). An additional 32 patients received 30 mg once per day. Median progression-free survival was 7.7 months in the once per day group versus 3.9 months in the twice per day group. Significant neuropathy and deep vein thrombosis each occurred in 3% of patients.[314] In 34 newly diagnosed myeloma patients, lenalidomide and dexamethasone was given as initial treatment. Lenalidomide dose was 25 mg/day on days 1 to 21 of a 28-day cycle. Thirty-one patients showed an objective response, including two who achieved CR. Another 11 patients achieved a near-CR or a very good partial response. The most common grade 3 or higher nonhematologic toxicities were fatigue (15%), muscle weakness (6%), pneumonia (6%), and rash (6%).[315] In relapsed and refractory myeloma, lenalidomide/dexamethasone is associated with an increased risk of venous thrombosis. This risk may be further increased with concomitant administration of erythropoietin.[316] The risk of thrombosis also is higher if lenalidomide is given as initial therapy, and thrombosis prophylaxis is indicated.[317]

Another thalidomide derivative CC-4047 (Actimid) has been tested in a phase I study of 24 relapsed or refractory myeloma patients. One patient developed deep vein thrombosis but was found to have a malignant melanoma; he died while the myeloma was stable. Three other patients developed thromboembolic complications after day 28. No other grade 3 or higher nonhematologic toxicities were seen. Dose-limiting neutropenia occurred in six patients a median of 3 weeks after the start of treatment. The maximum tolerated dose was considered 2 mg/day. Thirteen patients had a greater than 50% reduction in M protein, and four entered CR. All patients showed an increase in CD45RO on CD4 and CD8 cells, with a concomitant decrease in CD45RA.[318] This drug also potently blocks osteoclasts differentiation.[319] There is little doubt that lenalidomide, just like thalidomide, will be combined with conventional chemotherapy.

Bortezomib

Bortezomib is the first in a new class of pharmacologic agents that inhibit the proteasome. The proteasome is a multienzyme complex found in all eukaryotic cells that orderly degrades more than 80% of ubiquitin-tagged cellular proteins, which control cell division, survival, growth, and apoptosis. These proteins include cyclins, cyclin-dependent kinases, cyclin-dependent cyclin kinase inhibitors, oncogenes, tumor suppressor genes, and transcriptional activators or inhibitors. Bortezomib selectively and reversibly inhibits the chymotryptic but not the tryptic and post–glutamyl peptide hydrolyticlike activity of the proteasome. The major mechanism of action of bortezomib initially was thought to be related to inhibition of degradation of IκB. Its lack of degradation prevents activation and translocation of NF-κ B to the nucleus. Bortezomib was identified as an active drug in the NCI screening program. Its growth inhibitory effects correlated strongly with proteasome inhibition. Bortezomib has other activities in myeloma, such as prevention of adhesion of myeloma cells to stromal cells, induction of cytokines by the microenvironment, decrease in angiogenic activity, and direct apoptotic effect on myeloma cells.[320] In a phase II trial, 202 patients with relapsed myeloma were enrolled. As a requirement, the patients had to be refractory to their most recent chemotherapy. Patients were given bortezomib 1.3 mg/m^2 on days 1, 4, 8, and 11 every 3 weeks. In patients with suboptimal response, oral dexamethasone 20 mg was added the day of and the day after bortezomib administration. Of the evaluable patients, responses were seen in 35%, with 10% CR and near-CR. Median duration of response was 12 months. Grade 3 and 4 toxicities were thrombocytopenia (31%), neutropenia (14%), fatigue (12%), peripheral neuropathy (12%), and vomiting (8%).[321] Clinical factors predicting poor outcome with bortezomib were age 65 years and older and more than 50% plasma cell infiltration in the bone marrow for response, and thrombocytopenia, hypoalbuminemia, and more than 50% bone marrow plasma cell infiltration for time to progression. Chromosome 13 deletion and elevated β_2M levels were not predictive of poor outcome.[322] In a multicenter randomized study that included 669 relapsed myeloma patients, the efficacy of single-agent bortezomib was compared to that of dexamethasone. The response rate, including complete and partial responders, was higher in the bortezomib group (38% vs 18%;

$P < 0.001$). Complete responses were seen in 6% of the bortezomib patients versus less than 1% in the dexamethasone arm ($P < 0.001$). Median duration of response was 8 months in the bortezomib group versus 5.6 months in the dexamethasone group ($P < 0.001$).[323] Bortezomib therapy appears to be safe in patients with renal failure, although the numbers of patients studied was small.[324] Mean platelet count decreased by 60% during bortezomib treatment but recovered rapidly between treatments in a cyclical fashion. Mean percent reduction in platelets was independent of baseline platelet count. Bortezomib-induced thrombocytopenia appears to be due to a reversible effect on megakaryocytic function rather than a direct cytotoxic effect on megakaryocytes and their precursors.[325] Bortezomib was given alone or in combination with dexamethasone to 32 previously untreated myeloma patients. The response rate (CR + PR) was 88%, with CR and near-CR rate of 25%. Median time to response was 2 months. Bortezomib therapy did not influence stem cell collection. Grade 3 and 4 toxicities were sensory neuropathy in 16%, myalgia in 13%, and neutropenia in 16%.[326] In a phase I trial, bortezomib combined with pegylated liposomal doxorubicin was given to 42 patients with advanced hematologic malignancies, including 22 patients with myeloma. Eight myeloma patients achieved CR or near-CR, and another eight patients had partial responses. Maximal tolerated dose was bortezomib 1.5 mg/m^2 and pegylated doxorubicin 30 mg/m^2. Adverse events were fatigue in 88%, thrombocytopenia in 69%, peripheral neuropathy in 55%, and neutropenia in 45%.[327] Twenty-one untreated myeloma patients received a combination of bortezomib, doxorubicin, and dexamethasone (PAD) for four 21-day cycles. Patients then proceeded to autologous transplantation. The partial response rate was 95%, and the CR rate was 24%. This regimen allowed stem cell collection in 95% of patients; median number of CD34 cells per kilogram collected was 3.75 million. One patient developed grade 3 peripheral neuropathy; three patients experienced a varicella zoster infection.[328] Sixty newly diagnosed myeloma patients 65 years or older (50% older than 75 years) were treated with bortezomib plus MP. PR or better was observed in 89% of patients, and an IFE-negative complete response was seen in 32%. Results were superior to those obtained in historical controls receiving MP. Major toxicities (grade 3 and 4) were thrombocytopenia (51%), neutropenia (43%), and peripheral neuropathy (17%).[329] Response to bortezomib is associated with osteoblastic activation.[330] Bortezomib-associated neuropathy appears reversible in the large majority of patients after dose reduction or discontinuation.[331] Severe pulmonary complications after treatment with bortezomib have been reported by Japanese investigators.[332]

High-Dose Treatment and Autologous Transplantation

Application of HDT has been challenging in MM. Median patient age at diagnosis is 69 years, and almost half of patients experience some degree of renal insufficiency during their disease course. Many have inadequate hematopoietic stem cell reserve due to prolonged previous exposure to alkylating agents or radiation treatment to the spine and pelvis. Functional limitations due to skeletal pain or fractures and treatment-related immunosuppression further complicate the ability to deliver HDT to MM patients.

It has been more than 20 years since the late Tim McElwain and colleagues introduced HDT for MM. Administration of melphalan 100 to 140 mg/m^2, without stem cell support, induced biochemical and bone marrow CR in three (all previously untreated) of nine patients, which is much higher than the 3% to 5% complete response rate seen with conventional treatment.[333] Its efficacy subsequently was confirmed in larger studies.[334] However, high-dose melphalan induced prolonged aplasia and was associated with high morbidity and mortality rates.[333,335] This finding led other investigators to the concept of stem cell support and further escalation of the dose of melphalan, initially with autologous bone marrow,[336] and subsequently peripheral blood stem cells to reduce the duration of cytopenias and thereby the toxicity of the procedure. With the current use of peripheral blood stem cells, median duration of granulocytes less than 0.5×10^9/L and platelets less than 50×10^9/L is approximately 1 week (Fig. 87–12), reducing the transplant-related mortality (TRM) rate to less than 5%.[337]

In a study from the University of Arkansas group of 1000 consecutive MM patients with various lengths of preceding standard-dose treatment and intended to receive two courses of melphalan-based HDT (76% actually received two transplants), CR (defined as negative serum and urine immunofixation and <5% light chain–restricted plasma cells in the bone marrow aspirate and biopsy) rate achieved was 44%. Median duration of CR was 2.4 years. TRM was 2.7% with the first transplant and 4.8% with the second transplant.[166] Projected EFS and OS at 5 years were 25% and 40%, respectively. On multivariate analysis, CR rates were higher when standard treatment did not exceed 12 months and still was effective (chemosensitive disease), and in the absence of Δ13 abnormalities. Both EFS and OS were significantly longer in the absence of Δ13 abnormalities and with fewer than 12 months of prior standard treatment, low β_2M levels, and chemosensitive disease. Of 390 CR patients without Δ13, 35% enjoyed 5-year continuous CR compared with none of 54 patients with Δ13. The presence of Δ13 reduced the 5-year EFS from 20% to 0% and the OS from 44% to 16%. Total Therapy I was the first tandem autotransplant trial for 231 patients with newly diagnosed myeloma. With a minimum followup of 12 years, 27% of patients are still alive, and 10-year EFS and OS are 15% and 33%, respectively. OS was superior in the absence of a hypodiploid karyotype or deletion of chromosome 13, and in the presence of a low baseline CRP.[338]

The superiority of HDT over conventional treatment in terms of CR, CR duration, EFS, and OS has been shown convincingly in randomized,[339] case-control,[340] and population-based [341] studies. Attal et al.[339] compared in randomized fashion HDT followed by autologous bone marrow transplantation with standard treatment in 200 previously untreated patients younger than 65 years (IFM 90). Data were analyzed on an intention-to-treat basis. However, more than one fourth of patients randomized to HDT did not receive a transplant. Response rates (81% vs 57%), CR rates (22% vs 5%), and 5-year EFS (28% vs 10%) and OS (52% vs 12%) rates were significantly better in the transplant group. The study was criticized because of the relatively small number of patients and the poor response rate of the standard treatment arm, which compared unfavorably with other trials of standard treatment. In a multicenter UK study of 407 patients, higher CR rate (44% vs 8%), longer median progression-free survival (32 vs 20 months), and greater OS (54 vs 42 months) were found in the transplant arm compared to the standard chemotherapy arm.[342] In a nonrandomized elective single autograft study of high-dose melphalan use in 451 patients, CR and near-CR was observed in 59%. The 10-year probability of EFS and OS were 17% and 31%, respectively.[343] In a case-control study, the results of Total Therapy I were compared with the outcomes of untreated patients (matched for the major prognostic factors available) receiving standard treatment according to Southwest Oncology Group (SWOG) trials.[339] HDT induced higher response rates (85% vs 52%; $P < 0.001$) and extended EFS (49 vs 22 months; $P = 0.001$) and OS (62+ vs 48 months; $P = 0.01$). In a population-based study, the results of HDT in newly diagnosed, symptomatic patients younger than 60 years were compared with those of conventionally treated historic controls, most of whom fulfilled the criteria for HDT. Survival was prolonged in the HDT group compared with the control group (risk ratio for control group 1.62; $P = 0.001$).[341] Other studies have not confirmed the superiority of transplantation over conventional chemotherapy.[344–347] In Total Therapy II, including 668 newly diagnosed myeloma, all patients received identical intensive induction, transplantation, consolidation, and maintenance therapy but were randomized up front to either thalidomide or no thalidomide during treatment. With median followup of 42 months, the CR rate (62% vs 43%; $P < 0.001$) and 5-year EFS (56% vs 44%; $P = 0.01$) were superior in the thalidomide arm, whereas OS at 5 years was similar at approximately 65% in both arms. The shorter survival after relapse in the thalidomide arm (1.1 vs 2.7 years; $P = 0.001$) probably explains the lack of survival benefit in the thalidomide arm.[348]

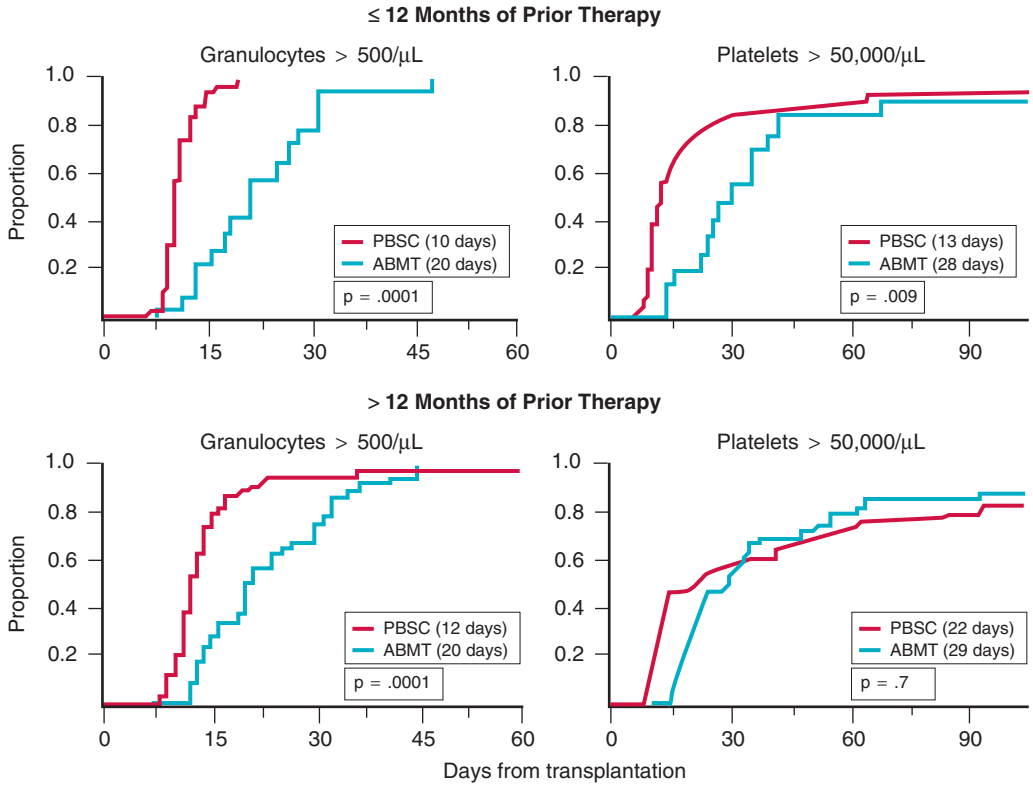

Figure 87–12 Hematologic recovery posttransplantation. ABMT, autologous bone marrow transplantation; PBSC, peripheral blood stem cell. *(From Barlogie B, Jagannath S, Tricot G, et al: Advances in the treatment of multiple myeloma. Adv Intern Med 43:279, 1998.)*

"Upfront" application of HDT has clinical benefits. More profound cytoreduction is associated with better quality of life, whereas development of drug resistance of the malignant clone is minimized. If the choice is made not to proceed with upfront standard treatment but to retain the option of HDT at relapse, hematopoietic progenitors should be collected and stored at the initiation of standard treatment, thus enabling adequate collections of stem cells and reducing damage to stem cells by long exposure to alkylating agents, thereby minimizing the risk of treatment-related MDS. The risk for treatment-related MDS is much higher when patients have received prolonged standard treatment before HDT. All seven patients with treatment-related MDS were identified from among a group of 117 transplanted patients who had received more than one cycle of conventional chemotherapy before enrollment in our transplant study. No treatment-related MDS was seen in a group of 71 patients who were transplanted after no or only one cycle of conventional chemotherapy.[349] However, since this report, some patients with minimal treatment before the first transplant subsequently developed treatment-related MDS. In the majority of cases of treatment-related MDS analyzed, the signature chromosome abnormalities of treatment-related MDS were retrospectively identified by FISH in the collected stem cell grafts, lending further support to the notion that the stem cells were already abnormal before transplantation.[350,351] A population-based survey covering two geographically distinct UK regions revealed that 57% of myeloma patients 65 years and younger do not receive transplantation for their disease.[352]

One Versus Two Courses of High-Dose Treatment

Despite the improvements achieved with application of HDT, the 7-year EFS in the IFM 90 trial was only 16% in the HDT arm, with no plateau in the survival curve.[353] Because achievement of CR or very good PR in this trial was believed to be a sine qua non for meaningful survival benefit, dose escalation subsequently was tested in a randomized fashion by the same group (IFM 94). A total of 399 untreated MM patients younger than 60 years were enrolled by 45 centers and randomized to either a single ASCT with melphalan 140 mg/m^2 and total body irradiation (TBI) or a double ASCT. The preparative regimen for the first transplant was melphalan 140 mg/m^2 and for the second was melphalan 140 mg/m^2 and TBI. A second randomization between bone marrow or peripheral blood stem cell support was performed after initial cytoreduction with VAD. Transplant-related deaths were 4% in the single ASCT arm versus 6% in the double ASCT arm; 85% of patients assigned to the single ASCT received the planned treatment versus 78% assigned to the double ASCT arm. By pooling the bone marrow and peripheral blood stem cell support data with a median followup of more than 75 months, the 7-year probabilities of EFS and OS are superior in the double transplant arm (20% and 42% vs 10% and 21%, respectively; $P < 0.03$ and $P < 0.01$, respectively). Surprisingly, no significant difference in the CR rate between the two arms was seen. Patients who had achieved at least very good PR did not benefit from a second transplant. Important prognostic factors for survival were baseline β_2M level, age, LDH, and treatment arm.[354] In the Bologna 96 trial of double versus single ASCT in previously untreated MM patients, significant prolongation of EFS was seen in the double ASCT arm (median 34 vs 25 months; $P = 0.05$). Again, no difference in the CR rate between the arms was detected. With median followup of only 3 years, no significant OS advantage has emerged yet, in keeping with the IFM 94 experience in which separation of the EFS and OS curves occurred only after 3 years.[355] In the European Group for Blood and Marrow Transplantation (EBMT) registry experience, 441 newly diagnosed, chemosensitive MM patients who received tandem autotransplants were compared with a matched group of 1380 patients who received only a single transplant. Median posttransplantation survival was 7.1 years for the tandem group and 5.6 years for the single transplant time group. Actuarial posttransplant survival rates at 7 years were 57% and 39%, respectively. Although the difference reached borderline statistical significance ($P = 0.1$) in this trial, the data taken together support the superiority of the tandem (versus single) autologous transplantation approach.[356] The optimal time to

perform a second transplant is before relapse and within 6 to 12 months after the first transplant.[357] In a trial of high-risk myeloma, defined as β_2M level and FISH deletion 13, 219 patients received a first transplant with melphalan 200 mg/m^2 and a second transplant with melphalan 220 mg/m^2. Patients were randomized to either receive or not receive an anti–IL-6 monoclonal antibody (IFM 99-04). No benefit of the monoclonal antibody was seen. However, 2-year survival was superior to that in previously studied patients receiving tandem transplants but with a lower dose of melphalan. Median EFS and OS were 30 and 41 months, compared to 15 and 25 months, respectively, in a similar group of patients treated previously. The survival in this high-risk group of patients was similar to that of all patients (good and bad prognosis combined) who received tandem transplants in the IFM 94 study.[358] The same IFM group compared tandem autologous transplants (IFM 99-04) to one autologous transplant followed by a dose-reduced allotransplant in 65 high-risk patients with a human leukocyte antigen (HLA)-identical sibling donor (IFM 99-03). With a median followup of 24 months, EFS of the 166 patients receiving tandem autologous transplants was similar to that of the 46 patients who completed the entire IFM 99-03 program. with a trend for a better OS in patients receiving tandem autotransplants. No benefit from the combination of autologous transplantation followed by reduced-intensity allotransplantation in high-risk patients was seen.[359]

Primary Refractory Disease

Dose escalation has consistently increased tumor cytoreduction and extended EFS and OS even in the subset of patients with primary refractory myeloma (disease progression or <50% reduction in monoclonal protein levels with initial standard-dose regimen), as shown in single-center and Intergroup trials. In a report from Royal Marsden Hospital of 222 patients, lack of response to induction treatment did not predict poor long-term outcome because a significant proportion of primary refractory patients responded to HDT. More specifically, among 130 patients who either attained or remained in CR after one course of HDT with melphalan 200 mg/m^2, 5-year OS was independent of response to primary treatment.[360] The Mayo Clinic compared the outcome of 50 patients with primary refractory myeloma to that of 101 patients with chemosensitive myeloma. The response rate in the chemorefractory patients was 92% versus 99% in the chemosensitive patients. The CR rate was 20% in chemorefractory patients versus 35% in chemosensitive patients ($P = 0.06$). One-year progression-free survival was 70% in the chemorefractory patients and 83% in the chemosensitive patients ($P = 0.065$).[361] In another study from the MD Anderson Cancer Center, the outcome of 89 consecutive patients refractory to dexamethasone-based chemotherapy was compared to that of 45 patients who refused or were unable to receive an autotransplant for socioeconomic reasons. After autotransplantation, the response rate was 69%, including 16% CR. Survival of the CR patients was significantly better than that of PR patients (>7 years vs 4.5 years). Median survival of transplanted patients was 27 months longer than for the controls ($P < 0.01$), even though the control patients had more favorable features.[362] The feasibility and efficacy of HDT in refractory MM (relapsed and primary refractory) were also shown in an Intergroup trial.[363] In contrast to experiences in other B-cell malignancies, such as relapsed non-Hodgkin lymphoma, primary refractory patients are good candidates for HDT and ASCT.

Graft Contamination by Myeloma

Ample and convincing evidence indicates that not only bone marrow but also peripheral blood stem cell grafts are contaminated with a small amount of myeloma cells.[364,365] Using quantitative polymerase chain reaction amplification assays of patient-specific CDR III DNA sequences from bone marrow and peripheral blood mononuclear cell samples, myeloma cells have been detected in nearly all patients.[366] Reinfusion of these cells may contribute to disease relapse, as shown to be the case in other hematologic malignancies, such as acute myeloid leukemia, neuroblastoma, and chronic myeloid leukemia.[367,368] Additionally, an inverse correlation between plasma cell contamination in the peripheral blood stem cell products and disease-free survival has been demonstrated in a small prospective study of 33 patients; the presence of more than 2×10^5 tumor cells per liter predicted an early relapse[369] but probably was more a reflection of the overall higher tumor burden in these patients. Other investigators have not confirmed this observation.[370,371] Different ex vivo purging techniques, based on chemical or immunologic approaches, have been used in an attempt to obtain tumor-free products. Delayed hematologic recovery and increased infectious complications have compromised the applicability of these strategies, despite their success in substantially reducing the autograft tumor burden.[372–374]

A multicenter phase III, randomized trial compared the hematologic recovery and toxicity after autologous transplantation using either unselected or CD34$^+$-selected peripheral blood stem cells.[375] Median time to neutrophil engraftment was 12 days for patients in both arms of the study, whereas median time to platelet engraftment was slightly prolonged (by 1–2 days) for patients receiving less than 2×10^6 CD34$^+$-selected cells per kilogram. No differences in the incidence or type of infections, EFS, and OS were seen between the two arms. Given the high cost of the procedure and the potential for delayed platelet engraftment and late (>1 year posttransplant) opportunistic infections, positive selection of CD34$^+$ cells should not be routinely performed outside of the context of a clinical trial.

Indirect evidence favoring the significance of reinfusion of "clean" grafts comes from an analysis of EBMT.[376] The outcomes of 25 MM patients who received transplants from twin donors were compared in a case-matched analysis to the outcomes of 125 patients who received ASCT and of 125 patients who received allogeneic transplantation. Although the CR rate was not statistically different among the three groups, median OS tended to be better (73 vs 44 months) and EFS was significantly better (72 vs 25 months) for the twin transplants compared with ASCT, and both (twin and autologous) were significantly better than those with the allogeneic transplants. A graft-versus-myeloma effect cannot be completely excluded, as a graft-versus-hostlike disease has been reported for syngeneic transplants.[377,378]

Conditioning Regimen

Most conditioning regimens are based on melphalan either alone or in combination with TBI. However, other alkylating agents, such as busulfan, carmustine, thiotepa, and cyclophosphamide, have been used. In a report from the Spanish Registry, no statistically significant differences in OS and EFS were seen among four conditioning regimens (melphalan alone vs melphalan/TBI or busulfan vs cyclophosphamide/busulfan alone), despite a trend for better response rates and somewhat improved EFS and OS associated with use of melphalan/busulfan.[379] In a French randomized study comparing the two most commonly used regimens (melphalan 200 mg/m^2 and melphalan 140 mg/m^2 plus TBI 800 cGy), the melphalan-alone arm was shown to be less toxic and probably more effective; the investigators recommended it as the standard of care.[380] Two other nonrandomized studies have shown that use of non-TBI conditioning is associated with better survival. In the University of Arkansas experience, use of TBI combined with melphalan 140 mg/m^2 led to higher TRM and inferior EFS and OS (despite identical CR rates) rates compared to conditioning with melphalan 200 mg/m^2 alone. The investigators hypothesized that more prolonged and severe immunosuppression in the TBI-treated group may be responsible for the adverse outcome.[381] The EBMT registry analysis on prognostic factors also showed that a non-TBI preparative regimen was independently associated with superior outcome.[382] Based on the IFM 99-04 study, higher doses of melphalan result in better outcomes.[358]

High-Dose Treatment in the Elderly and in the Presence of Renal Dysfunction

Most HDT trials have included relatively young patients with normal vital organ function. However, if a major impact on the outcome in myeloma is to be achieved, the fact that more than half of MM patients are older than 65 years at diagnosis cannot be ignored. Several studies have reported contradictory findings on the influence of increasing patient age on the ability to collect adequate numbers of stem cells. In a retrospective analysis of 984 patients (106 older than 70 years), increasing age inversely correlated with $CD34^+$ cell yield. However, the overwhelming majority (85%) of elderly patients still were able to collect at least 4×10^6 $CD34^+$ cells/kg, provided the length of the previously administered standard treatment was 12 months or less and the platelet count prior to mobilization was 200,000/μL or more.[383] Encouraged by the lower toxicity seen in the recent years (due to use of peripheral blood stem cells, hematopoietic growth factors, and improved supportive care), the University of Arkansas group retrospectively examined its experience with 49 newly diagnosed and previously treated patients older than 65 years after HDT and compared their outcomes with 49 younger patients, matched for relevant prognostic features.[384] Seventy-six percent of the younger group and 65% of the older group completed a second ASCT. Hematologic recovery and TRM were comparable among younger and older patients with first and second transplants. Multivariate analysis that included both younger and older patients showed pretransplant cytogenetic abnormalities and β_2M levels as critical prognostic features for EFS and OS, whereas age was insignificant. The outcomes of 71 MM patients (median age 64 years; 53 patients >60 years) who received two or three courses of melphalan 100 mg/m^2 followed by stem cell support were compared with the outcomes of 71 pair mates, matched for age and β_2M levels, who received standard treatment with oral MP.[385] The HDT regimen was well tolerated. Median EFS was 34 months in the HDT group and 17.7 months in the standard treatment group ($P < 0.001$). Median OS was 56+ and 48 months, respectively ($P < 0.01$). Therefore, it appears that myeloma in the elderly is not biologically different from the disease in younger patients and that HDT can be safely and effectively administered to the majority of older patients. However, because of significant toxicity, lower doses of melphalan (100–140 mg/m^2) should be administered to patients older than 70 years.

The same conclusion is applicable to myeloma patients with impaired renal function (including hemodialysis-dependent patients). The pharmacokinetics of intravenous high-dose melphalan are comparable regardless of renal function.[386] The presence of renal insufficiency did not affect the quality of stem cell collections or the engraftment kinetics in a group of 81 patients treated with 140 to 200 mg/m^2 and ASCT at the University of Arkansas.[387] Probabilities of EFS and OS at 3 years were 48% and 55%, respectively. In a study of 59 patients who received autotransplants while on dialysis, 5-year EFS and OS were 24% and 36%, respectively. Dialysis duration less than 6 months prior to transplant and pretransplant creatinine clearance greater than 10 mL/min were significant predictors of renal function recovery; 33% of patients on dialysis for less than 6 months recovered renal function versus 6% of those on dialysis for more than 6 months; 38% with creatinine clearance greater than 10 mL/min recovered renal function versus 11% of the other patients.[388] One fourth of dialysis-dependent myeloma patients became dialysis independent after autotransplantation.[388] The Royal Marsden group also confirmed that the presence of renal dysfunction did not affect EFS and OS in patients treated with HDT.[389] In a Danish study of 78 patients with normal renal function at diagnosis and transplantation, 30 patients with renal failure at diagnosis but normal at transplant, and 29 patients with renal failure at diagnosis and transplant, no differences in numbers of stem cells collected, time to engraftment, or response to transplantation was observed. One third of patients with renal failure at transplantation regained normal kidney function. However, significantly longer hospitalizations, increased use of blood products, and more infections were seen in patients with renal failure at transplantation. TRM was 17% in those patients compared to 0% and 1% in the other groups. Four of the eight patients on dialysis at transplantation died.[390]

Posttransplantation Manipulations

It is appealing to consider some form of posttransplant "consolidation" or "maintenance" treatment in myeloma. The theoretical advantages are eradication of graft-contaminating malignant cells and further cytoreduction of the remaining myeloma cells by killing newly cycling cells. The available data on its efficacy are limited. The role of interferon-α as posttransplant maintenance therapy was examined in a small trial of 85 patients who were randomly assigned to treatment with interferon-α (3×10^6 U/m^2 subcutaneously three times weekly until relapse) or no further treatment.[391] Although initial analysis showed a survival benefit favoring interferon use, the difference disappeared with longer followup. Two other studies, both in abstract form, reported conflicting results. The French registry study showed no significant impact on EFS and OS, whereas the EBMT registry showed that use of interferon-α appeared to improve survival.[382,392] Applying cytotoxic chemotherapy intermittently in the post-ASCT period in myeloma patients with high-risk disease did not show a significant benefit in a pair-matched analysis, but this finding requires study in a randomized fashion.[393] In a retrospective analysis comparing outcome of patients on Total Therapy II on the no-thalidomide arm (consolidation and maintenance) to that of Total Therapy I (no consolidation, only maintenance), CR rates were similar (43% vs 41%). However, 5-year continuous CR (45% vs 32%; $P < 0.001$) and 5-year EFS (43% vs 28%; $P < 0.001$) were superior with Total Therapy II, with a trend for improved OS (62% vs 57%; $P = 0.11$). A superior OS was seen for the two thirds of patients with no cytogenetic abnormalities.[394] Thalidomide maintenance prolonged EFS and OS after transplantation.[308]

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplantation may eradicate disease and restore hematopoiesis through the use of a tumor-free graft. Furthermore, the immunologic effect of the allograft (graft-versus-myeloma effect) has been clearly demonstrated.[252,395] However (and despite the introduction of nonmyeloablative conditioning regimens), the option of allogeneic transplant is limited to a relatively small minority of patients, given the overall median age of myeloma patients, the frequent existence of comorbid conditions, and the profound immunosuppression caused by the disease and its treatment (based on corticosteroids). In several published series, the median survival time after transplant has been approximately 1.5 years, with long-term survival (7 years) less than 30%. Relapse rates are approaching 70% (not appreciably different, but somewhat delayed from the tandem autotransplant experience), with late relapses occurring up to 10 years posttransplant, contrary to the experience in acute and chronic leukemias.[396,397] The major obstacle has been the high TRM, which reaches 40% to 50% during the first year,[396,398,399] partly reflecting the fact that allogeneic transplantation was mainly used as a last resort approach to relapsing patients. The Intergroup study of newly diagnosed MM patients closed the allogeneic transplant arm after enrollment of the first 31 patients because of a 50% mortality rate in the first 3-month posttransplant period. The exception to this excessively high TRM is a trial using CD6 depletion in 61 patients, with an early TRM of only 10% due to the fact that only 17% of the patients developed grade II or greater graft-versus-host disease (GVHD).[398] The CR rate was only 22%, and median EFS and OS were 12 and 22 months, respectively. The Seattle group reported on 80 MM patients, mostly with chemoresistant disease.[398] Sixty received marrow from HLA-identical sibling donors and 20 from unrelated or mismatched donors. Conditioning was achieved with busulfan and cyclophosphamide plus TBI. Prophylaxis against GVHD was cyclo-

sporine combined with methotrexate or prednisone. TRM was 56%; 15% of patients died of late (after day 100) complications. The CR rate achieved was 36%, and 5-year EFS and OS were 16% and 20%, respectively. In a multicenter analysis of 139 patients, a comparison was performed between TBI combined with either melphalan or cyclophosphamide. TRM at 1 year was similar with both regimens; however, the relapse/progression rate was significantly lower in the melphalan-treated patients (37% vs 81%; $P = 0.009$).[399] This study seems to indicate that the conditioning regimen is important for outcome and that the entire effect of allogeneic transplantation is not only a graft-versus-myeloma effect.

The favorable prognostic factors for long-term survival are similar to those for autologous transplant: low β_2M levels, limited previous treatment, and chemosensitive disease. Women appear to fare better, with the best combination being female donor and female recipient.[356] The EBMT Myeloma Registry performed a retrospective analysis comparing 189 allogeneic transplant patients with 189 case-matched autologous transplant controls.[396] Median survival was 18 months in the allotransplant group versus 34 months in the autotransplant group, despite the significantly higher relapse rate in the latter. The difference in relapse rate did not compensate for TRM (41% in the allogeneic transplant group vs 13% in the autologous transplant group). An update on 690 patients from EBMT reports an encouraging decrease in TRM in the period between 1994 and 1998 (approximately 25% and 30% at 6 months and 2 years, respectively) compared with the previous 10 years (1983–1993), believed to be due to decreased incidence of infections and interstitial pneumonitis and, possibly, implementation of allogeneic transplant earlier in the disease course. The improvement in TRM resulted in an actuarial survival rate of 50% at 4 years in the most recently treated group versus 30% in the previously treated group. However, no reduction in relapse rate was observed. No survival benefit was shown with use of peripheral blood stem cells compared with bone marrow.[400]

In an effort to decrease TRM, the Seattle group sought to separate the immunotherapeutic effect of the allogeneic transplant from the toxicity of the high-dose conditioning regimen. These investigators combined an autologous transplant (with low TRM) for maximal cytoreduction with a subsequent nonmyeloablative allogeneic transplant.[401] Fifty-four previously treated MM patients (median age 52 years, 52% with refractory or relapsed disease) received HDT with melphalan 200 mg/m^2 and ASCT, followed 40 to 229 days later (median 62 days) by TBI (200 cGy) and immunosuppression with mycophenolate mofetil (for 1 month) and cyclosporine (for at least 2 months) and unmanipulated peripheral blood stem cells from HLA-identical siblings. Fifty-two patients received the allografts (mostly on an outpatient basis) with minimal, if any, hematologic toxicity. All engrafted (90% and 99% of donor T-cell chimerism by postallotransplant day 28 and 84, respectively) with no late graft rejection. Eleven patients died after the allograft, three of progressive disease and eight of due to transplant-related complications. At median followup of 552 days after allograft, the OS rate is 78%. Acute GVHD (grades II–IV) developed in 38% of the patients; 46% required treatment of chronic GVHD. The overall response rate was 83%, with 57% CR. Others have reported similar results with the application of a dose-reduced conditioning regimen (melphalan, fludarabine, antithymocyte globulin) and allogeneic transplant from either a related or an unrelated donor following an autologous transplant (melphalan 200 mg/m^2).[402] Median interval between the two transplants was 4 months. Strictly defined CR rate was 73% after allografting. Thirteen of 17 patients with advanced myeloma are alive (12 progression-free) with median followup of 13 months after allogeneic transplant. The same conditioning regimen was used in 21 patients with advanced disease who received unrelated stem cell transplants. At median followup of 13 months, 2-year estimated OS and EFS are 74% and 53%, respectively.[403] In an update on 120 patients, TRM was 18%. Relapse after a preceding transplant was the most important risk factor for TRM, relapse, EFS, and OS. The risk of relapse decreased significantly in patients with chronic graft-versus-host disease. Even in the subgroup of patients with chemosensitive myeloma and no relapse prior to allotransplantation, 2-year EFS was only 60% with a related donor (n = 32) but 81% with an unrelated donor (n = 12).[404] A study from the University of Arkansas of 45 MM patients who received grafts from a sibling or an unrelated donor after dose-reduced conditioning regimens showed that chemosensitive and adequate performance status were the only significant factors for EFS and OS.[405] The EBMT reported the outcome of 229 patients who received an allograft for myeloma with reduced-intensity conditioning. Conditioning regimens were heterogeneous. TRM at 1 year was 22%. Three-year OS and progression-free survival were 41% and 21%, respectively. Inferior OS was seen in patients with chemorefractory myeloma, in those with more than one prior transplant, and in male patients with female donors. Grade II to IV acute GVHD occurred in 31%. Chronic GVHD was associated with better progression-free and OS, suggesting that a graft-versus-host effect is important. The probability of disease progression at 3 years was 50%.[406] With followup now extending to 7 years, it is clear that reduced-intensity conditioning regimens are associated with lower TRM but a higher rate of disease progression compared to myeloablative conditioning regimens. In an EBMT study, the rate of relapse after reduced-intensity conditioning was more than twice that seen with myeloablative conditioning ($P = 0.0001$).[407] KIR-ligand mismatching in the setting of reduced-intensity conditioning was found to be protective against relapse,[408] as had been shown in acute leukemia.

Is a Cure Possible with Autotransplants?

In a report from the University of Arkansas, the outcome and prognostic factors in a group of 515 consecutive newly diagnosed and previously treated MM patients intended to receive melphalan-based tandem autotransplants with followup of more than 5 years were studied. Cytogenetic abnormalities were detected in 34% of patients; 72% received two transplants less than 12 months apart. Median OS and EFS were 30 and 17 months, respectively; 121 (24%) of 515 patients had EFS for more than 5 years. On multivariate analysis, favorable factors for EFS greater than 5 years were the absence of chromosome 11 and 13 abnormalities (odds ratio 6.1), less than 12 months of preceding standard treatment (odds ratio 2.6), and pretransplant β_2M 2.5 mg/L or less (odds ratio 1.7). The EFS curve shows a rapid decline during the first 3 years, a slower decline between 3 and 7 years, and an apparently stable plateau after 7 years among 46 patients (Figs. 87–13 and 87–14). Forty patients (of the 46 on the plateau phase) had received two autotransplants, whereas two had received an allogeneic transplant as a second (consolidative) transplant. Median survivals of patients with 0, 1, 2, and 3 unfavorable factors were 37, 26, 14, and 7 months, respectively, whereas 7-year EFS was 36%, 15%, 10%, and 0%, respectively. By using a 1-year landmark analysis (and thus excluding patients who relapsed or died during the first posttransplant year), achievement of CR was not significant for EFS. Our data suggest that patients in CR more than 7 years posttransplant in all likelihood are cured, whereas non-CR patients with EFS more than 7 years may have "regressed" to an MGUS phase, with possibly very good long-term prognoses.[409]

Biologic Agents

Interferon

When used as a single agent, interferon-α has modest activity against myeloma, with an objective response rate of 10% to 20%.[410] In an attempt to improve the efficacy of first-line treatment, interferon has been combined with MP. In two randomized trials comparing MP with MP plus interferon, no survival difference was detected.[411,412] Also, no difference in survival was detected when interferon was used as maintenance after a plateau phase had been reached after standard treatment.[413] The Myeloma Trialists' Collaborative Group performed a meta-analysis of 12 induction and 12 maintenance trials, which

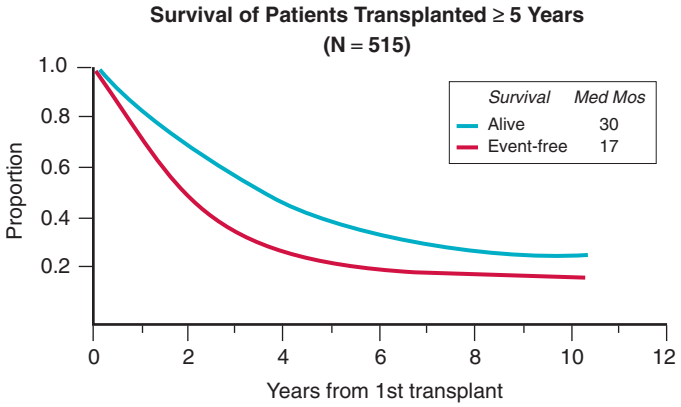

Figure 87–13 Event-free survival and overall survival of 515 patients receiving autotransplants and median followup of at least 5 years. *(From Tricot G, Spencer T, Sawyer J, et al: Predicting long-term [≥5 years] event-free survival in multiple myeloma patients following planned tandem autotransplants. Br J Haematol 116:211, 2002.)*

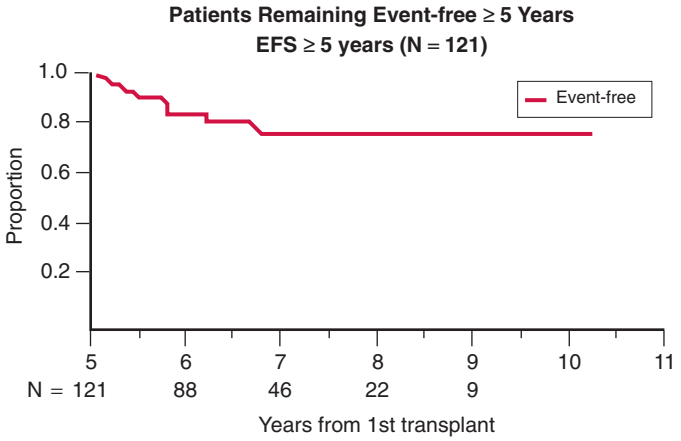

Figure 87–14 Event-free survival times of only those patients alive and without disease progression at 5 years. *(From Tricot G, Spencer T, Sawyer J, et al: Predicting long-term [≥5 years] event-free survival in multiple myeloma patients following planned tandem autotransplants. Br J Haematol 116:211, 2002.)*

included more than 4000 MM patients.[239] In induction trials, response rates were slightly better with interferon (57.5% vs 53.1%; $P = 0.01$). EFS was better with interferon (33% vs 24% at 3 years; $P < 0.00001$). Median time to progression was increased by approximately 6 months in both settings, whereas OS was slightly better with interferon (53% vs 49% at 3 years; $P = 0.01$), with median OS increased by approximately 4 months. Additionally, interferon-α did not extend survival when used as maintenance in the postautologous transplantation setting in one study,[391] but it did prolong survival in the retrospective analysis of EBMT registry, which addressed the same question.[356] Given the very modest benefit, toxicity, inconvenience, cost, and stem cell damaging potential of interferon, it should be used cautiously, if at all.

Supportive Care

Bisphosphonates

Bone involvement in MM contributes significantly to the morbidity of the disease. Bisphosphonates inhibit bone resorption in different ways: they block the development of osteoclasts from monocytes, induce osteoclast apoptosis, prevent migration of osteoclasts to the bone surface, and inhibit the production of bone-resorbing cytokines by bone marrow stromal cells.[414] In a prospective randomized trial, patients with symptomatic myeloma and at least one lytic lesion received either placebo or pamidronate 90 mg as a 4-hour intravenous infusion every 4 weeks for nine cycles in addition to antimyeloma treatment.[415] The proportion of patients who experienced any skeletal-related event (i.e., spinal cord compression, new fractures, need for radiation treatment, or surgery) was significantly lower in the pamidronate than in the placebo group (24% vs 41%; $P < 0.001$). Pain improved, and quality of life and performance status were better in patients who received pamidronate. The same results were observed after extended administration of pamidronate for 21 cycles.[416] Although OS times were not different in the two groups, pamidronate-treated patients who received salvage chemotherapy regimens lived longer than did patients on salvage treatment who did not receive the drug (21 vs 14 months; $P = 0.041$). Zoledronate (third-generation bisphosphonate) is much more potent in vitro (at least 100 times) than pamidronate and is administered as a 30-minute intravenous infusion. Zoledronate has only proved to be superior for treatment of hypercalcemia but not for prevention of skeletal-related events compared with pamidronate. Bisphosphonates are generally well-tolerated agents. Prolonged use by infusions at a more rapid rate or higher than recommended dose or frequency has caused nonspecific proteinuria and impaired renal function.[417] Focal segmental glomerulosclerosis was the underlying pathologic lesion. Even more intriguing (and perhaps more important than their bone-strengthening effects), bisphosphonates appear to have an antimyeloma effect in vivo, stimulate T-cell proliferation and function, and may modulate the adhesion molecule profile and thus overcome drug resistance by interfering with the malignant cell–extracellular matrix interactions.[418] Findings have shown that bisphosphonates inhibit production of IL-6 by marrow stromal cells and secretion of matrix metalloproteinase 1 (molecule critical for bone remodeling and tumor invasion).[419] Osteonecrosis of the jaw has been recognized as a complication of long-term bisphosphonates treatment.[420–424] Since its first description in 2003, hundreds of cases of osteonecrosis of the jaw have been reported worldwide. It is characterized by the appearance of necrotic bone in the oral cavity and affects either the mandible or the maxilla. Although it can develop spontaneously, it is more common after a surgical procedure such as dental extraction or implant.[421,424] The risk increases in patients who have been taking bisphosphonates for more than 3 years[421] and is more common in myeloma than in other cancers.[421] The risk is higher with zoledronate than with pamidronate.[421–424] The inhibitory effect of bisphosphonates on osteoclastic activity is thought to occur via suppression of bone remodeling resulting in microfractures that are not repaired, and perhaps angiogenesis. Bone histology often shows osteomyelitis, and microbiology may reveal actinomyces or mixed bacterial flora.[425] Whether a correlation exists between osteonecrosis of the jaw and avascular necrosis of the hip is unclear.

Avascular Necrosis of the Femur

Avascular necrosis of the bone is thought to be caused by a compromised blood supply. It typically occurs after trauma but may result from glucocorticoid therapy, radiation therapy, sickle cell anemia, and connective tissue diseases. The diagnosis is mainly based on MRI findings. Glucocorticoids reduce blood flow to the bone and induce apoptosis of osteoblasts and osteocytes. In a study of 553 patients with median followup of 33 months, the incidence of avascular necrosis was 9%. Median onset was 12 months. Multivariate analysis identified three major risk factors: cumulative dexamethasone dose, male gender, and younger age. It usually was asymptomatic, and only four of 49 patients with avascular necrosis required hip replacement. This complication was not more frequent in thalidomide-treated patients.[426]

Vertebroplasty and Kyphoplasty

Painful vertebral compression fractures traditionally have been managed with radiation therapy, analgesics, bed rest, and bracing.

Most patients experience limited, if any, benefits from these interventions. Cement augmentation of the vertebral body (vertebroplasty) has been used for pain relief in patients with spine involvement by various tumors, including MM.[427,428] The technique consists of percutaneous injection of low-viscosity liquid bone cement into the damaged vertebral body. Improvement in pain is reported by virtually all patients and is sustained in most patients for long periods.[429] Although significant durable pain relief is anticipated, vertebroplasty does not restore the loss of height of the vertebral body and does not correct the spinal deformity. Furthermore, a high incidence of cement leakage, especially if the bone contour is not intact, usually occurring in the paraspinal soft tissues, is seen in the majority of cases.[429] Although this leakage is of no clinical importance in the overwhelming majority of patients, it occasionally leads to nerve root compression that requires emergency decompressive surgery. Kyphoplasty is a more recently developed technique that involves the creation of a cavity in the vertebral body (through a trocar placement, drilling of a bone channel, and insertion of an inflatable balloon) and its filling with highly viscous cement. A report of 55 consecutive procedures performed in 18 MM patients (mean followup 7.4 months) showed significant pain relief, improvement in performance status, and an average 34% restoration of the vertebral body height loss. Asymptomatic cement leakage occurred in only 4% of procedures.[430] The technique is unsuitable when the posterior vertebral wall is deficient because of possible further displacement of bony fragments during the balloon inflation phase, possibly leading to spinal cord compression.

Erythropoietin

Anemia of variable severity affects more than two thirds of MM patients. Patients with MM have an inappropriate erythropoietin response for their degree of anemia. Overexpression of the Fas ligand, MIP-1α, and TRAIL by malignant cells triggers the death of immature erythroblasts.[431] In several randomized, placebo-controlled[432] and community-based studies, recombinant human erythropoietin has been shown to significantly decrease the frequency of transfusion requirements, increase the mean hemoglobin levels, and improve quality of life and performance status in anemic myeloma patients. The impact of treatment is greater in patients with limited preceding treatment. Furthermore, patients with mild anemia (Hb levels approximately 12 g/dL) should not be excluded from treatment, because the greatest incremental improvement in quality of life occurs when hemoglobin increases from 12 to 13 g/dL. Erythropoietin is well tolerated; the once-weekly epoetin alfa and darbepoetin every 2 weeks schedules are equally efficacious.[433] Administration of erythropoietin before autologous transplantation reduces transfusion requirements.[434,435] Erythropoietin may have an antimyeloma effect by decreasing hypoxemia in the tumor but also by activation of $CD8^+$ T cells.[436,437] Although it has been claimed that erythropoietin increases the risk of deep vein thrombosis when thalidomide or lenalidomide is given,[316] we did not observe such an increase in our Total Therapy II study.[438]

Approach to Therapy for Multiple Myeloma

Patients who are asymptomatic and have no end-organ damage should not be treated until clear evidence of disease progression is demonstrated by new lesions on skeletal survey, MRI, or PET scan, hypercalcemia, increase in M protein, or worsening renal failure or anemia due to myeloma. If a physician is unsure whether a patient should be treated after a complete workup has been performed, it usually is better to delay therapy and reevaluate after 6 to 8 weeks, with biweekly or weekly measurements of M protein in the blood and urine to determine the pace of myeloma progression. Remember that before any treatment is given, patients should undergo bone marrow aspirate and biopsy, skeletal survey, measurement of LDH, creatinine, complete blood count, CRP, and β_2M, serum protein electrophoresis, 24-hour urine collection to measure total Bence Jones proteinuria, serum and urine immunofixation electrophoresis, and determination of free light chains. It is important that patients undergo routine cytogenetic analyses. Cytogenetic analysis is preferable to FISH analysis. For patients who require treatment, sufficient evidence based on randomized, pair-mate historic, controlled, and population-based studies indicate that high-dose chemotherapy with stem cell support is superior to standard-dose treatment. It results in a higher CR rate and prolonged EFS and OS periods. Median OS of 10 years is realistic with optimal intensive treatment. Multiple studies have indicated that the best preparative regimen for autologous transplantation is melphalan 200 mg/m^2. Age should not be a contraindication to autologous transplantation. However, comorbid conditions, such as severely decreased cardiopulmonary function, major liver function abnormalities, and impaired mental status not due to metabolic causes, are contraindications to transplantation. Patients with renal failure also clearly benefit from autologous transplantation. In contrast with myeloma patients who are in good condition, patients with renal insufficiency and those older than 70 years do better with a reduced dose of melphalan at 140 mg/m^2. Before transplantation, patients should receive chemotherapy, including alkylating agents, but not melphalan, busulfan, or BCNU. The main goal of induction therapy is to collect a large number of stem cells that will allow up to four transplants if necessary. It probably is not appropriate to collect stem cells with growth factors in patients who have only been pretreated with VAD or dexamethasone/thalidomide. The quality of response prior to autologous transplantation is not important. The only mature study that has compared a single with tandem transplants has clearly shown a superior outcome with tandem transplants. It should be noted that the difference was evident only more than 3 years after the start of treatment. Patients without chromosome 13 deletions, without hypodiploidy, and without increased LDH levels at the time of diagnosis (75% of all patients) will do very well with tandem transplants. Median survival duration of these patients is predicted to be greater than 10 years, which is three times longer than that with conventional chemotherapy. Patients with increased LDH levels, hypodiploidy, or chromosome 13 deletion have inferior outcomes; however, among these patients, the best outcome is seen with tandem autologous transplants. In the patients who have increased LDH hypodiploidy, no benefit has been observed with allotransplantation or a combination of autologous transplantation followed by nonmyeloablative allotransplantation. Other treatment modalities for those patients must be identified and may include a combination of autotransplantation with immunotherapy such as tumor vaccination or natural killer cells. Application of the newer drugs, such as thalidomide, lenalidomide, and bortezomib, is best in the posttransplantation period after major tumor debulking, when the chances of developing resistance to these marginally active drugs is much lower. They are best used in combination with dexamethasone.

Patients who are not candidates for transplantation should be treated with combinations of cytotoxic drugs with the newer drugs, such as melphalan, thalidomide or lenalidomide or bortezomib and dexamethasone. Treatment should be continued for at least 12 months or until a clear plateau has been reached.

Supportive care in the treatment of myeloma is essential. All patients should begin receiving treatment immediately after diagnosis with monthly bisphosphonates, preferably pamidronate if renal function is preserved. Ideally, treatment should be combined with a calcium supplement and hormone replacement therapy in patients who do not have contraindications to such therapy. After 2 to 3 years of bisphosphonates therapy, the frequency should be reduced to every 3 months to decrease the risk of osteonecrosis of the jaw. Anemia should be corrected by administration of erythropoietin. Patients who do not respond to erythropoietin administration often benefit from intravenous iron administration. It is important to adequately control pain so that patients remain ambulatory and can perform their daily functions; this usually require opiates. In most cases, pain ultimately is best controlled by administration of high-dose chemotherapy and stem cell support. However, some patients will require

either vertebroplasty or kyphoplasty for persistent pain. Depression is very common, especially in the early stages of the disease. Antidepressants are indicated in at least one third of myeloma patients. During the early stages of chemotherapy, it is important to provide antibiotic prophylaxis, including antiherpetic and antifungal drugs and antibiotics. After transplantation, the risk of herpes zoster remains high and will require continued administration of an antiherpetic drug. Yearly influenza vaccinations are indicated for myeloma patients. As soon as immune function has recovered adequately after transplantation, patients should be revaccinated for tetanus and pneumococcal infections.

CHAPTER 88

WALDENSTRÖM MACROGLOBULINEMIA/LYMPHOPLASMACYTIC LYMPHOMA

Steven P. Treon, Evdoxia Hatjiharissi, Xavier Leleu, Aldo Roccaro, and Giampaolo Merlini

INTRODUCTION

Waldenström macroglobulinemia (WM) is a distinct clinicopathologic entity resulting from the accumulation, predominantly in the bone marrow, of clonally related lymphocytes, lymphoplasmacytic cells (LPC) and plasma cells that secrete a monoclonal IgM protein (Fig. 88–1).[1] This condition is considered to correspond to the lymphoplasmacytic lymphoma (LPL) as defined by the Revised European American Lymphoma (REAL) and World Health Organization classification systems.[2,3] Most cases of LPL are WM, with less than 5% of cases made up of IgA, IgG, and nonsecretory LPL.

EPIDEMIOLOGY AND ETIOLOGY

WM is an uncommon disease, with a reported age-adjusted incidence rate of 3.4 per million among males and 1.7 per million among females in the United States, and a geometrical increase with age.[4,5] The incidence rate for WM is higher among Caucasians, with descendants of Africans representing only 5% of all patients. A similar incidence was reported in a European-based study: 2.0 for females and 4.2 for males per million person-years.[6] However, a recent study conducted in U.K. reported a higher rate: 5.5 (7.3 for males and 4.2 for females) per million.[7] Genetic factors appear to be an important factor in the pathogenesis of WM. Approximately 20% of WM patients have an Ashkenazi (Eastern European) Jewish ethnic background, and there have been numerous reports of familial disease, including multigenerational clustering of WM and other B-cell lymphoproliferative diseases.[8–12] In a recent study, approximately 20% of 257 serial WM patients presenting to a tertiary referral had a first-degree relative with either WM or another B-cell disorder.[9] Frequent familial associations with other immunologic disorders in healthy relatives, including hypogammaglobulinemia and hypergammaglobulinemia (particularly polyclonal IgM), autoantibody (particularly to thyroid) production, and manifestation of hyperactive B cells have also been reported.[11,12] Increased expression of the *bcl-2* gene with enhanced B-cell survival may underlie the increased immunoglobulin synthesis in familial WM.[11] The role of environmental factors in WM remains to be clarified, but chronic antigenic stimulation from infections, certain drug and Agent Orange exposures remain suspect. An etiologic role for hepatitis C virus (HCV) infection has been suggested; however, in a recent study examining 100 consecutive WM patients, no association could be established using both serologic and molecular diagnostic studies for HCV infection.[13–15]

BIOLOGY

Cytogenetic Findings

Several studies, usually performed on limited series of patients, have been published on cytogenetic findings in WM, demonstrating a great variety of numerical and structural chromosome abnormalities. Numerical losses involving chromosomes 17, 18, 19, 20, 21, 22, X, and Y have been commonly observed, although gains in chromosomes 3, 4, and 12 have also been reported.[9,16–21] Chromosome 6q deletions encompassing 6q21–22 have been observed in up to half of WM patients, and at a comparable frequency among patients with and without a familial history.[9,21] Several candidate tumor suppressor genes in this region are under study, including BLIMP-1, a master regulatory gene implicated in lymphoplasmacytic differentiation. Notable, however, is the absence of IgH switch region rearrangements in WM, a finding that may be used to discern cases of IgM myeloma where IgH switch region rearrangements are a predominant feature.[22]

Nature of the Clonal Cell

The WM bone marrow B-cell clone shows intraclonal differentiation from small lymphocytes with large focal deposits of surface immunoglobulins, to lymphoplasmacytic cells, to mature plasma cells that contain intracytoplasmic immunoglobulins.[23] Clonal B cells are detectable among blood B lymphocytes, and their number increases in patients who fail to respond to therapy or who progress.[24] These clonal blood cells possess the peculiar capacity to differentiate spontaneously, in vitro, to plasma cells. This is through an interleukin-6 (IL-6)-dependent process in cells from patients with IgM monoclonal gammopathy of undetermined significance (MGUS) and mostly an IL-6-independent process in cells from WM patients.[25] All these cells express the monoclonal IgM present in the blood and a variable percentage of them also express surface IgD. The characteristic immunophenotypic profile of the lymphoplasmacytic cells in WM includes the expression of the pan B-cell markers CD19, CD20, CD22, CD79, and FMC7.2.[26–28] Expression of CD5, CD10, and CD23 may be found in 10% to 20% of cases, and does not exclude the diagnosis of WM.[29]

The phenotype of lymphoplasmacytic cells in WM suggests that the clone is derived from a post–germinal center B cell. This conclusion is further strengthened by the results of the analysis of the nature (silent or amino acid replacing) and distribution (in framework or CDR regions) of somatic mutations in Ig heavy- and light-chain variable regions performed in patients with WM.[30,31] This analysis showed a high rate of replacement mutations, compared with the closest germline genes, clustering in the CDR regions and without intraclonal variation. Subsequent studies showed a strong preferential usage of VH3/JH4 gene families, no intraclonal variation, and no evidence for any isotype-switched transcripts.[32,33] These data indicate that WM may originate from an IgM^+ and/or IgM^+ IgD^+ memory B cell. Normal IgM^+ memory B cells are localized to the bone marrow, where they mature to IgM-secreting cells.[34]

Bone Marrow Microenvironment

Increased numbers of mast cells are found in the bone marrow of WM patients, wherein they are usually admixed with tumor aggregates.[28,35] Recent studies have helped clarify the role of mast cells in WM. Coculture of primary autologous or mast cell lines with WM LPC resulted in dose-dependent WM cell proliferation and/or tumor

colony, primarily through CD40 ligand (CD40L) signaling. Furthermore, WM cells through elaboration of soluble CD27 (sCD27), induce the upregulation of CD40L on mast cells derived from WM patients and mast cell lines.[36]

CLINICAL FEATURES

The clinical and laboratory findings of patients with WM at time of diagnosis in one large institutional study[9] are presented in Table 88–1. Unlike most indolent lymphomas, splenomegaly and lymphadenopathy are prominent in only a minority of patients (≤15%). Purpura is frequently associated with cryoglobulinemia and more rarely with AL amyloidosis, whereas hemorrhagic manifestations and neuropathies are multifactorial in origin. The morbidity associated with WM is caused by the concurrence of two main components: tissue infiltration by neoplastic cells and, more importantly, the physicochemical and immunologic properties of the monoclonal IgM. As shown in Table 88–2, the monoclonal IgM can produce clinical manifestations through several different mechanisms related to its physicochemical properties, nonspecific interactions with other proteins, antibody activity, and tendency to deposit in tissues.[37–40]

MORBIDITY MEDIATED BY THE EFFECTS OF IgM

Hyperviscosity Syndrome

Blood hyperviscosity is affected by increased serum IgM levels leading to hyperviscosity-related complications.[41] The mechanisms behind the marked increase in the resistance to blood flow and the resulting impaired transit through the microcirculatory system are rather complex.[41–43] The main determinants are (1) a high concentration of monoclonal IgMs, which may form aggregates and may bind water through their carbohydrate component, and (2) their interaction with blood cells. Monoclonal IgMs increase red cell aggregation (*rouleaux* formation, see Fig. 88–2) while also reducing deformability. The possible presence of cryoglobulins can contribute to increasing blood viscosity as well as to the tendency to induce erythrocyte aggregation. Serum viscosity is proportional to IgM concentration up to 30 g/L, then increases sharply at higher levels. Increased plasma viscosity may also contribute to inappropriately low erythropoietin production, which is the major reason for anemia in these patients. Plasma viscosity may actually inhibit anemia-induced erythropoietin production.[44] Clinical manifestations are related to circulatory disturbances that can be best appreciated by ophthalmoscopy, which shows distended and tortuous retinal veins, hemorrhages, and papilledema (Fig. 88–3).[45] Symptoms usually occur when the monoclonal IgM concentration exceeds 50 g/L or when serum viscosity is >4.0 centipoises (cp), but there is a great individual variability, with some patients showing no evidence of hyperviscosity even at 10 cp.[41] The most common symptoms are oronasal bleeding, visual disturbances due to retinal bleeding, and dizziness that may rarely lead to coma. Heart failure can be aggravated, particularly in the elderly, owing to increased blood viscosity, expanded plasma volume, and anemia. Inappropriate transfusion can exacerbate hyperviscosity and may precipitate cardiac failure.

Cryoglobulinemia

In up to 20% of WM patients, the monoclonal IgM behaves as a cryoglobulin (type I), which leads to symptoms in 5% or less of the cases.[46] Cryoprecipitation is mainly dependent on the concentration of monoclonal IgM; for this reason plasmapheresis or plasma exchange are commonly effective treatment in this condition. Symptoms result from impaired blood flow in small vessels and include Raynaud phenomenon, acrocyanosis, and necrosis of the regions most exposed to cold (tip of the nose, ears, fingers, and toes), malleolar ulcers, purpura, and cold urticaria. Renal manifestations may occur but are infrequent.

Autoantibody Activity

Monoclonal IgM may exert its pathologic effects through specific recognition of autologous antigens, the most notable being nerve constituents, immunoglobulin determinants, and red blood cell antigens:

IgM-Related Neuropathy

In a series of 215 patients with WM, Merlini et al[46] reported the presence of symptomatic peripheral neuropathy in 24% of WM

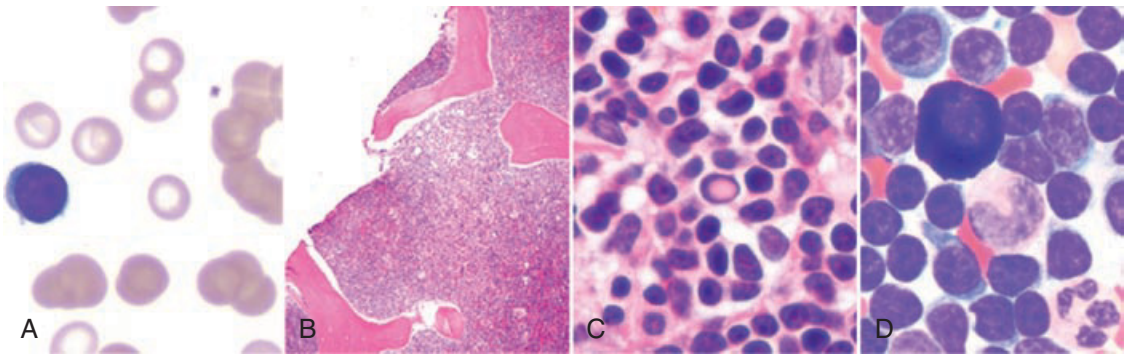

Figure 88–2 Lymphoplasmacytic lymphoma consistent with Waldenström Macroglobulinemia (**A**–**D**). The patient was a 78-year-old male who first presented with anemia. Serum electrophoresis demonstrated an IgM kappa monoclonal protein, and quantitative immunoglobulins showed an IgM of 5130 mg/dL. His serum viscosity was elevated at 2.9. The peripheral blood smear showed circulating lymphoma cells with slight plasmacytic appearance (**A**). There was also marked rouleaux formation of the red blood cells The bone core biopsy showed an interstitial and slightly paratrabecular infiltrate of malignant lymphoid cells (**B**), which at higher power included many with intranuclear inclusions or Dutcher bodies (**C**, *center*). The aspirate (**D**) was packed with lymphoplasmacytic cells associated with increased mast cells (*upper left*). The phenotype was CD19$^+$, CD20$^+$, IgM/kappa$^+$ with no CD5, CD10, or CD11c expression.

Table 88–2 Physicochemical and Immunological Properties of the Monoclonal IgM Protein in Waldenstrom Macroglobulinemia

Properties of IgM Monoclonal Protein	Diagnostic Condition	Clinical Manifestations
Pentameric structure	Hyperviscosity	Headaches, blurred vision, epistaxis, retinal hemorrhages, leg cramps, impaired mentation, intracranial hemorrhage
Precipitation on cooling	Cryoglobulinemia (Type I)	Raynaud phenomenon, acrocyanosis, ulcers, purpura, cold urticaria
Autoantibody activity to myelin-associated glycoprotein (MAG), ganglioside M1 (GM1), sulfatide moieties on peripheral nerve sheaths	Peripheral neuropathies	Sensorimotor neuropathies, painful neuropathies, ataxic gait, bilateral foot drop
Autoantibody activity to IgG	Cryoglobulinemia (Type II)	Purpura, arthralgias, renal failure, sensorimotor neuropathies
Autoantibody activity to red blood cell antigens	Cold agglutinins	Hemolytic anemia, Raynaud phenomenon, acrocyanosis, livedo reticularis
Tissue deposition as amorphous aggregates	Organ dysfunction	Skin: bullous skin disease, papules, Schnitzler syndrome GI: diarrhea, malabsorption, bleeding. Kidney: proteinuria, renal failure (light-chain component)
Tissue deposition as amyloid fibrils (light-chain component most commonly)	Organ dysfunction	Fatigue, weight loss, edema, periorbital purpura, hepatomegaly, macroglossia, organ dysfunction of involved organs: heart, kidney, liver, peripheral sensory and autonomic nerves.

patients, although prevalence rates ranging from 5% to 38% have been reported in other series.[47,48] An estimated 6.5% to 10% of idiopathic neuropathies are associated with a monoclonal gammopathy, with a preponderance of IgM (60%) followed by IgG (30%) and IgA (10%) (reviewed in Nemni et al[49] and Ropper and Gorson[50]). In WM patients, the nerve damage is mediated by several pathogenetic mechanisms: IgM antibody activity toward nerve constituents causing demyelinating polyneuropathies; endoneurial granulofibrillar deposits of IgM without antibody activity, associated with axonal polyneuropathy; occasionally by tubular deposits in the endoneurium associated with IgM cryoglobulin and, rarely, by amyloid deposits or by neoplastic cell infiltration of nerve structures.[51] Half of the patients with IgM neuropathy have a distinctive clinical syndrome that is associated with antibodies against a minor 100-kd glycoprotein component of nerve, myelin-associated glycoprotein (MAG). Anti-MAG antibodies are generally monoclonal IgMκ, and usually also exhibit reactivity with other glycoproteins or glycolipids that share antigenic determinants with MAG.[52–54] The anti-MAG-related neuropathy is typically distal and symmetrical, affecting both motor and sensory functions; it is slowly progressive with a long period of stability.[48,55] Most patients present with sensory complaints (paresthesias, aching discomfort, dysesthesias, or lancinating pains), ataxia and abnormal gaits, owing to lack of proprioception, and leg muscle atrophy in patients with advanced stage disease. Patients with predominantly demyelinating sensory neuropathy in association with monoclonal IgM to gangliosides with disialosyl moieties, such as GD1b, GD3, GD2, GT1b, and GQ1b, have also been reported.[56,57] Anti- GD1b and anti-GQ1b antibodies were significantly associated with predominantly sensory ataxic neuropathy.[58] These antiganglioside monoclonal IgMs present clinical features of chronic ataxic neuropathy with variably present ophthalmoplegia and/or red blood cell cold agglutinating activity. The disialosyl epitope is also present on red blood cell glycophorins, thereby accounting for the red cell cold agglutinin activity of anti-Pr2 specificity.[59,60] Monoclonal IgM proteins that bind to gangliosides with a terminal trisaccharide moiety, including GM2 and GalNac-GD1A, are associated with chronic demyelinating neuropathy and severe sensory ataxia, unresponsive to corticosteroids.[61] Antiganglioside IgM proteins may also cross-react with lipopolysaccharides of *Campylobacter jejuni*, an infection that is known to precipitate the Miller Fisher syndrome, a variant of the Guillain–Barré syndrome.[58] This finding indicates that molecular mimicry may play a role in this condition. Antisulfatide monoclonal IgM proteins, associated with sensory/sensorimotor neuropathy, have been detected in 5% of patients with IgM monoclonal gammopathy and neuropathy.[62] Motor neuron disease has been reported in patients with WM, and monoclonal IgM with anti-GM1 and sulfoglucuronyl

Figure 88–3 Funduscopic examination of a patient with Waldenström macroglobulinemia demonstrating hyperviscosity-related changes including dilated retinal vessels, peripheral hemorrhages, and "venous sausaging". *(Courtesy of Marvin Stone, MD.)*

paragloboside activity.[63] POEMS (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) syndrome is rarely associated with WM.[64]

Type II Cryoglobulinemia

The monoclonal IgM may have an autoantibody activity against the FC portion of IgG (monoclonal rheumatoid factors).[40] The cryoprecipitating property results from the size and limited solubility of the IgM–IgG immune complex. The systemic vasculitis that characterizes the disease appears to be caused by deposition of immune complexes on the walls of small vessels and subsequent activation of the complement cascade. Majority of patients with mixed cryoglobulinemias (MCs) are infected with hepatitis C virus (HCV), which is considered the triggering factor of the disease.[65] Not all patients infected with HCV have MCs, but their presence correlates with duration of the hepatitis. The cryoprecipitable immune complexes contain HCV core proteins and specific anticore IgG which are bound to IgM with rheumatoid factor activity. This large complex binds specifically to endothelial cells through the C1q receptor.[66] The monoclonal IgM rheumatoid factors are generated by an antigen-driven process. The clinical features of patients with MCs are purpura, arthralgias, weakness, liver involvement, renal involvement (cryoglobulinemic glomerulonephritis), peripheral neuropathy, and widespread vasculitis. The severity of vasculitic manifestations has little relationship with the serum level of cryoglobulins (cryocrit) or complement. Thermal amplitude, the temperature at which the immune complex precipitates, appears to be more important.

Cold Agglutinin Hemolytic Anemia

Patients with a monoclonal IgM may present with cold agglutinin activity. The IgM may recognize specific red cell antigens at low temperatures, producing a chronic hemolytic anemia. This disorder occurs in less than 10% of WM patients[67] and is associated with cold agglutinin titers greater than 1 : 1000 in most cases. The monoclonal component is usually an IgMκ and reacts most commonly with I/i antigens, with complement fixation and activation.[68,69] Mild chronic hemolytic anemia can be exacerbated by cold exposure but rarely does the hemoglobin level drop below 70 g/dL. The hemolysis is usually extravascular (removal of C3b opsonized cells by the reticuloendothelial system, primarily in the liver) and rarely intravascular because of complement mediated destruction of the red blood cell (RBC) membrane. The agglutination of RBCs in the cooler peripheral circulation also causes Raynaud syndrome, acrocyanosis, and livedo reticularis. Macroglobulins with the properties of both cryoglobulins and cold agglutinins with anti-Pr specificity have been reported. These properties may have as a common basis the immune binding of the sialic acid-containing carbohydrate present on red blood cell glycophorins and on Ig molecules. Several other macroglobulins with various antibody activity toward autologous antigens (ie, phospholipids, tissue and plasma proteins, etc) and foreign ligands have also been reported.

Tissue Deposition

The monoclonal protein can be deposited in several tissues as amorphous aggregates. Linear deposition of monoclonal IgM along the skin basement membrane is associated with bullous skin disease.[70] Amorphous IgM deposits in the dermis determine the so-called IgM storage papules on the extensor surface of the extremities—macroglobulinemia cutis.[71] Deposition of monoclonal IgM in the lamina propria and/or submucosa of the intestine may be associated with diarrhea, malabsorption, and gastrointestinal bleeding.[72,73] Kidney involvement is less common and less severe in WM than in multiple myeloma, probably because the amount of light chain excreted in the urine is generally lower in WM than in myeloma and because of the absence of contributing factors, such as hypercalcemia, although cast nephropathy has also been described in patients with WM.[74] On the other hand, the IgM macromolecule is more susceptible to being trapped in the glomerular loops where ultrafiltration presumably contributes to its precipitation, forming subendothelial deposits of aggregated IgM proteins that occlude the glomerular capillaries.[75] Mild and reversible proteinuria may result and most patients are asymptomatic. The deposition of monoclonal light chain as fibrillar amyloid deposits (AL amyloidosis) is uncommon in patients with WM.[76] Clinical findings and prognosis are similar to those of other AL patients with involvement of heart (44%), kidneys (32%), liver (14%), lungs (10%), peripheral/autonomic nerves (38%), and soft tissues (18%) occurring. However, the incidence of cardiac and pulmonary involvement is higher in patients with a monoclonal IgM than with other immunoglobulin isotypes. The association of WM with reactive amyloidosis (AA) has been documented rarely.[77,78] Simultaneous occurrence of fibrillary glomerulopathy, characterized by glomerular deposits of wide noncongophilic fibrils and amyloid deposits, has been reported in WM.[79]

Manifestations Related to Tissue Infiltration by Neoplastic Cells

Tissue infiltration by neoplastic cells is rare but can involve various organs and tissues, from the bone marrow to the liver, spleen, lymph nodes, and possibly the lungs, gastrointestinal tract, kidneys, skin, eyes, and central nervous system. Pulmonary involvement in the form of masses, nodules, diffuse infiltrate, or pleural effusions is relatively rare, since the overall incidence of pulmonary and pleural findings reported for WM is only 3% to 5%.[80–82] Cough is the most common presenting symptom in such patients, followed by dyspnea and chest pain. Chest radiographic findings include parenchymal infiltrates, confluent masses, and effusions. Malabsorption, diarrhea, bleeding, or obstruction may indicate involvement of the gastrointestinal tract at the level of the stomach, duodenum, or small intestine.[83–86] In contrast to multiple myeloma, infiltration of the kidney interstitium with lymphoplasmacytoid cell has been reported in WM,[87] whereas renal or perirenal masses are not uncommon.[88] The skin can be the site of dense lymphoplasmacytic infiltrates, similar

to that seen in the liver, spleen, and lymph nodes, forming cutaneous plaques and, rarely, nodules.[89] Chronic urticaria and IgM gammopathy are the two cardinal features of the Schnitzler syndrome, which is not usually associated initially with clinical features of WM,[90,91] although evolution to WM is not uncommon. Thus, close follow-up of these patients is warranted. Invasion of articular and periarticular structures by WM malignant cells is rarely reported.[92] The neoplastic cells can infiltrate the periorbital structures, lacrimal gland, and retroorbital lymphoid tissues, resulting in ocular nerve palsies.[93,94] Direct infiltration of the central nervous system by monoclonal lymphoplasmacytic cells as infiltrates or as tumors constitutes the rarely observed Bing–Neel syndrome, characterized clinically by confusion, memory loss, disorientation, and motor dysfunction (reviewed in Civit et al[95]).

LABORATORY INVESTIGATIONS AND FINDINGS

Hematologic Abnormalities

Anemia is the most common finding in patients with symptomatic WM and is caused by a combination of factors: mild decrease in red cell survival, impaired erythropoiesis, hemolysis, moderate plasma volume expansion, and blood loss from the gastrointestinal tract. Red cells are usually normocytic and normochromic, and rouleaux formation is often pronounced. The mean corpuscular volume as determined by an automated analyzer may be spuriously elevated owing to erythrocyte aggregation. In addition, the hemoglobin estimate can be inaccurate, that is, falsely high, because of interaction between the monoclonal protein and the diluent used in some automated analyzers.[96] Leukocyte and platelet counts are usually normal at presentation, although patients may occasionally present with severe thrombocytopenia. As reported above, monoclonal B-lymphocytes expressing surface IgM and late-differentiation B-cell markers are rarely detected in blood by flow cytometric analysis. A raised erythrocyte sedimentation rate is frequently observed in patients with WM and may be the first clue to the presence of the macroglobulin. The clotting abnormality detected most frequently is prolongation of the thrombin time. AL amyloidosis should be suspected in all patients with nephrotic syndrome, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Diagnosis requires the demonstration of green birefringence under polarized light of amyloid deposits stained with Congo red.

Biochemical Investigations

High-resolution electrophoresis combined with immunofixation of serum and urine is recommended for identification and characterization of the IgM monoclonal protein. The light chain of the monoclonal IgM is κ in 75% to 80% of patients. A few WM patients have more than one M-component. The concentration of the serum monoclonal protein is very variable but in most cases lies within the range of 15 to 45 g/L. Densitometry should be utilized to serially quantitate IgM levels because nephelometry is unreliable and shows large intralaboratory as well as interlaboratory variation. The presence of cold agglutinins or cryoglobulins may affect the determination of IgM levels and, therefore, testing for cold agglutinins and cryoglobulins should be performed at diagnosis. If present, subsequent serum samples should be analyzed under warm conditions for determination of serum monoclonal IgM level. Although Bence Jones proteinuria is frequently present, it exceeds 1 g/24 hours in only 3% of cases. Although IgM levels are elevated in WM patients, IgA and IgG levels are most often depressed and do not recover even after successful treatment.[97] In recent studies by Hunter et al,[98] mutations in the receptor transmembrane activator and calcium modulator and cytophilin–ligand interactor (TACI) were demonstrated in WM patients akin to those observed in patients with common variable deficiency disorder (CVID) suggesting a possible CVID background for WM patients.

Serum Viscosity

Because of its large size (almost 1,000,000 Da), most IgM molecules are retained within the intravascular compartment and can exert an undue effect on serum viscosity. Therefore, serum viscosity should be measured if the patient has signs or symptoms of hyperviscosity syndrome. Fundoscopy remains an excellent indicator of clinically relevant hyperviscosity. Among the first clinical signs of hyperviscosity, the appearance of peripheral and midperipheral dot and blot-like hemorrhages in the retina, which are best appreciated with indirect ophthalmoscopy and scleral depression.[45] In more severe cases of hyperviscosity, dot-, blot-, and flame-shaped hemorrhages can appear in the macular area along with markedly dilated and tortuous veins with focal constrictions resulting in "venous sausaging," as well as papilledema (Fig. 88–3).

Bone Marrow Findings

The bone marrow is always involved in WM. Central to the diagnosis of WM is the demonstration, by trephine biopsy, of *bone marrow infiltration by a lymphoplasmacytic cell population* constituted by small lymphocytes with evidence of plasmacytoid/plasma cell differentiation (Figs. 88–1 88–2B–D). The pattern of bone marrow infiltration may be diffuse, interstitial, or nodular, showing usually an intertrabecular pattern of infiltration. A solely paratrabecular pattern of infiltration is unusual and should raise the possibility of the diagnosis of a follicular lymphoma.[1] The marrow lymphoid infiltration should routinely be confirmed by *immunophenotypic studies* (flow cytometry and/or immunohistochemistry) showing the following profile: sIgM$^+$CD19$^+$CD20$^+$CD22$^+$CD79$^+$.[26–28] Up to 20% of cases may express either CD5, CD10, or CD23.[29] In these cases, care should be taken to satisfactorily exclude chronic lymphocytic leukemia and mantle cell lymphoma.[1] Intranuclear periodic acid–Schiff (PAS)-positive inclusions (Dutcher–Fahey bodies, see Fig. 88–1C)[99] consisting of IgM deposits in the perinuclear space, and sometimes in intranuclear vacuoles, may be seen occasionally in lymphoid cells in WM. An increased number of mast cells, usually in association with the lymphoid aggregates, is commonly found in WM, and their presence may help in differentiating WM from other B-cell lymphomas (see Fig. 88–1D).[2,3]

Other Investigations

Magnetic resonance imaging (MRI) of the spine in conjunction with computed tomography (CT) of the abdomen and pelvis are useful in evaluating the disease status in patients with WM.[100] Bone marrow involvement can be documented by MRI studies of the spine in more than 90% of patients, whereas CT of the abdomen and pelvis demonstrated enlarged nodes in 43% of WM patients.[100] A Lymph node biopsy may show preserved architecture or replacement by infiltration of neoplastic cells with lymphoplasmacytoid, lymphoplasmacytic, or polymorphous cytologic patterns. The residual disease after high-dose chemotherapy with allogeneic or autologous stem-cell rescue can be monitored by polymerase chain reaction (PCR)-based methods using primers specific for the monoclonal Ig variable regions.

PROGNOSIS

Waldenström macroglobulinemia typically presents as an indolent disease though considerable variability in prognosis can be observed. The median survival reported in several large series has ranged from 5 to 10 years.[101–107] Age is consistently an important prognostic factor (>60–70 years),[101,102,104,107] but this factor is often affected by comorbidities. Anemia, which reflects both marrow involvement and the serum level of the IgM monoclonal protein (because of the impact of IgM on intravascular fluid retention), has emerged as a

Table 88–3 Prognostic Scoring Systems in Waldenstrom Macroglobulinemia

Study	Adverse Prognostic Factors	Number of Groups	Survival
Gobbi et al[101]	Hb <9 g/dL Age >70 years Weight loss Cryoglobulinemia	0–1 prognostic factors 2–4 prognostic factors	Median: 48 months Median: 80 months
Morel et al[102]	Age ≥65 years Albumin <4 g/dL Number of cytopenias: Hb <12 g/dL Platelets <150 × 10^9/L Wbc <4 × 10^9/L	0–1 prognostic factors 2 prognostic factors 3–4 prognostic factors	5 year: 87% 5 year: 62% 5 year: 25%
Dhodapkar et al[103]	β_2M ≥3 g/dL Hb <12 g/dL IgM <4 g/dL	β_2M <3 mg/dL + Hb ≥12 g/dL β_2M <3 mg/dL + Hb <12 g/dL β_2M ≥3 mg/dL + IgM ≥4 g/dL β_2M ≥3 mg/dL + IgM <4 g/dL	5 year: 87% 5 year: 63% 5 year: 53% 5 year: 21%
Application of International Staging System Criteria for Myeloma to WM Dimopoulos et al[105]	Albumin ≤3.5 g/dL β_2M ≥3.5 mg/L	Albumin ≥3.5 g/dL + β_2M <3.5 mg/dL Albumin ≤3.5 g/dL + β_2M <3.5 or β_2M 3.5–5.5 mg/dL β_2M >5.5 mg/dL	Median: NR Median: 116 months Median: 54 months
International Prognostic Scoring System for WM Morel et al[107]	Age >65 years Hb <11.5 g/dL Platelets <100 × 10^9/L β_2M >3 mg/L IgM >7 g/dL	0–1 prognostic factors* 2 prognostic factors** 3–5 prognostic factors *excluding age **or age >65	5 year: 87% 5 year: 68% 5 year: 36%

strong adverse prognostic factor with hemoglobin levels less than 9–12 g/dL being associated with decreased survival in several series.[101–104,107] The cytopenias have also been regularly identified as a significant predictor of survival.[96] However, the precise level of cytopenias that has prognostic significance remains to be determined.[104] Some series have identified a platelet count less than 100–150 × 10^9/L and a granulocyte count less than 1.5 × 10^9/L as independent prognostic factors.[101,102,104,107] The number of cytopenias in a given patient has been proposed as a strong prognostic factor.[102] Serum albumin levels have also correlated with survival in WM patients in certain but not all studies using multivariate analyses.[102,104,105] High beta-2 microglobulin levels (>3–3.5 g/dL) have been reported in several studies,[103–107] a high serum IgM M-protein (>7 g/dL)[107] as well as a low serum IgM M-protein (<4 g/dL)[105] and the presence of cryoglobulins[101] to be adverse factors. Several prognostic scoring systems have been developed based on the parameters outlined above (Table 88–3).

TREATMENT OF WALDENSTRÖM MACROGLOBULINEMIA

As part of the 2nd International Workshop on Waldenström macroglobulinemia, a consensus panel was organized to recommend criteria for the initiation of therapy in patients with WM.[104] The panel recommended that initiation of therapy should not be based on the IgM level per se, since this may not correlate with the clinical manifestations of WM. The consensus panel, however, agreed that initiation of therapy was appropriate for patients with constitutional symptoms, such as recurrent fever, night sweats, fatigue due to anemia, or weight loss. The presence of progressive symptomatic lymphadenopathy or splenomegaly provides additional reasons to begin therapy. The presence of anemia with a hemoglobin value of 10 g/dL or less or a platelet count of 100 × 10^9/L or less owing to marrow infiltration also justifies treatment. Certain complications, such as hyperviscosity syndrome, symptomatic sensorimotor peripheral neuropathy, systemic amyloidosis, renal insufficiency, or symptomatic cryoglobulinemia, may also be indications for therapy.[104]

FRONTLINE THERAPY

Although a precise therapeutic algorithm for therapy of WM remains to be defined given the paucity of randomized clinical trials, consensus panels composed of experts who treat WM were organized as part of the 2nd and 3rd International Workshop on Waldenström macroglobulinemia and have formulated recommendations for both frontline and salvage therapy of patients with WM based on the best available evidence. Among frontline options, the panels considered alkylating agents (eg, chlorambucil), nucleoside analogues (cladribine or fludarabine), the monoclonal antibody rituximab as well as combinations thereof as reasonable choices for the upfront therapy of WM.[108,109] Importantly, the panel felt that individual patient considerations, including the presence of cytopenias, need for more rapid disease control, age, and candidacy for autologous transplant therapy, should be taken into account in making the choice of a first-line agent. For patients who are candidates for autologous transplant therapy, and in whom such therapy is seriously considered, the panel recommended that exposure to alkylator or nucleoside analogue therapy should be limited.

Alkylating Agent-Based Therapy

Oral alkylating drugs, alone and in combination with steroids, have been extensively evaluated for the upfront treatment of WM. The greatest experience with oral alkylating agent therapy has been with chlorambucil, which has been administered on both a continuous (ie, daily-dose schedule) and intermittent schedule. Patients receiving chlorambucil on a continuous schedule typically receive 0.1 mg/kg per day, whereas on the intermittent schedule patients will typically receive 0.3 mg/kg for 7 days, every 6 weeks. In a prospective randomized study, Kyle et al[110] reported no significant difference in the overall response rate between these schedules, although interestingly the median response duration was greater for patients receiving intermittent versus continuously dosed chlorambucil (46 vs 26 months). Despite the favorable median response duration in this study for use of the intermittent schedule, no difference in the median overall survival was observed. Moreover, an increased incidence of develop-

ing myelodysplasia and acute myeloid leukemia was associated with the intermittent (3 of 22 patients) versus the continuous (0 of 24 patients) chlorambucil schedule, which prompted the authors to express preference for use of continuous chlorambucil dosing. The use of steroids in combination with alkylating agent therapy has also been explored. Dimopoulos and Alexanian[111] evaluated chlorambucil (8 mg/m^2) along with prednisone (40 mg/m^2) given orally for 10 days, every 6 weeks, and reported a major response (ie, reduction of IgM by greater than 50%) in 72% of patients. Non–chlorambucil-based alkylating agent regimens employing melphalan and cyclophosphamide in combination with steroids have also been examined by Petrucci et al[112] and Case et al[113] producing slightly higher overall response rates and response durations, although the benefit of these more complex regimens over chlorambucil remains to be demonstrated. Facon et al[114] have evaluated parameters predicting response to alkylating agent therapy. Their studies in patients receiving single-agent chlorambucil demonstrated that age 60, male sex, symptomatic status, and cytopenias (but, interestingly, not high tumor burden and serum IgM levels) were associated with poor response to alkylating agent therapy. Additional factors to be taken into account in considering alkylating agent therapy for patients with WM include necessity for more rapid disease control given the slow nature of response to alkylating agent therapy, as well as consideration for preserving stem cells in patients who are candidates for autologous transplant therapy.

Nucleoside Stem Cell Analogue Therapy

Both cladribine and fludarabine have been extensively evaluated in untreated as well as previously treated WM patients. Cladribine administered as a single agent by continuous intravenous infusion, by 2-hour daily infusion, or by subcutaneous bolus injections for 5 to 7 days has resulted in major responses in 40% to 90% of patients who received primary therapy, whereas in the salvage setting responses have ranged from 38% to 54%.[114–121] Median time to achievement of response in responding patients following cladribine ranged from 1.2 to 5 months. The overall response rate with daily infusional fludarabine therapy administered mainly on 5-day schedules in previously untreated and treated WM patients has ranged from 38% to 100% and 30% to 40%, respectively,[122–127] which are similar to the response data achieved with cladribine. The median time to achievement of response for patients receiving fludarabine was also similar to cladribine at 3 to 6 months. In general, response rates and the duration of response have been greater for patients receiving nucleoside analogues as first-line agents, although in several of the above studies wherein both untreated and previously treated patients were enrolled, no substantial difference in the overall response rate was reported. Myelosuppression commonly occurred following prolonged exposure to each of the nucleoside analogues, as did lymphopenia with sustained depletion of both CD4$^+$ and CD8$^+$ T lymphocytes observed in WM patients 1 year following initiation of therapy.[114,116] Treatment-related mortality due to myelosuppression and/or opportunistic infections attributable to immunosuppression occurred in up to 5% of all treated patients in some series with either nucleoside analogue. Factors predictive of response to nucleoside analogues in WM included age at start of treatment (<70 years), pretreatment hemoglobin more than 95 g/dL, platelets more than 75 × 10 g/L, disease relapsing after therapy, patients with resistant disease within the first year of diagnosis, and a long interval between first-line therapy and initiation of a nucleoside analogue in relapsing patients.[114,120,126] There are limited data on the use of an alternate nucleoside analogue to salvage patients whose disease relapsed or demonstrated resistance after cladribine or fludarabine therapy.[128,129] Three of four (75%) patients responded to cladribine therapy when used to salvage patients who progressed following an unmaintained remission to fludarabine, whereas only 1 of 10 (10%) with disease resistant to fludarabine responded to cladribine.[128] Lewandowski et al[129] reported a response in two of six patients (33%) and disease stabilization in the remaining patients to fludarabine, in spite of an inadequate response or progressive disease following cladribine therapy. The long-term safety of nucleoside analogues in WM was recently examined by Leleu et al[130] in a large series of WM patients. A sevenfold increase in transformation to an aggressive lymphoma, and a threefold increase in the development of acute myeloid leukemia/myelodysplasia was observed among patients who received a nucleoside analogue versus other therapies for their WM.

CD20-Directed Antibody Therapy

Rituximab is a chimeric monoclonal antibody that targets CD20, a widely expressed antigen on lymphoplasmacytic cells in WM.[131] Several retrospective and prospective studies have indicated that rituximab, when used at standard doses (ie, 4 weekly infusions at 375 mg/m^2), induced major responses in approximately 27% to 35% of previously treated and untreated patients.[132–138] Furthermore, it was shown in some of these studies, that patients who achieved minor responses or even stable disease benefited from rituximab as evidenced by improved hemoglobin levels and platelet counts, and reduction of lymphadenopathy and/or splenomegaly. The median time to treatment failure in these studies ranged from 8 to 27+ months. Studies evaluating an extended rituximab schedule consisting of 4 weekly courses at 375 mg/m^2/week repeated 3 months later by another 4-week course have demonstrated major response rates of 44% to 48%, with estimates of time to progression ranging from 16+ to 29+ months.[138,139]

In many WM patients, a transient increase of serum IgM may be noted immediately following initiation of treatment with rituximab. Such an increase is not indicative of treatment failure, and whereas most patients will return to their baseline serum IgM level by 12 weeks some will continue to show prolonged elevations despite demonstrating a reduction in their bone marrow tumor load.[140–142] However, patients with baseline serum IgM levels more than 50 g/dL or serum viscosity greater than 3.5 cp may be particularly at risk for developing a hyperviscosity-related event, and in such patients plasmapheresis should be considered in advance of rituximab therapy.[141] Because of the decreased likelihood of response in patients with higher IgM levels, as well as the possibility that serum IgM and viscosity levels may abruptly rise, rituximab monotherapy should not be used as sole therapy for the treatment of patients at risk for hyperviscosity symptoms.

Time to response after rituximab is slow and exceeds 3 months on the average. The time to best response in one study was 18 months.[139] Patients with baseline serum IgM levels less than 40 to 60 g/L are more likely to respond, irrespective of the underlying bone marrow involvement by tumor cells.[138,139] A recent analysis of 52 patients who were treated with single-agent rituximab has indicated that the objective response rate was significantly lower in patients who had either a low serum albumin (<35 g/L) or an elevated serum monoclonal protein (>40 g/L M-spike). Furthermore, the presence of both adverse prognostic factors was related with a short time to progression (3.6 months). Moreover patients who had normal serum albumin levels and relatively low serum monoclonal protein enjoyed a substantial benefit from rituximab, with a time to progression exceeding 40 months.[143]

The genetic background of patients may also determine the success rate with rituximab therapy. In particular, a correlation between polymorphisms at position 158 in the Fc gamma RIIIa receptor (CD16), an activating Fc receptor on important effector cells that mediate antibody-dependent cell-mediated cytotoxicity (ADCC), and rituximab response has been observed in WM patients. Individuals may encode either the amino acid valine or phenylalanine at position 158 in the FcγRIIIa receptor. WM patients who carried the valine amino acid (either in a homozygous or heterozygous pattern) had a fourfold higher major response rate (ie, 50% decline in serum IgM levels) to rituximab versus those patients who expressed phenylalanine in a homozygous pattern.[144]

Combination Therapy

Because rituximab is an active and a nonmyelosuppressive agent, its use in combination with a variety of chemotherapeutic agents has been explored in WM patients. Weber et al[145] administered rituximab along with cladribine and cyclophosphamide to 17 previously untreated patients with WM. At least a partial response was documented in 94% of WM patients, including a complete response in 18% of patients; with a median follow-up of 21 months no patient has relapsed. In a study performed by the Waldenström Macroglobulinemia Clinical Trials Group (WMCTG), the combination of rituximab and fludarabine was evaluated in 43 WM patients, 32 (75%) of whom were previously untreated.[146] Ninety-one percent of patients enjoyed at least a 25% decrease in serum IgM levels, and response rates were as follows: CR 7%; PR 74.4%, and MR 9.3%. Hematologic toxicity was common with grade III, IV; neutropenia was observed in 58% of patients. Two deaths occurred in this study, which may have been related to therapy-related immunosuppression. With a median follow-up of 17 months, 34/39 (87%) remain in remission. The addition of rituximab to fludarabine and cyclophosphamide has also been explored in the salvage setting by Tam et al, wherein four of five patients demonstrated a response.[147] In another study of a chemotherapeutic agent in combination with rituximab, Hensel et al[148] administered rituximab along with pentostatin and cyclophosphamide to 13 patients with untreated and previously treated WM or lymphoplasmacytic lymphoma. A major response was observed in 77% or patients. In a study by Dimopoulos et al,[149] the combination of rituximab, dexamethasone, and cyclophosphamide was used as primary therapy to treat 70 patients with WM. On an intent-to-treat basis, a major response was observed in 70% of patients. With a median follow-up of 24 months, 60% of patients remain progression free. Therapy was well tolerated, though one patient died of interstitial pneumonia.

In addition to nucleoside analogue-based trials with rituximab, two studies have examined CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) in combination with rituximab (CHOP-R). In a randomized frontline study by the German Low Grade Lymphoma Study Group (GLSG) involving 72 patients (71% of whom had lymphoplasmacytic lymphoma), a significantly higher response rate (94% vs 69%) was observed among patients receiving CHOP-R versus CHOP, respectively.[150] Treon et al[151] have also evaluated CHOP-R in 13 WM patients, 8 and 5 of whom had relapsed or were refractory to nucleoside analogues and single-agent rituximab, respectively. Among the 13 evaluable patients, 10 patients achieved a major response (77%), including 3 CR and 7 PR, and 2 patients achieved a minor response.

The addition of alkylating agents to nucleoside analogues has also been explored in WM. Weber et al[145] administered two cycles of oral cyclophosphamide along with subcutaneous cladribine to 37 patients with previously untreated WM. At least a partial response was observed in 84% of patients, and the median duration of response was 36 months. Dimopoulos et al[152] examined fludarabine in combination with intravenous cyclophosphamide and observed partial responses in 6 of 11 (55%) WM patients with either primary refractory disease or who had relapsed on treatment. The combination of fludarabine plus cyclophosphamide was also evaluated in a recent study by Tamburini et al[153] involving 49 patients, 35 of whom were previously treated. Seventy-eight percent of the patients in this study achieved a response, and the median time to treatment failure was 27 months. Hematologic toxicity was commonly observed and three patients died of treatment-related toxicities. Two interesting findings in this study was the development of acute leukemia in two patients, histologic transformation to diffuse large cell lymphoma in one patient, and two cases of solid tumors prostate and melanoma), as well as failure to mobilize stem cells in four of six patients.

In view of the above data, the consensus panel on therapeutics amended its original recommendations for the therapy of WM to include the use of combination therapy with either nucleoside analogues and alkylating agents, or rituximab in combination with nucleoside analogues, nucleoside analogues plus alkylating agents, or combination chemotherapy such as CHOP as reasonable therapeutics options for the treatment of WM.[109]

SALVAGE THERAPY INCLUDING NOVEL AGENTS

For relapsed patients or those who have refractory disease, the consensus panels recommended the use of an alternative first-line agent as defined above, with the caveat that for those patients for whom autologous stem cell transplantation was being seriously considered, further exposure to stem cell-damaging agents (ie, many alkylating agents and nucleoside analogue drugs) should be avoided, and a non–stem cell toxic agent such as cyclophosphamide and thalidomide should be considered if stem cell grafts had not previously been harvested.[108,109] Recent studies have also demonstrated activity of several novel agents including bortezomib, thalidomide alone or in combination, and alemtuzumab. These agents can be considered for the treatment of relapsed/refractory WM. Lastly, autologous stem cell transplant remains an option as salvage therapy of WM patients particularly younger patients who have had multiple relapses, or have primary refractory disease.

Proteosome Inhibitors

Bortezomib, a stem cell-sparing agent,[154,155] is a proteosome inhibitor that induces apoptosis of primary WM lymphoplasmacytic cells, at pharmacologically achievable levels.[156] Moreover, bortezomib may also affect the bone marrow microenvironmental support for lymphoplasmacytic cells.[157] In a multicenter study of the Waldenström Macroglobulinemia Clinical Trials Group (WMCTG),[158] 27 patients received up to eight cycles of bortezomib at 1.3 mg/m^2 on days 1, 4, 8, and 11. All but one patient had relapsed/or had refractory disease. Following therapy, median serum IgM levels declined from 4.7 g/L to 2/.1 g/L ($P < 0.0001$). The overall response rate was 85%, with 10 and 13 patients achieving a minor (<25% decrease in IgM) and major (<50% decrease in IgM) response. Responses were promptly achieved, and occurred at a median of 1.4 months. The median time to progression for all responding patients in this study was 7.9 (range 3–21.4+) months, and the most common grade III/IV toxicities occurring in 5% or more of patients were sensory neuropathies (22.2%); leukopenia (18.5%); neutropenia (14.8%); dizziness (11.1%); and thrombocytopenia (7.4%). Importantly, sensory neuropathies resolved or improved in nearly all patients following cessation of therapy. As part of an NCI-Canada study, Chen et al[159] treated 27 patients with both untreated (44%) and previously treated (56%) disease. Patients in this study received bortezomib utilizing the standard schedule until they either demonstrated progressive disease, or two cycles beyond a complete response or stable disease was documented. The overall response rate in this study was 78%, with major responses observed in 44% of patients. Sensory neuropathy occurred in 20 patients, 5 with grade III and above, and occurred following two to four cycles of therapy. Among the 20 patients developing a neuropathy, 14 patients resolved and 1 patient demonstrated a one-grade improvement at 2 to 13 months. In addition to the above experiences with bortezomib monotherapy in WM, Dimopoulos et al[160] observed major responses in 6 of 10 (60%) previously treated WM patients treated with bortezomib, whereas Goy et al[161] observed a major response in one of two WM patients included in a series of relapsed or refractory patients with non-Hodgkin lymphoma (NHL) treated with this agent.

CD52-Directed Antibody Therapy

Alemtuzumab is a humanized monoclonal antibody that targets CD52, an antigen widely expressed on WM bone marrow LPC, as well as on mast cells that are increased in the bone marrow of patients with WM. These mast cells provide growth and survival signals to WM LPC through several TNF family ligands (CD40L, APRIL,

BLYS). As part of a WMCTG effort,[162] 28 subjects with the REAL/WHO clinicopathologic diagnosis of LPL, including 27 patients with IgM (WM) and 1 with IgA monoclonal gammopathy, were enrolled in this prospective, multicenter study. Five patients were untreated and 23 were previously treated, all of whom had previously received rituximab. Patients received three daily test doses of alemtuzumab (3, 10, and 30 mg IV) followed by 30 mg alemtuzumab IV three times a week for up to 12 weeks. All patients received acyclovir and Bactrim or equivalent prophylaxis for the duration of therapy plus 8 weeks following the last infusion of alemtuzumab. Among 25 patients evaluable for response, the overall response rate was 76%, which included 8 (32%) major responders and 11 (44%) minor responders. Hematologic toxicities were common among previously treated (but not untreated) patients and included grade III/IV neutropenia 39%; thrombocytopenia 18%; anemia 7%. Grade III/IV nonhematologic toxicity for all patients included dermatitis 11%; fatigue 7%; and infection 7%. CMV reactivation and infection was commonly seen among previously treated patients and may have been responsible for one death. With a median follow-up of 8.5+ months, 11/19 responding patients remain free of progression. High rates of response with the use of alemtuzumab as salvage therapy have also been reported by Owen et al[163] in a small series of heavily pretreated WM patients (with a median of four prior therapies who received up to 12 weeks of therapy (at 30 mg IV TIW) following initial dose escalation. Among the seven patients receiving alemtuzumab, five patients achieved a partial response and one patient a complete response. Infectious complications were common, with CMV reactivation occurring in three patients requiring ganciclovir therapy, and hospitalization for three patients for bacterial infections. Opportunistic infections occurred in two patients and were responsible for their deaths. An upfront study by the WMCTG examining the role of alemtuzumab in combination with rituximab is anticipated given the efficacy results reported in the above studies.

Thalidomide and Lenalidomide

Treatment with thalidomide as a single agent, and in combination with dexamethasone and clarithromycin, has also been examined in patients with WM, in view of the success of these regimens in patients with advanced multiple myeloma. Dimopoulos et al[164] reported a major response in 5 of 20 (25%) previously untreated and treated patients who received single-agent thalidomide. Dose escalation from the starting dose of 200 mg daily was hindered by development of side effects, including the development of peripheral neuropathy in five patients, requiring discontinuation of therapy or dose reduction. Low doses of thalidomide (50 mg orally daily) in combination with dexamethasone (40 mg orally once a week) and clarithromycin (250 mg orally twice a day) have also been examined, with 10 of 12 (83%) previously treated patients experiencing at least a major response.[165] However, in a follow-up study by Dimopoulos et al[166] using a higher thalidomide dose (200 mg orally daily) along with dexamethasone (40 g orally once a week) and clarithromycin (500 mg orally twice a day), only 2 of 10 (20%) previously treated patients responded. In a previous study, thalidomide and its analogue lenalidomide significantly augmented rituximab-mediated antibody-dependent cell-mediated cytotoxicity (ADCC) against lymphoplasmacytic cells.[167] Moreover, an expansion of natural killer cells has been observed with thalidomide, which in previous studies have been shown to be associated with a response from rituximab.[168,169] In view of these data, the WMCTG has conducted two phase II clinical trials in symptomatic patients with WM combining thalidomide or lenalidomide with rituximab.[170] Therapy consisted of thalidomide administered at 200 mg daily for 2 weeks, followed by 400 mg daily thereafter for 1 year. Patients received four weekly infusions of rituximab at 375 mg/m^2 beginning 1 week after initiation of thalidomide, followed by four additional weekly infusions of rituximab at 375 mg/m^2 beginning at week 13. Twenty-three of 25 patients were evaluable in this study and responses included: CR (n = 1); PR (n = 15); MR (n = 2); SD (n = 1) for an overall (ORR) and a major response rate of 78% and 70%, respectively. Median serum IgM levels decreased from 3. 7 (0.91–8.1 g/L) to 1.6 (.36–5.2 g/L) ($P < 0.001$), whereas the median hematocrit level rose from 33.0 (23.6%–42.6%) to 37.6% (29.3%–44.3%) ($P = 0.004$). With a median follow-up of 42+ months, the median TTP for evaluable patients on this study was 35 months, and 38+ months for responders. Responses were associated with a median cumulative thalidomide dose: CR/PR/MR (29,275 mg) vs SD/NR (7400 mg); $P = 0.004$. Responses were unaffected by FcγRIIIA-158 polymorphism status (81% vs 71% for VV/FV vs FF); IgM (78% vs 80% for <6000 mg/dL vs ≥6000 mg/dL); and B_2M (71% vs 89% for <3 g/dL vs ≥3 g/dL). Reduction of thalidomide dose occurred in all patients and led to discontinuation in 11 patients. Among 11 patients experiencing grade II or more neuroparesthesias, 10 demonstrated resolution to grade I (n = 3) or complete resolution (n = 7) after a median of 6.7 months (range 0.4–22.5).

In a phase II study of lenalidomide and rituximab in WM,[171] patients were treated with lenalidomide at a dose of 25 mg daily wherein therapy was administered for 3 weeks, followed by a 1 week pause for 48 weeks. Patients received 1 week of therapy with lenalidomide, after which rituximab (375 mg/m^2) was administered weekly on weeks 2 to 5, then 13 to 16. Twelve of 16 patients were evaluable and responses included: PR (n = 4); MR (n = 4); SD (n = 3); NR (n = 1) for an overall and a major response rate of 67% and 33%, respectively, and a median TTP of 15.6 months. In two patients with bulky disease, a significant reduction in node/spleen size was observed. An acute reduction in hematocrit was observed during the first 2 weeks of lenalidomide therapy in 13/16 (81%) patients, with a median hematocrit reduction of 4.4% (1.7%–7.2%), resulting in hospitalization in four patients. Despite reduction in starting doses to 5 mg daily, anemia continued to be problematic without evidence of hemolysis or more general myelosuppression. Therefore, the mechanism for pronounced anemia in WM patients receiving lenalidomide remains to be determined and the use of this agent among WM patients remains investigational.

HIGH-DOSE THERAPY AND STEM CELL TRANSPLANTATION

The use of transplant therapy has also been explored in patients with WM. Desikan et al[172] reported their initial experience of high-dose chemotherapy and autologous stem cell transplant, which has more recently been updated by Munshi et al.[173] Their studies involved eight previously treated WM patients between the ages of 45 and 69 years, who received either conditioning prior to transplant with melphalan at 200 mg/m^2 (n = 7) or melphalan at 140 mg/m^2 along with total body irradiation. Stem cell grafts were successfully collected in all eight patients, although a second collection procedure was required for two patients who had extensive prior nucleoside analogue exposure. There were no transplant-related mortalities and toxicities were manageable. All eight patients responded, with seven of eight patients achieving a major response, and one patient achieving a complete response, with duration of response ranging from 5+ to 77+ months. Dreger et al[174] investigated the use of the DEXA-BEAM (dexamethasone, BCNU, etoposide, cytarabine, melphalan) regimen followed by myeloablative therapy with cyclophosphamide, and total body irradiation and autologous stem cell transplantation in seven WM patients, which included four untreated patients. Serum IgM levels declined by more than 50% following DEXA-BEAM and myeloablative therapy for six of seven patients, with progression-free survival ranging from 4+ to 30+ months. All three evaluable patients, who were previously treated, also attained a major response in a study by Anagnostopoulos et al[175] in which WM patients received various preparative regimens and showed event-free survivals of 26+, 31, and 108+ months. Tournilhac et al[176] recently reported the outcome of 18 WM patients in France who received high-dose chemotherapy followed by autologous stem cell transplantation. All patients were previously treated with a median of three (range 1–5) prior regimens.

Table 88–4 Summary of Updated Response Criteria from the 3rd International Workshop on Waldenström Macroglobulinemia[174]

Complete response (CR)	Disappearance of monoclonal protein by immunofixation; no histological evidence of bone marrow involvement, and resolution of any adenopathy/organomegaly (confirmed by CT scan), along with no signs or symptoms attributable to WM. Reconfirmation of the CR status is required at least 6 weeks apart with a second immunofixation.
Partial response (PR)	A ≥50% reduction of serum monoclonal IgM concentration on protein electrophoresis and ≥50% decrease in adenopathy/organomegaly on physical examination or on CT scan. No new symptoms or signs of active disease.
Minor response (MR)	A ≥25% but <50% reduction of serum monoclonal IgM by protein electrophoresis. No new symptoms or signs of active disease.
Stable disease	A <25% reduction and <25% increase of serum monoclonal IgM by electrophoresis without progression of adenopathy/organomegaly, cytopenias or clinically significant symptoms due to disease and/or signs of WM.
Progressive disease (PD)	A ≥25% increase in serum monoclonal IgM by protein electrophoresis confirmed by a second measurement or progression of clinically significant findings due to disease (ie, anemia, thrombocytopenia, leukopenia, bulky adenopathy/organomegaly) or symptoms (unexplained recurrent fever ≥38.4°C, drenching night sweats, ≥10% body weight loss, or hyperviscosity, neuropathy, symptomatic cryoglobulinemia, or amyloidosis) attributable to WM.

Therapy was well tolerated with an improvement in response status was observed for seven patients (six PR to CR; one SD to PR), whereas only one patient demonstrated progressive disease. The median event-free survival for all patients without progressive disease was 12 months. Tournilhac et al[176] have also reported the outcome of allogeneic stem cell transplantation in 10 previously treated WM patients (ages 35–46) who received a median of three prior therapies, including three patients with progressive disease despite therapy. Two of three patients with progressive disease responded, and an improvement in response status was observed in five patients. The median event-free survival for nonprogressing, evaluable patients was 31 months. Concerning in this series was the death of three patients owing to transplantation-related toxicity. Anagnostopoulos et al[177] have also reported a retrospective review of WM patients who underwent either autologous or allogeneic transplantation. Seventy-eight percent of patients in this cohort had two or more previous therapies, and 58% of them were resistant to their previous therapy. The relapse rate at 3 years was 29% in the group receiving autografts and 24% in the group receiving allografts. Nonrelapse mortality however was 40% in the allogeneic group, and 11% in the autologous group in this series. In view of the high rate of nonrelapse mortality associated with high-dose chemotherapy and allogeneic stem cell transplantation, Maloney et al[178] have evaluated the use of nonmyeloablative allogeneic stem cell transplantation in five patients with refractory WM. In this series, three of three evaluable patients (all of whom had matched sibling donors) responded with two CR and one in PR at 1 to 3 years posttransplant. In view of the above data, the consensus panel on therapeutics for WM has recommended that autologous stem cell transplantation in WM be considered in the relapsed setting, particularly among younger patients who have had multiple relapses or primary refractory disease, whereas allogeneic and reduced intensity conditioning followed by allogeneic stem cell transplantation should be undertaken ideally in the context of a clinical trial.[108,109]

RESPONSE CRITERIA IN WALDENSTRÖM MACROGLOBULINEMIA

Assessment of response to a treatment option by WM patients has not always been judged using uniform criteria. As a consequence studies using the same regimen have reported significantly different response rates. As part of the second and third International Workshops on WM, consensus panels developed guidelines for uniform response criteria in WM.[179,180] The category of minor response was adopted at the Third International Workshop of WM, given that clinically meaningful responses were observed with newer biological agents and is based on a ≥25 to <50% decrease in serum IgM level, which is used as a surrogate marker of disease in WM. In distinction, the term *major response* is used to denote a response of ≥50% in serum IgM levels, and includes partial and complete responses.[180] Response categories and criteria for progressive disease in WM based on consensus recommendations are summarized in Table 88–4. An important concern with the use of IgM as a surrogate marker of disease is that it can fluctuate, independent of tumor cell killing, particularly with newer biologically targeted agents such as rituximab and bortezomib.[140–142,158,181] Rituximab induces a spike or flare in serum IgM levels that can last for months, whereas bortezomib can suppress IgM levels apparently independent of tumor cell killing in certain patients. In circumstances where the serum IgM levels appear out of context with the clinical progress of the patient, a bone marrow biopsy should be considered in order to clarify the patient's underlying disease burden. Soluble CD27 is currently being investigated by Ho et al[36] as an alternative surrogate marker in WM.

CHAPTER 89

IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS (PRIMARY AMYLOIDOSIS)*

Morie A. Gertz, Martha Q. Lacy, Angela Dispenzieri, and Suzanne R. Hayman

BACKGROUND

In 1858, Rudolf Virchow described the reaction of amyloid deposits with iodine and sulfuric acid.[1] This reaction was considered a marker for starch; hence Virchow used the term *amyloid*, meaning "starch-like," to describe the deposits. At approximately the same time, Professor Carl Rokitansky in Vienna had recognized lardaceous deposits in the viscera of patients with tuberculosis or syphilis.[2] The white shiny appearance of these deposits led him to conclude that they were of fat origin. Later, Carl Friedreich recognized that the waxy spleen described by Virchow contained no material structurally similar to cellulose and determined that the deposits were probably albuminoid.[3] Sir Samuel Wilks, the first physician to use bromide in the treatment of epilepsy, reported on a patient who had lardaceous changes of the liver with no obvious cause.[4] This may have been the first reported patient with primary amyloidosis (AL).

Congo red staining of amyloid was introduced by Bennhold in 1922,[5] and in 1927 Divry and Florkin described the green birefringence of amyloid under polarized light.[6] In 1959, Cohen and Calkins[7] recognized that all forms of amyloid had a fibrillar structure when viewed with the electron microscope. In 1968, Eanes and Glenner[8] reported that unlike normal proteins, which have an α-helical configuration, amyloid deposits form a β-pleated sheet, rendering them resistant to the action of solvents. The first purification of amyloid was described by Pras et al[9] in 1968. The first amyloid protein was sequenced in 1970 by Glenner et al,[10] who recognized it as the N-terminus of an immunoglobulin light chain. In 1974, Isobe and Osserman[11] first recognized that the Bence Jones proteins had a role in the pathogenesis of AL.

CLASSIFICATION

All forms of amyloid stain positively with Congo red, and this is the sine qua non for the diagnosis of this disorder. Amyloid deposits appear amorphous and extracellular when stained with hematoxylin and eosin. False-positive results have been reported with Congo red staining, however, and some experience with the technique is desirable.[12] All forms of amyloid are fibrillar in nature; the fibrils are rigid and nonbranching. In the early and mid-20th century, amyloidosis was classified by the anatomic distribution of the amyloid deposits and was assigned to one of three categories.

Familial amyloidosis was recognized by its presentation, which was usually a painful peripheral neuropathy with an autosomal-dominant inheritance pattern.[13,14] Mutations in a number of plasma proteins including transthyretin (TTR), apolipoprotein AI and AII, fibrinogen A α-chain, and lysozyme are associated with hereditary systemic amyloidosis. TTR amyloidosis is the most common and is usually associated with peripheral neuropathy. Mutations in the other proteins usually have no neuropathic consequences and instead principally cause renal and cardiac amyloidosis.

The secondary form of amyloidosis was characterized by the associated long-standing inflammatory disorder. One hundred years ago, this usually represented tuberculosis, leprosy, syphilis, and chronic infection such as bronchiectasis and osteomyelitis. Today, in Western countries, amyloidosis is commonly associated with chronic inflammatory polyarthritis syndromes such as ankylosing spondylitis and juvenile rheumatoid arthritis. It is also associated with Castleman disease and Crohn disease.

Fifty years ago, all forms of amyloidosis that were not secondary or familial were considered "primary." In the original terminology, "primary" meant "idiopathic" and most likely contained a heterogeneous combination of multiple forms of amyloidosis. Today, the term *primary amyloidosis*, or AL, refers to a systemic disorder with amyloid deposits consisting of immunoglobulin light chains or their fragments or heavy chains.

All forms of AL are associated with a clonal disorder of plasma cells, which may range from a small clonal population of 5% plasma cells or less in the bone marrow to overt multiple myeloma. Table 89–1 contains a modified classification of the more frequently described forms of amyloidosis.

PATHOPHYSIOLOGY

Amyloid fibrils can be produced in vitro by peptic digestion of purified monoclonal human immunoglobulin light chains. The light chains of patients with AL have an abnormal sequence and an abnormal tertiary structure that favors the β-pleated sheet configuration. Investigation of the thermodynamic properties of light chains that form fibrils and those that remain stable have shown an inverse relationship between thermodynamic stability and fibrillogenic potential. Structural parameters and overall thermodynamic stability contribute to the fibril-forming propensity of immunoglobulin light chains.[15] When injected into mice, immunoglobulin light chains purified from the urine of patients with AL produce human AL deposits,[16] whereas light chains from patients with multiple myeloma (and not AL) do not.

Two-thirds of patients with monoclonal gammopathy of undetermined significance or multiple myeloma have κ immunoglobulin light chains. Three-fourths of patients with amyloidosis who have a light chain have λ, which reflects the intrinsic "amyloidogenicity" of λ immunoglobulin light chains. The λ_{VI} is always associated with amyloid, suggesting that unique amino acid structures render these proteins amyloidogenic.[17]

A comparison of monoclonal proteins in AL and multiple myeloma is shown in Fig. 89–1. Amyloid-associated germline gene segments have been identified[18]; the λ_{III} family is found most frequently in amyloidosis. Two germline genes, 3r and 6a, belonging to the λ_{III} and λ_{VI} families contributed equally to encode 42% of amyloid variable λ regions. These same two gene segments have a strong association with amyloidosis and are most likely responsible for the λ light-chain overrepresentation typical of amyloidosis.[18]

The reason that patients with AL present with amyloid disease displaying organ tropism is unknown. The renal tropism of some chains was investigated.[19] Patients with clones derived from the 6a

variable λ_{VI} germline gene were more likely to present with renal involvement. Those with clones derived from the 1c, 2a2, and 3r variable λ genes were more likely to present with dominant cardiac and multisystem disease. Patients with variable κ clones were more likely to have dominant liver involvement.[19]

The classification of AL among patients with and without myeloma is usually made on the basis of clinical criteria, but considerable clinical overlap exists. The presence of multiple myeloma bone disease, such as lytic lesions, multiple compression fractures, or pathologic fractures of long bones, is rare in AL. Patients with AL and renal insufficiency rarely have myeloma cast nephropathy. Renal failure in these patients is usually tubular atrophy from glomerular amyloid and long-standing albuminuria. The percentage of bone marrow plasma cells is useful in making the distinction between AL and myeloma. We have arbitrarily defined patients as having multiple myeloma-associated amyloidosis if the bone marrow plasma cells exceed 30%.[20] Amyloidosis rarely evolves into overt multiple myeloma; it occurs in less than 0.5% of patients.[20]

The incidence of amyloidosis is 8 per million persons per year and is not increasing with time.[21] Amyloidosis is one-fourth as common as multiple myeloma but has an incidence similar to those of nodular sclerosing Hodgkin disease, Philadelphia chromosome-positive chronic myeloid leukemia, and polycythemia vera.

Chromosomal anomalies are seen often in the bone marrow plasma cells of patients with AL.[22] Studies of bone marrow samples found trisomies of chromosomes 7, 9, 11, 15, and 18 in 42%, 52%, 47%, 39%, and 33% of patients, respectively. Trisomy X was seen in 13% of women and 54% of men. Monosomy of chromosome 18 was seen in 72%. This aneuploidy supports the neoplastic nature of the disorder even though it is not proliferative over time. Fluorescence in situ hybridization analysis of the plasma cells of AL patients showed that 16 of 29 (55%) had a definite immunoglobulin heavy-chain translocation, and 5 additional patients (17%) had a pattern compatible with heavy-chain translocation.[23] Sixteen of 21 patients were confirmed to have t(11;14)(q13;q32), accounting for 76% of all immunoglobulin heavy-chain translocations.[24] Fifteen of 16 patients with an 11;14 translocation had cyclin D1 overexpression.

CLINICAL FEATURES

The most common presenting symptoms of amyloidosis are fatigue, dyspnea, edema, paresthesias, and weight loss.[25] The symptoms are generally not specific and not particularly helpful in formulating the differential diagnosis. Weight loss usually results in an investigation for occult malignancy. The fatigue can be misdiagnosed as functional or stress related. Patients with dyspnea on exertion regularly undergo coronary angiography; in most, no coronary artery disease is seen and the evaluation is halted. Lightheadedness is common but nonspecific. Hypotension is seen in patients with nephrotic syndrome because the hypoalbuminemia results in reduced oncotic pressure and contraction of the plasma volume. In cardiac AL, the stiffened heart has poor diastolic filling.[26] The stroke volume decreases, resulting in a decrease in systolic blood pressure. Amyloid autonomic neuropathy also produces orthostatic lightheadedness and occasionally syncope.[27]

The physical findings of amyloidosis can be highly specific but are only present in a minority of patients. Amyloid purpura is typical but is seen in only one-sixth of patients. The purpura occurs above the nipple line and is seen in the webbing of the neck, the face, and the eyelids (Fig. 89–2). The purpura may be subtle and limited to eyelid

Figure 89–2 Classic periorbital purpura associated with amyloidosis.

petechial lesions. Hepatosplenomegaly is seen in one-fourth of patients but is located more than 5 cm below the right costal margin in one-tenth of patients.[28] The presence of macroglossia is highly specific for AL[29]; it is not seen in familial, secondary, or senile systemic amyloidosis. Only 1 patient in 11 has an enlarged tongue; it can be overlooked because the most common finding is dental indentations on the underside of the tongue, which may not be inspected during a routine physical examination. If the tongue is enlarged, the submandibular salivary glands are also palpable (Fig. 89–3), which can be misinterpreted as submandibular lymph nodes. Salivary gland infiltration with amyloid can produce a sicca syndrome, and patients can be misdiagnosed as having Sjögren syndrome.[30]

Patients can be seen with diffuse vascular involvement without obvious visceral disease. Involvement of the small vessels supplying blood to major muscle groups can produce vascular occlusion and ischemic symptoms that include jaw,[31] calf, and limb claudication. Involvement of the coronary arteriolar system can produce true exertional angina without evidence of large vessel coronary disease. In one study, obstructive intramural coronary amyloidosis was found in 63 of 96 patients.[31] Myocardial ischemia was more common in patients with obstructive intramural coronary amyloidosis than those without (86% vs 52%). Syndromes of myocardial ischemia affected 25% of patients with obstructive intramural coronary amyloidosis.[32] For 11% of these patients, a syndrome of ischemia consisting of acute myocardial infarction or angina was the first manifestation of AL.

Most patients with AL and cardiac involvement have obstructive intramural coronary amyloidosis and associated changes of myocardial ischemia.[31] The presence of jaw claudication has led to an incorrect diagnosis of polymyalgia rheumatica.[33] Other manifestations of nonvisceral soft tissue infiltration include skeletal muscle pseudohypertrophy, which can produce the shoulder-pad sign.[34] Despite the enlargement of the muscles, patients frequently have diffuse muscular weakness and atrophy.[35] The creatine kinase concentration may be increased, which results in a polymyositis or inflammatory myopathy syndrome.

ESTABLISHING THE DIAGNOSIS OF AMYLOIDOSIS

The subjective symptoms associated with amyloidosis are vague.[36] The physical findings with AL may be highly specific but are present in only 15% of patients. Given that AL is rare, when should a clinician suspect this diagnosis and begin a diagnostic evaluation to confirm the diagnosis? The eight most common clinical syndromes associated with amyloidosis are (a) infiltrative cardiomyopathy manifesting as a spectrum from fatigue to overt congestive heart failure; (b) albuminuria with or without renal insufficiency; (c) peripheral neuropathy with demyelinating or axonal features; (d) unexplained hepatomegaly; (e) carpal tunnel syndrome; (f) enlargement of the tongue; (g) weight loss associated with intestinal symptoms of pseudoobstruction or malabsorption; and (h) "atypical myeloma" (Table 89–2). If any of these syndromes are seen in an adult, AL enters the differential diagnosis.

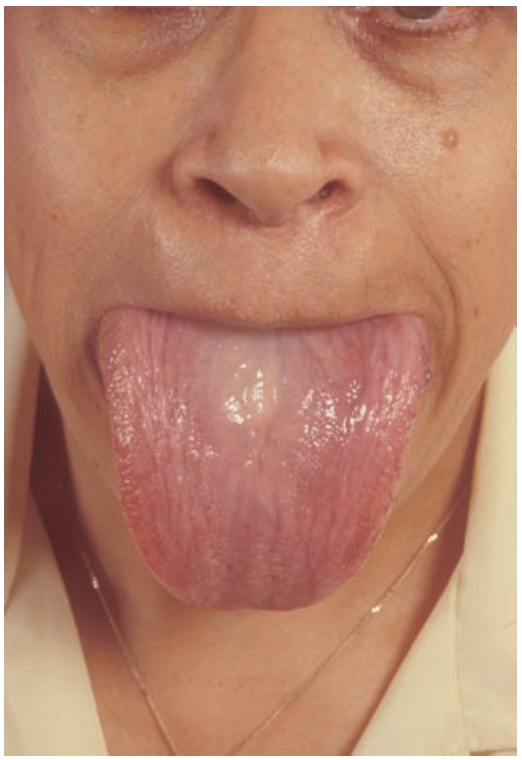

Figure 89–3 Massive enlargement of the tongue due to amyloid infiltration. This patient had severe obstructive sleep apnea, was unable to swallow solid food, and had obstructed eustachian tubes leading to bilateral serous otitis media.

Table 89–2 Syndromes in Primary Amyloidosis

Syndrome	Patients, %
Nephrotic or nephrotic and renal failure	30
Hepatomegaly	24
Congestive heart failure	22
Carpal tunnel	21
Neuropathy	17
Orthostatic hypotension	12

From Gertz MA, Lacy MQ, Dispenzieri A: Amyloidosis. In: Mehta J, Singhal S (eds.): Myeloma. London, Martin Dunitz Ltd., 2002, p 445–463. Used with permission.

Because of the presence of a monoclonal protein, patients are often extensively evaluated for multiple myeloma but are found to have less than 10% plasma cells and no lytic bone lesions, and a diagnosis of AL frequently is not considered by the clinician. By definition, patients with AL have a clonal population of plasma cells that produces the immunoglobulin light chain comprising the amyloid deposits. The finding of a monoclonal protein in a patient with a compatible syndrome would be compelling evidence for pursuing a diagnosis of AL (Fig. 89–4).

If a patient has one of the clinical syndromes outlined above, a sensitive and noninvasive screening test for AL should be used. Simple serum protein electrophoresis is not an adequate screen. The monoclonal proteins in patients with AL are frequently either small or limited to free light chains that do not produce a peak in the

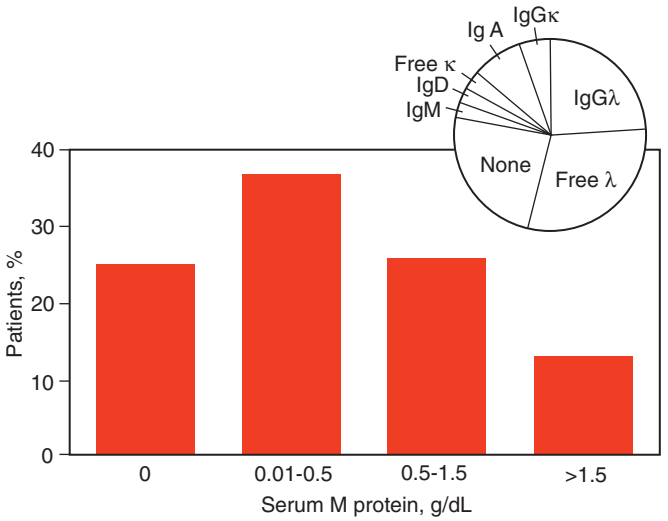

Figure 89–4 Serum monoclonal protein concentration in patients with primary amyloidosis. Pie chart shows distribution of serum immunofixation results. *(From Gertz MA, Lacy MQ, Dispenzieri A: Amyloidosis. In Mehta J, Singhal S [eds.]: Myeloma, London, Martin Dunitz Ltd, 2002, p 445–463. Figure 89–5 Distribution of urinary protein excretion in patients with primary amyloidosis. Pie chart shows results of urine immunofixation. *(From Gertz MA, Lacy MQ, Dispenzieri A: Amyloidosis. In Mehta J, Singhal S [eds.]: Myeloma, London, Martin Dunitz Ltd, 2002, p 445–463. Used with permission.)*

electrophoretic pattern. In addition, a high proportion of patients has significant albuminuria, which can obscure the presence of small monoclonal proteins in the urine (Fig. 89–5).

A serious consideration of AL requires immunofixation of serum and urine; urine immunofixation is mandatory because a fourth of patients do not have detectable light chains in the serum by immunofixation. By this method, a monoclonal light chain will be detected in 90% of patients with AL. Adding the free light-chain nephelometric assay increases the detection rate to 99%. An automated immunoassay for free light chains is more sensitive than immunofixation by at least a factor of 10. Quantification of monoclonal free light chains by nephelometry is more sensitive than immunofixation in serum samples from patients with AL and light-chain deposition disease. This method allows quantification of free light chains in patients who have no detectable serum or urine monoclonal protein concentration.[37]

Immunofixation of serum and urine combined with a free light-chain assay is the single best noninvasive screening panel when a patient is seen with a suggestive clinical syndrome. In patients who do not have a detectable light chain in the serum or urine, a bone marrow specimen will almost always demonstrate a clonal population of plasma cells by immunohistochemistry or immunofluorescence.

Because the production of immunoglobulin light chains by the plasma cells in AL is at a low level, a monoclonal protein occasionally may not be found. Presumably, the light chains are present, but the amounts are below the level of detection by conventional techniques. This may be a result of low-level production or rapid migration from the plasma compartment into the amyloid deposits. Occasionally, the light-chain fragments do not express epitopes recognizable by commercial light-chain antisera, which are directed against the entire immunoglobulin light-chain protein.

Virtually all patients with AL have a monoclonal protein in the serum or urine or clonal bone marrow plasma cells. If no immunoglobulin light chain is found in a patient with proven amyloidosis, other types of amyloidosis should be suspected, including familial, secondary, and localized. The presence of a monoclonal protein does not unequivocally prove that the amyloidosis type is AL. Three percent of patients older than 60 years have an incidental monoclonal gammopathy of undetermined significance.[38] It is therefore reasonable to believe that 3% of patients older than 60 years with localized, secondary, and familial amyloidosis have an incidental monoclonal protein in the serum. Case reports exist of patients with low-level monoclonal gammopathies associated with a nonimmunoglobulin form of amyloidosis. The possibility, albeit uncommon, of an incidental monoclonal gammopathy unrelated to the patient's amyloidosis must be kept in mind.

A nephelometric technique for analyzing circulating immunoglobulin light chains in the serum recognizes only free immunoglobulin light chains and not those that are part of the intact immunoglobulin molecule.[39,40] A study of approximately 100 patients, using antibodies specific for free immunoglobulin light chains, showed a sensitivity of nearly 90% for the nephelometric technique.[41] The sensitivity was the same for patients with κ and λ amyloid. In patients who had a known monoclonal light chain in the urine but negative serum immunofixation results, free light chains were detected in 85% of patients with κ and 80% of patients with λ. In a carefully evaluated group of patients with definite AL who had no detectable monoclonal protein in the serum or urine by immunofixation, a free light chain was found in 86% and a free λ light chain in 30%.[41]

The nephelometric method is a convenient assay for free light chain detection and allows classification of patients with amyloidosis as having AL.[42] Patients with familial, secondary, or localized amyloidosis are not expected to have an abnormal ratio of free light chains in the serum. If the serum free light-chain assay and serum and urine immunofixation results are all negative or normal, the likelihood of a diagnosis of AL is small.

The free light-chain assay also is useful in assessing the outcome of treatment of amyloidosis. Eighty-six patients whose abnormal free light-chain concentration decreased by more than 50% after chemotherapy had a 5-year survival of 88% compared with only 39% among patients for whom the free light-chain concentration did not decrease similarly.[43] The conclusion was that decrease in the free light chain by more than 50% after chemotherapy is associated with a substantial survival benefit.

The amyloid P component is a glycoprotein that comprises as much as 10% of the amyloid fibril by weight.[44] All forms of amyloid contain the P component. The amyloid P component is related structurally to C-reactive protein, an acute-phase reactant used in the screening of patients at risk for coronary artery disease. The amyloid P component is not irreversibly bound to the amyloid fibril but is in dynamic equilibrium with the normal plasma amyloid P component compartment.[45] It is found in all humans and maintains a stable plasma level throughout life.

Radiolabeled amyloid P component—with iodine 123[46] or iodine 131[47]—is a useful imaging agent for indicating amyloid deposits. Serialized serum amyloid P scintigraphic scans have been used to assess the response to therapy and have shown regression of established amyloid deposits after successful interruption of immuno-

globulin light-chain production.[48] This scan does not distinguish AL from the other forms of amyloidosis. Imaging indicates deposits in the spleen, liver, and kidneys in 87%, 60%, and 25% of patients, respectively.[49] Because of the cardiac blood pool, this technique is not useful in detecting myocardial amyloid deposits and is usually used in conjunction with echocardiography. The diagnostic sensitivity of serum amyloid P scintigraphy for AL is 90%, and specificity is 93%.[50] Myocardial uptake is not visualized in any patient. Splenic amyloid is present in 80% of patients, even though it is rarely detected clinically (14%). Tracer uptake in the liver and kidneys correlates with abnormal liver function and proteinuria. Bone marrow uptake is specific for AL but is only seen in 21%.[50]

Plasma clearance of the amyloid P component has been shown to correlate with survival. Rapid plasma clearance is associated with high body burdens of amyloid and shortened survival. Scintigraphic scans have shown that the distribution of amyloid within organs is nonhomogeneous, and imaging studies do not correlate well with the clinical degree of organ dysfunction.[51] Most patients have hepatic involvement by serum amyloid P scan, but palpable hepatomegaly with increased concentration of alkaline phosphatase is seen in no more than 15% of patients. Therapeutic clinical trials of agents that prevent the binding of amyloid P component to the amyloid fibril have been started.[52] The rationale is that inhibition of P component binding may destabilize the fibrillar structure of amyloid and result in more rapid catabolism by the body.

Although the presence of immunoglobulin free light chains, positive immunofixation results, or positive amyloid P component scans is highly suggestive of the diagnosis of AL, these findings are not substitutes for histologic confirmation of the disease. Amyloidosis is a serious life-threatening disorder, and some of the currently available therapies carry a considerable morbidity and mortality risk. Given the serious prognosis and potential for administering toxic therapies, a biopsy-proven diagnosis is vital. Although the presence of renal, cardiac, hepatic, or peripheral nerve amyloid is easily established by direct biopsy of these tissues, invasive diagnostic biopsies of these tissues are generally not required. Amyloidosis is a widespread disorder at diagnosis, with involvement of blood vessels even in the absence of clinical symptoms. Any biopsy that samples blood vessels can less invasively establish the diagnosis effectively and at a lower risk to the patient.

At Mayo Clinic, if a patient has a compatible clinical syndrome and screening suggests the presence of a free or monoclonal immunoglobulin light chain, the first diagnostic technique is generally subcutaneous fat aspiration[53] combined with bone marrow biopsy. The fat aspiration procedure performed by our nursing staff is risk free, and no infection at the site of puncture has occurred. Results are generally available in 24 to 48 hours, and the technique has a sensitivity of nearly 80% (Table 89–3). Thorough examination of three fat smears showed a sensitivity of 93% and a specificity of 100% for the test. The clinical utility of fat tissue aspiration was greater than that of rectal biopsy.[54] Fat aspiration is the preferred method for detecting amyloidosis, with a sensitivity of 80% using a routine approach and 90% with a thorough assessment by experienced interpreters.[54] Bone marrow biopsy shows amyloid deposits in half of patients if the biopsy specimen contains blood vessels.[55] A bone marrow biopsy is generally required because once a monoclonal protein has been found, determining the percentage of bone marrow plasma cells is vital to exclude the diagnosis of multiple myeloma (Fig. 89–6). In our experience, 90% of patients with AL have positive results of the subcutaneous fat aspiration and bone marrow biopsy.

Others have reported success using rectal biopsies[56] (Fig. 89–7), gingival biopsies, and minor salivary gland biopsies.[57] If noninvasive biopsies do not establish the diagnosis, biopsy of the affected organ can generally be performed quite safely. Endomyocardial biopsy is an outpatient procedure and can be done with low risk in experienced centers. Despite reports to the contrary, liver biopsy is exceedingly safe, with no reported fatalities in our experience with more than 100 liver biopsies and a bleeding risk of 4%, which required transfusion in 2%. Biopsy of uninvolved skin has been shown to be positive in 70% of patients with AL.[58]

The most common clinical presentation at Mayo Clinic is that of a patient referred to a nephrologist for nephrotic syndrome. Immunofixation of the serum and urine and free light-chain assay indicate presence of a light chain; fat aspiration is performed and is positive. Positive fat aspiration results eliminate the need for a renal biopsy in nearly 90% of patients, which results in reduced cost, eliminates the need for hospitalization, and decreases the risk to the patient.

The diagnosis of amyloidosis requires positive Congo red staining of tissues, but use of the Congo red stain is not simple.[59] False-positive results have been reported[60] because of overstaining of tissue or misinterpreting Congo red–positive fibrils of collagen and elastin as being amyloid. Conversely, we have seen patients whose rectal biopsy specimens were interpreted as collagenous colitis,[61] only later to be identified as AL. By routine hematoxylin and eosin staining, amyloid deposits in the glomerulus can be misinterpreted as hyalin. In our routine clinical practice, our cardiac pathologists prefer the sulfated alcian blue stain[62] for recognition of amyloid deposits in the myocardium. In our peripheral nerve laboratories, pathologists screen biopsy specimens with crystal violet and, if positive, subsequently confirm the diagnosis by using Congo red.

Table 89–3 Noninvasive Biopsy Results in 233 Patients with Primary Amyloidosis

Finding	No. of Patients (%)
Fat + Marrow +	138 (59)
Fat + Marrow –	30 (13)
Fat – Marrow +	38 (16)
Fat – Marrow –	27 (12)

DISTINGUISHING PRIMARY AMYLOIDOSIS FROM OTHER FORMS OF AMYLOIDOSIS

After a diagnosis of amyloidosis has been established, it is imperative to be certain that the amyloidosis is of the immunoglobulin light-chain type. Localized, familial, secondary, and senile systemic forms of amyloid are structurally dissimilar to that in AL, and the therapeutic approach is substantially different for each (Fig. 89–8). Only systemic AL has an underlying bone marrow plasma cell dyscrasia responsible for fibril deposition.

It is possible to misdiagnose hereditary amyloidosis as AL. Among 350 patients with amyloidosis in whom AL was suspected, 34 (9.7%) were found to have mutations consistent with familial amyloidosis, most often fibrinogen-A α-chain mutations and TTR mutations.[63] A low-grade monoclonal gammopathy was detected in 8 of the 34 (24%), which easily could have led to a misdiagnosis of AL. A genetic cause should be sought in all patients with amyloidosis in whom AL cannot be unequivocally confirmed by immunohistochemistry of the amyloid deposits.

The possibility of familial amyloidosis with an incidental monoclonal gammopathy must be kept in mind.[63] In 178 consecutive patients referred for amyloidosis, 54 were screened with primers to detect TTR, apolipoprotein, fibrinogen, and lysozyme variants.[64] Three patients had both a monoclonal gammopathy and an amyloid-associated mutation, were thought to have apparent AL, and were later found to have hereditary amyloidosis.[64] Techniques to unequivocally identify TTR amyloidosis include immunoaffinity chromatography and immunoprecipitation combined with mass spectrometry.[65] Matrix-assisted laser desorption ionization/time-of-flight mass spectrometry can also quickly detect TTR variants with small changes in molecular weight.[66]

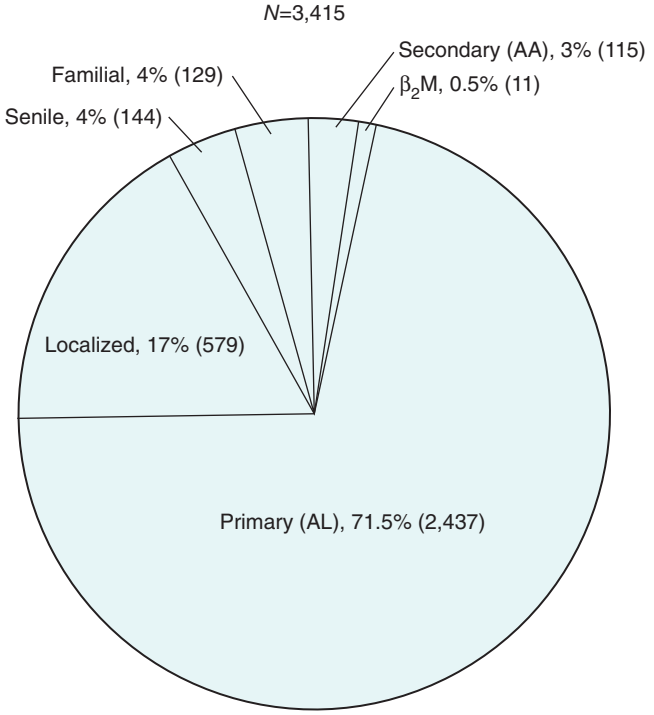

Figure 89–8 Distribution of the various forms of amyloidosis seen in patients at Mayo Clinic. β_2M, β_2-microglobulin.

Patients with localized amyloidosis can often have serious clinical problems such as hematuria, respiratory compromise, and visual disturbances. Patients with localized amyloidosis do not have development of widespread systemic vascular amyloid deposition. Localized forms of amyloidosis most commonly are derived from immunoglobulin light chains, but a bone marrow plasma cell dyscrasia is not present, and it is presumed that there was a localized synthesis of fibrillar material. Most patients with localized amyloidosis have involvement of the respiratory tract, genitourinary tract, or skin.

Amyloidosis involving the respiratory tract can be divided into tracheobronchial, pulmonary nodular, and pulmonary diffuse interstitial. The first two of these are forms of localized amyloidosis, and the third is a manifestation of systemic AL disease. In tracheobronchial amyloidosis, submucosal deposits (composed of immunoglobulin light chains) can produce obstruction, cough, dyspnea, wheezing, and hemoptysis. The most common site of involvement is the larynx and false vocal cords. The diagnosis is usually established bronchoscopically in a patient who presents with hoarseness. The treatment entails surgical excision[67] or the use of yttrium–aluminum–garnet laser resection of the tissue.[68] If extensive airway obstruction prevents passage of a bronchoscope, external beam radiotherapy (2000 cGy) can lead to dramatic improvement in symptoms, effort tolerance, bronchoscopic appearance, and forced expiratory volume in 1 second. If amyloidosis involves the pulmonary tissues, it can manifest as solitary nodules.[69] The diagnosis is usually made at thoracotomy or transthoracic needle biopsy, because these nodules are noncalcified and pulmonary malignancy must be excluded.[70]

Amyloid in the urinary bladder, urethra, or ureter is usually localized. Clinically, patients present with hematuria, and the cystoscopic findings of these bladder deposits are usually suspicious for transitional cell cancer.[71] Treatment consists of transurethral resection, fulguration, or partial cystectomy. We have experience with the use of intravesicular dimethylsulfoxide (DMSO) and have seen substantial regression of deposits in patients who were not candidates for surgical resection because of extent of disease. Amyloid in the ureter,[72] renal pelvis,[73] and urethra[74] usually presents with obstruction and colicky pain or hematuria; the preoperative diagnosis is usually malignancy. Recognition of ureteral amyloidosis is important because it prevents an unnecessary nephrectomy.

Amyloidosis of the skin can be classified into lichen, macular, or nodular.[75] The first two of these are localized forms of amyloid that never become systemic. Nodular amyloidosis may be a cutaneous manifestation of systemic AL. The deposits in macular and papular amyloidosis appear to be degenerated keratin protein.[76] Local therapy, including dermabrasion, is beneficial. An underlying inflammatory skin condition is usually present. Macular and lichen amyloidosis are benign conditions. Nodular amyloidosis is often an important clinical clue to a more serious life-threatening AL.

Amyloid found in the carpal tunnel may represent either a localized form or be part of AL.[77] Of 124 patients who had carpal tunnel syndrome as an isolated syndrome, the median survival was 12 years, and systemic AL developed in only two. Localized carpal tunnel amyloid is composed of TTR.

Diagnostic Pathway for Primary Amyloidosis

Consider primary amyloidosis in patients with
- Nephrotic-range proteinuria (nondiabetic)
- Cardiomyopathy (no ischemic history)
- Hepatomegaly (no filling defects on imaging)
- Peripheral neuropathy (nondiabetic)
- Atypical myeloma

Heighten suspicion
- Immunofixation of serum and urine, free light-chain assay

Confirm diagnosis histologically
- Fat aspirate and marrow biopsy stain with Congo red (90% sensitive)

Assess prognosis
- Echocardiography required (Doppler important)
- Brain natriuretic peptide and troponin

Treat
- Melphalan and prednisone
- High-dose corticosteroids
- Stem cell transplantation
- Organ transplantation

From Gertz MA, Lacy MQ, Dispenzieri A: Amyloidosis. In Mehta J, Singhal S (eds.): Myeloma, London, Martin Dunitz Ltd, 2002, p 445–463. Used with permission.

Amyloid may also be localized to the conjunctiva, orbits, or extraocular muscles. Conjunctival amyloid is best treated with surgical excision.[78] Localized amyloid has also been described in the breast, mesenteric lymph nodes, colon polyps, thyroid, ovary, and retroperitoneum. We have seen 4 patients with colon deposits of amyloid that resulted in bleeding, all of whom were followed up for more than 5 years without other manifestations developing. These patients had no evidence of a plasma cell dyscrasia. Finding traces of amyloid in surgical specimens from total hip arthroplasty is common.[79] Similar deposits can be seen at the time of knee arthroplasty[80] and are never associated with systemic disease.

Secondary amyloidosis (AA) also must be distinguished from AL.[81] AA can involve organs in a manner indistinguishable from AL but is not associated with an immunoglobulin light-chain disorder or clonal plasma cell disorder. AA is a consequence of long-standing uncontrolled systemic inflammation. Typically, elevation of the acute-phase proteins in the serum, serum amyloid A protein, or C-reactive protein parallel the activity of the underlying inflammatory process. In the Third World, AA is common because it can follow long-standing tuberculosis, lepromatous leprosy, malaria, and untreated syphilis. The most common clinical manifestation of AA is nephrotic-range proteinuria. Therefore, it is not easily distinguished clinically from AL.

In the West, AA is rare and found in only 2% of patients with amyloidosis at Mayo Clinic.[82] The most common causes are poorly controlled inflammatory polyarthropathies including ankylosing spondylitis,[83] juvenile rheumatoid arthritis,[84] psoriatic arthritis,[85] and rheumatoid arthritis.[86] The median duration of the arthritis is 15 years before the diagnosis of amyloidosis, and the underlying cause is usually obvious.[87]

In a 10-year study of 1000 patients with rheumatoid arthritis, 3.1% died of AA.[88] Amyloidosis can be seen in Crohn disease,[89] long-standing bronchiectasis,[90] cystic fibrosis, or chronic osteomyelitis.[91] The most common clinical manifestation is proteinuria followed by diarrhea and amyloid goiter. In these patients, the chronic, inflammatory, or infectious condition is usually present for many years and is easily recognized. These patients do not have a detectable immunoglobulin light chain or clonal plasma cell disorder. AA has been described in drug users who inject illegal substances subcutaneously.[92] The result is multiple skin abscesses that can produce the inflammation characteristic of AA.[93] Instances of AA have been described in Hodgkin disease[94] and in association with renal cell cancer.

Castleman disease (especially the plasma cell variant) complicated by AA has been reported. These patients typically present with a mesenteric mass; with successful abdominal surgery, proteinuria decreases and disappears.[95–97] Resection of the Castleman tumor has been documented to produce regression of the amyloid syndrome, even in advanced cases. AA has been seen in patients with paraparesis as a consequence of chronically infected decubitus ulcers[98] or chronic infection of the urinary tract, a consequence of urinary retention or a long-standing indwelling urinary catheter.[99] At autopsy, AA has been found in more than half of those with sustained spinal cord injuries in excess of 10 years. The presence of an amyloid goiter is characteristic of AA and is rarely seen in the other forms of amyloidosis.

AA amyloidosis can also be a consequence of hereditary periodic fevers characterized by recurrence of fever and inflammation separated by symptom-free intervals. Familial Mediterranean fever is the most frequent entity in this group, but hyperimmunoglobulinemia-D with periodic fever, tumor necrosis factor receptor-associated periodic syndrome, and cryopyrin-associated periodic syndrome are also seen.[100–102]

Familial amyloidosis is more common than AA in the United States. A clinical distinction for this variant can be difficult. These patients can present with cardiomyopathy,[103] peripheral or autonomic neuropathy,[104] and nephrotic syndrome.[105] The patients do not have a monoclonal gammopathy or plasma cell dyscrasia unless they have an incidental monoclonal gammopathy of undetermined significance. It is important to use immunostains on amyloid-containing tissues in an attempt to determine the protein subunit within the fibril. Typical immunostains include κ and λ immunoglobulin light chain, amyloid A antisera, TTR, fibrinogen, lysozyme, and apolipoprotein.

The most commonly reported forms of familial amyloidosis are a result of mutations of the TTR gene. More than 80 mutations in the TTR gene have been described and are associated with the development of either amyloid peripheral neuropathy or amyloid cardiomyopathy.[106] Half of the patients identified at Mayo Clinic with familial amyloid polyneuropathy do not have a positive family history, and lack of a family history is not useful in making the distinction.[107] Frequently, the history includes a family member dying of an obscure illness that is suspicious but has not been verified to be amyloidosis. Any patient with amyloidosis who does not have a detectable monoclonal protein or plasma cell dyscrasia should be carefully evaluated for the presence of familial amyloidosis.

Cardiac amyloidosis can be caused by mutations in the TTR gene and can also be seen with deposition of wild-type TTR in the heart.[108] So-called senile systemic amyloidosis usually manifests as amyloid cardiomyopathy in the elderly. Analysis of the cardiac deposits shows normal TTR that can be found in 8% to 25% of persons older than 80 years.[109] Familial amyloid cardiomyopathy was first recognized 45 years ago in a Danish kindred but has since been detected in pedigrees throughout the world. Onset of symptoms typically begins after age 60 years, which decreases the suspicion of a familial disorder. The clinical manifestations of both senile systemic amyloidosis and familial amyloid cardiomyopathy are quite similar: congestive heart failure or intractable rhythm disturbances. In one autopsy series, 21% of those older than 90 years had amyloid deposits.[109] Patients with senile systemic amyloidosis are older than those with AL. Proteinuria is generally not present in senile systemic amyloidosis, and the left ventricular wall thickness is substantially greater in senile systemic amyloidosis despite these patients' having less severe heart failure. The median survival has been reported to be 75 months.[110]

An important mutation of the TTR protein at position 122 was described in a 68-year-old African American man.[111] The allele responsible for this mutation is carried by 3.9% of African Americans—1.3 million people in the United States. This mutation is a major cause of cardiac amyloidosis among black Americans.[112] The finding of cardiac amyloidosis in an older adult in the absence of a monoclonal gammopathy should raise the possibility of familial amyloid cardiomyopathy or senile systemic amyloidosis.

Other mutant proteins have been shown to produce amyloidosis. Familial renal amyloidosis has been reported with deposition of a mutant fibrinogen α chain[113] or due to mutant lysozyme.[114] The clinical course in these patients is more indolent than in patients with nephrotic syndrome due to AL. We have seen such patients with slowly progressive proteinuria for more than a decade without development of extrarenal manifestations of amyloidosis and renal failure. There are no other clinical distinguishing features. Renal amyloidosis has been described in patients with mutations of apolipoprotein A-I[115] and A-II.[116] The clinical presentation is indistinguishable from that of AL; the main difference is the lack of a monoclonal immunoglobulin disorder.

Distinguishing familial amyloidosis from AL is critical because liver transplantation has been used successfully in more than 500 patients with familial amyloidosis.[117,118] In the forms of familial amyloidosis due to mutations of the TTR gene, TTR is produced in only the liver and choroid plexus, and subsequent liver transplantation induced regression of amyloid deposits.[119] The outcome of transplantation appears to be best for patients with a TTR Val30Met mutation. Liver transplantation is not curative in all. Morbidity is high in patients with significant nutritional disability before transplantation or neuronal dropout on a pretransplantation peripheral nerve biopsy. Progressive cardiac amyloidosis after liver transplantation has been reported.[120] The theory is that preexistent amyloid deposits in the myocardium, even when asymptomatic, can serve as the nidus for further deposition of wild-type TTR and progressive cardiac dysfunction and failure.[121]

Early liver transplantation can improve survival in familial amyloid polyneuropathy. For transplant recipients with a modified body mass index (which is multiplied by serum albumin level) greater than 600 $kg \cdot g \cdot m^{-2} \cdot L^{-1}$, improved survival has been noted compared with historical controls without transplantation. It is important for these patients to undergo transplantation when their nutritional status is good.[122] Domino liver transplantation, in which the recipient's liver is in turn given to another recipient, has been used for patients with familial amyloidosis, in one reported case resulting in the transmission of amyloidosis.[123]

In summary, any patient with amyloidosis who lacks a monoclonal protein in the serum and urine and does not have a plasma cell dyscrasia should be evaluated for the presence of localized, secondary, senile, or familial amyloidosis. Rarely, a patient with amyloidosis and a monoclonal gammopathy can also have a nonimmunoglobulin form of amyloidosis, and immunohistochemical staining of the amyloid deposits is warranted to exclude this possibility.

CLINICAL PRESENTATION OF PRIMARY AMYLOIDOSIS

A distinct male predominance in amyloidosis has been noted for more than 30 consecutive years. In Mayo Clinic patients with AL, 67% are male, whereas males comprise 52% of all multiple myeloma patients. The median age of patients with amyloidosis seen at Mayo Clinic is 67 years. The median age of patients with AL from Olmsted County, however, is 73 years, which may reflect referral bias of younger patients to an institution that has expertise in the disorder.

When patients are classified by a dominant organ manifestation, cardiac amyloidosis is the most common and is seen in 37.4% of patients (Fig. 89–9). Overt congestive heart failure is found in only half of patients with demonstrable cardiac amyloidosis. The others have manifestations that include fatigue, arrhythmia, or syncope. The widespread use of echocardiography has increased the recognition of cardiac amyloidosis.[124] Dominant renal amyloidosis is seen in 27.8% of patients. The most common manifestation is nephrotic-range proteinuria (albuminuria). Amyloid peripheral neuropathy is seen in 15.3%. Hepatomegaly is found in 17.7% of amyloidosis patients, but liver amyloidosis presenting as the dominant manifestation is seen in only 4.6%. Gastrointestinal tract amyloidosis manifested by intestinal bleeding, pseudo-obstruction, or diarrhea is seen in 7.1% of patients, and the other patients (7.8%) have a heterogeneous mix of soft tissue, vascular, tongue, periarticular, and interstitial amyloidosis.

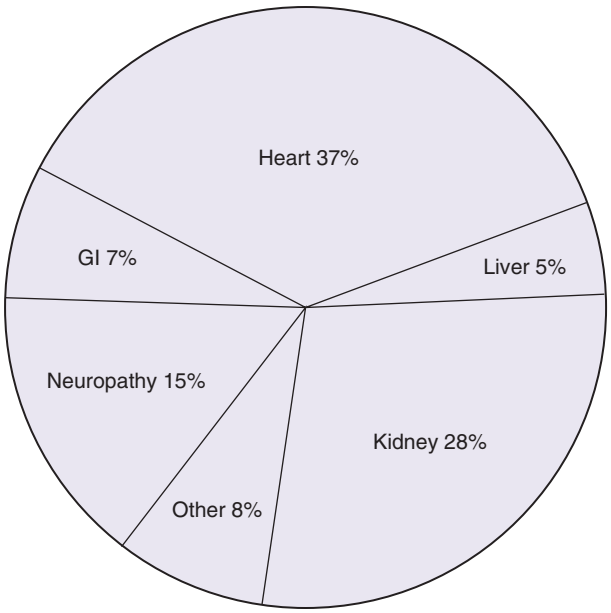

Figure 89–9 Distribution of dominant syndromes in patients with amyloidosis. GI, gastrointestinal.

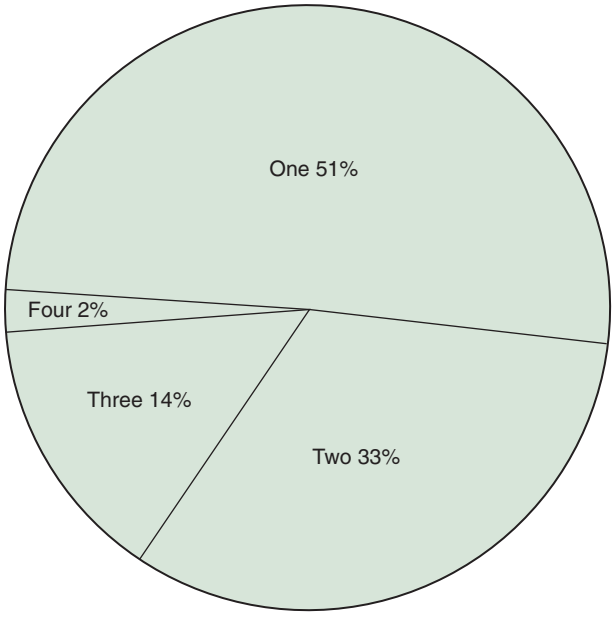

Figure 89–10 Number of organs involved at presentation in Mayo Clinic patients with amyloidosis.

In our patient population,[125] 49% presented with two or more organs involved (Fig. 89–10). In assigning a dominant organ of involvement, the designation is occasionally arbitrary because it is often difficult to distinguish which of the organs is responsible for the presenting symptoms. The organ most likely to be associated with additional visceral involvement was the liver.

If presentation with purpura alone is excluded, only 2.3% of patients presented with significant bleeding, 16.4% had carpal tunnel syndrome, and 19.6% had clinically overt congestive heart failure.[126] Symptoms included edema in 44.8% and fatigue in 46.4%. Nephrotic-range proteinuria was seen in 21%, orthostatic hypotension in 12%, lower extremity paresthesias in 34.9%, and weight loss in 51.7%. Anemia is uncommon in AL; 90% of patients have a hemoglobin value greater than 10 g/dL.[126] Only 1.5% of patients had

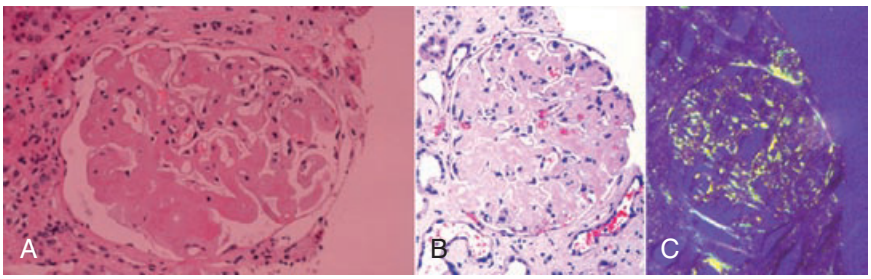

Figure 89–11 A, Amyloid deposits in the glomerulus. Note the amorphous nature that could easily be confused with hyalin degeneration (Hematoxylin and eosin; original magnification, ×100). **B,** A second case showing amyloid deposits (×100); **C,** Congo red stain with "apple-green" birefringence (×100).

a hemoglobin value less than 8 g/dL, and this was usually a sign of active intestinal tract hemorrhage or the anemia of renal failure. The median platelet count was 257×10^9/L; only 5.5% had a platelet count greater than 500×10^9/L. Thrombocytosis usually is seen with hepatic amyloidosis and hyposplenism.

A serum creatinine concentration greater than 2 mg/dL is present in 13.6% of patients at presentation.[126] An alkaline phosphatase concentration of 2 times the institutional normal value, which reflects hepatic involvement, is present in 6.7%. The median number of bone marrow plasma cells is 7% (range, 1%–30%) (Fig. 89–6); 11.3% of patients with AL have more than 20% plasma cells in the bone marrow without any other signs of multiple myeloma. The median 24-hour urine protein loss for all patients was 790 mg/24 h (Fig. 89–5). The monoclonal light chain is λ in 70%, κ in 19%, and no monoclonal protein is found in 11%. When an immunoglobulin (Ig) heavy chain was detectable in the serum, it was IgG in 58%, IgA in 10%, and IgM in 8% (Fig. 89–4). It is important to remember that amyloidosis is associated with IgM monoclonal gammopathies.[127] Waldenström macroglobulinemia has also been reported to be associated with amyloid arthropathy presenting as bilateral symmetric polyarthritis.[128]

Echocardiographic findings in the entire patient population demonstrate a median septal thickness of 14 mm.[126] The septal thickness is less than 15 mm in 53% and 15 mm or greater in 47%, reflecting a high proportion of patients with cardiac amyloidosis at diagnosis. The median survival of all patients is approximately 12 months. The 2- and 5-year survival rates are 33.6% and 15%, respectively. Variables important in survival prediction include the patient's performance status on the Eastern Cooperative Oncology Group scale, the presence of heart involvement as the dominant syndrome, and the involvement of two or more organs at presentation.

Kidney

When free monoclonal light chains are found in the urine, the differential diagnosis of the proteinuria is cryoglobulinemia,[129] amyloidosis, light-chain deposition disease,[130,131] and myeloma cast nephropathy. Immunofixation of the urine is important in the diagnostic evaluation whenever protein is present. Renal involvement is seen in 28% of patients,[126] but in the Italian Intergroup the frequency of renal involvement was nearly 50%.[132] In nondiabetic adults with nephrotic syndrome, amyloid is seen in 12% of biopsies. Survival is associated with the serum creatinine value at diagnosis.[133] The median survival of patients with a creatinine value less than and greater than 1.3 mg/dL was 25.6 and 15 months, respectively. Patients with increased protein excretion do not have shorter survival but do have a shorter time to the development of end-stage renal disease.[134] Fewer than 5% of patients with AL have urinary protein loss less than 150 mg/day. Two-thirds of patients have a light chain detectable in the urine and two-thirds a detectable light chain in the serum. In AL patients with greater than 1 g of proteinuria, a light chain can be found in as many as 86%. The ratio of κ to λ light chains in patients with nephrotic syndrome is 1 : 5. The median urinary protein loss in κ light-chain amyloidosis is 1.1 g/day; in λ light-chain amyloidosis, it is 4.6 g/day. There is no difference in the frequency of renal insufficiency in κ and λ light-chain amyloidosis.

Long-standing proteinuria results in hypoalbuminemia, which leads to decreased intravascular oncotic pressure. The clinical end result is transudation of fluid into the extracellular space with refractory edema. The use of diuretics can aggravate intravascular volume contraction and hypotension and reduces renal blood flow. In patients with advanced anasarca, bilateral catheter embolization of the renal arteries has been used.[135] The continuous loss of protein into the urine produces tubular atrophy and damage. Median time from the diagnosis of AL nephrotic syndrome to dialysis is 14 months; median survival from the start of dialysis in AL patients is 8 months. The cause of death in most is the development of cardiac amyloidosis. We have not recognized a difference in outcome between patients undergoing hemodialysis and peritoneal dialysis; 1-year survival is 68% after initiation of dialysis. The most important extrarenal complications of AL are heart failure, heart arrhythmias, and hypotension. Dialysis is regularly complicated by hypotension.

The amount of proteinuria is poorly correlated with the extent of amyloid deposits on biopsy (Fig. 89–11). Most patients with AL have normal-sized kidneys by ultrasonography. The urinary sediment shows fat but no casts or red blood cells. In a study of 118 patients with monoclonal gammopathies, 30% of those having a renal biopsy had AL.[136] Median survival in the group was 24 months, with death largely due to cardiac amyloidosis. Predictors of survival included age less than 70 years and high serum calcium and creatinine concentrations at presentation. It is rare for renal amyloidosis to develop if it is not present at diagnosis. We have seen four patients in whom nephrotic-range proteinuria developed after cardiac transplantation for amyloidosis. Presumably, in the past, these patients would not have survived long enough for renal amyloidosis to develop.

The cause of the proteinuria in AL is amyloid deposits disrupting the glomerular basement membrane. Immunotactoid (fibrillary) glomerulopathy is a fibrillar deposition in the kidney that can be confused with AL.[137] On electron microscopy, the fibrils of fibrillary glomerulopathy are twice the width of amyloid fibrils, and the deposits do not stain with Congo red. Light-chain deposition disease (Randall-type) represents the deposition of nonamyloid immunoglobulin light chains in a granular fashion on the tubular or glomerular basement membrane.[138] It can produce nephrotic syndrome and renal failure. Amyloidosis and light-chain deposition disease have been reported in the same patient.

Few reports exist of renal transplantation for AL. In a report on 12 patients, 2 of whom had AL, 4 were alive at 2 years, and in 2 of these 4, the renal biopsy showed recurrent amyloid.[139] In another report, 11 patients received transplants, and 3 showed recurrent amyloid deposits in the allograft at 11, 28, and 37 months.[140] In 45 patients with amyloidosis who received a renal transplant, the 3-year survival was 51%, which is inferior to the outcome of renal transplantation for primary renal disease.[141] The estimate for recurrent amyloidosis in a recipient of a renal transplant is approximately 20% at 1 year. On scintigraphy, uptake of radiolabeled serum amyloid was seen in 4 of 10 renal transplant recipients. Of 22 patients with renal amyloidosis, 7 had adrenal insufficiency and 4 died of hypoadrenalism.

We performed living donor kidney transplantation followed by autologous stem cell transplantation for AL patients with end-stage renal disease.[142] Two patients had complications and died 3 and 10 months later. Two patients had development of subclinical acute

cellular rejection, and one patient had acute rejection, all reversible. Six patients had successful stem cell harvest, and five underwent stem cell transplantation with good engraftment. Renal function stabilized after stem cell transplant in four and was decreased in one. The feasibility of donor kidney transplant with an autologous stem cell transplant for carefully selected patients has been established.[142] It is unclear whether stem cell transplant should precede or follow kidney transplantation.[143]

Heart

The heart is prognostically the most important determinant of outcome in AL. Patients present with infiltrative cardiomyopathy that leads to restricted ventricular filling and may present with disabling fatigue and unexplained weight loss. These patients have early diastolic dysfunction and no systolic dysfunction.[144] Chest radiography does not show cardiomegaly or pulmonary vascular redistribution. The ejection fraction is preserved on echocardiography. As a result of poor diastolic filling and normal contractility, the ejection fraction is normal, but end-diastolic volume is decreased as a result of poor filling, and this results in low cardiac output.[145] Electrocardiography typically shows low voltage, which is frequently overlooked.[146] Patients can be misdiagnosed as having ischemic heart disease because of the pseudoinfarction pattern seen in amyloidosis, with loss of the R wave in leads V1 through V3. Coronary arteriography is commonly performed during evaluation and is invariably normal.[147] Echocardiography shows thickening as a result of infiltration, but this can easily be misinterpreted as concentric left ventricular hypertrophy[148] or asymmetric septal hypertrophy (Fig. 89–12).

A patient with diastolic heart failure or restrictive hemodynamics should be evaluated for the presence of a monoclonal protein in the serum or urine.[149] The noncompliant left ventricle due to infiltration is referred to as the "stiff heart."[150] There is minimal effect on systolic function, and the ejection fraction is preserved until late in the course of the disease. Echocardiography can be frankly misleading owing to the normal ejection fraction and a lack of focal or segmental wall motion abnormalities.[151] The infiltration of the myocardial wall does result in thickening, but electrocardiography does not show the voltage changes of ventricular hypertrophy. Instead it shows low voltage or the pseudoinfarction pattern.

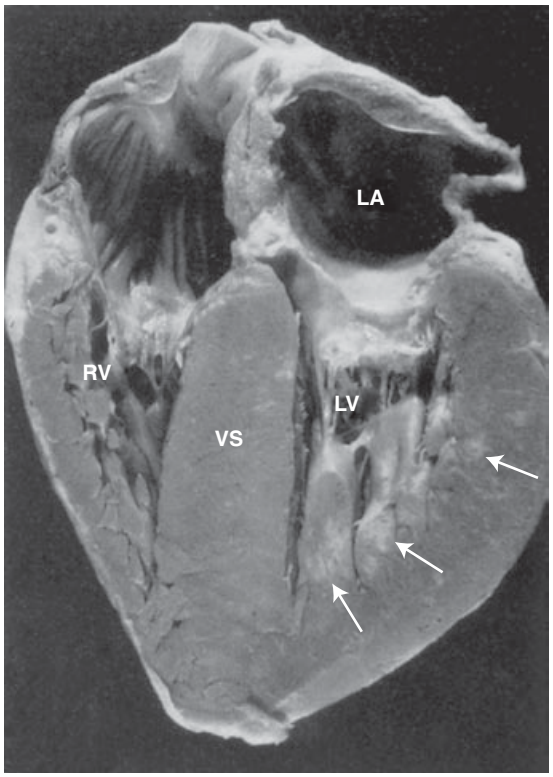

Figure 89–12 Autopsy specimen of cardiac amyloidosis. Arrows indicate the white deposits of amyloid that Rokitansky thought were "lardaceous." LA, left atrium; LV, left ventricle; RV, right ventricle; VS, ventricular septum.

Doppler studies are required to assess myocardial function in AL because Doppler echocardiography best demonstrates restriction to inflow during diastole.[152] The Doppler filling patterns closely relate to the extent of amyloid infiltration. Patients with early cardiac amyloidosis show abnormal relaxation. Patients with advanced cardiac AL show a short deceleration time consistent with restrictive physiology. The combination of decreased fractional shortening of less than 20% and a mean left ventricular wall thickness of 15 mm is associated with a median survival of only 4 months. A short deceleration time on Doppler echocardiography indicates restrictive physiology, and these patients have shortened survival compared with patients whose deceleration time exceeds 150 milliseconds.

The recent introduction of echocardiographic strain imaging demonstrated its ability to show functional abnormalities before any morphologic echocardiographic abnormalities were present.[153] When combined with tissue Doppler imaging, cardiac involvement can be detected in early stages.[153] Magnetic resonance imaging has also been applied to early detection of cardiac amyloidosis. The combination of widespread myocardial enhancement on delayed postcontrast inversion recovery T1-weighted images with features of restrictive cardiac disease is highly suggestive.[154]

Sudden death is a well-recognized complication of cardiac amyloidosis[155] whether or not the patient receives digoxin. Digoxin has never been demonstrated conclusively to increase the risk of sudden death in AL. Digoxin provides rate control in the presence of atrial fibrillation and is unlikely to improve myocardial performance because systolic function is so well preserved in AL.[156] The mainstay of supportive care in cardiac AL is the use of diuretics.[157,158] The presence of orthostatic hypotension and intravascular volume contraction can make diuretic therapy difficult and may cause syncope or an increase in the creatinine value. Pacemaker implantation is commonly required in patients with cardiac amyloidosis and syncope. The use of angiotensin-converting enzyme inhibitors, a standard for the management of heart failure, has an uncertain role in AL. The high frequency of hypotension associated with angiotensin-converting enzyme inhibitors limits their value in AL. The use of implantable cardioverter-defibrillator therapy has been reported. A defibrillator cannot consistently prevent cardiac death from amyloidosis.[159,160]

Of 204 patients with AL seen at Mayo Clinic, the median septal thickness was 14 mm.[161] The most common echocardiographic features are thickened right ventricular wall, interventricular septum, and left ventricular free wall. Typically, the left ventricular cavity size is decreased. Cardiac involvement is present on echocardiography in 41% of patients at presentation; overt congestive heart failure is present in 20%. If the interventricular septal thickness is 15 mm or greater, median survival is less than 1 year. If the septal thickness is less than 15 mm, the median survival can approach 4 years. Exercise-induced syncope has been associated with a median survival of 2 months and is presumed due to complex ventricular arrhythmias.[162] Any patient presenting with symptoms of a cardiomyopathy that does not have a clear-cut ischemic basis should have immunofixation of the serum and urine.

The pseudoinfarction pattern seen on electrocardiography may misdirect the evaluation toward coronary disease. Low voltage is seen on electrocardiography in nearly two-thirds of patients with cardiac AL.[163] Cardiac amyloidosis is characterized by atrial systolic failure and dilatation of the right ventricle. Thickening of the mitral and tricuspid valves is common and is an important clue to the diagnosis. Doppler examination regularly demonstrates clinically insignificant valvular regurgitation.[164] Atrioventricular pacing does not improve cardiac hemodynamics.

Restrictive cardiomyopathy can be confused with pericardial disease causing restriction.[165] Little clinical benefit has been reported

from pericardiectomy in patients with AL. An endomyocardial biopsy establishes the diagnosis of AL 100% of the time if at least three biopsy specimens are obtained.[166] Owing to poor contractility, the development of thrombi in the ventricular chambers is common. These can be sources of cardiac embolism resulting in stroke or arterial insufficiency of a lower extremity.[167] Atrial standstill is recognized in amyloidosis and is an indication for long-standing anticoagulation therapy. Rarely, patients can have occlusive deposition of amyloid in small-caliber coronary arterioles. These patients can have ischemic symptoms including exertional angina and true myocardial infarction.[32] Large-caliber coronary arteries show no abnormalities on angiography. Exercise testing regularly confirms ischemia, but the diagnosis is difficult to establish premortem.

We have seen 11 patients who presented with angina or unstable coronary syndromes.[31] Low voltage on electrocardiography was seen in only 2, and the median time from symptomatic angina to death was 18 months. Most diagnoses of cardiac AL with coronary artery occlusion were made at autopsy. Obstructive coronary amyloidosis is present in 66% of patients with cardiac involvement. None of these patients have obstruction of epicardial coronary arteries. Myocardial ischemia affects 25% of patients with obstructive intramural coronary amyloidosis. These patients present with ischemia and have normal angiographic studies but have small arteriolar amyloid disease.[31]

All patients with cardiac amyloidosis do not have AL. Familial forms of amyloid cardiomyopathy due to mutations at position 122 of TTR are commonly seen in older African American men. These patients do not have a monoclonal protein in serum or urine. Senile cardiac amyloidosis is associated with cardiac deposition of wild-type TTR.[168] The echocardiographic features of these forms of cardiac amyloidosis are indistinguishable, and all three show Congo red–positive deposits. One-fourth of patients older than 90 years have amyloid deposits in the heart. Failure to find an immunoglobulin light chain in the serum or urine should redirect the evaluation toward non–light chain forms of amyloid. Clues to senile systemic amyloidosis include male sex, advanced age, pronounced thickening of the interventricular septum (frequently greater than 20 mm), and TTR immunostaining of the endomyocardial biopsy.

Liver

Hepatomegaly is found by physical examination in one-fourth of patients and may be due to cardiac failure and hepatic congestion. Symptomatic hepatic involvement is present in 16% of patients. The most common clinical presentations are unexplained hepatomegaly and unexplained increase in the serum alkaline phosphatase value. There is high concordance between hepatic and renal involvement, and if the liver is involved, the kidney is the next most commonly involved organ. Half of patients with hepatic amyloidosis have greater than 1 g of protein in the urine in 24 hours. Proteinuria in a patient with hepatomegaly and an increased alkaline phosphatase value is an important clinical clue to the diagnosis of AL.[169]

Four clinical clues permit the prebiopsy recognition of hepatic amyloidosis: (a) presence of proteinuria; (b) monoclonal protein in the serum or urine; (c) Howell-Jolly bodies in the peripheral blood, which reflect splenic replacement with amyloid; and (d) hepatomegaly out of proportion to the degree of abnormality on liver function tests. Most patients have only an increased alkaline phosphatase value. The concentrations of aspartate aminotransferase and alanine aminotransferase are typically less than twice normal at diagnosis. The bilirubin value is normal. The finding of an increased bilirubin value in a patient with hepatic amyloidosis is usually a preterminal finding.[170] Rarely, hepatic amyloidosis occurs from splenic rupture with intraabdominal hemorrhage and, rarely, hepatic rupture.[171] Hepatic rupture has been diagnosed in AL, with computed tomography of the abdomen demonstrating subcapsular hematoma.[172] At the time of diagnosis of hepatic amyloidosis, the median liver span is 7 cm below the right costal margin; 50% of patients have a span between 5 and 9 cm.[173]

Ten percent of patients with hepatic amyloidosis on liver biopsy do not have palpable hepatomegaly and are diagnosed because of an unexplained increase in alkaline phosphatase concentration.[173] Splenomegaly is seen in 11% of these patients and nephrotic-range proteinuria in 36%. At diagnosis, the median elevation of the alkaline phosphatase value is 2.3 times the upper limit of normal. Patients with hepatic amyloidosis have a significantly higher level of C-reactive protein than do patients without hepatic amyloidosis. There is no difference in the ratio of κ to λ light chains in hepatic amyloidosis compared with other forms of amyloidosis.

Liver biopsy is not a high-risk procedure in these patients, and although reports of hepatic rupture have appeared in the literature, the bleeding incidence is 4%, with a transfusion need of 2%. We recently reported our updated experience with hepatic amyloidosis.[174] Seventy-two percent of patients had involuntary weight loss leading to an evaluation for occult malignancy. Clinicians considered amyloidosis in the differential diagnosis in only 26% before liver biopsy. Predictors of a poor prognosis included heart failure, an elevated bilirubin level, and thrombocythemia.[174]

Cholestatic jaundice is a preterminal finding.[175] Portal hypertension with varices and gastrointestinal tract bleeding is rarely seen.[176] Presumably, patients succumb to the effects of extrahepatic amyloid deposits before portal hypertension can develop. Ascites is commonly seen but is usually a consequence of concomitant nephrotic syndrome with hypoalbuminemia or of severe congestive heart failure rather than portal hypertension.[177] Liver biopsy shows perisinusoidal and portal deposition in most patients. Vascular involvement of the portal triads is common but not clinically important. The median survival after diagnosis was 8.5 months.

Radionuclide scintigraphy in amyloidosis is nonspecific, showing irregular distribution of the radionuclide[178] and absence of splenic uptake.[179] This form of imaging is not clinically useful. Angiography is also nonspecific, demonstrating luminal irregularity and abrupt changes in the caliber of the branches of the hepatic artery.[180] The hepatic artery is presumed to be compressed by sinusoidal amyloid deposition. Although hepatic biopsy is a safe technique, biopsy of the subcutaneous fat or the bone marrow yields a correct diagnosis in 90% of patients, so only a few patients should be subjected to transcutaneous liver biopsy.

Patients with hepatic AL have been treated with transjugular intrahepatic portal systemic shunting.[181] This can decrease portal pressures, ascites, and hydrothorax. In one patient, bilateral nephrectomy for uncontrolled nephrotic syndrome resulted in an improvement in liver function and normalization of hyperbilirubinemia.[182] The presence of hepatic involvement in amyloidosis does not adversely affect survival on multivariate statistical analysis. As noted, hepatomegaly may be from causes other than direct infiltration of the organ. In one report, hepatomegaly was due to passive congestion of the liver without hepatic amyloid deposits in three of nine patients.[183] A second study found that 20% of patients with amyloidosis and palpable hepatomegaly did not have parenchymal amyloid deposits at autopsy.[184]

The presence of hyposplenism on the peripheral blood film is highly specific for a diagnosis of amyloidosis. Conversely, hyposplenism is not a sensitive indicator of splenic involvement.[185] In one report, 12 patients with diffuse splenic involvement at autopsy did not have peripheral blood film evidence of hyposplenism.[185] Technetium scanning can indicate a decrease in splenic blood flow, but this correlates poorly with the findings on the peripheral blood film.

In summary, the cardinal features of hepatic AL are (a) hepatomegaly with increased concentration of alkaline phosphatase and minimal change in aspartate and alanine aminotransferases, (b) proteinuria, (c) a monoclonal light chain in the serum or urine, and (d) hyposplenism on peripheral blood film or technetium scanning.

Gastrointestinal Tract

Anatomic deposits of amyloid are seen in the gastrointestinal tract of most patients by screening rectal biopsy or upper endoscopy. These

deposits tend to be vascular, are in the submucosa, and are not associated with symptoms or clinical signs. Less than 5% of patients with AL present with symptoms referable to the gastrointestinal tract. The presence of anorexia and weight loss generally is not associated with substantial gastrointestinal tract deposits, and the cause of the weight loss is unrelated. Malabsorption defined by steatorrhea or a low serum carotene value is seen in less than 5% of amyloidosis patients. The symptoms of advanced intestinal amyloidosis include intestinal pseudo-obstruction,[186] and patients have been reported for whom exploratory laparotomy resulted in unnecessary morbidity. Some patients have severe intestinal dysmotility with vomiting and alternating diarrhea and constipation that can be managed only with long-term parenteral nutrition.[187] Abdominal distension and pain are common. Nausea is seen even with fasting. Cisapride has been reported to be effective for treating chronic intestinal pseudo-obstruction, but we have found it to be of limited value. The mechanism underlying gastrointestinal tract dysmotility can be a consequence of either direct mucosal infiltration or autonomic nerve damage.

We reviewed the cases of 19 patients seen at Mayo Clinic with small-bowel biopsy proof of AL; these patients represented only 1% of our total patient population with AL.[188] The most common presenting symptoms were diarrhea, anorexia, dizziness, and abdominal pain. The median weight loss was 30 lb. Half had orthostatic hypotension. A prolonged prothrombin time due to vitamin K malabsorption was seen in one-fourth. Depressed levels of factor X were also seen in a fourth of patients, but only one patient had less than 30% activity. Less than a third of the patients had an increased serum alkaline phosphatase value. Only 15% had hepatomegaly.

Barium studies of the upper gastrointestinal tract showed esophageal dysmotility or gastroesophageal reflux.[189] Dilatation of the small bowel has been seen only rarely. Small bowel barium studies show thickening or nodularity, dilatation with delayed transit, and fluid accumulation. Computed tomography is not helpful, showing mild splenomegaly or lymphadenopathy. Endoscopy demonstrates esophagitis, duodenitis, and gastritis but is frequently normal.[190] The median time from the onset of intestinal symptoms to a histologic diagnosis of AL is 7 months, but in one instance the diagnosis was delayed by 4 years. Laparotomy was performed in 4 of 19 patients, and even when the surgical tissue was obtained in 3 of the 4, Congo red stains were not performed initially. The most important features predicting survival were the hemoglobin level at diagnosis and the extent of weight loss. Patients who had weight loss greater than 20 lb had a median survival of 10 months, and the most common cause of death was nutritional failure (55%). A fourth died of cardiac amyloidosis.

The diarrhea of amyloidosis can be managed with loperamide and diphenoxylate; injections of long-acting octreotide also have been used. Ingested polyethylene glycol appears in the stool of amyloidosis patients 10 times faster than in normal subjects. These patients typically have autonomic neuropathy, which is most likely the cause of rapid transit. The severe chronic diarrhea is mediated by extremely rapid transit of chyme and digestive secretions.[191] The nausea is difficult to manage, even with phenothiazines or ondansetron. The most common preintestinal biopsy diagnosis is inflammatory bowel disease.

AL can present as ischemic colitis.[192] In this circumstance, deposits obstruct the vessels of the lamina propria and muscularis mucosa, and this leads to mucosal ischemia with sloughing of the lining and bleeding[193] (Fig. 89–13). Radiographic studies demonstrate luminal narrowing, thickening of mucosal folds, and ulcerations. The most common site of ischemia is the descending and rectosigmoid colon. Duodenal perforation due to vascular obstruction has been reported. After intestinal pseudo-obstruction develops, therapy for the underlying amyloidosis does not result in recovery of intestinal motility. Extensive replacement of the muscularis propria by amyloid deposits is particularly prominent in the small intestine.

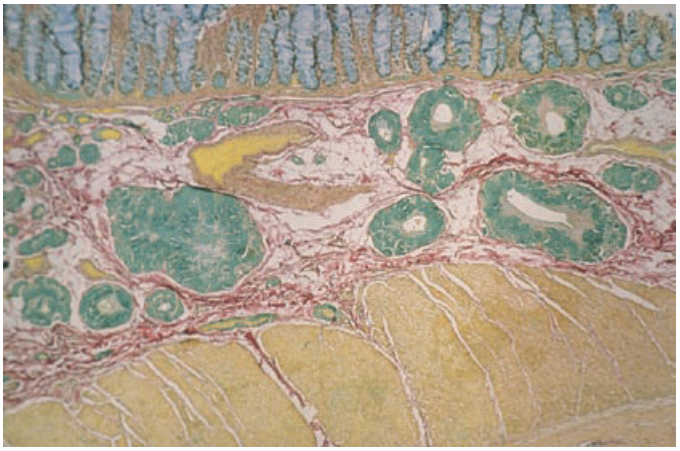

Figure 89–13 Rectal mucosal biopsy specimen demonstrates marked thickening of submucosal vessels with amyloid deposits. (Congo red; original magnification, ×100)

Nervous System

Amyloid involvement of the peripheral nervous system was first described in 1938.[194] The frequency of neuropathy in AL is 15% to 20%. Most patients are minimally symptomatic, and the clinical picture is dominated by cardiac or renal involvement. If patients present with a predominant neuropathic syndrome, the possibility of a familial amyloidosis syndrome must be kept in the differential diagnosis.[195] A monoclonal protein in the serum or urine would not be expected in patients with nonimmunoglobulin forms of amyloidosis. A diagnosis of amyloid neuropathy can be confirmed by sural nerve biopsy, but most patients with clinical and electromyographic evidence of neuropathy can be diagnosed by a fat aspirate, rectal biopsy, or bone marrow specimen.

The most common symptoms of amyloid neuropathy are paresthesias, muscle weakness, numbness, pain, orthostatic hypotension, urinary retention, and impotence. Syncope is seen in 12% of patients. The peripheral neuropathy has a characteristic dysesthetic feature with distal burning. The lower extremities are involved before the upper extremities in 90% of patients, and symptoms of autonomic failure are seen in two-thirds. Cranial nerve involvement is rare but has been reported.[196] Carpal tunnel syndrome is present in half of patients with neuropathy. One-third have significant weight loss. Atypical presentations of amyloid neuropathy can include mononeuropathy multiplex, painful sensory neuropathy, and primary demyelinating polyneuropathy.[197]

Echocardiography is abnormal in 44% of patients with neuropathy. Renal involvement is uncommon, occurring in only 5%. The neuropathy of AL may be demyelinating and results in an increased concentration of cerebrospinal fluid protein in one-third. Electromyography shows decreased amplitude of muscle action potentials, decreased or absent sensory responses, slowing of nerve conduction velocity, and fibrillation potentials on needle examination.[198] Axonal degeneration is detected by electromyography in 96% of patients.

On sural nerve biopsy, deposits of amyloid surround endoneurial capillaries or are found in the epineurium. Examination of teased fibers shows a decrease in myelin fiber density and axonal degeneration.[199] The median survival of patients presenting with AL neuropathy is 25 months.[200] Standard-dose chemotherapy rarely results in clinical improvement in the neuropathic symptoms. The neuropathy is progressive over time, and three-fourths of patients ultimately have restricted mobility, with one-third becoming bedridden. Survival is predicted by the serum albumin value of these patients at presentation. Patients whose serum albumin concentration is less than 3 g/dL have a median survival of 18 months, compared with 31 months if the albumin value is greater than 3 g/dL.

Associated autonomic neuropathy is an important diagnostic clue to AL as the cause of peripheral neuropathy.[201] Urinary dysfunction is a common manifestation of autonomic failure. Voiding difficulties are due to detrusor weakness and impaired bladder sensation. There is also evidence of detrusor denervation supersensitivity. This urinary dysfunction implicates postganglionic cholinergic and afferent somatic nerves.[202] Only diabetes mellitus generally produces a substantial autonomic component in patients with peripheral neuropathy.

The diagnosis of AL neuropathy is commonly delayed. The median duration of symptoms before diagnosis is 29 months. It is important that all patients with a peripheral neuropathy of unknown cause have immunofixation of serum and urine and an immunoglobulin free light-chain assay to search for a light chain.

The differential diagnosis of neuropathy associated with a monoclonal protein includes monoclonal gammopathy of undetermined significance–associated neuropathy, POEMS syndrome (osteosclerotic myeloma), and cryoglobulinemia. Amyloidosis preferentially causes the loss of small myelinated fibers and unmyelinated fibers. Electromyography detects changes in large myelinated fibers. Therefore, patients can have symptoms with paresthesias and normal electromyography results. The sural nerve biopsy is not 100% sensitive for the diagnosis. Of nine patients who had a sural nerve biopsy, the specimen did not show amyloid in six.[203] Amyloid can deposit proximally in the nerve root and lead to distal demyelination, and amyloid deposits will not be seen in a sural nerve biopsy specimen.

Respiratory Tract

Most patients with histologic deposits of amyloid in the respiratory tract are asymptomatic.[204] Most patients with pulmonary involvement also have cardiac involvement that dominates the clinical picture. If alveolar or interstitial amyloid is present, gas exchange is usually preserved until quite late in the disease.[205] Of 55 patients seen at Mayo Clinic with lung biopsy proof of amyloidosis, 20 had localized forms of pulmonary amyloidosis, predominantly nodular pulmonary amyloidosis.[206] These patients had a benign prognosis. Patients with tracheobronchial amyloidosis have been treated with neodymium : yttrium–aluminum–garnet laser therapy and external beam radiotherapy. Thirty-five of the 55 patients had pulmonary AL. These patients presented with radiographic findings of an interstitial or reticulonodular pattern with or without effusion. The median survival after diagnosis was 16 months. Bronchoscopic lung biopsy was safe and effective and was not associated with bleeding.

Chest radiography in pulmonary AL is nonspecific, showing an interstitial process that can be interpreted as lower lobe fibrosis.[207] Involvement of minor salivary glands is common and results in xerostomia.[208] These patients can be misdiagnosed as having Sjögren syndrome. Patients with amyloidosis associated with an IgM monoclonal protein have a higher prevalence of pulmonary involvement than patients with non-IgM amyloidosis. A monoclonal gammopathy is not associated with tracheal, bronchial, or nodular pulmonary amyloidosis and is seen exclusively in diffuse interstitial amyloidosis. Long-term observation for nodular pulmonary amyloidosis is justifiable. These patients can remain stable for long periods of time without requiring resection of the lung.[209] Patients with dyspnea from interstitial amyloidosis benefit from low doses of prednisone, even though this does not produce radiographic change.[210]

At autopsy, pulmonary involvement was reported in 11 of 12 deceased patients.[211] Amyloid deposition was in blood vessel walls and alveolar septum. Of the 12, dyspnea was present in 4, and pulmonary amyloidosis was directly responsible for death in only 1. Hemoptysis has been reported.[211] Ventilatory failure has been reported due to muscular infiltration of the diaphragm.[212]

Amyloid infiltration of skeletal muscles and the diaphragm has been reported.[213] Pleural infiltration can produce effusions.[214] Pulmonary hypertension with right-sided cardiac failure can be seen as a rare complication.[215] These patients have occlusive amyloid deposits in the pulmonary arteriolar circulation. None of these patients had echocardiographic evidence of amyloid deposition. In the presence of pulmonary hypertension, the median survival was 2.8 years. Treatment included calcium-channel blockers; however, patients tolerated these medicines poorly owing to concomitant orthostatic hypotension.

Coagulation System

Bleeding is a serious complication of amyloidosis. Factors contributing to the abnormal bleeding include coagulation factor deficiencies, hyperfibrinolysis, platelet dysfunction, and increased fragility of blood vessels.[216] Deficiency of factor X is well recognized.[217] The most common manifestation of bleeding is purpura due to fragile blood vessels infiltrated with amyloid.[218] Factor X deficiency is seen in less than 5% of patients. In a recent review, 8.7% of patients had factor X levels less than 50% of normal; serious bleeding is seen only in those with factor X levels less than 25% of normal.[219] Factor X deficiency is associated with extensive hepatic and splenic amyloidosis. Improvement in factor X levels has been reported with splenectomy,[220] use of oral melphalan and prednisone, and stem cell transplantation.[221] The use of recombinant human factor VIIa in the management of amyloid-associated factor X deficiency was reported in a 63-year-old woman with levels from 4% to 10% of normal.[222] Recombinant human factor VIIa was administered preoperatively and every 3 hours postoperatively for 48 hours to permit safe splenectomy. This was an effective means of controlling bleeding to allow for definitive surgical intervention.[222] Recombinant factor VIIa has now been widely used to treat intractable life-threatening hematuria, severe bleeding, and to support a hemicolectomy.[222–224]

The most common hemostatic abnormality in vitro is prolongation of the thrombin time.[225] This may be related to the low serum albumin values seen in patients with amyloidosis. Others have suggested the presence of an inhibitor to fibrin polymerization. Abnormal platelet aggregation has been reported, as have decreased levels of α_2-plasmin inhibitor and increased levels of plasminogen. Life-threatening bleeding is rare in AL, except for those few patients with severe factor X deficiency or ischemic colitis due to vascular obstruction. Bleeding in amyloidosis has also been reported as a result of a deficiency of factor V.[226] This deficiency was not due to acquisition of a factor V inhibitor. The bleeding in this case was fatal and unresponsive to fresh frozen plasma. At autopsy, massive hepatic deposits of amyloid were seen.[226]

Thirty-six patients underwent extensive coagulation profiling[225]; hemorrhagic manifestations were mild to moderate in nine and severe in only one. The most frequent in vitro abnormalities were prolongation of the thrombin time and reptilase time. Severe depression of factor X was seen in only one. The prothrombin times were prolonged in 8, and the activated partial thromboplastin time was prolonged in 25. None had a lupus anticoagulant.

We reviewed the medical records of 2132 patients with AL to identify patients with thromboembolism.[227] We identified 21 men and 19 women with a median age of 65 years. In 11 of 40, thromboembolism preceded the diagnosis of AL. In 9 of the 11, the event occurred 1 month or more before the diagnosis of AL. In 20 of 40 patients, thromboembolism occurred 1 month or more after diagnosis. Twenty-nine had a venous thrombosis and 11 had arterial clots. Thirty-seven of the 40 patients had an additional risk factor for thrombosis: nephrotic syndrome in 20, immobilization in 13, tobacco in 6, heart failure in 8, estrogens in 1, obesity in 4, aortic aneurysm in 1, and prosthetic material in 4. Two of the patients had an associated disseminated intravascular coagulation, and 5 had detectable activated protein C resistance. Eight of the 40 patients died within a month after the thrombotic event. Eighteen of the 40 died within 1 year. There were no associations with the type of heavy or light chain.[227]

PROGNOSIS

When a patient has a syndrome compatible with amyloidosis and is found subsequently to have a monoclonal protein or clonal plasma cell population, and the diagnosis is confirmed histologically, the next step is to assess prognosis. In a group of 153 patients with AL, the median survival was 20 months, with a 5-year survival of 20%.[228] Patients with congestive heart failure had a median survival of 8 months and a 5-year survival of 2.4%.[228] The best outcome occurred in patients with amyloid neuropathy as the sole manifestation of the disease: a median survival of 40 months and a 5-year survival of 32%. Patients may be classified clinically into five groups: heart failure or cardiomyopathy, nephrotic syndrome, peripheral neuropathy, liver, and other. Women have slightly better survival than men.

In a review of 229 patients with AL, heart failure and orthostatic hypotension were associated consistently with a median survival of less than 1 year.[25] With heart failure and nephrotic syndrome patients excluded, patients with peripheral neuropathy had a median survival of 56 months. Jaw claudication can be seen in as many as 9%. These patients have a survival of 42 months.[229] Patients with jaw claudication have predominantly vascular deposits and sparing of the viscera. They frequently have associated amyloid arthropathy and tongue enlargement.

The presence of hyposplenism on peripheral blood film was associated with a median survival of 4.4 months, reflecting advanced splenic and hepatic involvement.[230] The median survival of 80 patients diagnosed by a liver biopsy was 9 months, and 5-year survival was 13%.[169] The cause of death in most patients with amyloidosis was cardiac related—either heart failure or fatal arrhythmia. Echocardiography is important in the assessment of the patient's prognosis.[231] Although only 17% to 20% of patients have heart failure at presentation, nearly 40% have evidence of cardiomyopathy on echocardiography.[232] Early cardiac amyloidosis is characterized by abnormalities of relaxation. Advanced cardiac amyloidosis shows restrictive filling and a shortened deceleration time.[233] With Doppler echocardiography, patients can be divided into two groups on the basis of deceleration time greater or less than 150 milliseconds. The 1-year survival of patients with a deceleration time of 150 milliseconds or less was 49% compared with 92% for a deceleration time greater than 150 milliseconds. Doppler studies of right ventricular function correlate well with the degree of amyloid infiltration.[234]

Findings on renal biopsy have been reported to have prognostic value.[235] A lower percentage of glomerular capillary wall thickening, a higher incidence of amyloid deposits in vessels but not glomerular capillaries, and deposits of IgG and C3 in mesangial and glomerular capillary walls are all associated with a better prognosis. Urinary light-chain excretion and serum creatinine values are also important prognostic indicators. Increased serum creatinine values are associated with a median survival of 15 months.

Exertional syncope is an ominous finding and is associated with a high incidence of sudden death. This is usually an indication for consideration of an implantable defibrillator. Most patients with exertional syncope die within 3 months.[236]

The plasma cell labeling index measures the proliferative potential of the bone marrow plasma cells in AL. More than 95% of patients with AL have a demonstrable clonal excess of plasma cells in the bone marrow. The median survival of patients whose plasma cell labeling index was 0 (no proliferative plasma cells) was 30 months. Patients with a plasma cell labeling index greater than 0 had a median survival of 15 months.[237] Analysis of peripheral blood mononuclear cells in 147 patients with AL showed 16% of the patients to have detectable circulating plasma cells.[238] The median survival of patients with circulating plasma cells was 10 months compared with 29 months for patients without circulating plasma cells. In a multivariate analysis, the presence of circulating plasma cells and the serum β_2-microglobulin level were independent prognostic indicators of survival.[239]

The median survival of patients with an increased serum β_2-microglobulin value at presentation was 11 months, compared with 33 months in patients with a normal β_2-microglobulin value.[240] β_2-Microglobulin value is an independent predictor of survival, even in the presence of heart failure and renal failure. When the serum β_2-microglobulin value is combined with the presence or absence of circulating plasma cells, patients can be classified into three separate groups with median survivals of 4 months (circulating cells and increased β_2-microglobulin), 42 months (no circulating cells and normal β_2-microglobulin), and 21 months (one of the two variables abnormal).[239]

The time between diagnosis and referral for evaluation remains an important prognostic variable. When all patients seen at Mayo Clinic are assessed, the median survival is 2 years. However, when only patients seen within 1 month of diagnosis are considered, the median survival decreases to 13 months. This suggests significant referral bias, favoring patients physically able to come to a large amyloidosis treatment center. This information is important when interpreting the results of clinical trials from single centers.[126]

In a multivariate analysis of prognostic factors, the median survival of the entire group was 12 months, ranging from 4 months for those with overt heart failure to 15 months for those with peripheral neuropathy.[241] Heart failure, urinary monoclonal light chain, hepatomegaly, and multiple myeloma were all adverse factors influencing survival within 1 year after diagnosis. After the first year, increased serum creatinine concentration, multiple myeloma, orthostatic hypotension, and a monoclonal serum protein predicted poor survival.[241] Stratification for the impact of variables with an adverse effect on survival is important when comparing studies of therapy among various centers.

Recently, measurement of cardiac biomarkers has been shown to be critically important in assessing the prognosis of patients with amyloidosis. Brain natriuretic peptide (BNP) is a marker of ventricular dysfunction and has been used to assess prognosis in heart failure. When N-terminal pro-BNP (NT-pro-BNP) was quantified at diagnosis in 152 patients with AL and compared with echocardiography, two groups were distinguished on the basis of NT-pro-BNP levels.[242] Survival was vastly different in patients with elevated and normal NT-pro-BNP levels. This model for assessing prognosis was superior to echocardiography. Serum cardiac troponin value measurements combined with the NT-pro-BNP values were used in the development of a staging system for patients with amyloidosis.[243] Patients who had abnormal values for both parameters (stage III) had a median survival of 3.5 months, those with normal values for both parameters (stage I) had a survival of 26.4 months, and those with 1 of 2 abnormal values (stage II), 10.5 months.[243,244] The staging system using troponins and NT-pro-BNP was subsequently verified in a cohort of patients undergoing stem cell transplantation.[244] The three stages had median survivals of 66.1, 66.1, and 26.1 months, respectively.[245] Forty-nine percent of transplant patients were in stage I, 38% in stage II, and 13% in stage III. Levels of circulating cardiac biomarkers are the most powerful tool for staging patients with AL undergoing stem cell transplantation.[245]

Not only has the immunoglobulin free light chain been found to be important in classifying the type of amyloidosis and providing a method for assessing response, it has also been found to be of prognostic value.[244] Patients with higher baseline free light-chain levels had a significantly higher risk of death. Baseline free light chain correlated with serum cardiac troponin levels, and higher free light chain levels were associated with more organs with amyloid involvement. The absolute level of free light chain achieved after therapy predicted survival. Normalization of free light-chain level after transplantation predicted both organ response and complete hematologic response. Free light-chain measurements before and after treatment are important predictors of patient outcome.[244]

In summary, all patients being assessed for amyloidosis require echocardiography, including measures of diastolic performance, ejection fraction, and mitral deceleration time. The serum β_2-microglobulin concentration, the presence of overt congestive heart failure, and circulating plasma cells remain important measures affecting outcome. BNP and troponin levels are an essential part of the diagnostic evaluation of patients with AL.

THERAPY

Supportive Therapy for Primary Amyloidosis

Cardiac Amyloidosis

The primary modality of therapy for cardiac AL remains diuretic agents.[246] Diuretics decrease extravascular volume, which reduces the peripheral edema that limits these patients. Diuretic therapy helps decrease preload; filling pressures tend to be extremely high in patients with amyloidosis because of the restriction to cardiac inflow. Diuretic therapy is limited by hypotension, which, if associated with hypoalbuminemia from renal amyloidosis, can be difficult to manage.[247] Furosemide doses of 120 mg three times per day may be necessary for edema control. Metolazone can be beneficial in mobilizing fluid. Spironolactone has been shown to decrease mortality in patients with chronic heart failure, although it has not been specifically tested in amyloid cardiomyopathy. Digoxin has little beneficial effect on the diastolic heart failure seen in amyloidosis[248] but can be useful in controlling heart rate in patients with atrial fibrillation, which is generally difficult to convert to sinus rhythm. Nifedipine and diltiazem can precipitate congestive heart failure in patients with AL.[249,250] The use of angiotensin-converting enzyme inhibitors can reduce the afterload in patients with cardiac amyloidosis and has been shown to decrease mortality in patients with ischemic cardiomyopathy. In addition, lisinopril has been reported to reduce proteinuria in renal amyloidosis.[251]

Orthostatic hypotension in amyloidosis can be a major problem.[252] The use of a fitted thigh-high elastic leotard can actually decrease dependence on medications. If medications are necessary, fludrocortisone acetate 0.1 mg two to three times daily can be effective, but it produces some fluid retention and can aggravate supine hypertension.[253] Midodrine can be used in doses ranging from 2.5 to 10 mg two times daily.[254] Dosing should take place during the day to avoid nocturnal supine hypertension. This agent is rapidly absorbed from the intestinal tract, and peak serum values occur in 30 minutes. The maximum recommended dose is 30 mg per day, and the medication comes in 2.5- and 5-mg tablets. If renal insufficiency is present, the dose should be decreased because active metabolites are excreted renally. Adverse effects of midodrine include tachycardia, hypertension, and restlessness. In a patient who did not respond to midodrine and fludrocortisone, subcutaneous erythropoietin resulted in resolution of symptoms related to orthostatic hypotension unassociated with improvement of anemia.[255]

Cardiac transplantation has been used for patients with advanced cardiac AL. A survey of seven patients with a mean age of 46 years reported recurrent amyloidosis in two patients at $3\frac{1}{2}$ and 4 months, one of whom died 13 months after transplantation.[256] Five patients were alive at 32 months. A follow-up study of 10 patients showed recurrent amyloidosis in the graft in four of nine survivors.[257] One patient with AL survived 9 years after cardiac transplantation.[258] Ten patients (mean age, 54 years) received heart transplants; two died postoperatively, and the mean follow-up in the remaining eight patients was 50 months. Recurrent amyloid deposits in the cardiac allografts were demonstrable in 5 patients at 5 to 30 months (median, 12 months) after transplantation. Seven patients died at a median of 32 months; four of the seven died of extracardiac amyloidosis. The 1-year actuarial survival was 60%, and 5-year actuarial survival was 30%.[258]

A 47-year-old woman with AL cardiac amyloidosis received a heart transplant, followed 6 months later by a stem cell transplant in an attempt to prevent recurrent disease.[259] The patient died 2 years after stem cell transplantation, and the myocardium showed mild deposits of amyloid.[259] In 13 cardiac transplant patients with AL at Mayo Clinic, the actuarial 5-year survival was 50%.[260] We have performed stem cell transplantation in 11 patients who were recipients of cardiac transplants; 5 died and 6 were alive at 18, 19, 22, 23, 59, and 82 months after stem cell transplantation.

One study queried the United Network for Organ Sharing database and found 69 patients with amyloidosis who had cardiac transplants.[261] Five operative deaths occurred, and 29 late deaths occurred at a mean follow-up of 40 months. Nine patients died of amyloid-related complications, and graft vasculopathy developed in 1. The 1-year survival was 84% for men and 64% for women.[261] In a report from the United Kingdom, 24 patients had amyloid heart disease, 17 of whom had AL.[262] Survival of 10 patients was 50% at 1 year and 20% at 5 years after heart transplant. Amyloid recurrence in the grafts occurred at a median of 11 months. Extracardiac amyloid contributed to mortality in 70%. Seven patients with AL who also had chemotherapy had 1- and 5-year survival rates of 86% and 64%. The survival was less than after transplant for other indications. Progression of the AL contributed to the increased mortality.[262]

In a single-center report of five patients with cardiac AL, three were dead and two were alive at 60 and 41 months after transplant.[263] Two patients died of sudden death after 23 months and one of multiorgan failure because of progression of AL.[263] Because recurrent amyloidosis is such a common cause of morbidity, the use of stem cell transplantation to prevent disease recurrence after heart transplantation has been reported. Five patients had stem cell transplants after heart transplant, and three of the five were well without evidence of recurrent amyloid.[264] Two patients died at 33 and 90 months after heart transplant after relapse of the amyloidosis.[264]

Renal Amyloidosis

Diuretics can manage the edema of nephrotic syndrome. For patients in whom renal failure eventually develops, hemodialysis support is required. The results of dialysis in AL patients are inferior to those in patients with primary kidney disease.[265] In 61 patients with amyloidosis who had dialysis, 18 died within a month after starting therapy and 43 underwent dialysis for more than 1 month. Younger patients had better 5-year survival. The most important complications after initiation of dialysis were the subsequent development of cardiac and intestinal amyloidosis. Survival was not different between amyloidosis patients who received hemodialysis and those who received peritoneal dialysis.[265] Two-thirds of the deaths in our patient population were due to extrarenal amyloidosis progression, primarily cardiac.[133]

The use of lisinopril has been reported to decrease proteinuria in patients with nephrotic syndrome and can result in significant hyperkalemia. Enalapril has been reported to be effective in reducing proteinuria in steroid-resistant nephrotic syndrome.[266] The mechanism of action is thought to be hemodynamic and is potentially effective in amyloidosis as well.

Renal transplantation has been used in AL. Recurrent amyloidosis in the graft remains a major problem, however. We have performed renal transplantation in eight patients, six of whom had stem cell harvest; five of these underwent stem cell transplant.[142] Stable renal function was present in four. Sequential kidney and stem cell transplantation is feasible.[142] Others have argued that stem cell transplantation should precede kidney transplantation in an effort to produce a complete response before placement of the new organ.[143]

Survival is linked to the development of amyloidosis in the graft; it has been estimated that 1-year survivors have a 20% chance of amyloidosis developing in the transplanted kidney. Fifteen patients with renal amyloidosis underwent transplantation and had 42 to 216 months of follow-up (median, 73 months).[267] The grafts remained normal in all patients whose underlying amyloidogenic disorder had remitted. If the underlying precursor protein production had not remitted, abnormal uptake of radiolabeled serum amyloid P was found, reflecting the development of amyloid in the transplanted kidney. Patients with evidence of renal amyloid by serum amyloid P scan also had evidence of graft dysfunction.[267]

Three patients were reported who received kidney transplants after monoclonal light chain synthesis was suppressed by chemotherapy.[267] The response to chemotherapy was documented by eradication or reduction of immunoglobulin light-chain production. Three patients were alive at 4, 11, and 16 years after transplantation. Renal function in the AL patients remained normal. Renal transplan-

tation is therefore appropriate for patients whose light-chain production can be suppressed.[266]

Hepatic Amyloidosis

As is the case for all other types of AL, the mainstay of therapy for hepatic amyloidosis is suppression of the underlying plasma cell clone with chemotherapy. However, liver transplantation has been reported for the management of AL. A 61-year-old man was hospitalized for spontaneous splenic rupture.[268] Shortly after splenectomy, liver failure with jaundice, ascites, and hyponatremia developed. A subsequent hepatorenal syndrome with hepatic encephalopathy developed over 3 weeks. Hepatic transplantation was performed, and the patient was dismissed from the hospital with normal hepatic and kidney function. At 1-year postoperative follow-up, liver function was normal, although a liver biopsy showed amyloid deposits in the hepatic allograft.[268] Another patient with progressive hepatic failure from AL received a liver allograft.[269] The patient had development of recurrent amyloidosis that led to stem cell transplantation in an effort to suppress amyloid precursor protein production. After a second (tandem) transplantation procedure, the patient had no clinical evidence of recurrent amyloidosis at 28 months. Liver transplantation can be considered for patients with amyloidosis, but suppression of light-chain production is essential to prevent recurrent disease.[269]

Gastrointestinal Tract Amyloidosis

The most frequent symptoms related to amyloidosis of the gastrointestinal tract are diarrhea and constipation. In most patients, this is due to autonomic failure, but in some patients massive deposits develop in the mucosa and submucosa and result in a malabsorption syndrome. Loperamide, diphenoxylate, tincture of opium, and paregoric are used regularly and produce variable results. Octreotide in a long-acting formulation can decrease diarrhea when given in doses ranging from 10 to 30 mg every 4 weeks for 2 months, and then every 4 weeks, according to the response of the diarrhea. Rarely, ostomies are required for diarrhea control. Occasionally, widespread vascular obstruction of blood supply to the bowel develops, leading to massive bleeding and infarction for which surgical intervention is the only option. For nausea, abdominal distension, and pain, cisapride has been reported to provide symptomatic relief.[270]

Noncytotoxic Chemotherapy for Primary Amyloidosis

The primary approach to therapy has been to decrease production of the amyloidogenic light chain with therapy directed against the plasma cell population. DMSO has been used because of in vitro data suggesting an ability to solubilize amyloid deposits.[271] The benefit of DMSO is unproven, and it is infrequently used today to treat amyloidosis.[272] Colchicine has been shown to be effective in the treatment of AA associated with familial Mediterranean fever, a disorder characterized by recurrent peritonitis, pleuritis, synovitis, and rash. Before the introduction of colchicine, the 5-year survival of patients with familial Mediterranean fever was 20%. Nephrotic-range proteinuria and dialysis-dependent renal failure developed in these patients. Two double-blind, placebo-controlled trials showed that colchicine was effective in preventing attacks of serositis and reduced the frequency of amyloidosis.[273]

Given the success of colchicine for familial Mediterranean fever amyloidosis,[274] it was used in patients with AL. Fifty-three patients with AL received colchicine and were compared with retrospective controls.[275] The median survival of colchicine-treated patients was 7 months, compared with 1 year in melphalan-treated patients.[275] Today, colchicine is rarely used for AL. Colchicine is not effective for any of the hereditary periodic fever syndromes including hyperimmunoglobulinemia-D with periodic fever, tumor necrosis factor receptor–associated periodic syndrome, and cryopyrin-associated periodic syndrome.[102]

Cytotoxic Chemotherapy for Primary Amyloidosis

The same chemotherapy drugs used to treat amyloidosis have been used for the management of multiple myeloma. These include oral melphalan and prednisone; oral dexamethasone; combination chemotherapy, including vincristine, carmustine, melphalan, cyclophosphamide, and prednisone; and infusional vincristine, doxorubicin, and dexamethasone, thalidomide, and lenalidomide. These low-toxicity therapies can decrease the plasma cell burden to some degree. Many patients die of the disease before adequate time has elapsed to determine if they will achieve a response. Two prospective randomized studies have demonstrated a survival benefit for oral melphalan and prednisone compared with colchicine.[276,277] Unfortunately, the median survival is prolonged to only 17 or 18 months.

Responders to melphalan and prednisone have significantly prolonged survival compared with nonresponders.[228] Patients who have nephrotic syndrome have a better outcome in terms of response rate than those who have peripheral neuropathy or cardiac involvement. It is unclear whether clinical regression is associated with histologic regression because follow-up biopsies are done infrequently. However, the use of serum amyloid P component scanning has definitely indicated decreased uptake of the isotope at sites of previously known disease, which suggests resolution of the amyloid deposits. Melphalan is leukemogenic, and the risk of myelodysplasia developing is substantial.[278]

We have reported that even in the presence of significant cardiac amyloidosis, survival of more than 5 years was seen in 8 of 153 patients.[279] All long-term survivors received chemotherapy. All but 1 had a demonstrable response to chemotherapy. Continuous oral melphalan has been administered as a single agent for patients with cardiac amyloidosis who could not tolerate prednisone or stem cell transplantation. Seven of 13 evaluable patients achieved a partial hematologic response, 3 achieved a complete hematologic response, and 6 survived for longer than 1 year. Continuous low-dose oral melphalan can induce hematologic responses.[280]

Responses to melphalan and prednisone are uncommon if the serum creatinine value exceeds 3 mg/dL, if hyperbilirubinemia is present, or if the alkaline phosphatase value increases to more than 4 times the institutional normal.[228] In patients who have isolated nephrotic syndrome, a normal serum creatinine value, and a normal echocardiogram, the response rate to melphalan can exceed one-third of patients. It is rare to see symptomatic improvement in peripheral neuropathy after melphalan and prednisone therapy. The median time to response with melphalan is 1 year.[228]

In a 21-year period at Mayo Clinic, 841 patients with AL were evaluated.[281] The actuarial survival for the 810 patients diagnosed premortem was 51% at 1 year, 16% at 5 years, and 4.7% at 10 years (Fig. 89–14). We reported on 30 patients with survival for 10 years after diagnosis, all of whom received melphalan-based therapy.[281] Fourteen had complete eradication of the light chain from serum and urine. Of 10 patients with nephrotic syndrome, 4 had a greater than 50% reduction in proteinuria. Heart failure, older age, a creatinine value greater than 2 mg/dL, and bone marrow plasma cells greater than 20% were poor prognostic factors for long-term survival.[279,280]

Four patients in whom alkylating agents had failed were treated subsequently with vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD) as a 96-hour infusion.[282] Two of the patients had a 50% decrease in the serum monoclonal protein. The VAD regimen could be considered for patients with AL and has been reported as an induction treatment to decrease the plasma cell burden before stem cell transplantation.[282] The use of VAD resulted in improvement in patients' conditions, allowing them to receive high-dose chemotherapy and stem cell transplantation with reduced risk.[282] A series of patients from a single institution had successful use of VAD induction followed by melphalan-based stem cell transplantation.[283,284]

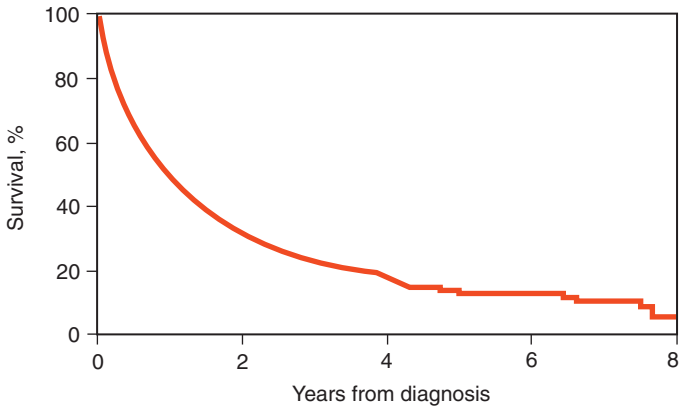

Figure 89–14 Overall survival of patients seen at Mayo Clinic with amyloidosis.

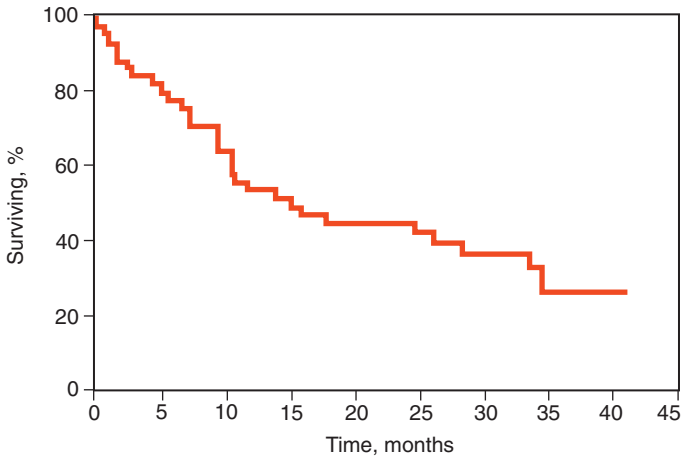

Figure 89–15 Survival of 55 patients with amyloidosis treated with high-dose dexamethasone.

In a three-arm study that accrued 219 patients over 10 years, patients were randomly assigned to receive colchicine, or melphalan and prednisone, or melphalan, prednisone, and colchicine.[276] Patients were stratified by age, sex, and major clinical manifestation of amyloidosis. Half had nephrotic-range proteinuria, and 20% had heart failure. The colchicine group survived a median of 8½ months, and the melphalan-containing regimens resulted in survivals of 17 months. Similar results were reported in patients treated with melphalan at Boston University.[277] We reported on the development of myelodysplasia in 10 of 153 patients who were treated with melphalan for AL.[278] Eight of the 10 died as a result of the myelodysplasia, including acute leukemia and progressive pancytopenia due to myelodysplasia. This group represents 7% of all patients treated with melphalan; the actuarial risk for survivors at 3½ years was 21%. The median survival after the diagnosis of myelodysplasia or acute leukemia was 8 months.

In one patient, the diagnosis of amyloidosis was established, and the patient received 28 months of oral melphalan, prednisone, and colchicine.[285] Five years later, he had dialysis-dependent renal failure with no other evidence of amyloidosis and received a renal transplant. He survived for 7 years; pancytopenia developed with bone marrow that showed dysplastic red blood cells but no acute leukemia. Cytogenetics were complex but included a 5q abnormality. Myelodysplasia developed 12 years after his diagnosis of amyloidosis.

High-dose dexamethasone as a single agent given at 40 mg on days 1 to 4, 9 to 12, and 17 to 20 every 5 weeks has been reported.[286] Responding patients received maintenance dexamethasone at 40 mg per day, 4 days per month for 1 year. Improvement in amyloid organ involvement was seen in eight of nine patients, and six of seven had a greater than 50% decrease in urinary protein loss with a median time to response of 4 months. Patients with heart failure did not benefit. Median survival of the cohort was 31 months. In a report on 93 patients treated with this regimen, 2-year overall survival was 60% and event-free survival was 52%.[287] Heart failure and β_2-microglobulin levels were the predictors of adverse outcome.[287] We treated 19 patients with high-dose dexamethasone therapy,[288] and 3 showed objective organ response. The median survival of the entire group was 11.2 months, but 3 were alive at 110, 116, and 119 months. Dexamethasone should be considered as an option for patients who are not suitable candidates for transplantation. Dexamethasone has also been used for patients in whom melphalan therapy had previously failed.[289] The objective response rate was 12% (Fig. 89–15). One patient was alive at 104 months.

Because high-dose dexamethasone therapy can be toxic in patients with AL, a lower-dose schedule has been reported: 40 mg on days 1 through 4 every 21 days for up to eight cycles.[290] Overall, 8 of 23 patients had a median time to response of 4 months (range, 2–6 months). This regimen has been used as a first-line therapy. This same group reported on the combination of low-dose melphalan and modified high-dose dexamethasone therapy.[290]

Melphalan has been combined with high-dose dexamethasone in patients with AL who were ineligible for stem cell transplantation, primarily because of cardiomyopathy.[291] Of 46 patients, a complete response was seen in 15 (33%) and a hematologic response in 31 (67%). Twenty-two patients (48%) showed an improvement in organ dysfunction. There was a strong correlation between hematologic and organ response. If the hematologic response was complete, the organ response rate was 87%. If the hematologic response was greater than 50%, organ function improved in 56%; patients with no hematologic response had no organ functional improvement. The 100-day mortality with this regimen was 4%. Cardiac failure resolved in 6 of 32 patients. The median time to response was 4.5 months, and only 11% had adverse effects.[291]

We studied 101 patients with AL; half received melphalan and prednisone and half received vincristine, carmustine, melphalan, cyclophosphamide, and prednisone.[292] Seventy-six of the 101 patients died, and the median overall survival for the entire group was 26.4 months, with no difference between the two arms. In this group of 101, 18 ultimately required dialysis therapy; 15 of the 18 have since died. The most common cause of death was intractable hypotension related to cardiac involvement while on dialysis. The three surviving dialysis patients have been alive for 87, 94, and 103 months. A myelodysplastic syndrome was documented in eight patients, all of whom have died, including one who received an allogeneic bone marrow transplant. The overall survival of these eight patients ranged from 18 to 90 months, with a median of 43 months. We also studied 45 patients who received the agent iodo-deoxydoxorubicin and found a response rate of 15%.[293]

Thalidomide has been shown to be active in the treatment of AL. In the initial report, six patients with AL were treated with thalidomide.[294] All patients had renal amyloidosis and were treated previously. The duration of thalidomide therapy was 3 to 9 months (median, 5 months). Four also received oral corticosteroids. An improvement was reported in five patients. Proteinuria decreased by more than 50% in two, and the serum albumin concentration improved in three. Two patients died, and four were alive and remained on therapy.[294]

In another report of 12 patients receiving thalidomide, 8 patients had renal, 4 had cardiac, 3 had liver, and 2 had soft-tissue amyloidosis.[295] Ten had received a prior stem cell transplant. The median maximum tolerated thalidomide dose was 500 mg. No patient had a 50% decrease in serum or urine monoclonal proteins. Five of 11 patients had a 25% to 50% improvement. Three patients had stable disease and three had progressive disease.[295] We have found thalidomide difficult to administer, and initial doses should not exceed 50 mg. It is unusual for patients with amyloidosis to tolerate more than 200 mg per day long term, and the toxicity is substantially greater in this population. We encountered edema and cognitive difficulties in 75%; dyspnea, dizziness, and rash in 50%; and two

deep venous thromboses. Median time on treatment was only 72 days.[296,297]

Thalidomide has been combined with dexamethasone therapy in 31 patients.[298] Forty-eight percent of patients achieved a hematologic response, with 19% complete responses and 26% organ responses. The median time to hematologic response was 3.6 months. Treatment-related toxicity was frequent at 65%.[298] Lenalidomide has been reported to be useful in the treatment of amyloidosis. A report on 34 patients was recently presented[299]; 8 of the 13 evaluable patients had a measurable response, 4 to lenalidomide alone. Nine other patients responded when dexamethasone was added. Lenalidomide appeared to be better tolerated than thalidomide.[299]

STEM CELL TRANSPLANTATION FOR PRIMARY AMYLOIDOSIS

The use of high-dose chemotherapy and stem cell transplantation for patients with amyloidosis remains controversial because this modality of therapy is associated with a high treatment-related mortality (Table 89–4).[300–313] Transplant-related mortality can range from 11% to 43%. Moreover, mortality has even been reported during stem cell mobilization using granulocyte colony-stimulating factor (G-CSF); these deaths were attributed to noncardiogenic pulmonary edema,[314] cardiac ischemia, or sudden rhythm disturbances with ventricular fibrillation. The significant visceral organ dysfunction that accompanies amyloidosis places patients at a high risk for complications developing. The number of organs involved at the time of transplantation is predictive of outcome. Patients who have one organ involved fare better than those who have two, and those who have more than two organs involved have an even poorer outcome.[315] Causes of treatment-related mortality in AL include gastrointestinal tract bleeding,[316] cardiac rhythm disturbances, and multiorgan failure.

At Mayo Clinic, high-dose chemotherapy and autologous stem cell transplantation has been performed in 270 patients with AL. The median age was 57 years. The median serum albumin level was 2.8 g/dL, which reflects a high prevalence of nephrotic-range proteinuria. Ten percent of patients had serum creatinine levels greater than 1.8 mg/dL. Alkaline phosphatase levels greater than twice normal, a marker for liver amyloidosis, were observed in 19% of patients. The median serum monoclonal protein concentration was 0.3 g/dL. A serum monoclonal protein component was found in 196 of the 270 patients. The median 24-hour urine protein excretion was 3.4 g/day (interquartile range, 0.24–7.1 g/day). Fifty-four percent had urinary protein loss greater than 3 g/day. Only 6% had monoclonal light-chain excretion of greater than 1 g in 24 hours. One-, two-, and three-organ amyloid involvement was seen in 48%, 38%, and 14% of patients, respectively.

Stem cell mobilization in patients with amyloidosis was achieved with G-CSF alone without prior cytotoxic chemotherapy. The median number of apheresis collections required to collect an adequate stem cell product was 3 (interquartile range, 2–4 aphereses). The median number of $CD34^+$ cells collected was 6.5×10^6/kg (range, 2.0–50.9 $\times$ 10^6 cells/kg). Hematopoietic growth factors were not administered after transplantation because of their ability to produce fluid retention in patients with cardiac and renal amyloidosis.

The 100-day mortality rate of these 270 patients was 11%, which compares favorably with reports from other institutions where morality rates as high as 40% have been reported.[307] Mortality (before day 100) at Mayo Clinic has progressively decreased over the years: from 12.1% of stem cell transplant recipients before 2004, to 10 of 107 consecutive transplant recipients (9.3%) since January 1, 2004.

Sixty-two percent of patients received conditioning therapy with melphalan at a dose of 200 mg/m^2, 26% received melphalan at 140 mg/m^2, and the rest received lower doses because of advanced cardiac amyloidosis. The intensity of chemotherapy delivered appears to be predictive of outcome.[317] Patients receiving full-dose melphalan fare better, although patients selected for full-intensity therapy tend to have less advanced disease and are somewhat younger.[317]

Bias is inherent in selecting patients for transplantation and the intensity of their conditioning. At Mayo Clinic, only one-fourth of patients encountered with amyloidosis ultimately go on to receive a stem cell transplant. Transplant recipients survive longer than patients not selected for transplant. In a case-matched control study, 63 transplant patients were compared with 63 conventionally treated patients matched for age, sex, cardiac function, creatinine, urinary protein loss, and liver involvement. An overall survival advantage for the patients undergoing transplant was observed.[318] In a report from the American Bone Marrow Transplant Registry of 107 patients treated with high-dose chemotherapy and autologous stem cell transplant at 48 centers,[319] the 30-day treatment mortality was 18%, and the response rate was 34%, with 33% having stable disease.[319] Only 11% of patients had posttransplant disease progression. The projected median survival was 47 months. Experienced transplant groups

Guidelines for Exclusion of Patients from High-Dose Chemotherapy and Autologous Stem Cell Transplantation

Absolute contraindication
- Clinical congestive heart failure
- Total bilirubin >3.0 mg/dL
- Echocardiographic ejection fraction <30%

Relative contraindication
- Serum creatinine >2.0 mg/dL
- Interventricular septal thickness >15 mm
- Age >60 years
- More than 2 visceral organs involved

Modified from Gertz MA, Lacy MQ, Dispenzieri A: Immunoglobulin light chain amyloidosis (primary amyloidosis, AL). In Gertz MA, Greipp PR (eds.): Hematologic Malignancies: Multiple Myeloma and Related Plasma Cell Disorders. New York, Springer-Verlag, 2004, p 157–195. Used with permission of Mayo Foundation for Medical Education and Research.

Risk-Adapted Approach to Primary Amyloidosis Therapy

Good risk
- One or two organs involved
- No cardiac involvement
- Creatinine clearance ≥51 mL/min
- Any age

Intermediate risk
- Younger than 61 years
- One or two organs involved
- Asymptomatic or compensated cardiomyopathy
- Creatinine clearance <51 mL/min

Poor risk
- Three organs involved
- Advanced cardiac involvement

Melphalan dosing as a function of risk group and age

Good risk	*Intermediate risk*	*Poor risk*
200 mg/m^2 if ≤60 years	140 mg/m^2 if ≤50 years	Standard therapy
140 mg/m^2 if 61–70 years	100 mg/m^2 if 51–60 years	Clinical trials
100 mg/m^2 if ≥71 years

appear to be able to achieve similar results as those of centers with a special interest in amyloidosis and transplantation.[320]

The 270 Mayo Clinic patients with amyloidosis received their transplants a median of 4.2 months after histologic diagnosis: one-fourth within 3 months and three-fourths within 7.2 months. The median actuarial survival for the entire group was 75 months. Predictors of survival included weight gain of greater than 2% during stem cell mobilization and an absolute lymphocyte count at day 15 of greater than 500/μL.[321] The number of organs involved appeared to be relevant to successfully predicting outcome (Fig. 89–16). Patients with two-organ involvement have a survival of 55 months; those with three-organ involvement, 25.5 months. The serum creatinine, troponin-T, and BNP levels (Fig. 89–17) and septal thickness were all significant predictors of outcome.

Stem cell transplantation has not yet been established as the therapy of choice for patients with amyloidosis. In a French multicenter randomized trial (MAG and IFM Intergroup), patients with amyloidosis received either high-dose chemotherapy and autologous stem cell transplantation or melphalan/dexamethasone therapy.[322] The median survival was 57 months in the melphalan/dexametha-

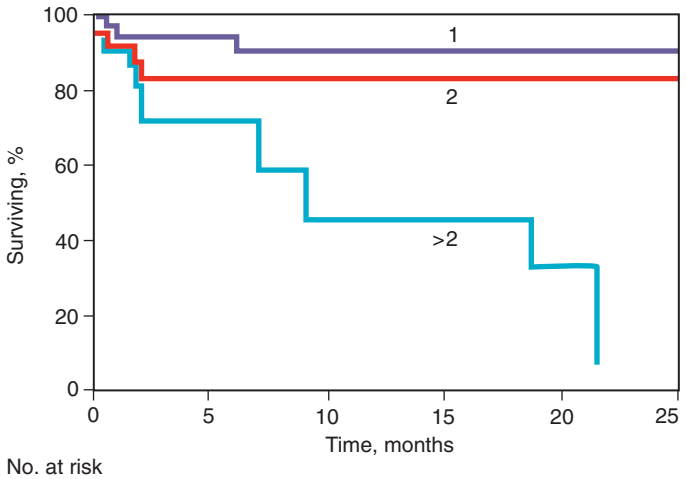
sone group and 49 months in the transplant group. Transplant patients received conditioning chemotherapy with either 140 or 200 mg/m² melphalan. The hematologic response rates were similar for both groups (65% vs 64%). These results suggest that overall survival may not be superior following stem cell transplantation as compared with melphalan/dexamethasone therapy.[322] The results of this study must be interpreted with caution because of the short median follow-up (29 months) and high transplant-related mortality (24%).

After transplant, responders to autologous stem cell transplantation have a superior survival as compared with nonresponders. Overall survival is linked to pretransplant free light-chain levels and the number of organs involved.[244,317] In centers performing stem cell transplantation, treatment-related mortality has ranged from 6% to 18%, hematologic complete responses from 16% to 50%, and organ responses from 34% to 64%.[323] Organ responses are time-dependent and may be delayed for up to 36 months after transplantation. The use of induction therapy with two cycles of melphalan and prednisone before stem cell transplant did not improve the rate of hematologic or organ response.[324]



Deaths have been reported during stem cell mobilization with cyclophosphamide plus G-CSF or G-CSF alone.[325] Hypoxia and hypotension may develop even in patients without cardiac involvement and may reflect a variant of pulmonary leukostasis syndrome. Excessive fluid accumulation during stem cell mobilization is an important predictor of 1-year survival.[326]

Toxic megacolon is a complication of high-dose chemotherapy.[327] Others have also reported fatal cardiac arrhythmias after infusion of DMSO-cryopreserved stem cell grafts.[328,329] The absolute numbers of $CD4^+$ T cells is significantly reduced after stem cell transplantation, raising the theoretical risk of serious opportunistic infections developing after transplantation. In a series of six patients, four had acute renal failure, one had splenic rupture, and one had severe gastrointestinal bleeding.[330,331] In a multicenter study of 15 transplant patients, there was no treatment-related mortality and 67% of patients experienced complete hematologic responses, which suggests the feasibility of performing stem cell transplantation at experienced transplant centers not associated with major amyloidosis referral centers.[332]

Amyloid-related cardiomyopathy is associated with a high rate of early mortality post transplant.[333] The median survival of patients with cardiac amyloidosis was 2 years. The overall median survival was 5.5 years, and the relapse rate of complete responders was only 5%.[333]

Most conditioning regimens used to treat patients with AL undergoing transplant include melphalan; currently, melphalan alone is preferred to melphalan plus total body irradiation. Complete hematologic response rates appear to be related to the dose of melphalan: 55% at 200 mg/m² and 35% at 100 or 140 mg/m².[317] Gastrointestinal tract bleeding is a frequent complication.[316] It is assumed that amyloid infiltration of the submucosa of the gastrointestinal tract followed by chemotherapy-induced mucosal erosion leads to exposure of amyloid-laden blood vessels, with resultant bleeding.

Despite the high mortality and morbidity associated with transplantation (Table 89–5), the hematologic and organ response rates far exceed the prior experience with conventional-dose melphalan. Improvement in quality of life has also been reported in melphalan-treated patients undergoing stem cell transplantation.[334] The best responses to transplant are seen in patients who have renal amyloidosis and nephrotic syndrome. We believe that the dose of melphalan used for conditioning must be modified according to patient risk factors. Clearly, patients with more than two major organs involved or severe cardiomyopathy are at a high risk when receiving melphalan doses of 200 mg/m² (Fig. 89–18). Patients with one or two organs involved, younger patients, and those without advanced cardiac disease are favorable candidates for stem cell transplants. A risk-

adapted stratification has been useful in selecting patients for therapy and assigning melphalan dose.[317]

The use of both conventional and high-dose chemotherapy has been shown to normalize factor X deficiency associated with amyloidosis.[335] Dose-intensive melphalan therapy improves nephrotic syndrome in patients with AL, but the benefit is limited to patients achieving eradication of the plasma cell dyscrasia.[336] A randomized study was performed comparing autologous stem cell transplantation with therapy with two cycles of oral melphalan and prednisone followed by stem cell transplantation.[337] The overall survival of patients 1 year after randomization was higher for those who went directly to transplantation.

The role of tandem transplants and nonmyeloablative conditioning regimens has yet to be defined in this setting. Tandem transplantation has been reported in four patients, all with nephrotic syndrome.[338,339] Two died, one of sudden death and one, who had sepsis with gastrointestinal tract bleeding, of complications of renal failure. Two of the patients are alive and in good health.

Patients who receive transplants for AL are highly selected on the basis of age, performance status, number of organs involved, absence of severe cardiomyopathy, and preserved renal function. The superiority of high-dose chemotherapy and autologous stem cells has never been demonstrated in a prospective study. Dispenzieri et al[340] reviewed an amyloidosis patient database to identify patients who might have been eligible for stem cell transplantation. The inclusion criteria of biopsy-proven amyloidosis, symptoms of amyloidosis, absence of multiple myeloma, restrictions on age, and adequate cardiac function led to the selection of 229 of 1,288 patients. The median survival of this group was 45 months, with 5- and 10-year survival rates of 36% and 15%, respectively (Fig. 89–19). Predictors of survival were size of the monoclonal protein component in the urine, number of organs involved (Fig. 89–20), serum alkaline phosphatase value, performance status, and weight loss. Being eligible for stem cell transplantation but not actually receiving the transplant was associated with a better outcome than not being eligible for transplantation.

In summary, with appropriate patient selection, stem cell transplantation is feasible but is associated with risks of higher morbidity and mortality than stem cell transplantation for other disorders.

INVESTIGATIONAL THERAPIES

In an experimental model in which mice are injected with human AL proteins, amyloidomas result.[341] When these animals receive injections of an anti–light chain monoclonal antibody having specificity for an amyloid-related epitope, the amyloidomas rapidly resolve. This monoclonal antibody is directed toward a β-pleated sheet conformational epitope expressed by AL proteins. The amyloidolytic response appears to be associated with the release of proteolytic factors. AL resolution can be induced by passive administration of amyloid reactive antibodies.[341] This approach is currently under evaluation.

Fourteen patients with AL received etanercept, an anti-TNF receptor monoclonal antibody, at 25 mg subcutaneously twice weekly.[342,343] Of 10 patients with adequate follow-up, 2 died and 8 are stable. One patient had an improved septal wall thickness. Three patients experienced a 25% to 50% decrease in the degree of macro-

glossia. Two patients with diarrhea had significant improvement. In 2 of 5 patients with peripheral neuropathy, disease progression was halted with therapy. Only 1 patient had adverse effects. Larger studies to further evaluate the role of etanercept in the management of AL are warranted.[342]

Lacy et al[344] reported the use of a dendritic cell–based idiotype vaccination for AL. Ten patients were treated and five had multiorgan AL. Three had received prior stem cell transplants. One patient had an objective response, with proteinuria decreasing by 95%. One patient had improvement of painful peripheral neuropathy. Specific T-cell proliferative responses to idiotype were detectable in the patient who had a clinical response. Optimizing patients' immune function and response will be the subject of future studies.

Use of antisense oligonucleotides for the inhibition of amyloid immunoglobulin production has been explored.[345] Antisense oligonucleotides against light-chain complementarity-determining regions prohibited light-chain production. It is possible to design specific complementary oligonucleotides, suggesting that treatment with antisense oligonucleotides could represent a rational approach to improve treatment outcomes in AL.[345]

Serum amyloid P binds to all forms of amyloid deposits. Drugs have been developed that act as competitive inhibitors of serum amyloid P binding to amyloid fibrils.[52] Such compounds dimerize serum amyloid P molecules, leading to their rapid clearance by the liver and depletion of circulating serum amyloid P. Such agents remove serum amyloid P from human amyloid deposits and may destabilize the existing amyloid fibrils, allowing for their dissolution.[52] Such a therapeutic approach is of great interest.

DEFINING RESPONSES IN PRIMARY AMYLOIDOSIS

Responses to therapy in patients with AL can be defined by improved organ function or by hematologic responses comparable to those seen in patients with multiple myeloma.[346] All patients who have a measurable serum or urine monoclonal protein should be monitored for changes in the size of the monoclonal protein peak after any therapeutic intervention. For patients who have only a free light chain that cannot be quantified, immunofixation is used to determine if the protein is present or absent. The recently introduced nephelometric free light-chain assay is extremely useful in monitoring patients serially to determine any decrease in circulating free light chain and has made the evaluation of response much easier.[41]

The utility of the free light-chain assay in predicting outcome has been validated as noted earlier in this chapter, with 5-year survival rates of 88% for responders and 39% for nonresponders.[43] In our experience, normalization of the free light-chain level was a better predictor of survival than was achievement of a complete hematologic response or normalization of the free light-chain ratio.[244] These results have been verified in a series of 25 patients with sequential free light-chain analyses.[347] All patients with a normalized κ to λ free light-chain ratio had a good prognosis.[347] The fraction of patients with serum free light-chain responses has been suggested to be higher in patients receiving high-dose melphalan than in those who receive conventional therapy.[348]

Free light-chain responses also seem to parallel decreases in NT-pro-BNP levels in cardiac responders to therapy. For patients in whom free light chain decreased by more than 50%, the NT-pro-BNP concentration decreased by a median of 48%, whereas in patients without such a free light-chain decrease, the NT-pro-BNP concentration increased by 47%.[349] The NT-pro-BNP decrease was greater in complete responders than in other responders. The decrease of free light chains translates to a simultaneous decrease of NT-pro-BNP and improved survival. Cardiac function in AL can improve due to a decrease in circulating amyloidogenic precursor, despite the amount of cardiac amyloid deposits remaining unaltered as measured by echocardiography.[349]

Organ-based response criteria have been defined for patients with amyloid nephrotic syndrome (Table 89–6).[350] Requirements for definition as an "organ response" include a 50% decrease in the 24-hour albumin excretion without an increase in serum creatinine value. For hepatic involvement, a 50% decrease in an increased serum alkaline phosphatase concentration with no increase in liver size is required. Echocardiographic regression of amyloidosis is difficult to assess because of variability in estimates of the interventricular septal wall thickness. Typically, a decrease in septal thickness of at least 2 mm is required. Neurologic responses can be documented by electromyography demonstrating improved nerve conduction velocities. A consensus panel has defined what constitutes organ involvement and treatment response in patients with AL.[350]

Table 89–6 Criteria for Amyloid-Related Organ Responses to Treatment*

Response	Progression
Heart	
Decrease of ≥2 mm in mean left ventricular wall thickness from baseline thickness >11 mm	Increase ≥2 mm in wall thickness
Two-class improvement in NYHA class	Two-class worsening in NYHA class
Kidneys	
>50% decrease in daily proteinuria without progressive renal insufficiency	>50% increase in daily proteinuria Progressive renal insufficiency
Liver	
A decrease in liver span of >50% A concomitant decrease of alkaline phosphatase by 50%	An increase in liver span of >25% An increase of alkaline phosphatase by 50%
Nervous System	
Autonomic: normalization of orthostatic vital signs and symptoms, resolution of gastric atony	Autonomic: progression of orthostatic vital signs and symptoms, increasing gastric atony
Peripheral neuropathy: resolution of symptoms	Peripheral neuropathy: progression of symptoms

NYHA, New York Heart Association.
*If organ function neither improves nor worsens, it is graded as stable.

CONCLUSION

AL is a disease for which therapy remains inadequate. The diagnosis should be suspected whenever a patient is seen with unexplained nephrotic syndrome, heart failure, neuropathy, or hepatomegaly. The first screening test should be immunofixation of serum or urine and the free light-chain assay. If a monoclonal protein is found, bone marrow biopsy and fat aspiration should be performed to obtain tissues for Congo red staining. Prognosis should be assessed by two-dimensional echocardiography and BNP and troponin level measurements. Monitoring therapy includes the use of immunoglobulin free light-chain assays by nephelometry. Systemic chemotherapy is appropriate for most patients. The response rates observed with stem cell transplantation are higher than those seen with standard therapy, and transplantation should be strongly considered if patients fulfill eligibility criteria. The use of solid organ transplantation remains investigational. The ideal treatment of AL remains unknown, but early diagnosis is essential to ensure superior outcome.

CHAPTER 90

ATYPICAL IMMUNE LYMPHOPROLIFERATIONS

Timothy C. Greiner and Thomas G. Gross

The development of modern classification systems for hematologic malignancies resulted from the recognition that specific histologic and cytologic patterns correlated with prognosis.[1] The Working Formulation for Clinical Usage predicted prognoses in many of the subtypes of lymphoma but was limited by the lack of immunophenotype and molecular data that the Revised European and American classification system proposed and the WHO classification system now provides.[1–3] These lymphoma classification systems can be reliably applied to most clinically relevant neoplastic lesions, but some lymphoproliferations are not addressed because they do not meet the pathologic definition of malignancy. No unifying system exists for classifying atypical or preneoplastic lymphoproliferations that provides prognostic information to predict whether a patient will have a self-limited illness or progress to lymphoma or death.

WHAT CONSTLTUTES AN ATYPLCAL LYMPHOPROLIFERATION?

The tremendous complexity of the immune system and its various responses to challenges has led to recognition of certain hyperplastic responses that are clearly benign and manifest specific histologic patterns when biopsied.[4] Examples of benign hyperplastic immune responses include follicular hyperplasia, in which B-cell areas of the lymph node increase in size and number. As a nonspecific diagnosis, follicular hyperplasia may be seen in a wide range of clinical presentations, from bacterial infections to generalized lymphadenopathy of acquired immunodeficiency syndrome (AIDS).[4] Sinus histiocytosis, in which benign histiocytes distend lymph node sinuses,[4] is seen in reaction to particulates and organisms in the hilar lymph nodes and in lymphoid drainage sites of carcinomas. Clearly benign or malignant lesions can be easily diagnosed by biopsy, clinicopathologic correlation, and the exclusion or establishment of clonal rearrangements.

A significant group of patients present with unusual clinical features, and their biopsies result in pathologic diagnoses that prompt the use of terms such as *atypical* or *suspicious for malignant lymphoma*, leaving the physician with incomplete information on how to treat the condition. Some disorders manifest with clinical features that suggest a malignant process but show characteristic histologic features that correlate with a benign outcome. Most of these processes are related to an abnormal immune response to some inciting stimulus. Others may sometimes result in the death of the patient, by progression to malignancy or by damage to or by the immune system. Accurate diagnosis requires careful correlation of immunohistologic, karyotypic, virologic, and genotypic analyses with the clinical findings. The more commonly encountered "atypical lymphoproliferations" related to viruses, drugs, genetic abnormalities, and unknown causes will be discussed (Table 90–1).

VIRUS-ASSOCIATED ATYPLCAL LYMPHOPROLIFERATIONS

Epstein–Barr Virus: Fatal Infectious Mononucleosis

Biologic Aspects

The prototypical cause of atypical lymphoproliferations is the ubiquitous Epstein–Barr virus (EBV).[5] EBV causes the well-characterized clinical syndrome of infectious mononucleosis (IM) (Chapter 54).[6] This discussion will not specifically address IM but will cover those lesions that fall outside the usual clinical spectrum of self-limited IM.

EBV, a large herpesvirus (172,000 base pairs), preferentially infects B cells in humans and causes lifelong infection.[6,7] The key to understanding atypical responses to EBV involves the relationship that is established between the virus and the immune system after primary infection.[8] Primary infection by EBV results in two main responses, depending on the age of the individual or the maturity of the immune system.[8] If the primary infection occurs in early childhood, the immune response and clinical symptoms are almost always silent, but about two-thirds of infected older children and adults will develop IM.[6] Once infected by EBV, an individual maintains a lifelong relationship with the virus in which a virus-driven B-cell proliferation is kept in check by the host immune surveillance. A low level of virus production occurs in the oropharyngeal region by unknown mechanisms; approximately 1 in 10^6 B cells in peripheral blood carries EBV.[9,10] The intimate association of oropharyngeal epithelium with oropharyngeal lymphoid tissue results in a constant cycle of circulating infected B cells. Disease results when the immune system is depressed, by iatrogenic means or by concurrent infections with other agents (Fig. 90–1).[8] The resulting immune suppression allows escape of EBV-infected B cells and resultant lymphoproliferation.[5,7,8,11] The self-limited course of IM contrasts with the atypical responses that can occur, such as fulminant infectious mononucleosis (FIM).[8,11] In FIM, the EBV nonspecific response, primarily the cellular response, is uncontrolled. FIM is characterized by extensive infiltration of parenchymal organs by polymorphous lymphoid cells (Fig. 90–2), primarily $CD8^+$ cells in various degrees of transformation and histiocytes with surprisingly few B cells.[8,11] The cells infected by EBV in FIM are usually T cells and may become clonal.[12,13] The extent of T-cell and histiocytic reactions in FIM is often dramatic and hemophagocytosis is common.[8,11–14]

Epidemiology

FIM occurs in approximately 1 in 3000 IM cases, or approximately 40 cases annually in the United States.[5,8] The explosive lymphoproliferation that occurs in FlM mimics that in certain hematologic neoplasms, such as lymphoid leukemia, and can obscure recognition

of FIM as a cause of death.[5,8,11–14] The median age at presentation is 13 years, with a 1 : 1 male/female ratio.[14]

Clinical Manifestations

Patients who progress to FIM initially present with the usual signs and symptoms of IM, including fever, sore throat, malaise, anorexia, nausea, vomiting, and a maculopapular rash, but these symptoms are usually more extensive than those of IM.[8,14] Patients initially present with an atypical lymphocytosis but subsequently develop severe, persistent pancytopenia, hepatic dysfunction resulting in fulminant hepatitis, meningoencephalitis, and various degrees of myocarditis.[5,8,11–15] The development of hepatic dysfunction, often with coagulation abnormalities secondary to liver failure or disseminated intravascular coagulation, and pancytopenia is an ominous sign, as are other signs of hemophagocytic syndromes, such as hypofibrinogenemia and elevated triglycerides.[8,11,15,16] The course and progression of the disease are variable, ranging from presentation in multiorgan failure developing over hours to persistent or recurring symptoms of IM for months.

Laboratory Diagnosis

The diagnoses of EBV-associated atypical lymphoproliferations and of FIM can be difficult, because the usual EBV antibody responses may be lacking or unusually high, and the clinical picture may resemble an acute leukemia, another malignancy, or overwhelming sepsis.[5,8,11–14] Reactive lymphocytes may be seen in the peripheral blood. An accurate diagnosis may require performing serologic studies

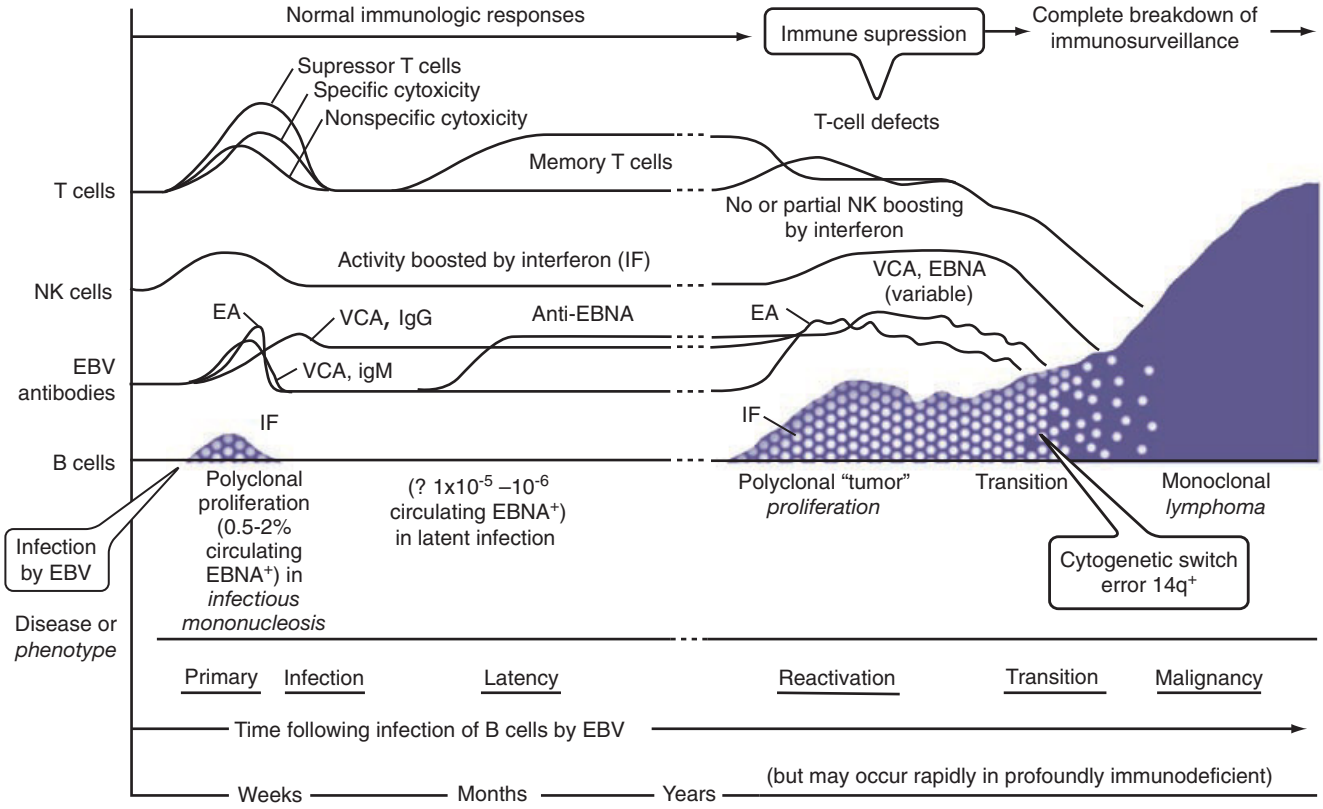

Figure 90–1 The EBV-immune system relationship and the development of lymphoproliferations associated with various immune deficits or diseases.

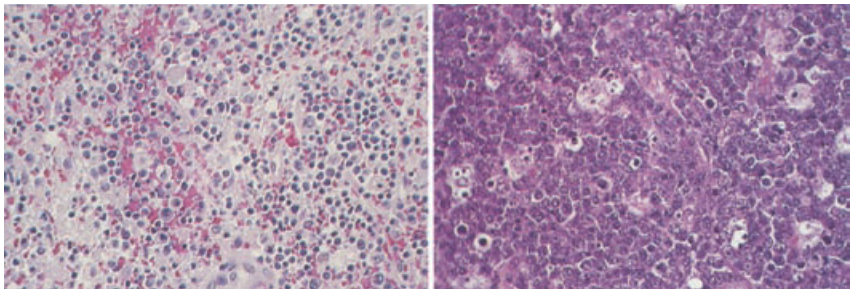

Figure 90–2 A, Florid fatal infectious mononucleosis involving a lymph node shows a polymorphous, immunoblastic infiltrate (H & E × 400). **B,** Burkitt type non-Hodgkin lymphoma, in contrast, shows a monomorphous infiltrate (H & E × 400).

of the EBV-specific antibodies to the viral capsid antigen (VCA), early antigen (EA), and EBV nuclear-associated antigen (EBNA). In situ hybridization is more sensitive than immunohistochemical staining of lymphoid tissue for latent membrane protein (LMP)-1.[17] Molecular analyses, such as Southern blot hybridization can be used to determine clonal integration, and quantitative viral load can be performed by polymerase chain reaction (PCR) studies.[18–20] Because FIM is rare, a search for a heritable immune deficiency in family members is mandatory.[8,11,15,16] Although FIM is the most common manifestation of males affected with X-linked lymphoproliferative disease (XLP), FIM can occur outside the context of XLP.[5,8,14–16] Clinically, FIM is indistinguishable from other viral-associated hemophagocytic syndromes (VAHS), familial hemophagocytic lymphohistiocytosis, and the accelerated phase of Chédiak–Higashi syndrome.[8,11,16]

Therapy

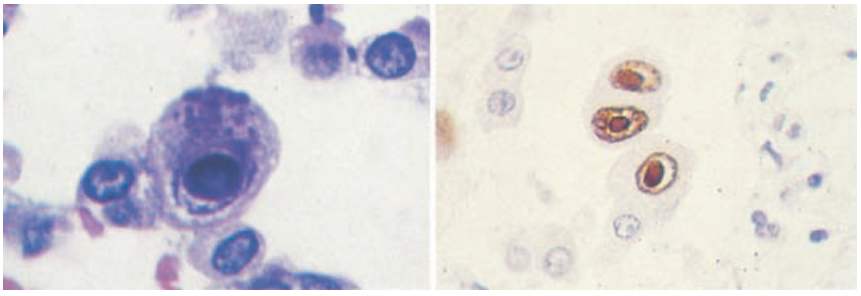
Treating FIM is difficult and often unsuccessful, with a median survival time of approximately 4 weeks.[15,21] Antiviral drugs, immunoglobulins, IL-2, IFNα, IFNγ, plasmapheresis, corticosteroids, and most cytotoxic drugs have been ineffective.[8,11] There is one report of 20 patients with IM and hemophagocytosis, without severe symptoms of FIM, successfully treated with chloroquine.[22] The most consistent success in the treatment of FIM is with the early use of etoposide, which reduces the activity of stimulated macrophages in vitro, in combinations with intravenous immunoglobulins or immunosuppression with corticosteroids and cyclosporin A or tacrolimus (FK506).[11,21,23–25] Therapy may be required for 6 to 12 months. These patients are profoundly immunocompromised from their disease and the therapy. Therefore, a successful outcome is dependent on the control of FIM symptoms, while preventing and treating life-threatening infectious complications. Even with remission of symptoms, recurrences are common and for those cases, the prognosis is poor. Allogeneic blood/marrow transplantation (BMT) is recommended for patients where the disease can be controlled and results in cures in up to half of the patients.[25–27]

Prognosis

Patients who develop FIM succumb to severe and progressive multiorgan failure, apparently brought on by anomalous cytotoxic T-cell and natural killer cell activities, which nonselectively destroy uninfected hepatocytes, bone marrow elements, skin, and other organs during the unrestricted polyclonal immune response initiated by the EBV infection.[5,8,11,13–15] Until recently, the median survival was 4 weeks.[15,21] However, with immunochemotherapy with etopside and allogeneic BMT as many as half of patients can survive.[25–27]

OTHER PRESENTATIONS OF EPSTEIN–BARR VIRUS LYMPHOPROLIFERATIONS

Rarely, elderly patients, malnourished patients, and those with cancer also develop EBV-associated atypical lymphoproliferations.[28] These patients usually have a secondary immunodeficiency. Most of them will have had a prior infection with EBV and will have achieved a virus-immune system balance before acquiring the immune deficiency, which then allows the virus to escape the defective immune surveillance mechanisms. Lymphoproliferations ranging from IM to FIM to overt lymphoma (see Fig. 90–2B) can then occur.[5,14] Patients with the acquired immunodeficiency syndrome also experience virus reactivation because the T-cell arm of the immune system is selectively attacked by the AIDS virus, resulting in loss of control over the persistent EBV infection.[5] Various lesions, including polyclonal immunoblastic proliferations, hairy leukoplakia of the tongue, leiomyosarcoma and lymphoma have all been associated with EBV.[29–31] Children with AIDS often develop lymphoid interstitial pneumonitis resulting from EBV-induced polyclonal B-cell proliferation.[32] Highly active antiretroviral therapy (HAART) has reduced the incidence and improved the outcome for HIV patients with lymphoma.[33–35]



CYTOMEGALOVIRUS

Cytomegalovirus (CMV), also a herpesvirus, can cause the mononucleosis syndrome but is usually latent until unmasked by immune deficiency, pregnancy, multiple drug exposures, or immune suppression. CMV causes less of a lymphoproliferative response than EBV, and activation often results in more extensive inflammation and tissue necrosis.[36] Diagnosis is made by appropriate serologic studies, by identification of characteristic nuclear inclusions in cytologic or tissue biopsy specimens (Fig. 90–3A) immunoperoxidase studies (see Fig. 90–3B), or by molecular techniques, including in situ hybridization and PCR.[36,37] Therapy includes the use of current antiviral agents, such as ganciclovir, foscarnet, or cidofovir.

VIRUS-ASSOCIATED HEMOPHAGOCYTIC SYNDROME

Introduction and Epidemiology

Virus-associated hemophagocytic syndrome (VAHS) is also included in the spectrum of atypical lymphoproliferations and usually occurs in the setting of immunodeficiency.[15,25,38] The syndrome was originally described in patients with viral infections but has subsequently been encountered in patients with fungal, bacterial, and parasitic infections; in immunodeficient patients; and in patients with T-cell lymphomas.[38] VAHS has now been classified as a secondary form of type-II histiocytic disease, termed histiocytic lymphohistiocytosis

A B

Figure 90–3 Cytomegalic inclusion disease. **A,** Characteristic cytomegalovirus (CMV) nuclear inclusion and cytoplasmic inclusions are evident (H & E × 1000). **B,** Immunoperoxidase with anti-CMV confirms the presence of cytomegalovirus (dilute hematoxylin counterstain × 400).

(HLH).[25] A familial form of HLH also occurs, called familial erythrophagocytic lymphohistiocytosis (FEL), which is an autosomal recessive condition, and has been associated with mutations in the genes encoding perforin, Munc 13–4, and syntaxin.[16] Evidence of viral infection does not rule out a genetic etiology of HLH.

Clinical Manifestations

Approximately 80% of patients with FIM exhibit clinicopathologic findings consistent with VAHS.[11,15,39] Patients with VAHS present with hepatosplenomegaly, abnormal liver function tests, fever, rashes, lymphadenopathy, coagulopathy, and pancytopenia, but may also present with central nervous system and pulmonary abnormalities.[11,16,39]

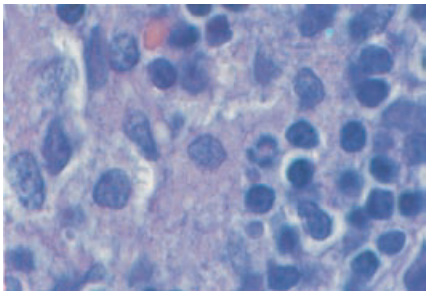


Figure 90–4 Virus-associated hemophagocytic syndrome. Extensive histiocytic erythrophagocytosis is evident in sinusoids of the lymph node. Histiocyte cytoplasm is distended by numerous red blood cell "ghosts" (H & E × 400).

Laboratory Diagnosis

Early in the course of VAHS, the bone marrow appears normal, but myeloid hyperplasia, lymphocytic infiltration, cellular necrosis, and increased macrophages subsequently appear.[39] Marked sinus histiocytosis with prominent erythrophagocytosis[39] (Fig. 90–4) is evident throughout the reticuloendothelial system of affected patients, and hyperplasia of the spleen can result in splenic weights in excess of 1 kg.[39] Histologic examination of lymph nodes, especially in HLH, shows lymphoid proliferation early in the disease, which is followed by lymphoid depletion at later stages. At necropsy, activated macrophages exhibiting phagocytosis, can be seen infiltrating areas of hemorrhagic necrosis.[15,16,39] The disease often terminates in a hemophagocytic syndrome with pancytopenia, jaundice, and marked erythrophagocytosis.

RETROVIRUSES AND LYMPHOPROLIFERATIONS

Human Immunodeficiency Virus

During the past decade, the RNA retroviruses have been implicated in a spectrum of lymphoproliferations. The AIDS retrovirus, human immunodeficiency virus (HIV), does not transform lymphocytes but selectively destroys helper T cells.[40] During acute HIV infection, a mononucleosis-like syndrome often occurs, and the virus can cause chronic, persistent lymphadenopathy characterized by florid follicular hyperplasia, follicular lysis, or follicular involution.[40] In situ hybridization of lymph nodes will demonstrate HIV sequences. Often EBV-positive cells will be increased 5- to 10-fold in lymphoid tissues of HIV-infected patients compared with those of non-HIV-infected patients. The T-cell immunodeficiency caused by HIV permits opportunistic viral, bacterial, protozoal, and fungal infections.

HUMAN T-CELL LEUKEMIA/LYMPHOMA VIRUS TYPE I

The most extensively studied transforming retrovirus is the human T-cell leukemia/lymphoma virus type I (HTLV-I), which is implicated in the endemic form of adult acute T-cell leukemia/lymphoma (ATL) in Japan and the Caribbean basin.[41] This virus has the capacity to selectively immortalize T cells in vitro, but HTLV-I infection alone is insufficient to cause malignancy, because only 1 in 2500 chronic viral carriers develop the T-cell malignancies after a long latent period.[41] HTLV-I infection is transmitted during sexual intercourse or by blood transfusion. The viral infection probably increases the likelihood of further cytogenetic events by stimulating T-cell lymphoproliferation. Seropositive asymptomatic carriers of the virus exhibit subtle signs of immunodeficiency.[41] Those who progress to ATL have HTLV-l-positive serology, generalized lymphadenopathy, hepatosplenomegaly, skin lesions, and distinct involvement of peripheral blood by a spectrum of malignant T cells ranging from small lymphocytes to bizarre hyperlobated forms.[41] Not all patients present with a leukemic phase. The prognosis for ATL patients is poor. If untreated, the median survival is weeks and even with chemotherapy expected survival is only months to a couple of years.[42] Of the many HTLV-infected patients who do not develop ATL, most are asymptomatic, but a small group may develop an early benign transient lymphocytosis; if subacute or chronic lymphocytosis persists, the risk of progression to ATL increases.

DRUG-ASSOCIATED LYMPHOPROLIFERATIONS

Although some drugs permit activation of latent viral infections such as EBV by causing immunosuppression, other drugs cause atypical lymphoid responses by a hypersensitivity reaction or by unknown mechanisms (Table 90–2). This results in lymphadenopathy mimicking lymphoma or skin lesions mimicking mycosis fungoides. Diphenylhydantoin (Dilantin) is a rare but well-documented cause of such responses.[43,44] The clinical presentation is similar to that of a viral infection and includes fever, rash, lymphadenopathy, and eosinophilia. Acquired immunoglobulin A deficiency may develop. The symptoms usually abate when the drug is stopped. The lymph node pathology may contain florid follicular hyperplasia, or it may be similar to that in infectious mononucleosis or paracortical expansion by a polymorphous immunoblastic infiltrate, which is sometimes mistaken for lymphoma.[43,44] Focal necrosis and Reed–Sternberg-like

cells may be evident. Hodgkin disease and non-Hodgkin lymphoma have been reported in association with diphenylhydantoin therapy.[44] Other hyperplastic lymphoid responses to drugs have been reported, including a hypersensitivity response to carbamazepine[45] that produces immunoblasts, which may be mistaken for peripheral T-cell lymphoma.[46–48] The immunosuppressive drugs, including cyclosporine, steroids, antilymphocyte globulin, tacrolimus, and cytotoxic agents usually unmask latent viral infections. Drug-induced atypical lymphoid infiltrates in the skin mimicking mycosis fungoides have been described with diphenylhydantoin, cyclosporine, and, most recently, imatimib.[49–51]

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS

Blood/marrow (BMT) and solid organ transplant (SOT) recipients are exposed to a variety of immunosuppressive agents, including prednisone, antimetabolites (azathioprine, methotrexate, and or mycophenolate mofetil) polyclonal antilymphocyte globulin, monoclonal antibodies (including anti-CD3, anti-CD25, etc), calcineurin inhibitors (cyclosporine, tacrolimus, etc), and/or mTOR inhibitors, such as rapamycin. These patients are at increased risk for malignancy, lymphoproliferative disease being most common following BMT and second only to nonmelanomatous skin cancer following SOT. Posttransplant lymphoproliferative disease (PTLD) includes predominantly atypical B-cell lymphoproliferations and, rarely, Hodgkin disease and T-cell lymphomas.[52–55] This discussion will be largely confined to the EBV-positive B-cell PTLDs.

Epidemiology

Over 90% of early (<1-year posttransplant) PTLDs are EBV-positive, whereas EBV is less frequently associated in late (>2 years) PTLDs.[56–58] The incidence of PTLD correlates with low T-cell immunity against EBV post-BMT[59] and in young children following SOT, which likely reflects EBV-naïve patients acquiring EBV infection.[60] Among bone marrow transplant recipients, those receiving T cell-depleted bone marrow allografts or anti-T cell therapy appear to be at particularly high risk for EBV-associated lymphoproliferation.[56] The prevalence and the posttransplantation interval that precedes development of PTLD vary with the type of organ transplanted and the immunosuppressive agents administered, though EBV naivety pretransplant and therefore young age appear to be the strongest risk factors for PTLD development.[57]

*Adapted from Jaffe ES, Harris NL, Stein H, et al: Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues. Lyon, IARC Press, 2001, p 264.

Biology and Molecular Aspects

These atypical lymphoproliferations can be aggressive with continued immunosuppression, even when polyclonal or oligoclonal, as defined by immunoperoxidase in situ hybridization or gene rearrangement studies. The clonal ambiguity has led to difficulties in diagnosis, nomenclature, and therapy.[61,62] A classification of PTLD, by Knowles, describes three main subgroups: plasmacytic hyperplasias, polymorphous PTLDs (Fig. 90–5), and monomorphous PTLDs, which include lymphoma and multiple myeloma.[63] This classification system is reflected in the recent WHO classification of hematologic malignancies, which includes PTLD (Table 90–3).[3] The monomorphous PTLDs have a higher incidence of clonal heavy-chain or light-chain immunoglobulin gene rearrangements. However, this subgroup also has a low incidence of chromosomal translocations and mutations in p53, compared with non-transplant-related lymphomas.[63] Deletions in LMP-1 do not predict for an aggressive tumor.[64] It has been proposed that bcl-6 mutations predict for poor survival; however, this finding has yet to be confirmed.[65]

The pathogenesis of PTLD is related to a disruption of the host's EBV immune surveillance by immunosuppression (see Fig. 90–1). During the first 6 months after transplant, the cytotoxic T-lymphocyte response to EBV is often absent.[59,66] In addition, patients on immunosuppression, such as cyclosporine, have an imbalance of T

cell-secreted cytokines, favoring B-cell proliferation.[67] Therefore, if immunosuppression is continued, EBV-infected B cells proliferate uncontrolled. The B-cell origin appears to be predominantly host cells in solid organ transplant patients[68] but are usually donor origin in bone marrow transplant patients.[68] The source of the virus is often the transplant graft.[69,70]

Clinical Manifestations

Patients with PTLD present in several ways: single mass lesions, such as lymphoma, infectious mononucleosis with tonsillar enlargement, cervical lymphadenopathy or hepatitis, or both, or a septic appearance with fever but no radiologically detectable mass.[52,61,62,71]

Laboratory Evaluation

Radiology studies may reveal a mass, a miliary pattern of PTLD may be seen in the lungs, or there may be no lesion at all. Peripheral blood will sometimes reveal circulating plasmacytoid lymphocytes or plasma cells. Quantitative measurements of EBV load in the peripheral blood often rise before the rapid development of PTLD lesions.[72,73] However, caution is advised as some patients do not develop increased levels of EBV and the diagnosis of PTLD, therefore, cannot always be predicted.[74] Tissue biopsy should be performed for immunophenotyping and in situ hybridization for EBV sequences, because LMP-1 protein will be negative in 25% of cases.[17] Typically, the lymphoid tissue is composed of plasmacytoid B cells, with few T cells and often regional areas of necrosis. Distinguishing between a polyclonal and a monoclonal PTLD often requires lymphoid receptor gene analysis, because up to 50% of PTLDs do not express surface immunoglobulin.[61]

Therapy and Prognosis

Mortality rates among patients with PTLD are as high as 50% to 90%, with about half of patients succumbing to tumor and 30% to 50% dying from treatment-related complications, including allograft rejection, infections, and end organ toxicity from cytotoxic therapies.[56–58,75–77] Successful treatment of PTLD is a therapeutic challenge, in part because of the patients' increased toxicity from chemotherapy, increased susceptibility to life-threatening infections, and the necessity to maintain the allograft, especially with vital organs (heart, lung, or liver). Reduction of immunosuppression is the most widely used approach.[57,78,79] Many times this is sufficient in controlling the disease, especially in localized, polyclonal cases or cases that manifest as infectious mononucleosis. Patients who do not tolerate reduction of immunosuppression (ie, graft rejection), or do not respond to immunosuppression reduction, require more aggressive therapy and have a much poorer prognosis. Antiviral agents (acyclovir or ganciclovir), and intravenous immunoglobulin (IVIG) have been used extensively for the prophylaxis and treatment of PTLD.[57,79] The efficacy of antivirals and IVIG is difficult to assess because reduction of immune suppression is almost always initiated simultaneously.

Surgery or radiotherapy are very effective in curing localized disease, but this represents only a small percentage of patients.[57,79] Monoclonal antibodies are attractive because of the favorable toxicity profile. In the past, anti-CD21 and anti-CD23 and more recently anti-CD20 (rituximab) have been successful in curing PTLD in both the BMT and SOT setting. Response rates with anti-B cell monoclonal antibodies results are variable, with complete response rates ranging from 25% to 75% and overall survival usually approximately 50%.[80–84]

Because virus-specific cytotoxic T cells (CTL) are critical in the control of EBV-driven B-cell proliferations, adoptive T-cell therapy is a logical approach.[85] To overcome potential risks of graft-versus-host disease or rejection, ex vivo generated EBV-specific CTLs have been used. This approach has been very successful at preventing and treating PTLD after BMT without significant GVHD.[86] However, the issue of using adoptive cellular therapy (DLI) in solid organ transplant (SOT) patients with PTLD is complex. First, cadaveric organs are most widely used; therefore, donor leukocytes are often not available and the use of closely matched relatives' leukocytes runs the risk of rejection and GVHD. Recent studies have demonstrated that recipient EBV-specific CTLs can be generated ex vivo and administered safely. As opposed to BMT, following SOT patients receiving EBV-specific CTLs have a less pronounced effect on reduction of viral load in peripheral blood and do not persist, which may necessitate multiple infusions to obtain a remission.[87,88]

The use of chemotherapy for a PTLD does not require waiting for the progression to the standard pathologic criteria for diagnosis of lymphoma because the polymorphous hyperplasia subgroup of PTLD can be equally lethal. Chemotherapy has been efficacious in treating PTLD in some patients. The intensive, multidrug regimens (ie, anthracycline-based) traditionally used to treat high-grade lymphomas are usually immunosuppressive enough to maintain the organ graft, but treatment-related death resulting from toxicity and infection has been in the 30% to 50% range in most series and the 1-year survival rate is only 40% to 45%.[75,76,89,90] A low-dose chemotherapy approach has demonstrated little toxicity and approximately 67% disease-free survival in children with PTLD following SOT.[91]

ATYPICAL LYMPHOPROLIFERATIVE DISEASE IN PATIENTS WITH AUTOIMMUNE DISORDERS

Other disorders of immune regulation have an increased prevalence of lymphoid neoplasia. Patients with autoimmune collagen-vascular disease (ie, rheumatoid arthritis) can develop non-Hodgkin lymphomas, which often arise in the setting of reactive lymphadenopathy.[92,93] These patients develop atypical lymphoid hyperplasia and non-Hodgkin lymphoma during methotrexate or azathioprine therapy.[94–96] Case reports describe spontaneous resolution on discontinuance of methotrexate.[95,96] Individuals with Sjögren syndrome also show a progression of lymphoid hyperplasia to frank neoplasia, with a risk 44 times that observed in the general population.[97]

GENETICALLY LINKED IMMUNODEFICIENCY AND LYMPHOPROLIFERATIONS

Subsequently, the triad of autoimmunity, immunodeficiency, and lymphoproliferation has been defined in an increasingly large group of patients with inherited and acquired immunodeficiency disorders. Below are described some of the more well characterized.

THE X-LINKED LYMPHOPROLIFERATIVE DISEASE

XLP disease illustrates the spectrum of lymphoproliferations that can occur in hereditary immune deficiencies—ranging from benign or fatal IM to non-Hodgkin lymphoma.[5,8,12–15] After EBV infection, chronic or fatal IM, acquired hypogammaglobulinemia, or agammaglobulinemia, pure red cell aplasia, necrotizing lymphoid vasculitis, or non-Hodgkin lymphoma ensues.[15,21]

Biologic and Molecular Aspects

The gene responsible for XLP, SH2D1A, was discovered in 1998.[98–100] The SH2D1A gene codes for a protein of 128 amino acid residues that consists of an SH2 domain and a 25-amino acid C-terminal tail.[98,99] SH2D1A is expressed throughout thymocyte development, as well as in $CD4^+$ and $CD8^+$ peripheral T cells.[100] The function of the SH2D1A protein appears to be in the regulation of immune responses. The SH2D1A protein interacts with several proteins, including SLAM (CD150, signaling lymphocyte activating protein),

and has also been called SLAM-associated protein (SAP).[99] Other proteins SH2D1A/SAP has been demonstrated to interact with are members of the CD2 superfamily of molecules, including CD2, CD4, CD583, CD84, Ly-9, 2B4, and with a new family of RasGAP adapter proteins such as p62Dok (Dok-1, downstream of kinases-1), p56Dok (Dok-2), and Dok-3.[101–105] The immunologic effects of SH2D1A interactions with these proteins is under investigation. Recent studies from sh12da-deficient mice demonstrate a phenotype that recapitulates that observed in affected males, that is, an exuberant and lethal CD8 T-cell response following lymphocytic choriomeningitis virus (LCMV).[106] In vitro studies have demonstrated that CD8 cytotoxic T cells from XLP males are deficient in killing autologous EBV B-cell lines.[107] As well, recent studies with sh2d1a-deficient mice over time develop problems with immunoglobulin class switching and defective memory humoral immune responses and ultimately hypogammaglobulinemia even without LCMV infection, again analogous to what is observed in affected males.[108] To date, however, it has not been demonstrated that sh2d1a-deficient mice have a high incidence of lymphoma or cytopenias.

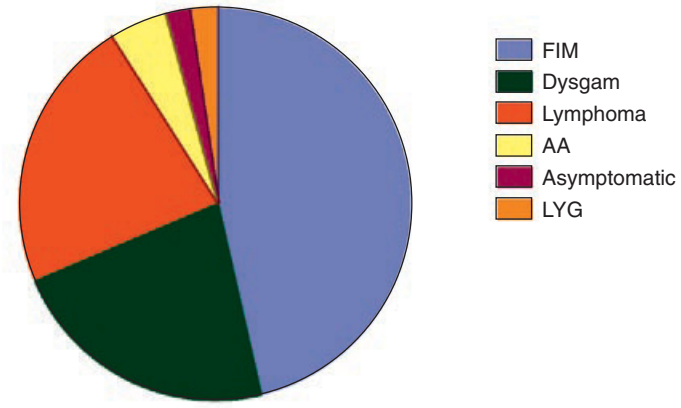

Figure 90–6 Frequency of phenotypes in X-linked lymphoproliferative disease. AA, Aplastic anemia; Dysgam, dysgammaglobulinemia; FIM, fulminant infectious mononucleosis; LYG, lymphoid granulomatosis/vasculitis.

CLINICAL MANIFESTATIONS

Initially, three phenotypes were described in XLP patients and these continue to characterize most patients: fulminant infectious mononucleosis (FIM or EBV-HLH), malignant lymphoma (LPD), and dysgammaglobulinemia.[15] Less commonly reported manifestations include disorders such as vasculitis, pulmonary lymphomatoid granulomatosis, and hematologic cytopenias, including aplastic anemia and pure red cell aplasia.[15,21] The "disease state" is capricious because it may feature a single phenotype, or two or more phenotypes, which may develop sequentially in susceptible individuals.[21] Reflecting the ubiquitous nature of EBV infection, FIM is the most common XLP phenotype affecting approximately 50% of patients. FIM or EBV-HLH observed in XLP is indistinguishable clinically from disease observed in patients without XLP and treatment and prognosis is identical.[8,11–16,27] Other than FIM, a lymphoproliferative disorder (LPD) develops in approximately 25% of XLP patients. Most lymphomas are of B-cell phenotype and are characterized by a small noncleaved (Burkitt) or diffuse large-cell histology.[109] Karyotypic analysis has not been extensively performed; however, the t(8;14) associated with Burkitt lymphoma is rare.[110,111] Approximately 10% of LPDs are not of B-cell phenotype.[21] There have been a small number of patients with Hodgkin disease or T-cell lymphoproliferative disorders, including lymphoblastic lymphoma, lymphomatoid granulomatosis, or angiocentric immunoproliferative lesions.[112] As in other immunodeficiencies, the role of EBV in the LPD of XLP is unclear, because about one half of the boys with LPD have no evidence of prior EBV infection, and EBV is detectable in only 25% of tumor specimens.[21]

Initially, it was believed that males affected with XLP only present with symptoms after primary EBV infection. Although IM is by definition caused by EBV, other XLP phenotypes can developed in EBV-seronegative patients.[21,113] Data from the XLP Registry demonstrated that at least 12.5% of affected boys will present with symptoms of XLP before exposure to EBV.[21] There is no difference of age at onset of clinical symptoms between males that have or have not been previously exposed to EBV.[21] Therefore, prevention of EBV infection in boys with XLP will not avert clinical manifestations. It is also curious that approximately 40% of the boys develop FIM after primary infection with EBV, but 60% never develop FIM but instead dysgammaglobulinemia, hematologic cytopenias, and a few have no symptoms at all.[21] These data suggest that other genetic or environmental factors, or both, influence host susceptibility to EBV and are important in the determination of the clinical phenotype of XLP. The disease should be suspected in families in which maternally related boys develop FIM, acquired hypogammaglobulinemia, agammaglobulinemia, or malignant lymphoma (Fig. 90–6).

The main differential diagnosis in these patients involves lymphoma versus florid IM. Patients who develop malignant lymphoma usually present with discrete mass(es), often extranodal, with or without dissemination at the time of diagnosis.[112] In contrast, patients with severe or fatal IM have a disseminated lymphoproliferation that may or may not present with generalized lymphadenopathy but does involve lymphocytic infiltration of multiple organ sites, including the skin, liver, spleen, lung, bone marrow, and brain.[11,15] Although most boys will not have a detectable immune defect prior to EBV infection, it has been shown that the cytotoxic T cells from affected males have a defect in killing autologous EBV-transformed cell lines,[108] and all boys over time will evidentially develop dysgammaglobulinemia even if not infected with EBV.[15,21]

LABORATORY EVALUATION

Before the isolation of SH2D1A, the gene known to be absent or mutated in XLP, it was often difficult to make a diagnosis of XLP based solely on clinical or laboratory features.[15] Now the diagnosis can more easily be made on the basis of the identification of an abnormal SH2D1A gene sequence or protein expression.[21,114] One might predict that mutations that delete the XLP gene or truncate the protein would be more likely to be associated with a severe phenotype, whereas missense mutations would occur preferentially in mildly affected patients. However, it is not uncommon to observe different phenotypes with identical mutations, even within the same family. No significant differences have been observed in the phenotypes or severity of disease based on the type (missense, nonsense, truncating) or localization of SH2D1A mutations. The age of onset of clinical manifestations of XLP varied considerably, from younger than 1 to 40 years, and there was no correlation with the type of mutation. Therefore, genetic analysis does not predict the phenotype or severity of disease.[21]

Therapy and Prognosis

Complete remissions (CR) at rates as high as 80% can be achieved in XLP boys presenting with lymphoma using standard lymphoma protocols; however, relapses or other manifestations (ie, hypogammaglobulinemia) are very common.[21] Boys with dysgammaglobulinemia receive monthly IgG infusions, but this does not prevent EBV infection and its sequelae. Several boys have developed FIM and died while receiving IgG supplementation.[15] Because FIM is essentially indistinguishable from other hemophagocytic syndromes (ie, HLH) it is now recommended that boys receive aggressive chemotherapy, to quell the immunologic anarchy of uncontrolled T-lymphocytes and macrophages, with etoposide (VP-16) to quench

macrophage activation and steroids or cyclosporine to downregulate T cells.[25] However, relapses are common, so the recommended therapy for FIM is now aggressive intervention with etoposide and immunosuppression and initiation of a search for a suitable bone marrow donor, with transplantation performed once the patient is stabilized.[27] Allogeneic hematopoietic stem cell transplantation remains the only curative therapy for XLP.[24]

OTHER HERITABLE IMMUNODEFICIENCY DISEASES WITH LYMPHOPROLIFERATIONS

Clinical Manifestations

A complete review of genetically linked diseases manifesting lymphoproliferation is beyond the scope of this discussion, but certain conditions have been sufficiently characterized to allow recognition (see Table 90–1). Both reactive lymphoproliferations and malignant transformation can be observed in these patients and more extensive evaluations, such as clonality and molecular genetics for oncogene activation may be required. As mentioned previously, there are genetic immunodeficiencies that primarily present as HLH, that is, perforin, munc13–4, and syntaxin 11.[16] One recent report suggests that perforin deficiency also increases the risk of lymphoma.[115] Chediak–Higashi syndrome also can manifest as an "accelerated phase" following EBV infection, which is indistinguishable from other EBV–HLH and patients are at increased risk for lymphoma.[16,116] Autoimmune lymphoproliferative syndrome (ALPS) is a recently described entity in which patients present as early as infancy with generalized lymphadenopathy, hepatosplenomegaly, hypergammaglobulinemia, and usually B-cell lymphocytosis. The autoimmune characteristics include hemolytic anemia, Guillain–Barrè syndrome, urticarial rash, glomerulonephritis, and idiopathic thrombocytopenia.[117] Recently, it has been demonstrated that a significant number of patients diagnosed with Evan syndrome have fas mutations or ALPS.[118] The risk of developing lymphoma, both Hodgkin and non-Hodgkin, is significantly increased for the life of patients with ALPS.[119] As in XLP, many of the lymphomas in patients with inherited immunodeficiencies are B-cell phenotype and associated with EBV, but this is not universal, suggesting the defect lies in more than an inability to control a viral infection, but in immunosurveillance against aberrant lymphoproliferation in general.[116]

Epidemiology

The incidence of cancer is greatly increased in patients with genetic immunodeficiencies, and lymphoproliferations are common.[116] Patients with primarily antibody deficiencies, such as X-linked agammaglobulinemia (XLA) and combined variable immune deficiency (CVID), also have an increased risk of epithelial cancers and adenocarcinomas.[116] Lymphomas predominate in diseases with a significant T-cell defect, such as XLP, severe combined immunodeficiency (SCID), Wiskott–Aldrich syndrome, ataxia-telangiectasia, X-linked hyper-IgM (CD40 ligand deficiency), Chediak–Higashi syndrome, perforin deficiencies, and autoimmune lymphoproliferative syndrome (fas deficiency).[116,118]

In autoimmune lymphoproliferative syndrome (ALPS), the pathology is characterized by an expansion of double-negative T cells ($CD3^+$, $CD4^-$, $CD8^-$) in lymph nodes, accompanied by a polymorphous infiltrate composed of plasma cells, small lymphocytes, and immunoblasts. Florid follicular hyperplasia is frequently present. Reduced apoptosis and an increased percentage of proliferative cells are seen.[119] The etiology of most patients with ALPS is impairment of apoptosis due to inherited heterozygous (Type O) or heterozygous mutations (Type 1) in the fas gene (CD95), or fas ligand.[116,120,121] Rare cases have been described of ALPS type II with mutations in caspase 10 or capase 8. In Type III, wherein no germline mutation of buccal mucosa has been identified,[121,122] heterozygous fas mutations have been observed in double-negative ($CD4^-$, $CD8^-$) T cells.[123]

Laboratory Evaluation

The diagnosis of lymphoma can be difficult in these patients, who frequently have reactive lymphoid hyperplasia or chronic granulomatous inflammation. Demonstration of EBV in lesions is helpful in evaluating a lymphoid lesion, but is not synonymous with lymphoma. EBV-positive cells can be found in greater than normal numbers in benign nodes, and EBV is not found in all the lymphomas.[124,125]

Therapy and Prognosis

Although complete remissions can be achieved in these patients, the outcomes for patients with primary immunodeficiencies and lymphoma compared with immunocompetent patients with lymphoma have been poor.[116,126] One reason is death due to chemotherapy toxicities, especially in conditions with DNA repair defects as well, that is, ataxia telangectesia or Bloom syndrome. Deaths due to infections and sepsis are also frequent, and relapses are also common.[116,124,126] Therefore, induction of remission with reduced-intensity or standard-dose chemotherapy followed by correction of the underlying immune defect (ie, allogeneic stem cell transplantation, if a suitable donor can be identified) offers the greatest chance of long-term survival.

ATYPLCAL LYMPHOPROLIFERATIONS OF UNKNOWN CAUSE ANGIOFOLLICULAR LYMPH NODE HYPERPLASIA

Epidemiology

Angiofollicular lymph node hyperplasia (AFH), or Castleman disease, has many other names, including giant lymph node hyperplasia, angiomatous lymphoid hamartoma, lymph node hamartoma, and lymph node hyperplasia of Castleman.[127] There is no gender or age preference, and most patients present with asymptomatic mediastinal masses, which are discovered on routine chest radiographic examinations. There are two types of localized AFH, the more common hyaline vascular (90%) and the plasma cell type (10%).[127]

Multicentric lesions have been identified in a subgroup of patients and may herald a higher risk of subsequent development of overt lymphoma.[127,128] Most reports in the literature favor the concept that the hyaline vascular type of AFH is a reactive chronic lymphoid hyperplasia.[129,130] The plasma cell type is considered to have an inflammatory pathogenesis, through chronic antigenic stimulation (ie, infection) or by an autoimmune mechanism. The plasma cell group tends to affect younger persons and has higher rates of mesenteric and retroperitoneal tumors.[127]

Clinical Manifestations

When symptomatic, the hyaline vascular subgroup of patients present with mass-related symptoms, such as pain, chronic cough, and obstruction. Clinical symptoms associated with the plasma cell type include fever, sweats, weight loss, and fatigue. Patients with multicentric disease can be extremely ill with malaise and cytopenias.[127,128]

Laboratory Evaluation

Associated laboratory abnormalities include anemia, an elevated erythrocyte sedimentation rate, hypergammaglobulinemia, hypoal-

buminemia, hyperferritinemia, and hypertransferrinemia.[127] The hyaline-vascular type has a histologic pattern characterized by follicular hyperplasia distributed evenly throughout the lymph node.[127] The follicles are unusually small, and their germinal centers are often penetrated by radial capillaries, which are surrounded by collagen or hyaline material, hence the name (Fig. 90–7).[127,128] The germinal centers are surrounded by multiple concentric layers of lymphocytes (see Fig. 90–7A).[127,129] In the plasma cell type, which is less common (10%) and may represent an earlier stage of the lesion,[127] the germinal centers are larger, the peripheral cuffs of mature lymphocytes are not as prominent, and their interfollicular areas are occupied by extensive sheets of plasma cells, occasionally including some atypical forms (see Fig. 90–7B). Immunohistochemical and gene rearrangement studies have identified clonal cell populations in some cases of multicentric AFH.[131,132]

BIOLOGY

Hypotheses for the causes of Castleman disease have included autoimmunity, disorder of cytokine production, and infection with the human herpes virus-8 (HHV-8). HHV-8, also called Kaposi sarcoma herpes virus (KSHV), has been associated with the multicentric form of Castleman disease in 25% of cases but not in pediatric patients or patients with the more common subtypes.[133,134] Because HHV-8 produces a viral form of the cytokine IL-6, it is relevant to Castleman disease. Experimental and clinical data indicate that IL-6 plays a pivotal role in the biogenesis of multicentric Castleman disease.[135] The hyperplastic germinal centers of these patients have been shown to produce excessive quantities of IL-6.[136]

Therapy

Localized Castleman disease is usually a self-limited process, curable with local surgical resection.[127,135,137,138] After local excision, there is frequently total disappearance of systemic symptoms with only rare local recurrences. Multicentric Castleman disease is a systemic disease associated with an aggressive, often fatal course associated with infectious complications, and a risk of developing malignancies, such as lymphoma or Kaposi sarcoma.[137] The median survival of patients with multicentric Castleman disease has been reported to be 29 months.[135] Twenty-six percent of patients in one series died within the first year of diagnosis.[135] A limited body of information is available regarding the treatment of multicentric Castleman disease.[133,135,139] A reduction in the quantity of involved tissue surgically or by radiation therapy may be an effective strategy to control the systemic signs and symptoms.[135] High doses of corticosteroids have been reported to result in sustained remissions, although continuous high-dose prednisone therapy is frequently required.[135] Chemotherapy with single agents or combination therapy used to treat non-Hodgkin lymphoma has resulted in partial responses, although occasionally patients may enjoy durable complete remissions.[135,140] Alleviation of the systemic manifestations of this disorder has been achieved with an anti-IL-6 monoclonal antibody and a humanized form of an anti-IL-6 receptor antibody.[139,141] Other therapies have included retinoic acid administration and bone marrow transplantation.[142–144] The use of rituximab has also been used with success.[145]

ANGIOIMMUNOBLASTIC LYMPHADENOPATHY WITH DYSPROTEINEMIA IS OFTEN A PERIPHERAL T-CELL LYMPHOMA

Clinical Manifestations

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) is the preferred term for a condition that occurs more often in elderly patients and is characterized by generalized lymphadenopathy, hepatosplenomegaly, fever, night sweats, weight loss, anemia (frequently caused by antibody-mediated hemolysis), and hypergammaglobulinemia and pruritic skin rashes.[146,147] Other terms for AILD include immunologic aberrations in idiopathic reticuloses, atypical lymph node hyperplasia with fatal outcome (immunodysplastic disease), diffuse plasmacytic sarcomatosis, chronic pluripotential immunoproliferative syndrome, immunoblastic lymphadenopathy, and lymphogranulomatosis X.[146,147] Most cases are now regarded as peripheral T-cell lymphoma-angioimmunoblastic type, in the WHO classification.[3]

Laboratory Evaluation

Biopsies of lymph nodes affected by AILD show complete effacement of the architecture, a prominent vascular proliferation, a florid immunoblastic proliferation, abundant plasma cells in clusters or sheets, burned-out germinal centers, focal necrosis, eosinophilic material, a background of mature lymphocytes, and, occasionally, eosinophils and neutrophils (Fig. 90–8).[146,147] Although AILD is considered a T-cell malignancy in most cases, the main differential diagnosis is lymphadenopathy secondary to a drug side effect of a hypersensitivity response. Serum protein electrophoresis reveals a polyclonal hypergammaglobulinemia, and a CBC shows mild to moderate anemia. The Coombs test is frequently positive. Clonal T-cell gene rearrangements are present in many cases supporting a diagnosis of peripheral T-cell lymphoma. Trisomy 3, trisomy 5, and an additional X chromosome are the most frequent chromosome aberrations in peripheral T-cell lymphoma-AILD. The unrelated clones have been hypothesized to be the consequence of increased genetic instability and an immune defect resulting in impaired clearing of damaged cells.[148,149]

Therapy

The median survival time of patients with AILD is 30 months.[146] Most patients are treated with prednisone or combination chemotherapy. The most important prognostic factor in AILD is achievement of complete remission. Randomized prospective treatment trials

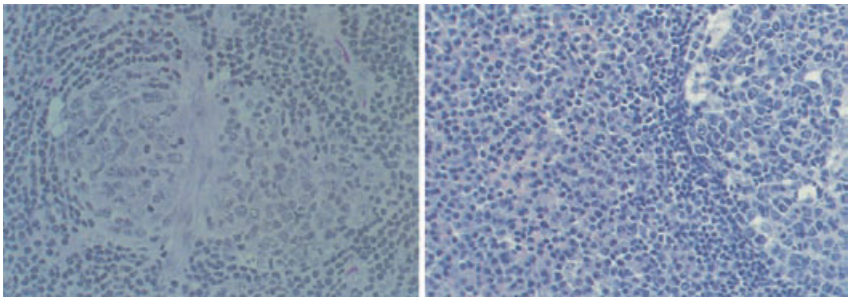

Figure 90–7 Castleman disease. **A**, The hyaline vascular subtype is characterized by small, sclerotic germinal centers, penetrated by a radial artery and surrounded by a cuff of lymphoid cells with onion skinning (H & E × 400). **B**, The plasma cell subtype shows larger germinal centers, with sheets of plasma cells in the interfollicular areas (H & E × 400).

are needed to determine optimal treatment. Although aggressive courses are observed in most patients, some patients experience a more indolent course or even spontaneous remissions. A prospective evaluation of standardized treatment in patients with AILD has been reported.[150] In this study, patients initially received prednisone therapy followed by five cycles of COPBLAM (cyclophosphamide, vincristine, prednisone, bleomycin, doxorubicin, and procarbazine) followed by two cycles of ifosfamide, methotrexate (IM) and VP-16. The combination chemotherapy was administered to patients who did not achieve a complete remission with prednisone or relapsed after prednisone therapy. Prednisone therapy was skipped in patients who presented with rapidly progressive life-threatening disease. Initial prednisone therapy led to resolution of B symptoms and reduction in tumor load in most patients.[150] The complete remission rate with prednisone only was 29%, and more than 60% of these patients eventually relapsed. In contrast, the complete remission rates after primary and secondary chemotherapies were 56% and 64%, respectively. Siegert and colleagues have concluded that primary chemotherapy is superior to sequential therapy with prednisone with or without chemotherapy. In their series, the projected event-free survival rate was 32% at 36 months, and no relapses occurred after 12 months.[150] Because of the high death rate resulting from *Pneumocystis carinii* and aspergillosis during treatment with prednisone or combination chemotherapy, strong consideration should be given to prophylactic therapy with trimethoprim-sulfamethoxazole and oral antifungal agents.[150]

Prognosis

Many apparent cases of AILD actually represent early T-cell lymphomas as clonal populations of T cells have been identified by Southern blot analysis and PCR.[151] Cytogenetic analysis and fluorescent hybridization demonstrate the clonal nature in many instances.[148,151] The overt malignant T-cell lymphoma is defined by the presence of clusters, islands, or diffuse infiltrates of monomorphic immunoblasts and has a much graver prognosis than AILD without evidence of clonality.[4,146,150]

HISTIOCYTIC NECROTIZING LYMPHADENOPATHY

Histiocytic necrotizing lymphadenitis (Kikuchi disease) is a pseudolymphomatous lesion that manifests as cervical lymphadenopathy and occurs predominantly in young women, often of Asian descent. Patients usually present with a cervical mass, but are otherwise asymptomatic and do not show evidence of IM.[151–153] The process usually resolves spontaneously in 1 to 4 months without further therapy.[153–155] These patients do not have an increased risk of lymphoma, and surgical excision is curative. Although the cause of histiocytic necrotizing lymphadenitis is unknown, its histologic and clinical features are similar to those of systemic lupus erythematosus,[156] and the disease may, in fact, reflect a self-limited autoimmune condition resembling systemic lupus erythematosus. Therefore, an autoimmune disorder, such as lupus, must be ruled out clonality when a pathologic diagnosis of Kikuchi disease is made.

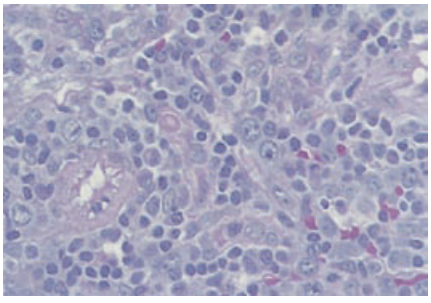

Figure 90–8 Angioimmunoblastic lymphadenopathy. A marked vascular proliferation with endothelial hyperplasia, small- and intermediate-sized immunoblasts, mature background lymphocytes, and reactive-appearing plasma cells are evident (H & E × 400).

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY

Clinical Manifestations

Patients with sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease) usually present with bilateral lymphadenopathy predominantly affecting the cervical region, and they usually exhibit some systemic symptoms, including fever, polyclonal hypergammaglobulinemia, and an increased erythrocyte sedimentation rate.[155,156] The disease occurs more frequently in black children.[157,158] The cause of the disease remains obscure. A relationship to an underlying immunodeficiency has been postulated.[159]

An Approach to the Diagnosis of Atypical Lymphoid Hyperplasias

Clinical

Accurate diagnosis of atypical lymphoproliferations requires a systematic approach. The patient's history and physical examination often suggest a malignant process, which requires a biopsy for confirmation. If the clinical features and biopsy findings are suggestive of a viral process, serology and virologic assays may be confirmatory, and the patient can be observed without further workup. If the family history and clinical features suggest a heritable immune defect, then pedigree and immunologic analyses of the patient and family members are mandatory. Conditions that have a characteristic histologic appearance (eg, Castleman disease) can be accurately diagnosed with histologic examination alone, but most patients will require application of more sophisticated diagnostic procedures on appropriately prepared specimens.

Laboratory

To obtain optimal results from a lymph node biopsy in the settings described in this chapter, close cooperation between the referring physician, surgeon, and pathologist is required. In our practice in the Nebraska Lymphoma Study Group, we sometimes see patients who have had one or more biopsies that have had improper handling of the tissue, negating the opportunity to perform adjunctive studies. These procedures require fresh tissue. The practice of placing the entire lymph node biopsy specimen in formalin is to be condemned for it is a frequent cause of a second biopsy. Therefore, a protocol to handle lymphoid tissue is mandatory to evaluate these difficult lesions. It is imperative for the referring physician to communicate the differential diagnosis of lymphoma, atypical immune response, transplant status, and recent drug history to the surgeon and pathologist so that fresh tissue is appropriately partitioned. At the Nebraska Lymphoma Study Group, fresh lymph node tissue is routinely frozen for possible molecular gene rearrangement analyses after routine histology. Other laboratories choose to form cell suspensions for flow cytometry. In addition, cytogenetic analysis is performed on a portion of the fresh tissue. Case records are maintained for each patient in our lymphoma registries. In situ hybridization for Epstein–Barr virus is performed in all cases of suspected immune deficiency. After a diagnosis of Epstein–Barr virus-positive lymphoproliferation, new masses are biopsied to rule out transformation to non-Hodgkin lymphoma.

Laboratory Evaluation

Biopsies reveal pericapsular fibrosis, dilatation of sinuses, numerous intrasinusoidal histiocytes, and abundant plasma cells. The most striking histiologic feature is the presence of lymphocytes and other hematopoietic cells within the cytoplasm of the sinus histiocytes called emperipoiesis.

Therapy and Prognosis

Clinically, in most of the patients the concern is to rule out non-Hodgkin lymphoma. However, the disease has a protracted but benign course; spontaneous regression of the lymphadenopathy and total recovery will occur in most cases.[157,158] Surgery or the administration of antibiotics, radiation, antituberculin therapy, or steroids have little impact on the course of the disease.[157,158]

CONCLUSION

Atypical lymphoproliferations occur in a variety of clinical settings in response to a variety of stimuli. Accurate diagnosis of these processes is made by careful clinicopathologic correlation and in some cases by genetic, immunologic, virologic, and molecular techniques. In many of these conditions, emphasis should not be placed on whether this is a malignant lymphoma but, rather, whether this is a lethal clinical condition requiring optional staged therapy.

CHAPTER 91

CLINICAL APPROACH TO INFECTIONS IN THE COMPROMISED HOST

Jo-Anne H. Young and Daniel J. Weisdorf

The clinical approach to infections occurring among hematology patients involves understanding host immune system defects and anatomic barrier disruption that predispose patients to infection. This chapter reviews specific hematologic conditions for their unique host defense defects and associated infections (Table 91–1), the host defense defects, and the differential diagnoses of common infectious pathogens (Table 91–2). To demonstrate how periods of predictable anatomic defects combine with severe immune compromise, the prevention, diagnosis, and management strategies for infections occurring in the hematopoietic stem cell transplantation (HCT) recipient are presented as models.

HEMATOLOGIC CONDITIONS PREDISPOSING TO INFECTION

Malignant Hematologic Disorders

Antineoplastic Therapy

During antineoplastic treatment, cytotoxic agents frequently are administered in combination with other immunosuppressive therapies, such as corticosteroids or radiation therapy. Several cytotoxic agents, notably methotrexate, cyclophosphamide, 6-mercaptopurine, and azathioprine, impair cell-mediated immunity.[1–3] Many of the drugs themselves (e.g., cyclophosphamide) can impair other immune parameters, including humoral responses, and can produce quantitative phagocyte defects.

Exogenous administration of glucocorticoids leads to increased susceptibility to infection. The degree of immunosuppression and the relative risk of infection depend on the dose and duration of use.[4] The major effect of steroids on granulocyte function is a decrease in chemotactic activity.[5,6] This accounts, in part, for the clinical observation that the signs and symptoms of severe infections may be masked or greatly reduced in patients receiving steroids. Steroids may enhance susceptibility to infection by means of negative effects on wound healing, skin fragility, monocyte and lymphocyte function, production of cytokines, and humoral immune responses.

Radiation therapy has been associated with granulocyte dysfunction and delayed wound healing.[7] Defects in cell-mediated immunity may persist for more than 1 year after intensive radiation therapy or after hematopoietic cell transplant.[8,9]

Interleukin (IL)-2 administration depresses host defense. Granulocyte function studies in patients receiving IL-2 demonstrate decreased production of superoxide, decreased chemotaxis, and decreased Fc γ receptor III (FcγRIII) expression.[10] Patients receiving high-dose IL-2 therapy have a predictable increased incidence of significant gram-positive infections, particularly those due to *Staphylococcus aureus*, so antibacterial prophylaxis is routinely added during IL-2 administration.[11,12]

Acute Leukemias

In patients with acute leukemias, infection is a major cause of morbidity due to drug-associated mucositis and therapy-induced neutropenia. Substantial improvements in supportive care management over the past 2 decades have allowed patients to complete adequate courses of antineoplastic treatment without succumbing to major infectious complications.[13] Most infections occurring during neutropenia are bacterial,[14,15] but patients with prolonged neutropenia are at additional risk for development of yeast and mold infections. The broad-spectrum antibacterial agents that are used empirically during neutropenia should achieve serum bactericidal levels against *Pseudomonas aeruginosa* in particular.[15,16] Patients with acute leukemia who progress to advanced therapies, such as hematopoietic cell transplant, have added risk for infections associated with acquired deficiencies in cell-mediated and humoral immunity, such as *Pneumocystis jiroveci* and cytomegalovirus (CMV) infections.

Chronic Leukemias

Patients with chronic myeloid leukemia do not have prominent host defense impairments, so infections are limited unless patients proceed to aggressive chemotherapy or HCT.[17] Host defense defects with tyrosine kinase inhibitors, such as imatinib or dasatinib, have not been described. Chemotherapy for blast crisis resembles therapy for acute leukemia.

Patients with chronic lymphocytic leukemia (CLL) are predisposed to infection due to immunodeficiency related to the leukemia itself (humoral and cellular immune dysfunction) and to therapy-related immunosuppression. In early B-cell CLL, the infectious risk is mainly related to unbalanced immunoglobulin chain synthesis and resultant hypogammaglobulinemia. In patients with advanced CLL, particularly after the introduction of therapy with purine analogues and monoclonal agents (e.g., rituximab, alemtuzumab[18–20]), neutropenia and defects in cell-mediated immunity are other factors predisposing to infection.[18–24] Fludarabine, the major first line therapy, results in prolonged and profound defects in cell-mediated immunity, thereby increasing susceptibility to *Pneumocystis*, yeast, and herpes group viruses (herpes simplex virus [HSV], varicella-zoster virus [VZV], and CMV). The risk of infectious complications increases with the duration of CLL, reflecting the cumulative immunosuppression related to its treatment.[25] The incidence of infection correlates with the serum levels of immunoglobulins (particularly IgG), which may be further impaired by use of rituximab. Patients with CLL should receive pneumococcal vaccination. Prophylaxis with pooled intravenous immunoglobulin (IVIg) decreases the incidence of minor or moderately severe bacterial infections,[26] but this benefit is challenged by the very high cost and the effect of such therapy.[27] Routine prophylaxis with IVIg is not recommended.

Lymphomas

Hodgkin and non-Hodgkin lymphoma are commonly associated with impaired cell-mediated immunity.[28–30] Although the degree of immune impairment may correlate with the extent of disease and often is compounded by administration of immunosuppressive therapy, the intrinsic impairment of cell-mediated immunity in Hodgkin lymphoma can persist even after apparent cure. Splenectomy-related infections occur with sepsis due to encapsulated bacte-

Table 91–1 Malignant and Select Nonmalignant Hematologic Diseases and Their Associated Infection-Predisposing Host Defects

Hematologic Condition	Infection-Predisposing Host Defects
Acute myeloid leukemia	Neutropenia; therapies such as dose-intensive chemotherapy and hematopoietic cell transplant may result in additional anatomic disruptions, cell-mediated defects, and humoral defects
Acute lymphocytic leukemia	Neutropenia; therapy effects similar to acute myeloid leukemia
Hairy cell leukemia	Neutropenia (also monocytopenia); abnormal humoral immunity; T-cell suppressing therapy
Chronic lymphocytic leukemia	Hypogammaglobulinemia; abnormal cell-mediated immunity
Chronic myeloid leukemia	No prominent host defects unless aggressive therapy, advanced stage, or postsplenectomy
Multiple myeloma	Hypogammaglobulinemia; other host defects may occur with aggressive therapy or advanced stage
Hodgkin/non-Hodgkin lymphomas	Abnormal cell-mediated immunity, therapy-related neutropenia, splenic dysfunction (if splenectomy or radiation)
Myelodysplastic syndromes	Functional or absolute neutropenia
Aplastic anemia	Neutropenia; abnormal cell-mediated immunity from immunosuppressive therapies (e.g., steroids, antithymocyte globulin, cyclosporine, hematopoietic cell transplantation)
Paroxysmal nocturnal hemoglobinuria	Deficient Fc receptor may contribute to abnormal cell-mediated immunity
Hemolytic states (thalassemia)	Gallstones may serve as a nidus for infection; splenic dysfunction or splenectomy
Sickle cell disease	Can be neutropenic with aplastic crisis; bone infarcts may serve as a nidus for infection; splenic dysfunction with poor complement activation and opsonization from autosplenectomy

rial organisms at a median of 22 months but sometimes many years after surgery.[31] Patients who progress to HCT are at additional risk for infections associated with peritransplant neutropenia and delayed immune reconstitution.[32,33]

Myelodysplastic Syndrome

Neutrophils and band forms from patients with myelodysplastic syndrome are functionally defective and probably are derived from a malignant clone of myeloid precursor cells.[34] Neutrophils from patients with myelodysplastic syndrome have deficiencies in myeloperoxidase,[35] elastase,[36] and integrins.[37] Lowered expression of granulocyte colony-stimulating factor receptor may be a partial explanation for neutropenia, although impaired maturation and accelerated apoptosis impair neutrophil production.[38] More than half of patients with myelodysplastic syndrome die within 3 years of diagnosis from infections, bleeding complications, or progression to acute leukemia.

Multiple Myeloma

Malignant plasma cells induce production of a macrophage protein that selectively suppresses B-cell function, so multiple myeloma is frequently associated with a variety of defects in humoral immunity.[39] Patients having myeloma with IgG paraprotein have an increased rate of catabolism of normal and clonal IgG. They also may have defects in complement and granulocyte function. Cell-mediated immunity is not impaired by the disease but is compromised by corticosteroids or cytotoxic therapy.[40]

Patients with multiple myeloma should receive pneumococcal vaccination. Antibody titers may rise after administration of the vaccine, but postimmunization titers may not reach a protective level.[39] In addition, postimmunization antibody levels fall rapidly in this population, in part because of the increased catabolism of immunoglobulins.[8] Revaccination should be considered but not sooner than 6 years after administration of the initial vaccine because revaccination may be associated with Arthus reactions or systemic reactions.[8] Prophylaxis with passive administration of immunoglobulin is not recommended.

Uncommon Malignancies

Patients with hairy cell leukemia develop mycobacterial disease relatively often, especially infection with atypical mycobacteria.[41] Reversal of host cellular immune defects with effective therapy can lead to rapid clinical response with eradication of mycobacterial infection.[42]

Defects in cell-mediated immunity have been postulated to explain the incidence of infection caused by intracellular pathogens in patients with the relatively rare T-cell malignancies mycosis fungoides[43] and T-cell CLL.

Nonmalignant Hematologic Disorders

Aplastic Anemia

This blood dyscrasia is associated with decreased peripheral blood cell counts due to marrow failure. The severity of pancytopenia is variable. Chronic neutropenia is the main cause of recurrent bacterial and fungal infections among patients. Periodontal infections are particularly common.[44] Treatment of the underlying hematologic disease is required to stop recurrent infections and cure some chronic infections. Therapy with immunosuppression or HCT is associated with the attendant risks of acquired defects in cell-mediated and humoral immunity, requiring careful attention to supportive measures that reduce infection risk.[45,46]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is an acquired clonal expansion of marrow stem cells that are deficient in the phosphatidylinositol-linked complement regulatory protein decay-accelerating factor. Patients with paroxysmal nocturnal hemoglobinuria are at some increased risk for bacterial infection due to a deficiency of this glycoprotein on the membrane of neutrophils.[47] In addition, neutrophils from some patients with paroxysmal nocturnal hemoglobinuria show a deficiency for FcγRIIIb,[48] but this receptor can be functionally replaced by FcγRII.[49] Modest and progressive granulocytopenia

Table 91–2 Host Defense Impairments and Their Associated Infectious Pathogens

Host Defense Defect	Pathogen Categories
Neutropenia	Enteric gram-negative organisms Gram-positive staphylococci and streptococci Anaerobes Yeast, particularly *Candida* species Molds, particularly *Aspergillus* species
Abnormal cell-mediated immunity	Atypical bacteria: *Legionella, Nocardia* *Salmonella* species *Mycobacteria* (*M. tuberculosis* and atypical mycobacteria) Disseminated infection from live bacilli Calmette-Guérin (BCG) vaccine Environmental fungi, including *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis* Endogenous yeast, particularly *Candida* species Herpesviruses Infections from live-virus vaccines *Pneumocystis (carinii) jiroveci* *Toxoplasma gondii* *Cryptosporidium* *Strongyloides stercoralis*
Immunoglobulin abnormalities	Gram-positive *Streptococcus pneumoniae, Staphylococcus aureus* Gram-negative *Haemophilus influenzae*, *Neisseria* species, enteric organisms Enteroviruses Disseminated infections from live-virus vaccines *Giardia lamblia*
Complement abnormalities C3, C5	Gram-positive *S. pneumoniae*, staphylococci Gram-negative *H. influenzae, Neisseria* species, enteric organisms
Complement abnormalities C5–C9	*Neisseria* species
Anatomic Disruption	**Pathogen Categories**
Oral cavity	α-Hemolytic streptococci, oral anaerobes *Candida* species Herpes simplex virus
Esophagus	*Candida* species Herpes simplex virus, cytomegalovirus
Lower gastrointestinal tract	Enterococcus, gram-negative enteric organisms Anaerobes *(Bacteroides fragilis, Clostridium perfringens)* *Candida* species *Strongyloides stercoralis*
Skin (IV catheter)	Gram-positive staphylococci and streptococci, *Corynebacteria, Bacillus* Atypical mycobacteria
Urinary tract	Enterococcus Gram-negative enteric organisms *Candida* species
Splenectomy	Encapsulated organisms: *S. pneumoniae, H. influenzae, Neisseria* *Capnocytophaga canimorsus* *Salmonella* (especially sickle cell disease) *Babesia*

progression to aplasia or leukemia may compound these risks. Vaccination against meningococcus is required prior to treatment with the complement inhibitor eculizumab.

Granulocytic Phagocyte Disorders

Defects in phagocyte numbers, structure, and function predispose patients to infection. Infections resulting from qualitative or quantitative defects in neutrophil production tend to be prolonged, recurrent, and respond slowly to antimicrobial therapy.

The clinical approach to infections is specific to each of these disorders and is beyond the scope of this chapter. However, chronic granulomatous disease is discussed because patients with this congenital immunodeficiency who survive into adulthood are at risk for severe infections. Chronic granulomatous disease results from defective or malfunctioning oxidative metabolism capacity of neutrophils. Recurrent infections with bacteria and fungi are common and

occasionally life threatening despite optimal antimicrobial therapy. Infections with *Staphylococcus* species and *Aspergillus* species can be particularly aggressive. Granulomata may form in response to infection, especially in the gastrointestinal and genitourinary tracts. Antibiotic prophylaxis has decreased the rate of bacterial infections. Important adjuncts to antimicrobial therapy may include interferon γ, colony-stimulating factors, granulocyte transfusions, and possibly gene therapy.[50,51]

Erythrocyte Disorders

Glucose-6-phosphate dehydrogenase deficiency is a sex-linked disorder. Both heterozygous females and homozygous males are protected against malaria. In contrast to this protective function, the enzyme deficiency is associated with excessively severe rickettsial infections.[52,53] Deficiency of this enzyme limits glucose metabolism through the hexose monophosphate shunt, resulting in an abnormal respiratory burst in neutrophils. Bacterial infections can occur if the deficiency is severe.

Hemoglobin Gene Variants

Patients with chronic hemolytic states may develop bilirubin gallstones, which can serve as a nidus for infection.[54,55] Defects in cell-mediated immunity have been described in patients with thalassemia.[56–58] Patients with sickle cell disease have an increased susceptibility to bacterial infections.[59] Defective alternative pathway function, especially in conjunction with asplenia, contributes to the propensity to bacterial infection.[60] Splenic involution results in depressed synthesis of alternate pathway factor(s) of complement and decreased phagocytic clearance of bacteria.[61] Phagocytosis of *Streptococcus pneumoniae* is abnormal, in part because of an inability to use the alternate pathway for C3 fixation as a means of opsonization. An increased risk for *Salmonella* infection appears to be unique to the sickle cell population. Patients with sickle cell anemia have been found to have anergy in association with zinc deficiency and decreased nucleoside phosphorylase activity.[62] Suppurative arthritis can occur after repeated episodes of hemarthrosis among patients with sickle cell disease. Patients with sickle cell disease die more frequently from infection than from any other cause.[63] Early pneumococcal vaccination and aggressive therapy, particularly of respiratory infections, are essential.

Coagulation Disorders

Hemophilias are sex-linked deficiencies of clotting factor VIII or IX. Septic arthritis should be considered in the differential diagnosis of any hemophiliac with repeated episodes of hemarthrosis whose articular signs and symptoms fail to improve quickly after administration of appropriate coagulation factor replacement.[64] Hemophiliacs who have acquired infection with human immunodeficiency virus (HIV)-1 from plasma-derived factor replacement therapy may develop severe impairment of cell-mediated immunity after this retroviral infection progresses to acquired immunodeficiency syndrome (AIDS). Abnormalities in cell-mediated immunity have been described in HIV-1–seronegative patients with hemophilia who have received factor VIII concentrates.[65,66]

Blood Groups

The Duffy blood group antigen serves as a receptor for *Plasmodium vivax* to invade erythrocytes.[67] Blood group O is associated with *Helicobacter pylori* infection and an associated increase in peptic ulceration because the Lewis(b) blood group antigen mediates *H. pylori* attachment to human gastric mucosa.[68]

Host Defense Impairment and Associated Infection Issues

Granulocytopenia

Profound or absolute granulocytopenia can occur in patients with aplastic anemia or leukemia or from chemotherapy used for treatment of various malignant diseases. Infection rates increase when granulocyte counts fall below 1000/mm^3, but the patient is most at risk for spontaneous infection when the count is below 100/mm^3.[69] The patient who is granulocytopenic from cytotoxic therapy can serve as a basic model for predicting infections that could occur in other patients with qualitative or quantitative granulocyte defects.

Granulocytopenia is defined as a cell count less than 500 neutrophils plus band forms per cubic millimeter. Profound granulocytopenia (<100/mm^3) often requires prophylactic broad-spectrum antibiotic therapy. Granulocytopenia predisposes to the development of bacterial and fungal infections but does not appear to increase the incidence or severity of viral and parasitic infections. Patients with moderate granulocytopenia (i.e., absolute granulocyte counts in the range from 500–2000/mm^3 that are not falling precipitously) should not receive prophylactic antimicrobial agents. These patients include those with myelodysplastic syndromes, newly diagnosed leukemias, early engraftment after hematopoietic cell transplant, and marrow suppression from various drugs, such as ganciclovir.

Colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF; filgrastim pegylated filgrastim], granulocyte-macrophage colony-stimulating factor [GM-CSF, sargramostim]) are routinely used in the management of hematologic disorders. A number of functional granulocyte parameters may be enhanced by G-CSF or GM-CSF, including enhanced per cell phagocytosis, oxidative metabolism, microbicidal activity, and antibody-dependent cytotoxicity. However, G-CSF or GM-CSF administration may decrease the motility of granulocytes, impair in vivo migration, and decrease bacteria-induced chemotaxis. The clinical significance of any of these effects remains to be established but is generally believed to be insignificant in light of the potency of these agents in shortening the depth and duration of therapy-induced neutropenia.

Defects in Cell-Mediated Immunity

Cellular immune dysfunction occurs in patients with lymphomas, in those with hematologic malignancies undergoing hematopoietic cell transplant, and patients with AIDS. T-cell function may be required for macrophage activation and subsequent microbicidal activity. The most frequently encountered pathogens are intracellular organisms because they can survive and even replicate inside macrophages in a nonimmune individual or in the absence of T-cell immunity. Other pathogens associated with infection in patients with cell-mediated immunity include bacteria (including *Mycobacterium tuberculosis*, atypical mycobacteria, *Salmonella, Legionella, Nocardia*, and *Listeria*); fungi (including the yeasts *Candida* and *Cryptococcus*; molds such as *Aspergillus*; endemic dimorphic fungi such as *Histoplasma* and *Coccidioides*; and *Pneumocystis*); viruses (including herpes group viruses [HSV, VZV, CMV] and respiratory viruses); and protozoa (*Toxoplasma gondii*, *Cryptosporidium*, and *Strongyloides stercoralis*).

Patients with defects in cell-mediated immunity or who are about to receive hematopoietic cell transplant should undergo risk factor assessment for reactivation of tuberculosis. Patients with a known history of an untreated but positive Mantoux test should receive prophylactic isoniazid to prevent reactivation and potential dissemination of tuberculosis. Patients without a prior Mantoux test but with risk factors for tuberculosis should undergo the Mantoux test before starting the conditioning regimen for HCT.[70–72]

Patients with defects in cell-mediated immunity are at risk for the development of disseminated infection due to live vaccines, even when the vaccine contains attenuated organisms. Accordingly, these patients should not receive vaccines containing bacillus Calmette-

Guérin (BCG), vaccinia/smallpox, measles, mumps, rubella, yellow fever, or oral polio. Hematopoietic cell transplantation recipients are eligible for revaccination with some of the live virus vaccines at the 2-year anniversary visit, provided the patient does not have graft-versus-host disease (GVHD) or is not receiving ongoing pharmacologic immunosuppression.

Defects in the Humoral Immune System

Immunoglobulin and complement are components of the humoral immune system. Immunoglobulin and complement both have associated phonic, lytic, and neutralizing activities, predominantly against bacterial infection. Patients with primary or secondary defects or deficiencies in humoral immunity are susceptible to recurrent pyogenic infections from polysaccharide-encapsulated bacteria, such as *Streptococcus pneumoniae, Haemophilus influenzae*, and *Neisseria* species. Hematopoietic cell transplant recipients who continue to receive immunosuppressants more than 100 days after transplantation should be given antimicrobial prophylaxis with coverage for encapsulated bacteria until immunosuppression is discontinued. Patients are also at risk for infections from enteroviruses and *Giardia lamblia*. Patients with low levels of circulating IgG may benefit from IVIg infusions, although use of IVIg infusions for routine prophylaxis must be weighed against the expense of this approach.

Abnormalities in Splenic Function

A number of hematologic disorders are complicated by either intrinsic splenic impairment or splenectomy. The spleen removes organisms from the blood that have been ineffectively opsonized by complement, serving an adjunctive role in fighting infection. It is involved in the regulation of the alternate complement pathway, and low levels of immunoglobulin and properdin have been reported in patients after splenectomy.[73,74] A decrease in the opsonic peptide tuftsin has been reported after splenectomy.[75] Alternate pathway defects may be particularly important in patients with splenic dysfunction associated with sickle cell disease.[76]

Asplenic or splenectomized patients are at increased risk for serious bacterial infections, primarily for infections caused by *S. pneumoniae, H. influenzae, Neisseria, Babesia*, and *Capnocytophaga canimorsus*. The initial presentation of even overwhelming infection can be subtle, with fever often the only sign. Accordingly, all asplenic patients with underlying hematologic disease who present with fever should be managed initially as potentially septic. Overwhelming infection after splenectomy occurs in approximately 7% of postsplenectomy patients, with 50% of infection-related deaths occurring in the first 3 months.[77] Prophylaxis against pneumococcal infection is used for asplenic patients who are small children or for those with increased immune impairment from malignant disease.

Pneumococcal, *H. influenzae* type b, and meningococcal vaccines should be administered to asplenic patients.[78] Patients with an intact spleen may respond better to pneumococcal polysaccharide vaccine than do splenectomized patients, so immunization is recommended as early as possible before elective surgery.[79] Additionally, immunization before splenectomy can result in protective pneumococcal antibody titers immediately after the operation. For patients with Hodgkin lymphoma, the antibody response to pneumococcal vaccine may not be affected by the timing of immunization relative to splenectomy.[80] Immunizations do not eliminate the risk of serious infection with encapsulated bacteria.

Anatomic Alterations in Host Defense

Immunocompromised patients frequently have disruptions in the skin and mucosa, which are important primary physical barriers against endogenous and exogenous sources of infections. Disruption of skin and mucosa may result from invasion by malignant cells, from the effects of chemotherapy or radiation therapy, from use of invasive diagnostic or therapeutic procedures (e.g., intravenous catheters), and from the effects of local infections, such as oral HSV. Such alterations may provide a nidus for microbial colonization, a focus for localized infection, and a portal of entry for systemic invasion. Organisms associated with defects in skin or mucosal surfaces depend on the site of breakdown, local colonizing flora, and other factors. Gram-positive organisms are associated with isolated disruption of the skin from an indwelling intravenous catheter, usually with coagulase-negative staphylococci, but also with *Corynebacterium jeikeium, Bacillus* species, and occasionally atypical mycobacteria.

Gastrointestinal mucosal integrity is frequently disrupted by chemotherapeutic agents. Because the gastrointestinal tract normally is colonized by a multitude of organisms, this state can lead to infection by aerobic gram-negative enteric and anaerobic bacteria, viruses, and yeast. Mucosal damage can allow normal flora to invade and become pathogens. Lower gastrointestinal ulcerations permit infections with *Bacteroides fragilis* or *Streptococcus bovis*.

Oral lesions are associated with HSV reactivation, ulceration, and possible bloodstream infection with other common oral flora such as α-hemolytic streptococci. Individuals with intact oral mucosa can experience periodic episodes of transient α-hemolytic or viridans streptococcal bacteremia secondary to toothbrushing.

The genitourinary tract mucosa may be disrupted by tumors, invasive procedures, or cytotoxic therapy, with subsequent colonization and the potential for local or invasive infection. The most common urinary tract pathogens are enteric gram-negative bacilli, enterococci, and *Candida albicans*. Viral reactivation is common, predominantly from adenovirus and polyomavirus (BK virus) but also from the herpesviruses (HSV and CMV).

The lung, genitourinary tract, biliary tract, and auditory canal are potential sites of mechanical obstruction, increasing the risk of localized infection. Obstruction may lead to stasis of local body fluids, with resultant overgrowth of potentially pathogenic colonizing organisms. Patients with chronic hemolytic states are prone to gallstones that can become a nidus for infection.

Anatomic alteration can predispose to infection simply by providing a nidus for growth of organisms. Many patients with sickle cell anemia and hemophilia have underlying anatomic abnormalities of the bones and joints as a result of vasoocclusive crises causing infarction of marrow, bony cortex, or synovium. In turn, these changes may predispose to infection such as osteomyelitis or arthritis.[81,82] Decreased local blood flow and increased bacterial adherence may be other contributing factors. Foreign bodies, such as prosthetic devices, can lead to persistent infection after even transient bacteremia.

Infection in Chemotherapy or Transplantation Patients with Acute Profound Neutropenia and Lymphopenia

This section outlines predictable infections that can present during acute profound neutropenia/lymphopenia.

Pulmonary Infiltrates

Pulmonary infections are common in the immunocompromised host (see box on Approach to Pulmonary Infiltrates). Chest radiography is a good initial screen, and it may provide useful information in terms of characterizing the nature of an infiltrate and assist the pulmonologist in determining where to direct the bronchoscope for highest yield. A specific infectious and noninfectious differential diagnosis exists for certain radiologic signs (Table 91–3).[83,84] For example, consolidative focal airspace disease most typically is associated with a bacterial pneumonia. A halo of interstitial changes around a pulmonary nodule or an air crescent above a pulmonary nodule most likely is due to aspergillosis. Although 90% of pulmonary nodules are due to fungal pneumonia (mainly aspergillosis), 10% have various etiologies, including septic bacterial emboli, *Nocardia*,[85] *Legionella*,[86] myco-

Approach to Pulmonary Infiltrates

Pulmonary infiltrates can be divided into three general categories: consolidative, interstitial, and nodular. A consolidative infiltrate may be bacterial, even polymicrobic, so sampling of the infiltrate through sputum or endotracheal tube suctioning for bacterial and fungal cultures is required. If either of these methods does not provide an adequate sample from a consolidative infiltrate or if these methods do not lead to a diagnosis, immediate bronchoscopy is indicated. If interstitial or nodular infiltrates are not peripheral (i.e., within the range of the bronchoscope), they should also be evaluated with timely bronchoscopy. An advantage of bronchoscopy, in addition to the ability to obtain a deep specimen, is that the samples usually are sent for a broad range of diagnostic tests. These tests usually are ordered from preprinted order sheets, which reduces errors. Most preprinted order sheets for bronchoalveolar lavage fluid will test for the following:

- Cytology, with the attendant Fite and Gomori methenamine silver stains
- Bacterial (gram) stain and aerobic culture
- Mycobacterial (acid fast bacillus) stain and culture
- Fungal (potassium hydroxide or calcofluor) stain and culture
- *Nocardia* culture
- *Legionella* culture
- Viral cultures for herpes viruses and respiratory viruses
- Rapid test for cytomegalovirus (shell vial or polymerase chain reaction [PCR])
- Rapid test for respiratory viruses during respiratory virus season (pooled respiratory virus shell vial, respiratory syncytial virus antigen, influenza A/B antigen)

Optional tests that can be requested from bronchoalveolar lavage fluid, some at significant extra expense, include the following:

- Stat mycobacterial stain (requires separate 5-mL volume that cannot be used later for culture)
- *Mycoplasma* pneumoniae PCR
- *Chlamydia* pneumoniae PCR
- Human herpes virus type 6 PCR
- Human metapneumovirus PCR
- *Aspergillus* galactomannan antigen
- Any of the above first-tier tests that your institution does not send on a routine basis (e.g., *Nocardia* or *Legionella*)

Invasive sampling may be the only definitive means for making a diagnosis of peripheral nodules. The two main options are percutaneous fine-needle aspiration or open lung biopsy (usually obtained through video-assisted thoracoscopic surgical procedure). In toto sampling of a lung nodule permits enough material for the whole range of the above diagnostic tests as well as histopathology. Of note, fewer lobectomies of unilateral pulmonary nodular infiltrates have been reported in recent years, probably a result of the frequent use of a broad range of less toxic antifungal medications.

bacterial infection (with cavitation),[70] Epstein-Barr virus (EBV)-related lymphoproliferative disease, relapsed malignancy, and pulmonary embolism (pleural based). Interstitial infiltrates can be caused by either respiratory viruses during the winter season (except for parainfluenza virus, which is nonseasonal), herpes viruses, *Pneumocystis*, edema, or idiopathic. A complete differential of causes of interstitial pneumonitis, a pulmonary syndrome often associated with HCT, is given in Chapter 113.

Pulmonary and sinus infections from inhaled molds are more likely occurrences as the duration of neutropenia lengthens, particularly beyond an initial 21-day window. For that reason, among hematopoietic cell transplant recipients without graft failure, invasive tissue mold infections occur at a low rate less than 3% before engraftment due to the environmental measures taken for air filtration.[87,88]

Table 91–3 Pulmonary Infiltrates and Their Association with Specific Infectious and Noninfectious Etiologies

Radiologic Sign	Differential Diagnosis
Interstitial infiltrates	Pulmonary edema Diffuse alveolar damage Idiopathic pneumonia syndrome Respiratory viruses: Respiratory syncytial virus, parainfluenza, influenza, adenovirus, enterovirus Herpes viruses: Cytomegalovirus, herpes simplex virus, varicella zoster virus, human herpes virus type 6 *Pneumocystis* pneumonia
Focal airspace disease	Bacterial pneumonia Fungal pneumonia
Nodules	Fungal pneumonia (aspergillosis) *Nocardia* *Legionella* Septic bacterial emboli Mycobacterial infection (with cavitation) Epstein-Barr virus lymphoproliferative disorder Relapsed malignancy Pulmonary embolism (pleural based)
Halo sign or air crescent sign	Aspergillosis

However, if endogenous aspergillosis infections are present on a subclinical level before hematopoietic cell transplant, the infection can rapidly escalate when the immune system is profoundly suppressed by the preparative regimen. This phenomenon manifests as early invasive aspergillosis (before day 40).[89] Therefore, patients at risk for occult mold infections in the lungs, sinuses, and, at times, the oral cavity (aplastic anemia, Fanconi anemia, myelodysplastic syndrome, heavily pretreated pneumonia) should have computed tomography (CT) scans of the lungs and sinuses before the onset of any profoundly immunosuppressive regimens, such as hematopoietic cell transplant and select nontransplantation regimens. High-risk patients may be given antimicrobial agents with activity against molds to either prevent or suppress invasive mold infections.

Fever

Despite the specific prophylactic measures directed against common pathogens, many fevers occur in neutropenic patients after transplantation or chemotherapy. Fever can be divided into three categories: infectious fever with an obvious source, infectious fever without an obvious source, and noninfectious fever. Risk factor assessment should include knowledge of the temporal relationship to blood product infusions; recent exposure to contagious infection; degree of fever and whether the fever is accompanied by chills, rigors, or diaphoresis; and response to antipyretics. Symptom assessment should include evaluation to assess sinus drainage, sore throat, ear pain, cough, sputum production, shortness of breath, diarrhea, and dysuria.

Daily examination of any severely immunocompromised patient should include vital signs, mental status, oral cavity, indwelling catheter exit site, skin, lungs, heart, and abdomen. The physical examination is helpful in determining the cause of fever among hematologic malignancy patients because particular infections, such as mucositis, line infections, sinusitis, and pneumonia, occur predictably among severely immunocompromised patients. When fever is present, the examination should be expanded to include the sinuses (especially if the patient recently underwent any nasal manipulations), neurologic

system, genitourinary system, and possibly the perineal area, looking for tenderness (neutropenic patient) or abscess (patient with neutrophils).[90]

The initial workup of fever, regardless of whether an infectious or noninfectious source is suspected, is identical and includes blood culture, culture of symptom-related sites even if there is no obvious source (e.g., sputum, urine, with/without stool, with/without cerebrospinal fluid), review of medication list for potential contributors to drug fever, review of recent transfusions, chest radiograph, and CT scan of any symptom-related body systems. Many times blood cultures are drawn through an existing indwelling line without being drawn from a peripheral site concurrently. Indications for drawing a peripheral culture include new heart murmur and recent access of an older IV access site.

Two common anaerobic infections occur during neutropenia at sites where biopsy is difficult or contraindicated. Typhlitis is preceded by fever, abdominal pain, and tenderness. CT scan of the abdomen shows signs of right-sided colonic inflammation.[91–95] Excessive soft-tissue swelling of the neck during mucositis can present as a Ludwig angina variant. Broadly active antianaerobic, aerobic, and possibly antifungal antimicrobial agents should be added for either of these clinical findings.

Bacteria

Because many fevers are caused by bacterial infections, broad-spectrum antibacterial prophylaxis is used during absolute neutropenia.[96,97] The exact agents used vary. Institutional protocols and resistance patterns drive selection of specific prophylactic agents. Implementation of prophylaxis with first fever or commencement of neutropenia and substitution of oral agents for intravenous agents among low-risk, febrile individuals has been suggested.[98]

Mucositis, with breakdown of oral and gastrointestinal mucosal barriers, is common during this period.[99,100] This condition can predispose to sepsis from colonizing mouth/gut, bacterial/fungal, and normal flora organisms. Bacteremia from *Streptococcus viridans* is common during the first several weeks of HCT, so prophylaxis with penicillin or cefazolin is routinely continued until approximately 21 days after transplantation.[101–105] Acute, fatal sepsis from gram-negative organisms is common if not prevented, so the minimum acceptable broad-spectrum prophylaxis standard involves monotherapy with an agent active against gram-negative bacilli.[106] Quinolone-resistant viridans group streptococci and gram-negative bacteria can be found in the oropharynx of neutropenic patients after brief exposures to quinolones.[107]

Central venous catheter placement through the skin can lead to blood infection from colonizing gram-positive skin organisms, despite sterile, operative placement of these catheters and antisepsis cleansing procedures.[108] Because the gram-positive bacteremias, including those caused by coagulase-negative *Staphylococcus* species, usually are not immediately life threatening, direct prophylactic coverage often is not immediately provided.[105,109,110] During workup of a new fever, some centers recommend administration of vancomycin for several days until blood cultures demonstrate no gram-positive bacteremia.

Once a gram-positive bacterial infection is identified, vancomycin therapy is used empirically until the susceptibility profile is available. At this point the regimen is tailored to a single agent. If the patient is known to be colonized with vancomycin-resistant enterococcus and the Gram stain indicates gram-positive organisms in chains, therapy for empiric vancomycin-resistant enterococcus is appropriate until the bacterial identification and susceptibility profile is available.

Once a gram-negative infection is identified, empiric therapy that includes *Pseudomonas* coverage is continued until the susceptibility profile is available. For many infections, the regimen then can be tailored to a single agent and continued for 2 weeks after the last positive culture in clinically responding patients. If the organism is known to have an inducible β-lactamase enzyme (e.g., *Enterobacter*), therapy is tailored to two agents with two different mechanisms of action.

For bloodstream infections, blood cultures should be followed daily for several days to determine the date of last positive culture. Removal of central venous catheters may be required for most, but not all, infections.[111] At the end of a 14-day treatment course beyond the last positive culture, the patient should continue a gram-negative prophylaxis regimen if still neutropenic.

Antimicrobial agents with anaerobic activity should be added for typhlitis, enlargement of neck soft tissues during mucositis (Ludwig angina variant), or culture-documented anaerobic infection. Antifungal agents should be part of the treatment regimen for typhlitis.[93–95]

Infrequently, tuberculous and nontuberculous mycobacteria are responsible for infections in the bloodstream, catheters, and pulmonary tree.[70,112,113] Nontuberculous (i.e., atypical) mycobacterial infections of central catheters or catheter tunnels require a high index of suspicion as well as specific culture media.[114] Organism identification and drug sensitivities may take several weeks. Tuberculous disease can be empirically treated based on risk factors. For patients without risk factors for tuberculosis, recovery of acid-fast bacilli will prompt therapy for suspected nontuberculous mycobacteria, usually with clarithromycin and either a quinolone or ethambutol until specific susceptibility information is available. Tailored therapy often continues for 3 to 6 months.

Viruses

Only one viral infection, herpes simplex, is common during the preengraftment phase of HCT or intensive, nontransplant therapy. Herpes simplex reactivation infections are treated with low doses of acyclovir adjusted for renal function (e.g., 5 mg/kg IV every 8 hours) or similar drugs, whereas VZV infections are treated with higher doses (e.g., 10 mg/kg IV every 8 hours or oral valacyclovir). Use of acyclovir to prevent reactivation of HSV will also prevent VZV reactivation.[115] Because many patients have not been exposed to acyclovir chronically (except for patients previously treated with recurrent courses of acyclovir for frequent outbreaks of genital herpes), there is little reason to expect resistance to acyclovir. However, HSV infections that appear or persist through acyclovir prophylaxis should be considered acyclovir resistant until viral sensitivity testing can be performed, and consideration should be given to initiating treatment with foscarnet or cidofovir. Reports of acyclovir-resistant varicella are extremely rare.[116] Foscarnet infusions affect calcium homeostasis, so monitoring of ionized calcium and phosphorus levels is required during clinical use of the drug. Cidofovir is well tolerated with probenecid and hydration, although renal toxicity has been recognized. Cidofovir, when combined with aggressive supportive measures, is considered an adjunct in treatment of several of the viruses associated with hemorrhagic cystitis[117,118] and disseminated adenovirus infections.[119] When clinically significant CMV infection occurs during neutropenia the antigenemia test cannot be used for diagnosis or monitoring of response to therapy. and DNA polymerase chain reaction (PCR) methods are preferred.[120,121]

Human herpesvirus type 6 (HHV-6) infection can manifest most commonly as fever or pancytopenia. Other recognized clinical syndromes include pneumonitis and encephalitis. Infection is diagnosed by quantitative PCR. Patients who undergo cord blood transplantation have a higher incidence of infection than do those who undergo unrelated bone marrow transplantation (87% vs 19%, $P < 0.0001$), although this analysis requires confirmation.[122] Virus detection at week 3 following transplant may be associated with early skin rash and acute GVHD but also may be asymptomatic. Prospective large-scale studies are needed to determine the role of HHV-6 infection. HHV-6 has 60% DNA homology with CMV, and treatment of documented infection usually is initiated with induction doses of foscarnet or ganciclovir. Responses to antiviral therapy are not universal, and benefits of foscarnet versus ganciclovir have not been determined.[123]

Respiratory virus infections are seasonal, except for parainfluenza.[83,84] A frequent pathogen with clinical significance is respiratory syncytial virus, although influenza, parainfluenza, adenovirus, enteroviruses, the herpesviruses (including HHV-6), human metapneumovirus, and rhinovirus also produce diffuse interstitial infiltrates and pneumonitis. HHV-6 and human metapneumovirus are not recovered with the usual tests ordered at the time of bronchoscopy, so a high suspicion for infection is required to order specific PCR testing.[124,125] Documented infection prompts contact and droplet isolation precautions. Treatment components may include aerosolized ribavirin, IVIg, and, in some cases, monoclonal antibody therapy. However, proof of efficacy of these treatments remains elusive. With respiratory syncytial virus infections, aerosolized ribavirin treatment appears safe, and trends of decreasing viral loads have been reported.[126] Secondary graft failure associated with parainfluenza virus infection has been reported following transplantation.[127]

Fungi

Most yeast infections are caused by *Candida*.[128] Candidal organisms that colonize the mouth and gut proliferate when antibacterial agents suppress the coexisting bacterial flora population. The current standard in the United States for more than a decade has been use of fluconazole to prevent *C. albicans* bloodstream and hepatosplenic infection among allogeneic hematopoietic cell transplant recipients.[87,88,129] However, fluconazole does not have activity against nonalbicans yeasts (e.g., *Candida glabrata, Candida krusei*) and all molds (e.g., *Aspergillus*, *Fusarium*, the Zygomycetes). Among patients colonized with yeast species other than *C. albicans* and among heavily pretreated patients who may have incubating mold infection, prophylaxis using an advanced-generation azole or an echinocandin is preferred.[130,131] Empirical treatment of yeast recovered from a sterile site should include coverage for a nonalbicans *Candida* species until the species is identified.

Use of twice weekly serum *Aspergillus* galactomannan enzyme-linked immunosorbent assay (ELISA) for the detection of invasive aspergillosis is a highly specific diagnostic tool. When used regularly, the galactomannan ELISA may allow for earlier diagnosis of invasive aspergillosis in some patients. The test is troubled by a low sensitivity and high frequency of false negative tests.[132–135] Several reports have described a high rate of false-positive galactomannan ELISA results for patients treated with piperacillin-tazobactam.[136] Administration of β lactams containing galactomannan is responsible for false-positive diagnostic results, even up to 5 days after cessation of treatment.

For bloodstream and other invasive tissue fungal isolates, the susceptibility profile should be reported with the following drug options: amphotericin, fluconazole, itraconazole, voriconazole, posaconazole, and caspofungin. After the susceptibility profile is available, the regimen can be tailored to a single agent. Long-term treatment with newer azoles may be valuable in responding patients. Echinocandins cannot be used to treat *Cryptococcus* or Zygomycetes. The Zygomycetes are susceptible to amphotericin and posaconazole. Echinocandin agents may be fungistatic, rather than fungicidal, in the case of mold infections because interruption of fungal cell wall synthesis is limited to areas of hyphal branch points and growing hyphal tips. Because susceptibility testing for the echinocandin agents is of uncertain reliability, use of an echinocandin after the susceptibility profile has returned should be limited to nonneutropenic patients with uncomplicated candidemia[137] or salvage therapy for aspergillosis. At present, the efficacy of combination drug therapy is unproven, but such therapy is often used in situations associated with high mortality. Clinical experience, but little clearly documented evidence, supports the value of extended combination antifungal therapy. Molds that often are resistant to amphotericin but may be susceptible to voriconazole or posaconazole include *Fusarium, Scedosporium* or *Pseudallescheria*, and *Trichosporon* (see box on Use of Antifungal Agents in Combination).

Use of Antifungal Agents in Combination

The development of new antifungal drugs gives the clinician more options for prophylaxis and therapy than in previous years. There is an overall level of simplicity to the drug choices once their mechanisms of action are understood. The polyenes, including amphotericin products and nystatin, attach onto ergosterol in the fungal cell membrane and are considered fungicidal, because cytoplasm leaks out and individual cells die. The azoles, including fluconazole, itraconazole, voriconazole, and posaconazole, prevent the formation of new ergosterol. Azoles are considered fungistatic, because removal of the drug permits cell regrowth. Theoretically, use of an azole together with a polyene may have an overall static effect for an established infection as the ergosterol target for the fungicidal polyene is depleted. The echinocandins, including caspofungin, micafungin, and anidulafungin, prevent interaction of the catalytic and regulatory subunits of the β glucan synthesis enzyme, so less β glucan is formed for the cell wall. The scaffolding for the fungal cell wall is not maintained, and a dividing cell may burst open when trying to extend the new cell wall over daughter cells. The echinocandins are considered fungicidal for yeasts but fungistatic for molds, as not every mold cell in a large tangle of fungal hyphae is actively dividing. Combination therapy may have the most effect when a cell wall agent (an echinocandin) is used together with a cell membrane agent (a polyene or an azole). There is no role for three-drug therapy (an echinocandin, a polyene, and an azole). The clinical response to combination therapy has been variable; however, the mortality rate appears to be lower with combination therapy than with monotherapy. Controlled trials are needed to determine the role of combination therapy.

Fever Without an Obvious Infectious Source

If there is no obvious source of infection in a hematopoietic cell transplant patient receiving standard antimicrobial prophylaxis before engraftment, then further systematic review of the patient is required. Figure 91–1 presents an 11-step guide to reviewing the HCT recipient for other infectious sources to ensure an appropriate evaluation. The basic differential diagnosis of noninfectious fever includes secondary malignancy (including posttransplantation lymphoproliferative disorders), transfusion of blood products, drug fever (including febrile response to growth factor), autoimmune phenomena, and endocrine disorders (e.g., as malignant hyperthermia). Transfusion-related fever and drug fever probably are the most commonly encountered causes of noninfectious fever in hematologic practice. Transfusion-related fever typically is self-limited.

Pulmonary infections are common in the immunocompromised patient (see Table 91–3).[83,84] Chest radiography is a good initial screen, but it may be more useful for characterizing the nature of an infiltrate and assisting the pulmonologist in determining where to direct the bronchoscope for the highest diagnostic yield of bronchoalveolar lavage. Although 90% of pulmonary nodules among transplantation recipients are due to fungal pneumonia (mainly aspergillosis), 10% have various etiologies, including *Nocardia*,[85] *Legionella*,[86] septic bacterial emboli, mycobacterial infection (with cavitation),[70] EBV-related lymphoproliferative disease, relapsed malignancy, and pulmonary embolism (pleural based).

A drug may cause fever by increasing metabolism, mimicking endogenous pyrogens, evoking a cellular or humoral immune response, interfering with heat dissipation peripherally, or damaging tissue. Drug-induced fevers typically begin 7 to 10 days after drug administration is initiated, are low grade, persist for as long as the drug is continued, cause eosinophilia in up to 20% of cases, and may be associated with a rash. Fever disappears soon after stopping an offending drug, usually over the course of 2 to 3 days. Certain drugs

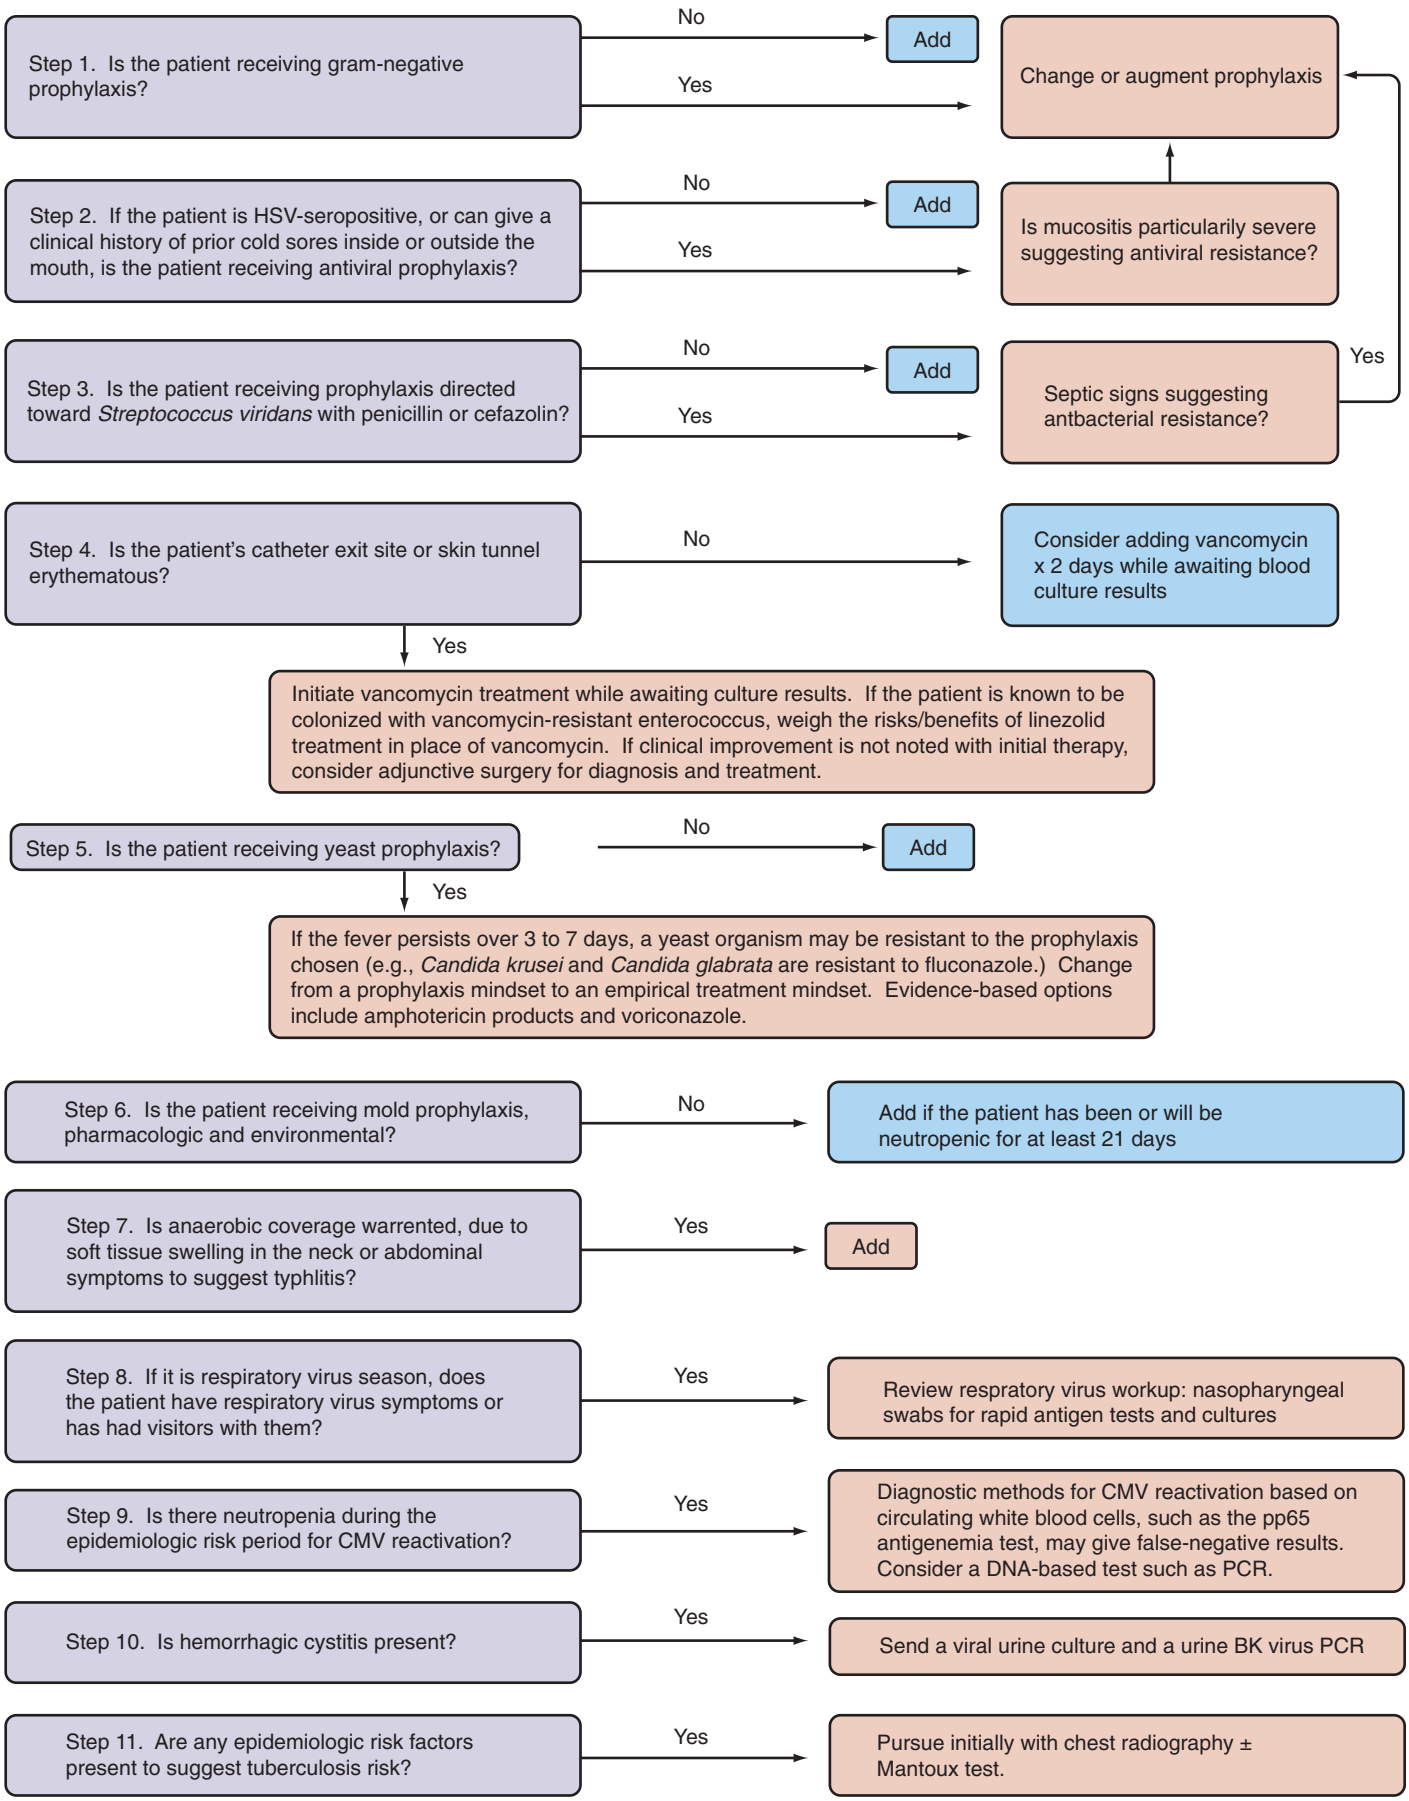

Figure 91–1 Systematic approach to causes of fever and infection in the high-risk hematology patient without an obvious source. This algorithm can be used for hematopoietic cell transplantation patients before engraftment or for patients who are receiving conventional, high-dose therapy for hematologic malignancies and are profoundly neutropenic. BK virus BK polyomavirus; CMV, cytomegalovirus; HSV, herpes simplex virus; PCR, polymerase chain reaction.

have a higher tendency to be associated with drug fever than others, such as β lactams, sulfonamides, vancomycin,[138] mycophenolate mofetil,[139] hydroxyurea,[140] and azathioprine. Administration of growth factor to neutropenic patients can result in prompt occurrence of fevers.

INFECTION MANAGEMENT IN THE HEMATOPOIETIC CELL TRANSPLANT RECIPIENT: A MODEL OF SEVERE IMMUNE DEFICIENCY

Pretransplantation Prophylactic Techniques in Hematopoietic Cell Transplant Recipients

Over the 4 decades that hematopoietic cell transplantation has evolved, antimicrobial prophylaxis regimens have advanced to prevent common or high-risk infections.[141,142] This is balanced by problems associated with the preventive regimen, including toxicity, overgrowth of resistant organisms, and sometimes high cost. Algorithms for these preventive regimens evolve with changes in epidemiology, diagnostic methods, or new treatment agents for infections. Despite an overall preventive approach, infections still occur when a severe immune defect persists, when the bolus of organisms is large, when diagnostic methods are not sensitive enough for early detection, or when infecting agents overcome the effect of the antimicrobial agents. Measures taken to prevent infection in the preengraftment hematopoietic cell transplant patient include pretransplantation serostatus blood workup, environmental measures to prevent infection (including frequent hand washing), and common sense.

Assessment of Pretransplantation Serostatus

Current pretransplant serologic testing of donor and recipient includes assaying for latent viruses (herpesvirus antibodies, hepatitis panels, and human T-cell lymphotrophic virus antibodies human T-lymphotropic virus 1/2 and HIV) and syphilis. Antibody tests that are checked variably among individual transplantation centers include VZV, EBV, and *Toxoplasma*.

Herpes Simplex Virus

If the antibody test for HSV indicates prior infection or if the patient provides a clinical history of prior HSV infection (i.e., mucosal sores), latent infection exists and has the potential to reactivate during periods of T-cell suppression and neutropenia. This patient requires prophylactic medication (e.g., acyclovir or oral valacyclovir), which targets HSV for the neutropenic phase of transplantation.[143–146] HSV lesions can appear as black scabs on the outside of the lips, white- to yellow-based ulcers when found on oral mucosa, or as an unusually severe exacerbation of mucositis or esophagitis. HSV prophylaxis administered until recovery from neutropenia may be helpful even in patients receiving nontransplantation chemotherapy such as acute leukemia induction therapy.[147]

Cytomegalovirus

If the candidate is CMV seropositive before transplantation, the recipient should be followed with periodic (usually weekly) diagnostic monitoring tests[148,149] (e.g., pp65 antigenemia[150] or PCR[151]) for 10 to 20 weeks. No special measures are needed during neutropenia because a detectable circulating white count usually is necessary for reactivation of CMV. If the patient is CMV seronegative before transplantation but the donor is seropositive, the same monitoring algorithm used for the CMV-seropositive patient is needed.

If the donor and recipient are CMV seronegative before transplantation, infection through blood products is possible; therefore, exclusive use of CMV-seronegative blood products or other means of preventing CMV seroconversion, such as leukocyte depletion by filtration, are recommended.[152,153] CMV monitoring should be followed weekly, but the duration of this testing can be shortened by 50%, to 6 to 10 weeks, because late infection in seronegative recipients is uncommon.

Varicella, Human Herpes Virus type 6, and Epstein-Barr Virus

A history of chickenpox is an adequate surrogate for performing the VZV antibody test. As an alternative to ordering varicella serology on every patient, the test could be ordered in patients with no history of varicella infection or vaccination.

Acyclovir used to prevent reactivation of HSV and CMV herpesviruses during neutropenia will also prevent occurrence of clinical VZV infection in most transplantation recipients. Later after transplantation, when acyclovir prophylaxis may have been discontinued, VZV reactivations usually are recognized and easily treated by their characteristic dermatomal distribution, using acyclovir or valacyclovir.[154,155]

Serology for HHV-6 is not tested before transplantation[156] because more than 95% of adults are seropositive for the virus. The transplantation recipient receiving minimal herpesvirus antiviral therapy during the transplantation procedure is at risk for reactivation of HHV-6.[123,157] Whether the CMV-seronegative or HSV-seronegative recipient with a CMV-seronegative donor who ordinarily would receive no antiviral prophylaxis is at highest risk is not known. Additionally, the consequences of asymptomatic and untreated HHV-6 infection are not known.

The vast majority of adult patients undergoing transplantation are EBV seropositive. EBV reactivation is in the differential diagnosis of any new mass, such as enlarged nodes or lung nodules after transplantation, and this reactivation usually occurs 1 to 24 months after the neutropenic phase of HCT.[158] Now that sensitive quantitative EBV viral load tests and effective treatments, such as rituximab, are available, investigators are ordering an EBV viral capsid antigen IgG level before transplantation to determine which recipients to target with quantitative viral load studies.[159] However, there are still many unknowns regarding this continuously changing algorithm. Which recipients require monitoring? Which quantitative assay should be used? How frequently should patients be monitored? What threshold of a detectable viral load should be used to begin treatment? Should this threshold differ in patients receiving immunosuppressive therapy or following mismatched or T-cell–depleted grafts, two recognized risk factors for EBV reactivation?

Hepatitis B and C

Hepatitis B (core antibody, surface antibody, and surface antigen) and hepatitis C serologies are tested in donor and recipient before transplantation. Hepatic dysfunction from either hepatitis B or C after hematopoietic cell transplant can lead to life-threatening liver complications, including venoocclusive disease and acute hepatic necrosis.[160–162] Short-term complications usually are due to hepatitis B, whereas the long-term complication of cirrhosis is due to hepatitis C.[163] The risk of hepatitis in the recipient can be reduced by antiviral therapy for recipients and donors who have detectable viral loads and by transfer of immunity from donor to recipient.[160] A hepatitis-infected individual can be used as a donor if no alternative donor is available or if the intended recipient already is seropositive.

The risk of transmission is small when the hepatitis B-seropositive donor has an undetectable viral load; however, careful followup of recipients is recommended.[164] A surface antigen-positive hepatitis B

donor with a high viral load should be treated with lamivudine or another agent to reduce the circulating viral load before transplantation.[165] High circulating hepatitis C viral load in the seropositive donor for a seronegative recipient is an indication for interferon or other antiviral therapy of the donor before HCT.[166]

If the potential recipient has serologic evidence of infection with hepatitis B or C before transplantation, viral load levels should be checked before and monitored after HCT. High hepatitis B viral load ($>10^5$ copies/mL) is the most important risk factor for reactivation in patients positive for surface antigen undergoing HCT.[164] High circulating hepatitis B viral load in the intended recipient is an indication for lamivudine.[164,165] There is no evident correlation between hepatitis C genotype and type or severity of liver disease after transplantation.[167] There is no effective therapy for hepatitis C in the HCT recipient.

Human Immunodeficiency Virus

A positive donor HIV test for a recipient candidate not known to be seropositive is a contraindication for donation. If the screening test for HIV is positive, a Western blot study should be completed to confirm the result because of the potential for false-positive testing. Appropriate counseling should be provided when a positive HIV test result is conveyed to a patient.[168]

Syphilis

Some screening tests indicate a need for therapy.[169] If the indirect screening test for syphilis returns positive and is confirmed by a direct test, high-dose penicillin treatment should be given for 10 days after transplantation, then *Streptococcus viridans* prophylaxis agent resumed until 21 days after transplantation.[170,171]

Toxoplasma

Historically, 15% of patients who undergo transplantation in the United States are seropositive for *Toxoplasma*, but this percentage may be higher for European centers.[172] The risk of reactivation among seropositive patients is 2%, for an overall incidence of less than 1% of HCT recipients.[172,173] It is suspected that sulfa-based regimens in low dose, such as those used to prevent *Pneumocystis* pneumonia, may be effective in preventing *Toxoplasma*.[173,174]

Review of Commonsense Measures to Prevent Infection

Commonsense measures that should be discussed before transplantation or aggressive nontransplantation chemotherapy include attention to diet, travel, crowds, and pets.[175] Additionally, a history of family or social exposure to tuberculosis should be used to guide whether or not a Mantoux test is applied before therapy.

Diet should be reviewed for herbal supplements or restricted foods.[175] Patients may not recognize that most supplements will have to be discontinued after HCT.[176] Ground meat products need to be thoroughly cooked so that bacteria, distributed onto meat in the grinding process, are killed. Any fruits or vegetables that cannot be peeled should be washed. Salad bars are associated with occasional transmission of infections. Food products that inherently contain infectious organisms should be avoided, including undercooked eggs. For example, Beano, pepper, and miso paste for soup[177] are known to have recovery of *Aspergillus* organisms when cultured. Blue cheeses have molds spiked into the cheese wheel as they are curing and should be avoided. Soft cheeses carry the potential risk of *Listeria* infection. Yogurt contains *Lactobacillus* that, rather than causing gut problems, has been found to cause infection in other sites,[178] including the lungs after aspiration events.

There are no particular travel restrictions, but strategies to minimize transmission of infectious diseases have been summarized.[175] Some social situations, such as sitting in a crowded movie theater or classroom, increase the risk of acquiring a viral illness. Turning away from individuals who are coughing or sneezing may be helpful in preventing the transmission of infections in this situation. Patients need instruction to remember to complete the cycle of infection prevention by washing their hands as soon as possible after being close to such an individual. Given outbreaks of Noroviruses (Norwalk-like viruses) on cruise ships and other types of outbreaks (e.g., *Staphylococcus*) commonly associated with the close living quarters during this type of vacation, cruise ships should be avoided.[179,180]

Healthy dogs and cats are considered acceptable pets. However, the immunosuppressed patient should not be responsible for scooping cat litter because of potential *Toxoplasma* cyst exposure. Similarly, the patient should not play in sandboxes because these areas are concentrated sites that feral outdoor cats may use as litter boxes. Because reptiles of many sorts have been reported to be infected with *Salmonella*, patients should not touch these animals or the insides or outsides of their cages or tanks. The heated water of tropical fish tanks carry *Mycobacterium marinum*. *Cryptococcus* and *Chlamydophila* (formerly *Chlamydia) psittaci* can be transmitted from large pet birds.

Environmental Measures to Prevent Infection

Persons entering the patient's room to perform an examination or touch the patient (including visitors as well as health care workers) should wash their hands outside the room.[181] Ideally, the institution will have handwashing sinks in the hallways outside patient rooms for this purpose. During respiratory virus season, the infection control department often adds extra signs to doorways and other places in the wards to remind visitors of the importance of hand washing. Staff and visitors without control of body secretions should not be permitted to have direct patient contact.

Some infectious situations require special isolation procedures.[181] Contact isolation (gloves and gowns) is used for patients with adenovirus, methicillin-resistant *S. aureus*, or *Clostridium difficile* infection. Droplet precautions are added to contact precautions for respiratory virus or varicella infection. Carriers of vancomycin-resistant enterococcus are placed in contact isolation until they meet defined criteria for discontinuation of isolation.

Laminar airflow is a cumbersome and expensive isolation technique that has been largely outmoded with advances in airflow and isolation technology as well as current antimicrobial therapy. Historically, it has been most commonly used for patients with aplastic anemia[46] or those receiving T-cell–depleted transplants.

High-efficiency particulate air (HEPA) filtration has replaced laminar airflow as the means for preventing infection through ventilation.[181] With at least 12 air exchanges per hour, HEPA filters are capable of removing particles greater than 0.2 μm in diameter, such as mold spores. Patients often ask if they should purchase portable HEPA filters for the home or apartment they will occupy after hospitalization. In the broadest sense, this is an extra measure that can be used on an individual basis. If portable HEPA filters are used, they should be obtained for each of the rooms that the patient will occupy during the day and night, and each unit should be sized for the individual room. A beneficial effect of HEPA filtration in the outpatient setting has not been demonstrated.

Hemorrhagic Cystitis

Hemorrhagic cystitis is hematuria that results from diffuse bladder inflammation and is not confined to the preengraftment period. If blood clots form, bladder irrigation may be required to break up an obstructive uropathy. Massive bladder hemorrhage can be a serious

clinical problem with a high mortality rate. Common causes include chemotherapeutic agents (cyclophosphamide or ifosphamide), radiation, viral infection, and rarely GVHD. Although CMV can be associated with hemorrhagic cystitis after hematopoietic cell transplant, adenovirus and polyomavirus infection (specifically BK viruria) often are responsible, especially when hemorrhagic cystitis lasts longer than 7 days.[182,183] Diagnosis is made by urine viral culture to rule out adenovirus and quantitative urine BK virus PCR.[184] Intravesical instillation of cidofovir has resulted in clinical improvement of both adenovirus- and BK virus-associated intractable hemorrhagic cystitis and is an attractive alternative to intravenous administration of cidofovir.[185,186]

Infection in the Hematopoietic Cell Transplant Recipient After Engraftment

Viral infections that reactivate after engraftment often are related to defective T-cell–mediated immunity.[187] Outpatient HCT recipients inhale mold spores and *Pneumocystis* cysts from the environment, so common exogenously acquired infections include aspergillosis and *P. jiroveci* (previously *carinii*).[187–189]

Cytomegalovirus

Use of prophylactic ganciclovir at engraftment usually is avoided because it leads to myelosuppression and possibly a higher incidence of late CMV disease.[150] Instead, the patient is treated with ganciclovir when weekly PCR or pp65 antigenemia monitoring test meets a positive threshold. Initial viral load levels do not predict disease.[190] CMV infections are treated with an induction ganciclovir regimen followed by approximately 6 weeks of a maintenance regimen (half the induction dose). The duration of induction (1–3 weeks) varies by institution, but in general 1 week is used for low-grade infection, 2 weeks for high-grade infection, and 3 weeks for end-organ disease. A rising viral load when checked weekly during the first month of preemptive therapy signals the need for continued induction dosing or repeat induction dosing.[191]

When the end-organ manifestation of CMV is pneumonitis (recovery of CMV from a deep lung specimen along with an infiltrate on chest radiograph), IVIg is added on an every-other-day basis for the duration of induction.[192,193] When CMV manifests in an end organ other than the lungs, use of IVIg is not as clearly useful. Some centers add IVIg when the patient's total IgG level falls below 400 mg/dL. Dosing schedules vary from IVIg given once weekly for 3 weeks to every other day for the duration of induction, similar to therapy for pneumonitis.[194] Ganciclovir resistance is uncommon.[195]

Varicella-Zoster Virus

Varicella-zoster virus reactivations from latency (zoster) usually are recognized by their characteristic dermatomal distribution. No temporal pattern is seen, viremia can occur concurrently, and multiple episodes are possible but uncommon. For patients who have been treated for a zoster episode after HCT, some centers provide acyclovir prophylaxis until 1 year after HCT. Less common VZV clinical manifestations that can result in severe infection and may require molecular testing[196] or viral culture for diagnosis include hemorrhagic pneumonia, hepatitis,[197] central nervous system disease,[198] thrombocytopenia, and retinal necrosis.[199]

Hematopoietic cell transplant recipients with a negative or unknown VZV disease history and a significant exposure to active varicella are susceptible to primary VZV infection. For these patients, varicella-zoster immune globulin should be provided within 96 hours of exposure. Patients with positive serology can become clinically reinfected after exposure and should be provided with acyclovir prophylaxis; however, such patients do not require varicella-zoster immune globulin.[200]

Epstein-Barr Virus

EBV causes asymptomatic but detectable viremia, hemophagocytic syndrome, or posttransplant lymphoproliferative disorder. Quantitative EBV viral load diagnostic testing is relatively new and not standardized, so the algorithms for monitoring and initiation of treatment vary. Recognition of greater than 1000 viral copies/mL of blood requires investigation, repeated testing, and possibly treatment, especially in high-risk patients. Some EBV reactivations are subclinical and require no therapy. Direct antiviral agents have limited impact on reducing detectable EBV viral loads. Posttransplant lymphoproliferative disorder after allogeneic transplantation most often is of donor origin. General treatment approaches involve reduction of immunosuppression plus rituximab. Both monomorphic and polymorphic histology (and immunophenotyping) may be seen. Monoclonal histology predicts an unfavorable prognosis.[201] The incidence of EBV-related complications is higher in mismatched donors, T-cell–depleted transplants, and patients receiving intensive immunosuppression (e.g., antithymocyte globulin).[202]

Invasive Mold Infections

Among HCT recipients studied at autopsy, yeast and mold infections were common, seen in more than 25% of deaths.[203] The probability of survival is higher in recent years, likely due to newer and safer treatment agents as well as nonmyeloablative conditioning.[189] Posaconazole is effective in preventing invasive fungal infections during GVHD.[204] Mold spores may initiate a localized infection in the lungs or sinuses that, after intensive immunosuppression for GVHD, may disseminate to the skin, abdominal organs, or central nervous system.[89,205] Treatment of central nervous system infections should include voriconazole, which attains cerebrospinal fluid levels approximately 50% those of plasma or central nervous system tissue levels approximately 200% those of plasma. Infection with Zygomycetes organisms has a later onset than infection with *Aspergillus* (after day 90) and possibly lower mortality.

Pneumocystis

The most common presenting symptoms of *Pneumocystis* infection are dyspnea, cough, and fever.[206] Diagnosis requires demonstration of the organism in silver-stained specimens (bronchoalveolar lavage or lung biopsy). Disease occurs by both new infection and activation of latent infection. Most patients present between day 40 and day 80 after HCT,[207] but cases as early as day 12[208] and as late as 42 months after HCT have been reported.[209] Once lymphocyte function is more fully reconstituted, *Pneumocystis* infections are rare. Prophylaxis options include trimethoprim-sulfamethoxazole, aerosol pentamidine, dapsone,[210,211] and atovaquone.[212] Among patients treated with dapsone after transplantation, increased red blood cell and platelet transfusion requirements are noted.[210] Prophylaxis is generally discontinued 1 to 2 years after HCT, or longer if immunosuppression is ongoing.

Parasitic Infections

Toxoplasma gondii is a ubiquitous pathogen that causes significant morbidity and mortality. Although relatively uncommon, toxoplasmosis is recognized as a cause of cerebral, ocular, and lung disease in immunocompromised patients.[173] Disseminated toxoplasmosis has resulted in graft failure in a cord blood transplant recipient.[213]

Accurate diagnosis of this treatable infection is critical. PCR-based testing has become an adjunct method for diagnosis, occasionally replacing tissue biopsy.

Infection Issues in the Late Posttransplantation Period

Encapsulated Organism Prophylaxis

Penicillin prophylaxis has decreased the incidence of infection-related morbidity and mortality from polysaccharide-encapsulated bacteria (*S. pneumoniae, H. influenzae* type b, *Neisseria meningitidis*). Penicillin-resistant pneumococcal infection has been reported, prompting consideration of alternate prophylaxis, such as a change from penicillins to quinolones.[214,215] Prophylaxis is generally discontinued 2 years after HCT, or later if GVHD and immunosuppression are ongoing at the 2-year time point. Once the patient is ready for vaccinations, conjugate pneumococcal, meningococcal, and *H. influenzae* type b vaccines are given.

Vaccination

Recipients of HCT frequently lose antibody responses to viral and bacterial pathogens previously targeted by childhood vaccination. Although practice varies among transplantation centers, killed-virus vaccines are often given at 1 year after HCT and live-virus vaccines approximately 2 years after HCT for patients without GVHD. For adults, Tdap (formulation of reduced-antigen, combined diphtheria-tetanus-acellular pertussis vaccine) has replaced Td (diphtheria-tetanus booster vaccine) as a means for decreasing the adult reservoir of pertussis.[216] For protection against hepatitis, the combined vaccine providing protection against both hepatitis A and B can be used.[217] The efficacy of vaccination is influenced by the time elapsed since transplantation, the nature of the hematopoietic graft, the presence of GVHD, and the use of serial immunization.[218,219] Despite this evidence, a national survey of HCT immunization practices revealed that vaccines are underused, and schedules for revaccination vary.[220,221]

CHAPTER 92

NUTRITIONAL SUPPORT OF PATIENTS WITH HEMATOLOGIC MALIGNANCIES

Polly Lenssen and Paula M. Charuhas

Patients with hematologic malignancies are highly heterogeneous in terms of their nutritional needs and requirement for nutritional intervention. Patients with aggressive leukemias and lymphomas receive the most intensive of oncologic therapies and frequently experience significant oral and gastrointestinal toxicities, decreased dietary intake, and weight loss. Patients with good-risk acute lymphocytic and chronic leukemias less commonly encounter significant nutritional problems, although the problem of overnutrition has been increasingly recognized in survivors of childhood acute lymphocytic leukemia (ALL).

Use of total parenteral nutrition (TPN) to prevent or treat malnutrition in cancer patients carries significant risks, and in the last decade more attention has focused on feeding patients by the enteral route. This chapter addresses the appropriate use of TPN, tube feeding, and other dietary intervention strategies, such as low microbial diets and high-dose vitamin supplementation, in patients with hematologic malignancies, with special focus on patients undergoing hematopoietic stem cell transplantation (HSCT).

NUTRITIONAL PROBLEMS

Protein-Calorie Malnutrition

Significant weight loss is not common in most patients with hematologic malignancies. In a classic study, DeWys et al.[1] reported that only 4% of patients with acute myeloid leukemia (AML), 10% with favorable-prognosis non-Hodgkin lymphoma, and 15% with unfavorable-prognosis non-Hodgkin lymphoma presented with more than 10% weight loss during the 6 months before initiation of chemotherapy. In children with newly diagnosed acute leukemia, primarily ALL, several large cohort studies found approximately 7% had malnutrition, defined as body mass index (BMI) ≤2 standard deviations compared with reference data or less than 90% weight for height.[2,3]

The risk for development of malnutrition subsequent to diagnosis depends on the toxicity of the therapy administered and the progression of the disease. For patients with hematologic malignancies who go on to HSCT, malnutrition is more prevalent. Deeg et al.[4] categorized a large cohort of adult and pediatric marrow graft recipients by weight status and found that except for chronic myelogenous leukemia in chronic phase and low-risk pediatric ALL, 8% to 28% of patients had mild to moderate malnutrition before transplantation (Table 92–1).

Limited data about the effect of protein-calorie malnutrition on outcome in hematologic malignancies are available. DeWys et al.[1] found that weight loss before diagnosis had no influence on survival in patients with AML but was associated with a significant decrease in survival in patients with favorable-prognosis and unfavorable-prognosis non-Hodgkin lymphoma. Sala et al.[5] reviewed the effect of malnutrition on outcome in pediatric cancer and found mixed results, with the largest cohort (1025 children with ALL) having no relation between nutritional status based on BMI and prognosis ($P = 0.72$). Likewise, BMI was not associated with prognosis in 621 consecutive patients treated for ALL at St. Jude's, nor did it affect the intracellular levels of thioguanine nucleotides and methotrexate polyglutamates or the systemic clearance of methotrexate, teniposide, etoposide, and cytarabine.[6] On the other hand, in an analysis of 768 children with AML, of whom 10.9% were lower than 10th percentile BMI and 14.8% greater than 90th percentile BMI, the underweight patients were less likely to survive than were patients with BMI in the more normal range (hazard ratio 1.85; $P = 0.006$) and more likely to experience treatment-related mortality (hazard ratio 2.66; $P = 0.003$). Similarly, overweight children with AML were less likely to survive (hazard ratio 1.88; $P = 0.002$) and more likely to have treatment-related mortality (hazard ratio 3.49; $P < 0.001$).[7] During HSCT, underweight patients are at increased risk for early death. Among adults, survival to day 150 after transplantation is significantly worse for patients at 85% to 95% ideal body weight (IBW; $P = 0.004$) or less than 85% IBW ($P = 0.0001$) than for patients at 95% to 140% IBW status. Underweight children had a less marked but similar decrease in survival compared with well-nourished children ($P = 0.22$ for < 85% IBW vs 95%–140% IBW, and $P = 0.01$ for 85%–95% IBW vs 95%–140% IBW).[4]

Weight loss of 10% to 15% correlates with a 20% loss of protein mass and clinically significant impairment of physiologic function.[8] Morbidity associated with malnutrition has included increased length of hospital stay and infectious complications. Horsley et al.[9] reported that malnourished HSCT patients, as defined by the patient-generated subjective global assessment tool, experienced an increased length of hospital stay ($P = 0.002$) compared to well-nourished patients in a prospective study of 66 patients. The adverse consequences of malnutrition on immunity, especially T-cell function, phagocytosis, and complement-mediated defenses, are well described.[10] The effects of malnutrition on gastrointestinal function and immunity may be particularly relevant during the intense treatment of hematologic malignancies, in which the breaching of the gastrointestinal barrier has been implicated as a source of bacteremias and sepsis.[11,12] Although the role of dietary variables in actual bacterial translocation and clinical infections has not been established in humans,[13,14] data in children with cancer support the adverse consequences of malnutrition on infection rates and anergy.[5,7]

Obesity

The concern about excess mortality as a result of inappropriate doses of cytotoxic therapy in obese patients has gained more interest as the prevalence of obesity has increased worldwide in adults and children. Adjusting doses down may result in insufficient tumor kill, whereas dosing on actual weight may result in too much organ toxicity. In a retrospective study of 4356 patients with ALL enrolled in Children's Cancer Group studies, Butturini et al.[15] reported that in patients aged 10 years or older, obesity was associated with an increased risk of leukemia relapse, whereas in patients younger than 10 years, no effect of obesity on disease outcome was observed. In a smaller cohort of Hispanic children with ALL (n = 322), obesity at diagnosis was not associated with decreased overall survival (hazard ratio 1.40) or event-free survival (hazard ratio 1.08).[16] Several studies have implicated obesity as contributing to mortality in pediatric AML[7] as well as in HSCT, including autografting[17–19] and allografting.[20,21] Deeg et al.[4] failed to find any association of obesity and mortality in the largest

Table 92–1 Patients with Malnutrition Before Marrow Grafting

	Adults		Children	
Diagnosis	Total N	N < 95% IBW (%)	Total N	N < 95% IBW (%)
AML, low risk	114	15 (13.2)	43	7 (16.2)
AML, high risk	307	40 (13.0)	105	24 (22.8)
ALL, low risk	35	4 (11.4)	21	0
ALL, high risk	158	28 (25.9)	217	25 (11.5)
CML, chronic phase	372	16 (4.3)	23	3 (13.0)
CML, other	206	32 (15.5)	33	8 (24.2)
Lymphoma, remission	92	7 (7.6)	18	4 (22.2)
Lymphoma, relapse	159	23 (14.5)	25	7 (28.0)

ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia; IBW, ideal body weight.

Data from Deeg HJ, Seidel K, Bruemmer B, et al: Impact of patient weight on nonrelapse mortality after marrow transplantation. Bone Marrow Transplant 15:461, 1995.

cohort (n = 2238) of adult and pediatric patients undergoing allogeneic or autologous HSCT. These data provide little firm ground on which to inform patients about risks associated with obesity or to make recommendations about healthy weight loss options in anticipation of HSCT.

Obesity as a consequence of therapy has been intensively investigated in childhood ALL Prevalence rates exceed 50% in children treated for ALL. A variety of contributing factors have been identified, including cranial radiation, treatment with prednisone and dexamethasone, decreased physical activity levels, younger age, female gender, and lower than expected total daily energy expenditures.[22–24] In young children aged 30 months or younger at the time of diagnosis, adiposity rebound occurs prematurely, possibly contributing to the high prevalence of obesity in long-term survivors.[25] Adiposity rebound, when BMI increases after its nadir in childhood, is a critical period for regulation of energy balance and adult obesity risk. The metabolic syndrome has been well described in obese survivors of ALL.[22,26–28] Effective interventions to reduce the risk of premature cardiovascular disease have not been defined; however, a rational approach focuses on minimizing excess weight gain by counseling patients on the benefits of proper diet and exercise during and after therapy.

Altered Metabolism

The metabolism of malignant bone marrow is markedly accelerated. Energy expenditure averages 35% to 50% higher than predicted in pediatric and adult patients with leukemia.[29–32] Rates of whole-body protein synthesis and breakdown are almost twice normal.[30,32] Similar derangements in energy and protein metabolism have not been found in patients with lymphoma.[32] Energy expenditure decreases in patients with acute leukemia within days of starting chemotherapy[31,33] providing further evidence that the leukemia itself induces the high metabolic rate. Analogously, maintenance chemotherapy in children with ALL in remission appears to exert no significant adverse effects on energy metabolism.[34,35]

During induction chemotherapy[31] or HSCT,[36] energy expenditure and protein losses appear to increase, although this finding is not consistent.[37] It is likely that the variability of diseases, treatments, and complications after transplantation make it impossible to generalize about the impact of HSCT on energy needs.

Several investigators have reported lower than expected resting metabolic rate in long-term obese survivors of ALL.[38–40]

Toxicities of Oncologic Treatment

The nutritionally relevant toxicities of oncologic treatment are summarized in Table 92–2. Aggressive multimodal treatment often produces multiple toxicities; when prolonged, it can lead to significant nutritional deficits, particularly in children. The nutritional consequences of biologic response modifiers are associated with anorexia and mild to moderate gastrointestinal disturbances.

ASSESSMENT OF ALTERED NUTRITION STATUS

Basic Evaluation

Initial and serial nutritional evaluation and screening are indicated in all patients with hematologic malignancies (see Algorithm for Nutrition Assessment and Intervention below). Early identification of poor dietary intake or depleted weight status (rapid weight loss or inadequate reserves compared with an IBW estimate or reference BMI for age and gender) may avert the morbidity associated with moderate to severe malnutrition. In a survey of 173 pediatric oncology patients of whom 45% had leukemia or lymphoma, Tyc et al.[41] found that poor oral intake, even as a subjective report, was the single best predictor of need for intervention with TPN or enteral tube feeding. In this cohort the mean length of time after diagnosis for nutrition support intervention was 33 weeks, suggesting that earlier identification of poor oral intake often may allow sufficient time to implement earlier intervention programs to increase caloric intake, including nutritional counseling and behavioral therapies. Earlier intervention potentially may circumvent the need for more invasive and costly nutrition therapies.

Weight assessment as an index of body composition is of less value in states of fluid imbalance (edema, dehydration, iatrogenic fluid overload). Weight must be interpreted with caution in metabolically stressed patients, such as those experiencing infectious complications or organ dysfunction with induction therapy or stem cell grafting.[42] Actual nutrient intake as documented by the dietitian often provides the best guide for judging nutritional adequacy during periods of stress. In many institutions, bedside metabolic monitors that measure energy expenditure and help establish the energy goals of nutrition therapy are available.

Measurements of serum albumin, prealbumin, and transferrin seem to reflect metabolic stress, not the adequacy of recent nutrient intake, in patients with leukemia undergoing induction chemotherapy[31,43] or HSCT.[36,44] Serum creatinine may be a surrogate for nutritional status in children. In 37 children with ALL, serum creatinine strongly correlated with serum creatinine and lean body mass ($r = 0.83$ at diagnosis, $r = 0.77$ on therapy, $r = 0.56$ off therapy).[45]

Pediatric Assessment

Accurate serial weight and height measurements are required for assessment of growth and development in children and adolescents. Weight for length in infants and children up to age 3 years and BMI for age in children older than 3 years are the appropriate tools for assessing adequacy of body reserves, using standardized charts.[46] Children less than the fifth percentile for length/height, weight, weight for length, or BMI for age require in-depth assessment and development of a nutrition care plan to improve nutritional status. Likewise, children who are not gaining and growing or who are experiencing weight loss require immediate dietary evaluation and intervention.

Serial heights should also be plotted on velocity charts.[47] Decreased height velocity has been observed in children with hematologic malignancies treated at all ages before puberty and with radiation, chemotherapy alone, and a variety of conditioning regimens with HSCT. The greatest risk factors are younger age, cranial irradiation, single-dose total body irradiation, and male gender.[48–51] The role of chronic nutrient deficiencies has not been investigated, although poor

Table 92–2 Nutritional Problems Associated with Treatment of Hematologic Malignancies

Treatment	Complications
Chemotherapy	
Alkylating agents[a]	Anorexia, nausea, vomiting Diarrhea: Carboplatin, carmustine, cisplatin, dacarbazine, lomustine, mechlorethamine, melphalan, streptozocin Hepatotoxic: Busulfan, carboplatin, carmustine, dacarbazine, lomustine, mechlorethamine, melphalan, streptozocin, thiotepa Hypoglycemia: Streptozocin Nephrotoxic: Carboplatin, carmustine, cisplatin, ifosfamide, lomustine, streptozocin Metallic taste: Cisplatin, melphalan Stomatitis: Carmustine, chlorambucil, ifosfamide, lomustine, mechlorethamine, thiotepa Taste disturbances: Carboplatin, cisplatin
Antitumor antibiotics[b]	Anorexia, nausea, vomiting, stomatitis, diarrhea Gastrointestinal ulceration: Dactinomycin, doxorubicin Hepatotoxic: Idarubicin, mitomycin C, mitoxantrone, plicamycin Nephrotoxic: Mitomycin C, plicamycin Taste disturbances: Bleomycin, dactinomycin, daunorubicin
Antimetabolites[c]	Anorexia, nausea, vomiting, mucositis, diarrhea Constipation: Cladribine, fludarabine, gemcitabine, hydroxyurea, pentostatin Hepatotoxic: Capecitabine, cytarabine, fluorouracil, mercaptopurine, methotrexate, thioguanine Malabsorption: Mercaptopurine, methotrexate Nephrotoxic: Cytarabine, pentostatin, mercaptopurine, methotrexate, thioguanine Taste disturbances: Methotrexate
Plant alkaloids[d]	Stomatitis, nausea, vomiting, diarrhea Anorexia: Etoposide, topotecan, vincristine Constipation, ileus: Vinblastine, vincristine Hepatotoxic: Etoposide, paclitaxel, vinblastine, vincristine, vinorelbine Nephrotoxic: Irinotecan, paclitaxel
Other[e]	Anorexia, diarrhea, fluid and electrolyte disturbances Diarrhea: L-Asparaginase, imatinib mesylate, pegaspargase, procarbazine Hyperglycemia: L-Asparaginase, pegaspargase Nausea, vomiting: Procarbazine Nephrotoxic and/or hepatotoxic: L-Asparaginase, pegaspargase, procarbazine Pancreatitis: L-Asparaginase Stomatitis: Procarbazine
Hormones[f]	Muscle and bone loss, hypokalemia, fat deposition and weight gain, sodium and fluid retention, glucose intolerance, hyperphagia, increased thirst, hypercalcemia, hyperlipidemia, osteoporosis, gastrointestinal upset, negative nitrogen balance Anorexia: Diethylstilbestrol, letrozole, tamoxifen Diarrhea: Letrozole Hepatotoxic: Tamoxifen Increased growth velocity: Fluoxymesterone
Irradiation	
Head and neck	Stomatitis, xerostomia, odynophagia and dysphagia, anorexia, taste alterations, dysosmia, osteonecrosis
Esophageal	Esophagitis, esophageal stricture
Stomach	Anorexia, gastritis, nausea, vomiting
Abdominal	Enteritis, diarrhea, steatorrhea, malabsorption, stenosis, obstruction, fistula formation, protein-losing enteropathy, fluid and electrolyte imbalances
Total body	Stomatitis, nausea, vomiting, diarrhea, taste alterations, xerostomia, growth failure
Biologic Agents[g]	
	Anorexia, nausea, vomiting, diarrhea Angioedema: Rituximab Hepatotoxic: Aldesleukin, interferon, interleukin Nephrotoxic: Aldesleukin Stomatitis: Aldesleukin
Hematopoietic Stem Cell Transplantation	
	Stomatitis, esophagitis, gastrointestinal ulceration, diarrhea, taste alterations, xerostomia Venoocclusive disease; Hepatic, renal, pulmonary dysfunction; multiple organ failure Acute and chronic graft-versus-host disease Infectious enteritis

[a]Busulfan, carboplatin, carmustine, chlorambucil, cisplatin, cyclophosphamide, dacarbazine, ifosfamide, lomustine, mechlorethamine, melphalan, streptozocin, thiotepa.
[b]Bleomycin, dactinomycin, daunorubicin, doxorubicin, epirubicin, idarubicin, mitomycin C, mitoxantrone, plicamycin.
[c]Azacytidine, capecitabine, cladribine, cytarabine, fludarabine, fluorouracil, gemcitabine, hydroxyurea, mercaptopurine, methotrexate, pentostatin, thioguanine.

nutritional status before HSCT was associated with decreased height velocity at 1 year after transplantation.[52] Optimizing nutritional intake is essential for children with hematologic malignancies to maximize their growth potential along the entire continuum of care for their disease (see Algorithm for Nutrition Assessment and Intervention below).

NUTRITIONAL INTERVENTION

Dietary Recommendations and Modifications

Dietary recommendations during periods of treatment toxicities and prolonged anorexia are accessible elsewhere,[53] including recommendations specific for pediatric[54] and adult[55] patients undergoing HSCT.

Appetite and taste perception can be influenced by central nervous system changes as well as by peripheral mechanisms associated with insults to chemosensory structures resulting from chemotherapy, radiation, poor oral health, altered salivary flow, and oral mucositis.[56] Up to 70% of patients receiving chemotherapy report changes in taste and smell. Cisplatin, cyclophosphamide, doxorubicin, carboplatin, 5-fluorouracil, levamisole, and methotrexate are associated with taste changes (see Table 92–2). In 284 adults surveyed by questionnaire after chemotherapy, taste changes were most often associated with xerostomia, nausea, and decreased appetite.[57] Taste changes may influence interest in eating and diet quality from several days to several weeks after HSCT. Mattsson et al.[58] reported significant hypogeusia immediately after HSCT in 10 patients compared with 10 control subjects, which can adversely impact oral intake at a time when nutritional requirements are elevated. Epstein et al.[59] surveyed 50 patients 90 to 100 days after HSCT and reported that 65% of patients still complained of changes in taste, ranked as mild, moderate or severe, at the time of the survey; smell changes and xerostomia were significantly correlated with changes in taste. However, these taste changes were reported to have a limited impact on perceived quality of life. Proper assessment and considerations of taste and smell alterations are essential to provide individualized diet recommendations.

Diet modifications may include changes in consistency, texture, temperature, taste, and smell of food, especially when patients experience mucositis, esophagitis, xerostomia, or dysgeusia. Reduction of fat and lactose content may decrease nausea or diarrhea. A dietetics professional can recommend appropriate nutritional supplements for patients who exhibit malabsorption or show an inability to gain weight. During hospitalization, a food service that is individualized and that includes frequent followup by trained nutrition staff best meets the needs of patients undergoing intense oncologic therapy.

Diet Guidelines for Immunosuppressed Patients

Historically, HSCT patients were treated with gastrointestinal decontamination in ultraisolation or high-efficiency particulate air (HEPA)-filtered environments and were served diets of varying microbial restrictions, ranging from "sterile" to "cooked food only."[60,61] Sterile diets are rarely served by institutions today because of high production costs[61] and the shift to ambulatory clinic treatment and care. Most hospitals acknowledge the need to impose dietary restrictions to limit pathogen exposure in patients with compromised immune function and routinely provide some form of low microbial food service to patients with neutropenia or who are undergoing HSCT.[62–64]

The protective benefit of low microbial diets against infection has not been established because of a lack of randomized controlled trials.[62,65] Nonetheless, the possibility that food may serve as a source of infection is evidenced by reports implicating food as sources of pathogenic organisms in immunosuppressed patient populations, including HSCT recipients.[66–74] Safdar et al.[75] suggested an association between reactivation of acute human cytomegalovirus infection in HSCT recipients and subsequent *Listeria monocytogenes* infection due to human cytomegalovirus–associated dysfunction in host cellular immune response. Other immunosuppressive conditions that diminish cellular immunity may increase the risk of listeriosis.[69,71–73] During a 15-year period that included 20,612 hospital admissions, Mora et al.[76] reported listeriosis infections in five children (three with leukemia, one with lymphoma, and one with a brain tumor), all of whom recovered after antibiotic treatment. Case reports of *L. monocytogenes* and *Clostridium botulinum* infections in HSCT recipients have proved difficult to attribute to contaminated foodstuffs.[70,71,74,75] The incubation period for *L. monocytogenes* (onset up to 30 days) as well as other foodborne illness organisms may be such that suspect foodstuffs have been discarded, and an accurate food intake history to identify the potential contaminated food is difficult. Furthermore, most *L. monocytogenes* infections in HSCT patients have been detected in the ambulatory care setting, making it more difficult to trace to specific food intake.[71,74,75] Fungal infections are common in the immunosuppressed host but difficult to link with food-originated infection. Numerous foods, such as aged cheeses, fermented products (e.g., miso, tempeh), and naturopathic substances,[77] may serve as sources of fungal infections. Bouakline et al.[78] examined the prevalence of fungal organisms in nonheat-sterilized foods. *Aspergillus* species were detected in 100% of black pepper and regular tea samples (unbrewed sample), 12% to 66% of fruits, 27% of herbal teas (unbrewed sample), and 20% of freeze-dried soup samples (not reconstituted). All soft cheese samples were contaminated by *Geotrichum* and yeast (*Candida norvegensis*), but processed cheeses were free of fungal organisms. The raw produce in this study was not washed before culturing, nor were the food cultures taken after brewing or cooking.

Low microbial or cooked food diets vary widely in terms of food choices (e.g., exclusion or inclusion of raw produce) and bacterial content and are generally empirically formulated, although some institutions culture foods and assess food acceptability when developing such diets.[61] Moe[79] cultured 198 foods prepared by conventional methods. Although 80% of beverages, starches, cooked meats and entrees, and frozen vegetables were acceptable, only 36% of pasteurized dairy products and 42% of dessert and snack items met minimal microbiologic criteria. Up to 17 different species of gram-negative rods in concentrations as high as 10^6 colony-forming units (CFU)/mL in milk, pudding, and ice cream were identified. Ayers et al.[66] found that serving foods containing only *Bacillus* resulted in transient colonization with *Bacillus* species in 41% of patients studied, but no infections occurred.

Fresh fruits and vegetables historically have been excluded from low microbial diets, placing patients at risk for micronutrient deficiencies.[65] Organisms routinely found on washed raw fruits and vegetables do not appear to be common sources of infection in immunosuppressed patients. At the Fred Hutchinson Cancer Research Center, 29 cultures of assorted raw, washed fruits showed gram-positive cocci and gram-negative rods (<4000 CFU/mL) that are commonly found in food (SN Aker, Unpublished Data, 2003). One of three strawberry cultures and two of three apricot cultures showed a range from 200 to 2000 CFU/mL of five mold types. Thirty-six samples of raw, washed vegetables resulted in a broader variety of gram-positive and gram-negative organisms at levels ranging from less than 200 to too numerous to count per milliliter, with few yeasts or molds. The organisms cultured from these fruits and vegetables are not representative of common infections routinely seen in immunosuppressed cancer and HSCT patient populations. Except for infrequent reports such as cyclosporiasis associated with imported fresh raspberries[80] and *Escherichia coli* 0157:H7 contamination of unpasteurized fruit juices[81] and raw vegetable sprouts, food outbreaks associated with raw, washed domestic fruits and vegetables are rare.

Use of strict isolation laminar airflow environments has been largely replaced with single and occasionally HEPA-filtered hospital rooms that use strict hand washing only for the neutropenic oncology

Algorithm for Nutrition Assessment and Intervention

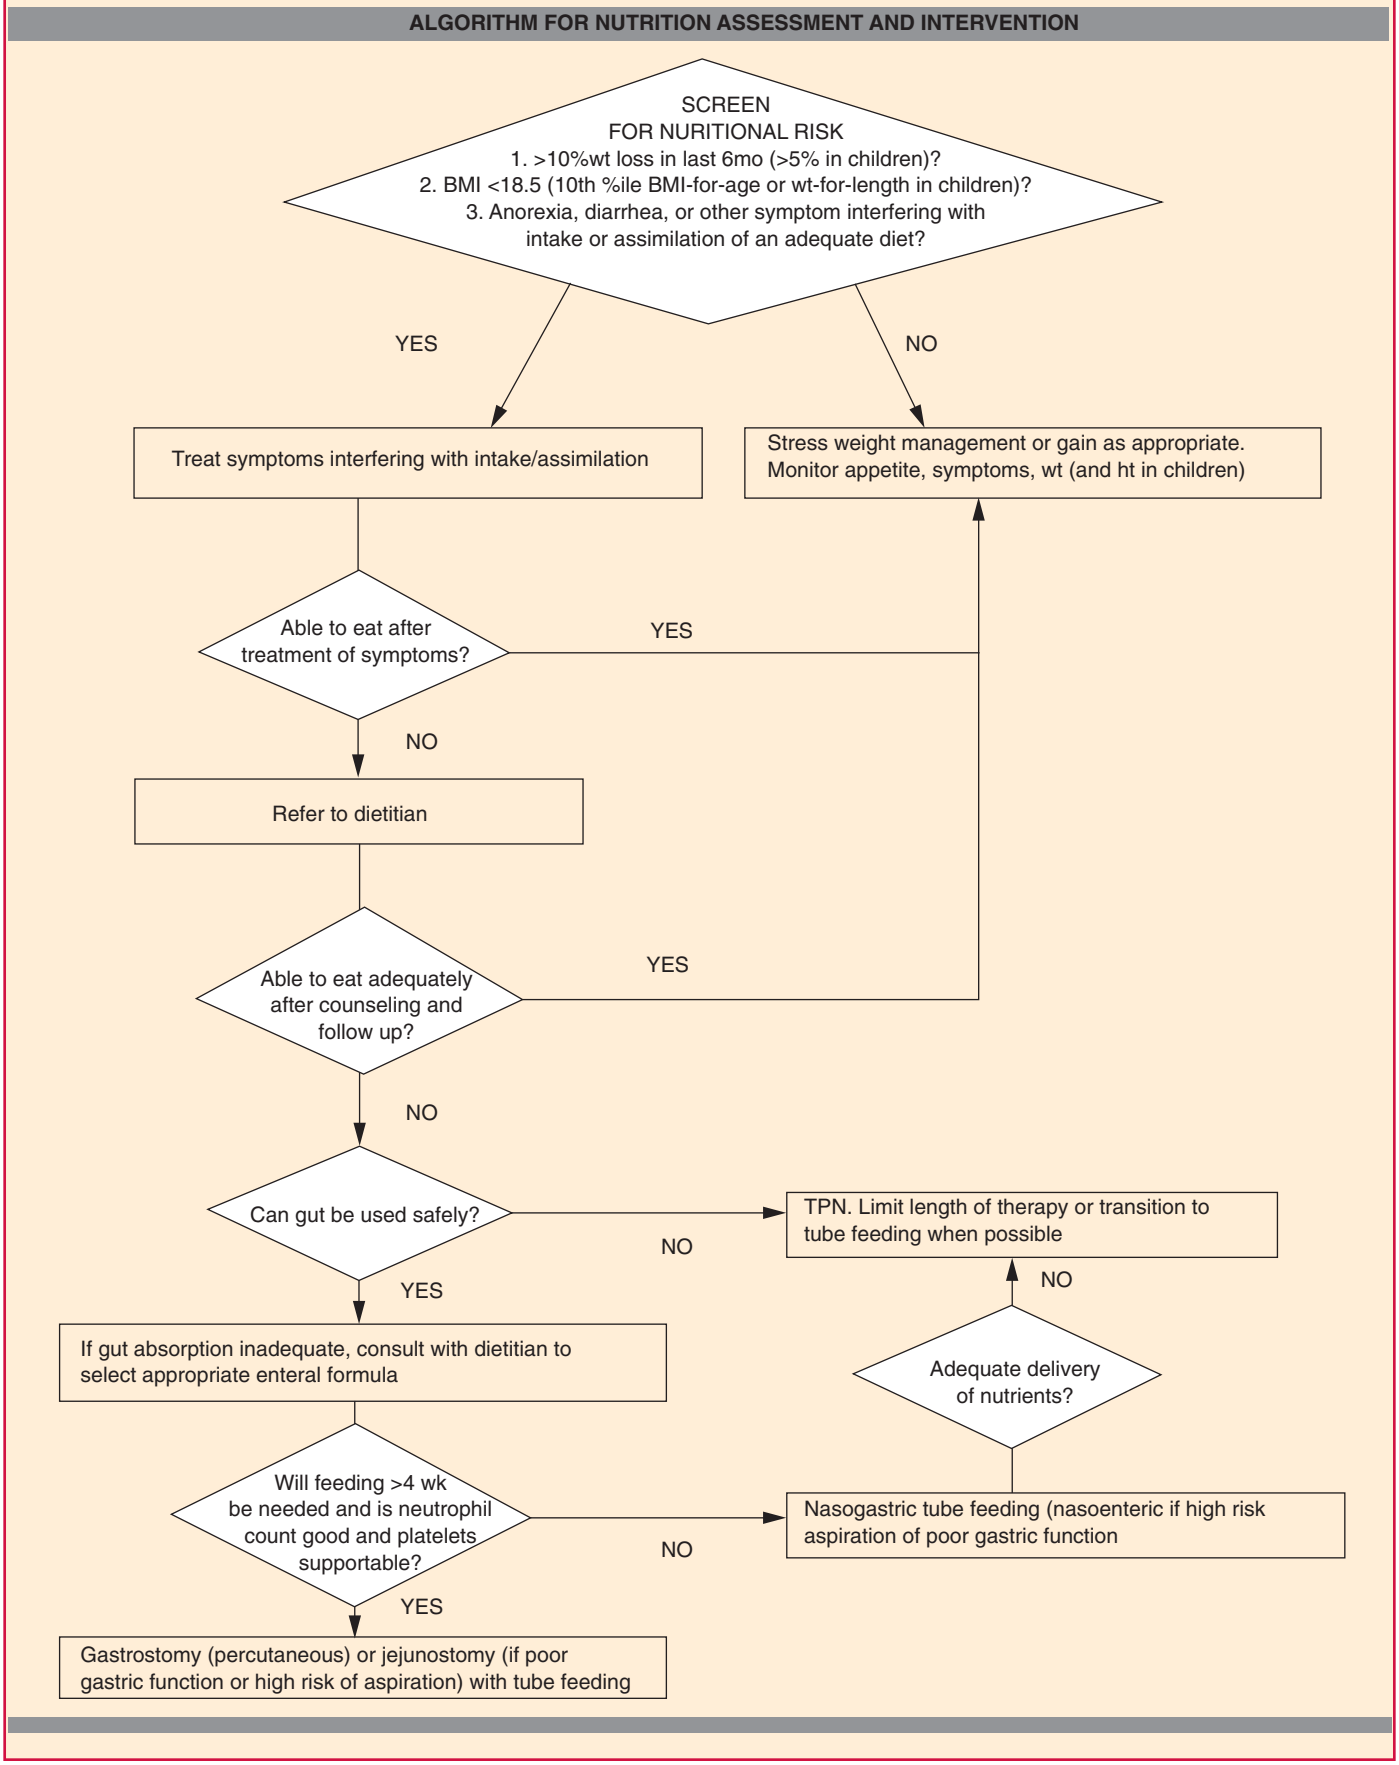

Table 92–3 Diet Guidelines for Immunosuppressed Patients

These diet guidelines restrict high-risk foods as *potential* sources of organisms known to cause infection in immunosuppressed persons. It is recommended that the following groups of patients use these diet guidelines while undergoing immunosuppressive therapy: oncology patients with low white blood cell counts (absolute neutrophil count $<1.0 \times 10^3$ μL) and hematopoietic stem cell transplant recipients for a minimum of 4 months after transplantation (autologous, allogeneic, syngeneic) and during subsequent immunosuppressive drug treatment of chronic complications (all transplant types).

Food Restrictions

- *Raw and undercooked* meat (including wild game), fish, shellfish, poultry, eggs, hot dogs, tofu, sausage, bacon
- Ready-to-eat deli and luncheon meats, salami, sausages, precooked ham (unless reheated until steaming)
- Cold smoked fish and lox, pickled fish
- *Unpasteurized* and raw milk, yogurt, cheese, or other dairy products
- Aged cheeses (e.g., bleu, Roquefort, Stilton)
- Refrigerated cheese-based salad dressings, (e.g., bleu cheese), not shelf stable
- Mexican-style cheeses (e.g., queso blanco fresco); uncooked soft cheeses, including brie, camembert, farmer's cheese, feta cheese; hot pepper–containing cheeses
- *Unwashed* raw vegetables and fruits and those with visible mold; all raw vegetable sprouts (e.g., alfalfa, mung bean)
- Commercial *unpasteurized* fruit and vegetable juices
- Raw and nonheat-treated honey
- Fermented miso products (e.g., miso soup), tempeh, maté tea
- Raw, uncooked brewer's yeast
- All moldy and outdated food products

or HSCT patient. The trend toward ambulatory treatment during periods of neutropenia has made obsolete past strict approaches to dietary precautions. Immunosuppressed patients with hematologic malignancies, wherever their care environment including the home, may best be counseled to follow a low-risk diet as summarized in Table 92–3. The goals of a low-risk diet are to minimize the introduction of high-risk foods and potential pathogenic organisms from food and to promote healthy food options as well as quality of life in patients who historically exhibit poor oral intake. Such diet guidelines ideally should be accompanied by education on food safety practices regardless of patient environment.

Tube Feedings

Published literature on tube feedings in patients with hematologic malignancies has increased, driven by the belief that enteral feeding better promotes gastrointestinal tract function and morphology, is less expensive, and has fewer complications than TPN. Enteral nutrition is not a benign therapy. In addition to the common sequelae of diarrhea and vomiting, nasoenteric tube feeding may result in nasopulmonary intubation, pulmonary aspiration, epistaxis, rhinorrhea, nasal alar pressure necrosis, sinusitis, otitis, laryngeal injuries, nasopharyngeal perforation, and intestinal perforation.[82] With percutaneous gastrostomies, infection, peritonitis, intestinal or gastric perforation or obstruction, and abdominal wall migration of tubes can occur.[83,84] Contaminated feeds are a concern, even with commercially sterile formulas, because of open feeding systems, inadequate hand washing, and prolonged hang times at room temperature, with the highest risk in patients receiving antacids, gastric acid inhibitors, H_2 antagonists, antibiotics, steroids, or immunosuppressive therapy.[85]

Not achieving goals of therapy and maintaining access appear to be the biggest obstacles with enteral feeds, leading to undernutrition or the need for supplementation with partial TPN. The inability to infuse adequate nutrition has led to TPN "rescue" rates ranging from 14% to 100% in patients undergoing HSCT as described in predominantly case series reports.[86–96] In studies that had lower TPN rescue rates, a more exclusive enteral approach resulted in significant weight loss,[92] decrease in body cell mass,[86] and an increase in the frequency of malnutrition in children.[93] In the latter study of children undergoing allogeneic (n = 42) or autologous (n = 11) HSCT, the percentage of patients less than 85% IBW pretransplant (6%) more than doubled to 14% at hospital discharge. Other reported complications of enteral feeds following HSCT include deficiencies of magnesium, phosphorus, zinc, and selenium,[87,93] delayed gastric emptying, and the inability to feed in the presence of large-volume diarrhea either after conditioning or with GVHD.[88,91,93]

Several groups have reported their experience with surgically or radiologically placed gastrostomies in pediatric cancer patients. Among a total of 152 patients in five reports,[89,90,97–99] 31% had a hematologic malignancy. In general, body weight goals were achieved and complications were considered minor. Infection at the tube site was the most common complication, ranging from 40% to 70% of patients in each series and occurring most frequently during periods of severe neutropenia.[88,91] Infection rates have ranged from 1.6 episodes per 1000 days[88] to 4.5 episodes per 1000 days,[92] generally lower than the 5 episodes per 1000 days reported for TPN.[100] Only two cases of peritonitis were reported in these series.[90] Gastric leakage was common, and bleeding at the tube site was less common. One patient required surgical exploration to control bleeding after the tube was accidentally dislodged.[98]

Despite the obstacles, preliminary data suggest that early enteral feeding following HSCT is associated with less GVHD and lower infection mortality at 100 days posttransplant.[96] Until randomized trials confirm positive clinical benefit and less risk with enteral feeds, patients with functional gastrointestinal tracts should be considered candidates for tube feedings (see Algorithm for Nutrition Assessment and Intervention). If the anticipated duration of enteral feeding is less than several months, nasoenteric placement is recommended. If a longer period of feeding is expected, a gastrostomy or jejunostomy placement should be considered. The most common practice for safe placement of a gastrostomy either surgically or endoscopically is with an absolute neutrophil count of 500 to 1000/mm^3 and platelet count greater than 50,000/mm^3. For nasal tubes, platelet counts in the range from 10,000 to 20,000/mm^3 probably are adequate. Because of the high rate of local infections and occasional serious infection, only patients who can manage scrupulous hygiene at home should be considered candidates for permanently placed tubes. Only commercially sterile products should be administered, preferably in a closed feeding system. In open systems, formula hang time should not exceed 4 hours. In patients with unexplained fever or diarrhea, the enteral feeding should be cultured. Whole-protein formulas may be tried in the absence of diarrhea; however, semielemental or elemental feeds may be better tolerated.

The view of the patient and family is an important aspect in choosing a mode of nutrition support. Scolapio et al.[101] reported that among hospitalized oncology patients, most preferred TPN to tube feeding, and among those who previously had tube feeding, 93% would choose TPN. Many of the studies described previously report that the multidisciplinary team, which includes the patient, must be committed to support enteral feeding as the primary mode of therapy. When patients refuse tube feeding, it is important to respect their decision.

Total Parenteral Nutrition

Infectious Complications

Most patients with hematologic malignancies have catheters placed for central venous access. In patients provided with TPN, an increase

in infection rates has been observed compared with patients with central catheters not on TPN.[44,100,102] In 310 children with cancer and central venous lines (including 244 patients with acute leukemia), administration of TPN was associated with a 2.4-fold increase in the risk of infection ($P < 0.001$), defined as documented catheter-related septicemia, catheter exit site, port or tunnel infection, or sepsis of unknown origin.[100] Among 104 adult and pediatric recipients of allogeneic marrow grafts, Weisdorf et al.[44] documented bacteremias in 72% of patients randomized to TPN versus 48% randomized to hydration therapy during the first posttransplantation month ($P < 0.001$). Lough et al.[102] demonstrated similar findings in a smaller study of 29 allogeneic and autologous transplant patients in which 57% of the patients randomized to TPN developed positive blood culture compared with less than 7% randomized to maintenance hydration for 14 days ($P < 0.05$). No deaths were attributed to the infectious complications described in these reports.

The association between TPN and infectious complications has been linked to a variety of etiologic factors, including excessive dextrose and total calorie infusion, inadequate glycemic control, lipids, insufficient glutamine, and lack of enteral stimulation of gut immunity. Elevated serum glucose levels impair neutrophil and complement function and predispose patients to *Candida* infections.[103,104] Interest in controlling blood sugar levels has grown since the publication of findings that intensive insulin therapy that maintained blood glucose level at or below 110 mg/dL reduced bloodstream infections by 46% and mortality by 34% in critically ill surgical patients.[105] In patients in a medical intensive care unit, however, insulin therapy was associated with greater mortality.[106] In the absence of data specific to patients with hematologic malignancies, strategies to control blood sugar in addition to insulin therapy involve matching the TPN prescription to metabolic needs (determined by indirect calorimetry or estimated by experienced clinician) and substitution of a greater proportion of dextrose energy with lipid.

Lipids have long been a concern in terms of infection risk. It appears that only large doses (up to 4 g/kg) or very fast infusion rates (100–200 mL/hour of 20% emulsions) cause any adverse effect on neutrophil, phagocyte, and reticuloendothelial system function.[107] No evidence indicates that lipids affect humoral immunity or the complement system, although their impact on T-cell lymphocyte activities is not clearly established.[108] In general, infusion of moderate amounts of lipids (25%–30% of total calories) over a minimum of 12 hours is considered prudent and safe practice. A large randomized trial failed to show an association between a moderate dose of lipid (25%–30% of total energy) versus a low dose (6%–8% of total energy to prevent essential fatty acid deficiency) and bacterial and fungal infections during the first hospitalization in patients undergoing HSCT.[109] Lipids containing medium-chain triglycerides are popular in Europe because they have improved bloodstream clearance and are purported to have immunologic benefits, but they are not approved for use in the United States. No clinical benefit was observed with use of a 50% medium-chain triglycerides/50% long-chain triglyceride mixture versus a 100% long-chain triglyceride–based lipid emulsion when provided as 30% of nonprotein calories in 36 patients undergoing HSCT, and fewer days of febrile neutropenia and antibiotic use were observed with the long-chain triglyceride group.[110]

The addition to TPN of pharmacologic doses of intravenous glutamine, a nonessential amino acid oxidized by stimulated lymphocytes and macrophages and intestinal mucosal cells, has been postulated to maintain the gut mucosal barrier during periods of gut rest and prevent infection associated with bacterial translocation, as has been described in animal models of methotrexate or radiation-induced intestinal injury.[111–113] In a Cochrane review of available trials in humans, TPN with glutamine was associated with a decrease in positive blood infections.[114] However, careful analysis of the data reveals that the Cochrane review counted colonization cultures from stool and other sites as blood infections. These studies are perhaps not as strong as suggested,[115,116] and other reviews caution against routine use until more studies demonstrate efficacy (Table 92–4).[91,117] In patients with AML undergoing chemotherapy, neutrophil recov-

ery was more rapid ($P = 0.052$) in patients receiving TPN supplemented with glycyl-glutamine dipeptide than in patients receiving nonsupplemented TPN; however, no difference in the occurrence of neutropenic fever, the recovery of $CD4^+$ or $CD8^+$ lymphocytes, or monocyte activation was observed.[118] Two clinical trials using alanyl-glutamine dipeptide described significantly more relapses in patients undergoing autologous HSCT randomized to glutamine supplementation.[119,120] Although infection data were not specifically reported, these data generate concern for the effect of glutamine supplementation on long-term survival in patients with hematologic malignancies. Glutamine enhances the synthesis of the intracellular antioxidant glutathione, such that pharmacologic doses given in the peritransplantation period could protect the tumor. To examine the key endpoints of relapse and survival, Powell-Tuck et al.[121] suggested that a glutamine study would require in excess of 160 patients, far more than any study published to date.

Efficacy

Do the benefits of weight maintenance and provision of macronutrient and micronutrient substrates outweigh the infectious risks of TPN? Expert reviews have generally concluded that TPN should not be a routine part of care for patients undergoing chemotherapy or radiation because of the complications associated with TPN. It is recommended only in patients with malnutrition and in children unable to grow and develop normally or with weight loss greater than 5% when oral or enteral feedings fail.[117,122–124] Many of the studies forming the basis of these reviews were performed several decades ago, when energy prescriptions were excessive. The efficacy of adjunctive TPN during therapy has not been adequately investigated in the current era, and the clinician must exercise judgment based on expected toxicities, ongoing surveillance of nutritional status, and ability of the family and team to overcome any barriers to alternatives, adequate volitional oral intake, or tube feeding.

Weisdorf et al.[44] reported TPN increased survival after HSCT. When data from other studies were combined in a meta-analysis, a nonsignificant trend for TPN to decrease mortality compared with intravenous hydration was noted.[114] The overall interpretation of the collective data is equivocal with a variety of published recommendations, including the routine use of TPN when prolonged gastrointestinal failure is expected,[114] more specifically in myeloablative conditioning regimens or refractory GVHD,[117] and finally leaving its use to the judgment of the responsible clinician.[123] As other supportive measures have altered the toxicity profile of HSCT and as reduced-intensity and nonmyeloablative conditioning regimens have been established as viable treatment options, the role of TPN and its substitution with enteral feedings requires reexamination.

Implementation and Formulations

Safe and appropriate TPN may be initiated and monitored in consultation with a hospital nutrition support service or with a nutrition support-certified or oncology dietitian. Table 92–5 outlines an approach to implementation of TPN.

Research on the pharmacologic applications of nutritional support has intensified with accumulating evidence on the modulation of physiologic, immune, and endocrine functions by nutrients. TPN solutions enriched with branched-chain amino acids have been investigated as a fuel source designed to blunt the muscle catabolism and obligatory nitrogen losses associated with HSCT, with mixed success.[36,125] Taurine, another nonessential amino acid not contained in adult TPN solutions, also may be deficient after HSCT.[126] Taurine conjugates hepatotoxic bile acids and improves bile acid secretory rates.[127] Glutamine-supplemented TPN was discussed earlier (see Infectious Complications above).

NUTRITION SUPPORT IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Standard supportive care during the first month after transplantation with myeloablative regimens has included TPN, and many patients with slow gastrointestinal healing or GVHD have relied on TPN to some degree for extended periods in the ambulatory setting. Among patients who are at increased risk for GVHD, early TPN intervention helps prevent significant weight loss before the onset of acute or chronic GVHD when metabolic needs appear higher and may be more difficult to achieve.[128] Less need for TPN has been described in patients whose source of stem cells was peripheral blood compared with bone marrow,[129] treatment occurred at home compared with the hospital setting,[130] or conditioning regimen was of reduced intensity.[131]

The decision to terminate TPN may depend on a constellation of clinical factors, including nutritional status, severity of gastrointestinal toxicities, ability to sustain or progress with oral intake, and the physiologic and psychological impact of TPN. In a large, double-blind trial that included adult and pediatric allogeneic and autologous transplant patients, Charuhas et al.[132] compared the effect of continuing TPN or changing to hydration fluids on the time to resumption of adequate oral intake in patients who were not able to eat 70% of estimated maintenance energy needs at the time of hospital discharge. Patients randomized to hydration fluids met oral calorie goals a median of 6 days sooner than did patients on TPN ($P = 0.049$) without evidence of adverse consequences, such as increased hospital readmissions or clinically significant weight loss, when TPN was withheld for up to 1 month. Discontinuation of TPN appears safe when patients are eating 30% of estimated energy needs at hospital discharge unless a clinical condition, such as malnutrition, malabsorption, or significant gastrointestinal toxicities, warrants otherwise.

Total energy and protein (oral plus TPN) support is recommended at stress levels (see Table 92–5) after myeloablative conditioning and during the neutropenic period based on the well-described losses of nitrogen and body cell mass.[36,44,133] Patients who still require TPN after engraftment and are otherwise without infectious problems or GVHD may be supported at maintenance needs. Use of specialty formulations was discussed earlier (see Implementation and Formulations above).

Few studies characterize micronutrient status after HSCT. Serum levels of the antioxidants vitamin E and β carotene in patients on TPN are markedly depressed, but the clinical significance is unknown.[134] Depleted antioxidant status is associated with increased free radical activity after transplantation[135,136]; however, no correlations have been established between these findings and the degree of toxicities observed with cytoreductive therapy nor the effect on tumor cell killing. In experimental models, vitamin C at therapeutic doses protects bone marrow cells.[137] In a prospective study, Bruemmer et al.[138] observed that pretransplantation intakes of more than 500 mg vitamin C and more than 400 mg vitamin E were associated with increased mortality or relapse in HSCT patients treated for acute leukemia. These studies suggest cautious use of antioxidants in the peritransplantation period (see box on Complementary and Alternative Nutritional Therapies).

Manganese toxicity that manifested as a Parkinson-like syndrome with brain magnetic resonance imaging suggestive of manganese accumulation has been described in a patient with cholestatic liver disease who received supplementation with manganese 0.3 mg/day during 2 months of TPN.[139] These investigators found elevated serum manganese levels in eight other transplant patients with liver disease, suggesting the need for manganese restriction in the presence of cholestasis.[139]

Oral and Gastrointestinal Complications

The degree of mucosal toxicity is regimen specific and has been characterized in four phases: an inflammatory phase caused by the

Table 92–5 Approach to TPN Management

1. Determine Macronutrient Requirements (Protein, Dextrose, Lipid, and Fluid)

Nutrient	Adult	Adolescent	Children
Protein (g/kg)			
Available as crystalline amino acids 4 kcal/g protein			
Maintenance	1.0	1.0	1.2 (7–10 years) 1.5 (4–6 years) 1.8 (1–3 years)
Stress	1.5–2.0	2.0	2.4 (7–10 years) 3.0 (1–6 years)
Energy (kcal/kg)			
Maintenance 1.2–1.3 × basal needs	25–30	40–50	50–60 (7–10 years) 60–70 (4–6 years) 70–85 (1–3 years)
Rehabilitation/stress 1.5 × basal needs	40–45	45–65	65–75 (7–10 years) 75–90 (4–6 years) 90–100 (1–3 years)
Carbohydrate (mg/kg/min)[a]	<5	<7–10	<10–15
Available as dextrose monohydrate 3.4 kcal/g			
Lipid	% of total kcal:	1–4 g/kg	
Available as long-chain triglycerides (soybean or safflower oil, egg yolk phospholipid) in 10% (1.1 kcal/mL) and 20% (2 kcal/mL) solutions; 30% (3 kcal/mL) solutions available for 3:1 compounding only; 20% and 30% lipids preferred because of lower phospholipid content	Minimum 6%–8% Maximum 60%		
Maintenance fluid	1500 mL/m^2	1500 mL/m^2	100 mL/kg up to 10 kg +50 mL/kg for each kg 11–20 kg +20 mL/kg for each kg 21–40 kg

2. Provide Electrolytes, Vitamins, and Trace Elements Daily, Altering Requirements Based on Organ Function

Electrolyte or Micronutrient	Adult	Adolescent	Children
Potassium[b] Available as phosphate, chloride, acetate salts. Increased needs with amphotericin, thiazide diuretics, foscarnet, steroids, anabolism, GI losses. Decreased needs with spironolactone, renal dysfunction, tumor lysis syndrome.		1–2 mEq/kg	2–4 mEq/kg
Sodium[b] Available as chloride, acetate, or phosphate salts. Increased needs with GI losses, syndrome of inappropriate antidiuretic hormone secretion. Decreased needs with pulmonary edema, congestive heart failure, venoocclusive disease.		1–2 mEq/kg	2–4 mEq/kg
Calcium Available as gluconate salt. Increased needs with foscarnet. Decreased need with renal dysfunction, tumor lysis syndrome, multiple myeloma, metastatic breast cancer.	10–15 mEq	10–30 mEq	1–2.5 mEq/kg
Phosphorus Available as potassium or sodium salts. Increased needs with diuretics, cyclophosphamide, cisplatinum, foscarnet, anabolism. Decreased needs with renal dysfunction.		10–40 mM	0.5–2 mM/kg
Magnesium Available as sulfate salt. Increased needs with amphotericin, cyclosporine, tacrolimus, cisplatinum, foscarnet, GI losses, anabolism. Decreased needs with renal dysfunction, tumor lysis syndrome.		16–32 mEq	0.25–0.5 mEq/kg
Zinc Available as chloride or sulfate salt in both single-entity and combination preparation. Increased needs with GI losses (5–10 mg/L of stool) wound healing.		2.5–5 mg	100 μg/kg[c]

Table 92–5 Approach to TPN Management—cont'd

Electrolyte or Micronutrient	Adult	Adolescent	Children
Copper Available as sulfate salt in both single-entity and combination preparation. Increased needs with GI losses. Decreased needs with cholestasis.		300–500 mg	20 μg/kg[c]
Manganese Available as chloride salt in both single-entity and combination preparation. Decreased needs with cholestasis.		60–150 μg	40–100 mcg
Chromium Available as chloride salt in both single-entity and combination preparation.	10–15 μg		5–15 mcg
Selenium Available as selenious acid in both single-entity and combination preparation.		30–60 μg	3 μg/kg (maximum 30 mcg)
Molybdenum Available as ammonium molybdate as single entity.	20–120 μg	5-10 mcg	0.25 μg/kg (maximum 5 mcg)
Vitamins Available as adult and pediatric multivitamin combinations of water- and fat-soluble vitamins or single infusions of cobalamin, folate, thiamine, pantothenic acid, pyridoxine, ascorbic acid, vitamin K. A D E B_1 (thiamine) B_2 (riboflavin) Niacin Folic acid B_5 (pyridoxine) Pantothenic acid Biotin[d] B_{12} (cobalamin) C K	3300 IU (990 RE) 200 IU (5 RE) 10 IU (6.7 RE) 6 mg 3.6 mg 40 mg 600 μg 4 mg 15 mg 60 μg 5 μg 200 mg 150 mg		2300 IU (690 RE) 400 IU (10 RE) 10.4 IU (7 RE) 1.2 mg 1.4 mg 17 mg 140 μg 1 mg 5 mg 20 μg 1 μg 80 mg 200 μg
Iron Available as iron dextran.	Contraindicated in patients with hematologic malignancies		
3. Monitor for Special Managements Issues			
Hyperglycemia	If preexisting diabetes or refractory to insulin, limit dextrose to <3 mg/kg/min in adults, <7–10 mg/kg/min in children; increase lipids to 50% total energy		
Hypertriglyceridemia	>500 mg/dL: Limit lipids to 4%–8% total energy to provide essential fatty acids >1000 mg/dL: discontinue lipids to decrease risk of pancreatitis		
Fluid overload	Provide concentrated dextrose, lipid, amino acid solutions to maximize nutrient support		
Altered liver function	Avoid overfeeding, provide balance of lipids and dextrose, provide some enteral feeds		
4. Monitor Ability to Eat, Transition to Tube Feeding, or Both, As Soon As Feasible			

[a]To calculate carbohydrate dose, divide total mg dextrose per day by 1440 min/day/kg weight. For example, 1700 mL 25% dextrose in a 70-kg patient = 425 g dextrose × 1000 mg/g ± 1440 min/day/70 kg = 4.2 mg/kg/min dextrose.

[b]After determining phosphate needs, remainder provided primarily as chloride salt (except in presence of metabolic acidosis) to meet chloride needs.

[c]Up to 5 years; older than 5 years, use lower limit of guidelines for adolescent and adult.

[d]Currently available multivitamin combinations do not contain biotin.

GI, gastrointestinal; IU, international unit; RE, retinol equivalent; TPN, total parenteral nutrition.

Complementary and Alternative Nutritional Therapies

Many patients elect to use complementary and alternative therapies, the most common of which include supplementation with vitamins and minerals. When cancer is diagnosed, significant lifestyle alterations often occur, and "wellness" recommendations are embraced. Diets and supplements may be used as an adjunct to primary treatment, to mitigate the side effects of the therapy, or to reduce the risk for disease recurrence. Above all else, complementary therapies appear to give patients hope.

It is a challenge for the oncologist to determine the safety and efficacy of "pharmacologic" doses of supplements when combined with conventional therapies. Antioxidants present a special conundrum because competing hypotheses rage. Experimental models support the idea that antioxidants may improve the efficacy of cancer treatment by increasing tumor response and decreasing toxic effects on normal cells and that antioxidants may decrease the efficacy of treatment by protecting cancer cells. A member of the oncology team must stay abreast of the results of ongoing clinical trials integrating alternative with conventional treatments. By providing patients with the latest evidence-based information and showing respect for their beliefs and choices, the clinician can help guide the level of alternative therapy that is reasonable. When a patient elects to use an alternative therapy, adverse effects or interactions with conventional treatments must be monitored.

We advise our patients to avoid the use of antioxidants in excess of or, for some nutrients, below the tolerable upper limits of the dietary reference intakes during treatment with irradiation or chemotherapy that relies on free radicals and reactive oxygen species as mediators of cytotoxicity: anthracyclines, bleomycin, dactinomycin, epipodophyllotoxins (i.e., topoisomerase II inhibitors such as etoposide or teniposide), platinum compounds, alkylating agents, and agents without established molecular pharmacology (e.g., plicamycin, tamoxifen, aromatase). These agents, as do isoflavonoids and many herbs (e.g., garlic, ginger, *gingko biloba*, ginseng), may further diminish platelet function and aggregation and must be used cautiously by patients with thrombocytopenia. To avoid excess intake, patients should not take an oral multivitamin or mineral supplement while receiving intravenous vitamins and minerals in parenteral nutrition.

Our Practice During High-Dose Chemotherapy or Irradiation.

Antioxidant	*Age*	*Dietary Intake (RDA or AI)*	*Reference Intake (RDA or AI)*	*Tolerable Upper Limit*
Vitamin A	Birth–6 months	400 µg[a]	600 µg	Limit intake to tolerable upper limits
	7–12 months	500 µg		
	1–3 years	300 µg

release of cytokines during conditioning therapy; an epithelial phase, when cells cease dividing and die; an ulcerative phase when microbes and endotoxins translocate into the bloodstream; and a healing phase, which can be prolonged with deep lesions and is more complex in the gut than in the mouth.[140] The severity of oral mucositis is increased in patients treated with total body irradiation[141] or who receive methotrexate as prophylaxis against GVHD.[142] Patients have identified the associated mouth pain as the single most debilitating side effect of HSCT.[143]

Characterizing the severity of lower gut toxicity is more difficult. Permeability studies and absorption studies are more objective approaches than are clinical symptoms. Increased gut permeability appears to precede clinical symptoms[144]; likewise, normal digestion and absorption appear impaired for prolonged periods, even in the absence of GVHD, as evidenced by abnormal d-xylose and Schilling test results at 4 months after transplantation,[145–147] suggesting a risk for subclinical nutrient deficiencies. However, with reduced-intensity regimens that included chemotherapy with fludarabine and antithymocyte globulin with busulfan or cyclophosphamide, intestinal permeability remained intact.[148]

The symptoms associated with mucosal injury (nausea, vomiting, diarrhea, oropharyngeal mucositis) inhibit oral intake for 1 month or longer (Fig. 92–1). Nutrition interventions have included ice chips or ice pops[149–151] and oral glutamine (see Table 92–4).[151–157] Six randomized studies of glutamine supplementation included patient groups heterogeneous for transplant type, diagnosis, and conditioning therapy, making interpretation of endpoints problematic. One study demonstrated oral glutamine supplementation reduced mucositis in a subset of patients receiving allografts, whereas patients receiving autografts who were provided glutamine in the same study experienced worse mucositis.[153]

In patients who received glutamine-enriched TPN solutions, only one study showed a decrease in the daily mucositis score. Thornley et al.[158] demonstrated reduced prevalence and severity of mucositis ($P = 0.008$ and $P = 0.004$, respectively) using a multiagent strategy consisting of ursodeoxycholic acid, folinic acid, and vitamin E in a pilot study of 37 pediatric transplant recipients.

Organ Complications

Sinusoidal Obstructive Syndrome (Venoocclusive Disease)

Insidious weight gain typically is the first sign of sinusoidal obstructive syndrome or hepatic venoocclusive disease (VOD). If it progresses, more severe symptoms of liver failure occur, including encephalopathy, coagulopathy, and renal failure,[159] all of which complicate nutrition management. Because fluids are limited to minimize edema and ascites, intravascular volume depletion and deterioration of renal function may occur. Conversely, repletion of the intravascular space often results in pulmonary edema and massive ascites. Use of continuous renal replacement therapy is helpful for removing fluid while providing nutrition support.

Determination of daily weights and frequent serum bilirubin levels in the immediate posttransplantation period facilitates early detection of disease in patients at increased risk. Nomograms for six time intervals between 1 day before transplantation and 16 days after transplantation that estimate the probability of developing severe VOD using total serum bilirubin and percent weight gain above baseline have been reported.[160] In patients with weight gain and decreased urinary sodium excretion, restriction of total fluid and sodium may decelerate fluid accumulation. Concentrated TPN solutions are indicated if renal perfusion is adequate. The capacity to eliminate intravenous lipids from the bloodstream should be monitored in patients with severe VOD. If encephalopathy develops, the benefits of HepatAmine (an amino acid solution with lower aromatic amino acids, tryptophan, and methionine content) have not been established.[161] If hyperbilirubinemia persists for more than 1 week, the biliary-excreted trace elements copper and manganese should be removed from TPN. Measurement of energy needs with indirect calorimetry, if available, may avert additive hepatotoxicity associated with overfeeding as well as the risks of debilitation with prolonged underfeeding.

Contraindicated Herbals During Therapy

- Alfalfa
- Borage
- Chaparral
- Chinese herbs
- Coltsfoot
- Comfrey
- DHEA
- Dieter's tea (including senna, aloa, rhubarb root, buckthorn, cascara, castor oil)
- Ephedra or ma huang
- Groundsel or life root
- Heliotrope or valerian
- Kava kava
- Laetrile (apricot pits)
- Licorice root
- Lobelia
- L-Tryptophan
- Maté tea
- Pau d' arco
- Pennyroyal
- Sassafras
- St. John's wort
- Yohimbe and yohimbine

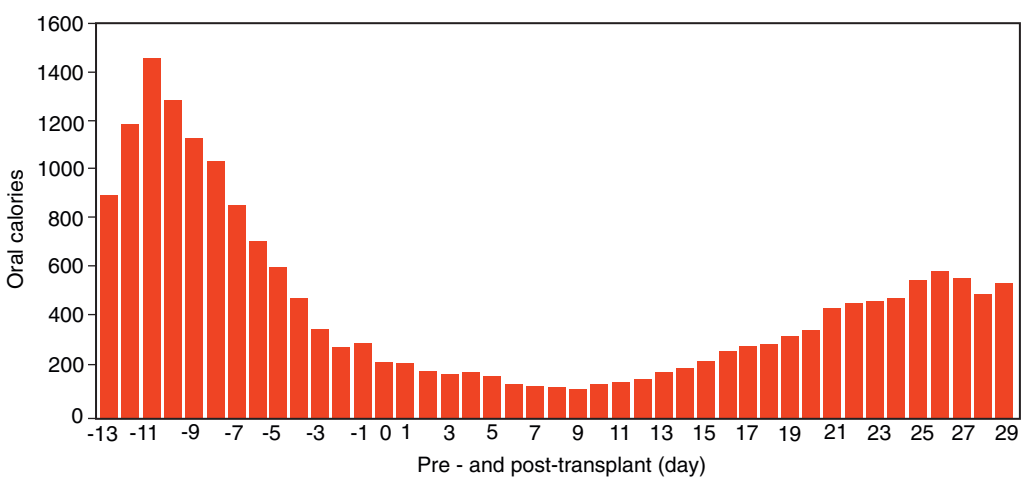

Figure 92–1 Average daily oral calorie intake of adult marrow transplant recipients undergoing myeloablative conditioning (n = 295).

Several case studies have described therapeutic responses to glutamine and vitamin E for VOD.[158,162,163] One prospective study described improvement in markers of hepatic function, protein C, and albumin when patients were provided glutamine compared with an isonitrogenous mixture of amino acids in TPN, although no cases of VOD occurred in either group.[164] Whether nutritional therapies play an adjunctive role in VOD management is not firmly established.

Renal Disease

Renal insufficiency typically is multifactorial and associated with total body irradiation, chemotherapy, drug toxicities, sepsis, and especially liver toxicity.[165] Renal damage manifested as doubling of the baseline creatinine level occurs in up to 75% of allograft patients.[166] An elevated blood urea nitrogen level, however, may be partially caused by nonrenal factors, including increased protein intake, gastrointestinal bleeding, or hypercatabolism. Prolonged protein restriction to minimize a rise of blood urea nitrogen should be avoided to ensure that adequate calorie and protein support are provided.

Maintaining intravascular volume and correcting electrolyte imbalances are essential in the management of renal complications. The large fluid load necessitated by TPN is problematic in the oliguric patient and if continuous renal replacement therapy is contraindicated requires daily manipulation, depending on urine output and clinical signs of fluid overload. Hypervolemic hyponatremia is treated with water restriction to prevent congestive heart failure. General indications for hemodialysis or continuous renal replacement therapy after HSCT are extracellular fluid volume expansion, acidemia, hyperkalemia, and azotemia. The primary goal of nutritional therapy for acute renal failure is to minimize uremia toxicity and other metabolic derangements and yet prevent malnutrition. Protein levels typically are restricted before dialysis by the TPN volume tolerated. During dialysis, protein intake should meet stress needs as defined in Table 92–5. Serum triglyceride levels must be monitored weekly because clearance of intravenous lipids may be reduced.[167] Water-soluble vitamins that are lost in the dialysate and the continuous renal replacement therapy circuit should be provided while standard intravenous multivitamins are decreased in an effort to prevent excessive serum vitamin A levels.[168]

Pulmonary Disease

Pulmonary edema due to increased capillary permeability after cytoreduction therapy may be compounded by iatrogenic fluid overload. Management includes reducing total sodium from oral intake, TPN, and medications, and using concentrated TPN solutions. During ventilator dependency, adequate TPN or tube feeding should be provided to preserve muscle reserves.

Graft-Versus-Host Disease

Acute Graft-Versus-Host Disease

Whether lipids favorably modulate GVHD by suppressing production of inflammatory cytokines through prostaglandin E_2-mediated pathways has interested several investigators. In a study of lipids and infection outcome, the secondary outcome of grade II to IV GVHD incidence was not different in patients receiving 25% to 30% or 6% to 8% of total calories as lipids, occurring in 77% and 75% of patients, respectively.[109] Time to acute GVHD (before 80 days posttransplantation), censored for death, relapse, and treatment failure, also did not differ. Other investigators compared very high doses of lipid (80% of total energy) to lipid-free TPN in 66 allograft recipients. Although incidence and median day of onset were similar between the groups, lethality of GVHD was decreased in the lipid group.[169] In a small study of oral eicosapentaenoic acid supplemented at 1.8 g/day from day 21 to day 180 posttransplantation, three patients who received eicosapentaenoic acid (n = 7) experienced grade II to III GVHD and all survived, whereas in the control group (n = 9), six experienced grade II to IV GVHD, and five died.[170]

In the most severe form of acute intestinal GVHD, voluminous diarrhea is a prominent manifestation, with the volume corresponding to the extent of mucosal damage. The diarrheal fluid is green and watery, with ropy strands of mucus, protein, and cellular debris, and often contains occult blood. Protein content is high, as evidenced by falling plasma protein levels or by measurements of fecal α_1 antitrypsin in fecal water.[171] Associated symptoms include anorexia, nausea, vomiting, and crampy abdominal pain, which may be related to food ingestion or may occur spontaneously because of the secretory nature of the diarrhea. Other causes of diarrhea should always be ruled out because enteric pathogens and late-onset toxicities due to the conditioning regimen may occur with signs and symptoms similar to acute intestinal GVHD.[172] Biopsy findings range from necrosis of individual intestinal crypt cells to total mucosal denudation.[173,174] Fluid and electrolyte management may be problematic in patients with large-volume diarrhea (>2.5–3.0 L/day). In severe disease, the patient initially is dependent on TPN because complete bowel rest helps decrease diarrhea. Additional daily zinc is recommended at 10 mg/L of stool volume in excess of 1 L. When diarrheal volumes diminish and abdominal pain subsides, isotonic oral liquid supplements are introduced to stimulate intestinal regeneration and assess absorption. Guidelines for the introduction of oral intake have been empirically derived using a five-phase regimen that emphasizes foods low in lactose, fat, fiber, and total acidity.[175] Antidiarrheal agents are generally contraindicated because of the risk for ileus and abdominal distension. Use of octreotide acetate has been reported to control diarrhea but may lower serum cyclosporine levels.[176–178] Ippoliti et al.[179] advocate administration of octreotide early in the course of GVHD as soon as onset of diarrhea is noted and discontinuation as soon as diarrhea resolves to prevent constipation and development of an ileus. If no benefit is seen in 4 to 7 days, then octreotide probably will not help.

Weisdorf et al.[180] described a syndrome of upper intestinal GVHD presenting clinically as anorexia, dyspepsia, food intolerance, nausea, and vomiting. Prolonged nausea and vomiting beyond day 20 posttransplantation and failure to progress with oral dietary intake constitute indications for endoscopic evaluation to establish a diagnosis of stomach or upper intestinal GVHD.[181] Upper gut GVHD is very responsive to steroids, and hyperphagia supplants anorexia.

The oral mucosa may be involved in acute GVHD. Oral examination reveals erythema and lichenoid changes that cannot be differentiated from conditioning-induced mucositis until approximately 3 weeks posttransplantation.[182,183] It may evolve into a chronic form, and patients may develop taste fatigue with prolonged use of oral supplements and bland foods, experiencing significant weight loss unless supported with TPN or tube feeding.

Acute liver GVHD is characterized by abnormal liver function tests, jaundice, and mild hepatomegaly. Hepatic synthesis and enterohepatic circulation of bile salts may be diminished or inhibited, resulting in steatorrhea and the need for fat restriction. In severe disease, encephalopathy and ascites ensue, with nutritional management similar to VOD.

Adequate nutrition is a vital adjunct to immunosuppressive drugs for treatment of acute GVHD. Energy needs during acute GVHD have been predicted at 45 to 50 kcal/kg in adults and 65 kcal/kg in children.[129] Drug therapy for GVHD often has a profound effect on nutritional status and may require nutritional intervention as summarized in Table 92–6.

Chronic Graft-Versus-Host-Disease

Clinical manifestations of chronic GVHD that may adversely affect nutritional status include anorexia, mucositis, xerostomia, dysphagia, esophageal stricture, cholestatic liver disease, diarrhea or steatorrhea,

Table 92–6 Nutritional Consequences of Graft-Versus-Host Disease Immunosuppression

Immunosuppressive Agent	Nutritional Effects	Recommended Interventions
Corticosteroids	Muscle wasting	Early intervention with physical therapy if exercise level low; high protein intake (twice normal requirements)
	Sodium and fluid retention	Low-sodium diet if edema limits mobility
	Hyperphagia and weight gain	Regular exercise, dietary counseling
	Hyperglycemia	Insulin therapy, blood glucose monitoring, dietary counseling to limit overfeeding and excessive total carbohydrate intake; oral agents have not been shown to be safe or efficacious
	Hyperlipidemia	Lipid-lowering agent if patient with history of pancreatitis or very high levels, reassess plasma lipids several months after discontinuation of drug to assure return to baseline level
	Bone loss, fracture risk	Vitamin D: 400–800 IU/day
Cyclosporine, tacrolimus	Renal insufficiency	Maintenance fluid or more via oral ± intravenous; routine monitoring serum creatinine
	Magnesium wasting	Magnesium replacement via oral ± intravenous route; oral dosing often limited by diarrhea (protein complex forms may be better tolerated); routine monitoring serum magnesium level
	Hyperglycemia	May exacerbate hyperglycemia observed with corticosteroids (see corticosteroids)
	Hyperlipidemia	Usually not to same degree as with corticosteroids (see corticosteroids)
	Hyponatremia	Limit free water, encourage fluid with solute
Mycophenolate mofetil	Diarrhea, vomiting	Rule out other causes of diarrhea; otherwise antiemetic therapy and adequate hydration status
Sirolimus	Hyperlipidemia	Monitor serum lipids frequently; if on total parenteral nutrition, provide lipid only for essential fatty acids; lipid-lowering agent if very high levels

Table 92–7 Nutrition-Related Problems 1 Year After Bone Marrow Grafting

	Chronic GVHD Status[a]		
Sign or Symptom	None (%)	Limited (%)	Extensive (%)
Weight loss	27	19	33
Weight gain	14	28	34
Oral sensitivity	7	14	41
Xerostomia	10	11	27
Stomatitis	3	3	14
Anorexia	3	6	13

Contractures	0	0	2

GVHD, graft-versus-host disease.

[a]Among 192 allogeneic transplant recipients, the percentage of total number of patients is shown.

Adapted from Lenssen P, Sherry ME, Cheney CL, et al: Prevalence of nutrition-related problems among long-term survivors of allogeneic marrow transplantation. J Am Diet Assoc 90:835, 1990.

dyspnea and limited exercise tolerance, restricted joint mobility, and generalized wasting (Table 92–7).[184] Weight loss can be profound, in one review as high as 34% of the pretransplantation weight. Among 93 patients evaluated a median of 2.4 years posttransplantation, 29% had moderate malnutrition (BMI 18.5–21.9 kg/m^2) and 14% had severe malnutrition (BMI < 18.5 kg/m^2), with patients with active chronic GVHD having significantly lower BMI than patients with inactive disease.[185] Only dysphagia and abdominal pain resulted in an increased likelihood of weight loss, whereas oral sensitivity, nausea, and anorexia did not, leading the authors to hypothesize a cachexia-like syndrome in chronic GVHD. The resting energy expenditure was measured in 13 patients with stable chronic GVHD who had suffered a maximum weight loss of 22% after transplantation and regained 15% of body weight at the time of measurement at day 518 ± 261 posttransplantation. All patients had chronic skin disease and sicca syndrome involving the eyes and salivary glands, and half also had involvement of the liver (n = 4) or lung (n = 3). Energy expenditure and fat oxidation were found to be significantly higher and carbohydrate oxidation significantly lower than in controls matched for sex, age, weight, and height.[186] Studies of weight loss are complicated by the finding of weight gain in many patients because of steroids and concomitant fluid and fat gain, which may explain why weight loss has not been a prognostic indicator.[187]

Oral disease is common, with frank stomatitis occurring in a significant portion of patients. Pain, burning, and loss of taste have been described as prodromes of chronic GVHD.[188] In severe cases, only bland liquids and soft foods may be tolerated. Complete nutritional supplements and nutrient-dense carbohydrate polymers are important dietary adjuncts in patients experiencing weight loss. If significant weight loss occurs, gastrostomy feeding may be indicated.

Esophageal webbing or stricture can result in severe swallowing difficulties.[189] Typical symptoms include pain and difficulty in swallowing food and pills as well as retrosternal pain caused by esophageal thinning. Webs and strictures are managed with periodic dilation. Diet tolerance varies widely and may be limited to liquids in patients with extensive webbing. Gastrostomy tubes may be indicated when the passage of food is obstructed.

Intestinal involvement presents with diarrhea, nausea and vomiting, and often complete dependence on enteral nutrition or TPN. In one series the incidence was 7.3% of all patients transplanted.[190] Bacterial overgrowth, medications, chronic liver GVHD, and pancreatic insufficiency may contribute to diarrhea or steatorrhea. When weight loss occurs in chronic liver GVHD, the relative contributions of deficient energy intake and malabsorption must be determined. Patients often are anorectic, yet others have good dietary intake but significant stool nutrient losses. A malabsorption workup may include quantitative stool fat collection, Sudan black stain for stool fat, stool for fecal elastase, serum carotene, serum xylose or Schilling test, or serum 25-hydroxyvitamin D. Vitamin D status is of special concern because inadequate hepatic and renal hydroxylation to the active metabolite may occur. In patients with malabsorption, moderate fat restriction, calorie supplementation with medium-chain triglycerides, and mineral and water miscible fat-soluble vitamin supplementation may be necessary interim measures. Some patients respond to pancreatic enzymes. In patients who fail to gain weight, a gastrostomy feeding should be considered given the known slow resolution of the disease.

Vitamin D and calcium status are jeopardized by use of sun-blocking agents to diminish photoactivation of skin GVHD and the almost universal use of steroids for treatment. Loss of vertebral bone mass at 1 year posttransplantation was described by Stern et al.[191] in a small series of patients treated with cyclosporine and corticosteroids. In another series of 39 patients followed for a median of 30 months (range 5–64 months), the allograft patients (n = 29) lost 11.7% of femoral neck and 3.9% of spinal bone mineral density compared with a nonsignificant decrease of 1.1% and an increase of 1.5% in the autograft patients (n = 10). Bone loss correlated best with the cumulative steroid dose, with spinal bone loss of 4% per 10 g of prednisolone and femoral neck bone at 9% per 10 g of prednisolone.[192] Several studies have described the prevalence of bone loss in children with chronic GVHD exceeding 50%.[193,194] The rate of bone loss appears to be highest in the first 6 months after HSCT,[195,196] and early intervention with calcium and vitamin D and aggressive ambulation is encouraged.

With the multiple problems that can interfere with a balanced nutrient intake, the need to avoid sun exposure, and drug-nutrient deficiencies (e.g., folic acid, trimethoprim-sulfasoxazole), a multivitamin and mineral supplement is recommended for all patients. In most cases, iron-free formulas are recommended, unless the patient has documented iron-deficiency anemia, because iron overload is a frequent finding in long-term survivors.[197,198] Iron-free or low-iron infant formulas are also recommend for young children. When skin disease is treated with psoralen plus ultraviolet A radiation, supplemental β carotene, which protects against ultraviolet radiation,[199] should be discouraged.

Children with extensive chronic GVHD represent a special risk group. Growth failure and studies of growth hormone efficacy have been reviewed by Brennan and Shalet,[200] who concluded that the data on catchup growth after steroid therapy were inconsistent and that other factors such as GVHD itself might play a role. The role of growth hormone is not fully delineated because of the lack of randomized controlled studies with documentation of final height for predicting the gain in stature. Although the contribution of poor nutrient intake as a factor in growth failure after HSCT has not been adequately investigated, children displaying weight loss, inappropriate weight gain, or growth failure deserve thorough nutritional evaluation to rule out treatable dietary deficiencies. Height should be monitored every 3 months posttransplantation for the purpose of early detection of growth failure.

Children may experience long-term metabolic alterations following HSCT that may adversely affect nutritional status.[201,202] Taskinen et al.[201] reported a 39% incidence of combined hyperinsulinemia and hypertriglyceridemia in pediatric transplant patients compared to 8% in leukemia patients and none in healthy controls ($P = 0.0015$) as a late effect following HSCT. An increased incidence of diabetes mellitus has been reported in long-term survivors of pediatric HSCT.[201,203] In a retrospective review of more than 700 transplant survivors, the prevalence of diabetes mellitus type 1 was 0.52%, or three times higher than the prevalence in the general U.S. population, whereas the prevalence of diabetes mellitus type 2 was 9% among leukemia survivors and 2% among aplastic anemia survivors, both higher than expected.[203] Patients should be educated and monitored for the development of diabetes, with appropriate therapy instituted.

CHAPTER 93

PSYCHOSOCIAL ASPECTS OF HEMATOLOGIC DISORDERS

Ruth McCorkle and Elizabeth Cooke

Major changes in the understanding and treatment of cancer have led to a wider range of treatment options and increasing length of survival for people diagnosed with hematologic cancers. Regardless of the advances and concomitant survival increase, a diagnosis of a hematologic malignancy can have great impact on the psychosocial aspects of the lives of cancer survivors and their families because diseases of the blood are widely perceived as serious and often fatal. Psychological, social, economic, cognitive, and existential stressors are common experiences for cancer survivors. Despite the increasing focus of long-term survivorship issues within the past 20 years by providers, policymakers, and the general public, ongoing progress must continue to provide interventions and services to meet the psychosocial aspects of quality cancer care for patients and their families.[1,2] Psychosocial interventions and services are those that enable patients, their families, and health care providers to optimize health care and health care outcomes by managing the psychological, social, and behavioral aspects of cancer and its consequences.

Psychosocial aspects associated with cancer may be intensified in patients with hematologic malignancies because of their association with an uncertain prognosis, a prolonged treatment course often involving numerous hospitalizations, and the systemic nature of the diseases.[3] Discomfort from painful medical procedures, body image disturbances because of hair loss, central line catheters, sexual dysfunction related to fatigue and fertility, and role and relationship disruptions resulting from lengthy hospitalizations and fear of premature death are just a sampling of the issues that confront patients with hematologic malignancies, highlighting the necessity for monitoring of and attention to the psychosocial needs that accompany all aspects of these diseases. Involvement with a complicated and fragmented health care delivery system, the need for episodic and aggressive treatment, remissions and exacerbation of acute and uncomfortable symptoms, family separation, financial burden, functional limitations, and role disruptions are a few of the issues that characterize the life of patients with hematologic malignancies, not to mention the threat to life imposed by these diagnoses. Many nonmalignant hematologic conditions are associated with chronic morbidity, shortened survival, and many of the issues just listed.

This chapter provides information on factors that affect psychosocial adjustment among patients with hematologic malignancies, the wide range of psychological responses that are possible throughout the illness trajectory, and the efficacy of various modes of psychosocial interventions and services to minimize distress and promote adaptation. Some practical guidelines regarding patient management and identification of patients who may require formal psychiatric consultation are offered.

ACCOMPANYING TRENDS IN PSYCHOSOCIAL ISSUES

Within the last 20 years has been a shift to include quality-of-life components in the care of cancer survivors. This shift is due, in part, to the birth of the survivorship moment. Since the inception of the National Coalition for Cancer Survivorship in 1985, there has been increasing growth in legislation, education, and advocacy of cancer survivors. This movement has continued with new definitions of the word "survivor" by the Center for Disease Control, Lance Armstrong Foundation, National Cancer Institute, and the Institute of Medicine report released in 2006.[4] Patients with a hematologic cancer experience a wide range of psychosocial issues as cancer survivors. For example, one study with more than 600 hematopoietic stem cell transplantation (HSCT) survivors found that, relative to healthy controls, survivors reported poorer physical, psychological, and social functioning with changes that were long-lasting and had a profound impact over several years.[5]

CLINICAL COURSE OF HEMATOLOGIC MALIGNANCIES

In contrast to many solid tumor cancers, treatment of hematologic malignancies often involves numerous and lengthy hospitalizations and ongoing outpatient monitoring of the patient's condition. The clinical course of cancer typically follows one of several possible trajectories (Fig. 93–1).[6] A number of patients respond to the curative attempt with long-term remission, remain well, and, after a period, are considered cured. Some patients have a positive response to a curative attempt but then relapse. Other patients begin treatment with a hope for cure but do not respond and progressively decline. In some patients, the disease is too far advanced when diagnosed, and they experience a rapid progression of their disease.[6]

This model is useful in understanding the medical consequences of the cancer and its treatment, but a number of other models have been developed to classify the cancer course from a patient management perspective. One model is the cancer control continuum, which describes the stages of prevention, early detection, diagnosis, treatment, survivorship, and end-of-life care.[7] Another model from the patient's perspective is Mullan's three seasons of survival: acute, extended, and permanent.[8] Mullan's conceptualization was expanded by Dow[9] to include the following: surviving the diagnosis and treatment, extended survival, surviving with uncertainty, and permanent survival. Dow's model[9] combined with the cancer control continuum provides a template for this chapter and the cancer experience for patients diagnosed with hematologic cancers.

Acute Season: Time of Diagnosis

Being diagnosed with a hematologic malignancy can be devastating. The time of diagnosis has been described by a cancer survivor as a lightening bolt through a stop sign.[10] It is a time of intense stress and likened to a personal disaster in the patient's and family's life.[9] Often these patients describe vague symptoms such as fatigue for weeks, even months, or they are treated in urgent care centers for bronchitis or other infections only to be diagnosed with an unexpected catastrophic illness such as leukemia. The period from time of diagnosis through initiation of treatment is characterized by sometimes fast-paced medical evaluation and treatment, the development of new relationships with unfamiliar medical personnel, and the need to integrate a barrage of information that is at best frightening and confusing. Within the context of this anxiety-provoking situation, a decision must be made regarding treatment. As one man aptly stated, "a decision upon which my very life or death might be based." This statement illustrates the tremendous responsibility, concern, and isolation that many people experience during this period.[11]

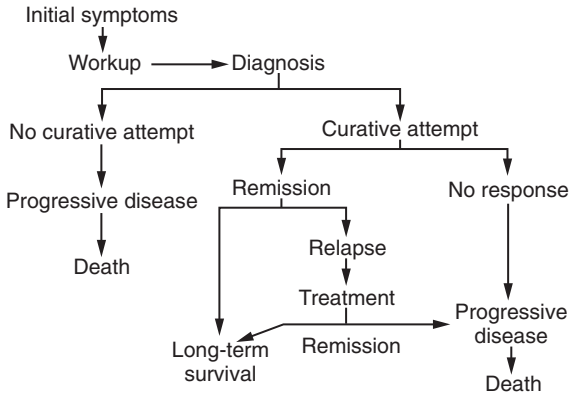

Figure 93–1 Clinical course of a patient with a hematologic malignancy. (Adapted from Lesko LM: Hematopoietic dyscrasias. In Holland JC [ed.]: Psychooncology. New York, Oxford University Press, 1998, p 408.)

Factors that May Predict Poor Coping in Patients with Cancer

- Past psychiatric history
- Limited social support
- Alcohol or drug abuse
- Recent losses
- Advanced disease
- Uncontrolled symptoms
- Pessimistic outlook on life
- Multiple obligations
- Avoidance coping
- Lower functional status
- Smoking cessation
- Higher regimen-related toxicity

Initial response to a diagnosis may be profoundly influenced by a person's prior association with cancer.[6] Those with memories of close relatives with cancer often demonstrate heightened distress, particularly if the relative died or had negative treatment experiences. During the diagnostic and early treatment periods, patients may search for explanations or causes for their cancer and may struggle to give personal meaning to their experience.[12] Because many clinicians are guarded about disclosing information until a firm diagnosis is established, patients may develop highly personal explanations that can be inaccurate and provoke intensely negative emotions. Ongoing involvement and accurate and repeated information from key health care providers help to minimize patients' uncertainty and the development of maladaptive coping strategies based on erroneous beliefs.

Because the time of diagnosis usually is a time of crisis, care must be given to assess multiple areas of the patient's psychosocial status. Weissman and Worden[13] described the first 100 days after diagnosis as the period of an "existential plight." They documented that patient concerns initially focused on existential issues of life and death more than on concerns related to health, work, finances, religion, self, or relationships with family and friends. Although extreme and sustained psychological reactions as the first response to a cancer diagnosis are unusual, careful assessment of the nature of the patient's reaction remains important. Initial reactions often are predictive of later adaptation.[14,15] Early assessment by clinicians can help to identify people who are at risk for later adjustment problems and in greatest need of ongoing psychosocial support.[16–20] (see box on Factors That May Predict Poor Coping in Patients with Cancer). Major depression and depressive symptoms occur frequently in patients with cancer, with a prevalence rate of 10% to 25%.[21,22] Both anxiety and depression are easy to assess in the patient and family, and timely referral for assistance during this period may lay a foundation of adequate coping throughout the cancer trajectory. During this time, many providers are conveying large amounts of information to patients and family members. It is not always easy for patients to differentiate the importance of each communication and prioritize their problem-solving behaviors. Consequently, providers must repeat information at several contacts and inquire about the patient's and families' understanding of facts and treatment options. Often patients and families describe that they are in a state of numbness and that information is not really understood, comprehended, or processed.

Although the literature substantiates the devastating psychological impact of a cancer diagnosis, it is also well documented that many patients cope effectively. Positive coping strategies, such as taking action and finding favorable characteristics in the situation, have been reported as effective. Maintaining optimism[23] and having an active determination to recover have been associated with positive adjustment. Contrary to the beliefs of many clinicians, denial has also been found to assist patients in coping effectively with a diagnosis of cancer, unless used to an excessive degree. With the firm establishment of the cancer diagnosis, planning for treatment begins. If patients have been given a clear explanation of their condition while encouraged to maintain hope, the initial reaction of shock, fear, and desperation can give way to a sense of optimism. Health care providers have an important role in monitoring and possibly mediating psychosocial adjustment. Keeping patients informed and actively involved in their care and being aware of the unique meaning that people may associate with a diagnosis of cancer are vital. Patients who have a pervasive and unyielding negative affect that persists long after the crisis of diagnosis may require ongoing psychosocial monitoring and referral for services and supportive interventions throughout their treatment and disease course.[24]

Acute Phase: The Treatment Decision

Psychosocial factors are critical parameters in considering which treatment is best for a particular patient.[25] The development of a treatment plan should include information about all aspects of medical/surgical treatments as well as what is known about the psychosocial sequelae. Often, patients react to a diagnosis of cancer with feelings of fear and helplessness. Patients look to the primary oncologist for a curative treatment that also can preserve their quality of life. Patients may feel vulnerable and believe that complete reliance on the oncologist is essential. Combating feelings of helplessness during this period can help patients alleviate painful anxiety. This is best done by a member of the health care team who has established a treatment alliance with the patient. The health care provider must make the patient feel like a partner in everything that takes place. This is especially true regarding decisions about treatment options. Giving information to patients and families often alleviates anxiety and uncertainty because patients feel more in control.

Active treatment of cancer usually initiates another acute phase of the cancer experience. It can occur while a patient is receiving treatment or as a complication of treatment. An important standard of clinical practice, based on extensive research, is to provide patients with information that will prepare them on what to expect during their treatment. Research by Johnson provides convincing evidence that patients who receive specific information about the nature, pattern, and timing of treatment side effects report less disruption in activity than those who are not given this detailed information.[26,27] Some providers wait until patients complain about potentially expected side effects. When this happens, patients may become skeptical about the completeness or accuracy of any future information given by the person. This potential distrust has important implications for decision making, patient choice of care setting in the future, and recommendations made by patients to others who are seeking a source of cancer care.

Often during the treatment phase increasing burdens are placed on the immediate caregiver and family to support the patient's schedule for treatment, multiple admissions, and increasing dependency.[28]

Often the patient is unable to work, and financial stressors accumulate. Sensitivity and awareness by providers to social, economic, and relationship stresses are needed to assist with referral for social services or psychological assistance. Support groups with other patients can be helpful during this time. Evidence clearly indicates that sharing a common experience in a support group can have psychological benefit.[29]

Decision for Hematopoietic Stem Cell Transplantation

HSCT is becoming a standard treatment of many hematologic malignancies and nonmalignant diseases. Both autologous and allogeneic transplant numbers are increasing worldwide.[30] Although mortality has improved over the years since transplants began in the 1970s, treatment-related mortality continues to cause significant anxiety in patients and families. The procedure for transplantation is complex, can cause intense psychological distress, and extreme social strain on the patient's caregiver, friends and family members. Often the psychological and social issues can be more challenging for the health care team than the medical issues. Because HSCT is an intense and distinctive experience for patients and families and has the potential to cause prolonged psychological distress unlike other experiences with oncology patients, the issues unique to this population warrant a separate discussion.[31]

HSCT patients face physical and psychological stresses of hospitalization and social isolation for weeks to months during their initial recovery; therefore, a thorough pretransplant psychosocial evaluation to identify those patients at risk for development of psychosocial morbidity and to initiate timely interventions to optimize adaptation is recommended. The time of transplantation when the infusion of cells occurs can be a special moment for patients, with patients often referring to the date of transplant as a "birthday" or special anniversary date. Often family members are gathered at the bedside to celebrate the long awaited event of the transplant. However, the weeks following transplant can be difficult psychologically. The threat of death continues to be real, and patients experience social isolation, bodily discomfort, major body image changes, and a sense of loss of control. These issues lead to a myriad of emotions; including hope, anger, depression, anxiety, anticipation, guilt, and joy.[31] Prieto et al.[19] assessed 220 inpatients after transplantation and found that the psychiatric disorder incidence after admission followup was approximately 22%. They identified the following variables as risks factors for psychiatric morbidity: younger age, women, past psychiatric history, lower functional status, pain, smoking cessation, and higher regimen-related toxicity. They reported that although the isolation period has decreased substantially over the last decades, patients still experience anxiety from isolation. They also reported high anxiety when the isolation is lifted and patients are "exposed" to a "germ-filled" environment with all its implications.[19]

Often patients are not prepared for the slow gradual speed of recovery after transplantation. Patients are more familiar with recovery after surgery that takes days to weeks, and they are unprepared and overwhelmed with the long recovery that can take weeks to months or even months to years. Heinonen et al.[32] studied allogeneic patients during the first 3 years after transplantation and found that patients perceived their quality of life worst after the first year than prior to transplant. During this time, patients continue to feel functional limitations, and both autologous and allogeneic patients report usual somatic symptoms, such as fatigue, as the most common distressing occurrences after transplantation.[33–35] Periods when patients are particularly psychologically vulnerable during the first year include admission workup, directly before transplant, discharge from the inpatient setting, between 3 and 5 months, and between 6 and 9 months.[15,36–38] Other factors that have been identified as related to psychological distress and poor health after transplantation are the following: pre-HSCT psychological and psychological status, anxiety, depression, poorer quality of life, disease recurrence, negative mood, type of transplant, locus of control, low social support, presence of graft-versus-host disease (GVHD), and caregiver/family distress.[31,34,39]

The financial burden for patients who undergo bone marrow transplantation (BMT) can be overwhelming, including medical expenses for the patient and marrow donor in the case of an allogeneic BMT, potential travel expenses, and loss of income for other family members.[40] Patients and their immediate families often are far from their usual support systems because of the distance to the BMT center. In some cases, family members who have not been close in the past may be forced by the situation to interact with each other, leading to additional stress.

The first few years after transplantation, patients and family members may continue to experience physical and psychological sequelae from the transplant, although the literature is clear that most patients return to a productive life with high quality of life. Heinonen et al.[32] identified the following factors that predicted a poorer quality of life in patients 1 to 5 years after transplant: age, long-term sequelae, chronic GVHD, and short followup by the treatment center.[32] Patient and families are ready to put the experience behind them, only to discover that the experience of transplant has forever changed the patient's outlook, priorities, and family network. Fear of recurrence and feelings of uncertainty related to future relationships, work, and financial strain continue.[29] There is discordance between the patients' pre-HSCT expectations and the everyday symptoms that limit their physical abilities. Besides fatigue, which continues to be the dominant symptom, another distressing issue is cognitive dysfunction as patients return to the workplace and reenter school.[29] Educating patients about some expected common short-term side effects can reduce anxiety. Neurocognitive side effects of treatment can be long term in high-risk patients but are mostly temporary, including diminished concentration, short-term memory loss, decreased speed of information, and loss of effective problem-solving abilities. Sexuality issues are another area of great concern for patients in the posttransplant period. Barriers for discussion and lack of referrals for supportive services in this area may be related to the patient's embarrassment, the clinician's lack of knowledge, or the focus on other issues that may be interpreted as more critical. Common sexual issues after transplant include vaginal dryness and distressing menopausal symptoms in women and erectile dysfunction in men.[41]

Patients who experience long-term physical symptoms after transplantation may be at risk for long-term psychological distress.[28] Despite the fact that patients are followed by transplant physicians longer than are patients with nonhematologic malignancies; this population often is referred back to primary care physicians 1 to 2 years after transplant. Primary care clinicians do not have the knowledge or experience to tie physical complications to the effects of chemotherapy, radiation, and GVHD, so ongoing communication between the providers and the transplant team and center is imperative. Long-term effects may include persistent viral, bacterial, and fungal susceptibility, GVHD, oral dental caries, muscle atrophy, pneumonitis, gonadal dysfunction, sexual dysfunction, endocrine abnormalities, cataracts, ocular sicca syndrome, reduced bone mass, secondary malignancies, and cognitive dysfunction.[42] In addition to monitoring physical complications, the American Society for Blood and Marrow Transplantation consensus statement recommends annual evaluation of patients' psychological status. Health care providers must have a high level of vigilance to assess depression in both the family caregiver and the patient years after transplant, with clinical assessments recommended annually after transplant. Gruber et al.[43] assessed 163 patients for long-term psychosocial effects as far as 16 years posttransplant and found that the majority of patients had serious problems with "physical fitness," followed by pain and fear/psychological stress. Thirty percent of these patients did not return to work, and the subgroup of unemployed patients had higher scores for pain, depression, sleep disorders, depression, impairment in social functioning partnership, and family life. In spite of the range of problems, only 9.8% of these patients reported accessing psychological support.

The concept of posttraumatic growth (PTG) after transplantation has been evolving. By definition, the potential for PTG requires that patients experience a stressful event and subsequently experience positive psychological outcomes or benefits. As early as 1996, Fromm

identified positive sequelae possible after transplantation, including the development of a new philosophy of life, greater appreciation of life, making changes in personal characteristics, and improving relationships with family and friends. Potential predictors of PTG among posttransplant patients include good social support, little avoidance coping, younger age, less education, greater use of positive reinterpretation, problem solving, seeking alternative rewards, more stressful appraisal of the experience, and more negatively biased recall of pretransplant levels of psychological distress.[18,44] Discussing the PTG potential with patients and making referrals for counseling to experienced clinicians who are aware of the potential for PTG are essential. Although patients report long-term psychosocial effects after transplantation, they may be reluctant to accept help and fail to access psychological resources and social support.[43] These patients must be encouraged to use resources and seek psychological support, because this experience may impair the patient's and families' ability to cope with life after transplant. In an article about HSCT patients' experiences with a support group, Sherman et al.[29] identified the themes of meaning and changing of perspectives as patients expressed their struggles with redefining themselves, their priorities, and their values.[29] Some patients wanted to change their former values and behaviors. The support group experience may be therapeutic for patients who often do not have physical signs of transplant to the untrained eye but continue to experience increasing or unresolved psychological and physical issues.[28] Sharing a common experience may encourage patients to believe that their symptoms and feelings are not unique and may decrease their feelings of isolation.

Extended Phase: Surviving Diagnosis and Treatment

As the treatment and acute side effects improve and subside, patients often feel that the whirlwind has passed, only to be confronted with uneasy silence. Weeks and months of clinic and physician appointments, infusions, and admissions stop or trickle to a small steam of appointments. Families that have been functioning on a grinding schedule of crisis mode find the change almost paralyzing. Adding to this halt of activity, health care providers have a tendency to limit their contacts when patients' physical statuses have stabilized. This is a critical time when psychosocial interventions and supportive services from other members of the health care team must be instituted for patients and family members to deal with the uncertainty and anxiety of waiting. Fears and anxieties change from fighting the disease to returning to life.[9] Because of less contact with the primary treatment oncologists, patients and families perceive a withdrawal of support from the medical team. Therefore, there is a need to establish mechanisms to monitor these patients and family members for ongoing and increasing psychological distress, including anxiety and depression.

Extended Phase: Relapse of the Disease

The time of recurrence of cancer has been reported to be more distressing for patients and family members than the initial diagnosis. The recurrence of the disease can plunge the patient and family into despair and crisis as the realization that death may occur despite the ongoing fight to live. The psychosocial issues experienced by the person with cancer depend in part on the clinical course of the disease process. As the disease progresses, the person often reports an upsetting scenario that includes uncertainty, frequent pain, disability, increased dependence, and diminished functional ability.[6]

The development of a relapse after a disease-free interval can be especially devastating for patients and those close to them. The medical workup often is difficult and anxiety provoking, and psychosocial problems experienced at the time of diagnosis frequently resurface, often with greater intensity.[6] Shock and depression often accompany relapse and require patients and family members to reevaluate the future. In spite of the overwhelming nature of the psychosocial responses, however, most patients do cope effectively with progressive disease, and it is important to recognize that intense emotions do not necessarily equate with maladaptive coping. Investigators studying quality of life in patients with cancer have demonstrated a clear relationship between a person's perception of their quality of life and the presence of discomfort.[45,46] As uncomfortable symptoms increase, perceived quality of life diminishes. An important goal in the psychosocial treatment of patients with advanced cancer centers on optimal symptom control.

An issue that repeatedly surfaces among patients, family members, and professional care providers is the use of aggressive treatment protocols[47] in the presence of relapse and progressive disease. Patients and families often request participation in experimental protocols, even when there is little likelihood of extending survival. Controversy continues about the efficacy of such therapies and the role health care providers can play in facilitating patients' choices about participating.

The need for health care providers to establish structured dialogue among patients, family members, and other providers regarding treatment goals and expectations is essential. That certain patients respond to investigational treatment with increased hope, despite progressive disease, should be a consideration in treatment planning. The need to separate and clarify the values, thoughts, and psychological reactions of care providers, patients, and families to these delicate issues is important if individualized care with attention to the particular patient's psychosocial needs is to be provided.

Permanent Phase: Survivorship

The definition of a long-term survivor has changed radically. Initially, individuals who had survived cancer-free for longer than 5 years were considered "survivors and cured." More recently the term has been used to define individuals who have completed the acute phase of illness. Others use the term for all patients diagnosed with cancer. Some people would prefer changing the term to "thrivers," champions, or fighters.[4] In this chapter, the term *survivor* is used to define a person who is diagnosed with cancer and the *permanent phase* as the phase when therapy has been completed permanently.

Successful treatment of hematologic malignancies has resulted in cure for many patients and progressively longer lives for others. However, longer survival is not without significant psychological sequelae.[48–53] Innovative and new treatments may produce long-term physiologic consequences, such as infertility, treatment-related toxicity, persistent side effects, and organ system failure that can magnify and exacerbate the psychological issues initially associated with diagnosis and treatment.[45,54] The overwhelming evidence from the literature involving survivors with hematologic malignancies is that, on the average, most do very well after the initial adjustment in the first 1 to 3 years after treatment.[50,55,56] Most long-term BMT survivors express satisfaction with their quality of life and describe themselves as productive, stable, and well adjusted without significant physical, functional, psychological, and social problems related to their disease or BMT treatment. However, there is a group of patients with a high rate of psychosocial morbidity who are vulnerable to ongoing and intermittent psychosocial distress. Empirical evidence showed that as many as 9% to 30% of long-term survivors with hematologic malignancies experience significant psychological distress, including anxiety, depression, and posttraumatic distress symptoms.[48,52,57]

Psychological aspects of survivorship may include concern over termination of treatment, fear of relapse, preoccupation with somatic symptoms, reentry into previous roles, lingering affinity with death, and financial, job, and insurance difficulties. These issues may manifest in a variety of ways, including denial of past illness, leading to medical compliance issues; ongoing problems with anxiety, panic, and depression; and inability to reenter or modify previous roles. Fear of recurrence by both patients and family members can severely impact quality of life.[8] In her classic article "The enduring seasons in survival," Dow[9] stated that the season of extended survival is dominated by fear of recurrence. In fact, Baker et al.[58] showed in a group of cancer survivors that "being fearful my illness will return," "concern

Table 93–1 Long-term Consequences of Therapies for Hematologic Cancers

Diminution of support from others
Disruption in sexual functioning
Fertility

about relapsing," "fears about the future," and "difficulty making long-term plans" were a problem 68%, 60%, 58% and 41% of the time.

There is increasing interest in patients' experiences with posttraumatic stress disorder (PTSD). Studies have consistently described a higher incidence of PTSD in patients with hematologic malignancies than in the average population.[59–62] Predictors of PTSD severity among patients with hematologic diagnosis include higher levels of distress and high avoidance coping coupled with low social support.[18] These researchers describe how providers can assess coping and presence of family support and potentially mitigate the effects of a distressing experience with the cancer diagnosis. Considerable evidence indicates that the wide range of surgical, chemotherapeutic, and radiation therapies leaves permanent damage to organs and physiologic functioning and disfigurement across the different hematologic diagnoses (Table 93–1). Health care providers should be mindful of psychological sequelae among patients, even within the context of remission and a hopeful prognosis, and refer patients and family members to a mental health specialist for further evaluation, as needed.

Permanent Phase: Terminal Stage and End-of-Life Care

Technologic advances in health care have improved the potential for cure of many previously fatal hematologic malignancies. However, many patients still have disease that is unresponsive to treatment, continues to progress, and is considered incurable. When cure is acknowledged to be impossible and alternative efforts to combat the progress of disease are exhausted, patients are recognized as terminally ill or dying. In this situation, some authors advocate a palliative care approach with no active treatment and a shift in the emphasis of medical care from the pursuit of cure to supportive and hospice care, including the provision of care and comfort, control of distressing symptoms, and maintenance of quality of life at an optimal level.[63–65] However, this paradigm currently is shifting in the field of palliative care to initiate palliative care alongside curative treatment with the philosophy that it should be implemented across the illness trajectory, with the promotion of quality of life through the relief of suffering.[66] The new World Health Organization definition states "Palliative care is an approach to care which improves quality of life of patients and their families facing life-threatening illness, through prevention, assessment and treatment of pain and other physical, psychological, and spiritual problems."[67]

The root of palliative care began with the hospice movement. Since the concept of hospice was first introduced in England in the 1960s, hospice care has been recognized as the state-of-the-science end-of-life care, and hospice services now are available around the world. However, hospice care has not been integrated into the care of patients dying with hematologic malignancies.[68,69] Despite the strong emphasis of providing end-of-life care in accordance with patients' wishes[70] and empirical studies[70,71] showing that most terminal patients prefer spending their final days of life and dying at home, hematologic malignancy is the only diagnosis that has been repeatedly and consistently shown to predict hospital death.

The reasons for such insufficiency have been attributed to patient and family difficulties in acknowledging and accepting the poor prognosis and imminent death, health care providers' attitudes toward aggressive treatment for hematologic malignancies and reluctance to shift to end-of-life care, and profound symptom distress and dramatic changes in physical conditions experienced by patients at the end of life.[72] Health care providers, first and foremost, must examine their own attitudes toward death and dying and avoid imposing their own values on patients and their families. Respecting patient and family wishes, appropriately managing and alleviating distressing symptoms, and providing care tailored at meeting patients' needs can help patients dying of hematologic malignancies reach the end of life with peace and dignity.

FACTORS THAT INFLUENCE PSYCHOSOCIAL ADJUSTMENT

Psychosocial responses to cancer vary widely and are influenced by several factors that clinicians should bear in mind when considering the responses of individual patients. A review of the literature points to key factors that may have an impact on psychosocial adjustment. They include demographic and disease factors, previous coping strategies and psychological stability, and the existence of social support.

Demographic and Disease Factors

Gender, age, type of treatment, and time interval after treatment have been consistently documented as important predictors for psychosocial adjustment and quality of life for patients with hematologic malignancies. A significantly higher anxiety score,[73] constant fatigue,[74] sleep problems,[75] no return to work,[76] and more impaired quality of life[74] were observed more in women than in men. The presence of current sleep problems[75] and fatigue[74,77] were associated with older age at BMT. Poor quality of life after treatment[78,79] was associated with higher age of the recipient at the time of the transplant, poorer self-image and overall cognitive functioning,[51] and inability to return to work.[73]

Different treatment modalities introduce different degrees of side effects, symptoms, and impact on quality of life. Significant differences were found between transplant groups with regard to loss of appetite, physical and role functioning, symptom distress, sexual impairment, infertility, mood, and overall quality of life.[15,54,55,79–82] Without exception, the greatest difficulties in psychosocial adjustment were observed among patients who underwent allogeneic BMT, followed by autologous BMT recipients and patients who received conventional or maintenance chemotherapy. The latter groups experienced the least impairment in quality of life and psychological distress. Patients who underwent transplant also had more psychiatric morbidity if they experienced lower functional status and higher regimen-related toxicity[19]

Time since BMT or completion of treatment was an important factor for facilitating psychosocial adjustment and improving quality

of life. In general, during the first year after BMT, patients perceived their physical and overall well-being as being worst, experienced more anxiety and total mood disturbance, and reported the highest degree of illness intrusiveness in every aspect of life.[15,54,55,79–82] Improvement in functional status and quality of life, significant decrease of anxiety and depression, and levels of satisfaction with life were frequently observed with the passage of time after BMT.

Previous Coping Strategies and Psychological Stability

One of the key predictors of psychosocial adjustment to cancer is the psychological stability of the person before diagnosis. People with a history of poor psychosocial adjustment before development of cancer are at highest risk of psychological decompensation and should be monitored closely throughout all phases of treatment.[83] This is particularly true of people with a history of a major psychiatric syndrome, psychiatric hospitalization, or both.[19]

Because a person's coping style is determined relatively early in life and remains stable over time and across situations, it serves as a useful predictor of adjustment to cancer. Several investigators have identified specific personality characteristics, coping strategies, and life experiences that enhance or inhibit positive adjustment to cancer.[84,85] Empirical evidence also demonstrated the beneficial impact of positive coping strategies and personality attributes on long-term survival.[86–88] Coping strategies found to be most effective include a "fighting spirit," hopefulness and acceptance of the situation, a belief that life has purpose and coherence, and having a feeling of control over events, resulting in active participation in treatment and engagement in daily life. By contrast, poor adjustment and even PTSD have been associated with avoidant coping strategies, anxious preoccupation and high distraction, prior negative sexual experiences, body image problems, and inhibition in discussing personal and sexual problems.[18] One study showed that patients who smoke are at higher risk for psychiatric morbidity, perhaps due to the potential development of depression and or anxiety with withdrawal symptoms.[19] It is important to include smoking history in the patient's assessment of substance control use when preparing patients for treatment.

Existence of Social Support

Social support, network size, satisfaction with social support, and reliance on formal and informal social ties have consistently been found to influence a person's psychosocial adjustment to cancer.[89,90] The ability and availability of significant others in dealing with a diagnosis and discussion of treatment options can significantly affect the patient's view of himself or herself. Patients diagnosed with all types of life-threatening chronic disorders experience a heightened need for interpersonal support. Those who are able to maintain close connections with family and friends during the course of illness are more likely to cope effectively with the disease than are those who are not able to maintain such relationships.[56,87,89]

Living with a chronic illness often requires continuing care and management by a team of specialists. Use of supportive care services has been tied to improved quality of life; therefore, it is in the patient's best interest to access services needed for psychological distress.[89] Care usually is provided through followup visits to ambulatory or outpatient clinics and consulting rooms, rather than through hospitalization. However, several barriers that may impair the outpatient cancer survivor from accessing health care services include economic and financial constraints.[91]

Traditionally, patients are not referred to home nursing care routinely once they are discharged from the hospital. An initial home nursing visit can be invaluable in assisting patients and families with the transition, in addition to identifying areas in which ongoing assistance is needed. Home care referral can assist families that are increasingly relied on within the current health care system to be the major providers of care outside the hospital (see box on Caregiver Burden).[92]

Caregiver Burden

The phenomenon of caregiver burden acknowledges that cancer affects not only the patient but also members of the family.[92] The burden that caregiving places on the family highlights the family's needs and the importance of targeting education and support information that can help reduce caregiver burden. Helping to arrange respite care for family members primarily responsible for the care of patients also aids in relieving caregiver burden.

DIFFERENTIATING PSYCHIATRIC COMPLICATION FROM EXPECTED PSYCHOLOGICAL RESPONSES

Most patients do not react to a diagnosis and treatment for cancer by developing a clinically diagnosable psychiatric condition. However, in some cases a psychiatric syndrome does occur. If the patient's problems become severe, that is, if the provider believes that supportive measures are insufficient and ineffective in controlling psychological distress, referral to a psychiatric clinician is indicated. Factors that can prevent adjustment to cancer and its treatment include a history of significant depression, manic-depressive illness, schizophrenia, neuroses, organic mental conditions, personality disorders, lack of social support, and inadequate control of physical discomfort.

Because transient symptoms of anxiety and depression are common in patients with cancer, the ability of health care providers to distinguish expected reactions from more severe psychiatric complications is crucial. Anxiety and depression are common symptoms that are particularly evident at transition points during the clinical course of cancer. These symptoms usually subside within 2 to 4 weeks and are responsive to supportive reassurance and information regarding what to expect during the course of treatment. For a proportion of patients, psychological distress does not subside with usual interventions. Unfortunately, nonpsychiatric care providers often miss clinically relevant and severe psychiatric syndromes. Detecting serious psychiatric problems in patients can be difficult because several of the diagnostic criteria used to evaluate the presence of severe depression (e.g., lack of appetite, insomnia, decreased sexual interest, diminished energy) may overlap with usual disease and treatment effects. It is not unusual for health care providers to confuse their own fears about cancer with the psychological reactions of their patients (i.e., "I too would be extremely depressed if I were in a similar situation"; see box on Screening for Psychological Distress).

Most patients manifest transient psychological symptoms that are responsive to support, reassurance, and information about what to expect regarding the cancer course and its treatment. Some require more aggressive psychotherapeutic interventions, such as pharmacotherapy and ongoing psychotherapy. The following guidelines can assist the clinician in identifying those patients who exhibit behavior suggesting the presence of a psychiatric syndrome.

General guidelines designed to assist in distinguishing patients who should be referred for evaluation by a trained psychiatric clinician include the following:

1. History of psychiatric hospitalization or significant psychiatric/personality disorder
2. Persistent refusal, indecisiveness, or noncompliance with regard to needed treatment
3. Persistent symptoms of anxiety and depression that are unresponsive to usual support from health care providers or family members;

Screening for Psychological Distress

A number of tools have been developed to screen for psychological distress, but they have not been consistently incorporated into clinical care.[93,94] One tool that is easy to administer and that patients report as capturing their problems is the *distress thermometer*.[95] The tool is similar to pain measurement scales that ask patients to rate their pain on a scale from 0 to 10 and consists of two parts. The first part is a picture of a thermometer, and patients are asked to mark their level of distress. A rating of 4 or above indicates that a patient has symptoms indicating a need for evaluation by a mental health professional and potentially has a need for referral for services. The patient then is handed a second part of the tool and is asked to identify which items from a six-item problem list (illness-related, family, psychological, practical, financial, or spiritual effects) relate to the patient's distress (Fig. 93–2).[95,96] Lee et al. [97] found that the distress thermometer was a useful tool for screening transplant patients before admission. Pretransplant distress appeared to be highly predictive of distress posttransplant and was a feasible marker to target screening and intervention programs.

symptoms may present in the form of constant fear associated with treatment and procedures or excessive crying and hopelessness that worsen rather than improve with time
4. Abrupt, unexplained change in mood or behavior
5. Insomnia, anorexia, diminished energy out of proportion to expected treatment effects
6. Persistent suicidal ideation
7. Unusual or eccentric behavior or confusion (may be indicative of an organic mental disorder)
8. Excessive guilt and self-blame for illness
9. Evidence of dysfunctional family coping or complex family issues

After referral to a psychiatric specialist, one or a combination of several therapeutic modalities may be used. Cancer and its treatment may precipitate an exacerbation of an underlying mental illness to which a patient was predisposed and that may require extensive treatment (e.g., hospitalization for a psychosis, ongoing pharmacotherapy or psychotherapy). A discussion of these specialized forms of treatment is not given here, but the interested reader can consult appropriate standard texts.[20]

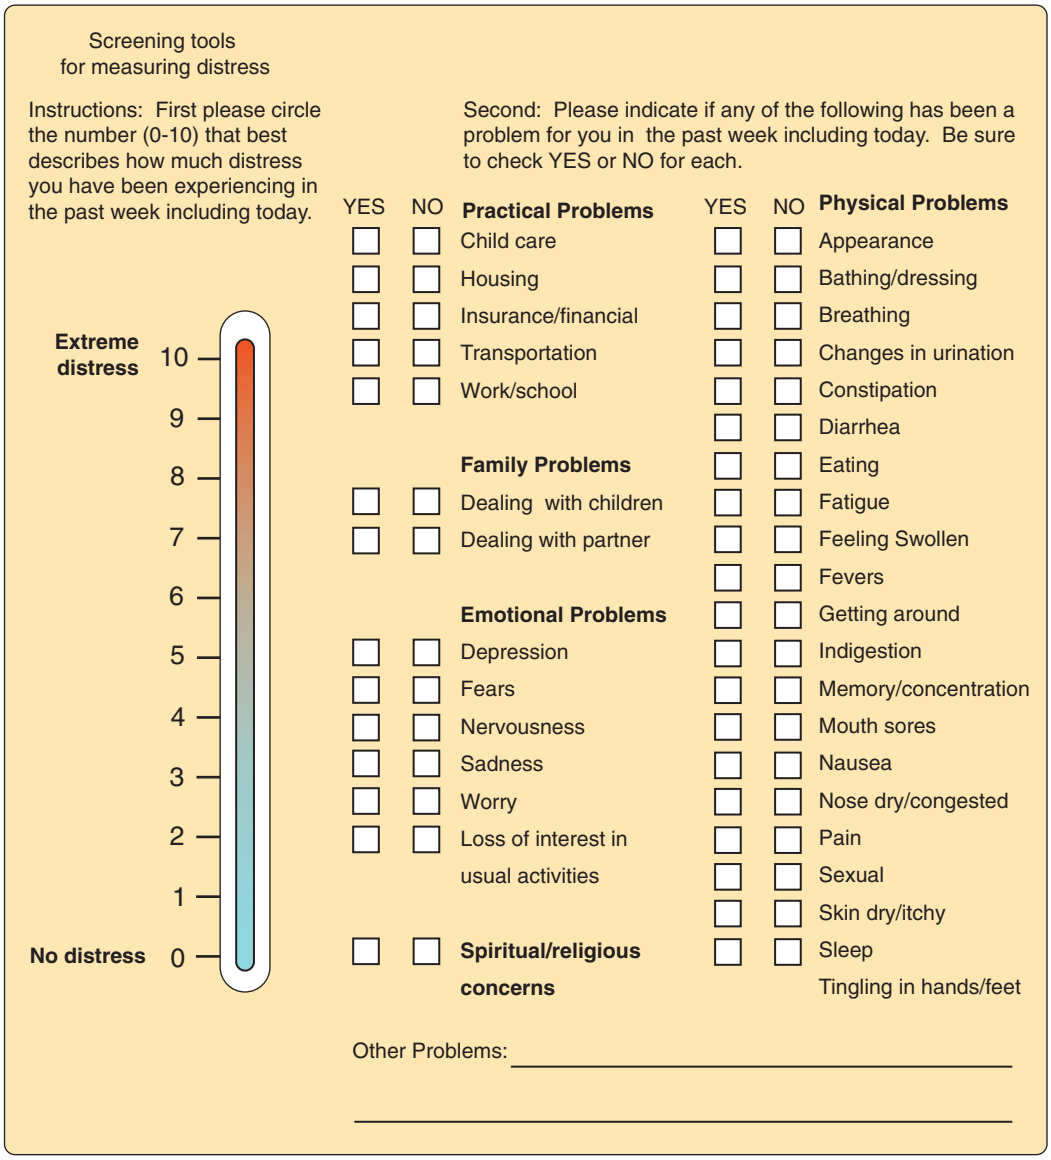

Figure 93–2 National Comprehensive Cancer Network (NCCN) Distress Management Guideline DIS-A-Distress Thermometer. (From the National Comprehensive Cancer Network 1.2005 Distress Management, The Complete Library of NCCN Clinical Practice Guidelines in Oncology [CD-ROM]. Jenkintown, PA, National Comprehensive Network, 2005.)

MANAGEMENT OF PSYCHOSOCIAL PROBLEMS

Interventions for these patients center on the uniqueness of the experience. In the initial phase of the experience, 50% of patients have psychological distress, including both anxiety and depression.[96] A growing body of literature provides evidence that patients may experience PTSD.[98] Increased length of survival from time of diagnosis has highlighted the need for psychopharmacologic, psychotherapeutic, and behaviorally oriented interventions to reduce distress, promote adjustment, and improve quality of life for patients with hematologic malignancies. Because of the increasing complexity of patient care, a multidisciplinary approach that includes regular avenues and options for communication about patient management and status updates is imperative. Numerous studies have documented the efficacy of a variety of modalities in managing psychosocial problems for such patients. Problems that can be managed effectively include psychological distress such as anxiety and depression; sexual dysfunction; body image disturbances; marital and family difficulties; noncompliance, pain, and neurologic complications such as delirium and dementia induced by brain metastasis or treatment; anticipatory and posttreatment nausea and vomiting; and anorexia and feeding problems.

Pharmacologic Interventions

Pharmacotherapy, as an adjunct to one or more of the psychotherapies, can be an important aid in bringing psychological symptoms under control. For patients with excessive anxiety, factors other than a psychological state must first be evaluated. Metabolic abnormalities, pain, hypoxia, and drug withdrawal states all can present as anxiety. Medications such as steroids and antipsychotics, often used to control nausea, can cause anxiety characterized by agitation and motor restlessness. Many common medications and substances are associated with anxiety and depression. After medical or drug-induced causes for anxiety are ruled out, an anxiolytic agent is the treatment of choice, except for patients who present with panic episodes, in whom tricyclic antidepressants are most efficacious. Medications are most effective when used at adequate dosages and as standing orders. Use of these medications may assist the patient to participate in psychotherapy, which can provide more permanent control over psychological symptoms. Anxiety that develops in the context of the terminal stages of cancer often results from hypoxia or an untreated pain syndrome. Intravenous morphine sulfate and oxygen usually are effective palliative treatment. All pharmacologic treatments must be monitored for effectiveness and side effects.

Patients commonly demonstrate transient depressive symptoms at various points in the disease trajectory, particularly during the palliative care period when a hope for cure is not possible. In patients who exhibit prolonged or severe depressive symptomatology, a major depressive illness must be considered. Depression can be related to a recurrence of a past depressive disorder or the stress associated with treatment, or it can be a result of the illness process or treatment agents. Antidepressant medications are easily administered and are an effective treatment strategy. Disadvantages include the need for repeated visits to health care practitioners to monitor patient response and adjust the dosage, possible adverse side effects and medical reactions, potential use in suicide attempts, and the need for strict adherence to the medication schedule. Patients should be informed that most antidepressant medications must be taken for 3 to 4 weeks before a significant response is achieved. The clinician must be aware that suicidal patients become more energized with medications and appear to look better long before their depressive feelings and suicidal thoughts are relieved. Careful monitoring of suicidal ideation should continue for weeks after the patient appears improved.

Certain medications and cancer treatment agents can produce severe depressive states. A diagnosis of major depression in medically ill patients relies heavily on the presence of affective symptoms such as hopelessness, crying spells, and guilt; preoccupation with death or suicide; feelings of diminished self-worth; and loss of pleasure in most activities such as being with friends and loved ones. The neurovegetative symptoms that usually characterize depression in physically healthy individuals are not good predictors of depression in the medically ill because disease and treatment can also produce these symptoms. A combination of psychotherapy and antidepressant medication often proves useful in treating major depression in medically ill patients.[99] Antidepressant medications may take 2 to 6 weeks to produce their desired effects. Patients may need ongoing support, reassurance, and monitoring in the period before the antidepressant effects of medication are achieved. Patients must be monitored closely by a consistent provider during the initiation and modification of psychopharmacologic regimens.

Psychotropic drugs are highly effective for treatment of anxiety, depression, agitation, and confusion in patients with hematologic malignancies.[100] It is beyond the scope of this chapter to include the current medications recommended for common psychiatric disorders. A comprehensive discussion of psychotropic drugs by classification is summarized in the quick pocketbook reference for oncology clinicians.[100] Medications specific for the management of anxiety, depression, and delirium also are presented.[101]

Psychotherapeutic Modalities

"Returning to normal" is a prominent theme in the clinical management of patients but is not always possible for patients with hematologic malignancies.[102,103] Survivors of cancer continue to face challenges with long-term physical and psychological symptoms long after treatment has ended, and data indicate that they report more contact with mental health providers than do people without cancer.[91] The American Society for Blood and Marrow Transplantation released a joint recommendations statement on screening and preventative practices for long-term survivors of hematopoietic cell transplantation and state that "a high level of vigilance for psychological symptoms should be maintained. Clinical assessment is recommended throughout the recovery period, at 6 months, 1 year and annually thereafter, with mental health professional counseling recommended for those with recognized deficits."[42] The number of intervention studies designed with the hematologic population is limited; however, growing interest in survivorship is changing the research climate in this area.

Support groups can provide a therapeutic experience for patients and family members. Initial evidence suggests that support groups may help reduce health care costs along with depression, mood disturbance, and psychiatric symptoms in patients.[104] Patients often feel alone in their distress and report that sharing a common experience normalizes their feelings, provides an avenue for emotional support, facilitates dialogue to problem solve, and offers opportunities to learn from other patients. Support groups facilitated by professionals such as social workers, nurses, or psychologists can provide a forum for health and psychological education and provide patients with printed literature and online community-based resources. Sherman et al.[29] found that psychoeducational support groups facilitated by professionals were a helpful strategy for patients' post-HSCT psychological recovery.

Other modalities have been shown to be effective with patients.[103,104] Studies have consistently shown that relaxation training with or without guided imagery or hypnosis may have some benefit with improving quality of life, symptom management, and anxiety and depression management.[103,105,107] It is a skill taught to patients that takes minimal time. It does, however, require that patients be motivated to learn and practice new techniques and a way of coping. Cognitive therapy/reappraisal, problem solving, and stress management training also have been shown to be helpful in the general cancer population.[98,103,106] Fritzsche et al.[107] identified that a considerable need for psychotherapeutic treatment of inpatient hematology patients best handled by mental health professionals. They described a psychosomatic liaison service that provided psychosocial support for patients with hematologic malignancies, including patients going through transplant. The service screened patients for anxiety, depres-

Table 93–2 Therapeutic Modalities Useful for Patients and Family Members

Modality	Selected Indications	Goals and Advantages	Comments
Individual psychotherapy	Prolonged adverse reactions to diagnosis, treatment, and other aspects of chronic illness (e.g., anxiety, depression)	Supports patient and enhances ability to cope with distressing feelings Short-term therapy; focused and goal directed	Pharmacotherapy and family involvement are useful adjuncts in some cases
Support groups	Patients desire contact with others who are experiencing chronic illness	Supports patient and enhances coping ability Usually does not involve a fee Patients benefit by observing coping strategies of others	Expands social network of patients with limited support systems
Family and marital therapy	Relationship problems secondary to illness (e.g., family tension, role changes, conflict, sexual problems)	Assists couples to clarify problems and facilitates solving them together Addresses role changes in the family system	Problems, issues, and concerns about relationships including children can be addressed
Mind–body therapies, including progressive muscle relaxation, yoga, guided imagery, Reiki, meditation, hypnosis, biofeedback	Patients desire assistance with control of pain, anxiety, anticipatory and posttreatment nausea and vomiting, fears associated with medical procedures	Increases sense of control and participation in treatment Individualized to meet patient's preferences and circumstances Time limited and goal directed Evaluated in terms of observable changes in symptoms	Realistic goals should be stated explicitly (some patients may view these therapies as a cancer cure)

sion, poor coping, quality of life, and psychosocial openness for support and provided psychotherapy, relaxation training, or group therapy as interventions. Although all transplant patients received support from the team, 23% on the hematology patients on the general ward received additional psychosocial interventions.

Other evidence-based interventions that have been found to be helpful in the general oncology population include individual and group counseling, family therapy, music, and art therapy. In comparison to patients with solid cancers, there should be a low threshold for referral for psychosocial support for patient and families faced with a hematologic malignancy because the primary treatment is intense and long and associated with sensitivity to potential barriers such as economic constraints, including lost of insurance. It has been estimated that one of six cancer survivors with mental health problems who need services are unable to access those services due to cost.[91] If cost is prohibitive and referral to a psychologist is not feasible, both patients and providers must investigate other potential providers, such as chaplains, art therapists, music therapists, social workers, and psychiatric advanced-practice nurses who might be able to see patients as part of their work responsibilities. Other possibilities include online support groups and advocacy organizations, including local wellness communities.

Depending on the nature of the problem, the treatment modality may take the form of individual psychotherapy, group therapy, family therapy, marital therapy, behaviorally oriented therapy, or some combination.[108] Increasing evidence supports use of an aerobic exercise program for patients with hematologic malignancies.[109–111] Researchers have concluded that fatigue and loss of physical performance in patients undergoing BMT may improve with exercise.[110] Others have found increased muscle strength after allogeneic BMT.[111] Table 93–2 outlines the major psychotherapeutic modalities and their advantages, goals, and indications.

CONCLUSION

The psychosocial issues faced by people diagnosed and treated for hematologic malignancies are influenced by sociocultural, medical, family, and individual factors. Although involvement in decision making clearly is a positive aspect of current cancer therapies, great care should be taken to ensure the communication of timely, repeated, and relevant information consistent with the patient's needs, tolerance, and comprehension. A multidisciplinary approach is essential to guarantee the communication of timely and essential information to all patients. Patients should be given the opportunity to speak with multiple members of the interdisciplinary treatment team and other patients who have experienced similar management and treatment protocols. Care should be taken to provide needed information from a variety of expert perspectives while respecting the unique characteristics, psychosocial profiles, needs, and desires of each individual. In treatment settings with limited resources, every effort should be made to enlist the help and support of providers and services that can assist patients with their complex treatment decisions. Referral to community resources and support services after discharge from the hospital often is helpful, even for patients who cope well with initial treatment.[20]

Most patients undergoing cancer treatment, as well as their families, experience expected periods of psychological turmoil that occur at transition points along the clinical course of cancer. In a small proportion of patients more severe psychiatric complications may occur, warranting referral to a psychiatric specialist, including psychiatrists, social workers, psychologists, and psychiatric nurses. Screening for ongoing psychiatric problems must become standard care. A variety of psychotherapeutic modalities are useful for helping patients work through the expected psychological responses to cancer as well as more severe responses.[24] Supportive psychotherapeutic measures should be used routinely because they minimize distress and enhance feelings of control and mastery over self and environment. For these reasons alone, their value in the care of patients with cancer is paramount. For patients who are not responsive to routine support and information, referral to a psychiatric specialist may be indicated.

Throughout the clinical course of cancer, the patient's relationship with health care providers and the presence of a supportive social network are important factors that can ensure successful negotiation of the many physical and psychosocial demands imposed by a cancer diagnosis and treatment. As scientific inquiry continues to produce vast but sometimes conflicting information regarding etiology and treatment of cancers, concurrent research regarding the psychosocial aspects of hematologic malignancies is crucial. This line of inquiry will, at the very least, assist in promoting psychosocial well-being in patients and family members faced with an extreme and unexpected life crisis. At best, expanding the knowledge base relative to the psychosocial aspects of cancer may provide some "missing links"

regarding psychosocial adaptation and quality of life and their impact on survival. Their results underscore the recommendations of the recent Institute of Medicine report that all cancer care should ensure the provision of appropriate psychosocial health sevices.[108] Minimally, patients must be screened for emotional distress and evaluated for additional services.

CHAPTER 94

PAIN MANAGEMENT AND ANTIEMETIC THERAPY IN HEMATOLOGIC DISORDERS

Craig D. Blinderman, Bridget Fowler, and Janet L. Abrahm

Relieving the pain of patients who have hematologic disorders requires a multifaceted approach.[1,2] An understanding of the taxonomy of pain, basic pain pathophysiology, and a systematic evaluation of the pain complaint will provide a rational basis for treatment decisions. After the source of the pain has been identified, appropriate nonpharmacologic and pharmacologic therapies can be initiated. The neurosurgical and anesthetic procedures for the management of cancer pain are not discussed in this chapter; those interested in these techniques are referred to several excellent reviews.[1–6]

TAXONOMY OF PAIN

Although there is no one standardized classification system for cancer pain, several systems have been proposed.[7–14] Cancer pain syndromes, and thus by analogy pain syndromes in hematologic disorders, may be classified temporally, pathophysiologically, etiologically, or according to distinct clinical-anatomical entities, or any combination thereof. Clinically, it is useful to determine both the etiology and inferred pathophysiology in the assessment of the pain complaint, as this may suggest the use of specific therapies. A conceptually useful taxonomy therefore categorizes pain as *nociceptive* (somatic or visceral), *neuropathic*, or *idiopathic*. Nociceptive pain refers to pain that is sustained predominantly by tissue injury or inflammation. Nociceptive somatic pain is described as sharp, aching, stabbing, throbbing, or pressure-like. Nociceptive visceral pain is poorly localized and is usually described as crampy pain (eg, obstruction of hollow viscus), or as aching and stabbing (eg, pain secondary to splenomegaly). Neuropathic pain is sustained by abnormal somatosensory processing in the peripheral or central nervous system. Sensations described as "burning," "shock-like," and "electrical" typically suggest neuropathic pain. On physical examination, patients may have allodynia (pain induced by nonpainful stimuli) and hyperalgesia (increased perception of painful stimuli). In the absence of evidence sufficient to label pain as either nociceptive or neuropathic, we may use the term *idiopathic*. However, in patients with hematologic disorders, this term should lead to additional workup and a search for an underlying etiology and pathophysiology.

BASIC PAIN PATHOPHYSIOLOGY

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.[15] For a patient to feel pain,[1] a signal arising from a noxious stimulus in the periphery must be transmitted to the centers in the brain that create the experience of pain. After activation of peripheral receptors by chemical, thermal, or mechanical stimuli, the signal passes along unmyelinated A-delta or C fibers and enters the spinal cord via the dorsal root ganglion. Chemicals released at the site of tissue injury mediate or modulate the transmission of the pain signal. Arachidonic acid metabolites, bradykinin, adenosine, serotonin, nitric oxide, prostaglandins, and lipoxygenase products have all been identified as playing a role in initiating or increasing the transmission of the pain signal in peripheral nociceptors.[16]

The dorsal horn of the spinal cord is where the peripheral signals are received and modulated. The excitatory amino acids (eg, glutamate and aspartate) and neuropeptides (eg, substance P and calcitonin gene-related peptide) enhance transmission of the peripheral signal.[1,17] But a complex interaction of other neurotransmitters (ie, γ-aminobutyric acid [GABA], glycine, adenosine, bombesin, cholecystokinin, dynorphin, enkephalin, neuropeptide-Y, neurotensin, substance P, somatostatin, and vasoactive intestinal peptide) determines whether the signal will proceed up the spinothalamic tract.[1] The signals that are transmitted ascend in one of the two contralateral spinothalamic tracts: the paleospinothalamic tract, which mediates the "suffering" and autonomic reactions to pain, or the neospinothalamic tract, which localizes the pain and records its intensity.[1]

Descending pathways originating in the central nervous system can inhibit transmission of the pain signal. A modulatory network with major relays in the midbrain periaqueductal gray and rostral ventromedial medulla exerts control over dorsal horn nociceptive transmission and is the central substrate of opioids-both endogenous and exogenous.[18] This major pain-modulating pathway involves regions of the frontal lobe, amygdala and hypothalamus, all of which have projections to the periaqueductal gray. The periaqueductal gray inhibits spinal nociceptive neurons via connections in the rostral ventromedial medulla and the dorsolateral pontine tegmentum. The neurotransmitters involved in this and other central inhibitory pathways include serotonin, norepinephrine, cholecystokinin, neurotensin, acetylcholine, cannabinoids, and the endogenous opiates β-endorphin, enkephalin, and dynorphin.[18]

Opiate receptors for endogenous and exogenous opioids are present in the dorsal horn of the spinal cord, in those ventromedial thalamic nuclei that transmit signals from the paleospinothalamic tract, in the periaqueductal gray, the periventricular diencephalon, and the amygdala.[18] The analgesic affects of opioids is thought to be due to the reduction of neurotransmitter release (eg, glutamate, substance P, and others) from presynaptic nociceptive fibers as well as postsynaptic inhibition of neurons transmitting the painful signal to the brain.[17]

The *N*-methyl-D-aspartate (NMDA) receptor at the level of the spinal cord plays an important role in chronic painful states. Chronic pain or long-term opioid therapy may result in activation of the NMDA receptors. Activation of the NMDA receptor initiates intracellular processes that lead to several neuronal plastic changes that in turn result in enduring increases in neuronal excitability.[19] Antagonists of these receptors, for example, ketamine[20] and dextromethorphan,[21] may enhance analgesia and reduce the amount of opioid analgesics required. Further studies are necessary to determine the clinical role of NMDA antagonists.

Several reviews have described the diverse pathophysiologic processes involved in neuropathic pain.[22,23] Most neuropathic pain syndromes are the result of peripheral nerve injury. Following injury, changes occur at the molecular level, within the nerve itself, and within the spinal cord and brain. At the molecular level, there is upregulation in the expression of both tetrodotoxin-sensitive (TTX-S) and tetrodotoxin-resistant (TTX-R) Na channels. These Na channels are the targets for many of the adjuvant medications used to treat neuropathic pain, for example, local anesthetics, antiarrhythmics, anticonvulsants, and tricyclic antidepressants.[24] Other cellular components that are thought to play a role in neuropathic pain include TRPV-1 channels, N and P/Q type voltage-gated calcium channels, purine receptors (P2X), TrkA, proton receptors, and cannabinoid

receptors (CB1, CB2).[22] Additional changes take place within the nerve itself. Following injury to peripheral nerves, there is a subsequent change in the phenotype of the nerves by de novo gene expression.[25] Both injured and unaffected nerves develop a sensitivity to a number of factors to which they were previously insensitive, and also respond to subthreshold stimuli. Such sensitization may lead to ectopic and spontaneous activity in tissue nociceptors, perhaps explaining paroxysmal episodes of pain. A host of chemical and inflammatory mediators further alter the gene expression of nerves, leading to increased sensitivity. At the level of the spinal cord, several processes occur that alter the way sensory nerves function, thus maintaining a pathologic pain state. These processes can be described as reorganization, sensitization, and disinhibition.[24] Reorganization refers to the phenomenon of new connections being established in the laminae of the spinal cord, for example, A-beta fibers (which normally transmit light touch) sprout into lamina II of the dorsal horn, replacing C-fibers that transmit nociceptive information to second-order neurons. Dorsal horn neurons also become sensitized as a result of repeated firing from peripheral nerve fibers. The release of substance P, CGRP, and other neuropeptides lead to the activation of the NMDA receptor, release of nitric oxide postsynaptically, with subsequent excitation of pain transmission neurons. Microglia activation also plays a role in sensitizing and maintaining pathologic pain states.[26] Finally, disinhibition at the level of the spinal cord is thought to be a result of interneuron death in lamina II, downregulation of GABA and opioid receptors, and increased production of cholecystokinin.[24]

Table 94–1 Common Pain Syndromes in Hematologic Malignancies

Procedure-related Pain	
Bone marrow biopsy	
Central catheter placement	
Lumbar puncture headache	
Therapy-related Pain	
Myalgias (eg, from corticosteroid withdrawal)	
Myopathy	
Oropharyngeal mucositis	
Postherpetic neuralgia	
Osteoporosis	
Peripheral Neuropathies (eg, secondary to chemotherapy agents)	
Visceral pain syndromes (eg, typhlitis, hemorrhagic cystitis, enteritis)	
Pain from Hematologic Malignancy	
Pain Syndrome	**Cause(s)**
Bone Pain	Bone marrow expansion/infiltration Bone infarct/necrosis Osteomyelitis Compression fracture Hemarthrosis
Visceral Pain	Tumor involvement Splenomegaly Lymphadenopathy/lymphadenitis
Headache	Meningeal infiltration, infection Brain metastasis or primary tumor
Neuropathic Pain	Paraproteins with antimyelin properties Amyloid infiltration Peripheral nerve compression Spinal cord compression

EVALUATION OF THE PAIN COMPLAINT

Initial Evaluation

Effective pain management requires a comprehensive assessment of the patient's pain. Pain reports by patients should be believed. The clinician may not be aware that the clinical presentation of a patient suffering from chronic pain is very different from that of a patient in acute pain. If a patient does not manifest the common autonomic manifestations of acute pain (eg, tachycardia, sweating, elevated blood pressure) or facial grimacing, the clinician might doubt that the patient is suffering from severe pain. A patient with severe but chronic pain does not manifest these autonomic findings, but often is withdrawn, quiet, depressed, or irritable and can move very little spontaneously but complains of discomfort when moved. When the pain is relieved, these patients often exhibit completely different behaviors, becoming mobile, engaged, and involved with other people. The first component in the assessment is to believe the patient's complaint.

Patient reports of pain are valid, reliable, and reproducible.[1] A variety of assessment tools that can be completed within 5 to 10 minutes are available.[1,27,28] The pain complaint should be characterized by a number of descriptors: pain location, intensity, quality, onset, and duration; location and patterns of radiation; and what relieves or exacerbates the pain and its functional consequences, including how the pain affects the patient's ability to sleep or eat and how it affects physical activity, relationships with others, emotions, and concentration. Most patients with chronic cancer pain also experience periodic flares of pain, or "breakthrough pain."[29] An important subtype of breakthrough pain is "incident pain," which is caused by voluntary activity. The initial evaluation should determine the extent to which the patient suffers from breakthrough pain and if it is provoked by movement (nociceptive) or tends to be paroxysmal in nature (neuropathic). This subjective information, combined with the physical examination and diagnostic studies, may identify a specific pain syndrome and its implied pathophysiology.

In the patient with a hematologic disorder, the cause of pain may be: the disease itself, the specific therapy for the disease, diagnostic procedures related to the disease, or unrelated disorders (Table 94–1). Splenomegaly, bone injury (eg, infarction, infection, hemarthroses, infiltration), leptomeningeal infiltration, and spinal cord compression frequently accompany hematologic diseases. Chemotherapy and radiation therapy can cause mucositis, typhlitis, hemorrhagic cystitis, and peripheral neuropathy; corticosteroid withdrawal may cause myalgias.[30] Immunosuppression, caused by the diseases themselves or by the therapies used to treat them, may lead to painful infections such as perirectal abscesses, herpetic or candidal esophagitis, and herpes zoster. Patients with sickle cell disease have a number of causes for both acute and chronic pain (Table 94–2).

Distress, however, may arise from nonanatomic sources. The pain complaint may represent the patient's only means of expressing nonspecific feelings of distress to the physician. Chapman[31] recognized three categories of this distress: anxiety, arising from fear of disfigurement or of uncontrollable pain, fear of loss of social position or of self-control, or fear of death; anger at the failure of the physicians to provide a cure; and depression from the loss of physical ability, a sense of helplessness, and the impact of financial problems. In addition to these psychological, social, and financial contributions, spiritual concerns may exacerbate any concomitant painful sensations.[32] Alleviating them may significantly reduce distress and decrease the need for pain medications or other interventions.[33]

For the patient whose complaint of pain does not seem to have a straightforward explanation or who has not responded well to the therapeutic maneuvers outlined subsequently, additional questions must be asked to uncover the source of the distress. Patients may deny their disease and use the complaint of pain to justify their incapacity. Their denial is demonstrated by answers to the following types of questions. *How would life be different without the pain?* Such patients give unrealistic assessments of the extent of their abilities "if only the pain were gone." Answering another question may reveal hidden fears, resentments, and distrust of the physician: *What do you think is causing the pain?* Unrealistic expectations of pain treatment

Table 94–2 Classification of Pain Syndromes in Sickle Cell Disease

Pain Secondary to the Disease Itself
Acute pain syndromes
Acute chest syndrome
Calculus cholecystitis (pigment stones)
Hand–foot syndrome (in children)
Hepatic crisis
Priapism
Pulmonary infarction
Recurrent acute painful episode
Splenic sequestration (in children)
Chronic pain syndromes
Arthropathies/arthritis
Avascular necrosis
Chronic osteomyelitis
Intractable chronic pain
Pain secondary to therapy
Loose prosthesis (in patients post arthroplasty for avascular necrosis)
Opioid withdrawal
Postoperative pain
Pain due to Comorbid Conditions
Leg ulcers
Neuropathic pain

Adapted from Ballas SK: Pain management of sickle cell disease. Hematol Oncol Clin N Am 19:785, 2005.

may be revealed by answers to the following question: *To what extent do you expect your pain to be relieved?* The patient may expect that taking one pill each day will provide total relief, whereas the physician expects that even a multimodality regimen will relieve only 75% of the pain. A "contract" detailing the expectations of the patient and physician may be formulated once these unspoken assumptions are understood. Other sources of confusion in the way the patient communicates the type of pain experienced can be clarified by the answer to the following question: *Do you seem to show your feelings about the pain to the same extent that your family and friends do?* Patients may come from cultural backgrounds different from the person reporting the pain, and people with cultural differences often report pain very differently.[34–36] For example, patients from a "stoic" cultural upbringing may not communicate their distress to their spouse, who may then question the patient's need for opioid pain medication (ie, if they themselves were in that much pain, they would be sure to tell their spouse). Unless the cultural differences are explored, adequate pain control may not be achieved.

Continued Assessment

A standardized measurement tool, for example, verbal rating scale or a visual analog scale, should be consistently used during follow-up visits. These measurements are thought to be more accurate than mere qualitative descriptors, such as "the pain is better." Using, for example, a scale of 0 (*no pain*) to 10 (*the worst pain one can imagine*), a decrease in pain intensity from 10 to 8 indicates that the patient needs a stronger pain medication, whereas a decrease from 10 to 3 suggests that the current medication regimen is effective. This inference can be confirmed by asking the patient, "Is this level of pain relief acceptable to you?"[1] The ongoing assessment should also pay attention to changes in the phenomenology of the pain, new occurrences of pain, or a change in the location of pain—all of which may suggest progression of disease in the patient with a hematologic disorder.

The successful outcome of pain therapy should be more than simply the lowering of pain intensity scores. Passik and Weinreb developed a useful mnemonic device for the assessment of pain therapy in chronic nonmalignant pain known as the "4 A's": analgesia, activities of daily living, adverse events, and aberrant drug-taking behaviors (eg, repeated dose escalation or noncompliance, hoarding drugs, acquiring drugs from other medical sources).[37] By focusing on these relevant domains in the continued assessment of the pain therapy, the clinician is able to determine if the therapy makes a true difference in the patient's life, stabilizes or improves psychosocial functioning, manages side effects, and provides a means of assessing for aberrant drug behaviors. Ultimately, the goal should be to lower the pain *to a level acceptable to the patient* and to improve the patient's level of functioning.

THERAPY

A major component of pain therapy is an attempt to ameliorate the underlying cause of the pain. Surgery, chemotherapy, radiation therapy, and antibiotics may all be employed. However, the pain can still be treated effectively during diagnostic testing to define the cause, during specific therapy, or after all disease-related therapies are exhausted.

The goal of pain management is to relieve pain while preserving the patient's ability to perform normal activities. This requires expertise on the part of health care personnel, who seek to maximize the relief obtained while minimizing side effects and alterations in daily routines. A multifaceted approach is required that includes nonpharmacologic approaches, correct use of a variety of medications and anesthetic techniques so that pain will be relieved with a minimum of side effects, and patient and family education at each step to foster communication and cooperation with the therapeutic plan.

NONPHARMACOLOGIC METHODS OF PAIN MANAGEMENT

Cognitive–Behavioral Interventions

Education and Reassurance

Patients with serious hematologic disorders are often required to undergo extensive diagnostic testing, which can include painful procedures. A rehearsal of the planned test or procedure, including a discussion (or view) of the appearance of the room and the length of time to be spent in the test apparatus, can minimize the patient's anxiety. Such explanations, offered preoperatively, lessen the need for postoperative medication and shorten the patient's hospital stay.[38] If conscious sedation is not planned, a pleasant distraction may be helpful to divert attention from certain procedures (eg, bone marrow aspiration or biopsy) that take place in the physician's office or in the patient's room.[39] For example, the physician might encourage the patient to bring in a CD or MP-3 player with earphones so that the patient can listen to a favorite piece of music or a book on tape while the procedure is taking place. Alternatively, the physician might turn on the television or radio in the patient's room and encourage the patient to pay attention to that, rather than to the procedure. Patients with a good imagination can pretend to be in a place they have previously enjoyed (eg, at the beach or in the mountains). They can dissociate themselves[40] from the procedure by concentrating on those pleasant memories and thereby diminishing the painfulness of the procedure.

Hypnosis

Practitioners with formal training in hypnosis can use more elaborate hypnotic techniques to help their patients deal with painful procedures or conditions.[39,40] Hypnosis takes advantage of the natural ability to enter a trance-like state. An athlete "playing through the

pain" is an example of the spontaneous induction of such a state. Patients who are trained to enter a trance can modify their perception of pain and diminish sleeplessness, anxiety, and the anticipation of discomfort.[41] Hypnotic training of patients with sickle cell anemia or hemophilia decreases the frequency and pain intensity of painful crises[42] or bleeding episodes,[43,44] respectively.

Even in the absence of a formal hypnotic induction, the words used by the practitioner to describe procedures are very important. For example, the suggestion that skin coolness and numbness will persist after application of an alcohol swab may markedly diminish the discomfort of starting an intravenous line. Using the phrase "You will feel something; I'm not sure what you will feel, because everyone feels this a little differently" in place of "This is going to hurt a lot!" gives the patient permission to alter the sensation and may also diminish the experience of pain.

Cognitive–Behavioral Techniques and Counseling

The cognitive–behavioral approach addresses a number of psychosocial and behavioral factors that contribute to the patient's experience of pain.[45] These techniques have demonstrated clinical utility for patients with a wide range of chronic pain syndromes.[45] Psychological counseling, as part of a multidisciplinary approach to pain treatment, provides education, support, and skill development for patients with pain. It can improve patients' abilities to communicate their pain to health care personnel and may be effective in overcoming anxiety and depression. Spiritual counseling may help patients who have lost hope, can find no meaning in their lives, or feel they are being punished or have been forsaken by God.[46] They may interpret their pain in light of these feelings. Through counseling, they can regain a sense of worth and belonging. As they recast the pain in its true light, its intensity is often diminished.

Cutaneous Techniques

Acupuncture, massage, vibration, and applying cold or heat to the skin over injured areas are often very effective. Cold wraps, ice packs, or cold massage using a cup filled with water that has frozen into a solid piece of ice relieve the pain of muscles that are in spasm from nerve injury. Heat from heating pads, hot wraps, or paraffin treatments can soothe injured joints but should not be used over areas of vascular insufficiency.[47] Transcutaneous electrical nerve stimulation devices are indicated for patients with dermatomal pain, such as postherpetic neuralgia or radiculopathy from spinal cord compression.[48] For optimal effect, a physiatrist or physical therapist familiar with the device should train the patient in its use.

EMLA, a cream containing two topical anesthetics (2.5% lidocaine and 2.5% prilocaine) is used, especially in children, to decrease the pain of superficial cutaneous procedures (eg, venous cannulation or skin anesthesia before lumbar puncture, bone marrow aspiration, or biopsy).[49–51] In adults, it is used before access of implanted vascular access devices or central nervous system ports. To achieve anesthesia, the EMLA cream must be applied 1 to 1.5 hours before the planned procedure in a mound under a semipermeable dressing such as Opsite or Tegaderm.[52,53] When EMLA is used as directed, methemoglobinemia has not been a problem even in infants as young as 3 months old.[54,55] Skin blanching occurs, sometimes exceeding or equaling the frequency of that found with placebo moisturizing cream placed under the occlusive dressing.[53,56] ELA-Max, a cream containing 4% lidocaine, is available over the counter and is an alternative to EMLA cream. Because it does not contain prilocaine, there is no risk of methemoglobinemia.

Lidocaine patches can be used over areas of hyperesthesia, as can occur in patients with postherpetic neuralgia or nerve entrapment by vertebral body collapse.[57] The patch is applied to the affected area for no more than 12 consecutive hours a day and can be cut to size. Use should be avoided over areas of broken skin and in patients undergoing radiation therapy. Extended application of lidocaine patches has been safely applied for up to 24 hours/day for up to 4 days with minimal systemic absorption in healthy volunteers and in postherpetic neuralgia patients.[58]

Radiation Therapy

Radiation therapy is commonly used in the management of painful bone lesions, spinal cord compression, bulky lymphadenopathy, and symptomatic splenomegaly in patients with hematologic malignancies.[59] Radiotherapy is the treatment of choice for local metastatic bone pain in most situations; however, patients with underlying pathologic fractures may require surgical fixation prior to radiotherapy. Randomized trials have shown that single-fraction radiotherapy is as effective as multifraction radiotherapy in relieving pain due to metastases. However, there are higher rates of retreatment, and single-fraction radiotherapy may not prevent pathologic fractures or spinal cord compression.[60] In patients with poor performance status or a short life expectancy, a single dose (8 Gy) of radiation or a hypofractionated course (20 Gy/5 fractions) may be preferable and less burdensome.

Surgery

Surgical intervention is often required in patients with impending or actual pathologic fractures or an unstable spine.[61,62] The patient's functional status and quality of life are important considerations regarding the appropriateness and timeliness of surgical intervention.

Vertebroplasty and Kyphoplasty

Vertebroplasty and kyphoplasty are relatively new surgical techniques used to stabilize vertebral compression fractures and reduce pain. Vertebroplasty is a procedure where bone cement, usually polymethylmethacrylate, is injected into the vertebral body. With kyphoplasty, a balloon is first inserted into the vertebral body, followed by inflation then deflation, before cement is added. Balloon kyphoplasty has been shown to stabilize pathologic vertebral fractures caused by multiple myeloma and to significantly reduce pain.[63,64]

Anesthetic Techniques

Trigger-point injections, nerve blocks, and neurolytic procedures are useful for acute and chronic localized pain. After excisional biopsy of an axillary lymph node, for example, a burning, constricting pain in the posterior arm and chest wall may develop; this pain is often promptly relieved by trigger-point injection.[65,66]

Lymphoma or myeloma may involve the spine and lead to vertebral collapse or pain from progressive disease that is refractory to antineoplastic therapy. Such pain is often particularly difficult to manage. Insertion of temporary or permanent indwelling epidural or intrathecal catheters to deliver opioids, local anesthetic agents, clonidine, or combinations of these and other agents can be very effective, especially in relieving lower thoracic or lumbar spine pain, as well as pelvic and lower extremity pain.[67–69] Those interested in the indications for and techniques of the anesthetic and neurolytic procedures are referred to several reviews.[5,6,70]

PHARMACOTHERAPY

Drugs useful for pain relief include nonopioid analgesics, opioids, and adjuvant analgesics. Most patients require a combination of medications for optimal pain relief (Fig. 94–1).

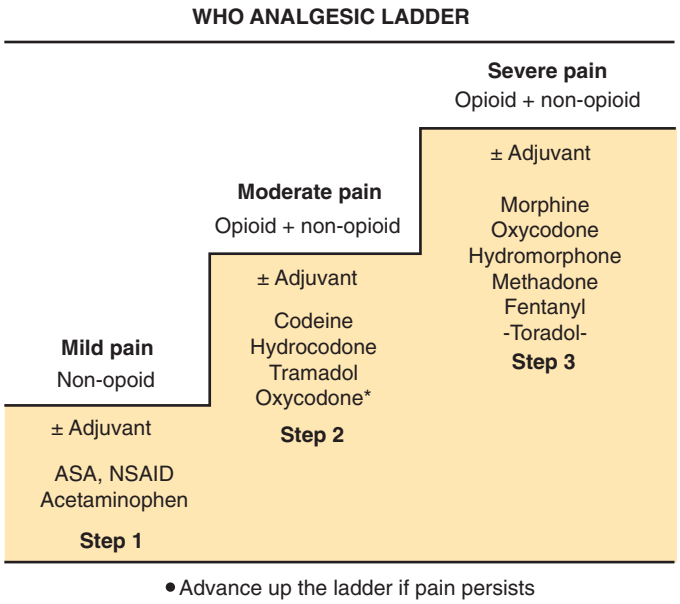

Figure 94–1 Strategy for pharmacologic management of pain using the WHO analgesic ladder. Multiagent therapy is usually required for optimal pain management. Patients with mild pain should be started on a nonopioid analgesic, and those with moderate pain on a step 2 opioid. Many patients can benefit from the addition of a nonopioid to the opioid (eg, for bone pain) or an adjuvant agent to the opioid (eg, for neuropathic pain). If this combination does not produce adequate relief or the patient presents with severe pain, step 3 opioids should be begun initially. Toradol (Ketorolac) is an NSAID with the pain-relieving potency of a step 3 opioid. Many patients can benefit from the addition of nonopioid analgesics or adjuvants, if indicated. ASA, aspirin; NSAID; nonsteroidal antiinflammatory drug.

Nonopioid Analgesics

Nonopioid analgesics should be given to patients with mild to moderate pain. Tramadol, which both weakly inhibits norepinephrine and serotonin reuptake and weakly binds to mu-opioid receptors and has opioid-induced side effects, but is not an opioid, also relieves mild to moderate pain. A dose of 100 mg is more effective than 60 mg of codeine.[71] Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) including COX-2 inhibitors are especially useful as antiinflammatory agents as they decrease local prostaglandin release through the inhibition of cyclooxygenase (though the mechanisms for their analgesic properties are not as clear).[72,73] Acetaminophen is an effective analgesic but only a weak antiinflammatory agent. Higher doses than that used for analgesia may be needed for its antiinflammatory effect. Acetaminophen's weak inhibition of cyclooxygenase may be due to the presence of high concentrations of peroxides found in inflammatory lesions.[74,75] It is important to prescribe an adequate dose of each drug at regular intervals, switching to another nonopioid analgesic only when maximal doses of the first have become ineffective.

Ketorolac tromethamine (Toradol) is an NSAID of particular value in relieving moderate to severe acute bone pain.[76] A dose of 30 mg of ketorolac given intramuscularly equals the pain-relieving potency of 15 mg of morphine intramuscularly, and acute toxicity is minimal if the total daily dose is under 100 mg.[77] Intravenous administration is less painful and equally effective as an intramuscular injection. Ketorolac may also be given orally, although it has a delayed peak response and is considered less potent. However, ketorolac has all the side effects of the NSAIDs and is not recommended for use beyond 5 days.[78] If that degree of pain relief is needed chronically, an opioid agent should be substituted.

Because the NSAIDs can cause renal insufficiency in a significant number of patients, renal function should be assessed 1 or 2 weeks after initiation of any of these agents. NSAIDs should be used with caution in patients with a history of aspirin allergy or asthma because they can precipitate bronchospasm in as many as 20%.[79] Significant edema can occur in patients with cirrhosis or congestive heart failure.[79,80] The relatively selective COX-2 inhibitors, such as etodolac, meloxicam, celecoxib, and nabumetone, should not, and apparently do not, cause gastrointestinal side effects with the same frequency as nonselective NSAIDs.[80] If NSAIDs are required in patients with a history of significant gastritis or ulcer disease or who are older than 70 years, COX-2 inhibitors or concomitant proton-pump inhibitors should be considered.[81,82]

The nonopioid analgesics should be continued in appropriate cases when opioid analgesics are added, because they can potentiate the pain-relieving effect of the opioid (see Fig. 94–1).[83] However, when aspirin or acetaminophen is included in a fixed drug combination (eg, Percodan, Percocet), toxicities may develop if the patient takes the pills more often than the prescription indicates. The metabolism of salicylates is limited by the capacity of the hepatic microsomal system. Once that is saturated, salicylate levels are dependent on renal clearance. Small increases in maintenance doses can lead to serious salicylism.[84] Patients with low albumin levels or acid urine are particularly susceptible to the development of salicylate toxicity.[85] Daily intake of acetaminophen should not exceed 4 g because of the potential hepatic toxicity.

Opioid Analgesics

Patient Education

Opioid analgesics are the mainstay of therapy for moderate to severe pain of malignant or nonmalignant origin. To ensure patient compliance with an opioid prescription, however, education of other members of the health care team, the patient, and the family is often required to dispel the many misconceptions associated with opioid therapy. Even physicians who are cancer specialists may hesitate to prescribe opioids as needed for patients with severe pain.[86]

Fear of addiction is a common cause of inadequate dispensing of opioids[87] and a barrier to their acceptance by patients.[86] The physician can increase compliance by providing a full explanation of the differences between addiction and physical dependence, along with reassurance that research has repeatedly indicated that patients with malignancies who take opioids do not become addicts.[88,89] Patients may also fear that if they take opioid medications for moderate pain, the medications will no longer be effective if more severe pain occurs. Because this fear, if unexpressed, can lead to undertreatment, the topic should be addressed even if the patient does not raise the question. A functional goal of therapy, such as returning to a favorite hobby or reinstituting normal activities of everyday life, may enable the patient and the family to accept the opioid. Misconceptions about religious teachings may prevent health care personnel, patients, and their families from giving or accepting adequate pain medication. Catholics, for example, may not be aware of the Church's position, as stated in the current catechism, that opioids may be used at the approach of death, even if their use ultimately shortens the patient's life.[90,91] The Church does not consider this use of pain medication to be a means of suicide or euthanasia.[92]

Choice of Medication

Because a wide variety of medications is available, pharmacokinetic considerations and side-effect profiles should be considered when choosing opioid agents. Intermittent moderate to severe pain lasting hours to several days is amenable to oral analgesics with short half-lives (3–4 hours) with appropriate potency (eg, immediate-release oxycodone, morphine, hydromorphone [Dilaudid], or oxymorphone (when available)). Severe pain of relatively constant intensity should be treated with oral sustained-release morphine or oxycodone (taken every 8 or 12 hours[93,94]), methadone (taken every 8 hours), or transdermal fentanyl (renewed every 48 to 72 hours). Twelve- to 24-hour

Management of Severe Pain

Opioid therapy is the cornerstone of management of the patient presenting with severe pain. Our practice is to begin with reassurance of patients and their families. We tell them that to relieve the pain as quickly as possible, we will initiate the use of intravenous opioid medications immediately, but that we will begin oral pain medication as soon as the pain is well controlled. Without this explanation, patients have misinterpreted a "morphine drip" as an indication that they were considered terminal. The starting dose is calculated from the patient's baseline opioid requirement (10% of their 24-hour opioid dose) or weight (eg, 0.05 mg/kg/hour of morphine). The patient is monitored continuously and given an opioid bolus dose. If the patient was on standing opioid medication, the medication is continued, when possible, or converted to an intravenous drip, if necessary. Pain is reassessed every 20 minutes after the patient receives a bolus dose. If the pain remains severe (7, 8, or 9/10), the bolus dose is doubled. If the pain has decreased to moderate (4, 5 or 6), another bolus at the same dose as the immediately previous dose is used. If the pain is less than 4, the patient is carefully monitored. At 4 to 8 hours, either a continuous infusion is begun or the ongoing infusion rate is adjusted upward according to the amount of opioid taken as boluses during that period. There is no maximal opioid dose; we give whatever is required to relieve the pain. If the patient falls asleep, this is usually an indication that pain relief has been achieved, not that the dose should be lowered. We lower the dose if the respiratory rate falls to below 10 to 12 breaths per minute.

Agents to prevent side effects are begun along with the opioid. All patients are given a stool softener and an irritant agent such as senna one or two tablets orally daily, up to a maximum of eight pills per day. If a more laxative effect is needed, lactulose (15–30 mL) or polyethylene glycol (17 g) is added. In opioid-naive patients, prochlorperazine [Compazine] (10 mg, taken orally two or three times daily) is ordered as needed to treat the common development of nausea. In patients with bone or nerve pain, appropriate adjuvants are added.

When pain relief is adequate, the patient is converted to an equivalent dose of oral or transdermal opioid. If morphine is used, for example, the patient will need three times the parenteral dose that was effective (see the box on Relative Potencies of Commonly Used Opioids). For example, a patient who requires 10 mg of morphine per hour (ie, 240 mg/24 hours, given intravenously) will need 720 mg/day of the oral sustained-release agent (240 mg × 3). This can be given orally as 360 mg every 12 hours. Two hours after the oral opioid is begun, the drip is discontinued. Short-acting immediate-release morphine should be available for rescue dosing at 10% of the total daily dose. For this patient, 60 to 90 mg is recommended. If the amount of opioid taken as a rescue dose is significant (>25% of the daily dose) for 1 or 2 days, the total dose of long-acting agent is adjusted upward accordingly.

formulations of oral morphine (eg, Kadian, Avinza) are available; for patients unable to take pills, the capsule can be opened and the pellets sprinkled on food or suspended in water and given through a feeding tube[95] (see the boxes on Relative Potencies of Commonly Used Opioids and Choice of Medication).

Practical Considerations When Using Opioids

Although methadone is not a new drug, it is increasingly used for patients with moderate to severe pain. It is by far the least expensive of the opioids[98]; can be given by oral, rectal, intravenous, or epidural routes; and has particular usefulness in patients with neuropathic pain.[99] Methadone is structurally unrelated to morphine and fentanyl and can be used in the rare case of true allergy to these. It is also helpful when patients are suffering from neurotoxic side effects of the high doses of other opioids that are often needed to control severe neuropathic pain. Methadone is an opioid receptor agonist and a presynaptic inhibitor of NMDA.[100] Patients with neuropathic pain and patients on opioids chronically have increased levels of NMDA receptors in the dorsal horn of the spinal cord. NMDA antagonizes the activity of the opiate receptors. Blocking the NMDA receptors therefore enhances the analgesic effect of externally administered opioids. Ketamine, a pure NMDA antagonist, similarly enhances opioid efficacy but is associated with more cognitive side effects than methadone.[9]

Methadone interacts with inducers and inhibitors of the cytochrome P450 system. It is extensively metabolized by CYP1A2, CYP3A4, and CYP2D6; the first two are induced by a number of drugs and other substances (eg, cigarette smoke), and the last enzyme has a genetic polymorphism. Drug levels of desipramine and zidovudine increase when patients are receiving methadone. Drugs that lower the levels of methadone include phenytoin (by 50%), phenobarbital, carbamazepine, rifampicin, and risperidone, each of which has precipitated withdrawal symptoms.[100] Drugs that raise the serum methadone levels include ketoconazole, fluconazole, and the selective serotonin reuptake inhibitors (SSRIs) (except venlafaxine), which raise methadone levels in CYP2D6-positive patients (rapid metabolizers).[99]

Methadone can cause prolongation of the QT interval. A mean methadone dose of 400 mg/day (SD = 283 mg) was found in 17 patients with torsades de pointes.[101] In an evaluation of reports of methadone-related adverse events to the FDA, approximately 1% of the greater than 5000 reports were of QT prolongation or torsades de pointes. The median dose was 345 mg, with a range of 29 to 1680 mg.[102] Drugs that also prolong the QT interval, such as metoclopramide and olanzapine, should be used with caution in patients receiving significant doses of methadone. Gabapentin, the drug used most often as a neuropathic pain adjuvant, does not interact with methadone metabolism.

Other difficulties with using methadone lie in its variable and long biologic half-life and the controversy about its equianalgesic dosing range. Some studies have reported that the equianalgesic dose of morphine to methadone varies as the dose of morphine increases.[103] Dose ratios vary from 4:1 at morphine doses of 30 to 90 mg, to 6:1 at 90 to 300, and to 8:1 at doses of more than 300 mg of morphine. Other studies report a ratio of 20:1 for doses of oral morphine equivalents greater than 1000 mg.[104] Some physicians advise a 3-day conversion to methadone. The first day, the dose of the old opioid is reduced by one-third, and one-third of the calculated dose of methadone is given; the second day, the dose of the remaining opioid is reduced by one-half, and only rescue doses of methadone are given every 4 hours; the third day the old opioid is discontinued, and the standing dose of methadone is adjusted to reflect the rescue doses.[99] When converting patients directly from intravenous fentanyl to intravenous methadone, a conversion ratio of 25 μg/hour of fentanyl to 0.1 mg/hour of methadone has been found in a pilot study to be a safe and effective initial infusion rate.[105]

A new opioid to the US market that is now available in both extended release and immediate release is oxymorphone. Oxymorphone extended release has been found to provide safe and effective pain relief for cancer pain.[106,107] Oxymorphone extended release is dosed twice daily and is approximately twice as potent as oxycodone.[108]

Levorphanol, which is chemically similar to dextromethorphan (an NMDA antagonist and cough suppressant), is a potent opioid that may be considered for patients with severe cancer pain. It was originally synthesized as an alternative to morphine more than 40 years ago. It has a greater potency than morphine, approximately 5 times as potent in its oral formulation. Analgesia is achieved through its agonistic activity at mu, delta, and kappa opioid receptors, as well as by its antagonism of NMDA receptors. Levorphanol can be given orally, intravenously, and subcutaneously.[109]

Buprenorphine has long been used to treat patients with addiction as an alternative to methadone. The new buprenophine patch has been found to be effective in patients with cancer and noncancer pain.[110,111] Postmarketing surveillance has indicated that 81% of patients achieve good or very good pain relief and approximately 50% of patients did not require additional medications for breakthrough pain.

Meperedine is 8 to 10 times less potent than morphine and has a short duration of action, approximately 2 to 3 hours. Normeperidine, an active metabolite that induces dysphoria, is excitatory to the central nervous system and can cause agitation, tremors, myoclonus and seizures, especially in high doses, with prolonged use, or in renal failure.[112] Normeperidine has a half-life of 13 to 24 hours, which can lengthen with renal failure.[113] The seizure incidence is further increased if the opioid antagonist naloxone (Narcan) must be given.[114] Therefore, meperidine is not recommended for chronic use in patients with long-lasting moderate to severe pain.[1]

Routes of Delivery

Opioids can be delivered noninvasively (orally, rectally, transmucosally, or transdermally) or invasively (subcutaneously, intravenously, or by spinal infusion). For patients switched from oral or rectal to parenteral or spinal medication, or vice versa, the dose must be altered accordingly to avoid overdose or undertreatment (see the box on Relative Potencies of Commonly Used Opioids). No matter which route is chosen, patients experiencing continuous pain should receive the analgesics regularly and be awakened, if necessary, to administer medications that will prevent recurrence of the pain.[1]

Oral Route

Most patients can achieve excellent pain relief with short-acting or sustained-release oral opioid preparations. The typical onset of short-acting opioids via the oral route is 45 minutes to an hour, with a typical duration of action of around 3 to 4 hours. When tablets and capsules are not feasible, many liquid forms are available in various concentrations. Some solutions do contain alcohol, which can be irritating to patients with oral lesions.

Rectal Route

Rectal opioids (eg, morphine and hydromorphone) replace subcutaneous or intramuscular injections in patients who are suddenly unable to take oral medications. They have about the same potency and half-life as orally administered agents[115–118] and must therefore be administered frequently. Although not approved by the US Food and Drug Administration (FDA), in single-dose bioavailability studies of sustained-release morphine preparations, despite delayed absorption from the rectal route, total morphine absorption over 24 hours was equivalent, whether the drug was given orally or rectally.[115–118]

Transdermal Route

The transdermal fentanyl patch delivers the lipophilic fentanyl into the fat-containing areas of the skin. The drug diffuses continuously from the patch's reservoir through a rate-controlling membrane and is absorbed from the skin depot into the bloodstream, where it is rapidly metabolized.[119] The onset of pain relief is delayed approximately 12 hours and a relatively constant plasma concentration of fentanyl is not reached until approximately 14 to 20 hours after the initial patch is placed.[119] Liberal rescue medication must therefore be provided during the first 24 hours of use of the patch.[120] Similarly, if a patient develops signs of fentanyl overdose, naloxone (Narcan) must be given until the skin reservoir has become depleted.[121] Approximately 50% of the drug is still present 24 hours after patch removal.[122] Converting patients from oral or parenteral medication to the patch is easily accomplished[123] (see the box on Relative Potencies of Commonly Used Opioids). A new patch is applied every 72 hours, although up to 25% of patients require a new patch every 48 hours.

The transdermal system is an effective method of delivering pain relief for patients with a stable level of chronic moderate to severe pain, no oral route available, or no desire to take pills. Side effects include those due to the contact adhesive, along with those commonly associated with other opioids, but may be better tolerated than those caused by morphine.[122–124]

The transdermal system should not be used in septic patients, those experiencing acute pain, those with markedly fluctuating opioid requirements, cachectic patients, or individuals with significant dermatologic insults (ie, skin grafts-versus-host disease or diffuse varicella). When the patient's temperature rises to 40°C, drug absorption from the skin can increase by as much as 35%.[119] If hepatic function is impaired or sepsis or shock develops and blood flow to the liver decreases, plasma concentrations may rise sharply.[122] Patients with cachexia lack the subcutaneous tissue necessary for formation of a drug reservoir. Lower doses may also be required in elderly patients[125] or in those with respiratory insufficiency.

Transmucosal Route

Oral transmucosal fentanyl citrate (Actiq) induces rapid analgesia with a short duration of affect, and is an effective treatment in the management of breakthrough pain.[126,127] A new commercially available fentanyl buccal tablet (Fentora) employs an effervescent delivery technology to enhance the rate and extent of absorption through the buccal mucosa. It was found to be both efficacious and safe in the treatment of cancer-related breakthrough pain.[128]

Subcutaneous and Intravenous Routes

Continuous subcutaneous or intravenous administration of opioids can provide pain relief in the shortest amount of time, with a minimum of oversedation. The drugs can be delivered by portable infusion pump and initiated or continued in the home.[129–131] Guidelines for their use are available.[132,133] Patient-controlled analgesia (PCA) systems for subcutaneous or intravenous drug delivery have the advantage of responding to the individual patient's threshold for pain while eliminating delays when nurses must administer supplemental medication.[134] The pumps administer a continuous fixed infusion of the opioid chosen and allow the patient to self-administer boluses of additional medication at frequencies chosen by the physician. By recording the additional amounts of self-administered medication, the devices also facilitate the adjustment of the continuous dose required for pain relief.

Spinal Route

Epidural or intrathecal opioid infusions, which include the option of patient-controlled epidural analgesia, can be helpful for select patients.[135] The infused opioids block pain transmission by binding to receptors in the dorsal horn of the spinal cord.[17] Because the drug is being infused in close proximity to the receptors, only a small amount of opioid is needed and the systemic side effects are reduced. Problems with this delivery system in patients who are not opioid naive[136] are listed in Table 94–3. If tolerance to the opioid develops and higher doses are required for relief, the incidence of side effects will approach that of systemically administered opioids. Addition of local anesthetic or alpha-adrenergic agent (eg, clonidine)[137] or other agents[67–69] to the epidural opioid infusion allows for fairly rapid lowering of the opioid concentration and reestablishment of opioid sensitivity.[136,138]

Adjuvant Analgesics

Adjuvant analgesics are a diverse class of medications, which typically have indications for conditions other than pain. They have analgesic properties and are often used when an opioid regimen is unable to

provide sufficient analgesia or is associated with dose-limiting side effects.

Neuropathic Pain

Adjuvant agents are often needed for patients with neuropathic pain. Several classes of medications may be considered for the treatment of neuropathic pain. Anticonvulsants, antidepressants, alpha-2-adrenergic agonists, corticosteroids, topical agents, GABA agonists, and NMDA receptor antagonists have some evidence for the pharmacologic management of neuropathic pain.[139–142] However, the analgesic antidepressants and anticonvulsants are typically preferred for treating neuropathic pain secondary to cancer.[144]

The anticonvulsant gabapentin (Neurontin) has the fewest side effects and is very effective for patients with neuropathic pain from tumor, peripheral neuropathy from tumor or treatment, and postherpetic neuralgia.[139–142] In spite of its name, it has no effect on GABA, but rather binds to the alpha-2-delta subunit of the N-type calcium channels in neurons within the dorsal horn, thus inhibiting calcium influx and diminishing neuronal hyperactivity.[143] To minimize sedation, doses should be low at first (eg, 100 mg three times daily or 300 mg at bedtime) and should be increased as tolerated every 3 to 5 days until analgesia is achieved. The effective dose varies between 900 and 3600 mg daily in divided doses. The pharmacokinetics of gabapentin are unique in that it has a ceiling effect related to a saturable transport mechanism in the gut, such that the effects of this drug may plateau during dose escalation.[144] The most common dose-limiting side effect is sedation. Gabapentin needs to be renally dosed in patients with decreased creatinine clearance. Peripheral edema related to gabapentin may require diuretics. Pregabalin (Lyrica) has the same mechanism of action as gabapentin and has been found to be effective in patients with neuropathic pain.[145,146] Pregabalin can be started at 50 mg BID or TID, with the usual effective dose between 150 and 300 mg BID. Pregabalin is more efficiently absorbed through the gastrointestinal tract and the absorption is proportional to the dose throughout the effective dose range[146] making titration simpler. In addition to the gabapentinoids (gabapentin and pregabalin), there is some evidence for the use of other anticonvulsants (eg, phenytoin, carbamazepine, lamotrigine, topiramate, tiagabine) for neuropathic pain syndromes.[142,144]

Tricyclic antidepressants (eg, amitriptyline, nortriptyline) are effective agents for neuropathic pain.[147] The tricyclics, when used as adjuvant analgesics, are effective faster and at lower doses than when they are used as antidepressants (eg, amitriptyline is effective within 2–3 days at 50–100 mg/day).[147] However, because of their anticholinergic side effects, they should be used with caution in the elderly or in patients who have cardiac conduction abnormalities or bladder outlet obstruction. Selective serotonin and norepinephrine reuptake inhibitors (SSNRIs), for example, venlafaxine and duloxetine, have been shown to be analgesic for a number of neuropathic pain syndromes.[148–152] There is less evidence supporting the use of selective serotonin reuptake inhibitors (SSRIs) for neuropathic pain.

Table 94–3 Adverse Effects from Spinal Infusions: Catheter-Related Effects

Opioid	Anesthetic	Epidural	Subarachnoid
Respiratory depression	Hypotension	Insertion related (eg, hematoma)	Insertion related (eg, hematoma)
Sedation		Fibrosis Skin abscess	Cerebrospinal fluid leak Meningitis

Data from Paice JA, Williams AR: Intraspinal drugs for pain. In McGuire DB, Yarbro CH, Ferrell BR (eds.): Cancer Pain Management, 2nd ed. Boston, Jones & Bartlett, 1995, p 131.

Corticosteroids given epidurally, intravenously, or orally are useful as antineoplastics (eg, in leukemia, lymphoma, and myeloma) and can also provide nonspecific relief for patients with spinal cord compression and plexus infiltrations. Doses of 16 to 100 mg of dexamethasone are needed to reduce vasogenic edema in spinal cord compression,[153] but lesser doses (6–20 mg/day) can be helpful in patients with plexus injuries.[30] Patients must be monitored for the development of oral or esophageal candidiasis and steroid-induced delirium.

Bone Pain

Adjuvants for bone pain include NSAIDs, corticosteroids, bisphosphonates[154,155] and the radiopharmaceuticals, strontium chloride (^{89}Sr)[156] and samarium153-lexidronan.[157] Multiple studies have demonstrated the efficacy of bisphosphonates in reducing skeletal complications and pain from bone metastases.[158–161] Pamidronate and zolendronate are recommended for patients with multiple myeloma and other hematologic malignancies with painful bone lesions.[162,163] However, the long-term use of bisphosphonates is associated with a small but meaningful risk of osteonecrosis of the jaw.[164] The limitations of radiopharmaceuticals include cost and cytopenias.[80] Given the limited evidence available, a recent Cochrane review did not support the use of calcitonin for control of pain from bone metastases.[165]

Management of Opioid-Related Side Effects

Sedation

The addition of 2.5 to 7.5 mg of dextroamphetamine or methylphenidate[166–168] (taken orally twice daily) has been shown to reduce opioid-induced sedation and at times allow for escalation of opioid doses without sedation. These medications also improve cognitive function and symptoms of depression. Methylphenidate may also enhance the analgesic effects of opioids.[168] They should be avoided in patients with anxiety, moderate to severe hypertension, agitation, thyrotoxicosis, tachyarrhythmias, severe angina pectoris, and closed-angle glaucoma. Modafinil (Provigil), a novel psychostimulant with a mechanism of action different than the amphetamine derivatives (approved for narcolepsy and fatigue related to multiple sclerosis), has also been found to be effective for opioid-related sedation.[169]

Constipation

Constipation is the most common opioid-induced side effect.[170] Laxatives should therefore be given routinely, not on an as-needed (PRN) basis,[1,170,171] to patients treated with any of the drugs listed in the box on Relative Potencies of Commonly Used Opioids. Detailed bowel preparation recommendations can be found,[171,172] but no regimen has been studied in a controlled fashion. Commonly used stool softeners and stimulants include docusate sodium, senna, lactulose, and polyethylene glycol. A combination of a stool softener and laxative seems to be a rational choice for patients on chronic opioids, for example, docusate sodium with senna. Promotility agents most directly counter the mechanism of opioid-induced constipation. Continuous subcutaneous or intravenous infusion of metoclopramide (to 60 mg/day)[173] reverses the "opioid bowel syndrome,"[174] enabling patients to continue with oral opioids. Bulk-forming laxatives such as psyllium and methylcellulose should be avoided as they increase stool volume without promoting peristaltic action. For refractory opioid-induced constipation, a trial of oral naloxone, methylnaltrexone, or alvimopan may be initiated.[175,176] These mu-opioid receptor antagonists act locally to reverse the effects of opioids on the gut. There is minimal systemic absorption and subsequently a low risk for precipitating opioid withdrawal or worsening pain with use of these medications.

Nausea

Prochlorperazine (10 mg taken two to three times daily) or metoclopramide (10 mg taken three to four times daily) can prevent the nausea that occurs in most patients during the first days of opioid therapy. Relieving constipation or changing the opioid (eg, from morphine to oxycodone) often eliminates the later development of nausea. Rarely, patients need oral or intravenous ondansetron (8 mg taken two or three times daily).[177]

Insomnia

Antidepressants such as nortriptyline, mirtazapine, and trazodone are preferred sleep medications for patients on opioids. Benzodiazepines (eg, temazepam, 15–30 mg before sleeping) may also be used effectively. These patients should be monitored for daytime somnolence and mental status changes. Barbiturates and chloral hydrate are not good first-line choices, as these drugs can produce excessive daytime sedation.

Respiratory Depression

Naloxone (Narcan), given intravenously, reverses opioid-induced respiratory depression, although repeated doses are often required.[30] Respiratory depression can occur in patients with mild to moderate pain during the initial use of opioids, although it is rare in patients with severe pain or in those chronically receiving opioids. Caution should be exercised before administering naloxone to the patient who is chronically receiving opioids to avoid precipitation of severe pain and withdrawal. In such cases, it is inadvisable to administer the usual 0.4 mg/mL dose; rather, 0.4 mg of naloxone should be diluted with 9 mL of saline and 1 to 2 mL of this dilute mixture given every 2 to 3 minutes until the patient is rousable and breathing at least 10 times/minute. Do not give enough to fully waken the patient or withdrawal is likely to ensue.[1] In a comatose patient, endotracheal tube placement is recommended to prevent aspiration from the salivation and bronchial spasm that will be induced.[1] Naloxone should not be administered to an alert patient.

SPECIFIC CLINICAL PROBLEMS

Oral Complications

Oral complications of chemotherapeutic and marrow transplant regimens can be frequent causes of pain. A thorough dental evaluation and prompt treatment of infections can minimize the discomfort arising from underlying periodontal disease and caries; secondary bacterial, viral, and fungal infections; and mucositis.[178] Preventive regimens include saline, sodium bicarbonate, or chlorhexidine gluconate rinses, acyclovir, antifungals, and ice.[179] Sucralfate,[180] capsaicin,[181] and granulocyte colony-stimulating factor[182] diminish the incidence, duration, and intensity of chemotherapy-induced mucositis. Viscous lidocaine (Xylocaine) or a slurry of sucralfate, dyclonine, or Kaopectate in diphenhydramine provides symptomatic treatment of mucositis pain.[179] For individual lesions, benzocaine in Orabase can be helpful. Milk of magnesia, which dries out the mucosa, is not recommended.[178] The more severe cases, occurring in marrow transplant recipients, usually require infusional opioid therapy, delivered by standard drip or PCA.[183] Pilocarpine (5–7.5 mg three or four times daily 1 hour before meals) reverses xerostomia from neck irradiation[184] and opioids. Sugar-free hard candy is also useful for opioid-induced xerostomia and dysgeusia.

Coagulation Disorders

Patients with inherited or acquired disorders of coagulation may have excessive risks of bleeding if aspirin-containing pain relievers are used.[185,186] If acetaminophen is not effective, these patients may obtain significant relief from the nonacetylated salicylates, such as salsalate (Disalcid) or choline magnesium trisalicylate (Trilisate), which do not prolong the bleeding time.[186–188] Because these agents share aspirin's ability to compete with warfarin for albumin binding,[85] the careful monitoring of patients' coagulation parameters is recommended when these drugs are started or stopped.

Celecoxib, in phase II[189] and two phase III placebo-controlled trials enrolling patients with arthritis,[190] showed no "meaningful" effect on platelet aggregation or thromboxane B_2 levels.

Postherpetic Neuralgia

Postherpetic neuralgia can be a difficult problem for patients with hematologic disorders and has been the subject of several reviews.[139,141,191] Most patients with symptoms for less than 6 months experience spontaneous resolution of pain.[101] For those with long-term symptoms, gabapentin is the agent of choice.[139,140] If the patient cannot tolerate gabapentin or pregabalin, amitriptyline is effective in 60% to 70% of patients.[192,193] Elderly patients, however, often do not tolerate the anticholinergic side effects well. Nortriptyline (Pamelor), a less anticholinergic tricyclic antidepressant, may be useful in these patients. Sustained-release oxycodone or morphine, topical lidocaine gel, or ointment (5% to 10%)[194] and EMLA[195] may also be effective. Topical capsaicin (0.075%), which depletes substance P, has shown efficacy in a multicenter, double-blinded, randomized, placebo-controlled trial.[196] Capsaicin (0.075%) is also used for musculoskeletal discomfort. Transcutaneous electrical nerve stimulation devices provided relief for 1 year in 50% of postherpetic neuralgia patients, and 30% were pain free at 2 years.[48] Patients with severe pain refractory to these therapies may benefit from a combination of intrathecal methylprednisolone and lidocaine. Acute herpes zoster pain may be diminished by a combination of acyclovir and prednisone.[197]

Sickle Cell Anemia

Patients with sickle cell anemia suffer from chronic and episodic pain despite optimal medical therapy.[198] Chronic arthritic pain can be treated with physical therapy and full doses of antiarthritic medication, but some patients require low doses of chronic opioid therapy to maintain independent functioning. Several studies have confirmed the safety and efficacy of long-term opioids in the treatment of pain of nonmalignant origin.[199–202] In some cases, joint replacement may be required.

Sixty percent of sickle cell patients will have an episode of severe pain each year.[198] When a patient with sickle cell anemia experiences a severe episode of pain, it is always important to attempt to define the precise cause of the pain before attributing it to a vasoocclusive crisis. To manage crisis pain, except in patients with renal failure, nonopioid analgesics are used to treat bone pain (see Fig. 94–1). Preliminary studies have shown inhaled nitric oxide to be a potentially effective treatment for acute pain crises.[203]

Treating patients with sickle cell pain is complex and requires understanding that much of the pain in adults with this illness is chronic, with intermittent, recurring painful episodes. In fact, the frequency of painful crises may increase as the patient ages and is subject to progressive damage of bones, joints, and tissues. Uncontrolled pain accounts for more than 90% of hospital admissions in adults with sickle cell disease.[204] Using short-acting analgesics on an as-needed basis exposes the patient to periods of insufficient analgesia, anticipation and anxiety, and may lead to drug-seeking behavior.[199] Thus, intravenous analgesics should be started as a continuous infusion or with patient-controlled pumps.[199,205] Once adequate analgesia is obtained, a long-acting opioid, or a sustained-release opioid, may be initiated with intermittent use of rescue medication. In adult patients with frequent episodes of painful crisis, the use of long-acting opioid medications reduces visits to the emergency department and hospitalizations and shortens the lengths of stay in hospital.[199,206]

Relative Potencies of Commonly Used Opioids

Drug	*Epidural*	*SC/IV (mg)*	*PO (mg)*
Morphine	1	10	30
Codeine		130	200
Oxycodone		N/A	20
Hydromorphone	0.15	1.5	7.5
Methadone*		*	
Oxymorphone		1	10
Levorphanol		2	4
Fentanyl		0.1	N/A
Meperidine (Demerol)**	75		300

*Methadone is approximately half as potent orally as it is intravenously. It is usually not given subcutaneously because of local irritation
**Not recommended for patients with chronic pain

Conversions Between the Transdermal Fentanyl Patch and Morphine

	Morphine (mg/24 hour)	
Fentanyl (µg/hour)	Oral	IM/IV
25	50	17
50	100	33
75	150	50
100	200	67
125	250	83
150	300	100

Using Opioids With Short or Long Half-Lives[96]

Short

"Rescue Doses"
Incident pain, eg, with movement
Breakthrough pain: Pain that recurs between regularly scheduled doses
Dosing: 10% of the total 24-hour opioid dose
For example, rescue dose for patient on 300-mg sustained-release morphine twice a day
300 mg + 300 mg = 600 mg; 10% of 600 mg = 60 mg
Elderly patients
Impaired renal function
Impaired hepatic function

Long (eg, Methadone)

Patients with a history of drug abuse
For basal opioid therapy if not using sustained-release or transdermal opioids

Management of Opioid Side Effects

Adverse Effect	*Management Considerations*
Allergic reaction	True allergic reactions are rare (ie, IgE involvement). Symptoms are usually secondary to mast cell activation and subsequent histamine release. Selection of another opioid class is usually necessary only if the patient has had a true allergic reaction (eg, rash, hives, difficulty breathing) and not simply a sensitivity to histamine release. Opioid Structural Classification: *Phenanthrenes*—codeine, hydrocodone, hydromorphone, levorphanol, morphine, oxycodone, oxymorphone *Phenylpiperidines*—fentanyl, meperidine, sufentanil *Diphenylheptanes*—methadone, propoxyphene
Delirium, confusion, hallucinations	Dose reduction Use different opioid Neuroleptic therapy: Haloperidol 0.5 to 1 mg PO/IV BID-TID *or* Olanzapine 2.5 to 5 mg QD-BID
Constipation	Begin bowel regimen when opioid therapy is initiated. Include a mild stimulant laxative ± stool softener as routine prophylaxis. eg, Senokot 1 to 4 tabs PO QHS-BID ± Colace 100 mg PO BID-TID Consider adding Lactulose or Miralax when necessary. In patients who are NPO, consider metoclopramide 10 mg IV q 6 hours.
Myoclonis	Dose reduction Use different opioid Pharmacologic therapy: Clonazepam 0.25 to 0.5 mg PO TID *or* Baclofen 5 to 10 mg PO TID

Adverse Effect	*Management Considerations*
Nausea/vomiting	Tolerance may develop Antiemetic therapy: fixed schedule for a few days, then PRN dosing Prochlorperazine 10 mg PO q 6 to 8 hours or 25 mg PR q 12 hours *or* Metoclopramide 10 to 40 mg PO/IV q 6 hours *or* Haloperidol 0.5 to 2 mg q 6 to 12 hours *or* Phenergan 6.25 to 12.5 mg PO/IV q 6 hours *or* Scopolamine patch change every 3 days
Pruritus	Pruritus in the absence of evidence of rash/allergic reaction is a central mu-related phenomenon (not histamine) Pharmacologic Treatment: Nubain 5 mg IV q 6 hours prn Consider switching opioids for refractory pruritus.
Respiratory depression	Hold opioid Supportive measures Consider dilute naloxone: Dilute 0.4 mg (1 mL) of naloxone in 9 mL of saline to yield 0.04 mg per mL. Administer to patient in 1- to 2-mL increments (0.04–0.08 mg) at 2- to 3-minute intervals until response. If no change in respiratory depression after 0.4 mg naloxone has been titrated, consider etiologies other than opioid-induced
Sedation	Tolerance typically develops Hold sedatives/anxiolytics Hold opioid Dose reduction; if persistent Consider CNS stimulants (eg, increase caffeine intake, methylphenidate, or dextroamphetamine 2.5 to 5 mg daily, or QAM and at noon).

Meperidine should be avoided in this population and has been associated with seizures in 1% to 12% of these patients.[207]

Patients With Opioid Addiction

A team approach, including the patient's family and drug counselor, maximizes the coordination of care for these patients. Opioid requirements may be significantly higher, and dosing intervals are shorter in the addict.[208,209] In patients on methadone maintenance, therapeutic dosing must be provided over and above their baseline dose.[208] In all cases, the goal should be to deliver adequate medication to relieve the patient's pain. It has been recommended that the physician always work from a written treatment plan, that one physician prescribe all psychotropic medication, that information about the patient's drug use be obtained from additional sources, and that when the question of addiction first arises, consultation be obtained from an addiction medicine specialist.[209] If opioids are needed, patients should be given limited quantities of long-acting or sustained-release medications on a scheduled basis.

Former opioid abusers themselves and the physicians caring for them hesitate to use opioids for pain relief, as they fear inducing a relapse of the addiction.[210] This concern is based on the observation that once a receptor has been habituated to the opioid, it retains its avidity for opioids, even after a long period of abstinence.[208] In addition to those previously described, suggested techniques to minimize these risks include discussion of the individual's concerns and increased involvement by the patients in their recovery programs.[208]

Graft-Versus-Host Disease

For patients who have undergone bone marrow transplantation, graft-versus-host disease (GVHD) can be a significant problem.[211] Of the usual triad of hepatitis, dermatitis, and gastroenteritis, it is the intestinal involvement that usually causes the greatest physical pain. Abdominal cramping and voluminous diarrhea are the hallmarks of bowel GVHD. Treatment often begins with intravenous opioids given through a patient-controlled analgesia pump. Addition of octreotide continuous infusion at 50 to 100 μg/hour or intermittent dosing at 500 μg every 8 hours may be effective in decreasing the volume of diarrhea and level of abdominal pain.[212]

Peripheral Neuropathy Due To Chemotherapy Agents

Several chemotherapy agents used in the treatment of hematologic malignancies can cause painful peripheral neuropathy. The vinca alkaloids, most notably vincristine, are neurotoxic, but they are not always associated with painful neuropathy. Thalidomide, lenalidomide, bortezomib, cisplatinum, oxaliplatin, and paclitaxel are all commonly used agents that carry a significant risk of causing painful peripheral neuropathy. The most common mechanism of neuropathy is damage to the axons starting with the most distal branches. This is the result of chemotherapy's ability to damage DNA replication, leading to apoptosis.[213]

Studies have evaluated numerous agents for prevention of painful peripheral neuropathy, although there have not been any magic bullets. Most of the research has focused on taxane and platinum-based chemotherapy agents. Amifostine and leukemia-inhibitory factor do not prevent neurotoxicity induced by these agents.[213] Magnesium and calcium infusions have been shown to prevent neurotoxic symptoms associated with oxaliplatin without affecting its antitumor activity.[214] Glutathione at doses of 1500 mg/m^2 administered prior to each dose of oxaliplatin for 12 cycles prevented grade 2 to 4 toxicities compared to placebo with no effect on response rate.[215] Vitamin E has been shown to prevent neurotoxicity associated with cisplatin in small open-label evaluations.[216,217] Glutamine 10 g three times daily for 4 days has had positive results as a neuroprotective agent in paclitaxel-treated patients.[218] Acetyl-l-carnitine 1 g three times daily has been reviewed in the treatment of cisplatin- and paclitaxel-induced peripheral neuropathy, although there have been no randomized studies.[219,220]

Treatment of chemotherapy-induced painful peripheral neuropathy includes the usual agents used for patients with neuropathic pain from any etiology (ie, anticonvulsants, tricyclic antidepressants, and occasionally tramadol or opioids). In addition to treating these painful symptoms of neuropathy, the doses of the chemotherapy often require reduction or even discontinuation of therapy.[221]

Problems of the Elderly

Pain management in the elderly is complicated by difficulties in pain assessment and by the altered pharmacokinetics of opioids and of psychotropic adjuvant medications.[222] Elderly patients may underreport pain.[223] Physicians may ascribe observed limitations in social contacts and physical activities to age-related changes when they are pain-induced limitations.[224] Family members can be crucial to the success in managing an elderly patient's pain.

Elderly patients are particularly susceptible to the side effects of NSAIDs and opioids, and patients taking them should be monitored closely.[224] In elderly patients (70 to 89 years old), the volume of distribution for opioids is generally smaller, the drugs have longer plasma half-lives, and renal and hepatic clearances are decreased, all of which can prolong the duration of effect.[224] The effective doses for these patients are one-half to one-fourth of those needed in younger patients.[222,224] Drugs with short half-lives (eg, morphine, oxycodone, hydromorphone) should be used, and initial doses should be low.[224] Patients should be monitored carefully for the development of sedation or confusion, especially if they are receiving antihistaminic agents (eg, famotidine, diphenhydramine), drugs with anticholinergic activity, or hypnotics.

The acute urinary retention due to opioids (especially in patients with prostatic hypertrophy) and the hypotension and tachycardia caused by tricyclic compounds can occur more frequently and be more clinically severe in this population. The starting dose of nortriptyline should be low (usually 10 mg at bedtime), and the dose should be slowly increased as tolerated. Treatment of opioid-related urinary retention may include generic (Proscar) (5 mg daily) in patients with benign prostatic hypertrophy and bethanechol (10–50 mg three times daily) to help increase bladder smooth-muscle tone.

ANTIEMETIC THERAPY

A number of effective antiemetic therapies are used to prevent the nausea and vomiting induced in patients by treatment of their hematologic disorders with chemotherapy or radiation therapy. These antiemetic therapies markedly improve patients' quality of life. The vast majority of patients can expect complete control of vomiting,[225] and most patients also are free of nausea.

PATHOPHYSIOLOGY OF NAUSEA AND VOMITING

Nausea is the subjective sensation that precedes vomiting. It is caused by stimulation of one or more of four sites—the gastrointestinal tract, the vestibular system, the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle, or higher centers in the central nervous system (Fig. 94–2). The gastrointestinal tract can activate the vomiting center by stimulation of mechanoreceptors or chemoreceptors on glossopharyngeal or vagal afferents (cranial nerves IX and X) or by release of serotonin from gut enterochromaffin cells, which in turn stimulates serotonin (5HT3) receptors on vagal afferents. The vestibular system activates the vomiting center when stimulated by motion or disease (eg, labyrinthitis) or when sensitized by medication (eg, opioids). Histamine (H1) and acetylcholine M1 receptors are present on vestibular afferents. Endogenous or exoge-

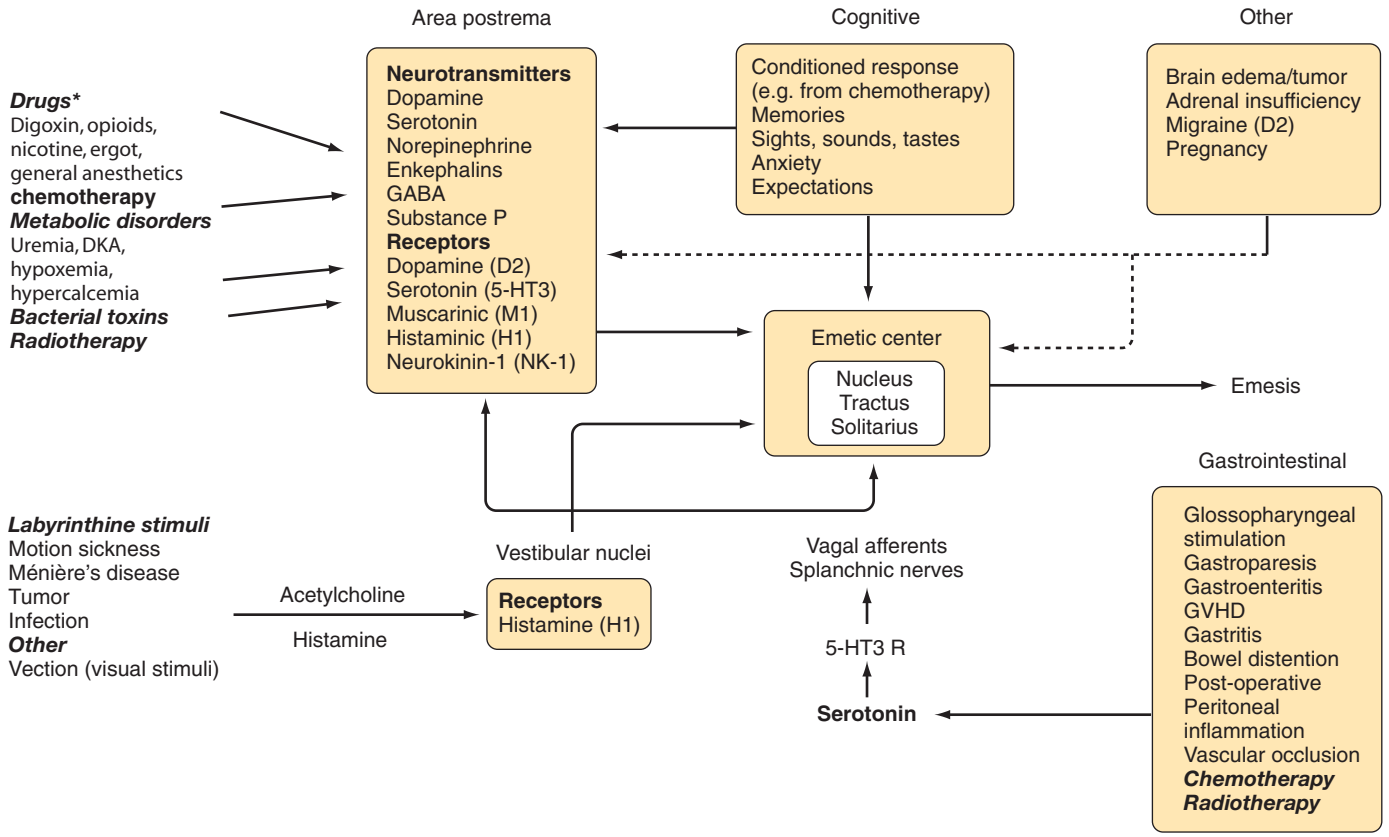

Figure 94–2 Pathophysiology of nausea and vomiting.

nous blood-borne toxins may activate chemoreceptors in the area postrema of the floor of the fourth ventricle via dopamine type 2 receptors. Finally, higher central nervous system centers may activate or inhibit the vomiting center. In addition, there may be direct activation of H1 receptors in the meninges, secondary to increased intracranial pressure.[226]

The means by which chemotherapy agents induce vomiting are still incompletely understood but the most likely mechanism is believed to include stimulation of the chemoreceptor trigger zone. Other causes of nausea and vomiting in the hematologic patient include stimulation of the cerebral cortex, gastritis and GERD, delayed gastric emptying, radiation enteritis, constipation, esophageal candidiasis, inner ear processes, hypoadrenalism, hypercalcemia, changes in taste and smell, and anticipatory nausea.[226,227]

Although the sites of emetic action of the chemotherapeutic agents have not been identified, blocking agents directed against type 3 serotonin receptors (5-HT_3 receptors), dopamine (D_2) receptors, and neurokinin (NK_1) receptors have been effective in inhibiting chemotherapy-induced nausea and vomiting (CINV).[227] Higher centers in the brain, such as the cortex, are also believed to be involved in producing anticipatory nausea and vomiting. Cognitive therapy, as well as antianxiety and amnesic agents, may provide effective antiemesis.

EVALUATION

Risk factors for developing CINV include age less than 60 years, female gender, history of motion sickness, and hyperemesis gravidarum.[228] Patients who have a history of alcohol intake of more than five alcoholic drinks per day (>100 g of alcohol) tend to have less nausea and vomiting. This has been studied carefully in patients receiving high-dose cisplatin therapy[227,229] but has been anecdotally observed in patients receiving other agents.

Anticipatory

Anticipatory nausea and vomiting (ANV) is believed to be a classic conditioned response.[230] Chemotherapy administration (the unconditioned stimulus) results in nausea and vomiting (the unconditioned response). Clinic sights, smells, and sounds are the conditioned stimuli. After frequent pairings of chemotherapy administration and the clinic sights, smells, and sounds, the responses (nausea and vomiting) can be triggered in the absence of any chemotherapy by the clinic sights, smells, or sounds or simply by seeing clinic personnel, even at a location distant from the site of treatment.

Patients who are at risk for developing ANV are those who have already experienced posttreatment nausea and vomiting. The risk of developing ANV increases with the increasing frequency, severity, and duration of the symptoms.[230] Other possible predisposing factors include susceptibility to motion sickness,[231,232] awareness of tastes or odors during infusions, younger age, lengthier infusions, greater autonomic sensitivity, and general anxiety or emotional distress.[230]

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Acute CINV is defined as nausea or vomiting, or both, occurring within 24 hours of administration of the agent. The emetogenic potential of the drugs[233,234] is shown in the box on the Emetic Risks of Chemotherapy. Although most drugs produce emesis 1 to 2 hours after they are given (in patients who have never before received chemotherapy), the onset of emesis from high-dose intravenous cyclophosphamide is delayed until 9 to 18 hours after treatment,[235] and nausea and vomiting from high total doses of cisplatin can occur 24 to 72 hours later.[236]

Combination Antiemetic Regimens

Highly Emetogenic

Prophylactic

5HT3 RA PO/IV 30 minutes before chemotherapy each day for the duration of chemotherapy +
Dexamethasone, 12 to 20 mg PO/IV 30 minutes before chemotherapy each day for the duration of chemotherapy +
Aprepitant, 125 mg PO 1 hour before chemotherapy (use 12-mg dose of dexamethasone)

To prevent or manage delayed nausea and vomiting after chemotherapy

For 2 to 5 days after chemotherapy:
Dexamethasone, 8 mg PO each day
Aprepitant, 80 mg PO each morning on days 2 and 3 (see above)

Moderately Emetogenic

Prophylactic

5HT3 RA PO/IV 30 minutes before chemotherapy ±
Dexamethasone 8 to 12 mg PO/IV 30 minutes before chemotherapy

To prevent or manage delayed nausea and vomiting

Dexamethasone 8 mg PO once daily for days 2 and 3

Low Emetogenic Potential

Dexamethasone 8 mg PO/IV 30 minutes before chemotherapy as needed *or*
Metoclopramide 10 to 20 mg PO/IV 30 minutes before chemotherapy as needed *or*
Compazine10 mg PO/IV 30 minutes before chemotherapy as needed

(From: Kris MG, Hesketh PJ, Sommerfield MR, et al: American Society of Clinical Oncology guideline for antiemetics in oncology: Update 2006. J Clin Oncol 24:2932, 2006.)

Emetic Risks of Chemotherapy

High (>90%)
Carmustine (>250 mg/m^2)
Cisplatin
Cyclophosphamide (>1500 mg/m^2)
Dacarbazine (>500 mg/m^2)
Dactinomycin
Mechlorethamine
Streptozocin
Moderate (30%–90%)
Carboplatin
Cyclophosphamide (<1500 mg/m^2)
Cytarabine (>1 g/m^2)
Doxorubicin
Epirubicin
Idarubicin
Irinotecan
Ifosfamide
Oxaliplatin

Low (10%–30%)
Aldesleukin (IL-2)
Asparaginase
Bortezomib
Cetuximab
Cytarabine (<1 g/m^2)
Docetaxel
Etoposide
Fluorouracil
Gemcitabine
Methotrexate
Mitomycin
Mitoxantrone
Paclitaxel
Pemetrexed
Temozolomide
Topotecan
Thiotepa
Trastuzumab

Minimal (<10%)
Bleomycin
Bevacizumab busulfan
Capecitabine
Fludarabine
Rituximab
Vincristine
Vinblastine
Vinorelbine

THERAPY

Anticipatory Nausea and Vomiting

The best way to prevent ANV is to give aggressive antiemetic therapy and to treat anxiety with the appropriate agents. However, in patients for whom this approach has not been successful and in whom ANV develops, a variety of behavioral techniques have been helpful. These include hypnosis,[237] progressive muscle relaxation with guided imagery,[238] systemic desensitization,[239] and distraction.[240] Results may be optimized if a therapist trained in these techniques works with the patient, but patients can use progressive muscle relaxation with guided imagery on their own.[238]

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Most studies of the potent antiemetic agents have been conducted in patients receiving therapy with cisplatin, a drug of high emetic potential. Although cisplatin is not generally used to treat patients with hematologic malignancies, the data are included in the following discussion, as the findings can probably be extrapolated to other drugs of equivalent or less emetogenic potential. When available, data regarding efficacy in patients receiving radiation therapy or emetogenic drugs commonly used to treat hematologic disorders are reviewed. The choice of antiemetic agents depends on the emetogenic potential of the chemotherapy or radiation therapy regimen, the side-effect profiles of the antiemetic agents, and patient preferences and characteristics.

The emetogenic potentials of commonly used chemotherapeutic agents are outlined in the box on the Emetic Risks of Chemotherapy. Risks of specific side effects help to guide antiemetic choice. Younger patients have a higher incidence of CINV and of metoclopramide-related acute dystonic reactions; trismus or torticollis was seen in only 2% of patients older than 30 years of age but in 27% of younger patients.[241] Even if they are receiving only moderately emetogenic therapy, they should be given an antiemetic regimen; for high-emetogenic drugs.[242] Younger patients find cannabinoids (such as Marinol) more effective than do older patients because they can better tolerate the side effects associated with the therapeutic doses of these agents.[243] Elderly patients also have high risks of extrapyramidal side effects and are more susceptible to anticholinergic and sedating side effects.[242] 5-HT$_3$ receptor antagonists are therefore preferred to regimens containing metoclopramide and diphenhydramine.

5-HT_3-Receptor Antagonists: Ondansetron, Granisetron, and Palonosetron

Ondansetron, granisetron, and palonosetron are the best studied of the 5-HT_3-receptor antagonists (5HT RA). This class also includes the drugs dolasetron and tropisetron. Several studies of patients receiving regimens that included cyclophosphamide, methotrexate, or doxorubicin showed significant efficacy and the superiority of ondansetron over placebo.[244–246] Ondansetron also demonstrates efficacy in patients with emesis (induced by non–cisplatin-containing chemotherapy) that has been refractory to standard antiemetics, with complete control achieved in 50% of these patients.[247,248] When dexamethasone is added, the rate of control is as high as 91%.[249]

Ondansetron effectively prevents nausea and vomiting in patients treated with highly emetogenic agents for acute leukemia,[250,251] for multiple myeloma (ie, high-dose melphalan),[252] or who are being prepared for bone marrow transplantation with cyclophosphamide and total-body irradiation.[253,254] In the transplantation recipients, 83% of patient-days were without any vomiting or retching, and in another 10%, there were no more than two emetic episodes. Ondansetron is also effective in preventing emesis induced by single- or multiple-fraction radiation therapy.[255,256] Ondansetron is as effective as metoclopramide in preventing nausea induced by cisplatin[257–259] or by cyclophosphamide alone or with doxorubicin chemotherapy.[260–262]

Oral granisetron has shown equivalence to ondansetron in studies of patients receiving cisplatin- or carboplatin-based regimens.[225,263,264] In patients receiving moderately emetogenic therapy, oral granisetron with dexamethasone was as effective as intravenous ondansetron and dexamethasone.[265,266] Oral or intravenous granisetron and dexamethasone were effective in a bone marrow transplantation program in which patients were treated with Cytoxan and total body irradiation,[267] and these agents, along with oral prochlorperazine, were also effective in patients undergoing peripheral blood stem cell transplantation for which patients received Cytoxan, VP-16 or thiotepa, and cisplatin.[268]

Palonosetron is a second-generation 5-HT_3 receptor antagonist with higher potency, stronger receptor-binding activity, and longer half-life than the other drugs in this class. Palonosetron 0.25 mg intravenous has been studied in moderately and highly emetogenic chemotherapy. Current guidelines do not designate palonosetron as superior although several subgroup analyses of the registrational noninferiority trials have been reported in which palonosetron was superior. Current studies seek to find palonosetron's place in therapy. Ondansetron and the other 5-HT_3 receptor antagonists have far fewer side effects than high-dose metoclopramide. Reports of extrapyramidal reactions are rare,[269] and sedation, dystonic reactions, akathisia (eg, severe restlessness, "ants in pants" feeling), and tardive dyskinesias do not occur. Patients can develop constipation, mild headache, and elevated levels of transaminases.[225]

The therapy of choice for moderately or highly emetogenic chemotherapy is therefore a 5-HT_3 receptor antagonist plus a corticosteroid (usually dexamethasone).[225]

Corticosteroids

The mechanism of the antiemetic action of corticosteroids remains undefined. Corticosteroids are effective when used alone to prevent emesis induced by agents of moderate or low emetogenic potential.[270–272] They are also a useful component of antiemetic therapy regimens that include ondansetron, granisetron, or metoclopramide and add efficacy in randomized controlled trials.* Dexamethasone and methylprednisolone are the best-studied agents, but no trials have demonstrated the superiority of one corticosteroid over another.

Metoclopramide

Metoclopramide is a substituted benzamide that promotes gastric motility and reduces the emetic activity of chemotherapy agents by blocking dopamine receptors (at low to moderate doses) and 5-HT_3 receptors (at high doses) in the chemoreceptor trigger zone. Owing to a more favorable side-effect profile, $5HT_3$ antagonists have replaced high-dose metoclopramide. At lower doses, metoclopramide is useful in treating mild to moderate and delayed nausea and vomiting. Delivery of the drug on a schedule that maintains adequate levels during expected emesis appears to be important.[225]

The side effects, which may be caused by the interaction of metoclopramide with dopamine receptors, can be quite troublesome. They include akathisia, dystonic reactions (age related), sedation, and diarrhea. Benzodiazepines such as lorazepam can prevent or reverse the akathisia, and diphenhydramine or benztropine can prevent or reverse the dystonias.[274] However, these agents induce additional side effects, including dry mouth and sedation. Short-term, high-dose metoclopramide or the long-term use of the drug has been associated with persistent and disabling movement disorders, especially tardive dyskinesias.[275,276] Metoclopramide finds its role in low-dose (10–20 mg taken two to four times daily) prevention and management of mild to moderate nausea and vomiting.

NK-1 Inhibitors

Substance P can cause emesis,[277] and it appears to play a role in chemotherapy-related nausea and vomiting. Its effects are mediated through NK-1 receptors.[278] Agents that cross the blood–brain barrier and inhibit NK-1 activity (eg, aprepitant) are more effective than granisetron and dexamethasone alone in moderating acute chemotherapy-related nausea and vomiting, and they are particularly effective in decreasing delayed nausea and vomiting occurring after cisplatin chemotherapy.[279] The need for continued dexamethasone with the NK-1 inhibitor has not yet been determined, and comparisons with the metoclopramide and dexamethasone regimen for delayed nausea and vomiting have not yet been performed. Aprepitant is an inhibitor of CYP3A4, and therefore may cause elevation of chemotherapy agents primarily metabolized by this route; however these elevations are not considered clinically significant and there are no recommend dose adjustments. Aprepitant can cause significant decreases in the prolongation of the international normalized ratio induced by warfarin.

*References 225, 263, 264, 266, 268, and 273.

Combination Antiemetic Therapy

For drugs with low or moderately low emetogenic potential, no antiemetic drug, or dexamethasone alone may be sufficient. For drugs with higher emetogenic potential, standard antiemetic treatment usually includes combinations of several antiemetic agents along with agents designed to treat anxiety, cause amnesia, or prevent known side effects. These combinations frequently include a 5-HT_3 receptor antagonist such as ondansetron, a corticosteroid such as dexamethasone, and optional lorazepam for anxiety-related symptoms. For drugs with high emetogenic potential, it is important to give antiemetic therapy for an adequate period before administering chemotherapy agents and to continue to prevent emesis for approximately 24 to 72 hours after the drugs have been given. For highly emetogenic combination chemotherapy with significant incidences of delayed nausea and vomiting, such as cisplatin-containing regimens, aprepitant (NK-1 inhibitor) should be added to the antiemetic combination.[280] Transdermal scopolamine adds efficacy when added to a standard regimen of metoclopramide and dexamethasone.[281]

Benzodiazepines

The benzodiazepine lorazepam has only mild antiemetic activity, when used as a single agent.[274] It is used frequently in the treatment and prevention of nausea and vomiting, in particular when there is anxiety associated with the nausea and vomiting. It markedly decreases the akathisia and anxiety associated with metoclopramide therapy and induces a dose-related memory loss and marked sedation.[274,282,283]

Other Drugs

Other agents that are more active than placebo include the butyrophenones haloperidol and droperidol,[284] the phenothiazine prochlorperazine,[285] and the cannabinoids dronabinol (THC) and nabilone.[225,286,287] These agents are less effective drugs than the agents previously mentioned, and all cause sedation. The butyrophenones produce dystonic reactions, akathisia, and occasionally hypotension. The cannabinoids cause ataxia, dry mouth, orthostatic hypotension and dizziness, euphoria or dysphoria, and a feeling of being "high."[288] Scopolamine, a centrally acting anticholinergic, can be effective for patients with a vertiginous component to their nausea. (see box on Combination Antiemetic Regimens).

Patient preferences regarding degree of alertness can help the health care provider choose an antiemetic regimen, as can the level of anxiety the provider observes in the patient. Some patients do very well with regimens that include no antianxiety agents; others may benefit from the inclusion of those agents, despite the somnolence that accompanies their use.

CHAPTER 95

PALLIATIVE CARE

Janet L. Abrahm and Joanne Wolfe

Palliative care in children and adults is centered on the wishes and goals of patients and their families. Palliative care practitioners require expertise in communication, in treatment of physical symptoms, and in relieving sources of social, psychological, and spiritual distress. Each section of this chapter will first review core elements of palliative care for children and then for adults.

PEDIATRIC PALLIATIVE CARE

I just wish that I had armfuls of time.

—(4-year-old child)[1]

Pediatric palliative care is an emerging frontier in the comprehensive care of children. The recent Institute of Medicine Report *When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families*[2] (Table 95–1) highlights its critical importance. In the last few years, a powerful statement by the American Academy of Pediatrics,[3] the findings of a comprehensive British report on children with life-threatening and terminal conditions,[4] and two earlier Institute of Medicine studies[5,6]—as well as other documentation[7–10]—set the stage for this seminal report. A comprehensive definition is:

> *Palliative care for children and young people with life-limiting conditions is an active and total approach to care, embracing physical, emotional, social, and spiritual elements. It focuses on enhancement of quality of life for the child and support for the family and includes the management of distressing symptoms, provision for respite, and care through death and bereavement.*[4]

As this field develops, there is much debate about the terms *life-limiting* and *life-threatening*. Life-threatening is a broader concept, in that it includes illnesses for which cure is possible, although the threat of a fatal outcome exists (eg, childhood malignancies). Of course, an illness may begin as life-threatening and convert into a life-limiting condition, as when a child relapses and curative options no longer exist. Life-limiting conditions are those for which there is no reasonable chance of cure from the outset; even if children survive for years and decades, they will not live out a normal life expectancy.

In addition to end-of-life care for the child (and bereavement follow-up for the family), pediatric palliative care includes care throughout the trajectory of the child's illness, including respite as an important component. This is one major difference from traditional adult cancer-based end-of-life care. Other differences from adult palliative care include:[4,11]

- Smaller numbers of dying children than adults mean that there is less professional expertise and underrepresentation of children in palliative care protocols.
- The heterogeneity of illnesses, many rare, requires the involvement of many disciplines and specialists.
- Many children have genetic diseases so there may be more than one affected child in a family.
- The time course of some illnesses is extremely variable. Pediatric palliative care may extend over years, even decades.
- A broad developmental spectrum is represented, including changes in the individual child through time.
- The underlying principles and ethics of palliative care are universal across the life span. However, as in all specialties, children bring with them unique issues and dilemmas.

A child or adolescent diagnosed with a life-threatening or life-limiting illness throws an assumed sequence out of order. A time of role reversal is expected, when children will care for dying parents. When parents instead find themselves watching their child face death, a sense of tragic absurdity prevails. Not only is time shortened, but its order is shattered. A child or adolescent with a life-threatening illness represents a premature separation to the family. Even before the child has become a differentiated individual through a natural developmental sequence, that child is wrenched away. There is little preparation for separation by death when a psychological separation has not yet been effected. The adolescent who is beginning to negotiate an independent existence is often the hardest to face when that "moving forward" is irreversibly halted, or at least disrupted. A child has not even had the time to begin to form life goals.[12]

The necessity for palliative care—the concept and the clinical approach—may emerge at different points in the illness trajectory, depending on the prognosis for the child, the decisions that must be made in choosing treatment options, and always, the management of pain and suffering in the provision of optimal quality of life. One of the foremost goals is to initiate palliative care for children earlier in the illness trajectory—in a proactive manner—so that effective care planning can be implemented. Care of the family, with a particular focus on the young siblings, is a priority.

COMMUNICATION

Good communication can dispel fears of abandonment. Breaking bad news and discussing prognosis with patients with advanced disease are occasions when physicians can demonstrate their commitment to an ongoing partnership with patients and families. Conversations must demonstrate respect for cultural differences[13–15] and the conviction that growth can occur even at the end of life.[16] If done well, the groundwork will be laid for further discussions of patient hopes and fears, goals, values, and spiritual concerns that form the basis of decisions about resuscitation and artificial life support.[17]

Communication with a child . . .

When I first heard my diagnosis, one question kept going around and around in my head: "How long do I have, Doc?"

—(12-year-old child)[1]

Children with serious hematologic disorders have usually lived with the illness over a prolonged period of months or years. Their knowledge, understanding, and awareness of their precarious life situation are often profound, at physical, cognitive, and emotional levels.

Table 95–1 Summary of the Institute of Medicine Report: When Children Die: Improving Palliative and End-of-Life Care for Children and Their Families

Improve Organization and Delivery of Care
Emphasis is placed on the development of care guidelines and protocols in all pediatric settings, the development of regional information programs and resources in rural areas, and policies and procedures for involving children in decision making.
Reform Financing of Palliative Services and Hospice Care
Vast changes in public and private health coverage: add hospice, change eligibility rules, provide outlier payments, extend coverage for counseling family members and for bereavement follow-up.
Better Prepare Health Professionals
Create educational experiences and curricula that will provide basic and advanced competence in palliative, end-of-life, and bereavement care.
Strengthen Research Base for Effective Care
Emphases include appropriate quality-of-life measures, effective symptom management, impact of perinatal death on parents and siblings, impact of sudden death on family and professional caregivers, efficacy of bereavement interventions, models for provision of care, financing alternatives, effective strategies for educating professionals.

From Institute of Medicine: When Children Die: Improving Palliative and End-of-Life Care for Children and their Families. Washington, DC, National Academy Press, 2003.

The doctors think my bone marrow is fine for now—and for now is for now.

—(8-year-old child)[12]

The protective stance of the past stated that disclosure to the child of his or her prognosis (and even, in some instances, the diagnosis) would cause increased anxiety and fear. Since the 1980s, however, a shift toward open communication has been evident.[18] To shield the child from the truth may only heighten anxiety and cause the child to feel isolated, lonely, and unsure of whom to trust.

In communication with the life-threatened child at any juncture in the illness, "The truth is not a principle nor a duty nor a rule. The truth is an atmosphere of exchange, of listening, and of respect for the child and his needs. The truth is a state."[19] The precedent for a climate that enables such honest interchange is created from the time of diagnosis. The individual child's competence and vulnerability serve as the context for decisions regarding disclosure at any point in the illness trajectory. Considerations about what, or how much to tell, include the child's age, cognitive and emotional maturity, family structure and functioning, cultural background, and history of loss.[1] These same factors determine at the end-of-life, with extreme sensitivity to how the parents have chosen to inform the child throughout the illness experience, how the child has understood and processed information up to this time, and what the child is now asking—implicitly and explicitly—about his or her situation.

BREAKING BAD NEWS

Table 95–2 contains an outline of the suggested steps to take when breaking bad news.[20–22] For adult patients with advanced disease, the goal is to establish or strengthen trust and reassure them that the physician is committed to caring for them. To do this well, physicians need to believe that they have not failed the dying patient, medicine has.

PROGNOSIS AND DECISION MAKING

Surveys of bereaved parents indicate that physician communication about prognosis is not optimal.[23] At the same time, emerging data suggest that bereaved parents consider high-quality communication as the top value when reflecting on physician quality of care.[24] Parents value clear information that is communicated sensitively, and inclusive of the child, when developmentally appropriate. When it comes to discussing prognosis, a majority of parents want as much information as possible.[25] Furthermore, although many parents find prognostic information about their child upsetting, they still want prognosis to be discussed. The data suggest, however, that parents are overly optimistic about the child's chances of cure in comparison to physicians, and this is especially true when the prognosis is uncertain.[26] Being aware of these trends may help physicians to discuss prognosis with greater clarity.

Table 95–2 Breaking Bad News

1. Make yourself, the patient, and the family comfortable.
2. Find out what they know.
3. Indicate that you are planning to tell them something that is unpleasant and may be disturbing.
4. Find out whether they want to be told, or whether they want someone else to be told.
5. Find out how much they want to know (ie, the big picture versus all the details).
6. Tell them in words they can understand, allowing time for questions along the way.
7. Respond to their feelings.
8. Let them know that this is only the first of many discussions with you.
9. Ask them to summarize what they heard you say; ask if they have further questions.
10. Arrange your next meeting with them.

Data from Abrahm JL: Update in palliative medicine and end-of-life care. Annu Rev Med 54:53, 2003.

One side of my head says: "Think optimistic." The other side says: "What if this treatment doesn't work?"

—(11-year-old-child)[1]

The child is often aware of the diminishing curative or life-prolonging options that he or she faces. It is at this time that the child may ask anxiously: "What if this medicine doesn't work? What will you give me next?" The child experiences a profound sense of loss of control. It is at this time that families are confronted by a series of decisions regarding the nature and intensity of medical interventions they wish to pursue. This process can be excruciating: they do not want their child to suffer more, yet they often cannot tolerate the thought of "leaving any stone unturned" in the quest for a cure or prolonged time, however minuscule the chance. The physician and team's role shifts from leadership in recommending a curative treatment plan to the clarification of experimental and palliative options and consequences. In most instances, the parents make the decision; however, to varying degrees, the child may be involved in such discussions.[1,12,27] Hinds and colleagues have demonstrated that when asked in a sensitive manner, children as young as 10 years of age are able and willing to talk about their experiences and end-of-life decisions.[27]

During the last decade, there has been increased recognition of the child's participation in making treatment decisions. Crucial to this process is an assessment of the child or adolescent's ability to appreciate the nature and consequences of a specific medical decision. This becomes particularly complex when the wishes of the child differ from those of the parents. Because actual assessment tools are only in the early stages of development[28,29] professionals must rely exclusively on their clinical judgment to assess children's understanding of

the contingencies they are facing. This is often a juncture when input from members of the interdisciplinary team can be crucial: children often express their understanding, awareness, and thoughts about treatment options and living or dying to individuals other than their parents or primary physician.

The following example illustrates the remarkable capacity of a young child to address the transition to palliative care.

A 7-year-old girl told her parents that she was too tired to fight anymore, and that she wanted to give up. She added: "If I have to continue suffering, I would rather be in heaven." These statements were major determinants in the parents' choosing a palliative care plan without any further attempts at life-prolonging treatment. She went home on hospice care and died peacefully several weeks later.[1]

ADULT PATIENTS

Adult patients and families want to be prepared. The vast majority (80%–98%) want to be able to name someone to make decisions, know what to expect about their physical condition, have financial affairs in order, know that the doctor is comfortable talking about death and dying, feel that the family are prepared for their death, have funeral arrangements in place, and have treatment preferences in writing.[30] For this to happen, physicians must tell patients how long they are likely to have left to live. Because prognoses are shrouded in uncertainty, however, the natural tendency is to avoid the discussion altogether.[31]

Physicians may assume that patients who want to know their prognosis (or their caregivers) will raise the subject with them. There are no data, however, on how often patients with advanced refractory disease ask about their prognosis. Sometimes patients fail to report unrelieved pain[32] or their preferences about resuscitation.[33]

There are significant benefits from having a discussion of prognosis with a relatively asymptomatic patient with a limited time left to live and his or her caregivers. Patient preferences for resuscitation are affected by the likely outcome of treatment, especially bad functional or cognitive outcomes,[34] and by his or her understanding of their prognosis. Caregivers, similarly, are usually unaware that the patient is incurable or that he or she would benefit from hospice care until they hear it directly from their physician.[35] For them to choose, therefore, physicians must provide the most accurate data they can. It is equally important that patients with very poor prognoses understand how limited they really are. Patients who thought they had a greater than 10% chance of surviving 6 months, for example, usually wanted to be resuscitated. Patients who thought they had a less than 10% chance of surviving 6 months overwhelmingly chose comfort care and did not want to be resuscitated.[36]

What should be the approach, however, for patients too sedated to participate in the discussion? When decisions need to be made about continued support or allowing natural death, should their sedation be lessened in hopes they could take part in the conversation? Several authors have suggested that if a patient has a terminal, irreversible illness, waking would likely involve physical, psychological, and spiritual suffering, and the patient or surrogate has clearly stated the wish to allow natural death in these circumstances, the patient need not be awakened before life-sustaining treatment is withdrawn.[37,38] All agree that the decision should be reached through a joint decision-making process with the family, surrogate decision maker, and medical team and relevant others (social workers, chaplains who knew the patient). The focus then changes to intensive comfort care for the patient and the family with special attention to spiritual needs, cultural values, privacy, and physical comfort.[39]

Cultural Considerations

Consensus evidence and case series suggest that communication difficulties may be avoided if physicians and nurses explore with patients and families both the context and the structure of discussions about end-of-life care.[40] African Americans and non-Hispanic whites differ in who they want present (extended family, friends, and pastor versus immediate family only), focus and tempo of the discussion (spiritual concerns, lack of trust, concerns about DNR orders and hospice, allowing adequate time for decisions and not feeling pressure to make them vs concerns about prognosis, irreversibility of the illness, quality of life, financial concerns, and medical choices),[41,42] and having durable power of attorney or living will in place (more common in non-Hispanic whites),[40,42,43] or knowing about hospice programs.[43] More patients not of non-Hispanic white or African American descent prefer to have surrogates informed of their prognosis and make treatment decisions for them. Some patients from Asian, Bosnian, or Italian American cultures may perceive the frank communication of a serious illness or prognosis as "at a minimum, disrespectful, and more significantly, inhumane."[40] In addition to culture, "Patients' functional and cognitive abilities, age, racial and ethnic backgrounds, and desire to avoid burdening loved ones may influence attitudes and definitions of autonomy."[44] To respond to the vast cultural and spiritual variation in disclosure, decision making, and "quality living," clinicians should query into the *preferences* of patients and families before confronting them with bad news and critical decisions regarding end-of-life care, and remain sensitive to their changing needs and preferences by adopting a case-by-case approach. It is important to determine from the patient whether he or his designees, therefore, are to be involved in these discussions, and to respect that choice as the exercise of that patient's autonomy. To ensure such clear communication, therefore, every effort should be made to provide a qualified translator in conversations about prognosis and goals of care where the clinician is not a fluent speaker of the patient's language.[40]

Impact on Hope

The rigors of treatment regimens and the physical and emotional demands of the complex care required for advanced disease tend to isolate patients and their families and focus all their hopes on disease remission. They may have forgotten how to hope for anything else. Physicians and the teams they work with can help patients with advanced hematologic diseases develop new kinds of hope by encouraging them to reintegrate into activities that were meaningful before their disease began and they rearranged their lives around treatment schedules. Most patients hope for time to say their good-byes, to bring closure to their lives, and to leave their legacies: videotapes, scrapbooks, letters, DVDs, and presents for children or grandchildren for events far into the future.

As disease progresses, despite ongoing treatment, patients who have begun to reengage in nontreatment-related activities and who have developed a broader relationship with their physicians are more likely to understand that the physician is not abandoning them when he or she says that the goals of treatment should be comfort. Such patients do not complain that stopping treatment is "waiting around to die" because they have other activities to fill their days.

CAREGIVERS

Families and other nonprofessional caregivers provide the vast majority of care for patients with advanced cancer, which is thought to be worth the equivalent of more than $250 billion a year.[45] Caregivers of patients with advanced illness are stressed by the patient's disability and degree of suffering, the lack of coordination of care, and underlying family, work, or financial pressures.[46] Increased stress occurs at transition points, such as placing patients in a nursing home or deciding to change the focus of care to intensive comfort or, when necessary, to withdraw life-sustaining technology.[46] Caregiving can take a physical and psychological toll on the caregivers, with increased prevalence of depression, decrease in self-care and preventive care, and perhaps increased mortality. For caregivers of cancer patients,

Caregiver Support

Sources of caregiver stress
- Patient disability
- Degree of patient suffering
- Lack of coordination of care
- Underlying family, work, or financial pressures
- Periods of increased stress
- Symptom exacerbation

Transitions
- Moving patient to a nursing home
- Changing the focus of care to intensive comfort

Consequences of caregiver stress
- Depression
- Decrease in self- and preventive care
- Fatigue
- Increased mortality (data equivocal)

Supportive measures
- Decreasing patient suffering
- Management of symptoms and other sources of distress

Decrease/share care burden
- Hospice home health aides
- Hospice volunteers
- Friends and family members
- Availability for questions

Education
- Safety and use of medications (especially opioids)
- Anticipated potential emergencies
- Dying process

Skill building
- Physical care
- Transfers

Counseling
- Mental health providers
- Chaplains

fears of addiction and side effects of pain medications and the presence of unrelieved pain are associated with increased rates of depression. Caregiver satisfaction and quality of life are improved when caregivers are able to have questions answered. Providing information and increasing coping skills can improve caregiver knowledge and skill but even providing respite care has not lessened the sense of burden or depression.[46] As many as 32% of caregivers either have a major psychiatric condition (panic disorder, major depression, posttraumatic stress disorder, or generalized anxiety disorder) or access mental health services after the patients' diagnosis.[45] Caregivers are likely to need the support of many members of the team, therefore, to continue in their difficult role.

RELIEF OF SUFFERING

Suffering includes physical, psychological, social, and spiritual dimensions.

Symptom Management in Children

Therapist: If you could choose one word to describe the time since your diagnosis, what would it be?

Child: PAIN.[1]

Maintaining patient comfort is a critical issue throughout treatment, as well as during the end stages of life. Although effective pain control is a hallmark of palliative care, pain is only one of many distressing symptoms.[8,10,11] The spectrum of physical symptoms includes (although it is not limited to) dyspnea, fatigue, seizures, loss of appetite, nausea and vomiting, constipation, and diarrhea. Several comprehensive studies,[47–49] in which bereaved parents were interviewed regarding their children's end-of-life care, indicated that optimal symptom management is still far from being achieved, even in major pediatric teaching centers. Liben[11] presents a succinct overview of symptom management in pediatric palliative care. Relief of a child's end-of-life distress may have long-lasting implications for bereaved parents, who are negatively affected by the child's experience of pain years beyond their child's death.[49]

Psychological symptoms such as depression and anxiety are also prevalent in children at the end of life.[47] Hinds and colleagues have shown that children also experience existential concerns.[50] Creating opportunity for communication around these sources of distress involves using creative strategies that incorporate the developmental stage of the child. Strategies may involve verbal communication using open-ended questions, such as "What are you hoping for?" and "What are you worried about?"[51] However, many children communicate best through nonverbal means such as through artwork and music. Children may be more willing to "talk things over" with puppets or stuffed animals rather than real people. Importantly, euphemistic expressions about death can be confusing or even frightening (for instance, equating death with sleep may result in the child's being afraid of going to bed) and should be avoided.

Needless to say, parents of children with life-limiting conditions also experience distressing symptoms such as anxiety, depression, and spiritual concerns.[52,53] Recognition by the pediatric clinician may serve families well while the child is alive and during bereavement.

Symptom Management in Adults

Pain and antiemetic therapy for adults is reviewed elsewhere in this volume. Anxiety, depression, delirium, and control of symptoms occurring in the last days of life are reviewed subsequently. Interested readers are referred to other references for reviews of assessment and management of other common troubling symptoms and syndromes in adults (eg, PTSD, substance abuse, major psychiatric illnesses, personality disorders, or demoralization).[54–59]

Among social sources of distress are financial concerns and, with increasing debility, the loss of roles in the community, the workplace, and even in the family.[60] Worries about burdening the family or that the family will fail them when they really need them may lead patients to request physician-assisted suicide.[61,62] Social workers are the key team members who can help alleviate or at least ameliorate these sources of distress and can help the caregivers cope.

Physicians should also explore religious and spiritual concerns and understand what rituals will be important at the end of life. For these patients "spiritual distress and spiritual crisis occur when individuals are unable to find sources of meaning, hope, love, peace, comfort, strength and connection in life or when conflict occurs between their beliefs and what is happening in their life".[63] Patients who use "positive" religious coping (eg, prayer, feeling a sense of connectedness to a religious community, having a positive relationship with God) have been found to have better mental health status, growth with stress and in the spiritual dimension, as well as a better overall quality of life.[64] Patients who use "negative" religious coping (eg, ascribe their illness to a punishing God or one who has abandoned them) have a poorer quality of life. Clinicians should therefore include either a formal or informal[63] spiritual assessment for all patients diagnosed with life-limiting diseases.[63–67] Psychological, spiritual, or religious counseling may be needed to help these patients reconnect and find what they have lost.

PSYCHOLOGICAL CONCERNS

As Dr Susan Block states in her 2006 review of psychological issues in end-of-life care, "Grief, sadness, despair, fear, anxiety, loss and loneliness are present, at times, for nearly all patients facing the end of their lives."[58] For patients to cope with the diagnosis and its implications, they need "good communication and trust among patient, family, and clinical team, the ability to share fears and concerns, as well as meticulous attention to physical comfort and psychological and spiritual concerns."[58] For a thorough discussion of the patient assessment, which includes "developmental issues; meaning and impact of illness; coping style; impact on sense of self; relationships; stressors; spiritual resources; economic circumstances; physician-patient relationship,"[58] please refer to Dr Block's review.[58]

Anxiety and Depression

It is noteworthy that the psychological states of depression and anxiety are often not recognized as symptoms in children and, in many instances, are inadequately addressed. Significant anxiety is found in approximately 25% of adult patients with cancer.[58] Patients with panic disorders, agitated depression, phobias, obsessive–compulsive disorder, delirium, posttraumatic stress disorder, or with adjustment disorders can all present with anxiety.[58] Anxiety in dying patients may arise from worries about the future (uncontrolled symptoms, family concerns or concerns about death); isolation from loved ones; sepsis; hypoxia; metabolic abnormalities; withdrawal from alcohol,[68] opioids, or benzodiazepines; drug reactions (eg, akathisia from metoclopramide, phenothiazines, and butyrophenones); paradoxical agitation from benzodiazepines and olanzapine;[69,70] and uncontrolled pain). Nonpharmacologic treatments, such as relaxation training, hypnosis, supportive psychotherapy, and counseling, are very effective.[54] Pharmacologic treatments usually include benzodiazepines (eg, the short-acting lorazepam 0.5–2 mg every 2 hours as needed or long-acting clonazepam 0.5 mg PO three times daily), selective serotonin reuptake inhibitors (see later in this section), and, when there is evidence of delirium, neuroleptics (see in Delirium). A Cochrane review, however, did not feel there was adequate systematic evidence for the effectiveness of pharmacologic therapy of anxiety in patients at the end of life.[71]

At least 7% of patients with advanced cancer meet criteria for a major depressive disorder, 41% of whom had a previous history of major depressive disorder.[72] It can be difficult to discern which patients with advanced disease are depressed or grieving. The usual somatic signs of depression or grief (eg, anorexia, sleep disturbances, fatigue, or weight loss) are common in this population. Depressed patients, however, will be anhedonic, and feel worthless, guilty, hopeless, or helpless.[73] Grieving patients, in contrast, are very sad, but they are able to find happiness in some circumstances and can plan for the future.[58] Pain, a past or family history of substance abuse, depression, or bipolar illness are major risk factors for depression.[58] Terminally ill patients responding "Yes" to the screening question "Are you depressed?" are very likely to be confirmed as depressed in a more comprehensive evaluation.[58,74] Useful follow-up questions include "How do you see your future?" "What do you imagine is ahead for yourself with this illness?" "What aspects of your life do you feel most proud of, most troubled by?"[73]

As part of the treatment of depression, pain must be brought under control.[73] Counseling can explore patient fears, provide emotional support, help patients review their lives, and find the meaning and areas of accomplishment in them. A variety of models of therapy are used and none has been shown to be superior over the others.[58] The psychostimulants dextroamphetamine and methylphenidate (2.5–5 mg, 8 AM and noon; maximum dose 60–90 mg daily) often act within a few days.[75] The selective serotonin uptake inhibitors (SSRIs) are the first choice when immediate onset is not needed because they usually take several weeks to show effect. Useful agents include citalopram (Celexa) and paroxetine (Paxil) (10 mg PO daily initially; maximum 60 mg PO daily); escitalopram (Lexapro) (10 mg PO daily initially, maximum 20 mg PO daily); sertraline (Zoloft) (50 mg PO daily initially, maximum 200 mg PO daily); fluoxetine (5 to 10 mg PO daily initially, maximum 60 mg PO daily); venlafaxine (Effexor) (37.5 mg PO twice daily initially, maximum 225 mg PO daily) inhibits norepinephrine, serotonin, and dopamine reuptake. Major side effects of the SSRIs include hyponatremia, sexual dysfunction or loss of libido, and gastrointestinal complaints (eg, nausea, diarrhea, and foul-smelling flatus). Modafinil may also be an effective adjuvant agent to reduce SSRI-related sedation.[76] The exact mechanism of action of mirtazapine (Remeron) (15 mg PO at bedtime initially; maximum 45 mg PO at bedtime) is unknown.

If the patient is expected to live longer than weeks to a few months, a stimulant and an SSRI should be started simultaneously, and the stimulant can be titrated off several weeks later. Tricyclic antidepressants are less useful in these patients because of their side-effect profile.

If the patient does not respond to first-line agents, a psychiatrist should be consulted. Referral to a psychiatrist is also necessary when the physician is unsure of the diagnosis; the patient is psychotic, confused or delirious; the patient previously had a major psychiatric disorder; the patient is suicidal or requesting assisted suicide; or there are dysfunctional family dynamics.[73]

Delirium

Delirium occurs in up to 80% of dying patients.[77] Delirious patients can be agitated or hypoactive or vacillate between the two.[78] Symptoms of delirium include insomnia and daytime somnolence, nightmares, restlessness or agitation, irritability, distractibility, hypersensitivity to light and sound, anxiety, difficulty in concentrating or marshaling thoughts, fleeting illusions, hallucinations and delusions, emotional lability, attention deficits, and memory disturbances.[79]

Validated delirium screening and severity tools are available,[80] but a comprehensive psychiatric evaluation is recommended to exclude other disorders, such as anxiety, minor depression, anger, dementia, or psychosis.[78] The cause of delirium is determined in approximately 43% of cases,[81] and it is often multifactorial.[81,82] Medications, especially opioids, NSAIDs, and high-dose corticosteroids, often contribute.[81,82] Opioid-induced CNS toxicities are more common in patients with renal dysfunction, on high doses of opioids for long periods of time, with impaired cognition before starting the opioids, with dehydration, or taking other psychoactive drugs.[83] Other causes include metabolic abnormalities (hypercalcemia, hyperglycemia, or uremia), malnutrition, dehydration, hypoxia, fever, infection, uncontrolled pain, hepatic failure, primary brain tumor, and brain metastases.[79,81]

Treatment for delirium should begin while the underlying cause(s) are being treated. In addition to the medications listed in Table 95–3, it is helpful to make the patient's surroundings as familiar as possible, restore aids to hearing and sight if they are needed, reorient the patient frequently, and have family members, friends, or well-known caregivers present.

MANAGEMENT CONCERNS DURING THE LAST DAYS OF LIFE

For some families, there is the possibility of planning ahead and choosing a setting for their child's death-home, hospice, or hospital. The child may express a preference about where he or she feels safe, or prefers to be. Clear information about how the child is likely to die and professional support to validate the family's choice are crucial. Even more important is the explicitly stated "permission" from all members of the professional team that the family may change their choice freely at any time—that all options remain open and that no decision is irrevocable. Although in the current zeitgeist, there is

Table 95–3 Delirium

Drug	Dose	Comment
Antipsychotics		
Haloperidol	0.5–5 mg PO, IM, SC, IV*	Do not exceed 20 mg in 24 hours
	Repeat q 2–12 hours as needed	Maintain the patient on the effective dose (divided into a bid dose) then taper over 2 weeks, as tolerated
Quetiapine	25–250 mg PO tid	Particularly useful in elderly patients with evening delirium Start 25 mg h.s. for 3–4 days
Olanzapine	2.5–15 mg PO qd	Start 2.5–5 mg PO bid (2.5 mg for elderly); also antiemetic
Risperidone	0.5–3 mg PO bid	Start 1 mg PO bid (0.5 mg in elderly)
Chlorpromazine	25–50 mg PO/IV/PR q 6–8 hours	Sedating; in very agitated patients, may give q 1 hour until sedated
Sedatives		
Lorazepam	0.5–2 mg PO, SL, IV q 1–4 hours	Add to haloperidol for patients with an agitated delirium Tablets can be used PR for terminal delirium.
Diazepam	10–30 mg PO, PR qd	Useful PR for patients unable to take oral medication
Clonazepam	0.5–2 mg PO bid–tid	Tablets have been used PR for terminal delirium; do not exceed 20 mg/24 hours
Midazolam	30–100 mg IV, SC over 24 hours	IV drip or SC infusion for terminal delirium

*Oral doses are half as potent as parenteral doses.

strong advocacy for children to die at home, professionals must bear in mind that for some children and families, the hospital is a better option, and that choice must be respected. In the past, siblings were rarely included in these discussions, and were often inadequately prepared for the eventuality of a child dying at home. It is only recently that their voices are beginning to be heard.

The Dying Child

Therapist: Are you in any pain? Does anything hurt?
Child: My heart.
Therapist: Your heart?
Child: My heart is broken. . . . I miss everybody.[84]

The distillation of anticipatory grief to its essence marks the imminence of death. At times imperceptibly, at other times dramatically, the child who has been living with the illness is transformed into a dying child.

The end point of the terminal phase is often marked by a turning inward on the part of the child, a pulling back from the external world. Cognitive and emotional horizons narrow, as all energy is needed simply for physical survival. A generalized irritability is not uncommon. The child may talk very little, and may even retreat from physical contact. Although such withdrawal is not universal, a certain degree of quietness is almost always evident. The child is pulling into himself or herself, not away from others. This behavior is a normal and expectable precursor to death—a form of preparation for the ultimate separation that lies ahead.[1]

Adults

Physical symptoms that occur in the last week to days before an adult's death include the following: pain, 70%; noisy or moist breathing, restlessness/agitation/delirium, 60%; urinary incontinence or retention, 50%; dyspnea, 20%; and nausea and vomiting, 10%.[54] Patients may also experience fatigue. Hunger and thirst are unusual.[85] Treatments for problems at the end of life are reviewed in Table 95–4.

HOSPICE PROGRAMS

In the United States, most hospice care takes place in the home, although patients can be admitted to nursing homes for brief periods (usually 5 days) to provide a respite for the family caregivers, or to the hospital (usually for up to 14 days) if symptoms cannot be controlled at home. The Medicare Hospice Benefit does not require a do not resuscitate (DNR) status, but does requires that the attending physician and the hospice medical director certify that the patient has a prognosis of 6 months or less to live, if the disease follows its usual course.[86] Medicare reimburses hospice programs approximately $130 per day per patient to provide the routine care described in Table 95–5. Therefore, the cost of transfusions typically required for many patients with hematologic malignancies, even at the end of life, may make it difficult for hospice programs to enroll patients insured by Medicare alone. Other insurance programs, thankfully, often will allow their patients to receive transfusions and hospice care. Early referral to hospice can decrease the risk of major depressive disorder and better quality of survival.[87] Notably, many children are not referred to hospice because their illness experience is inconsistent with hospice specifications—prognosis is uncertain; there is a blending of goals, which can result in more costly health care; and providers' lack of pediatric expertise. In a survey of 632 pediatric oncologists, Fowler and colleagues demonstrated that continued disease-directed therapy was cited as the most common reason for not making a referral, especially when the hospice did not admit children receiving chemotherapy.[88] Thus, despite the availability of this medical benefit adults and children are often left without the intensive support needed to receive end-of-life care in the home.

BEREAVEMENT

Bereavement follow-up by the professional team is an intrinsic component of comprehensive pediatric palliative care. Bereaved families often express the sentiment of a double loss: loss of their child and loss of their professional "family"—the treatment team whom they have known and trusted, often over months and years.[2,89] Parental grief has been recognized as more intense and longer-lasting than other types of grief.[90] Contact from a team member after the child's death not only assuages the family's sense of abandonment; it can

Table 95–4 Treatment of Problems at the End of Life

Problem	Agent(s)	Routes, Doses	Comment
Baseline pain	Morphine, hydromorphone, oxycodone SL oral concentrates, SQ infusions	Scheduled Individualized	
	Fentanyl	Transdermal, individualized	
Breakthrough pain "Death rattle"	Concentrated oxycodone or morphine solutions	Individualized	Intermittent
	Scopolamine	Gel; Transderm Scop patch 1–3 q 3 days	
	Hyoscyamine	0.125–0.25 SL tid to qid	
	Glycopyrrolate	0.1–0.2 mg IV tid to qid	
Delirium	Haloperidol	2–4 mg PO, PR or 1–2 mg SQ, IV q 1–2 hours	
	Olanzapine	2.5–10 mg PO bid, Start 2.5 mg for elderly	
	Chlorpromazine	25–50 mg PO, IV, PR q 4–8 hours	
	Midazolam	2–3 mg IV load; 0.5–1 mg/hour initial	Palliative sedation
	Pentobarbital	3 mg/kg IV load; 1–3 mg/kg/hour IV drip 120–200 mg PR q 4 hours	Palliative sedation
Dyspnea (anxiety)	Lorazepam	1 mg PO, SL, IV q 2 hours	
Dyspnea (other)	Morphine/oxycodone	5–10 mg SL oral concentrate q 2 hours	
	Morphine	2–3 mg IV q 2 hours	
	Chlorpromazine	25–50 mg PO, IV, PR q 4–12 hours	
Nausea	Combinations of lorazepam, metoclopramide, dexamethasone, and/or haloperidol as indicated	Compounded suppositories with desired agents (depending on presumed cause of nausea) PR q 6 hours	
Anxiety	Lorazepam	1 mg PO, SL, IV q 2 hours

Transportation when medically necessary for changes in level of care (ie, inpatient or "respite" in nursing home)

serve a crucial preventive role by identifying families at particular risk and identifying resources for them.[91]

Each bereaved person's loss is unique, but many people manifest similar symptoms of grief, some of which become less persistent as they rebuild their lives.[92,93] Recurrent intense symptoms typically occur at the anniversary of the death of the patient, but can occur at unpredictable times, induced by reminders of the deceased. Just as in the patients described above, survivors' grief must be differentiated from depression. Survivors appreciate calls or letters from the patient's physician and nurses.[94] For patients enrolled in hospice, a formal bereavement program is offered for the family throughout the first year after the patient's death. After the formal program ends, the bereaved are welcome to continue to participate in any bereavement activities that have been meaningful to them.

At the time of death, survivors may seem numb, confused, or dazed, and experience disbelief.[94,95] By the second month after the death, yearning has replaced disbelief.[87] During the next months, disbelief, depressed mood, and yearning decline gradually, and by 6 months after the death, most people will have accepted the reality of the death and begin to think about reengaging in relationships and work, and discover new meaning and purpose.[87] By a year or two, most survivors have accommodated to their loss.[87,92] They become aware of the changes that must be made if they are to resume old relationships and responsibilities or to establish new ones and risk recurrent loss.[92]

Approximately 10% to 20% of survivors, however, suffer either from depression or from a symptom complex called "complicated grief." Patients with depression manifest "symptoms of sadness, impassivity, and psychomotor retardation"[87] but they are not yearning for the deceased or unable to accept the death. Depressed survivors benefit from counseling and consideration of pharmacologic treatment.[87,96] Patients with Prolonged Grief Disorder, in contrast, have grief that causes serious functional impairments, with profound yearning for the deceased as well as feelings of "numbness, feeling that part of oneself has died, assuming symptoms of the deceased, disbelief, or bitterness."[87,97] Such patients are at increased risk of medical and psychiatric illness[98] and should be referred for psychiatric or spiritual counseling. Persons at higher risk for this disorder include those with a history of attachment disorders (childhood abuse, childhood separation anxiety), aversion to lifestyle changes, being unprepared for the death and unsupported after it. Additional risks include a "dependent, close, confiding" relationship with the deceased.[87] Unfortunately, although there is no randomized controlled trial of a pharmacotherapy that is effective for the extreme grief symptoms,[87,97] there is a novel effective psychotherapy developed specifically for this disorder that is superior to standard interpersonal psychotherapy.[99]

INTERDISCIPLINARY TREATMENT TEAM

Thank you for giving me aliveness.

—(6-year-old child)[1]

Palliative care demands the combined expertise of an interdisciplinary treatment team to address medical, psychological, social, and spiritual

concerns of the child, siblings, parents, and close family. This knowledge-based expertise must be provided within a context of ongoing accessibility and availability to the family, granting them a sense of the team's abiding presence.

Yet, even while providing this steady care for the patient and family, professional caregivers are often experiencing their own distress in a sort of parallel process.[1,2,12,89,100] The professional often feels anguish and helplessness in witnessing a child endure pain and suffering—physical or psychic. He or she often identifies with the parents of the child. This reaction intensifies when the caregiver is also a parent, especially if his or her healthy child is of the same age as the patient. For the caregiver who does not yet have children, the specter of a fatally ill child may loom threateningly. In a survey,[89] staff cited the personal pain of losing a child as the most difficult experience in their work with dying children.

For all these reasons, the professionals who engage in this extraordinarily rich and demanding work articulate significant needs for support themselves.[2,89] Otherwise, the toll of cumulative unresolved grief exacts a heavy toll in their personal and professional lives. A cohesive team and/or the opportunity for individual and group consultation are crucial for those who are intimately engaged in repeated cycles of attachment and loss with dying children and their families.

CHAPTER 96

INDWELLING ACCESS DEVICES

Douglas E. Brandoff and Janet L. Abrahm

Indwelling devices that permit chronic access to the venous and central nervous systems have permitted novel and more comfortable forms of treatment for children and adults. Indwelling central venous access devices are useful for patients who require frequent withdrawal of blood specimens or administration of blood or blood products, peripheral stem cell apheresis, parenteral nutrition, or infusional therapy with medications such as chemotherapeutic agents, deferoxamine, amphotericin, or pain medications. These devices also facilitate therapies in the outpatient and home settings. Similarly, through the use of indwelling epidural or intrathecal catheters and Ommaya reservoirs, prolonged access to the cerebrospinal fluid (CSF) may be obtained for the delivery of chemotherapy, antibiotics, antifungal agents, or pain medications. The choice of the appropriate device and application of careful maintenance procedures can minimize the associated complications and maximize the patient's quality of life. As therapies continue to become more intensive, maintenance of adequate, reliable venous access is a critical issue for the management of many patients with hematologic diseases. Since 1973, when the Broviac catheter was first introduced, the sizes and uses of indwelling central venous access devices (CVADs) have expanded dramatically. It is estimated that more than 5 million CVADs are placed in patients in the United States every year.[1]

INDWELLING CENTRAL VENOUS ACCESS DEVICES

Chronic venous access devices can minimize the physical and psychological discomforts of repeated venipuncture; prevent venous thrombosis, phlebitis, and vesicant infiltration; maintain patient mobility; and minimize hospital stays. Certain patients with hematologic diseases are at increased risk for the development of thrombophlebitis from standard (peripheral) intravenous lines and may therefore be best served by an indwelling access device. Factors associated with this increased risk include age of the patient (>60 years); certain characteristics of the solutions being infused (eg, hypertonicity of the solution, irritating diluents such as alcohol, highly acidic or alkaline pH, particulate matter in the solution); type of drugs infused (vesicant chemotherapy, certain antibiotics, dexamethasone, furosemide, phenytoin); factors associated with the catheter itself and its insertion (size and composition, traumatic insertion, microbial contamination); and duration of infusion (85% of cases of phlebitis occur 24 to 48 hours after placement of the intravenous line).[2–6] Because patients with these risk factors or with visibly poor peripheral venous access can usually be identified before therapy begins, early placement of an indwelling device is reasonable. To minimize the occurrence of septic episodes, the devices should be placed before the administration of agents that induce neutropenia.[7–9] With platelet transfusions, catheters and ports can be safely placed surgically or radiologically in patients whose thrombocytopenia (platelet count <50,000/mm^3) is caused by conditions other than disseminated intravascular coagulation.[9,10]

DEVICE TYPES

Catheters

In all indwelling catheters used for prolonged central venous access, the proximal capped portion of the catheter exits from a subcutaneous tunnel on the chest or abdominal wall while the distal tip is indwelling in a central vein (Fig. 96–1).[11] All catheters are composed of radiopaque elastomeric hydrogel, polyurethane, or silicone elastomer but differ in types of opening and internal diameter.[12] Catheter design varies among manufacturers with some catheters having end openings at the distal tip, others having side openings, and some having end and side openings.[13]

Catheters with a simple opening at the distal tip include those placed at the bedside (ie, midline catheters and peripherally inserted central catheters [PICCs]) and the tunneled Hickman, Broviac, and apheresis catheters, which are surgically inserted. Hickman catheters can have single, double, or triple lumens and have an anchoring cuff in subcutaneous tissue. Broviac catheters have a smaller internal lumen diameter than Hickman catheters. Midline catheters, which do not extend into the veins beyond the arm itself, come in 28 to 16 gauges and are 3 to 8 inches long with single or double lumens. Their use is restricted to nonirritating and nearly isoosmotic therapies, and has fallen increasingly out of favor.[6,12,14,15] The PICCs, which terminate in the superior vena cava, vary in size from 1.9 French (Fr) to 6 Fr for the single-lumen catheters and 3 Fr to 7 Fr for double-lumen catheters, and they are 15 to 27 inches long.[12,14,16,17] The tunneled catheters range from 2.7 Fr to 12.5 Fr and are 29.5 to 42.7 inches long.[12] For apheresis (eg, for peripheral stem cell harvest, for preoperative exchange transfusions or vasoocclusive crisis in patients with sickle cell disease[18]), 8.4 Fr to 13.5 Fr catheters are available and are 5.4 to 18 inches long.[12,19]

Valved catheters (eg, Groshong, PASV) are available in a variety of internal diameters and are designed to prevent the reflux of blood into the catheter tip. The valve allows the catheter to be flushed with saline solution rather than heparin. The PASV has a pressure-sensitive valve at the proximal end, and the Groshong three-position slit valve is adjacent to a closed distal tip. The valve remains closed at rest but opens outward for infusion when positive pressure is applied and opens inward for aspiration when negative pressure is applied.[20] Valved catheters are also available as peripherally inserted devices.

For patients requiring multiple simultaneous therapies, nutritional support or infusional therapy along with blood sampling and blood product administration, all the previously mentioned catheters are available with double lumens, and there is a triple-lumen tunneled catheter available.[12,21] Double-lumen devices have 1.3-mm internal diameters or 1.0-mm and 1.6-mm internal diameters; those with triple lumens have 1.0-mm, 1.0-mm, and 1.25-mm internal diameters.

Implantable Central Venous Devices (Ports)

In the United States, more than 200,000 ports are implanted annually and their use is increasing.[22] Totally implantable central venous access devices consist of single- or dual-lumen ports that may be round, square, oval, or hexagonal[12] and are connected to a radiopaque silicone elastomer or polyurethane catheter (Fig. 96–2).[11,12] Ports are also available in low profile (less depth) designs. The port includes a self-sealing silicone septum with a body of plastic or metal, both of which can cause an artifact on magnetic resonance imaging (MRI).[12] The artifact effect is greater with stainless steel than with plastic. Many ports now available are marketed as being MRI compatible.

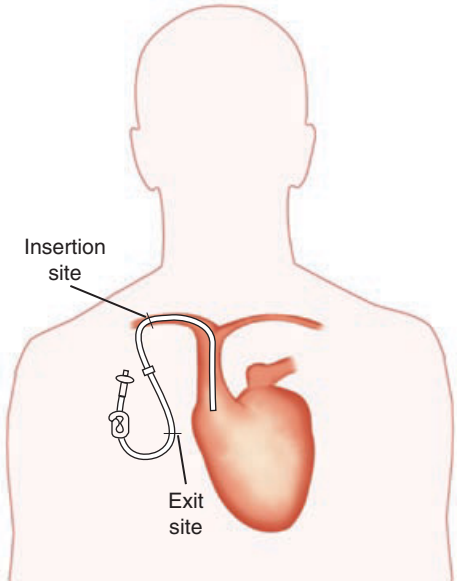

Figure 96–1 Schematic diagram of an indwelling central venous catheter in place. *Insertion site* refers to the insertion of the proximal end of the catheter into the chest wall. Clamp attached to the catheter is shown next to the Luer-Lok cap at the distal end. *(Adapted from Hickman Subcutaneous Port, Use and Maintenance, and How to Care for Your Hickman or Broviac Catheter. Cranston, RI, Davol Inc.)*

No portion exits onto the chest wall. This port is surgically placed in a subcutaneous pocket, and the catheter is inserted into a central vein. The single or double port is connected to a standard or valved catheter. Attached catheters range from 4 Fr to 12 Fr and from 19.7 to 34.5 inches long.[12] Ports are available as one- or two-piece systems. The position of the distal tip of the two-piece system is more easily adjusted during insertion as it can be shortened at the port pocket before connection to the reservoir. However, with the two-piece system there is the potential for disconnection of the port from the catheter with resultant infiltration into the port pocket.

The Vortex port is designed with a tangential rather than perpendicular outlet tube to promote more efficient and thorough flushing of the port chamber. This design appears to inhibit buildup of thrombus or drug residuals in the port chamber, resulting in fewer complications than those associated with traditional ports.[22] The OmegaPort allows access from multiple angles rather than at 90 degrees only.[23] The CathLink port is designed with a series of panels with centrally located openings replacing its silicone septum and without a reservoir. The CathLink is accessed by standard 20-gauge over-the-needle peripheral intravenous catheters.[9]

Ports that can be placed in the antecubital fossa are also available (eg, the PAS).[8,12,24–26] The peripherally implanted ports are smaller and flatter than the standard port and have 3 Fr to 7 Fr catheters.

Other implantable devices have self-contained pumps. These devices and guidelines for their use are discussed elsewhere.[27–30]

DEVICE CHOICE

Patient characteristics and preference, as well as the duration of use, purposes for which the device is required, and relative complication rates all aid in deciding among the types of catheters and in choosing between catheters and ports (Table 96–1).[6,8,11,21,31–37]

Patient Characteristics and Preference

The peripheral devices are helpful in patients with chest wall abnormalities that preclude the use of centrally placed catheters or ports (eg, subcutaneous carcinoma of the chest wall, open wounds, tracheostomies, or fibrosis induced by radiation therapy).[9,21]

Valved catheters that do not require heparin for maintenance are particularly appropriate for patients with known heparin allergy, for

those who develop heparin-induced thrombocytopenia (HIT) from heparin flushes, and in whom continuation of a CVAD is desirable. Although rare, HIT from catheter flushes alone has been documented with heparin flush doses as low as 60 units per day.[38] Valved catheters require somewhat less care than standard catheters and may be preferred for patients unable to care for a Hickman or Broviac catheter at home.[20,39,40]

Children and adolescents have lower risks of complications with ports than with catheters.[33] Four prospective, nonrandomized studies indicated a significantly lower complication rate for the ports than for the catheters, especially in the youngest children.[31,33,41] Implantable devices have several advantages for children in particular: they are cosmetically acceptable, cause less limitation of activities, are at less risk of accidental dislodgment or damage, and require less care when not in active use.[42] Ports also have a lower rate of infectious complications in adult patients.[1,43–45] Ports are also useful for adult patients who are unable to care for a catheter or who do not wish to do so, and for those who prefer a less visible access device.

Port systems are less successful in patients with hematologic malignancies as there is an increased risk for developing any type of complication (eg, infection, thrombosis). Ports are also less successful when placed outside the cervical or infraclavicular areas; this may be caused by factors such as tendencies for groin infections or catheter thrombosis in low-flow vessels.[46]

In obese patients and in patients with thrombocytopenia, the subcutaneous location of the ports poses a problem. In the obese patient, it may be difficult to access a port placed deep in the antecubital fossa or chest wall. Needle stability may also be an issue for obese patients. If the needle length is not sufficient, it may be displaced or lifted out of the port by shifting flesh (ie, if the patient lies on the affected side). For the patient with chronic thrombocytopenia (platelet count <20,000/mm^3), neither type of port may be satisfactory because of the risk of hematoma associated with the recurrent needle punctures required for access.

For hemophiliac patients, consensus recommendations for central venous access devices (CVAD) have been published to help guide clinicians in patient selection. Ports are recommended both for patients with and without inhibitors, in part to minimize infectious risks. CVADs can be advantageous for small children requiring frequent factor infusions; to facilitate home-based treatment and/or prophylaxis; rapid and reliable response to a spontaneous bleeds or for administration of immune tolerance therapy.[47]

For sickle cell patients requiring chronic apheresis red cell exchange, reported experiences have been limited but poor with permanent access devices such as Vortex ports and double/dual ports. They have proven unable to accommodate the flow rates required by apheresis machines.[48]

Duration of Use

Because a surgical procedure is not needed, midline catheters and PICCs are useful for patients needing only short-term access, usually several weeks to months. The average PICC is in place for 2 to 10 weeks, but they have functioned for more than 300 days.[6,16,49,50] In patients needing a longer duration of infusion and more extensive supportive care, surgically placed catheters and ports are generally preferred. Catheters and ports have remained in place safely for months to years.[51,52] Most ports remain in place until the patient dies. Of 707 ports studied in an oncology population, 72.4% were still in place at the patient death (2 to 1960 days), and only 13.5% were removed at the end of therapy.[46]

There are significant differences in costs among the different types and methods of insertion (ie, peripherally inserted versus radiologically placed versus surgical placement).[15] Although the initial installation cost is greater for the ports than for the tunneled or nontunneled catheters, the replacement and maintenance costs of the catheter make it more expensive after 6 months of use.[33–35] The peripherally placed port is even more cost-effective than a standard port because it does not require fluoroscopy, an operating room, or a physician for placement; physician assistants can place them safely.[12,53–55]

Purpose for which the Device is Required

PICCs are used for antifungal therapy, hyperalimentation, or infusion of chemotherapy regimens that may include vesicant agents.[14,40,56,57] Their smaller bore makes them less useful for blood drawing or transfusion. Contraindications to PICCs include ipsilateral local cellulitis, thrombophlebitis, conditions that affect venous return (eg, lymphedema, previous axillary node dissection, hypercoagulopathy).[15,58] Peripheral ports are not recommended when fluids or blood products must be given rapidly, because the flow rate may be significantly less than that of standard central lines or ports placed in the chest.[55] They have only a single lumen and therefore have limited usefulness for complex multidrug therapies or simultaneous infusions. The smaller septum also tolerates fewer punctures (100 to 500 versus up to 4000), depending on the needle size.[14,59]

In general, surgically implanted catheters are more useful than ports or PICCs in patients in whom frequent access to the device or frequent blood drawing or blood product administration is needed.[8] The larger-bore catheters are more useful for blood drawing and blood product administration, because the incidence of clotting after such use is lower with them than with smaller-bore devices.[51] If a port or a PICC is chosen, the catheter with the largest bore is recommended. In the larger-gauge PICCs, which collapse easily, blood drawing is usually more successful if a syringe is used instead of a vacuum tube collection system.[56]

Continuous vesicant infusion may be more safely accomplished with catheters, as they avoid the danger of needle dislodgment and disconnection of the catheter from the septum associated with the implanted ports.

For support during autologous or allogeneic bone marrow transplantation, double- or triple-lumen catheters are used.[60,61] In transplantation patients undergoing peripheral stem cell apheresis, silicone apheresis or the largest-bore standard catheters is preferred, because the internal diameter of the smaller catheters may not support the apheresis procedure.[62] The complication rates for the large-bore catheters in transplantation recipients are similar to those of other central venous catheters used for pheresis or transplantation, or both.[63]

RELATIVE COMPLICATION RATES

Midline catheters are associated with lower rates of phlebitis than short peripheral catheters and with lower infection rates and lower costs than PICCs or tunneled catheters.[6] PICCs cause more phlebitis than tunneled catheters, and earlier reports indicated that the infection rates associated with their use were also higher than those for

tunneled catheters. Some studies, however, suggest that the infection rates may be the same for PICCs and tunneled catheters.[6,9] One prospective study of 351 oncology patients found a relatively high complication rate with PICCs; 33% of catheters were removed because of complications, including infection, thrombus, phlebitis, occlusion, leakage or broken catheter, and accidental removal.[64]

Conflicting data have been reported regarding the relative complication rates seen with tunneled catheters and ports, although the overall complication rate is probably less for the ports than for the catheters. Five of six prospective, randomized trials and all retrospective studies, including one cohort study and one matched study, found significantly higher rates of complications with tunneled catheters than with ports.[6,8,65,66] Only catheter occlusion is no more likely with catheters than with ports.[8] Patients with ports also reported fewer restrictions in activity and hygiene.[65] In one study, PASV ports had fewer instances of poor blood return and less nursing access time compared to nonvalved devices.[67]

In HIV-infected patients, retrospective studies demonstrate that catheters[68–70] appear to cause more infectious complications than ports (0.47 to 0.97 cases per 100 days versus 0.17 to 0.39 cases per 100 days).[70,71] Patients receiving infusional ganciclovir through catheters for cytomegalovirus retinitis who had neutrophil counts of less than 1000/mm^3 were at particular risk for early septicemia.[70]

Hemophiliacs have higher infection rates than the oncology population for external and implanted venous access devices (71% versus 41%). Hemophilia patients with fully implanted CVADs were 31% as likely to develop an infection as those with external devices.[47] The presence of inhibitors seems to increase the infection rate, though the incidence of infection in inhibitor patients with ports was only 33% of that with external catheters.[47,72–74] There has been debate over potential bleeding risks into a port pocket, with associated infectious risk, versus ample risk reduction with newer recombinant hemostatic regimens such as activated prothrombin complex concentrate or rFVIIa. Given these considerations, this meta-analysis supported the use of fully implantable ports for hemophiliacs with inhibitors.[47]

Sickle cell patients may also have higher complication rates of sepsis and thrombosis than the oncology patient. This may be due to the hypercoagulable state and frequent admissions with resultant antibiotic resistant colonization.[75] Because of a high rate of complications (0.4 cases per 100 patient-days in this small study), one institution has discontinued the use of implanted ports in its sickle cell population.[76]

In children with cancer, one observational study showed risk factors for central venous catheter (CVC)-related complications included having a hematologic malignancy Risk Ratio (RR 3.0) and being younger than 6 years of age at time of insertion (RR 2.5). Single-lumen Hickman/Broviac catheters had fewer complications and greatest catheter survival, compared to double-lumen catheters or PASV.[77]

Choice of Device

We recommend indwelling venous access devices based on patient characteristics and preference, anticipated duration of use, purpose(s) for which the device is required, and relative complication rates among catheters and ports.

PICCs are an appropriate choice when patients have chest wall problems, have outpatient-based treatments, and/or have thrombocytopenia. PICCs can be selected when duration of use will be 3 months or less. They allow for vesicant infusions, antifungal therapies, and hyperalimentation.

Peripheral ports are appropriate for patients with chest wall problems receiving outpatient-based treatments. They may be used longer than PICCs, but not longer than 6 months.

Tunneled catheters may be chosen for patients with thrombocytopenia who require frequent access, rapid infusion, or administration of vesicants. Valved catheters that do not require heparin are useful for patients who should not receive it. Like peripheral ports, they may be used for up to 6 months.

Ports are appropriate for outpatients, particularly children or adolescents, but they may be problematic in patients who are obese, especially if they are thrombocytopenic. They are used for rapid infusions and administration of vesicants, and, if they have more than one lumen, hyperalimentation. They allow for the longest duration of use of the various devices (>6 months).

DEVICE INSERTION

Catheters

Catheters can be inserted nonsurgically or surgically. Midline catheters and PICCs are placed nonsurgically in the hospital or in the home by appropriately trained physicians, nurses, or physician assistants.[12,40,56] Insertion failure can occur in 8% to 22% of attempts, although the failure rate decreases with experience.[16] After careful skin preparation using a sterile technique (and for large-gauge introducers, local anesthesia), the catheter is inserted 1 to 2 inches above or below the antecubital fossa into the basilic, cephalic, or median cubital vein. PICC catheters are advanced into the superior vena cava (or, less frequently, the axillary, innominate, or subclavian vein) and secured by sutures or sterile tape. Placement above the antecubital fossa is more acceptable to patients and interferes less with patients' activities of daily living.[78] Radiologic confirmation of tip placement should be obtained before initiating therapy.[79]

Tunneled Hickman, Broviac, and valved catheters (and ports) are inserted surgically in an operating suite or minor procedure room, physician's office, radiology suite,[80] or at the bedside.[9] All catheter insertion techniques include creating a subcutaneous tunnel on the anterior chest wall, pulling the catheter up through the tunnel, and positioning the catheter cuff in it, leaving its remaining proximal portion with the Luer-Lok tip exiting from the tunnel on the chest wall (see Fig. 96–1).[8,20,31,81] The distal catheter tip is then usually placed percutaneously or by a cutdown technique into the central circulation through the axillary, subclavian, internal jugular, or cephalic vein[29,82] and threaded into the superior vena cava under fluoroscopic guidance.[12] Cutdown technique greatly diminishes the possibility of pneumothorax or hemothorax as the vessel is cannulated under direct visualization.[45] Literature from the dialysis population and a retrospective study of oncology patients suggest that there is a lower incidence of symptomatic venous thrombosis when the catheter is inserted through the internal jugular vein.[83,84]

The catheter position in the superior vena cava at the right atrial junction[9] should be confirmed by chest radiography. In patients expected to need crutches for a prolonged period, catheters should be inserted through the internal or external jugular vein or in the subclavian vein lateral to the midclavicular line to prevent pinching the catheter in the costoclavicular space, which leads to catheter pinch-off and fracture.[37]

No significant differences have been found in time to failure or in infection or obstruction rate of catheters inserted percutaneously ("blind" or landmark technique) rather than under direct visualization.[29,85,86] Real-time ultrasound-guided insertion techniques are associated with fewer placement failures and complications compared with landmark techniques.[87] One study of 589 blind placements had a 92% success rate, with 2.9% of catheters requiring repositioning.[88] Especially thin or obese patients are identified as higher risks for insertion failure and complications when the landmark technique is used. Other patients at higher risk are those who have had previous major surgery or previous central venous access devices.[89]

Catheters should be inserted by experienced personnel, however, as complication rates fall with increasing experience in catheter insertion.[51,90,91] Long-term central venous access devices are increasingly placed with interventional radiology techniques. These image-guided techniques have a 99% success rate at a lower cost than surgical placement and with a comparably low infection rate.[92,93] Placement

using interventional radiology is often obtainable in a more timely manner than surgical placement.[94] If the chest wall or the vessels of the upper body are not usable, an alternative site is the inferior vena cava, which is accessed through the femoral or saphenous vein or by a translumbar approach directly into the inferior vena cava.[29,45,62,95–98]

Ports

Ports are surgically inserted into the antecubital fossa or chest or abdominal wall with the patient under local anesthesia.[99] If possible, they should be placed in the nondominant arm or in the side of the chest near it to minimize the probability of needle dislodgment or coring of the port septum during continuous access.[28]

The peripheral port can be inserted at the bedside by physicians or physician assistants.[9,53–55] It consists of an implantable port with an attached polyurethane radiopaque catheter, the distal tip of which contains an electromagnet. The port is placed percutaneously in a pocket in the antecubital fossa. The venous catheter is introduced using the same techniques as described earlier for PICCs without attached ports.[53–56] Fluoroscopy is unnecessary, as the progress of the catheter toward the right atrium can be externally tracked with a hand-held sensor wand (Cath-Finder) that detects the electromagnet in the distal tip.[12] A chest radiograph to verify catheter position is still recommended before infusion.[79]

The chest wall ports are placed into a subcutaneous pocket in the infraclavicular space, and the attached catheter is placed under fluoroscopic guidance into the subclavian, jugular, or cephalic vein and threaded through the superior vena cava to the junction with the right atrium (see Fig. 96–2). No portion of the device remains visible.

DEVICE MANAGEMENT

Catheters

Care of nontunneled and tunneled catheters is begun by the nurses and later taught to patients and their families. To minimize infectious complications, it is preferable to assign this responsibility (as well as infusions and blood sampling through the catheter) to nurses expert in catheter care and use.[6,31,100,101] Standard procedures are available and should be adopted by each institution, to be followed by all who care for the patient.[14,21,40,56]

Patient and family education in catheter care is required to maintain patency, to prevent damage to the external portion of the catheter, to prevent air embolization, and to reduce the risk of infection.[20,32,40,56,102] Instructions should cover permissible activities, techniques of dressing changes, heparin instillation, and changing the Luer-Lok plug, as well as emergency care in the event of damage to the external portion of the catheter. This educational program should be started well in advance of patient discharge to ensure patient and family competence; it may be reinforced by an educational booklet,[103] by attendance at a "hands-on" class, or by nurses sent into the home, at least initially, to verify compliance with procedures. Patients with catheters or ports in place should be given written information about the device[28] as well as a medical alert card, necklace, or bracelet indicating its location and type of access and a person to be contacted if problems arise.[40]

Dressing changes for surgically inserted catheters require a sterile technique for 2 weeks after insertion, until fibrous growth into the cuff is complete.[11,32] The catheter exit site is cleaned with an antiseptic solution. Povidone iodine has been commonly used in the United States, but chlorhexidine-based solutions may be preferable because they have been shown to reduce the risk of catheter colonization and catheter-related bloodstream infection (CRBSI).[104,105]

A formulation of chlorhexidine with isopropyl alcohol has been approved by the US Food and Drug Administration (FDA) for catheter site use and has been available for over-the-counter purchase since 2005.[106,107] Sterile dressing changes are done every 3 to 7 days for 2 to 3 weeks after insertion, depending on the dressing materials used (more frequently for povidone iodine and less frequently for chlorhexidine).[11,21,32,105]

The type of dressing, if any, needed to cover the site once the incision is healed is controversial.[14,21,32,40,108] One prospective, randomized study indicated that when a rigorous cleaning protocol was followed, the incidence of site infection was not different whether standard gauze and povidone iodine, a transparent polyurethane dressing (eg, OpSite, Tegaderm) permeable to water vapor, or no dressing was applied.[109] Another study, however, found an increased risk of infection when transparent dressings were used.[110] A chlorhexidine-impregnated sponge dressing decreased the risk of catheter colonization and catheter-related infection in a prospective, randomized study.[111] The advantages and disadvantages of transparent dressings, gauze, or no dressing have been reviewed.[40]

Dressings should be replaced whenever damp, loosened, or soiled.[43] Moisture vapor-occlusive dressings are strongly recommended for patients with tracheostomies or open wounds near the catheter site. After 2 to 3 weeks, a clean technique is used in some institutions for nonneutropenic patients, and a Band-Aid or small gauze dressing may be used to cover the exit site.[11,112] More complete guidelines for access and maintenance of surgically inserted catheters are available.[6,14,21]

The effectiveness of antibiotic or iodine ointment used at the exit site in the prevention of infection has not been conclusively proved. Any ointment used should be checked for compatibility with the catheter material. Some ointments may allow fungal growth. For these reasons, their routine use is not recommended.[43,108]

The catheter is not usually considered to be securely anchored in place until 10 to 21 days after catheter placement, although insertion site stitches are usually removed after 10 days. Even then, catheters should not be allowed to hang freely; instead, they should be taped to the chest wall or inserted into a brassiere cup.[40] A clamp should be immediately available in the event of any breaks in the line. Some manufacturers include a clamp placed on the catheter. Patients should be advised to keep the catheter out of the reach of pets or small children who could inadvertently dislodge the catheter by pulling on it.

Because a thrombus on the catheter tip can be the nidus for a bacterial or fungal infection,[113,114] every effort should be made to prevent one from forming. Heparin should be instilled in nonvalved catheters after each episode of blood drawing or blood product administration and when the catheters are not being used for intravenous therapy. A wide variety of flushing regimens are reported in the literature with various concentrations and volumes of heparin and frequencies although few regimens are based on research. Based on a review of the available research-based practice, a flushing regimen of 5 mL of 10 units/mL heparin one or two times per week is recommended.[115] In one study, twice-weekly flushing, rather than daily, resulted in a 33% decrease in catheter-related bacteremia without an increase in thrombus or intraluminal clots.[116] A further decrease in intraluminal infection rate in immunocompromised, nonneutropenic patients with tunneled catheters may be provided by adding vancomycin to the heparin flush.[117,118] However, the antibiotic flush has been associated with increased antibiotic resistance and allergic reactions.[108] Recommendations for PICC flushes range from 3 mL of heparin (100 units/mL daily) to 3 mL of 10 units/mL three times per week.[14] The dose of heparin used to flush the catheter should not alter the patient's clotting factors. At a minimum, the flush should be twice the volume of the catheter plus any add-on devices.[119]

The use of the heparin flush alters coagulation tests if blood is drawn through the catheter.[120] The first 10-mL sample shows spurious elevations in levels of fibrin degradation products, prothrombin times, partial thromboplastin times, and spuriously low fibrinogen levels. Elevations in the prothrombin time and partial thromboplastin time will persist in the second 10-mL sample.

Valved catheters require a 5-mL to 10-mL normal saline flush weekly or after use.[11,20,21,39] The Groshong-type valve can be kept in

the open position by small clots or solid residues from medications, allowing blood to flow back into the catheter, forming a clot.

Investigators have examined the potential role for using thrombophylaxis for cancer patients with central venous access devices. The most recent data show no proven role for using mini-dose warfarin or low molecular weight heparin. Their use has been shown to be safe and well-tolerated in such patients with hematologic malignancies and pronounced thrombocytopenia.[121] Some experts still advocate thrombophylaxis for patients at high risk for developing catheter-related complications. One study suggested fewer clinical and asymptomatic thrombotic events in patients treated with continuous infusion of unfractionated heparin (UFH) 100 international units/kg/day versus placebo (1.5% vs 12.6%)[122] Dalteparin prophylaxis using 5000 international units once daily did not reduce frequency of central venous catheter-related thrombosis in cancer patients.[123]

For apheresis catheters used for peripheral stem cell harvest, a regimen of aspirin (325 mg/day) begun the day after catheter placement led to a greater number of thrombosis-free apheresis procedures than were observed with historic control subjects.[124] More detailed guidelines for nursing education and practice regarding maintenance of catheters are available.[14,119]

Ports

Ports can be used immediately after insertion. However, because postoperative edema and discomfort often delay any attempts at access for several days, patients should be sent from the operating room with the Huber needle in place and ready for use.[14,28,40] Incisions should have a dressing until the sutures are removed. If skin closure is accomplished with surgical adhesive, a dressing is not required after the operative day and the site may get wet after the first day although it may be preferable to delay this longer.[108]

To access a port that has no needle in place, the skin is prepared with antiseptic; povidone-iodine or chlorhexidine are recommended.[14,43] Anesthetic agents that may be applied include ice or a cold pack for a few minutes, a freezing agent (ethylene dichloride), or topical anesthetic cream (EMLA), which must be applied one hour before needle insertion.[125] A 19- to 22-gauge Huber needle (depending on the product to be infused) is inserted (see Fig. 96–2).[28] This steel needle has a deflected point and side opening, designed to prevent coring of the septum.[27] The needle is primed with saline, attached to a saline-containing syringe and then inserted perpendicular to the septum.[126] Correct placement in the port can be confirmed by aspiration for blood return. However, aspiration for blood may be unsuccessful, usually because the needle is misaligned or a fibrin sheath has formed, creating a ball-valve effect. If there is no swelling, the port flows well to gravity and there is no other symptom to suggest a potential problem, the needle can be assumed to be correctly placed and the port safely used for nonvesicant infusions.[11] If access is difficult, it may be helpful to palpate the site while comparing it with a recent radiograph. Access may also be accomplished under fluoroscopy if standard technique by palpation is unsuccessful. Detailed accessing procedures for drawing blood and for administering drugs and blood products are available.[14,28,119,126]

During use, the port is covered with a sterile dressing. A transparent, occlusive dressing may be preferable to help stabilize the needle and prevent inadvertent dislodgment. Dressing guidelines for external catheters can be followed for ports. The needle is changed weekly. After each use or every 4 weeks, implanted access devices also require heparin instillation or a 20-mL saline flush for valved ports.[11,27,40] A variety of heparin concentrations and volumes have been reported. Use and maintenance of the peripheral port are essentially the same as for ports implanted in the chest wall.[24] More detailed guidelines for nursing education and practice regarding the maintenance of implanted ports and reservoirs are available.[14,119,127] Ongoing discussion continues regarding optimal maintenance procedures. One author suggested that assessments may be possible at a lesser frequency than every month, with greater cost-effectiveness, equal patient safety, and greater convenience.[128]

DEVICE REMOVAL

Device removal should be considered when it is no longer needed, in part to minimize risks of thrombosis and infection. Nontunneled catheters are removed nonsurgically by applying steady tension. If the catheter appears to be stuck, measures should be taken to reverse vasospasm (eg, application of warm compresses, flushing with normal saline).[12] If the catheter remains fixed, a cutdown on the venous insertion site to remove thrombotic material is usually effective.[9] Tunneled catheters should be removed by surgical cutdown around the cuff, which should be entirely removed.[9] For cases in which bacterial studies of the internal catheter tip are desired, blunt dissection of the cuff, with transection of the catheter above it and sterile removal of its inner portion, can be performed under local anesthesia.[129,130] Ports, including the reservoir, catheter, and all suture materials, are removed surgically with the patient under local anesthesia.[9]

COMPLICATIONS

Complications of indwelling vascular access devices include those occurring during the initial placement, cutaneous reactions to standard care materials, mechanical problems, phlebitis and infiltration, infection, hemorrhage, catheter occlusion of nonthrombotic or thrombotic origin, and vesicant drug extravasation.

Children

Pediatric-specific studies have cited age (younger than 5 years in one, younger than 2 years in another), use of multilumen catheters, absence of skin exit site suture, and platelet transfusion at time of insertion as the most common reasons for premature catheter removal.[131,132] Pediatric cancer patients with external catheters had more complications requiring device removal compared with port devices (23% vs 9%; infection occurred in 6% ports and 16% external catheters); occlusive events requiring removal occurred in 1.5% ports and 4.5% external catheters; fewer occlusive events in patients receiving urokinase vs heparin (23% vs 31%).[133]

Initial Placement

Rarely, patients who have had a midline catheter composed of a hydrogel elastomer inserted and flushed experience an anaphylactoid reaction (5% of which are complicated by cardiac arrest).[6,134] This reaction was not seen when silicone midline catheters were used.[135] Approximately 1% to 4% of patients in whom a central catheter is inserted percutaneously develop a pneumothorax.[9] Other surgical complications include hemothorax, arterial venous or cardiac perforation, brachial plexus injury, air embolism, and pericardial tamponade.[9,87]

Cutaneous Reactions

Approximately 5% of patients develop skin reactions to the products used in caring for the devices.[136] These reactions include erythema, urticaria, exanthematous or purpuric eruptions, and skin peeling or abrasion. These skin abnormalities must be distinguished from exit-site infections by appropriate culturing of the site for bacteria. In uninfected patients, changes in the dressing material, tape, and local skin care regimen are effective in reversing the skin abnormalities.[136] Skin reactions may be compounded when the patient has received radiation therapy to the area covered by the dressing.

Skin erosion over the implanted ports, caused by malnutrition, separated wound edges, local infection, or carcinoma metastatic to the skin, occurs in 3% to 10% of patients, and removal of the port is always required.[40,137] Peripheral ports may cause this complication more frequently than ports placed on the chest or abdominal wall.[9]

In very thin patients, the risk of erosion may be lower when a low profile rather than standard depth port is used.[59]

MECHANICAL PROBLEMS

Catheters

Damage to the external segment of the tunneled catheter includes separation between the Luer-Lok connection and the tubing; cracks caused by repeated cross-clamping, if rubber-tipped forceps are not used; and cuts made by scissors mistaken for clamps.[11] Catheter repair kits should therefore be available. Patients should also be instructed to contact their physicians or the oncology nursing staff immediately if the catheter is damaged at home.

Catheter fractures and emboli occur in about 0.2% of subclavian catheter insertions.[9] The internal portion of the catheter usually fractures at the junction of the clavicle and first rib,[138] and angiographic studies reveal the pathognomonic catheter pinch-off sign.[139] Catheter pinch-off occurs when catheters inserted medially to the midclavicular line become compressed by shoulder movements.[139] The resulting fragments migrate to the right heart or pulmonary artery and cause thromboses, cardiac arrhythmias, and fatal emboli; extravasation of fluids, lymph, or vesicant agents may also ensue at the site of breakage.[9,138] Patients complain of pain or swelling at the port or vein insertion site, chest pain, cough, or palpitations.[138] Catheter fragments are usually retrievable with interventional radiology techniques.[138,140,141]

PICC lines can also embolize if they are sheared by needles, sutures, or surgical instruments while they are being inserted. If the fragment cannot be prevented from migrating more proximally by applying local pressure at the break site or by placing a tourniquet proximal to the site, it can be removed by venous cutdown.[138,142] If it has migrated, percutaneous techniques or a thoracotomy will be required,[138,142] but some fragments are never retrieved. Apheresis catheters placed in the inferior vena cava can also develop fractures of the external segment, with visible leakage,[62] and they can be repaired using the kits mentioned earlier. Fractures of the internal portion of the catheter, however, require catheter removal. Most of these fractures can be detected by injecting radiologic contrast material through them and observing the flow of the dye fluoroscopically.[62]

Ports

The port may migrate or flip within its pocket because of defective suturing or excessive arm movement, or because of manipulation by the patient.[40,143] This malposition can be surgically corrected.

PHLEBITIS AND INFILTRATION

Phlebitis and infiltration are uncommon complications associated with properly positioned centrally placed access devices but are noted with the peripheral port[9] and in 2.2% to 23% of patients with PICCs.[6,25,56,144,145] Two studies of cancer patients with PICCs had comparable rates of phlebitis at 6.6% and 7%, respectively.[36,64] A randomized, controlled trial compared the complications associated with steel needles; small-bore, short Teflon catheters; and PICCs.[146] PICCs were associated with the highest incidence of phlebitis (27%) and the lowest incidence of infiltration (8.1%), steel needles were associated with the lowest incidence of phlebitis (8%) and the highest incidence of infiltration (45%), and Teflon catheters fell in between, with 19% to 20% incidences of phlebitis and infiltration. An aseptic phlebitis may occur within the first week after PICC insertion. It can be prevented by administration of nonsteroidal antiinflammatory agents[53] or treated with warm compresses applied for 48 to 72 hours.[15,56] Catheter removal is usually not required.

Infection

Definitions

The Centers for Disease Control and Prevention have established the following definitions for catheter- and port-associated infections.[43]

Localized catheter colonization: Significant growth of a microorganism (>15 CFU) from the catheter tip, subcutaneous segment of the catheter, or catheter hub.

Exit-site infection: Erythema, or induration within 2 cm of the catheter exit site, in the absence of concomitant bloodstream infection (BSI) and without concomitant purulence.

Clinical exit-site infection (or tunnel infection): Tenderness, erythema, or site induration of more than 2 cm from the catheter exit site along the subcutaneous tract of a tunneled catheter (ie, Hickman or Broviac) in the absence of concomitant BSI.

Pocket infection: Purulent fluid in the pocket of a totally implanted intravascular catheter that may or may not be associated with spontaneous rupture and drainage or necrosis of the overlaying skin in the absence of concomitant BSI.

Infusate-related bloodstream infection: Concordant growth of the same organism from the infusate and blood cultures (preferably percutaneously drawn) with no other identifiable source of infection.

Catheter-related bloodstream infection: Bacteremia or fungemia in a patient with an intravascular catheter with at least one positive blood culture obtained from a peripheral vein, clinical manifestations of infections (eg, fever, chills, or hypotension), and no apparent source for the BSI except the catheter. One of the following should be present: a positive semiquantitative (>15 CFU/catheter segment) or quantitative (>10^3 CFU/catheter segment) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a 5:1 ratio for central venous catheter (CVC) versus peripheral; or differential period of CVC culture versus peripheral blood culture positivity of more than 2 hours.

INFECTION

Incidence

When expressed as infection rate per 1000 patient days, the highest risk exists with peripheral catheters placed by surgical cutdown; the next highest risk is with peripheral steel needles. Cuffed catheters and cuffed implantable devices have lower risks of infection than uncuffed ones. Cuffed devices share the lower rates of infection with outpatient, PICC and peripheral IV catheters, as well as ports.[147] Increasingly, standardized infection control procedures are utilized to help reduce CRBSI, as published by the CDC in 2005.[148]

Between 1% and 9% of patients experience infection at the exit site, tunnel, or pocket. Retrospective and prospective studies showed exit-site infections to be responsible for 39% to 45.5% and tunnel infections for 20.3% to 22% of all catheter-related infections.[51,149] Most catheter-related bloodstream infections for catheters in place for less than 10 days are of cutaneous origin from the insertion site, and gain access extraluminally, whereas for long-term devices in place for more than 10 days, luminal colonization is the major mechanism of CRBSI.[150] Prophylactic antibiotics have not consistently proven beneficial in preventing these infections, and their use is not recommended.[6,32,51] Catheters and cuffs coated or impregnated with antimicrobial or antiseptic show some promise in decreasing CRBSI. The compounds used are chlorhexidine/silver sulfadiazine, minocycline/rifampin, and platinum/silver, but there are concerns about the emergence of resistant organisms with these catheters.[43] The evidence supporting use of these compounds to reduce risk for CRBSI is equivocal for short-term CVCs and inconclusive for long-term CVCs

in place longer than 10 days.[151] One randomized controlled study found low-dose unfractionated heparin via continuous infusion (100 units/kg/day) helped decrease fibrin deposition and decreased rates of CRBSI to 6.8% from 16.6%.[152] However, use of heparin remains controversial with questions of physical compatibility, chemical stability, and condition-limiting factors such as HIT.[153]

Infections are generally prevented by meticulous insertion and maintenance techniques.[100,154] PICCs inserted at the bedside versus those inserted by interventional radiologists show a higher rate of infection, probably because of insertion conditions (aseptic technique at the bedside versus sterile technique in the interventional radiology suite).[64,155] With maximal barrier precautions, however, catheter insertion at the bedside is associated with no higher infection incidence than placement in the operating room.[6]

The incidence of device-associated infection varies depending on the type of device inserted and the medical disorder of the patient. Conditions associated with CVC infections are more anecdotal and based on weaker evidence.[154] Overall, the incidence of midline catheter-associated infections is 0.8 per 1000 days of patient use[134] and that of tunneled catheters is approximately 1 to 3 per 1000 days of patient use.[32] Cumulative incidence of PICC-related BSI is 2.1 per 1000 PICC-days (range 0–6.5). The risk of PICC-related BSI per 100 PICCs is 3.2 overall; 2.5 in adults and children, and 3.8 in neonates.[156] The use of multiple-lumen catheters probably increases the infection rate significantly.[6] In one study, the sepsis rate for double- and triple-lumen catheters was comparable at 13% and 16%, respectively, but infections occurred significantly earlier with the triple-lumen catheters (a mean of 54 days vs 141).[45] There are fewer catheter-related bacteremias in TIVADs (totally implantable venous access devices) than tunneled catheters. Valved catheters have not altered the rate of infectious complications. Several social conditions contribute to greater risk of indwelling venous access device infections, including poor hygiene, and low socioeconomic status. For pediatric cancer patients, increased risk of infection is associated with language barriers limiting parental understanding of how to care for CVC.[154] The infection rate with implanted ports is lower, 0.2 to 0.3 per 1000 patient-days for ports inserted on the chest wall and 0.8 per 1000 patient-days for PAS Ports.[32,44,157,158] A prospective study of chest implanted ports revealed infection rates of 2.1% for local infections (ie, with cellulitis around the insertion site or reservoir), 2.2% for port pocket infections, and 4.4% sepsis.[46]

Neutropenic patients, particularly with a hematologic malignancy, have a near 14% greater risk of developing CRBSI.[159] Patients with HIV infection[68–71] and those receiving a bone marrow transplant,[60,61,160] have significantly higher rates of catheter- and port-related infections. Patients with hemophilia had a pooled incidence of 0.66 infections per 1000 CVAD days; age greater than 6 years and the use of fully implanted CVADs significantly reduced the risk of infection, while the presence of inhibitors significantly increased the risk.[47] For adult patients with sickle cell disease, bacterial infections are a leading cause of mortality, and one study cited a greater incidence of bloodstream infections (BSI) in younger patients with HbS disease, on transfusion and/or desferrioxamine programs, and in patients with a central venous catheter. Of all BSI episodes in these sickle cell patients, 41% were attributed to a venous catheter, and device infection occurred in 77% of patients with tunneled implantable ports.[161]

Patients with acute leukemia have a higher rate of infection than other patients with a cancer diagnosis, in part due to greater numbers of manipulations of the catheters, and possibly also due to longer periods of neutropenia.[35,154,162] They are also at higher risk for developing septicemia as a consequence of prolonged neutropenia.[163] The presence of a CVC increases the risk of infection in the early phases of low-intensity ALL treatment in pediatric patients.[164] Some tunneled catheters have a silver-impregnated collagen cuff in addition to the Dacron cuff to decrease infection rates but its usefulness is not definitive.[165] One prospective study cited a difference between CVAD-related infections in outpatients versus inpatients (25-fold higher incidence rate during hospital stay) for pediatric oncology patients. The cumulative incidence of CVAD-related BSI for these pediatric oncology inpatients was 2.21/1000 utilization days (UD) for Broviacs and 3.73/1000 UD for ports.[166]

Organisms

The most common organisms associated with hospital-acquired CRBSI are coagulase-negative staphylococci (37%), *Staphylococcus aureus* (13%), enterococci (13%), and *Candida* (8%).[43] Staphylococcal and candidal organisms adhere to the fibrin or fibronectin sheaths surrounding indwelling catheters, and some staphylococci produce a "slime" that further promotes bacterial proliferation on the catheter surface as the slime protects the organisms from phagocytes, antibodies and antibiotics.[106,114,167] Catheters with siliconized latex and polyvinyl chloride catheters have been shown to have more bacterial adherence than catheters made from other materials.[154] Coagulase-negative staphylococci also adhere to polymer surfaces more readily than other organisms. Other gram-negative organisms, including *Pseudomonas*, also cause infection.[9,168] *Pseudomonas* is particularly problematic when showering or swimming has been allowed. *Xanthomonas* (*Stenotrophomonas maltophilia*) infections can be particularly troublesome because of increasing multidrug resistance, formation of biofilm, and their prevalence in immediate post-CVC insertion setting and longer term indwelling setting. They are more prevalent in cancer patients with three independent risk factors: pneumonia, neutropenia at onset of bacteremia, and admission to ICU within one month of onset of bacteremia.[169,170]

A reported 5.4% to 9.9% of infecting organisms are fungal, three-fourths of which are *Candida* species,[5,32,51,171,172] although nosocomially acquired cutaneous infections with *Aspergillus flavus* have been noted at the sites of insertion and along the subcutaneous tract of Hickman catheters.[173–175] *Candida* infections in the oncology or bone marrow transplantation population are associated with a high mortality rate.[106] Infection with drug-resistant non-*C. albicans* is increasing in frequency in patients with CVCs.[176,177] In HIV-positive patients, staphylococci are the most common infecting organisms,[68–70] but *Pseudomonas* species causing fatal septicemia,[68,70,178–181] other gram-negative organisms,[182] and lactobacilli[183] are increasingly reported. Liposomal amphotericin B was successful in eradicating a port-associated fungemia from *Fusarium oxysporum* in an HIV-infected patient.[184] Septicemia due to catheter infection by typical or atypical *Mycobacterium* species has also been noted.[31,185–188]

S. aureus is the most common organism infecting ports of patients with hemophilia, especially those with inhibitors.[72,189] Other implicated organisms in hemophilia patients include *Pseudomonas* species, *Enterobacter cloacae*, *Escherichia coli*, *Klebsiella* species, *Serratia liquefaciens*, and *Acinetobacter* species.[47]

In adult sickle cell patients with CVADs, infections were seen with *Staphylococcus aureus*, *Escherichia coli*, *Acinetobacter* species, and *Pseudomonas*.[161]

INDICATIONS FOR REMOVAL

Debate continues over cost-effectiveness and salvage rates for catheters once CRBSI is documented.[190]

Exit-Site and Tunnel Infections

Exit-site infections caused by bacteria rarely require catheter removal for resolution, because most (69% to 100%) respond to antibiotics alone.[51,90,91,149,191] These infections are most often caused by *Staphylococcus epidermidis*.[29,32] Similarly, with implanted ports, infections of the skin pocket have been found to resolve in about 70% of cases without removal of the device.[31,32,52,99,191]

Tunnel infections or port pocket abscess, by contrast, usually do not respond to antibiotics; they have been reported to resolve without catheter removal in only 25% to 50% of cases.[1,51,90,91,149] Catheters were removed from all patients with cutaneous *Aspergillus* infection,

INFECTIOUS INDICATIONS FOR DEVICE REMOVAL[1,166]

Venous Access Devices

Tunnel infection or port pocket abscess
Catheter-related bacteremia caused by *Staphylococcus aureus, Xanthomonas, Pseudomonas* spp, mycobacteria, *Bacillus and Corynebacterium* species
Catheter-related fungemia
Septic thrombosis
Endocarditis
Osteomyelitis
Sepsis with signs of shock/persistent end-organ dysfunction
Central venous thrombosis

Central Nervous System Access Devices

Deep catheter track or epidural space infection

six of whom recovered after antifungal therapy and local wound care[172] (see box on Infectious Indications for Device Removal). Resolution of leukopenia was required for infection resolution. Similarly, *Mycobacterium*[31] and atypical mycobacterial infection of the tunnel or exit site requires catheter removal as well as excision of infected tissue.[188]

Septicemia

In a patient with septicemia and a catheter or port in place, it is often difficult to determine whether the catheter itself is truly infected or whether the bacteremia is from another source. Quantitative culture is the most sensitive technique,[6] but the semiquantitative roll-plate method is most often used to diagnose catheter-related infections.[192,193] Both, however, require that the catheter be removed. Quantitative blood culture techniques can be used with a catheter in place. If the colony count in cultures of blood drawn from the catheter is 5 to 10 times greater than the count in cultures of peripherally drawn blood, the infection is very likely to be catheter related.[6] For presumed *Candida* infection, it has been suggested that molecular analyses of material from various anatomic sites may help determine the true source of the infection (eg, sputum versus blood) and prevent needless device removal.[194]

In assessing the cause of infection in a patient with a port, care must be taken not to draw blood for culture through a possibly infected port pocket unless the Huber needle is already in place. Accessing a port through an infected port pocket could introduce organisms into the reservoir and from there into the systemic circulation.[40,191,195] To determine whether a port is truly infected, material within the port should also be cultured after it is removed.[196]

When another source is definitely identified, however, the catheters can usually be left in place, because the incidence of hematogenous colonization is low (1%).[51,81] When there is no thrombophlebitis, even when the catheter is believed to be the source of the infection, or when no source is clearly identified, resolution of bacterial septicemia occurs in 75% of episodes without removal of the catheter.[32,197]

The possibility of clearing the infection without catheter removal, however, is much lower in patients with septic thrombophlebitis, occluded catheters, exit-site infections, or bacteremia due to *S. aureus*, *Xanthomonas*, or *Pseudomonas* or fungal septicemia.[9,32,70,198,199] In one retrospective review, adult cancer patients with candidemia did just as well with catheters left in place as those whose catheters were removed;[200] and in one pediatric study, *Candida* fungemia was treated successfully with the line left in place.[7] In other studies, children and adults with catheter-related candidemia had higher rates of treatment failure, secondary complications, and mortality if the catheters were left in place during antifungal treatment.[201–203] Line removal is recommended when the fungemia is line related.[204] Successful surgical removal of right atrial thrombi superinfected with *Candida tropicalis* or *S. epidermidis* has been reported in several patients, including those with sickle cell anemia.[205,206] Replacement of catheters on the contralateral side within 1 to 3 days after removal is usually not associated with recurrent catheter infection.[81,99]

Antibiotic lock therapy (ALT), with and without concomitant parenteral therapy, has shown success in the prevention and treatment of catheter-related bacteremia when intraluminal infection is likely. Several trials have reported catheter salvage without relapse.[1,106] It involves instillation of an antibiotic solution, at a concentration of 1 to 5 mg/mL, into the catheter hub. The solution remains in place for a predetermined amount of time and is withdrawn before the next dose of intravenous antibiotic or medication. ALT itself allows much higher concentration and longer duration of activity of antibiotics at the colonized intraluminal/infected catheter surface without the potential side effects of systemic exposure. It also helps eradicate biofilm-forming bacteria. The goals include prolonging catheter life and reducing patient morbidity and costs associated with catheter-related infections. ALT can also be an option for salvaging venous access when venous access is otherwise limited, and patients have a CRBSI that has not progressed to septicemia and does not involve tissue infection at insertion or tunnel site.[153] ALT has been less effective for treating infections of implantable ports than infections from other types of CVCs.[153]

The most efficacious concentration and duration of ALT remains unclear, though the Infectious Disease Society of America recommends catheter locking for 14 days, with daily changing, in addition to 7-day systemic administration of antibacterial treatment for uncomplicated catheter-related bacteremias. It should be combined with systemic treatment for at least the first 72 hours.[166] At this time, no evidence-based recommendations are available regarding optimal concentration or intraluminal dwell time.[166] Combination ALT including minocycline/vancomycin, minocycline/rifampin, vancomycin/rifampin, is more effective in vitro against biofilm-forming coagulase negative staphylococci.[153,166] M-EDTA (minocycline plus EDTA) has demonstrated activity against gram-positive and gram-negative bacteria, as well as *Candida* species. A randomized control trial is needed to judge its efficacy for long-term CVC infections.[151] In general, ALT has not been as successful for fungal infections.[1,106]

In existing studies, several factors limit how best to use ALT. These include a lack of data from large, randomized control trials, comparing the efficacy of ALT to systemic antibiotics for treatment of line infections. Additionally, differences in antibiotics used for ALT, heterogeneity in study populations tested, presence or absence of heparin, and inconsistent definitions of catheter-related sepsis further complicate the generalizability of existing data. Overall, it appears ALT alone shortens the length of hospital stay, compared with systemic antibiotic therapy for treatment of line infections.

Taurolidine has been found to have broad bactericidal and fungicidal efficacy in vitro. It is active against methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococcus (VRE) and is felt not to select antibiotic-resistant microorganisms. It also might inhibit biofilm formation. Experiences are limited and require more study.[166]

Hemorrhage

Despite the frequent occurrence of thrombocytopenia in patients with indwelling access devices, few bleeding complications are associated with their placement or with the placement of the larger apheresis catheters.[81,90] Capillary fragility from prolonged steroid therapy,

however, may contribute to perioperative hemorrhage.[90] Pressure dressings and platelet transfusions given pre- and postoperatively usually control local oozing.[81] However, in patients with uncontrolled disseminated intravascular coagulation, excessive bleeding has occurred with catheter insertion; many groups consider disseminated intravascular coagulation an absolute contraindication to catheter placement.[32,81,90] In contrast, catheters and ports have been placed without excessive bleeding in patients with hemophilia when factor levels were maintained at 100% preoperatively and for 5 days postoperatively.[189,207]

CATHETER OCCLUSION

Nonthrombotic Causes

Although a clot is the most common cause of occlusion,[167] inability to aspirate blood from the port or catheter does not necessarily mean that it has clotted. Other causes include a malpositioned Huber needle, catheter abutment against the wall of the vein, catheter kinking, catheter pinch-off, precipitation of drug solutions in the catheter lumen, development of fibrin sheaths, and catheter migration with resultant malposition of the tip.[40,167,208] Tip migration secondary to growth, especially during periods of growth spurts, is a problem specific to the pediatric population. Tip placement should be evaluated regularly as the child grows in height.[209] Algorithms for the evaluation and treatment of catheter occlusion are available.[167]

Catheter abutment may resolve by changing the patient's position or by performing a Valsalva maneuver.[21,28,40] Pinch-off occurs when the catheter is placed too medially and is compressed between the clavicle and first rib. Repositioning patients with catheter pinch-off often relieves the compression and reestablishes catheter function; but this is impractical for long-term catheter use, and the catheter usually needs to be repositioned.[138]

Precipitation of incompatible solutions occurs with etoposide, calcium, diazepam, phenytoin, heparin, and total parenteral nutrition (TPN) infusions.[167] Catheter blockage due to precipitation of calcium carbonate was reported at from 8 to 24 weeks in 50% of patients with metastatic colon carcinoma receiving once weekly 24-hour infusions of high-dose 5-fluorouracil (2600 mg/m^2) and leucovorin (500 mg/m^2).[210] Although precipitates may occasionally resolve with warm soaks over the tunnel site, dilute solutions of hydrochloric acid have successfully cleared precipitates from TPN solutions alone or with lipids, etoposide, calcium salts plus sodium bicarbonate, and heparin with incompatible antibiotics.[9,167] A solution of 0.1 normal HCl to equal the volume of the catheter is instilled and allowed to stand for 20 to 60 minutes.[141,167] Febrile reactions may occur. Sodium bicarbonate has resolved phenytoin, ticarcillin clavulanate, and oxacillin precipitates.[211,212] Lipid buildup or occlusions may respond to 70% ethanol instilled for 1 to 2 hours or sodium hydroxide (0.1N).[14,141]

Fibrin may start depositing on a catheter within 24 hours of insertion and may be present in as many as 67% of catheters.[213,214] Withdrawal occlusion secondary to the ball-valve effect of a fibrin sheath accounts for 10% to 57% of catheter occlusions.[11,29,208,215] The fibrin sleeve itself may embolize.[216,217] Presence of a fibrin sheath increases the risk of infection.[108] Techniques using nonlytic and lytic agents to remove the sheaths have been described.[28,40] Lytic therapy is discussed later.

Maintaining correct position of the catheter tip can help prevent numerous complications. Catheter migration occurs in 5.5% to 29% of insertions when the subclavian approach is used.[218] Review of the patient's chest radiograph most commonly shows the malpositioned catheter tip to be in the ipsilateral jugular vein, axillary vein, or in the contralateral brachiocephalic vein. When the catheter is in the jugular vein, patients often complain of a whooshing or gurgling sound when the line is flushed.[14] Venous thrombosis can occur as a result of damage to the endothelium, turbulence created by the tip at venous branching points, or insufficient dilution of infusate that causes thrombophlebitis. Catheter erosion through the vessel or cardiac wall can produce extravasation, fistula formation, and pericardial tamponade.[138] Catheters inserted into the left internal jugular or subclavian veins have also eroded into the bronchi; the ensuing venobronchial fistulas were associated with cough, pneumonia, and respiratory failure.[219] Repositioning the catheter can usually be done by interventional radiologists without catheter removal.[208,218]

PICC malposition ranges from 21% to 55%.[138] PICCs should be well secured at the insertion site to prevent "pistoning" in the vein, which increases the possibility of phlebitis or infection.[141] The catheters can usually be repositioned by trained nurses employing simple bedside techniques.[134] Migration of the apheresis catheter in the subcutaneous space also manifests as access failure, because the catheter tip is pulled back to the wall of the inferior vena cava or out of the intravascular space.[62] Intravascular malposition can be corrected by tip deflectors or J-wires.[220]

Thrombosis

Thrombosis can occur in the catheter itself or in the superior vena cava or veins of the upper extremity. While asymptomatic thromboses have been reported in rates up to 60%, most recent studies show an incidence of symptomatic catheter-related DVT to be lower than 6%, with similar rates of catheter-related DVT for access achieved through the subclavian and jugular veins.[221] Almost all central indwelling venous access devices become coated with a fibrin sheath within days of insertion, and accordingly, the majority of CVC-related thrombi arise within 30 days of initial placement.[222]

Several potential risk factors for indwelling access catheters and cancer patients have been studied. Catheter tip placement has been implicated in the formation of extraluminal thrombosis, with location high in the SVC accounting for a greater incidence of thrombosis than placement in the distal SVC or right atrium (62%–78% vs 16%).[45,46] Thrombogenicity was shown to be lesser in silicone and polyurethane CVC compared to polyvinylchloride and polyethylene CVC. Studies have yielded contrasting and inconclusive results regarding the impact of underlying thrombophilic states. In one study, factor V Leiden (FVL) and the prothrombin G20210A mutation (PGM) increased risk of CVC-related thrombosis threefold and led to a disproportionately high percentage of CVC thrombotic episodes.[223] In another study, neither PGM nor FVL were associated with thrombosis in cancer patients with ports, although a positive association was noted with elevated homocysteine levels.[224] Additional risk factors include greater than one attempt at insertion, a previous catheter (with vessel wall trauma and endothelial damage), ovarian cancer, and left-sided insertion site. There were no clear differences in the rate of CVC-related thrombosis with regard to chemotherapy administration methods (push/bolus vs infusion).[221,225] A threefold increased rate of catheter failure from thrombosis was noted for triple-lumen compared to double-lumen Hickman catheters.[222]

More clearly, a bidirectional impact of infection and thrombosis has been well-documented. One study reported a RR of 17 for developing clinical thrombosis manifestations after an episode of CVC-related infection, with 57% risk after an episode of CVC-associated septicemia versus 27% risk in patients with local CVC-infection only. Even in those patients with subclinical thrombosis, CVC-related infection occurred in 92%, compared with 7% without thrombosis.[226]

For pediatric patients, those with ALL receiving L-asparaginase and external catheters had 3.9 fold higher risk of CVC-thrombosis compared to children with implanted ports. Children with leukemia, neuroblastoma, and Hodgkin lymphoma with FVL, protein C deficiency, and high lipoprotein (a) levels had a significant association with symptomatic CVC-related thrombosis.[122]

For hemophilia patients, thrombosis has been a relatively rare event. A pooled incidence thrombosis of 0.056 per 1000 CVAD days has been cited, with no cases documented of superior vena cava syndrome or catheter-associated pulmonary embolism. Furthermore, neither age nor the presence of inhibitors significantly altered the thrombotic incidence. However, because thrombotic complications

have been documented less extensively for hemophiliac patients (especially compared with infectious complications), the true extent of subclinical and clinical complications is unknown.[47]

For sickle cell patients, although the condition itself is considered hypercoagulable, it remains unclear how this, coupled with the presence of indwelling access devices, affects the incidence of clinically significant and symptomatic thrombosis.

A particularly vexing problem has been with frank development of upper extremity DVT (UEDVT). Spontaneous UEDVT has been reported to be 2.6-fold to 2.8-fold more likely in patients with active cancer, with the additional presence of an indwelling venous access device increasing the risk further. Clinical UEDVT has been reported to occur in 0% to 9% of patients with chest ports and 2% to 30% with arm ports. All told, central venous access devices account for 75% of all cases of UEDVT.[227] Another consideration is the postphlebitic and postthrombotic syndrome following UEDVT. Reported rates among cancer patients range from 4% to 30%.[121,122,222]

Noninvasive methods used for diagnosis of catheter-related thrombosis and/or UEDVT, including duplex ultrasound,[228–230] Doppler imaging,[228,231] and plethysmography,[228] have low sensitivity or have not been reliable. Color Doppler duplex sonography has been shown to have sensitivity 78% to 100% and specificity 82% to 100% for diagnosis of UEDVT. The primary difficulty remains the presence of overlying bones which may make difficult the visualization and direct assessment via compression techniques.[232] Nuclear scans can confirm patency of the line and vein, rule out superior vena cava syndrome, confirm catheter tip placement, demonstrate collateral circulation, and assess the presence of a fibrin sheath at the tip of the central line.[233] Spiral computed tomography (CT) can be helpful for suspected catheter-related thrombosis involving the brachiocephalic vein or superior vena cava (SVC), and for those with suspected pulmonary embolus.[122] Magnetic Resonancy Venography (MRV) has been studied but not proven to be a reliable alternative. Flow scintigraphy can be done faster than conventional venography, at lower cost, with lower radiation exposure, and with lower procedural risk (eg, reaction to iodinated contrast).[233] If venous obstruction is demonstrated, intraluminal versus extraluminal obstruction may be further defined by venography if clinically warranted.[52,62,228,233] In patients with prior central venous catheterization associated with deep venous thrombosis, preprocedural duplex ultrasound may be useful to predict the success of repeat catheter placement.[234]

THERAPY

The course of action is unclear in patients undergoing high-intensity antineoplastic therapy who develop asymptomatic subclavian, or innominate vein thromboses. Patients with symptomatic upper extremity deep venous thrombosis (DVT) require therapy. They may develop septic thrombophlebitis,[32,51] superior vena cava syndrome, major long-term upper extremity disability, venous gangrene, and pulmonary emboli. In one retrospective study and review, 12% of patients with catheter-induced upper extremity DVT developed pulmonary emboli, 40% of which occurred in patients receiving anticoagulant therapy.[228] A 16% incidence of pulmonary emboli was found in a prospective study of patients with upper extremity DVT in whom lung scans were performed within 24 hours of venographic diagnosis of the thrombosis.[235] Patients with polyurethane and siliconized catheters had a significantly lower incidence of emboli than those with polyvinyl chloride or polyethylene catheters (7% vs 26%).[235]

The National Comprehensive Cancer Networld (NCCN) published guidelines in late 2006 for catheter-related UEDVT to help guide clinicians in evaluation and treatment.[236] They suggest anticoagulation be used if DVT is present, the catheter is required, and there are no relative contraindications to anticoagulation. Suggested duration of therapy includes all time with the catheter in place, and for 1 to 3 months following its removal. If DVT symptoms or presence of clot persist despite this therapy, the catheter should be removed. If anticoagulation is contraindicated, then the catheter should be removed, the patient followed for any changes in relative contraindications, and anticoagulation initiated if otherwise permissible. A minimum of 3 to 6 months for DVT, 6 to 12 months for PE, and indefinite anticoagulation if active cancer or persistent risk factors, was recommended.

Management of Catheter Occlusion

Catheter occlusion, whether partial (sluggish flow), complete (inability to infuse or withdraw), or withdrawal type, have all been successfully treated with thrombolytic agents. Streptokinase, urokinase, and recombinant alteplase (t-PA) have all been used. Bolus thrombolytic therapy has reopened occluded catheters in 85% to 90% of episodes, and removal of the catheter is not usually required.[237–241] No excessive bleeding has been noted, even in patients with hemophilia.[189] Streptokinase is not commonly used because of its antigenic properties and associated allergic and anaphylactic reactions.[242] Urokinase was commonly used at a dose of 5000 units/2 mL until 1999, when the FDA reported the potential for viral contamination and it was removed from distribution.[243] No fevers, coagulation abnormalities, or other adverse reactions have been noted with urokinase. It is available again in recombinant form and has demonstrated efficacy for lysis of intraluminal thrombosis. Alteplase (t-PA) has demonstrated superiority and has become the preferred therapeutic option. A randomized trial comparing bolus urokinase (10,000 units) with t-PA (2 mg) suggested marked superiority for t-PA. Twenty-five of 28 t-PA–treated versus 13 of 22 urokinase-treated catheters returned to normal function; 17 versus 7 were normal radiographically; and 13 versus 4 needed only one drug instillation.[241] Alteplase is available for catheter clearance in a 2 mg/2 mL vial, a volume sufficient to fill most catheter lumens. The technique is to fill the catheter lumen plus 0.2 mL to ensure that the t-PA has close contact with any fibrin/clot at the distal tip of the catheter. It should dwell for 30 minutes to 2 hours and then be withdrawn. The dose may be repeated if withdrawal is unsuccessful.[212,242,244,245] If this is unsuccessful, an infusion of TPA 2 mg/50 mL infused over 4 hours may be used.[165] One Phase II trial examined Alfimeprase (recombinant fibrolase) because of its ability to cleave fibrin independently of plasminogen activation, as is necessary for t-PA, urokinase, and streptokinase.[246] Further study is planned.

For extraluminal thrombi refractory to the bolus administration of thrombolytics, options to dissolve the thrombus include infusions of t-PA, urokinase, or streptokinase through a catheter placed at or within the clot.[141,237,247] High-dose streptokinase therapy is effective[247] but expensive and is associated with a high incidence of bleeding. It is not recommended for patients with such bleeding risks as thrombocytopenia or mucositis. Infusion of urokinase for 24 to 72 hours restored catheter patency in 74% of patients (81% of those with clots present less than 7 days and 56% of those with clots present more than 7 days).[237] Infusion into the superficial venous circulation of the involved extremity was not effective. Even though a low infusion concentration was used (5000 international units/hour of streptokinase or 500 to 2000 international units/kg/hour of urokinase), a systemic lytic state was documented. Urokinase infusion should not be undertaken in patients with contraindications to systemic fibrinolytic therapy.[248] Another regimen for refractory clots involves an infusion of urokinase (40,000 units/hour) for 6 hours. This regimen led to dissolution of thrombi in 90% of patients; a repeat 6-hour infusion raised the dissolution rate to 95%.[249,250] Infusions as short as 1 to 3 hours were successful in one half the cases studied.[251] Addition of heparin to the 1- to 12-hour infusion did not improve the results.[251] No bleeding complications were seen. In patients with catheter tips placed below the carina and not adherent to the venous wall, there is a low risk of reocclusion; these catheters need not be removed.[251] Successful clot resolution with urokinase was reported for 50% to 87% of patients.[31,99]

Once patency is restored, heparin is usually given for 5 to 7 days. Studies have shown an increased risk of recurrent DVT/PE in cancer patients. Currently there is no sound evidence to guide duration of

anticoagulant therapy in these patients. The recommended practice is to continue treatment while there is evidence of active cancer and while the patient is receiving antineoplastics.[252]

Vesicant Drug Extravasation

It is very unusual for a spontaneous leak to form in a large-bore catheter, but an attempt to irrigate an occluded catheter with a small syringe can cause a rupture through which the drug can extravasate.[11,81] Occlusion of the catheter tip by a fibrin sheath may force drugs back up the sheath and through the exit site of the catheter.[52,140,253] This so-called back-tracking appears to be more common with percutaneously placed access devices.[138]

Leaks may develop if the catheter is disconnected from the reservoir or if the catheter is punctured by mistake by the Huber needle.[40] Outpatients using a port for continuous infusion of chemotherapy can experience drug extravasation if the Huber needle is dislodged from the septum.[129,254–256] Even usually nonvesicant drugs can produce skin necrosis severe enough to warrant removal of the port.[129] Use of the Port-A-Cath port, which has a thicker septum than the Mediport and Infus-A-Port devices, has been associated with only a 3% to 4% incidence of extravasation.[99,254–256] The thickness of the septum has been postulated to be responsible for the low incidence of needle displacement noted with the Port-A-Cath,[256] but no randomized trials have compared complications associated with the three devices. Selection of an appropriate length Huber needle and securing the needle to the chest wall with tape or a transparent occlusive dressing can provide some protection against dislodgment. If infusion pumps are used, attention must be paid to minimizing tension between the needle and the infusion tubing.

Treatment of Vesicant Drug Extravasation

Treatment protocols for vesicant drug extravasation, including those recommended by the Oncology Nursing Society,[257] are outlined in Table 96–2.[258–263] When these protocols were used, 89% of vesicant extravasations were reported to resolve without additional therapy.[258] However, 30% of anthracycline extravasations progressed to ulceration. A prospective uncontrolled study of anthracycline extravasation showed that the application of DMSO four times each day for 4 days prevented progression to ulceration in all patients.[264]

At many centers, it is recommended that an extravasation kit be kept in units in which vesicant drugs are given. The kit includes the appropriate medications, as well as order sheets preprinted for immediate use. For most vesicant drugs there is no proved antidote or local care measures. The antidote for vinca extravasation, hyaluronidase, is no longer commercially available. In general, whether an antidote is to be administered through the device or not, as much of the residual drug as possible should be aspirated from the needle, tubing, and tissues. Any antidote may then be administered. If swelling or pain persists for 72 to 96 hours after drug administration, a plastic surgeon should be consulted.

CENTRAL NERVOUS SYSTEM ACCESS DEVICES

In patients with hematologic disorders, devices that permit chronic access to the CNS are useful for a variety of purposes. The available devices include temporary or permanent epidural catheters, ports with attached silicone elastomer catheters, implanted pumps with attached silicone elastomer catheters, and Ommaya reservoirs. The choice of device is determined by a number of factors, including available routes, duration of therapy, cost, efficacy for the therapy planned (eg, antineoplastics vs pain medications), and the ability of the patient and family to care for the device.[265]

Catheters

Local anesthetics alone or combined with fentanyl, other opioids, and medications given through temporary epidural catheters (in place for less than 5 days), have successfully managed the pain and have improved oxygenation in children with sickle cell crisis.[266] Chronic epidural access has become widely available since the development of a permanent epidural catheter that can be placed percutaneously.[267] The catheters are most commonly used for pain control. Some catheters are one piece, and others consist of three pieces: two radiopaque silicone rubber catheters, an epidural segment (1.3-mm outer diameter), and an exteriorized line (3.1-mm outer diameter, 0.68-mm inner diameter) with an external Luer connector and a subcutaneous Dacron cuff and a splice segment that joins the two catheter segments.[267]

Insertion

Catheter insertion is done under local anesthesia or conscious sedation.[267] A paravertebral incision is made at the level of the L2 dorsal spine, and the epidural portion of the catheter is inserted through a 14-gauge Hustead or Tuohy needle to the desired spinal cord level. Epidural placement is verified by fluoroscopy and sensory blockade. The exteriorized line is then tunneled from a subcostal location on the mid-nipple line around to the lower end of the paravertebral incision, and the splice segment is secured to the two catheters and then to the supraspinous tissue to avoid kinking. A Millex-OR 0.22-μm filter is attached to the Luer connector, and a locking Luer injection cap is connected to the filter.

Access and Management

The catheter can be used immediately. Bolus doses can be given from a syringe, or the catheter can be connected to external pumps that deliver continuous infusion opioid with bolus rescue doses or combinations of opioids and local anesthetics. Only preservative-free solutions should be used. Wound and catheter exit-site cleaning and dressing changes are recommended until the last sutures are removed, usually after 3 weeks. After that, the exit site is cleaned every other day with povidone iodine, and the filter and injection port are changed weekly using sterile technique.[14,267] More detailed nursing protocols for accessing and managing these catheters and for monitoring patients receiving epidural opioids are available.[14] Patient and family education in catheter care can be effectively supplemented by referral to a home health care or hospice agency.[265]

Complications

The catheters can remain safely in place for months,[268] but even temporary catheters can rarely cause serious infections if left in place for days to weeks.[269] Complications include those attributable to the opioids being infused, pain during injection,[270] myoclonus,[271] epidural fibrosis,[272] obstruction and dislocation,[270,273] and infection.[268,270,274,275] Patients whose catheters take longer to insert have higher infection rates.[275] Exit-site and superficial catheter track infections occur infrequently (in approximately 10% of patients).[268,274] The epidural space infection rate has been reported as 1 in 1702 days of catheter use, similar to the infection rate of 1 in 1045 per days of use associated with the Hickman catheter.[269] *S. aureus* and *S. epidermidis* account for two-thirds of all infections.[268,269] Exit-site and superficial catheter track infections may be cleared without catheter removal,[268,274] but catheter removal is required for patients with deep catheter track or epidural infections (see Table 96–3 and the box on Infectious Indications for Device Removal).[268]

Table 96–2 Management of Vesicant Drug Extravasation

Drug Therapy	Local Care	Antidote Administration
Antibiotics		
Doxorubicin	Cold/ice pack for 15–20 min qid for 24–48 hours	Apply 1–2 mL of 99% DMSO to site every 6 hours.
Mitomycin-C		Apply 1–2 mL of 99% DMSO to site every 6 hours.
Vinca alkaloids		
Vincristine	For all vincas, elevate and apply warm pack for 15–20 min at least qid for 24–48 hours.	
Vinblastine		
Vindesine		
Vinorelbine		
Taxane		
Paclitaxel	Cold/ice pack 15–20 minutes qid for 24–48 hours.	
Alkylating agents		
Mechlorethamine		Mix 1.2 mL of 25% sodium thiosulfate with 8.4 mL of sterile water for injection. Through existing IV line, inject 2 mL of antidote for each 1 mg of drug extravasated. Remove needle and inject subcutaneously around site.
Cisplatin (only if >20 mL of 0.5 mg/mL concentration infiltrates)		Use sodium thiosulfate as above, 2 mL for each 100 mg of cisplatin infiltrated.

Pathogen	Source	Notable Complications
Gram-positive bacteria	Hub; skin at exit site of device	
Coagulase-negative staphylococci		
Methicillin-resistant *S. aureus*		Local/systemic suppurative complications
Staphylococcus epidermidis		
Enterococci, including vancomycin-resistant *Enterococcus*	Intestines	
α-hemolytic streptococci	Oropharynx	
Gram-negative bacteria		
Pseudomonas aeruginosa		
Klebsiella spp.		

Epidural Ports and Implanted Pumps

Epidural ports (eg, Port-A-Cath) and implanted pumps (eg, Infusaid, Medtronic) have also been used to deliver bolus or continuous infusions of opioids into the epidural or intrathecal space to relieve pain of malignant or nonmalignant origin.[271,274] Subarachnoid infusions using the implanted pumps are recommended as efficacious and cost-effective for patients with a relativel long life expectancy (>3 months).[271] The use of implanted pumps has been reviewed elsewhere.[276]

Complications include those previously described for implanted ports and pain on injection of morphine, pump pocket seromas, CSF leaks, CSF hygromas, and postspinal headache.[271,277] But the use of injection ports appears to reduce the rate of complications associated with percutaneously inserted epidural catheters. A retrospective comparison of catheters with or without associated injection ports indicated that those attached to ports became dislodged much less frequently and were associated with one-half the infection rate per 1000 patient-days.[278] Port removal rates for infection were similar to removal rates of ports used for vascular access (10%).[277] Because the seromas act as growth media for bacterial contamination, they should be monitored carefully. The management of hygromas and postspinal headache is reviewed elsewhere.[271] Ports and pumps can also erode through the skin.[14] Detailed access and management procedures for epidural ports and implanted pumps and for monitoring patients receiving opioids through them are available.[14,30]

Ommaya Reservoir

The Ommaya reservoir device was first described in 1963 by Ommaya,[279] and with minimal changes, it is still used for access to the spinal fluid within the cerebral ventricle. The reservoir is used to remove CSF for culture, cytology, or measurement of drug levels; to drain cysts in craniopharyngiomas and astrocytomas; to administer antibiotics or antifungal agents; to administer intraventricular chemotherapy to treat leukemic or carcinomatous meningitis; to administer interferon or lymphokine-activated killer cells directly into a tumor; and to administer opioid pain medications.[265,280]

The device consists of a dome- or mushroom-shaped capsule with a top made of a self-sealing silicone elastomer that can be punctured numerous times without leaking. The flat base of the capsule, by contrast, is composed of firm polypropylene and is not easily punctured. An outlet arm connected to a ventricular catheter is attached at the base, laterally or in the center, extending downward. Capsules range from 12 mm in diameter (for babies) to 30 mm. Those commonly used for adults have an internal volume capacity of 1.45 to 2.4 mL.

Insertion

The Ommaya reservoir is placed subcutaneously by a neurosurgeon.[281] Before insertion, CT is generally required to evaluate ventricular size and placement. Presoaking the device in bacitracin to prevent subsequent infection has been advocated.[282] For placement, the ventricular catheter is passed through a burr hole into the frontal horn of the right lateral ventricle or, if necessary, into that of the left lateral ventricle or the ventricle body. The catheter end is connected to the base or side arm of the capsule, which then is fitted into the burr hole or a subgaleal pocket. The Silastic skirt of the reservoir may be sutured to the periosteum. A postoperative CT scan is suggested to verify the catheter tip position. Stereotactic techniques are used when the ventricle is small or misplaced.[283]

Accessing the Device

The Ommaya reservoir can be used immediately postoperatively for sampling CSF or for injection of drugs. Usually, however, it is not accessed until the third postoperative day.[280] The thoroughly cleaned, gently shaved scalp is prepared with three iodine scrubs, and with the use of a sterile technique, the reservoir is accessed obliquely with a 23- or 25-gauge butterfly needle inserted with the bevel downward.[280] The CSF can be directly aspirated, or antibiotics or chemotherapeutic agents can be administered through a second syringe attached to the butterfly needle. After removal of the needle, the injected medication can be gently pumped into the spinal fluid by emptying the capsule using repeated pressure, but to allow CSF to refill the reservoir, the clinician should avoid steadily compressing the device.[284] After the incision has healed and the stitches have been removed, no special local care or flushing is required. The device can remain in place for months or years. More detailed accessing and management guidelines are available.[14]

Complications

Infection

In general, the Ommaya reservoir has proved very safe, with a complication rate of 9% to 20%,[281,282,285–287] although higher rates were reported in the past.[288] The most common complication is infection, which occurs in about 1% to 15% of patients,[286,287] especially those who have undergone radiation therapy or who required a second surgical procedure for revision of the catheter.[281] Most infections have been caused by *S. epidermidis*, but infections from numerous other gram-positive and gram-negative bacteria and fungal organisms have been documented.[286,289] In general, the device is not removed, and patients are treated as though they had meningitis. For infections with *S. epidermidis*, vancomycin is given intravenously[290] or, in refractory cases, instilled into the reservoir.[291] Removal of the reservoir is sometimes required.

Miscellaneous Complications

Neurologic complications are rare when the catheter is placed into the nondominant ventricle, but a variety of other complications, which occur infrequently, have been reported. These include intraventricular hemorrhage or subdural hematoma shortly after catheter placement; leakage of CSF around the catheter, primarily in patients with increased intracranial pressure, which caused backflow of fluid along the catheter and produced a subgaleal collection[288,292]; reservoir leaks after repeated use[285]; occlusion by cellular debris or, when a catheter is placed directly into a tumor, by very proteinaceous tumor fluid[285]; obstruction by lodging of the catheter in brain tissue or abutment against a ventricle wall[285]; seizures immediately after injection of medications[285]; white matter disease (leukoencephalopathy or brain necrosis), most often due to methotrexate injection through the Ommaya device, although found with systemic administration of methotrexate as well[285,293]; and tumor growth around the cannula. In one case, the catheter may have permitted the spread of Burkitt lymphoma cells from the meninges into the cerebral tissue, where the tumor was found.[294]

CHAPTER 97

LATE COMPLICATIONS OF HEMATOLOGIC DISEASES AND THEIR THERAPIES

Wendy Landier and Smita Bhatia

Survival of patients with hematologic malignancies has improved markedly over the past 3 decades. The population of long-term cancer survivors continues to grow. Sixty-six percent of adults and 79% of children with malignancies survive 5 years after diagnosis.[1] It is estimated that there are more 10 million 5-year cancer survivors in the United States, and approximately 15% of these survivors have been alive for 20 years.[2]

With this success comes the need to consider the long-term morbidity and mortality associated with the treatments responsible for increased survival. Late effects among individuals treated for cancer have been the topic of numerous reviews.[3–8] Disease- or treatment-specific subgroups of long-term survivors have been shown to be at risk for developing adverse outcomes, including premature death, second neoplasms, organ dysfunction (e.g., cardiac, pulmonary, gonadal), reduced growth and development, decreased fertility, impaired intellectual function, difficulties obtaining employment and insurance, and overall reduced quality of life.

Hematopoietic cell transplantation (HCT) is the treatment of choice for patients with hematologic malignancies experiencing recurrent disease after therapy with conventional regimens and for those with disease characteristics associated with a very poor prognosis when treated with conventional chemotherapy and radiation regimens. Complications observed after HCT often have a multifactorial origin encompassing issues related to prior cancer therapy, intensity of the preparative regimen, graft-versus-host disease (GVHD), and other posttransplantation complications.[9–16]

This chapter summarizes select long-term adverse outcomes in individuals treated with conventional therapy and HCT for hematologic malignancies. Recommendations for providing ongoing followup care to this population of survivors are reviewed.

CARDIAC EFFECTS

Chronic cardiotoxicity after therapy for hematopoietic malignancies usually manifests as cardiomyopathy, congestive heart failure, or pericarditis. The anthracyclines, notably doxorubicin and daunorubicin, are well-known causes of late-onset cardiomyopathy, characterized by increased afterload followed by development of a dilated, thin-walled left ventricle that eventually becomes poorly compliant. A review of 30 published studies determined that the frequency of clinically detected anthracycline-related congestive heart failure among survivors treated for cancer during childhood ranged from 0% to 16%.[17] In an analysis across reported studies, the type of anthracycline (e.g., doxorubicin) and the maximum dose given in a 1-week period (i.e., >45 mg/m^2) was found to explain a large portion of the variation in the reported frequency of anthracycline-induced congestive heart failure. The incidence of anthracycline-induced cardiomyopathy, which is dose dependent, may exceed 30% among survivors who received cumulative doses in excess of 600 mg/m^2.[18] Moreover, a cumulative anthracycline dose greater than 300 mg/m^2 administered during childhood has been associated with an 11-fold increased risk for clinical heart failure, compared with a cumulative dose of less than 300 mg/m^2, with the estimated risk of clinical heart failure increasing with time from exposure and approaching 5% after 15 years.[18]

The incidence of subclinical anthracycline-related myocardial damage has been the subject of considerable interest. A review of the literature on subclinical cardiotoxicity among children treated with an anthracycline found that the reported frequency of subclinical cardiotoxicity varied considerably across the 25 studies reviewed (frequency range 0%–57%).[17] Steinherz et al.[19] found that 23% of 201 patients who had received a median doxorubicin cumulative dose of 450 mg/m^2 had echocardiographic abnormalities a median of 7 years after therapy. In a group of childhood leukemia survivors who received a median doxorubicin cumulative dose of 334 mg/m^2, progressive elevation of afterload or depression of left ventricular contractility was present in approximately 57% of patients.[20] Because of marked differences in the definition of outcomes for subclinical cardiotoxicity and because of the heterogeneity of the patient populations investigated, accurate evaluation of the potential long-term outcomes within anthracycline-exposed patient populations or the potential impact of the subclinical findings is difficult.

Among anthracycline-exposed patients, the risk for cardiotoxicity can be increased by mediastinal irradiation,[21] uncontrolled hypertension,[22,23] underlying cardiac abnormalities,[24] exposure to chemotherapeutic agents other than anthracyclines (e.g., cyclophosphamide, dactinomycin, mitomycin C, dacarbazine, vincristine, bleomycin, and methotrexate),[23,25,26] and electrolyte imbalances such as hypokalemia and hypomagnesemia.[27] Risk also is increased for survivors who are female,[28] who are African American,[29] and who were very young (age <5 years) at the time of therapy.[30]

Chronic cardiac toxicity associated with radiation alone most often manifests as pericardial effusions or constrictive pericarditis, sometimes in association with pancarditis. This risk is associated with radiation dose and volume and is lifelong; absolute risk increases with length of time since exposure.[31] Although a 40-Gy dose of total heart irradiation appears to be the usual threshold, pericarditis has been reported after doses as low as 15 Gy, even in the absence of radiomimetic chemotherapy.[32] Symptomatic pericarditis, which usually develops 10 to 30 years after irradiation, is found in 2% to 10% of patients.[33] Subclinical pericardial and myocardial damage as well as valvular thickening may be common in this population.[34] Coronary artery disease has been reported after radiation to the mediastinum, although mortality rates have not been significantly higher in patients who receive mediastinal irradiation than in persons in the general population.[35]

Data regarding late cardiotoxicity after HCT are scarce, with studies limited because of small sample size and short followup.[9,36] Late cardiac dysfunction after HCT is multifactorial in origin. Factors that may increase the risk for its development include prior therapy with anthracyclines, total body irradiation (TBI), cyclophosphamide, and other cardiotoxic drugs. Damage often is subclinical and may not be detected by routine methods of investigation. More invasive methods, such as radionuclide angiography, may be required.

Comorbidities resulting from cancer treatment may increase the risk for cardiovascular disease in survivors. Oeffinger et al.[37] found that 62% (16/26) of young adult survivors of childhood acute lymphoblastic leukemia (ALL) had at least one cardiovascular risk factor (obesity, dyslipidemia, increased blood pressure, insulin resistance) potentially related to their cancer treatment. Patients treated with cranial radiation therapy had an increased incidence of obesity and dyslipidemia compared with those who received chemotherapy alone.

Given the known acute and long-term cardiac complications of cancer therapy, prevention of cardiotoxicity is a focus of active investigation. Previous reports have suggested that doxorubicin-induced cardiotoxicity can be prevented by continuous infusion of the drug.[38–40] Lipshultz et al.[41] compared cardiac outcomes in children with leukemia who received bolus or continuous infusion doxorubicin and reported that continuous doxorubicin infusion over 48 hours did not offer a cardioprotective advantage over bolus infusion. Both regimens were associated with progressive subclinical cardiotoxicity.

Agents such as dexrazoxane, which remove iron from anthracyclines, have been investigated as cardioprotectants. Clinical trials of dexrazoxane have been conducted, with encouraging evidence of short-term cardioprotection among children.[42] In a study of 206 children with ALL who were randomly assigned to receive doxorubicin with or without dexrazoxane, Lipshultz et al.[43] demonstrated that patients treated with doxorubicin alone were significantly more likely to have elevated troponin T levels, indicative of myocardial injury, than those who received doxorubicin with dexrazoxane, with no difference in event-free survival at 2.5 years. However, comprehensive long-term followup is required to document that dexrazoxane does have a cardioprotective effect while maintaining comparable event-free survival.[44,45] No peer-reviewed, published, randomized controlled trials have addressed the efficacy of dexrazoxane for preventing cardiac toxicity in adult patients receiving doxorubicin-based therapy for malignancies other than breast cancer. The long-term avoidance of cardiotoxicity with use of dexrazoxane has yet to be sufficiently determined.

PULMONARY EFFECTS

Compromise of pulmonary function among survivors of hematologic malignancies has been reported after conventional therapy for Hodgkin lymphoma[46–48] and leukemia[49,50] and after HCT.[10,11,51] Impairments evident by pulmonary function testing include reductions in total lung capacity, forced vital capacity, forced expiratory volume, and gas transfer, suggesting obstructive and restrictive defects. Risk factors include exposure to certain chemotherapeutic agents (particularly bleomycin), radiation to the chest, underlying lung disease, and younger age at exposure to the pulmonary-toxic therapeutic agents.

Significant late toxicities involving the airway and lung parenchyma, including restrictive and chronic obstructive lung disease and bronchiolitis obliterans, are observed in 15% to 40% of patients after HCT. Restrictive lung disease is related to pretransplant chemotherapy as well as therapeutic exposures used during conditioning.[52] Bronchiolitis obliterans has a strong correlation with chronic GVHD, has been reported in up to 14% of allogeneic transplantation recipients, and carries a mortality rate of 50%.[53]

ENDOCRINOLOGIC EFFECTS

Thyroid

Patients with hematologic malignancies who are treated with cranial, craniospinal, or mantle irradiation are at increased risk for thyroid complications. Among survivors of Hodgkin lymphoma (and, to a lesser extent, leukemia), abnormalities of the thyroid gland, including hypothyroidism, hyperthyroidism, and thyroid neoplasms, have been reported to occur at rates significantly higher than those found in the general population.[54–56] Hypothyroidism is the most common nonmalignant late effect involving the thyroid gland. After exposure to radiation at doses greater than 15 Gy, laboratory evidence of primary hypothyroidism is evident in 40% to 90% of patients with Hodgkin lymphoma and non-Hodgkin lymphoma.[55,57,58]

In an analysis of 1791 5-year survivors of pediatric Hodgkin lymphoma (median age at followup 30 years), Sklar et al.[54] reported the occurrence of at least one thyroid abnormality in 34% of subjects. The risk of hypothyroidism was increased 17-fold compared with sibling controls. Increasing dose of radiation, older age at diagnosis of Hodgkin lymphoma, and female gender were identified as significant independent predictors of increased risk. The actuarial risk of hypothyroidism for subjects treated with 45 Gy or more was 50% at 20 years after diagnosis of Hodgkin lymphoma. Hyperthyroidism was reported to occur in only 5%.

In another large cohort of 1677 patients with Hodgkin lymphoma treated with irradiation involving the thyroid at Stanford University Hospital between 1961 and 1989 (mean age at diagnosis 28 years, mean duration of followup 9.9 years), the actuarial risk of developing thyroid disease was 52% at 20 years and 67% at 26 years after treatment. In this population, the actuarial risk of developing overt or subclinical hypothyroidism was 44% by 25 years after therapy; the risk of developing thyroid cancer was 1.7% (15.6 times the expected risk).[55]

Most cases of overt hypothyroidism after HCT result from primary hypothyroidism caused by radiation injury. The incidence of hypothyroidism after HCT depends on the type of myeloablative conditioning regimen, ranging from as high as 90% after exposure to single-dose TBI to 10% to 15% after fractionated TBI.[13,14]

Thyroid nodules are common in patients treated with neck radiation for Hodgkin lymphoma, but the majority of these nodules do not undergo malignant transformation.[59,60] In a study of 647 children treated for Hodgkin lymphoma, 67 developed thyroid nodules during or after therapy (median time between diagnosis of Hodgkin lymphoma and thyroid nodule 10.5 years, range 0.2–24.8 years). All but one of these patients had received neck radiation as part of their therapy, with a median dose to the thyroid of 35 Gy. Seven (10%) of the 67 nodules were malignant.[59]

Growth

Poor linear growth and short adult stature are common complications after successful treatment of hematologic malignancies in childhood. The adverse impact of central nervous system (CNS) irradiation on adult final height among childhood leukemia patients has been well documented, with final heights below the fifth percentile in 10% to 15% of survivors.[61–64] The effects of cranial irradiation appear to be related to age and gender, with females and children younger than 5 years at the time of therapy being more susceptible. The precise mechanisms by which cranial irradiation induces short stature are not clear. Disturbances in growth hormone production have not been found to correlate well with observed growth patterns in these patients.[65,66] The phenomenon of early onset of puberty in girls receiving cranial irradiation may play some role in the reduction of final height.[67,68] Results regarding the impact of chemotherapy on final height in childhood leukemia survivors not treated with cranial irradiation are conflicting.[62,69]

Impaired linear growth after HCT likely is due to an interaction of multiple factors, including host characteristics (young age), treatment exposures (prior cranial irradiation, TBI), and post-HCT complications, such as chronic GVHD.[14] Findings suggest that final height is unaffected in children who receive busulfan or cyclophosphamide as pretransplant conditioning.[70]

Obesity

An increased prevalence of obesity has been reported among survivors of childhood ALL.[71] In an analysis from the Childhood Cancer Survivor Study, Oeffinger et al.[72] compared the distribution of body mass index of 1765 adult survivors of childhood ALL with that of 2565 adult siblings of childhood cancer survivors. Survivors were significantly more likely to be overweight (body mass index 25–30) or obese (body mass index ≥30). Risk factors for obesity were cranial irradiation, female gender, and age 0 to 4 at diagnosis of leukemia. Females diagnosed before age 4 years who received a cranial radiation dose more than 20 Gy were found to have a 3.8-fold increased risk for obesity. Obesity has the potential to adversely impact the

overall health status of survivors and is associated with insulin resistance, diabetes mellitus, hypertension, and dyslipidemia. Growth hormone deficiency related to cranial radiation may predispose adult survivors of childhood ALL, particularly females, to metabolic syndrome.[73]

Gonadal Dysfunction

Treatment-related gonadal dysfunction has been well documented in male and female patients after therapy for hematologic malignancies. A reasonable body of research provides a basis for counseling patients regarding the long-term gonadal effects of radiation and chemotherapy.

Radiation effects on the ovary are age and dose dependent. It has been estimated that 50% depletion in oocytes occurs after the ovaries are exposed to 2 Gy.[74] Amenorrhea develops in approximately 68% of prepubescent females treated with ovarian doses of 12 to 15 Gy for Hodgkin lymphoma, whereas 100% of adult females older than 40 years sustain irreversible ovarian failure after doses of 4 to 7 Gy.[75] Spinal irradiation for treatment of childhood leukemia appears to result in clinically significant ovarian damage in some survivors.[76] Cranial irradiation in young girls is associated with an increased risk for premature puberty.[77]

The effects of radiation on testicular function, including germ cell number and Leydig cell function, have been investigated. Reduced sperm production has been observed after testicular doses of 1 to 6 Gy and follows a dose-dependent pattern.[78] Azoospermia has been reported among patients with Hodgkin lymphoma with calculated testicular irradiation exposures ranging from 1 to 3 Gy.[79] Testicular doses between 4 and 6 Gy have been associated with prolonged azoospermia and decreased testicular volume.[80] The limited data on the long-term outcomes of very young males treated for Hodgkin lymphoma suggest germ cell effects similar to those seen in older patients with Hodgkin lymphoma.[81] Leydig cells, although also impacted by radiation in a dose-dependent fashion, require higher exposure levels to sustain damage than those seen for the germ cells.[82] Testicular dose of 24 Gy among prepubertal males have been reported to be associated with delayed pubertal development and abnormal testosterone and gonadotropin levels.[83–85]

Ovarian and testicular damage can result from chemotherapeutic agents, with alkylating agents showing the strongest association. Effects of chemotherapy on gonadal function typically are gender, age, and dose dependent. The ovaries tend to be less sensitive to the effects of alkylating agent exposure than are the testes. Ovarian dysfunction has been well documented in patients with Hodgkin lymphoma treated with alkylating agents, singly or in combination (e.g., MOPP regimen consisting of mechlorethamine, Oncovin [vincristine], procarbazine, and prednisone or a COPP regimen consisting of cyclophosphamide, Oncovin [vincristine], procarbazine, and prednisone).[86,87] MOPP and COPP regimens have been reported to result in azoospermia in more than 90% of exposed males.[88] Even with a reduction in the dose of cyclophosphamide in the hybrid COPP/ABV regimen for treatment of Hodgkin lymphoma, the majority of young males are infertile, likely due to the procarbazine component of this regimen.[89]

Young boys and adolescent males with aplastic anemia who receive standard-dose cyclophosphamide alone (200 mg/kg) as the pretransplant conditioning regimen appear to retain normal Leydig cell function, as do males who receive busulfan and cyclophosphamide, with normal plasma concentrations of luteinizing hormone (LH) and testosterone and normal progression through puberty.[14] Germ cell damage can occur and is more likely among patients treated after puberty.[90] Semen analyses have been normal in approximately two thirds of men after high-dose cyclophosphamide, and several men have fathered normal children. Men treated with TBI-based regimens who have not received prior testicular irradiation generally retain normal Leydig cell function, regardless of their age at treatment.[90] Germ cell dysfunction occurs in all men treated with TBI-based regimens, and azoospermia is the rule.

Female patients treated with high-dose cyclophosphamide alone retain normal ovarian function, regardless of age at exposure, although these subjects may be at increased risk for early menopause as they reach the third decade of life.[91] These individuals can sustain a normal pregnancy resulting in normal offspring. Females treated with busulfan and cyclophosphamide are at very high risk for ovarian failure and premature menopause.[92] The outcome of ovarian function after TBI appears to be determined by the age at exposure. Approximately 50% of prepubertal girls receiving fractionated TBI enter puberty spontaneously, and premature ovarian failure is seen in all patients older than 10 years of age when treated with TBI.[14] Pregnancies among survivors of TBI are at increased risk for spontaneous abortion.[93]

Pregnancy Outcomes

Offspring of survivors of childhood hematologic malignancies do not appear to be at increased risks for cancer or congenital malformations.[94] In a study of 593 adult survivors of childhood ALL, 15.7% (93/593) of survivors (mean age 22.6 years) had given birth to or fathered a total of 140 liveborn offspring, compared with 29.8% (122/409) of sibling controls (mean age 25.2 years). There was no significant difference in the rate of birth defects between offspring of survivors (3.6% [5/140]) versus sibling controls (3.5% [8/228]; relative risk 1.02; 95% confidence interval 0.34–3.05).[95]

MUSCULOSKELETAL EFFECTS

Avascular necrosis (osteonecrosis) is seen in pediatric and adult survivors of hematologic malignancies. Most often it is a consequence of therapy with corticosteroids, particularly dexamethasone, and occurs in up to 10% of patients.[96–98] This complication usually develops during or shortly after completion of therapy but may progress over time. Avascular necrosis of bone after allogeneic marrow transplantation is a frequent complication, with the reported incidence as high as 8% to 10% in long-term survivors.[99] Identified risk factors include prolonged steroid therapy for GVHD, male gender, and TBI. The mean latency period is 18 months. The hip is the most commonly involved joint (80%); however, the knee, wrist, and ankle joints also are affected in some patients. The probability of a patient requiring total hip replacement after diagnosis of AVN of the femoral head is 80% at 5 years.[100]

Osteopenia is commonly seen in survivors of hematologic malignancies.[101–103] Risk factors include therapy with corticosteroids, methotrexate (given at higher doses), and cranial irradiation with resultant pituitary insufficiency or gonadal dysfunction. Survivors of HCT are at increased risk for reduced bone mineral density. Identified risk factors in these patients include treatment with corticosteroids for chronic GVHD, prior cranial irradiation (resulting in growth hormone deficiency), and gonadal failure.[14] Lifestyle factors that increase the risk for osteopenia include lack of regular weight-bearing exercise, inadequate calcium and vitamin D intake, smoking, and excessive alcohol consumption.[104,105]

Radiation to the trunk (e.g., thoracic, abdominal, spinal) or TBI administered before skeletal maturity is achieved are risk factors for development of scoliosis and kyphosis.[106] Patients at highest risk are those who were very young at the time of radiation and those with a coexisting history of abdominal or thoracic surgery.

NEUROCOGNITIVE EFFECTS

Among survivors of childhood leukemia, neurocognitive late effects represent one of the more intensively studied topics.[107–110] Early curative regimens for childhood ALL relied heavily on cranial irradiation, usually in doses of 24 Gy.[107] Results from studies of neurocognitive outcomes in early populations of ALL survivors (particularly younger children) are directly responsible for the marked reduction in the use

of cranial irradiation, which currently is reserved for treatment of very-high-risk subgroups or patients with CNS involvement. As a general rule, neurocognitive deficits usually become evident within several years after CNS-directed therapy and tend to be progressive in nature. Leukemia survivors treated at a younger age (i.e., <6 years) may experience significant declines in intelligence quotient (IQ) scores.[111] However, reductions in IQ scores typically are not global but reflect specific areas of impairment, such as attention and other nonverbal cognitive processing skills.[112,113] Affected patients may experience information processing deficits resulting in academic difficulties. These patients are particularly prone to problems with receptive and expressive language, attention, and visual and perceptual motor skills, most often manifested as academic difficulties in the areas of reading, language and mathematics. Assessment of educational needs and subsequent educational attainment have demonstrated that survivors of childhood leukemia are significantly more likely to require special educational assistance but have a high likelihood of successfully completing high school if they receive appropriate educational services.[114,115] Chemotherapy- or radiation-induced destruction of normal white matter partially explains intellectual and academic achievement deficits.[116] The pathogenesis of CNS damage is only partially understood. Evidence suggests that therapy-related direct effects on intracranial endothelial cells and brain white matter, as well as immunologic mechanisms, play roles.

A spectrum of neuropathologic syndromes related to leukoencephalopathy[117] may occur in survivors of childhood hematologic malignancies, including radionecrosis, necrotizing leukoencephalopathy, mineralizing microangiopathy and dystrophic calcification, cerebellar sclerosis, and spinal cord dysfunction, manifesting clinically as ataxia, spasticity, dysarthria, hemiparesis, or seizures. Imaging abnormalities are not always evident in these patients. Leukoencephalopathy has been primarily associated with methotrexate-induced injury of white matter. However, cranial irradiation may play an additive role through disruption of the blood–brain barrier, allowing greater exposure of the brain to systemic therapy. Although some abnormalities have been detected by diagnostic imaging studies, the abnormalities observed have not been well demonstrated to correlate with clinical findings and neurocognitive status.

Many survivors of adult-onset hematologic malignancies experience impairments of neurocognitive function, including memory loss, distractibility, and difficulty performing multiple tasks. These patients may concurrently suffer from mood disturbances and symptoms that compromise their ability to function adequately, including fatigue and pain.[118]

Survivors of hematopoietic stem cell transplantations are at risk for neurocognitive late effects. Prospective, longitudinal evaluations of intellectual and adaptive functioning of children receiving a transplant have revealed declines in intellectual function, particularly among those younger than 6 years of age at the time of transplantation.[119] Among the adult populations, studies in general have reported good levels of function and well-being in long-term survivors of transplantation, although there are increasing reports of fatigue, lack of energy, sleep problems, sexual dysfunction,[120] and cognitive dysfunction[121–124] (see box on Neuropsychological Sequelae after Hematopoietic Cell Transplantation in Adults).

Neuropsychological Sequelae after Hematopoietic Cell Transplantation in Adults

The few studies describing neurocognitive sequelae in adults undergoing hematopoietic cell transplant (HCT) suggest that these patients are at risk for developing adverse sequelae related to neuropsychological functioning, such as slowed reaction time, reduced attention and concentration, and difficulties in reasoning and problem solving[121]; memory impairment[122–124,194]; problems with executive functioning and processing speed[123]; and cognitive impairment.[121–123] Reduced memory function is associated with older age, longer interval since HCT, chronic graft-versus-host disease, and long-term cyclosporine use.[195] Other predictors include fatigue and poor physical functioning. Lower education level and poorer social functioning appear to impact cognitive performance.[123] Therefore, it is prudent to query post-HCT patients regarding perceived deficits in neuropsychological functioning and to refer patients with these problems to a neuropsychologist who is experienced in the followup care of HCT patients.

OTHER TOXICITIES

Ocular Effects

Survivors of hematologic malignancies are at risk for development of cataracts as a consequence of therapy with corticosteroids, cranial irradiation,[125,126] TBI,[127] or busulfan.[128] Hoover et al.[126] evaluated 82 ALL survivors, all of whom received treatment with prednisone (3.4–10.2 g/m^2/year) and cranial irradiation (1800–2800 cGy). At a mean of 32 months after completion of therapy, 52% of patients had evidence of posterior subcapsular cataracts; however, the cohort had minimal ocular morbidity, with median visual acuity of 20/20 in the affected eyes (range 20/15 to 20/50). Holmstrom et al.[128] studied a cohort of 45 children who were followed for 2 to 10 years after HCT; 95% (20/21) of children conditioned with TBI and 21% (5/24) of children conditioned with busulfan developed cataracts. Belkacemi et al.[129] studied 1063 patients who underwent HCT for acute leukemia; the overall 10-year incidence of cataracts in this group of patients was 50%. Single-dose TBI was associated with a 60% incidence of cataracts. Fractionated TBI was associated with a 43% incidence in those receiving six or fewer fractions and a 7% incidence for those receiving more than six fractions. Factors independently associated with increased risk for cataract formation in this cohort were older age (>23 years), allogeneic blood marrow transportation, higher dose rate (>0.04 Gy/min), and steroid administration for more than 100 days. Xerophthalmia may occur as a late complication due to decreased lacrimation resulting from damage to the lacrimal gland during radiation or, in HCT patients, from chronic GVHD.[130]

Audiologic Effects

Survivors of hematologic malignancies who received platinum chemotherapy, those who underwent cranial irradiation at a young age (especially during infancy),[131] and those who required supportive therapy with aminoglycoside antibiotics[132] are at risk for therapy-related hearing loss. Hearing loss associated with ototoxic agents generally is sensorineural in origin and usually is irreversible. Although a low incidence of hearing loss has been reported in survivors of hematopoietic cell transplant performed in childhood, the risk is elevated threefold to fourfold over that in the general population.[127]

Dental Effects

Children whose teeth have not completely developed at the time of cancer treatment are most vulnerable to dental complications, and treatment with chemotherapy during early childhood may result in qualitative problems with enamel and root development.[133] However, patients of all ages who received radiation therapy involving the head or neck (including cranial irradiation and TBI) are susceptible to dental complications, most often manifesting as increased susceptibility to dental caries and gingivitis as a result of diminished salivary gland function. Patients who have undergone HCT are at increased risks for dental caries and gum disease; abnormalities of tooth development are seen in survivors who underwent HCT during childhood.[134] Younger age at transplantation (especially <6 years) and TBI doses greater than 10 Gy are associated with the greatest risk.[135]

Hepatic Effects

Although acute hepatic dysfunction may be seen with certain chemotherapeutic agents, including antimetabolites and anthracyclines, late hepatic toxicity has not generally been seen. However, reports of chronic hepatotoxicity and portal hypertension have emerged in survivors of childhood ALL who received 6-thioguanine–based maintenance therapy,[136–138] and these survivors require long-term surveillance for this complication.[139] Chronic viral hepatitis, resulting from transfusion of contaminated blood or serum products, should be considered in the differential diagnosis of all survivors with persistently elevated alanine aminotransferase levels. Hepatitis C is the most prevalent type of hepatitis seen in survivors transfused before universal screening of the blood supply for this infection (implemented in the United States in July 1992). Cirrhosis and hepatocellular carcinoma are potential sequelae of untreated chronic viral hepatitis and potential causes of morbidity and mortality in this population. In a cohort of 431 pediatric patients in Italy who were diagnosed with leukemia or lymphoma before 1990 and completed treatment before August 1994, 17.2% (74/431) were anti–hepatitis C virus positive.[140] Hepatocellular carcinoma or progression to liver failure was not seen in this group of patients after a 14-year median followup; however, due to the natural history of this disease, a longer followup is required to clearly define the risk of chronic hepatitis C virus infection in this population. In a study of 3721 survivors of HCT,[141] the cumulative incidence of cirrhosis was estimated at 0.6% after 10 years and 3.8% after 20 years. The major risk factor for development of cirrhosis in this cohort was chronic hepatitis C infection, evident in 81% (25/31) of patients with cirrhosis. These Seattle investigators estimate that approximately 30% to 35% of their patients transplanted before 1991 were infected with hepatitis C and are at risk for development of cirrhosis and related complications.

Second and Subsequent Malignancies

A *second cancer* is defined as a histologically distinct cancer that develops after the first cancer. In total, 95,000 of the approximately 1.2 million new cancers diagnosed every year in the United States are second cancers. Second cancers account for approximately 6% to 10% of all cancer diagnoses and are the fourth or fifth most common cancer in the United States.[142,143]

Several large epidemiologic studies have attempted to determine the magnitude of the burden of second cancers after primary cancers in adulthood. For example, 470,000 cancer patients registered between 1953 and 1991 in Finland were followed for the development of a second cancer.[144] Overall, the cohort was not at increased risk for developing a second cancer compared with the risk of cancer in an age- and gender-matched healthy population. However, patients younger than 50 years at the time of diagnosis of their primary cancer had a 1.7-fold increased risk for developing a second cancer. Another cohort of 633,964 cancer patients diagnosed between 1958 and 1996 in Sweden and followed for the development of subsequent cancers revealed a modestly increased risk (less than twofold) compared with the general population.[145] A third cohort of 250,000 patients followed for the development of a second cancer in the United States revealed that cancer patients had a 1.3-fold increased risk for developing a second cancer compared with the general population.[146] However, when determining second cancers after cancers occurring in childhood or adolescence, a clearer and somewhat different picture emerges.

Several studies following large cohorts of childhood cancer survivors have reported a threefold to sixfold increased risk for a second cancer compared with the background incidence of cancer in the general population, and this risk continues to increase as the cohort ages. Followup of a Nordic cohort of 30,880 patients diagnosed with their first cancer at 21 years of age or younger between 1943 and 1987 resulted in the identification of 247 second cancers.[147] The estimated cumulative incidence of second cancers in this cohort was 3.5% at 25 years, and the cohort was at a 3.6-fold increased risk for developing a second cancer compared with an age- and gender-matched healthy population. In a report, a retrospective cohort of 13,581 children diagnosed with common cancers in the United States before age 21 years between 1970 and 1986 and who survived at least 5 years was followed for the development of second cancers. The estimated cumulative incidence of second cancers was 3.2% at 20 years. Overall, the cohort was at a 6.4-fold increased risk for developing a second cancer. The relative risk of developing a second malignancy was significantly increased for survivors of non-Hodgkin lymphoma (relative risk 3.2), leukemia (relative risk 5.7), and Hodgkin lymphoma (relative risk 9.7). However, only 1.9 excess malignancies occurred per 1000 years of patient followup; therefore, even though the incidence of a second cancer is greater in those whose first cancer occurred in early life, the annual excess risk of second cancers in this group still is very small.[148]

Second cancers are conventionally categorized into two major types: acute leukemia and myelodysplastic syndromes or solid tumors. The latency between diagnosis and treatment of the primary cancer and the development of a secondary leukemia is generally short, whereas nonhematopoietic malignancies or solid tumors seem to have a longer latency, and the risk continues to rise for 2 or more decades.[149]

Evaluations of large cohorts of patients diagnosed with childhood ALL and entered into therapeutic trials of the Children's Cancer Group have shown that the cumulative incidence of second and subsequent malignancies is only approximately 2% at 15 years from diagnosis and treatment of ALL.[150,151] CNS tumors, the most common second malignancy observed among survivors of childhood ALL, are predominantly associated with exposure to cranial irradiation.[148] Histologically, radiation-related late-occurring neoplasms include high-grade gliomas, (glioblastomas and malignant astrocytomas), peripheral neuroectodermal tumors, ependymomas, meningiomas, and basal cell carcinomas.[150–153] Potential risk factors for secondary CNS tumors include younger age at radiation, inherited genetic predisposition to cancer, and genetic profile with regard to genetic polymorphisms involved in metabolizing enzymes. An example of a polymorphism that has been found to be predictive of the risk of secondary CNS tumors in childhood ALL is thiopurine *S*-methyl-transferase.[154] Other commonly reported second cancers within the population of ALL survivors include thyroid cancer, lymphoma, and acute myeloid leukemia (AML). Secondary thyroid malignancies, typically papillary carcinoma, are generally associated with radiation exposure to the thyroid gland as part of CNS irradiation, either prophylactic or for treatment of CNS leukemia. Thyroid malignancy has been reported to represent between 6% and 17% of secondary cancers among large cohorts of ALL survivors[148,150,151] and typically develops 10 or more years from treatment. As is true of *de novo* thyroid malignancy, the long-term outcome of survivors diagnosed with a secondary thyroid malignancy is excellent. The risk of secondary AML after therapy for ALL is generally low, except among patients treated with epipodophyllotoxin therapy in whom a cumulative risk of 3.8% at 6 years has been reported.[155] Secondary AML associated with topoisomerase II inhibitors is characterized typically by a shorter latency period (3–5 years from therapeutic exposure) than that seen for secondary AML after alkylating agents, lack of a myelodysplastic phase, and the presence of 11q23 rearrangements with mutations in the *MLL* gene. Epipodophyllotoxin-associated secondary AML depends more on the schedule of drug administration than on total cumulative dose.[156]

Because the survival rate for pediatric patients with Hodgkin lymphoma has been high for more than 3 decades, a considerable amount of outcomes-based research is focused on the occurrence of second malignancies in this population. Survivors of pediatric and adolescent Hodgkin lymphoma clearly represent one of the subgroups of cancer survivors who are at very high risk for secondary cancer. This is particularly true for patients who received earlier regimens with predominantly radiation-based therapies in whom an approximate 10-fold increased risk has been reported.[148] A number of studies, including cohorts ranging from 499 to 5925 patients with Hodgkin lymphoma, have reported cumulative risks of second malignancies ranging from 7.6% at 20 years to 18.0% at 30

years.[148,149,157–159] Early studies of survivors of Hodgkin lymphoma identified the increased risk of secondary leukemias among patients treated with MOPP-based therapy, which included mechlorethamine and cyclophosphamide.[160,161] These alkylating agent-associated secondary leukemias are characterized as having a relatively short latency period (mean approximately 7 years), presence of monosomy 5 or monosomy 7, and often preceded by a phase of myelodysplasia.[162] The risk of therapy-related leukemia usually does not extend beyond the first 10 to 15 years after therapeutic exposure.

There is increasing interest in the investigation of the associations between therapy-related myelodysplasia or acute leukemia and polymorphisms in specific drug-metabolizing enzymes capable of metabolic activation or detoxification of anticancer drugs, such as NAD(P)H:quinone oxidoreductase (NQO1), glutathione *S*-transferase (GST)-M1 and -T1, and CYP3A4.[163–165] Evidence indicates that the NQO1 polymorphism is significantly associated with the genetic risks of therapy-related acute leukemia and myelodysplasia. Individuals with the CYP3A4-W genotype may be at increased risk for treatment-related leukemia by increasing the production of reactive intermediates that might damage DNA.

Breast cancer is the most commonly reported second malignancy among female survivors of childhood Hodgkin lymphoma treated with mantle field irradiation, and the risk remains markedly elevated for many decades after exposure.[148,149,157–159] An update of the Late Effects Study Group cohort found female survivors had a 55-fold increased risk for breast cancer compared with the general population, and the cumulative incidence of developing a secondary breast cancer approached 20% at age 45 years.[166] Moreover, 40% of identified cases were found to have developed contralateral disease. Secondary thyroid cancer, the second most common solid tumor reported among survivors of childhood Hodgkin lymphoma, is strongly associated with radiation therapy, occurs more frequently in females, and is associated with an approximately 36-fold increased risk over the general population. As the cohort of pediatric survivors of Hodgkin lymphoma continues to age, an increasing number of other forms of malignancy associated with an excess risk likely will emerge. Extended followup of early cohorts have already reported excess risks for lung and gastrointestinal cancers.[166–170]

HCT recipients have a fourfold to sevenfold increased risk for developing a second cancer, particularly Epstein-Barr virus-related posttransplantation lymphoproliferative disease, myelodysplastic syndromes, and a variety of solid nonhematopoietic tumors.[171–173] Research indicates that the determinants of risk of second cancers are multifactorial. Second cancers are more likely to develop in survivors who were diagnosed with cancer at a younger age, after exposure to high-dose radiation therapy and certain chemotherapeutic agents, and in those with a known genetic predisposition to cancer.[148–150,174,175] Although we have begun to understand some of the causes of second cancers, we still have much to learn about the nature of the interactions among the treatments given for the initial cancer, genetic susceptibility to cancer, medical complications, and an individual's lifestyle choices in the genesis of subsequent new cancers.

Late Mortality

Late recurring disease as well as sequelae of treatment of hematologic malignancies can have a direct or indirect impact on overall mortality. Several large studies of late mortality among 5-year survivors of childhood cancer have been conducted.[176,177] In a study of 5-year survivors in the United States,[176] the probability of survival 25 years after diagnoses of leukemia, Hodgkin lymphoma, and non-Hodgkin lymphoma was 87%, 81%, and 90%, respectively. The standardized mortality ratio (SMR; i.e., observed deaths to expected deaths) for death due to subsequent cancer, cardiac complications, or pulmonary conditions was statistically significantly elevated among leukemia patients (SMR from 3.8 for cardiac complication to 17.4 for second cancer), Hodgkin lymphoma patients (SMR from 12.0 for pulmonary condition to 24.0 for second cancer), and non-Hodgkin lymphoma patients (SMR from 6.5 for cardiac complication to 15.6 for second cancer).

Late mortality due to recurrent disease and complications of therapy has been described among patients who underwent HCT for hematologic malignancies.[178,179] Socie et al.[178] reported that among 6691 individuals who underwent allogeneic transplant for hematologic malignancies and were free of disease 2 years after transplantation, the probability of living for 5 more years was 89%. The authors concluded that the disease probably is cured in patients who receive an allogeneic stem cell transplantation as treatment for AML, ALL, chronic myeloid leukemia (CML), or aplastic anemia and who remain free of their original disease 2 years later. However, for many years after transplantation, the mortality rate among these patients is higher than that in a normal population. Bhatia et al.[179] assessed late mortality in 854 survivors who underwent autologous HCT for hematologic malignancies and survived 2 or more years after transplant. At a median followup of 7.6 years. overall survival was 68.8% ± 1.8% at 10 years, and the cohort was found to be at a 13-fold increased risk for late death compared with the general population. Relapse of primary disease (56%) and subsequent malignancies (25%) were leading causes of late death.

Psychosocial Effects

Survivors of hematopoietic malignancies are at risk for adverse psychosocial outcomes that may impact the overall quality of life, including anxiety, depression, posttraumatic stress disorder, and barriers to accessing the health care system due to problems obtaining health insurance coverage. The impact of cancer therapy on psychosocial functioning is dependent on many variables, including intensity and duration of therapy, treatment-related complications, family functioning, developmental processes, and treatment-specific sequelae such as altered cognitive and physical functioning.[180]

Results from an analysis of 5736 long-term survivors of childhood leukemia and lymphoma demonstrated that although a relatively low proportion reported symptoms indicative of depression (4.6%) and somatic distress (10.8%), they were significantly more likely to report these symptoms compared with sibling controls.[181] Long-term survivors of adult-onset Hodgkin lymphoma report poorer health-related quality of life, primarily in physical health, compared with a healthy general population.[182] Survivors of Hodgkin lymphoma also appear to be at increased risk for psychosocial distress compared with acute leukemia survivors; areas of greatest impact for these patients include impaired family and sexual functioning.[183] There is growing interest in the reported occurrences of fatigue and sleep disturbances among cancer survivors, particularly those with Hodgkin lymphoma,[6,184,185] which may contribute to depression.

Fatigue, psychological distress, psychiatric symptoms, mood disturbances, and sexual difficulties are commonly reported by HCT survivors.[186] Risk factors for impaired health-related quality of life include older age, advanced disease at transplantation, presence of chronic GVHD, and lower level of education. Fatigue and sleep disturbances have been reported in up to 65% of patient cohorts studied,[187] and sexual disturbances are prevalent in 25% of HCT survivors[188] (see Evaluating Survivors for Potential Late Effects below).

POTENTIAL LATE EFFECTS BY DIAGNOSIS

Therapeutic approaches to hematologic malignancies vary widely depending on the patient's age at diagnosis, biologic subtype and staging of disease, year (era) of diagnosis, and physician/institutional preference. Even though two patients may share an identical diagnosis, their risks for late effects may differ significantly due to differences in therapy, age at exposure to therapy, or individual variations in the ability to handle the therapy (polymorphisms in drug-metabolizing enzymes). General associations of late effects with conventional treatment of common hematologic malignancies are reviewed in Tables 97–1 to 97–3. The risk for specific late effects in survivors who have undergone HCT depends on the conditioning regimen, donor source, complications experienced during the transplantation

Table 97–1 Late Effects Associated with Conventional Therapy for Acute Lymphoblastic Leukemia and Non-Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Vincristine	Peripheral neuropathy, Raynaud phenomenon
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Mercaptopurine	Hepatic dysfunction (rare)
Thioguanine	Portal hypertension, hepatotoxicity (when used continuously in maintenance therapy)
Methotrexate (systemic)	Osteopenia, osteonecrosis, renal dysfunction (rare), hepatic dysfunction (rare)
Methotrexate (intrathecal) Cytarabine (high-dose)	Neurocognitive deficits, clinical leukoencephalopathy
Cranial or craniospinal irradiation	Neurocognitive deficits, clinical leukoencephalopathy, cataracts, hypothyroidism, second malignant neoplasm in radiation field (e.g., skin, thyroid, brain), short stature, scoliosis or kyphosis, obesity
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML
Cyclophosphamide	Hypogonadism, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or myelodysplastic syndrome
Blood products	Chronic viral hepatitis, human immunodeficiency virus

AML, acute myeloid leukemia.

Table 97–2 Late Effects Associated with Conventional Therapy for Acute Myeloid Leukemia

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary acute myeloid leukemia
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Cytarabine (high dose)	Neurocognitive deficits, clinical leukoencephalopathy
Blood products	Chronic viral hepatitis, human immunodeficiency virus infection

process, presence or absence of GVHD, and prior cancer therapy. Transplantation-related sequelae have been reviewed throughout the text of this chapter.

Acute Lymphoblastic Leukemia

ALL, like most hematologic malignancies, is a heterogeneous disease. Therapy for ALL ranges from a relatively innocuous, antimetabolite-based approach for low-risk childhood ALL[189] to marrow-ablative therapy followed by HCT for very-high-risk disease in all age groups.[190,191] The risk of long-term complications in individual survivors varies widely and is dependent on the specific therapy received as well as the patient's age at the time of treatment. Potential late effects that may occur as a consequence of conventional therapy for ALL are listed in Table 97–1.

Acute Myeloid Leukemia

Therapy for AML is generally more intense and of shorter duration that that used for treatment of ALL. Higher doses of anthracycline

Evaluating Survivors for Potential Late Effects

To diminish the incidence and severity of untoward late effects and to improve the quality of survival for patients with hematopoietic malignancies, systematic evaluation of outcomes with subsequent modification of current and future therapies is required. To decrease late morbidity and mortality rates and to meet the specialized health care needs of this group of patients, ongoing comprehensive followup care with attention to early detection and intervention for late effects are essential.

Patients are generally eligible to enter formal long-term followup care when the risk of relapse of their primary disease is minimal. For most hematologic malignancies, this occurs when a patient is free of disease for 5 or more years and is at least 2 years off therapy. When a patient enters long-term followup, the focus of care shifts from management of the acute toxicities of therapy and vigilant surveillance for disease recurrence to a survivorship model of health maintenance or promotion and management of treatment-related late effects. Effective management of these late effects requires ongoing surveillance, early intervention, and, when possible, prevention.

The long-term complications of treatment for which an individual survivor is at risk are determined by several factors, including the patient's diagnosis, age at treatment, specific chemotherapeutic agents received (including cumulative doses), specific radiation fields and doses, therapy-related complications, degree of psychosocial support received, genetic predisposition, and current health-related behaviors (e.g., diet, physical activity, tobacco and alcohol use). Because of the impact of cytotoxic agents on growing tissues and organs, survivors treated during childhood or adolescence appear to be at higher risk for late complications than are those who received treatment after achieving physical maturity.

Table 97–3 Late Effects Associated with Conventional Therapy for Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Bleomycin	Pulmonary dysfunction
Vincristine, vinblastine	Peripheral neuropathy, Raynaud phenomenon
Procarbazine, mechlorethamine, dacarbazine	Hypogonadism, infertility, secondary AML or MDS
Cyclophosphamide	Hypogonadism, infertility, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Mantle irradiation	Hypothyroidism, premature cardiovascular disease, cardiovalvular disease, cardiomyopathy, arrhythmias, carotid artery disease, scoliosis or kyphosis, second malignant neoplasm in radiation field (e.g., thyroid, breast), pulmonary dysfunction
Inverted Y irradiation	Hypogonadism, infertility, adverse pregnancy outcome, second malignant neoplasm in radiation field (e.g., gastrointestinal)
Splenectomy	Acute life-threatening infections
Blood products	Chronic viral hepatitis, human immunodeficiency virus

AML, acute myeloid leukemia; MDS, myelodysplastic syndrome.

chemotherapy are often used, as is consolidation therapy with HCT. Typically, patients with AML receive less CNS-directed therapy than do those with ALL. Examples of potential late effects associated with conventional therapy for AML are listed in Table 97–2.

Hodgkin Lymphoma

Therapy for Hodgkin lymphoma relies heavily on the use of alkylating agents, antitumor antibiotics (including anthracyclines and bleomycin), corticosteroids, and radiation therapy. Many survivors are asplenic as a consequence of surgical staging. Examples of potential late effects associated with conventional therapy for Hodgkin lymphoma are listed in Table 97–3.

Non-Hodgkin Lymphoma

The potential late effects after therapy for non-Hodgkin lymphoma are therapy specific and similar to those experienced by survivors of ALL (see Table 97–1). Patients whose treatment included HCT are also at risk for transplantation-related sequelae.

Chronic Myeloid Leukemia

Long-term survivors of CML usually either have undergone HCT or are receiving imatinib mesylate (Gleevec) long term. Although therapy for CML differs from therapy for AML in that it generally does not require intensive pretransplantation chemotherapy; nevertheless, there is a significant risk for late effects as a result of the transplantation conditioning regimen as well as the treatment for and sequelae of GVHD.[15] As new therapies (e.g., imatinib mesylate [Gleevec]) for CML continue to emerge, potential late effects of these therapies in survivors will require study (see box on Late Effects Research: What Is Needed and Providing Clinical Care to Survivors above).

Late Effects Research: What is Needed

Medical Issues Faced by This Population

Cancer survivors are at increased risk for adverse outcomes, including the following:

- Premature death
- Second neoplasms
- Organ dysfunction (e.g., cardiac, pulmonary, gonadal)
- Impaired growth and development
- Decreased fertility
- Neurocognitive impairment
- Difficulties obtaining employment and insurance
- Overall reduced quality of life

Options for Physicians Providing Care to This Population

- Models of care delivery:
  - Pediatric oncology-based
  - Adult oncology-based
  - Community medicine-based
- Guidelines for ongoing screening and management:
  - Screening for potential complications
  - Health protective counseling or interventions
  - Management of identified complications

Major Clinical and Research Challenges

Cancer survivorship research continually changing because of new:

- Therapeutic agents and combinations of agents
- Radiation oncology techniques
- Surgical procedures
- Supportive care techniques

Future Directions

Much of the available information relates to outcomes within the first decade after treatment, and only minimal data address the longer-term outcomes that may occur later.

Research is needed to more clearly define the survivors at greatest risks for specific outcomes.

Research is needed to identify genetic predispositions to certain key outcomes and the roles of gene–environment interactions.

Research is needed to identify the role of lifestyle choices (e.g., alcohol, tobacco, diet, exercise) in terms of modification of the risks for these late outcomes.

Research is needed to understand the potential long-term impact of cancer therapy to effectively counsel survivors and offer effective intervention strategies to prevent or minimize the impact of adverse late effects.

Interventions are needed to include scientifically valid, evidence-based recommendations for clinical followup of survivors, which should include screening for potential late effects and application of proven approaches for health promotion.

PROVIDING CLINICAL CARE TO SURVIVORS

A comprehensive treatment summary should be prepared for each patient entering long-term followup (Table 97–4) and a copy given to each survivor with instructions to share this information with all

Table 97–4 Comprehensive Treatment Summary

Topic	Specific Information To Include
Demographics	Name Record number or patient identification number Date of birth Gender Race or ethnicity
Diagnosis	Date or age at diagnosis Referring physician or institution Treating physician or institution Presenting symptoms Past medical history Family history (including cancer in first- or second-degree relatives) Physical examination findings at presentation Initial diagnostics (complete blood cell count, chemistry panel, radiographic studies) Diagnostic procedures (biopsies, cytologic studies) Pathology (morphology, histology, cytochemistry, flow cytometry) Cytogenetics Central nervous system status (if applicable) Stage (if applicable) Metastatic sites (if applicable) Initial response to therapy (e.g., rapid early response [RER], slow early response [SER], date first complete remission achieved) Relapse(s) dates, age at relapse(s), relapse site(s)
Treatment	Date of initial treatment (initiated and completed) Date(s) for treatment of relapse (initiated and completed) Final off-therapy date Chemotherapy agents received, including route of administration (list all) Cumulative doses (in mg/m^2) and age at treatment for all alkylators, anthracyclines, and heavy metals Dose ranges for cytarabine and methotrexate (e.g., standard dose vs high dose ≥1000 mg/m^2) Radiation fields, doses, shielding, age at treatment Surgical procedure(s) Transfusion(s), including all blood or serum products Stem cell transplantation(s), including donor source, preparative regimen, GVHD prophylaxis or treatment
Acute complications	Significant therapy-related complications (e.g., tumor lysis, septic shock, typhlitis, acute GVHD) Significant treatment required for complications (e.g., hemodialysis, amphotericin, aminoglycosides)
Complications after therapy	Significant complications after completion of therapy (e.g., herpes zoster, acute life-threatening infection after splenectomy)

GVHD, graft-versus-host disease.

health care providers. Survivors should undergo annual comprehensive, multidisciplinary health evaluations (Fig. 97–1) with special attention to the detection of potential late effects specific to the patient's diagnosis and treatment history (Table 97–5). Guidelines for long-term followup of survivors of hematologic malignancies and those who underwent hematopoietic cell transplant in childhood, adolescent, or young adulthood have been developed by the Children's Oncology Group[192] (available at www.survivorshipguidelines.org). Because certain late effects have prolonged asymptomatic intervals before becoming clinically evident (e.g., late-onset congestive heart failure as a result of anthracycline-induced cardiomyopathy), ongoing evaluation is important for identifying and providing early intervention for these potential complications. Health education regarding potential health risks and risk reduction measures should be provided to each survivor. Targeted health education materials related to potential late complications of therapy during childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group[193] (available at www.survivorshipguidelines.org). After completion of each annual evaluation, identified late effects should be systematically recorded, and recommendations for any additional testing and for health maintenance and promotion should be shared with the patient and his or her primary health care provider. To optimize future followup care for all survivors, patients should be invited to participate in any relevant research studies for which they are eligible (see box on Late Effects Research: What Is Needed).

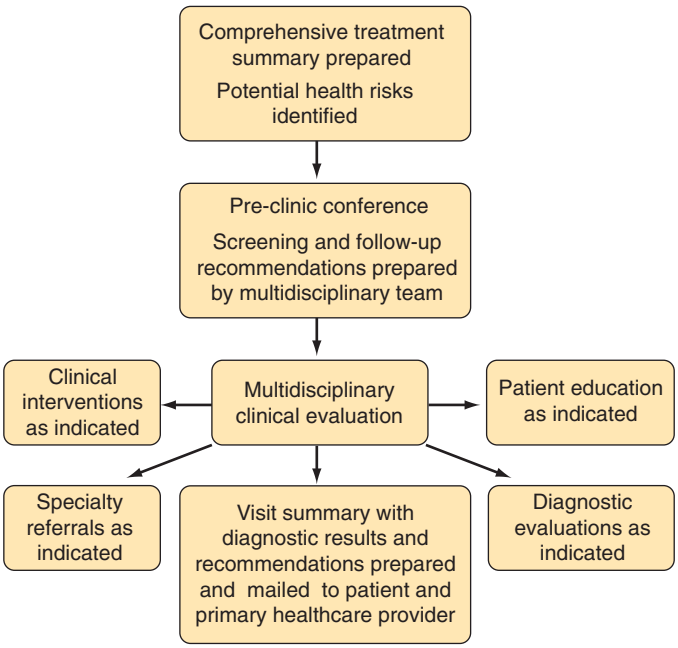

Figure 97–1 Annual comprehensive multidisciplinary health evaluation for the cancer survivor.

Table 97–5 Monitoring for Potential Late Effects

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Adverse psychosocial effects (e.g., depression, anxiety, posttraumatic stress disorder, limitations in health care access)	Diagnosis and treatment of hematologic malignancy	Clinical evaluation: yearly	Psychological or social work consultation if indicated
Dental abnormalities (abnormal tooth development; increased susceptibility to caries and gum disease)	Chemotherapy Cranial irradiation TBI	Dental examination: every 6 months	Professional dental cleaning every 6 months; use of fluoridated toothpaste; topical fluoride applications as indicated; Panorex radiograph before orthodontic or dental procedures for patients treated before completion of tooth development
Peripheral neuropathy Raynaud phenomenon	Vincristine Vinblastine	Neurologic examination if symptomatic	Physical therapy if indicated; advise patient to protect against precipitating factors (e.g., cold environment)
Neurocognitive deficits	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation TBI	Formal neuropsychological testing: baseline on entry to long-term followup; repeat as clinically indicated if evidence of impaired performance Clinical evaluation: yearly, including assessment of educational and vocational progress	Referral for specialized educational services, curricular modifications, or vocational training programs if indicated
Clinical leukoencephalopathy	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation	Clinical evaluation: yearly Brain MRI or CT if clinically indicated	Neurology consultation if clinically indicated
Cataracts	Corticosteroids Busulfan Cranial irradiation TBI	Funduscopic examination and visual acuity evaluation: yearly Ophthalmologic examination: yearly for patients who received TBI or cranial radiation ≥30 Gy; every 3 years for cranial radiation <30 Gy	Ophthalmology consultation if abnormalities detected
Xerophthalmia	Chronic GVHD related to HCT	History and eye examination: yearly	Artificial tears, ophthalmology Consultation if indicated
Xerostomia	Cranial irradiation Chronic GVHD related to HCT	Dental evaluation: every 6 months	Meticulous oral hygiene Artificial saliva products if indicated
Hearing loss	Platinum chemotherapy Aminoglycoside antibiotics Cranial irradiation	History and physical examination: yearly Audiogram: baseline at entry into long-term followup, then as clinically indicated; every 5 years for cranial radiation dose ≥30 Gy	Audiology consultation if indicated
Hypothyroidism Thyroid nodules Thyroid malignancy	Cranial, cervical, spinal, mantle, thoracic, or mediastinal irradiation TBI	Free T_4, TSH, thyroid examination: yearly	Endocrine or surgical referral as indicated

Table 97–5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Cardiomyopathy Arrhythmias Subclinical left ventricular dysfunction	Anthracyclines Chest or thoracic irradiation (e.g., mantle, mediastinal)	Detailed history of exertional tolerance (e.g., dyspnea on exertion, chest pain): yearly ECG (for evaluation of QT interval): baseline on entry into long-term followup; echocardiogram: baseline on entry to long-term followup, then every 1 to 5 years as indicated based on age at therapy and total anthracycline or radiation dose	Cardiology consultation if indicated; additional cardiology evaluation of patients who are pregnant or planning to become pregnant if patient received ≥300 mg/m^2 of an anthracycline, radiation dose ≥30 Gy, or any dose of anthracycline combined with irradiation
Pericarditis Pericardial fibrosis Valvular disease Premature atherosclerotic heart disease	Chest or thoracic irradiation (e.g., mantle, mediastinal)	Consider cardiology consultation 5–10 years after irradiation to evaluate risk for coronary artery disease in patients who received doses ≥40 Gy Fasting glucose and lipid profiles: every 3–5 years	Cardiology consultation if indicated; additional cardiology evaluation in patients who are pregnant or planning to become pregnant if patient received anthracycline combined with radiation, ≥300 mg/m^2 anthracycline, or radiation dose ≥30 Gy
Pulmonary dysfunction (fibrosis, interstitial pneumonitis)	Bleomycin Busulfan Chest/thoracic irradiation TBI Chronic GVHD related to HCT	Pulmonary function testing and chest radiograph: baseline at entry into long-term followup and as clinically indicated for patients with progressive dysfunction	Pulmonary consultation for symptomatic patients; influenza and pneumococcal vaccine; counsel patients to avoid smoking and avoid scuba diving
Thrombosis Vascular insufficiency Infection of retained cuff or line tract	Central venous catheter	History and physical examination: yearly as clinically indicated	Surgical referral as indicated
Hepatic dysfunction	Mercaptopurine, thioguanine, methotrexate (systemic) HCT	ALT, AST, bilirubin: baseline on entry into long-term followup; repeat if clinically indicated	If abnormal results on baseline studies, obtain prothrombin time (to assess hepatic synthetic function) and viral hepatitis screening
Chronic viral hepatitis	Blood products	Hepatitis C antibody and HCV-RNA by PCR: once if transfused before universal screening of blood supply (1992 in the United States) Hepatitis B surface antigen and core antibody: once if transfused before universal screening of blood supply (1972 in the United States)	Gastroenterology or hepatology consultation and annual AFP for patients with chronic hepatitis; hepatitis A and B immunizations in patients lacking immunity
HIV infection	Blood products	HIV-1 and HIV-2 antibodies: once if transfused before universal screening of blood supply (1985 in the United States)	Infectious disease consultation for patients with confirmed infection
Life-threatening infection	Splenectomy Splenic radiation ≥40 Gy Chronic active GVHD	Physical examination at time of febrile illness to evaluate degree of illness and for potential source of infection	Administer parenteral antibiotics and continue close medical observation in patients with temperature ≥38°C (101°F) or other signs of serious infection; immunize with pneumococcal, meningococcal, and HIB vaccines

Continued

Table 97–5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Iron overload	HCT (and patients requiring multiple red blood cell transfusions)	Serum ferritin: at entry into long-term followup	If abnormal, consider chelation, or repeat as clinically indicated until within normal limits
Bowel obstruction Chronic enterocolitis Fistulas and strictures	Abdominal surgery Abdominal or pelvic irradiation Chronic GVHD related to HCT (esophageal strictures, vaginal stenosis)	History and physical examination: yearly and as clinically indicated Serum protein and albumin levels: yearly in patients with chronic diarrhea or fistula	Surgical and gastroenterology consultations as clinically indicated
Renal insufficiency	TBI Abdominal or splenic irradiation Ifosfamide Platinum chemotherapy Methotrexate	Blood pressure: yearly Urinalysis: yearly BUN, creatinine, electrolytes, calcium, magnesium, phosphorus baseline and repeat as clinically indicated	Nephrology consultation for proteinuria, hypertension, progressive renal insufficiency
Hemorrhagic cystitis Bladder fibrosis Dysfunctional voiding Bladder malignancy	Cyclophosphamide Ifosfamide Irradiation of abdomen, pelvis, iliac, inguinal sites	Urinalysis: yearly Voiding history: yearly	Urology consultation for incontinence, dysfunctional voiding, macroscopic hematuria (culture negative)
Growth hormone deficiency	Cranial irradiation TBI	Height, weight: every 6 months during puberty until growth is complete Obtain bone age in poorly growing children	Endocrine referral for patients failing to follow normal growth curve
Overweight/obesity	Cranial irradiation	BP, growth percentile, BMI: yearly	Endocrine referral as indicated
Metabolic syndrome	TBI	Fasting glucose, lipid profile, and insulin levels every 2–5 years	
Hypogonadism Infertility	Alkylating agents Cranial irradiation Abdominal or pelvic irradiation Testicular irradiation Spinal irradiation >25 Gy TBI	Menstrual history, sexual function, height, weight: yearly Pubertal history, Tanner stage: yearly until maturity FSH, LH, estradiol or testosterone: baseline at age 13 years (females) or 14 years (males) or at entry into long-term followup and for clinical symptoms of estrogen or testosterone deficiency Semen analysis: as indicated or requested by patient	Endocrine referral for hypogonadal patients (for hormone replacement therapy); reproductive endocrinology referral for patients desiring evaluation of fertility options
Precocious puberty	Cranial irradiation	Physical examination, height, weight, Tanner stage: yearly until maturity LH, FSH, estradiol or testosterone: as clinically indicated in patients with accelerated pubertal progression Obtain bone age in rapidly growing prepubertal children	Endocrine referral as indicated
Adverse pregnancy outcomes (e.g., spontaneous abortion, premature delivery, low birth weight infant)	Irradiation of abdomen, pelvis, iliac, inguinal, paraaortic sites TBI	History: yearly and as clinically indicated	High-risk obstetric care

Table 97–5 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Osteopenia, osteoporosis	Corticosteroids Methotrexate (high-dose systemic) HCT	Bone density study (DEXA scan or quantitative CT scan): baseline at entry into long-term followup, repeat as clinically indicated	Calcium and vitamin D supplementation; weight-bearing exercise; treatment of exacerbating conditions (e.g., hypogonadism); consider pharmacologic intervention (e.g., bisphosphonates)
Avascular necrosis	Corticosteroids HCT	History: yearly; MRI if clinically indicated	Orthopedic consultation if indicated
Scoliosis/kyphosis	Irradiation of trunk (e.g., mantle, spine, abdomen, pelvis)	Physical examination of spine: yearly (every 6 months during pubertal growth spurt) Radiologic imaging of the spine if clinical evidence of scoliosis or kyphosis	Orthopedic referral
Joint contractures	Chronic GVHD related to HCT	Physical examination: yearly	Orthopedic referral if indicated
Chronic infection	Chronic GVHD related to HCT	History: yearly	Prophylactic antiinfective agents; infectious disease consultation if indicated
Vitiligo Scleroderma Joint contractures Nail dysplasia Dysplastic nevi Skin cancer Secondary benign or malignant neoplasms in radiation field	Chronic GVHD related to HCT Irradiation (any field)	Physical examination: yearly Careful physical examination, inspection and palpation of irradiated skin and soft tissues: yearly	Dermatology or rehabilitation consultation if clinically indicated Dermatology or surgical referral and radiographs if indicated for any suspicious lesions
Bone malignancies Brain tumor	Cranial irradiation	History and physical examination: yearly Brain MRI: baseline at maturity for all patients and as clinically indicated	Neurosurgical consultation as indicated
Breast cancer	Chest or thorax irradiation ≥20 Gy (mantle radiation field)	Clinical breast examination: yearly until age 25 years, then every 6 months Mammogram: yearly beginning at age 25 or 8 years after irradiation (whichever comes last)	Teach breast self-examination; instruct patient to perform monthly self-examination and report changes immediately; surgical consultation if clinically indicated
Gastrointestinal malignancy	Abdominal, pelvic, spinal irradiation ≥30 Gy	Colonoscopy every 5 years beginning 10 years after radiation or at age 35 years, whichever comes last; or more frequently as clinically indicated	Surgical consultation if indicated
AML (preceding myelodysplastic phase associated with alkylating agents)	Anthracyclines Epipodophyllotoxins Alkylating agents Stem cell priming with etoposide Autologous transplantation for NHL or Hodgkin lymphoma	Physical examination, CBC and differential: yearly for 10 years after therapy Bone marrow evaluation if clinically indicated	Counsel patient to report fatigue, bruising, bleeding, bone pain

AFP, α-fetoprotein; ALT, alanine aminotransferase; AML, acute myeloid leukemia; AST, aspartate aminotransferase; BMI, body mass index; BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood cell count; CT, computed tomography; DEXA, dual-energy x-ray absorptiometry; ECG, electrocardiogram; FSH, follicle-stimulating hormone; GVHD, graft-versus-host-disease; HCT, hematopoietic cell transplantation; HCV, hepatitis C virus; HIB, *Haemophilus influenzae* type B; HIV, human immunodeficiency virus; LH, luteinizing hormone; MRI, magnetic resonance imaging; NHL, non-Hodgkin lymphoma; PCR, polymerase chain reaction; T_4, thyroxine; TBI, total body irradiation; TSH, thyroid-stimulating protein.

CONCLUSION

As therapies for hematopoietic malignancies continue to improve, followup care for survivors of these diseases must be provided in a comprehensive manner. To minimize treatment-related sequelae and provide early intervention for identified late effects, the risks of long-term complications for each individual survivor must be evaluated; however, it is important to keep these risks in perspective. In reality, most survivors of hematologic malignancies have the potential to lead full lives with excellent performance status and minimal to no physical limitations. The overall goal of followup care is to assist each patient to maximize his or her full potential for a healthy life while balancing the small, but real, risk of potential complications that may arise. Providing this type of ongoing comprehensive followup care to survivors of hematologic malignancies is an essential service.

CHAPTER 98

OVERVIEW OF CELL- AND IMMUNE-BASED THERAPIES

Philip McGlave

INTRODUCTION

The use of cell- and immune-based therapies to treat hematologic disorders has come of age. Over the last 50 years hematopoietic cell transplantation has evolved into curative therapy for a variety of marrow failure states, hematologic malignancies, immune deficiencies, and inborn errors of metabolism. Appreciation of the graft versus tumor effect has provided a foundation for the treatment of hematologic malignancies with donor leukocyte infusions that exploit the allogeneic response of donor T lymphocytes, and experimentation with infusion of other allogeneic effector cell populations such as natural killer cells (see Fig. 98–1). During this era, investigators have made remarkable progress in the use of reduced-intensity conditioning, alternative donors for transplantation and measures to prevent and treat graft-versus-host disease (GVHD) and infections. Parallel studies have demonstrated the efficacy of humanized monoclonal antibodies used alone or conjugated to radioactive isotopes to treat hematologic malignancies. Collectively, these advances have expanded the population eligible for cell- and immune-based therapies to include nearly all children and adults. This chapter provides a brief overview of principles underlying the treatment of hematologic disorders with cell and immune-based therapies. These topics are discussed in depth in Chapters 98 to 113.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Transplant Terminology

The first successful hematopoietic cell transplants in humans were performed by infusion of hematopoietic progenitor and stem cells derived from the marrow of identical twins (syngeneic transplant). Application of transplant therapy broadened with the use of hematopoietic cells obtained from either related or unrelated donors (allogeneic transplant) suitably matched at the human leukocyte antigens (HLA), or even with a patient's own hematopoietic cells (autologous transplant). Although the term *bone marrow transplantation* (BMT) is historically applied to the field, *hematopoietic cell transplantation* (HCT) may be more appropriate because stem and progenitor cells are needed for prompt and complete engraftment in the clinical arena, and their source may be not only marrow but peripheral blood (PB), umbilical cord blood (UCB), or even fetal liver.[1,2]

Allogeneic Transplant Principles

Successful allogeneic HCT depends on principles demonstrated first in animals and then in the human clinical setting. Hematopoietic stem and progenitor cells obtained from donor marrow or other sources are infused intravenously, home to the recipient's hematopoietic microenvironment, and engraft.[3,4] Under optimal circumstances the recipient's immune system will tolerate engraftment of donor cells so that neither nonengraftment nor late graft failure occurs. Immune effector cells from the donor will interact with recipient cells and tissue in a fashion that ensures sustained engraftment and does not provoke fatal GVHD. Eventually, reconstitution of B lymphocyte, T lymphocyte, and natural killer (NK) cell function occurs, a stable chimeric state predominates, and a long-lasting graft-versus-tumor (GVT) effect is sustained.[5–7]

Donor–Recipient Histocompatibility

Transplantation of allogeneic cells requires careful matching of donor and recipient. Failure to do so is associated with delayed or incomplete engraftment and with GVHD. Graft failure and GVHD can occur when immunocompetent cells of host or donor origin respectively respond to alloantigens encoded on the major histocompatibility complex (MHC) and peptides presented in association with these antigens.[8,9] The MHC is located on chromosome 6 in humans and contains two distinct human HLA families implicated in alloreactivity. HLA class I antigens are encoded by three dominant loci termed HLA-A, HLA-B, and HLA-C. HLA class II antigens are encoded by three loci termed HLA-DR, HLA-DP, and HLA-DQ. Historically, HLA antigens were defined by serologic testing. More recently, families of alleles corresponding to the HLA antigens have been identified by molecular methods, and donor–recipient HLA characterization now depends heavily on these molecular methods.[10]

In both the related and unrelated donor transplant setting, optimal clinical results are achieved when donor and recipient are matched at HLA class I and HLA class II. Successful allogeneic transplantation can occur, however, even with some degree of HLA mismatch.[11] For example, successful transplant of HLA haploidentical related donor hematopoietic cells after T lymphocyte depletion has been reported,[12,13] and some degree of donor–recipient HLA mismatch is common in adult, volunteer unrelated donor transplant and unrelated umbilical cord blood transplant.[14] Both graft failure and GVHD can occur even in cases where apparent MHC matching is achieved, and in some cases mismatch of antigens not recognizable with current testing methods may have clinically relevant consequences.[15]

Graft-Versus-Host Disease

GVHD is the most important cause of mortality, morbidity, and diminished quality of life after allogeneic HCT. Early observations suggested that GVHD occurred when immune effector T lymphocytes engrafted and subsequently attacked host tissue. Recent observations have characterized a more complex process underpinned by host tissue damage and release of inflammatory factors, involvement of host as well as donor cells implicated in inflammation, antigen presentation, and immune effector function and modulation by regulatory T (Treg) cells and other cell populations.[16–19] Acute GVHD occurs in the first few months after engraftment, whereas a somewhat different clinical syndrome termed chronic GVHD typically evolves later in the transplant course. Chronic GVHD often appears as a sequela of acute GVHD and can be a chronic illness resulting in physical stigmata as well as malabsorption, chronic infection, failure to thrive, and generalized debility. GVHD can be exacerbated by HLA mismatch, infection, prior host tissue damage associated with the underlying disease, previous therapy, or tissue damage associated with the preparative regimen.[20–24]

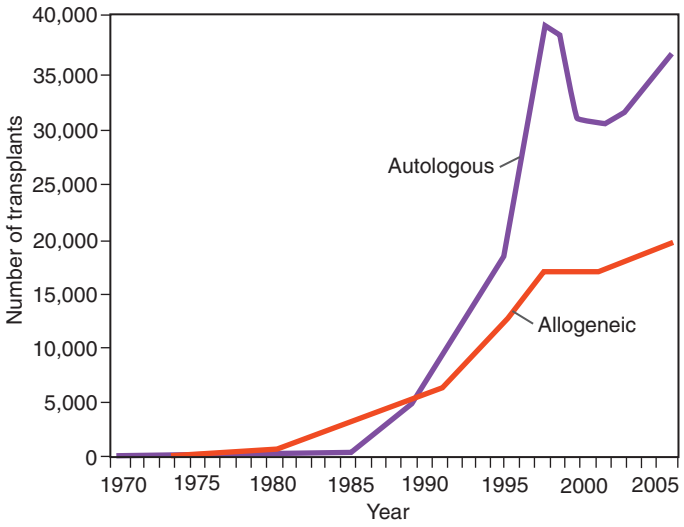

Figure 98–1 Annual numbers of hematopoietic cell transplants worldwide. There are now an estimated 50,000 to 60,000 autologous and allogeneic hematopoietic cell transplants performed each year. (Adapted from CIBMTR Summary Slides, 2007.)

Cyclosporine has become the backbone of in vivo GVHD prophylaxis and treatment. This compound inhibits calcineurin cell membrane flux and has a specific suppressive effect on T lymphocyte function. Cyclosporine, tacrolimus, or related calcineurin inhibitors may be used alone or in combination with other agents that have specific effects on lymphocytes such as sirolimus, agents with general immunosuppressive functions such as steroids, methotrexate or antithymocyte globulin, or with promising agents such as rituximab, whose mechanism of action in GVHD is not entirely understood.[25]

Acute GVHD can also be prevented or ameliorated by ex vivo depletion of T lymphocytes (T-cell depletion) from the hematopoietic stem and progenitor cell inoculum. Ex vivo T-cell depletion can be accomplished by negative selection of T cells with monoclonal antibodies used alone, conjugated to toxins (immunotoxins) or by physical methods such as elutriation.[26] Alternatively, positive selection of hematopoietic cells based on physical properties such as CD34 expression (CD34 selection) can provide an inoculum enriched for hematopoietic progenitors and depleted of T lymphocytes. Antibodies specifically targeting T cells can also be used for in vivo T-cell depletion.[27]

Graft-Versus-Tumor Effect

Early investigators postulated that effective antitumor therapy with hematopoietic cell transplantation might require not only an ablative effect of the preparatory conditioning regimen but also an ongoing allogeneic graft versus tumor (GVT) or graft versus leukemia (GVL) effect.[28] Subsequent reports of a high incidence of relapse after T cell-depleted related donor transplant therapy for chronic myelogenous leukemia (CML), and of the reinduction of cytogenetic and molecular remissions after donor leukocyte infusion (DLI) supported the importance of the GVT effect.[29,30] Recent studies implicate an interplay of donor and recipient T lymphocytes and, possibly, a role for NK cells in the GVT effect.[31–34] In any case, the GVT effect plays an important role in the long-term suppression of malignant clones of host origin, which sometimes survive even the most rigorous preparative regimens.

Conditioning Regimens for Allogeneic Transplantation

Historically, recipients were treated with an immunosuppressive conditioning regimen to ensure engraftment of donor hematopoietic stem cells. A regimen of high-dose cyclophosphamide (CY) used alone was immunosuppressive and could be used successfully to condition patients with nonmalignant conditions such as severe aplastic anemia, immunodeficiencies, or inborn errors of metabolism for HCT.[35] Regimens containing high-dose cyclophosphamide used first in combination with total body irradiation (CY/TBI) or subsequently with busulfan (BU/CY) were considered "ablative" and were used to provide immunosuppression and tumor suppression in patients receiving HCT therapy for a variety of malignancies.[36–39] Acceptance of the GVT effect led to speculation that "reduced-intensity conditioning" (RIC) regimens could be employed to treat hematologic malignancies with HCT. Such regimens provided adequate immunosuppression for engraftment, relied on the GVT effect for ongoing tumor suppression, and spared patients the toxicity associated with ablative conditioning.[40,41] Reduced-intensity conditioning regimens may use cyclophosphamide or TBI, but at markedly reduced doses. Other immunosuppressive agents such as antithymocyte globulin or fludarabine may also be effective.[42,43] Reduced-intensity conditioning is often used in older, debilitated, or heavily pretreated patients in whom the toxicity associated with ablative conditioning would be unacceptable.

Alternative Donors

Application of allogeneic HCT has broadened as investigators demonstrate that donors other than HLA-identical or 1 antigen mismatched siblings can be used successfully. Recently, there has been resurgent interest in the use of HLA haploidentical related donors for HCT. HLA haploidentical transplant is appealing because a suitable related donor is usually available. However, such transplants require aggressive immunosuppression, and effects on engraftment, GVHD, and immune reconstitution are not yet fully understood.[12,13] Adult volunteer unrelated donors (URD) have been used successfully as a source of hematopoietic cells for transplantation for more than 30 years.[44–47] Results with an HLA-matched URD transplant performed in younger patients are comparable to HLA-matched sibling transplant.[48] The process of donor identification and hematopoietic cell procurement has been vastly aided by the development of international registries such as the National Marrow Donor Program (NMDP), with more than 30,000 transplants facilitated from 1987 to 2007.[49,50]

Perhaps the most exciting recent development in the field of HCT has been the successful use of umbilical cord blood (UCB) derived from related or (more commonly) unrelated donors as a source of donor stem and progenitor cells.[51,52] The establishment of a worldwide network for UCB cell procurement, typing, and storage has resulted in the collection and cryopreservation of more than one-quarter million cords and has facilitated more than 7000 unrelated donor UCB transplants. Recent clinical studies suggest that the use of pooled cells from two cords (double cord blood transplant), each partially or completely HLA-matched with the recipient, can provide timely engraftment even in larger, unrelated recipients.[53] Most recently, UCB transplant after RIC has been tested successfully.[54] Collectively, these advances in the use of alternative donors combined with standard ablative or RIC regimens suggests that transplants will be available for the majority of children and adults who are otherwise suitable candidates for such therapy.

Clinical Application

The first successful use of human hematopoietic cell transplantation was reported in the late 1950s by E. Donnall Thomas and colleagues, who demonstrated that marrow cells from identical twin donors could reconstitute hematopoiesis after supralethal irradiation therapy for acute lymphocytic leukemia.[55] Subsequently, other groups used HCT to restore immune function in children with immune deficiencies and to attempt correction of inborn errors of metabolism.[56,57]

By the late 1970s, Thomas and his group had ushered in the era of successful antitumor therapy with hematopoietic cell transplantation when they reported that HLA-matched sibling transplantation could be used to correct refractory cases of acute leukemia.[58] A similar story unfolded in the treatment of CML and other hematologic malignancies, as well as severe aplastic anemia and other marrow failure states.[59–63] Dramatic improvement in transplant outcome occurred when investigators realized that transplant therapy was most effective when used early in the disease course, rather than as a "last resort."[64]

Broad acceptance of alternative donors by the transplant community has greatly broadened the pool of eligible transplant recipients.[65,66] Successful use of RIC approaches has also opened transplant to older and more debilitated patients and seems to be particularly useful in CML and some low-grade lymphoid malignancies. Collectively, these advances now permit allogeneic transplant therapy for the majority of suitable candidates in ages ranging from infancy to the eighth decades.

A Primer On Terminology

The field of blood and bone marrow transplantation is changing rapidly, and so is the terminology. In fact, we now use the term *hematopoietic cell transplant* (HCT) instead of *bone marrow transplant* because we often obtain hematopoietic stem and progenitor cells from the peripheral blood after mobilization, or even from *umbilical cord blood* rather than from the marrow. Some terms have not changed, however. *Syngeneic transplants* require an identical twin donor whereas *allogeneic transplants* draw on other related or unrelated human donor sources. Of course, we can also use the recipient as a source of his or her own cells in the *autologous transplant* process. We can prepare recipients for HCT with an *ablative* conditioning regimen. However, *reduced-intensity conditioning* or even *nonmyeloablative conditioning* regimens may have advantages in some settings and can be effective because we now realize that donor cells exert a *graft-versus-leukemia* or *graft-versus-tumor* effect. This beneficial immune-mediated effect of allogeneic HCT must be distinguished from acute or chronic *graft-versus-host disease* resulting from an interaction of donor immune or effector cells with host cells and tissue, and leading to a variety of often serious clinical problems.

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION

Autologous Transplant Principles

Autologous hematopoietic cell transplantation is most commonly used to reestablish hematopoiesis after high-dose cancer chemotherapy or radiation therapy. This approach permits the use of antitumor agents in doses much higher than can be provided in a conventional therapy setting. Autologous HCT is most useful in circumstances where a correlation exists between increased therapy dose and tumor response, and where the dose-limiting feature of therapy is hematopoietic suppression.

In selected cases, autologous HCT may have advantages over allogeneic transplant. There is no need to identify an HLA-compatible related or unrelated donor. Immunologic complications of allogeneic transplantation such as graft failure and GVHD are avoided. The use of immunosuppressive agents for transplant preparation, GVHD prophylaxis, and GVHD treatment is unnecessary. Not surprisingly, transplant mortality is low. Older patients tolerate the autologous transplant procedure relatively well. Hospital stay and convalescence periods are shorter. With the judicious use of prophylactic and empiric antimicrobial therapy, nutritional support, a state-of-the-art clinic facility and dedicated caregivers, many autologous transplants may even be performed in the outpatient setting.[67]

Unfortunately, autologous transplant has important drawbacks. The benign hematopoietic stem and progenitor populations may be reduced or damaged by previous therapy, resulting in delayed or partial engraftment.[68] The inoculum, whether derived from marrow or blood, may be contaminated with clonogenic malignant cells capable of re-establishing primary tumor growth in the transplanted patient.[69] The risk of relapse is compounded because autologous HCT does not produce an ongoing GVT effect analogous to that observed after allogeneic transplant. Finally, autologous transplant may increase the risk of secondary, therapy-related myeloid leukemias or myelodysplastic syndromes.[70]

Priming and Mobilization

The priming process facilitates collection by apheresis of a mobilized peripheral blood mononuclear cell population enriched for hematopoietic progenitors. In some cases, priming is performed with growth factor alone or, in some cases, with a combination of chemotherapy and growth factors.[71,72] The use of chemokines in the CXCR family during the mobilization process may further enhance the yield of hematopoietic progenitors. These agents interfere with adhesion of hematopoietic progenitors in the microenvironment and promote their circulation in the peripheral blood.[73] The use of these various mobilization approaches can result in WBC and platelet engraftment within 2 weeks. The shortened time to engraftment associated with peritransplant use of hematopoietic growth factors, antimicrobial agents, and transfusions have resulted in a shift to outpatient-based autologous HCT.[67]

Clinical Application

Autologous HCT therapy for selected subsets of patients with acute myelogenous leukemia (AML) in first remission as well as some cases of Hodgkin and non-Hodgkin lymphoma can result in long-term disease-free survival.[74–76] Autologous transplant therapy can also prolong survival when used as therapy for myeloma.[77] Innovative trials with tandem autologous transplants or autologous followed by RIC allogeneic HCT (auto/allo transplant) in the treatment of myeloma have been undertaken; however the roles of single auto, tandem auto, or "auto/allo" tandem HCT in the treatment of myeloma have not yet been determined definitively.[78–81] As noted above, there is an unexpectedly high incidence of myelodysplastic syndrome and other hematologic malignancies after autologous HCT. It is not known if this is a result of an underlying predisposition for hematologic malignancies in these patients, damage to hematopoietic progenitors during the conventional and autologous transplant therapy, or a combination of these factors.[82–84]

NEWER APPROACHES TO CELL- AND IMMUNE-BASED THERAPIES

Effector Cells

Although there has been a long-standing acceptance of the GVT effect, clinical application was first demonstrated in 1990 when Kolb infused donor leukocytes into relapsing allogeneic transplant recipients.[29] In these cases, and in scores of cases reported subsequently, DLI produced a rapid reversal of the relapsing hematologic malignancy.[85–87] Optimal timing, number, and cell dose of the DLI is not known. GVHD and graft failure can complicate DLI therapy, especially if there is limited donor chimerism at the time of DLI.[88,89] Donor leukocyte infusion may be more effective in the treatment of some relapsing diseases such as CML and low-grade lymphoid malignancies and less effective in the treatment of other hematologic malignancies.

Investigators have speculated that natural killer (NK) cells may have an antitumor effect.[90,91] Recent reports suggest that "killer immunoglobulin receptors" (KIRs) found on NK cells are implicated in killing of host leukemia cells after HCT, although the importance of KIR is not fully understood.[33,92] Clinical trials of allogeneic NK infusion without allogeneic HCT have also demonstrated unexpected remissions in refractory AML patients.[93] Collectively, these observations suggest that allogeneic NK cells may be useful in the treatment of select hematopoietic malignancies, even in the nontransplant setting.

Antibody and Radioimmunotherapy

The development of rituximab, a humanized monoclonal antibody that recognizes the CD20 receptor on benign and malignant B-cells, has had a profound effect on the therapy of B-cell lymphoma. This antibody has efficacy in both low-grade and aggressive lymphomas and can be used successfully alone and in combination with conventional chemotherapy, even in the elderly.[94,95] Recently, anti-CD20 antibody has been conjugated to either ^{90}Yttrium or ^{131}Iodine. Both radioimmunoconjugates have activity against a spectrum of B-cell lymphomas.[96,97] Efforts are now focused on determining the optimal treatment strategies for the use of rituximab and of anti-CD20 radioimmunoconjugates alone or in conjunction with conventional chemotherapy.[98] It seems likely that the development of these and other antibodies and immunoconjugates recognizing specific cell surface receptors on malignant cells will change our approach to the treatment of hematologic malignancies including choice of initial therapies, approach to refractory or recurrent disease, and timing of HCT.[99,100]

Long-Term Effects and Quality of Life

As the field evolves, investigators have begun a systematic attempt to understand the impact of cell- and immune-based therapies not only on the disease process but on the quality of life and on well-being in long-term survivors (see Fig. 98–2). Such studies have demonstrated significant problems with growth and retardation in children, the development of second tumors, long-lasting adverse effects on physical and mental health, sexual function, capacity to return to work, and even overall economic status.[101–103] These important observations are being incorporated into the informed consent process and should lead to judicious choices of initial therapy and increased efforts to provide ongoing medical, counseling, and financial help for patients receiving cell- and immune-based therapies.[104,105]

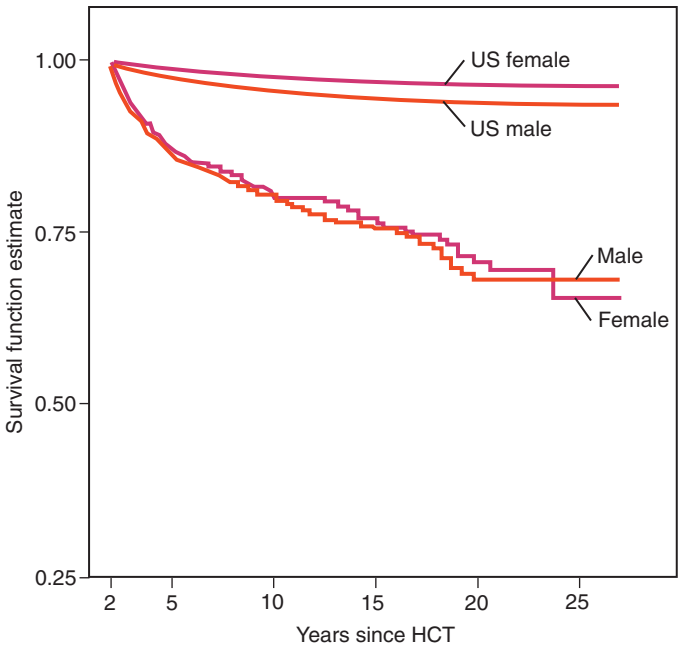

Figure 98–2 Assessment of late mortality in 1479 allogeneic HCT recipients surviving more than 2 years from transplant. Transplant survivors have a significantly higher mortality rate than that of the general population, even after 15 years. Leading causes of death are relapse and complications of chronic GVHD. CHAPTER 99

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACQUIRED NONMALIGNANT DISEASES AND MYELODYSPLASTIC SYNDROME

Bart L. Scott and H. Joachim Deeg

BACKGROUND

Systematic research into the possibility of marrow (hematopoietic cell) transplantation (HCT) began after the observations of the medical effects of radiation exposure at Hiroshima and Nagasaki.[1] Studies on total body irradiation (TBI) in animal models showed that shielding of the spleen during TBI, implantation of autologous or syngeneic spleen or infusion of syngeneic marrow following TBI rescued animals from the radiation induced marrow syndrome.[2,3] The most effective way of hematopoietic reconstitution was by intravenous (IV) injection of hematopoietic cells. By a mechanism now termed "homing" and mediated by a series of receptors and counter-receptors on cells and vascular endothelium, injected cells reached the marrow cavity and other hematopoietic organs and settled in supportive niches. Studies in several animal models then showed that hematopoiesis in lethally irradiated animals was restored by parabiosis with a normal animal, proving in principle the presence of circulating stem cells in peripheral blood.

While the infusion of autologous or syngeneic hematopoietic cells rescued marrow-ablated animals without complications, animals given cells from histoincompatible (allogeneic) donors developed "secondary disease," now known as graft-versus-host disease (GVHD).[3] These observations showed convincingly that transplantation of spleen or marrow cells not only resulted in hematopoietic reconstitution, but also conveyed immune effects.[4] The development of moderate GVHD was associated with improved survival in mice with leukemia, due to what has been termed a graft-versus-leukemia (GVL) effect.[5] However, no such benefit could be expected in recipients transplanted for nonmalignant disorders.

The first modern transplant attempts, beginning in 1957, were in patients with end-stage leukemia, and results were discouraging: Patients transplanted from syngeneic (monozygotic twin) donors did well immediately posttransplant but died from progressive leukemia; patients transplanted from allogeneic donors died with severe GVHD.[2,6] Beginning in the late 1950s, Dausset and others, showed that, similar to observations in mice, differences in major histocompatibility complex (MHC) antigens triggered immune reactions of the donor cells against the patient.[7] These insights, considerable work in animal models, and pioneering work by Thomas, Good, Santos and others, ushered in the modern era of hematopoietic cell transplantation (HCT).[2]

Table 99–1 lists acquired nonmalignant disorders that have been treated by HCT. The indications for HCT are continuously under revision as new treatment strategies evolve. While the number of separate disease entities amenable to transplantation is considerable, the large majority of transplants are currently performed to cure malignancies, and a smaller proportion for nonmalignant disorders.

RATIONALE FOR HEMATOPOIETC CELL TRANSPLANTATION FOR NONMALIGNANT DISEASES

HCT may serve as a rescue procedure generally in patients with malignant disorders treated with high-dose cytotoxic regimens or as replacement therapy in patients with missing, aberrant, or defective lymphohematopoietic cells, including marrow failure and autoimmune disorders.[8,9] In both situations, however, HCT also has immunotherapeutic effects, which may provide important signals to eradicate the patient's disease. In addition, HCT serves as a vehicle for gene therapy (Chapter 101)[10] and possibly as a strategy to establish tolerance for solid organ transplantation.

DONOR SELECTION

Potential donor categories are listed in Table 99–2. The preferred donor is a genotypically HLA-identical sibling, available in approximately 25% to 30% of patients who have living siblings. In addition, about 1% of patients have phenotypically HLA-matched donors within the family, and a few patients will have identical twin donors. A haploidentical donor (such as a parent or child) would be available for most patients, but HLA and non-HLA differences may result in major morbidity and mortality due to GVHD and rejection, although recent work shows that it is possible to overcome those hurdles.[11]

Approximately 70% to 75% of patients, who could benefit from HCT, lack a suitably matched related donor. This need has driven (a) efforts at improving the techniques of autologous transplantation, and (b) the development of unrelated donor registries. Thanks to the efforts of the National Marrow Donor Program (NMDP; www.marrow.org) and registries in Great Britain, France, Germany, Japan, Taiwan and other countries, there are now about ten million volunteer donors who have been typed for HLA-A and -B antigens, and many also for HLA-C, DRB1, and DQB1 antigens, a rapidly growing proportion of them by "high resolution" typing, ie, by DNA sequencing. Computer inquiries based on the patient's HLA typing quickly generate an idea as to the probability of identifying unrelated donors. In North America, the probability of finding a suitably matched unrelated donor is about 75% for whites; the probability is lower for patients of different ethnicity.[12]

An autologous stem cell approach may be possible with acquired disorders. Granulocyte colony-stimulating factor (G-CSF) mobilized peripheral blood progenitor cells (PBPCs) have been harvested and transplanted even in patients with severe acquired aplastic anemia. In patients with paroxysmal nocturnal hemoglobinuria (PNH) normal ($CD34^+$, $CD50^+$, $CD59^+$) hematopoietic precursors are present, and the possibility of using those for transplantation has been suggested.[13] Results in animals, eg, with experimental allergic encephalomyelitis, suggest that transplantation of autologous stem cells depleted of T lymphocytes can even restore neurologic function by eliminating Vβ-8positive autoreactive T cells.[14] Transplantation for various autoimmune disorders is a rapidly developing area of research, and new insights are likely to advance this field in the near future.[15,16]

Regardless of the stem cell source, problems with hematopoietic reconstitution may be encountered in patients whose disease is associated with defects in the marrow microenvironment.

PREPARATION FOR HEMATOPOIETIC CELL TRANSPLANTATION

Rationale for Conditioning

In preparation for HCT, patients generally receive cytotoxic or immunosuppressive treatment "conditioning" with the following objectives:

1. To eradicate or at least reduce the number of abnormal or defective cells below detectable levels; this applies to allogeneic, syngeneic, and autologous transplantation.
2. To suppress the patient's immunity, natural or acquired through allosensitization, to prevent rejection of donor cells; this applies to allogeneic but not to autologous cells (which constitute an "autoplantation" rather than a transplantation) or to syngeneic cells, which should not encounter a histocompatibility barrier. However, immunosuppression is needed in preparation for some syngeneic transplants in many patients with aplastic anemia, apparently to eliminate autoimmune reactivity, which may interfere with sustained hematopoietic reconstitution.
3. The concept that conditioning is required to create space for donor cells is no longer tenable, as there is good evidence that donor cells create the space required for their engraftment and expansion.[17] However, observations in patients who are prepared for HCT with reduced-intensity conditioning (RIC) or nonmyeloablative regimens have shown that a certain degree of "debulking" of patient cells is required to provide an advantage to donor cells so that they can progressively replace patient cells.[18]

Exceptions to the requirement of conditioning exist in patients with severe immunodeficiency disorders in whom even HLA-haploidentical stem cells may engraft without conditioning.[19]

Modalities of Conditioning

Various therapeutic modalities are being used to prepare patients for transplantation. In principle, they comprise:

1. **Irradiation**: Irradiation is given in several forms: external beam total body irradiation (TBI), total lymphoid irradiation (TLI) or modifications thereof delivered at various exposure rates, fractionation schedules and total doses have been used extensively. There is a strong trend to avoid or reduce the radiation dose in patients who are transplanted for nonmalignant disorders. With transplants from HLA-nonidentical or unrelated donors, TBI is often used at higher total doses, eg, 11 × 120 or 6 × 200 cGy given over 3 to 4 days. TBI doses as low as 200 cGy, often combined with chemotherapy, have been used in reduced intensity conditioning (RIC) or nonmyeloablative regimens. For some malignant disorders, bone seeking isotopes (eg, holmium) have proven useful. Yet another strategy has employed radioisotopes such as ^{131}I or ^{90}Y, conjugated to monoclonal antibodies directed to lymphoid or myeloid antigens (eg, CD20, CD45).[20]
2. **Chemotherapy**: Chemotherapy, particularly cyclophosphamide ([CY] 120–200 mg/kg over 2–4 days), is included in many regimens. In patients with aplastic anemia and Fanconi anemia, CY has been used successfully as single agent for transplant conditioning. Others have combined CY with busulfan ([BU] ± antithymocyte globulin [ATG]). Busulfan, when given orally, may show considerable variations in plasma levels, which may result in significant differences in toxicities and clinical responses.[21] These variations can be minimized by monitoring of steady state plasma levels of BU (BUss), and dose adjustments to target BUss to predetermined plasma levels.[22] Recent trials using once-a-day rather than every 6 hours dosing with the IV preparation suggest that this is a well-tolerated and practical approach.[23] Another increasingly used agent is fludarabine, given either in combination with BU[24] or treosulfan[25]or in RIC as part of nonmyeloablative approaches in combination with low-dose TBI or with melphalan.[18,26,27]
3. **Biologics**: Biological reagents, such as ATG, a polyclonal heterologous antibody preparation generated in horses or rabbits, or monoclonal antibodies directed at T-cell antigens or adhesion molecules are employed primarily to suppress recipient immunity. Specific monoclonal antibodies targeted at cancer cells, such as radiolabeled anti-CD45[28] are also under active investigation for conditioning. Similarly, monoclonal antibodies (eg, anti-CD33) conjugated to chemotherapeutic agents have been tested in transplant conditioning regimens.[29]
4. **Cellular Therapy**: Viable donor buffy coat in addition to marrow cells has been used to facilitate engraftment in patients with aplastic anemia but has been abandoned because of a high incidence of GVHD.[30] The observation that broad T-lymphocyte depletion of donor marrow increased the probability of graft failure has led to protocols of partial T-cell-depletion, selective T-cell add back or, more recently, the infusion of NK cells[31] or regulatory T cells, to assure engraftment, prevent disease recurrence, or modulate GVHD.

Other procedures include plasmapheresis of the patient to remove isoagglutinins directed at the donor's ABO blood group or, conversely, removal of plasma from the donor marrow to remove isoagglutinins directed at recipient cells. Alternatively, the donor red blood cells with which recipient antibodies may react are removed, thus minimizing the risk of hemolysis and possibly accelerating the tempo of erythroid reconstitution. With the use of PBPCs, such procedures are usually not required since these preparations are largely red blood

cell depleted and of small volume, so that isoagglutinin amounts may be negligible.

TRANSPLANT PROCEDURE

Sources of Hematopoietic Stem Cells

Hematopoiesis during embryogenesis evolves from a mesodermal (yolk sac), a hepatosplenic, and a medullary stage. At the time of birth, the bone marrow has generally become the only site of hematopoiesis. In adult humans extramedullary hematopoiesis occurs only under pathologic conditions (eg, chronic myelogenous leukemia, myelofibrosis). Accordingly, hematopoietic stem cells can be obtained from fetal (but not adult) livers, whereas an adult donor usually can donate stem cells only in the form of bone marrow or from peripheral blood where some stem cells circulate (Table 99–3).

a. Bone Marrow
In the adult human, bone marrow is the major reservoir of hematopoietic stem cells, which might also have potential as adult organ-specific stem cells (stem cell plasticity).[32,33] Marrow is harvested with the donor under anesthesia, and under sterile conditions. Generally multiple small-volume aspirates of marrow are obtained from both posterior iliac crests.[34]

b. Peripheral Blood Progenitor Cells (PBPC)
Under steady state conditions, only low numbers of hematopoietic stem cells circulate in peripheral blood.[35] However, peripheral blood contains dramatically increased numbers of early hematopoietic precursors during the recovery phase following cytotoxic therapy.[36] A single leukapheresis on a normal donor may suffice to harvest the numbers of cells required for a transplant, generally at least 5×10^6 $CD34^+$ cells/kg of recipient weight. The use of G-CSF mobilized PBPCs rather than marrow is associated with more rapid hematopoietic recovery. However, there is convincing evidence that the incidence of chronic GVHD is higher than with marrow cells, and PBPC should not be used indiscriminately as a source of hematopoietic stem cells in patients with nonmalignant diseases.

c. Umbilical Cord Blood
Umbilical cord blood is another source of hematopoietic stem cells.[37] Cord blood cells maybe less immunocompetent than adult cells and might carry a lower risk of inducing GVHD than adult marrow cells, although this notion has recently been challenged. While the concentration of stem cells in cord blood is high (frequency of long-term culture-initiating cells approximately 1:100 as compared to 1:500 in peripheral blood), the small volume usually available (50–150 mL) may limit the use of these cells for transplantation, particularly to adult patients. Recent trials suggest that the transplantation of two cord blood units may overcome this problem.[38] Additional studies will determine whether expansion of available cells in vitro will be feasible and useful.

d. Fetal Liver
For several months during fetal development, the liver is physiologically part of the hematopoietic system, and fetal liver cells, a mixture of hepatocytes and hematopoietic stem cells can be used for transplantation. Fetal liver cells have been studied extensively in experimental models and have been shown clinically to reconstitute successfully both hematopoietic and immunologic systems in children with congenital immunodeficiencies.[39] Because of ethical concerns and the development of alternative approaches, fetal liver cells are currently used only by a few investigators and for selected indications.

PERI- AND POSTTRANSPLANT CARE

Complications of HCT are related to the underlying disease, therapy given before transplantation, the preparative regimen (regimen-related toxicity [RRT]), the interactions of donor cells with recipient tissues (GVHD), and prophylactic and therapeutic measures administered after HCT.

Many transplant recipients have received therapy for extended periods of time before HCT. Patients with aplastic anemia who have HLA-identical related donors and are no more than 45 years of age generally receive a transplant as first-line therapy; all others are initially treated with immunosuppressive therapy, transfusions and hematopoietic growth factors. Only when these attempts fail and an alternative, usually unrelated, donor is identified, will HCT be considered. As a result, patients become allosensitized and frequently are platelet transfusion refractory. Over prolonged periods of neutropenia and immunosuppression, many patients become colonized by fungal organisms. While only hematopoietic reconstitution can eradicate these organisms, aggressive antibacterial and antifungal therapy must be given in the peritransplant period. In heavily transfused patients iron overload is the rule, and chelation therapy should be instituted (for ferritin >1000 ng/mL). Recent reports indicate that transplant outcome is inferior in patients with iron overload.[40,41]

Except for patients who are prepared with nonmyeloablative regimens, all patients experience pancytopenia before hematopoietic reconstitution from the transplanted (donor-derived) stem cells occurs. Pancytopenia may last 3 weeks with marrow cells, but possibly only 10 to 12 days with PBPCs. With single-unit cord blood transplants, recovery may take 5 to 6 weeks. The administration of growth factors such as G-CSF or granulocyte/macrophage colony-stimulating factor (GM-CSF) early after marrow transplantation has been shown to accelerate granulocyte recovery, although treatment with growth factor is not considered standard.[42] After transplantation of mobilized PBPCs, growth factors may show little or no acceleration of hematopoietic recovery as the transplanted cells were already "activated" by G-CSF mobilization. Whether a different effect will be seen with cells mobilized by the CXCR4 antagonist AMD3100 remains to be determined.[43] Virtually all marrow recipients conditioned with conventional regimens will need transfusion support with platelets and red blood cells. Erythropoietin administration may slightly speed reticulocyte recovery and moderately reduce red blood cell transfusion requirements.[44] Thrombopoietin (megakaryocyte growth and differentiation factor) and interleukin-11 can enhance platelet production; however, side effects are considerable and both have had only a limited impact on HCT.

Infection prophylaxis consists primarily of systemic broad spectrum antimicrobials. The indications for granulocyte transfusions, eg, in granulocytopenic patients in whom bacterial or fungal infections are not controlled by antimicrobials, have remained controversial. Treatment of patients in laminar air flow rooms and with gastrointestinal decontamination may reduce the frequency of infections and the duration of febrile episodes.[45] Because of an 80% to 90% risk of reactivation of herpes simplex virus (HSV), prophylaxis with acyclovir is given for at least 2 to 3 months after HCT. Some protocols also include the infusion of IV immunoglobulins on a weekly basis, although available data indicate that this strategy will benefit only

patients with IgG levels <400 mg/L. Trimethoprim/sulfamethoxazole is administered primarily for *Pneumocystis jiroveci* prophylaxis but also reduces the incidence of other infections, in particular in patients with chronic GVHD. Fluconazole is administered as antifungal prophylaxis for 2 to 3 months (or longer), and has a long-term protective effect against *Candida* related morbidity and mortality.[46] Ongoing trials are aimed at determining the place for newer agents, such as caspofungin and posaconazole.[47] Ganciclovir and valacyclovir provide good prophylaxis and are effective as preemptive therapy in patients with evidence of cytomegalovirus (CMV) reactivation. Epstein-Barr virus (EBV) reactivation is more frequently seen in patients who receive T cell depleted, HLA-nonidentical transplants, and in vivo anti–T cell reagents. Anti-CD20 antibodies, eg, rituximab, at doses of 375 mg/m^2, have been effective in controlling the rise of EBV DNA titers in blood.

Because of mucositis and gastroenteritis, many patients are unable to eat early posttransplant and require parenteral nutrition and hydration. Oral intake is less of a problem in patients prepared with RIC regimens.

All allogeneic transplant recipients receive some form of GVHD prophylaxis.[48] Modalities involve administration of immunosuppressive agents such as methotrexate (MTX), cyclosporine (CSP), FK506 (tacrolimus), mycophenolate mofetil (MMF), rapamycin (sirolimus), and others, either alone or in combination. Currently, the two most widely used regimens are combinations of MTX, 10 mg/m^2 IV on day 1, 3, 6, and 11 (or 15 mg/m^2 on day 1, and 10 mg/m^2 on days 3, 6, and 11), and CSP or tacrolimus, given daily starting on day −1 (or −3), and continued at gradually tapering doses for 6 to 12 months.[49,50] It is recommended that plasma levels for both CSP and tacrolimus be monitored as frequently as twice a week during the early course after HCT, to maintain therapeutic but nontoxic levels. As an alternative or adjunct to immunosuppressive therapy, T lymphocytes, responsible for triggering GVHD, are depleted from the donor marrow in vitro before infusion.

CLINICAL RESULTS

Aplastic Anemia

The term "aplastic anemia," is actually a misnomer since, as originally described by Ehrlich, not only erythropoiesis but all cell lineages are defective, and the marrow appears empty.[51] T-cell–mediated destruction or suppression of bone marrow hematopoietic cells plays a central role in most cases. The differential diagnosis may be difficult, and the distinction from a hypoplastic myelodysplastic syndrome (MDS; refractory anemia [RA]) may be impossible. However, patients with clonal cytogenetic abnormalities (approximately 50% of patients with MDS) should be treated as MDS because transplant regimens as used for aplastic anemia have been unsuccessful.[52]

Historically, the course of aplastic anemia, was considered as progressively, inexorably, and more or less rapidly fatal. In the past 30 years, morbidity and mortality from aplastic anemia have been reduced significantly as a better understanding of the disease pathophysiology has led to effective therapies, ie, immunosuppressive treatment[53,54] and allogeneic HCT.

Hematopoietic recovery is often incomplete after immunosuppressive treatment, but tends to be complete and stable after HCT (with the exception of an occasional patient who rejects the donor cells). Nevertheless, ex-vivo studies suggest that at the level of hematopoietic precursor cells recovery may not be complete with either approach.[55] However, although the development of clonal hematopoietic disorders, such as PNH or MDS, is extremely rare after HCT, it has been observed in 15% to 30% of patients given immunosuppressive therapy.[56] For this reason, HCT from HLA-identical siblings is the treatment of choice for patients younger than 45 or 50 years of age, despite treatment-related morbidity and mortality. Older patients and patients without HLA-identical related donors generally receive first-line therapy with immunosuppressive drugs.

Syngeneic Transplants

Infusion of genetically identical hematopoietic stem cells without pretransplant conditioning should correct marrow function if marrow failure simply resulted from a lack of or a defect in stem cells. Conversely, if marrow failure was due to an active immune process, that process may also affect the transplanted genotypically identical donor cells. In this case, effective therapy would require conditioning of the patient even in the absence of histocompatibility barriers. If marrow failure was secondary to defects in the marrow microenvironment, it is unlikely that HCT would correct the defect unless donor-derived cells contribute to the microenvironment. In about half of the 100 identical twin transplants for aplastic anemia, transplantation was successful without conditioning. The remaining patients achieved long-term hematopoiesis only when given high-dose immunosuppression with cyclophosphamide or other agents.[57]

Allogeneic Transplants

Progress in the prevention and treatment of graft rejection, and acute and chronic GVHD has resulted in significant improvements in long-term outcome. In young patients with aplastic anemia who have HLA-identical sibling donors, HCT is the treatment of choice. Opinions in regard to the upper age limit of patients differ, although 45 to 50 years is accepted by many transplant centers.

In early trials, 30% to 60% of previously transfused and, thereby, allosensitized patients who were conditioned with cyclophosphamide failed to achieve sustained donor cell engraftment, and only about 40% survived long-term. In contrast, among untransfused patients, only 5% failed to engraft, and 81% survived with sustained donor-derived hematopoiesis.[58] The infusion of viable donor leukocytes in addition to the marrow or the use of TBI (eg, 300 cGy) or TLI (400–750 cGy) given in combination with cyclophosphamide, reduced the incidence of graft failure to 5% or less even in transfused patients, and 70% to 80% of patients survived with sustained engraftment.[59,60] However, one disadvantage of the addition of donor leukocytes, which contain immunocompetent peripheral blood T lymphocytes, was an increased incidence of chronic GVHD (as high as 50% even in children), and the enthusiasm for this approach has decreased.[59] The use of irradiation, in particular limited field irradiation, has been associated with an increased risk of posttransplant malignancies.[61] Furthermore, radiation exposure is associated with impaired growth and development in children and infertility in adults.[62,63]

Studies in patients who rejected a first marrow graft after conditioning with cyclophosphamide showed that a combination of equine ATG and cyclophosphamide was effective in the majority of patients in securing sustained engraftment of a second marrow infusion.[64] Based on these results, this regimen (cyclophosphamide 4 × 50 mg/kg plus ATG 3 × 30 mg/kg, both given IV) was, therefore, introduced as conditioning for first transplants. With this strategy, 95% of patients engrafted and approximately 88% survived long term (Fig. 99–1). The incidence of chronic GVHD, still a major problem after transplantation, was also reduced.[65]

Progressively improving survival figures (Fig. 99–2) have also been reported in retrospective studies by the IBMTR and EBMT groups.[60,66] While changes in conditioning regimens have contributed to these improvements, the use of leukocyte-depleted transfusion products, thereby reducing the frequency of allosensitization, advances in antibiotic therapy, and improved methods for the prevention and treatment of GVHD were equally important.[65–67] Results of representative trials are summarized in Table 99–4.

Unfortunately, only 25% to 30% of patients have HLA-matched related donors. The remaining patients first receive immunosuppressive therapy and are transplanted only if this approach fails.[68–70]

Representative trials are summarized in Table 99–5. A report from the Fred Hutchinson Cancer Research Center showed that 30% to 45% of patients who were transplanted from HLA-nonidentical

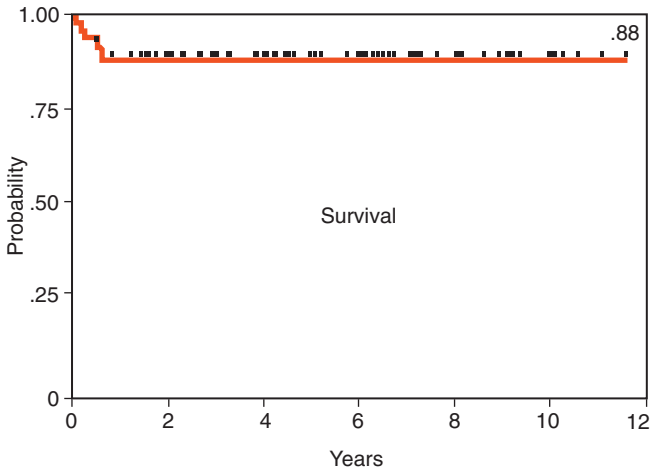

Figure 99–1 Kaplan-Meier probability of survival among 94 patients with aplastic anemia transplanted from HLA-identical related donors. *(From: Storb R, Blume KG, O'Donnell MR, et al: Cyclophosphamide and antithymocyte globulin to condition patients with aplastic anemia for allogeneic marrow transplantations: the experience in four centers. Biol Blood Marrow Transplant 7:39, 2001, used with permission.)*

related donors after conditioning without the use of TBI failed to achieve engraftment, and only 15% to 35% survived. With the use of TBI (eg, 6 × 200 cGy) in addition to cyclophosphamide, engraftment was generally achieved, and 50% of patients survived long term, albeit with considerable morbidity.[68]

The establishment of registries of HLA typed unrelated donors has provided the option of HCT for patients without related donors, and the use of high resolution HLA typing has allowed for the search and selection of unrelated donors who are matched with a given patient at the molecular level. The outcomes with unrelated donor HCT has remained somewhat inferior to that obtained with HLA genotypically identical sibling donors. Among 298 patients, reported to the IBMTR, who received matched unrelated donor transplants between 1991 and 1997, the 5-year probability of survival was 44% for those 20 years of age or younger, and 35% for those 21 to 40 years of age.[71] A retrospective analysis of 141 patients transplanted under the auspices of the NMDP yielded similar results and showed that patients transplanted within a year of diagnosis had a much higher probability of long-term survival than patients transplanted later in their disease course. The most important factor, however, was HLA matching by high resolution typing.[72] A more recent prospective NMDP-sponsored trial involving 87 patients was aimed at optimizing the transplant conditioning regimen (Fig. 99–3A and B).[69] Patients were conditioned with cyclophosphamide and ATG as used for HLA-identical sibling transplants[65] and, in addition, received TBI in deescalating doses (from 3 × 200 to 1 × 200 cGy). All patients had failed to respond (or lost their response) to nontransplant immunosuppressive therapy. Graft failure occurred in less than 5% of patients. With donors who were identical for HLA-A, -B, -C, -DRB1, and -DQB1 by high-resolution typing, best results were obtained with a TBI dose of 200 cGy, which resulted in long-term survival of 66%. Among patients less than 20 years old at HCT who received 200 cGy of TBI (in addition to ATG and cyclophosphamide), 5-year survival was 78%. Among 23 patients transplanted from less than completely HLA-matched donors, 45% and 50% are surviving after TBI doses of 200 and 400 cGy, respectively. The TBI dose-limiting toxicities were pulmonary complications.

An alternative source of stem cells may be cord blood. Laughlin et al reported results in 562 cord blood recipients including 21 patients with aplastic anemia. Among 19 patients able to be evaluated patients, eight patients had sustained engraftment.[73] However, more recent data from Europe and the US in larger numbers of patients indicate a higher success rate.[38]

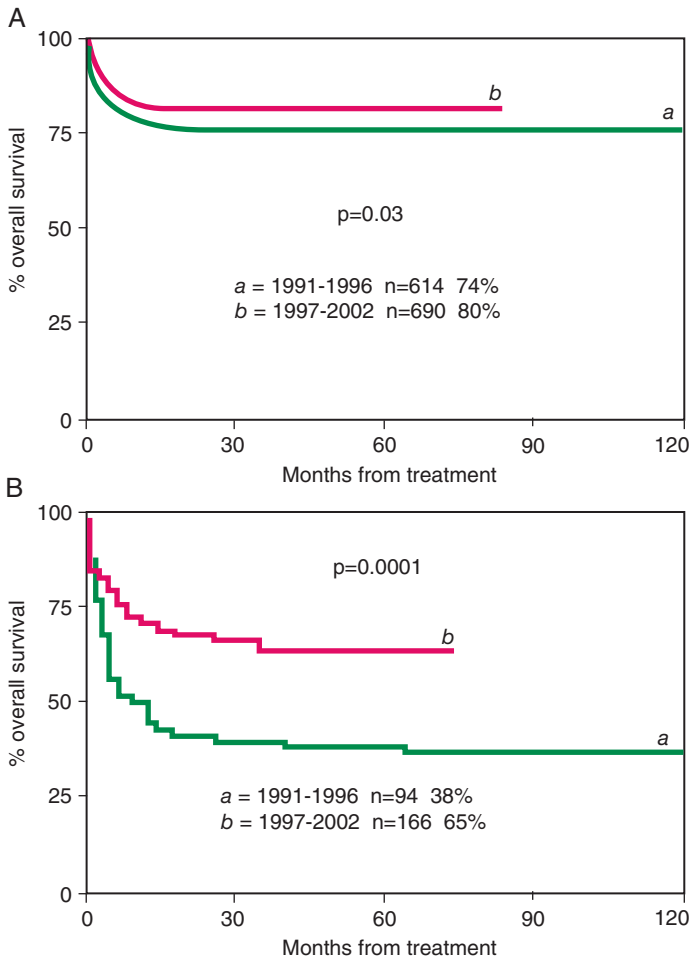

Figure 99–2 Actuarial survival of patients undergoing HCT from HLA-identical siblings (**A**) or from alternative donors (**B**) by time period (1991–1996 and 1997–2002). Results have improved significantly over time for patients transplanted both from HLA-identical siblings (74% versus 80%, $P = 0.03$) and from alternative donors (38% versus 65%, $P = 0.0001$). *(From: Locasciulli A, Oneto R, Bacigalupo A, et al; on the Behalf of the Severe Aplastic Anemia Working Party of the European Blood and Marrow Transplant Group: Outcome of patients with acquired aplastic anemia given first line bone marrow transplantation or immunosuppressive treatment in the last decade: a report from the European Group for Blood and Marrow Transplantation. Haematologica 92:11, 2007.)*

Autologous HCT

If aplastic anemia was a stem cell disorder, autologous HCT would not be an option. However, if the disease is immune mediated and residual normal stem cells are present, it is possible that treatment with G-CSF to mobilize stem cells, and "conditioning" treatment given before reinfusion of those stem cells, so that autoreactive (and marrow-suppressive) lymphocytes are eliminated, the reinfused cells meet growth conditions that allow hematopoietic repopulation. Some data to that effect have been reported.[74] Similarly, there are data to show that patients can recover hematopoiesis following the infusion of high doses of cyclophosphamide, without stem cell administration,[54] although this approach has remained controversial.[75]

Pure Red Cell Aplasia

As discussed in Chapter 31, pure red cell aplasia is associated with various disorders, eg, with parvovirus B19 infection, chronic lympho-

cytic leukemia, and immune diseases. It usually responds to steroids and immunosuppressive therapy. Some patients who present with red cell aplasia of undetermined etiology and who do not respond to treatment with glucocorticoids or other nontransplant regimens aimed at the underlying disorder have undergone HCT. These patients are transplanted with conditioning regimens as used for aplastic anemia. No large series has been reported. Registry data suggest that problems with sustained engraftment may be more common than with other marrow failure states.[76]

Paroxysmal Nocturnal Hemoglobinuria (PNH)

PNH is an acquired clonal disorder of hematopoiesis resulting from the expansion of a clone that arises by somatic mutations in the X-linked PIG-A gene in pluripotent hematopoietic stem cells. This gene encodes a protein that affects the synthesis of glycosylphosphatidylinositol (GPI), an anchor for numerous cell surface antigens, eg, CD59. Recent data indicate that various genes that are involved in the expression of the anchor protein can be mutated and lead to similar phenotypes. These mutations are necessary but may not be sufficient to cause the PNH disorder. Autoreactive cytotoxic T cells target GPI in normal hematopoietic stem cells, while PNH cells "escape" damage and tend to expand.[77] Patients with PNH classically present with hemolytic anemia, venous thrombosis, and deficient hematopoiesis associated either with marrow aplasia or with a cellular marrow. Some patients show evolution into MDS or acute leukemia. PNH clones may also be present in patients who present with the classic features of aplastic anemia or MDS.[78]

Allogeneic HCT is effective therapy for PNH patients with either aplastic or cellular marrows. Transplantation corrects hematopoiesis and resolves thrombotic complications.[79,80] HCT from syngeneic donors without preceding conditioning failed to correct the underlying disease. This observation confirms the assumption that the PNH clone has a survival and proliferative advantage, and requires cytotoxic therapy for elimination.[81] In at least one syngeneic transplant recipient with PNH "recurrence" molecular analysis revealed that a new PNH clone had arisen.[82]

Investigators of the IBMTR presented information on 57 patients with PNH transplanted between 1978 and 1995.[83] Two patients were transplanted from monozygotic twin donors and were alive 8 and 12 years after HCT, respectively. The 2-year survival among 48 patients transplanted from HLA-identical siblings was 56%. Among 7 patients transplanted from alternative donors, there was one survivor at 5 years. Major complications were graft failure and infections. Nonmyeloablative HCT may further improve results in patients with PNH.[80,84]

It has been suggested that normal $CD34^+CD38^-$ hematopoietic precursors can be collected from the blood of patients with PNH and used as a source for autologous transplantation after separation of $CD34^+/CD38^-/CD59^-$ cells.[13] This strategy would offer the possibility of HCT with normal autologous cells in patients with PNH, although it might be difficult to collect sufficient numbers of normal precursors because of the majority of precursors in circulation after G-CSF mobilization are clonal.[85]

Myelodysplastic Syndrome (MDS)

MDS is one of the most common hematopoietic disorders in older adults. There are an estimated 15,000 to 20,000 new cases annually in the US. Among 70-year-old individuals (average age at diagnosis), the incidence is estimated at 20 to 40 per 100,000 per year.[86] The number of new cases will likely increase because of the increasing proportion of older adults (primary MDS), and because of increasing numbers of patients who survive after treatment for cancer or other diseases (secondary MDS). Clinically, MDS comprises a group of disorders in which the clonal proliferation of pluripotent

hematopoietic cells results in a very heterogeneous clinical syndrome characterized by ineffective hematopoiesis and a propensity to progress to marrow failure with severe pancytopenia or to transform into acute myeloid leukemia (tAML). Clinical and possible pathophysiologic overlap with aplastic anemia, myeloproliferative disorders, and acute leukemia can make the differential diagnosis challenging.

While several therapeutic strategies are being pursued, the only current therapy with proven curative potential for patients with MDS is HCT. However, MDS often has a protracted course, and many patients are in their 60s, 70s, or older, and the morbidity and mortality associated with HCT may be prohibitive. A decision-making analysis by Cutler et al suggested that patients with advanced/high-risk MDS (IPSS intermediate-2 or high-risk groups) had the best life expectancy if HCT was carried out without delay (assuming the patient was a candidate for HCT and a donor could be identified); patients in the low risk group did benefit from initial conservative management followed by HCT if and when the disease showed signs of progression.[87] For patients in the intermediate-1 risk group, there was little difference between early and late HCT, and decisions should probably be made on a case-by-case basis, dependent on disease manifestations. For example, patients with isolated severe neutropenia or thrombocytopenia may have a poor prognosis (without HCT) even though they may fall into IPSS categories low or intermediate-1. In addition, recent data show that red blood cell transfusion dependence is an important negative risk factor for survival.[88] Whether transfusion dependence also adversely affects transplant outcome remains to be determined.

Transplant outcome in patients with MDS is related to disease stage (marrow myeloblast count), prognostic score (IPSS), cytogenetic findings,[89] possibly remission status before transplantation, iron overload, source of stem cells, comorbid conditions, and preparative regimen.[40,90–93] In early clinical trials, transplant success showed a strong inverse correlation with patient age. Age continues to be a relevant factor for transplant success, but less so than in the past, and the development of reduced intensity nonmyeloablative conditioning strategies has further attenuated the impact of age.[94,95]

Less Advanced/Low-risk MDS

The best results with HCT are achieved in patients with low myeloblast counts in the marrow (less <5%) and in patients who lack high-risk cytogenetic markers; these are generally patients with low IPSS scores. The European Group for Blood and Marrow Transplantation (EBMT) reported results on 131 patients with MDS transplanted from HLA-identical sibling donors. The 5-year relapse-free

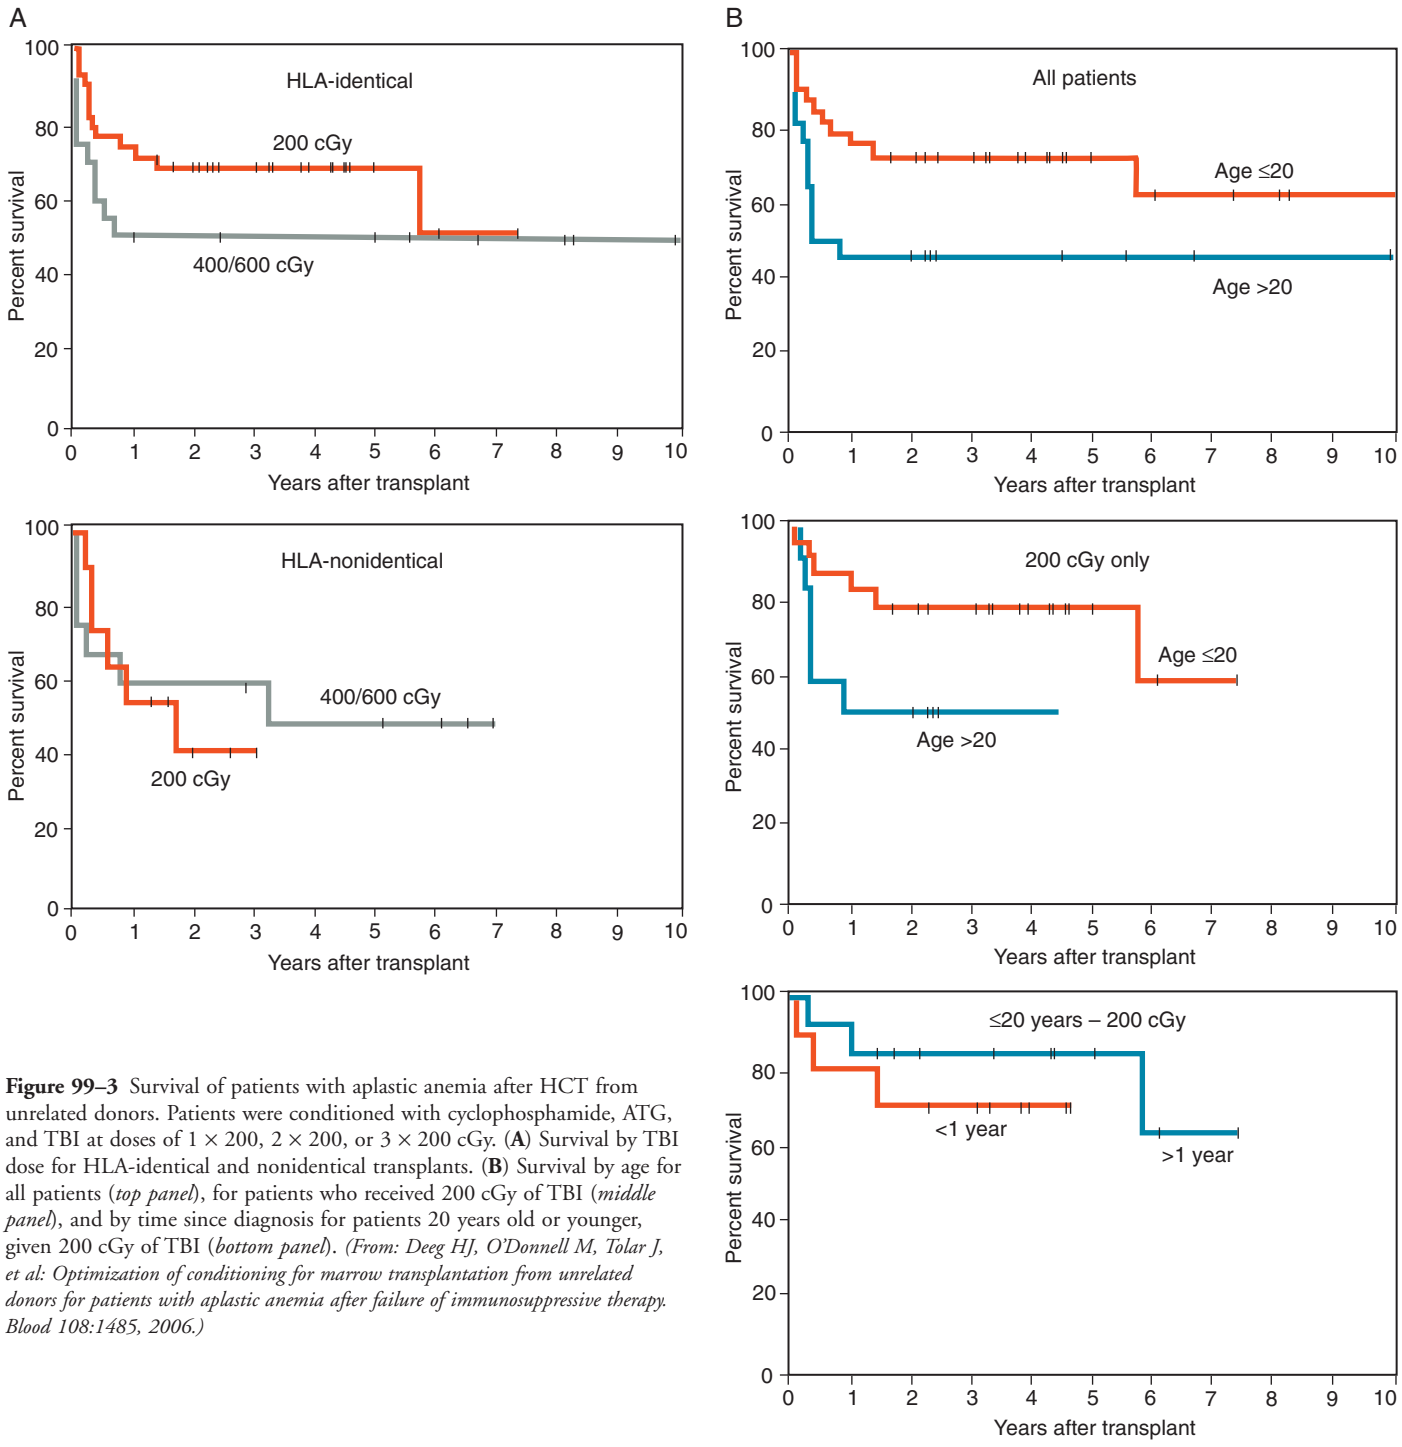

Figure 99–3 Survival of patients with aplastic anemia after HCT from unrelated donors. Patients were conditioned with cyclophosphamide, ATG, and TBI at doses of 1 × 200, 2 × 200, or 3 × 200 cGy. (**A**) Survival by TBI dose for HLA-identical and nonidentical transplants. (**B**) Survival by age for all patients (*top panel*), for patients who received 200 cGy of TBI (*middle panel*), and by time since diagnosis for patients 20 years old or younger, given 200 cGy of TBI (*bottom panel*). *(From: Deeg HJ, O'Donnell M, Tolar J, et al: Optimization of conditioning for marrow transplantation from unrelated donors for patients with aplastic anemia after failure of immunosuppressive therapy. Blood 108:1485, 2006.)*

survival (RFS) was 52%, and the relapse rate was 13%.[96] The same group reported a RFS of 24% at 2 years with a relapse rate of 13% for patients transplanted from unrelated HLA-matched donors.[97] The International Bone Marrow Transplant Registry (IBMTR) reported results in 452 patients with MDS transplanted from HLA-matched siblings, showing a 3-year RFS of 40%, although only 140 patients (31%) had less than 5% blasts at HCT. Treatment-related mortality (TRM) was 37%, and the relapse rate was 23%. High marrow blast count and high IPSS score were significantly correlated with relapse. Relapse-free survival was 72% for patients younger than 18 years.[98] In a cohort of 510 patients with MDS transplanted from unrelated donors, those conditioned with busulfan and cyclophosphamide (BUCY) fared better than patients conditioned with other regimens, in particular regimens containing high-dose TBI.[90] A study at the FHCRC in patients conditioned with a targeted BUCY regimen showed a 3-year RFS of 68% with related donors and 70% with unrelated donors. Among 69 patients with RA/RARS, the non-relapse mortality rate (NRM) was 31%, and relapse occurred in 5% of patients.[99] Survival in patients 55 to 66 years of age was comparable to that in younger patients.

In several studies, improved survival was independently associated with higher donor cell dose, recipient CMV seronegativity, shorter

interval from diagnosis to HCT, and transplantation in more recent years.

Advanced/High-risk MDS

The success rates of HCT decline as the nontransplant prognosis of MDS worsens, particularly with an increase in the marrow myeloblast count above 5%. Intensification of conditioning regimens aimed at reducing the relapse risk has been associated with higher rates of NRM, and no improvement in survival.[93] The IBMTR reported results in 352 patients with high-risk MDS transplanted from HLA-matched sibling donors; most were conditioned with TBI-based regimens. The 3-year RFS was 63% for patients younger than 18 years and 33% for older patients.[98] The EBMT reported a 5-year RFS for patients transplanted from related donors of 34%, 19%, and 26% for RAEB, RAEB-T, and tAML, respectively; the relapse rate was approximately 50% for the entire cohort. The 2-year RFS for patients transplanted from HLA-matched unrelated donors was 27%, 8%, and 27% for RAEB, RAEB-T, and tAML, respectively.[96,97] A study from the FHCRC center in patients with RAEB transplanted after conditioning with targeted BUCY showed 3-year RFS of 45% with related donors and 40% with unrelated donors. The corresponding figures for RAEB-T/tAML were 33% and 17%, respectively. The data also indicate that the IPSS correlates strongly with outcome; patients with low IPSS scores had the highest probability of RFS and the lowest rates of relapse (Fig. 99–4A and B).[92]

Another trial examined a combination of BU and TBI without high-dose CY. Sixty patients with advanced MDS, tAML or CMML were transplanted from related (n = 20) or unrelated (n = 40) donors with a 3-year Kaplan-Meier estimate of survival of 26% and a relapse rate of 25%.[99] This was comparable to an earlier trial examining the combination of BUCY and TBI.[100] However, NRM was 38% at 100 days.[99] This observation suggested that further increases in the conditioning intensity (with the aim of reducing relapse frequency) were unlikely to improve overall survival.

In an effort to reduce toxicity, the tolerability and efficacy of fludarabine in combination with BU has been tested.[23,101] Bornhauser et al prepared 42 patients with high-risk hematologic neoplasms (38 with MDS) with a fludarabine plus oral BU combination for HCT from related (n = 16) or unrelated (n = 26) donors. The probabilities of overall survival and RFS at a median follow up of 18 months were 42% and 35%, respectively. All patients achieved engraftment, and the day 100 mortality was 7%.[101] Similarly, the M.D. Anderson group used a regimen of IV BU and fludarabine given consecutively for 4 days to treat patients with advanced myeloid malignancies (22 patients had MDS). The 1-year RFS and TRM were 52% and 3%, respectively.[23] Encouraging studies such has these have stimulated interest in further modifications of conventional conditioning regimens to reduce toxicity while maintaining efficacy.

Generally, patients who received G-CSF mobilized PBPC had superior outcome compared to patients who received marrow stem cells in all subgroups of MDS, although differences were often not significant.[92,102] Thus, there has been progress with related and unrelated transplants for advanced and less advanced MDS. However, while early nonrelapse mortality has been reduced to 10% or less, 3-year mortality has remained in the range of 25% to 35%.

Reducing Transplant-related Toxicity

Major efforts have been directed at preventing or attenuating transplant-related complications. This is particularly important in patients with MDS who tend to be older and often have significant comorbidities. Nonmyeloablative/reduced intensity conditioning regimens in preparation for allogeneic HCT (also referred to as "mini-transplants") have been developed by several groups.[103] The basic principle behind these regimens is to provide sufficient immunosuppression to secure donor cell engraftment and then rely on the graft-vs-tumor effect mediated by donor-derived cells to eradicate the underlying

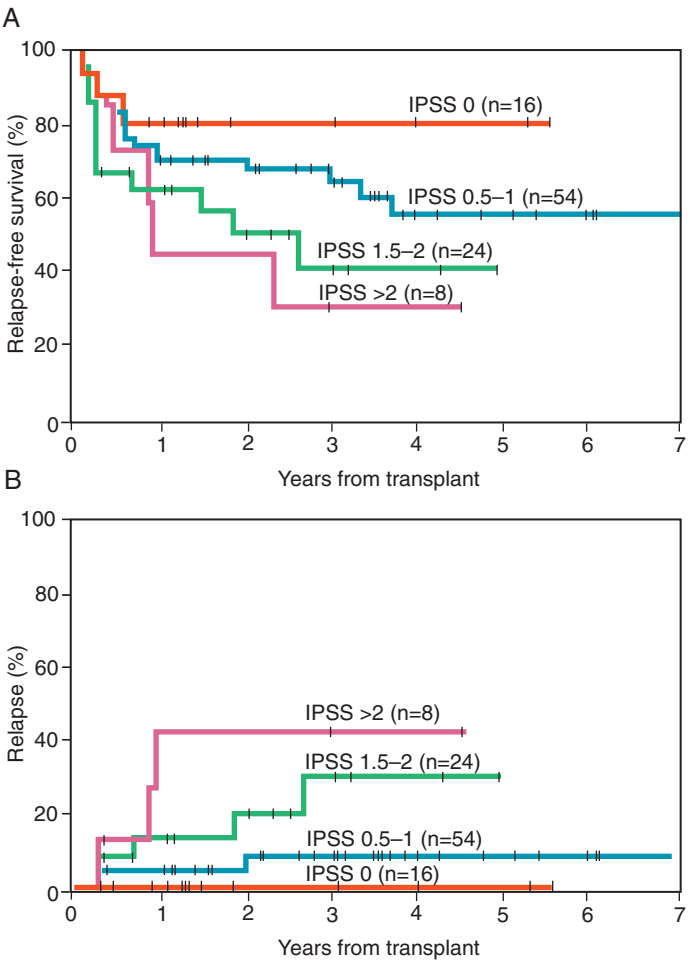

Figure 99–4 Impact of IPSS score on transplant outcome in patients with MDS. The + indicates censored patients; in 7 patients, an IPSS score could not be assigned. (**A**) relapse-free survival. (**B**) Cumulative incidence of relapse. *(From: Deeg HJ, Storer B, Slattery JT, et al. Conditioning with targeted busulfan and cyclophosphamide for hemopoietic stem cell transplantation from related and unrelated donors in patients with myelodysplastic syndrome. Blood 100:1201, 2002.)*

disease. Initial regimens consisted of low dose busulfan ± other agents or low dose (200 cGy) TBI ± fludarabine.[104,105] Subsequently, many groups have adopted similar regimens but have increased the intensity. Conventional conditioning regimens have been attenuated, leading to a broad spectrum of regimens aimed at eradicating the patient's disease while minimizing NRM.[106]

A multicenter study examined the use of NMA conditioning to transplant patients with MDS (n = 77) or MPD (n = 14) from related (n = 49) or unrelated donors (n = 42). The median patient age was 59 (range 6–72) years, and conditioning consisted of fludarabine and 200 cGy of TBI. With a median follow-up of 2 years, the estimated overall survival for the entire cohort was 37%, with a relapse rate of 43%. Patients with advanced MDS had a higher relapse rate than those with low-risk disease.[105]

Several groups have tested combinations of fludarabine and BU as part of RIC regimens.[107,108] Kroger et al reported on 37 patients with MDS or tAML conditioned with such a regimen from related (n = 19) or unrelated donors (n = 18). TRM was 27%, and with a median follow-up of 20 months, the 3-year estimated disease-free survival was 38%, with a relapse rate of 32%.[107] Spanish investigators reported results on 37 patients with MDS or AML transplanted from HLA-identical siblings following a fludarabine/BU conditioning regimen. The 1-year TRM and RFS were 5% and 66%, respectively.[108]

Other studies have incorporated the anti-CD52 antibody alemtuzumab as part of a RIC regimen as a method of in vivo T-cell depletion.[109,110] One study examined the use of a fludarabine/BU/alemtuzumab regimen and reported results on 75 patients with MDS receiving unrelated donor transplants. The 3-year actuarial survival was 43%, and the cumulative incidence of extensive chronic GVHD was 22%. This analysis also indicated that the disease status at HCT and the presence of comorbidities were independent risk variables for overall survival; however, patient age and cytogenetic abnormalities did not significantly affect outcomes.[109] A prospective phase II study by van Besien reported results on a RIC conditioning regimen consisting of fludarabine, melphalan, and alemtuzumab in 52 patients with AML and MDS. After a median follow-up of 18 months, the relapse rate was 27%, TRM was 33%, and RFS was 38%. The cumulative probability of extensive chronic GVHD was 18%. High-risk disease and performance status were the major adverse factors for outcome.[110]

While NMA/RIC regimens were developed to reduce toxicity, concern has been expressed regarding efficacy. Three recent retrospective analyses sought to address this question in patients with MDS and tAML; all three studies suggested that conditioning intensity did not affect overall survival.[93,111,112]

An analysis of results in 150 patients with AML and MDS transplanted at our center also showed that conditioning intensity did not significantly affect survival. One hundred twelve patients receiving myeloablative conditioning with BUCY were compared to 38 patients conditioned with a NMA regimen of fludarabine 90 mg/m^2 with or without 200 cGy of TBI. Patients receiving NMA conditioning were older, had higher risk disease by IPSS, higher comorbidity scores, and importantly, had enjoyed more durable responses to pre-HCT chemotherapy. The 3-year RFS and overall survival did not differ significantly between the two groups.[111]

Alyea et al carried out a retrospective analysis of 136 patients transplanted for MDS and tAML. Outcomes among 97 patients receiving myeloablative conditioning with CY combined with either BU or 1400 cGy TBI were compared to those among 39 patients receiving NMA conditioning with fludarabine and low-dose BU. This study also showed no statistically significant difference in overall survival and RFS between the two groups. Of note was that patients receiving NMA conditioning had higher rates of relapse, but the impact on survival was counterbalanced by a higher rate of TRM in patients receiving myeloablative conditioning.[112] Martino et al recently reported the results of an analysis in 836 patients with MDS, comparing high-dose (n = 621) with reduced-intensity (n = 215) regimens (Fig. 99–5A and B).[93] For all age and MDS categories, treatment-related mortality was lower but relapse rates were higher with RIC, and relapse-free survivals were comparable for the two cohorts, 35% and 39%, respectively.

Since patients selected for RIC as compared to more conventional myeloablative regimens were not comparable in regards to risk factors in these retrospective studies, conclusions must be drawn cautiously. Only prospective randomized trials will provide definitive answers. Furthermore, it would be wrong to simply contrast myeloablative to NMA/RIC regimens. As emphasized in several recent reviews,[106,113] a broad spectrum of conditioning regimens using various modalities has been developed. It is quite likely that what is "optimal" for one disease category may be "suboptimal" (either too intense or insufficient) for another, and what may yield superior results in patients whose disease is in remission at the time of HCT, may lead to disappointing outcomes in patients with disease burden at HCT.

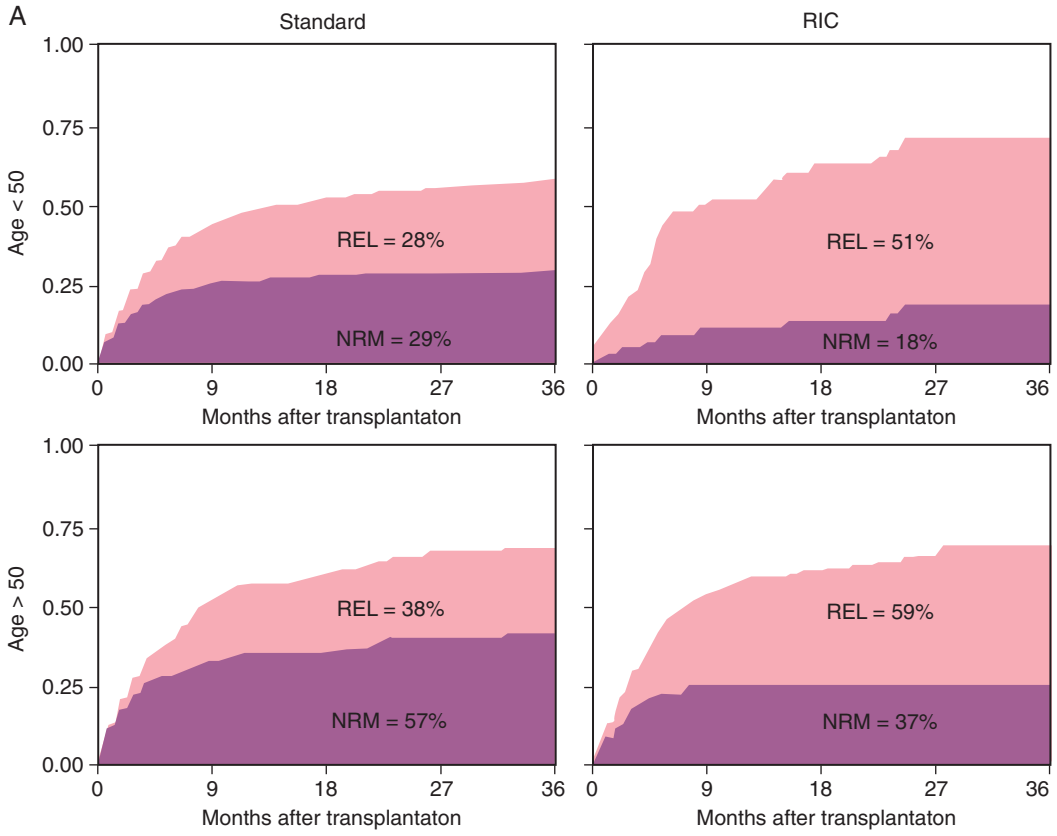

Figure 99–5 Incidence of relapse (REL) and non–relapse mortality (NRM) in patients with MDS conditioned with conventional regimens (standard) or reduced intensity regimens (RIC) and transplanted from HLA-identical sibling donors. **A**) Outcome by age (years). **B**) Outcome by pretransplant chemotherapy: no therapy (*top panel*), therapy but not achieving complete remission (*middle panel*), and achieving complete remission (*bottom panel*). *(From: Martino R, Iacobelli S, Brand R, et al; for the Myelodysplastic Syndrome subcommittee of the Chronic Leukemia Working Party of the European Blood and Marrow Transplantation Group: Retrospective comparison of reduced-intensity conditioning and conventional high-dose conditioning for allogeneic hematopoietic stem cell transplantation using HLA-identical sibling donors in myelodysplastic syndromes. Blood 108:836, 2006).*

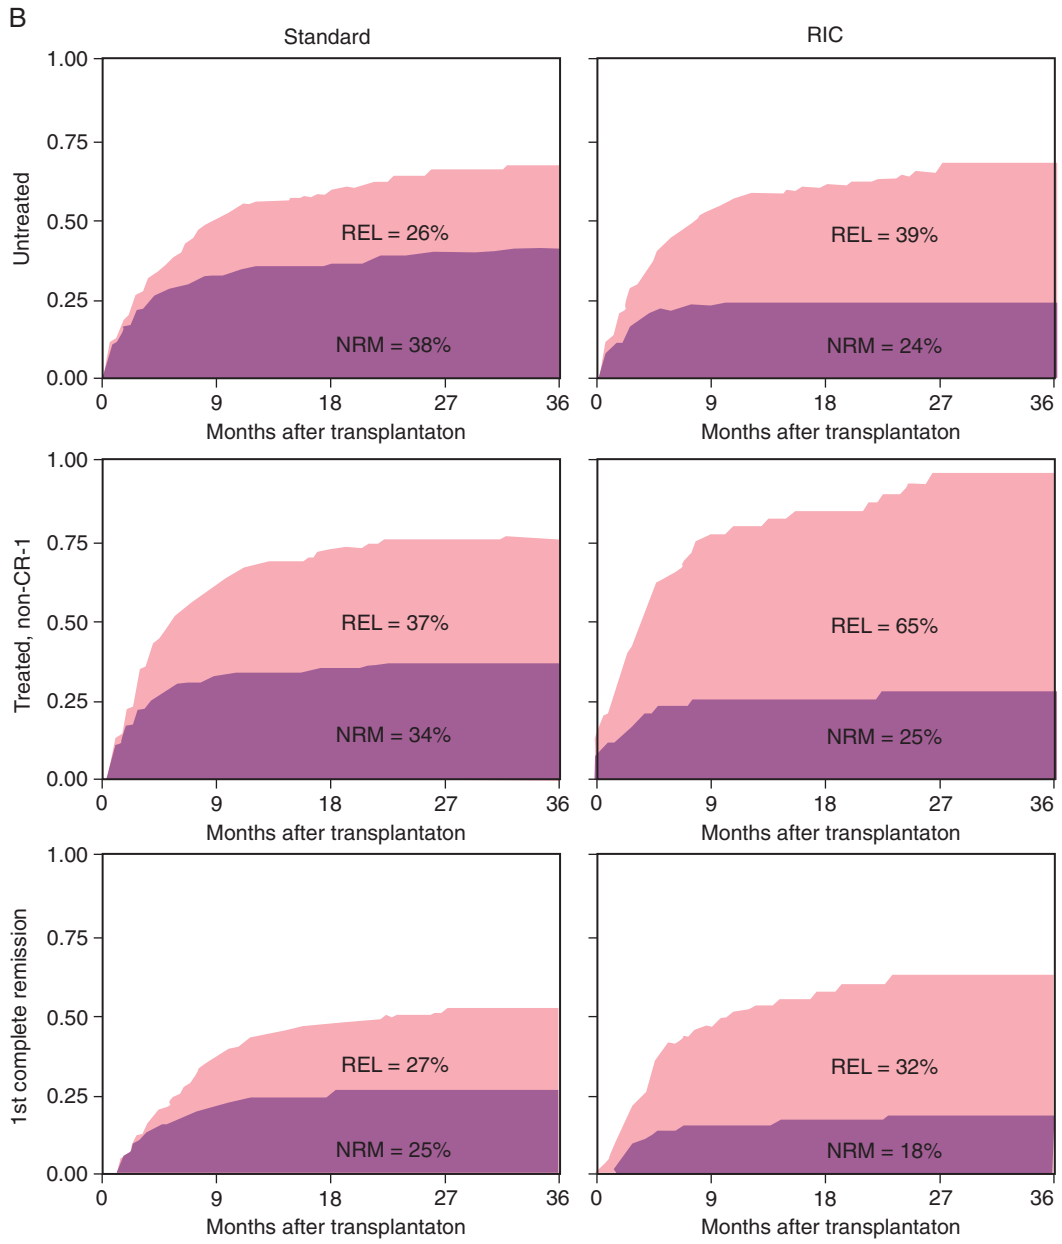

Figure 99–5, cont'd

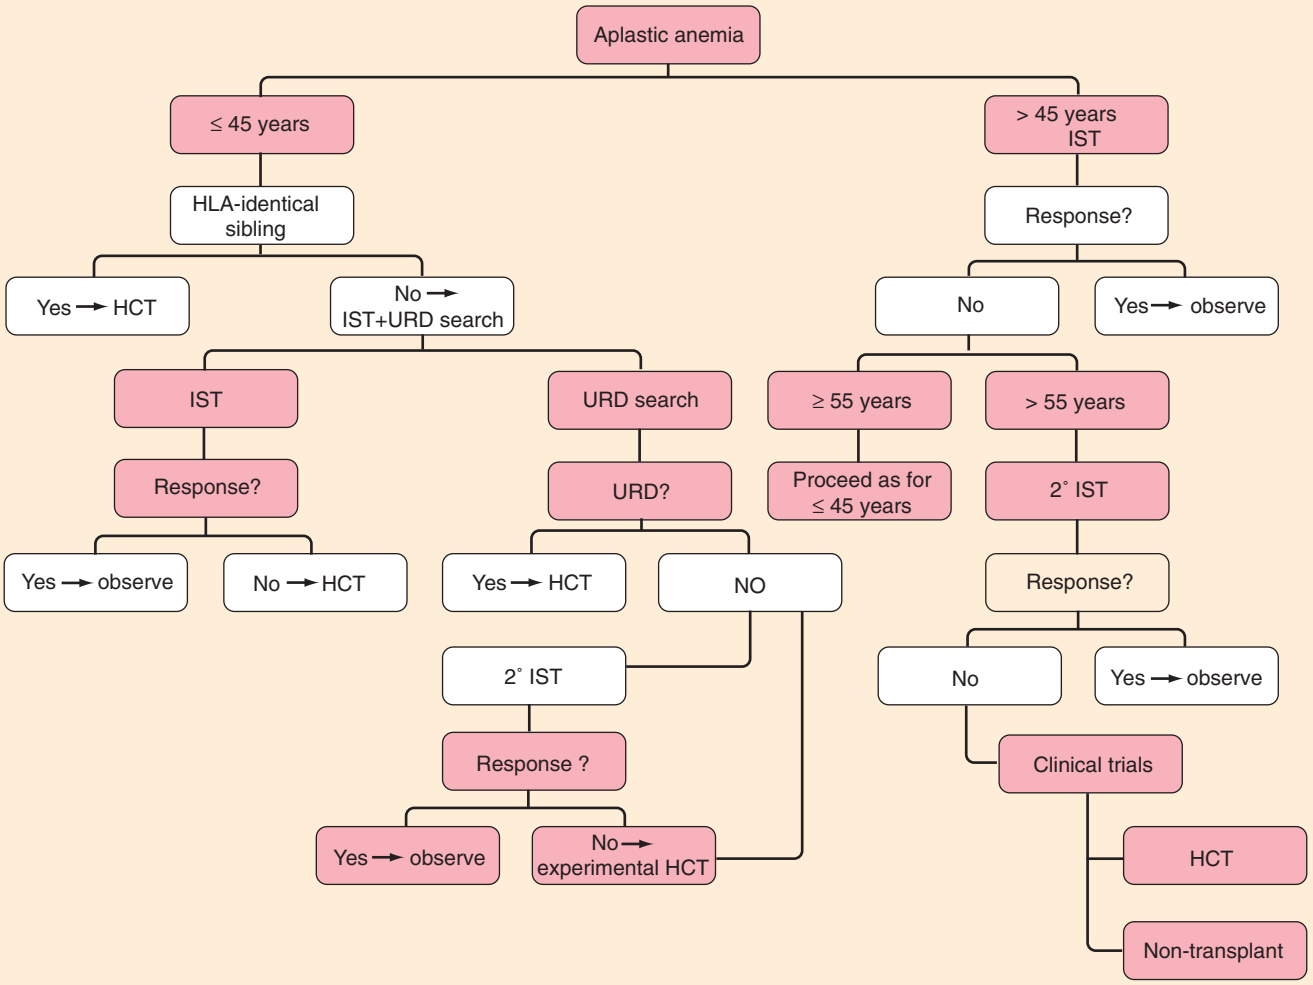

Autologous HCT

In MDS marrow, normal and clonal hematopoietic precursors coexist. If sufficient normal precursors could be harvested without contamination by clonogenic MDS cells, autologous HCT should be feasible. The EBMT group reported autologous transplant results in 79 patients with MDS or tAML who achieved complete remissions after induction chemotherapy, and showed a 2-year relapse-free survival, relapse rate, and treatment-related mortality of 34%, 64%, and 5%, respectively.[114] Among 19 patients with MDS, the 2-year disease-free survival, relapse rate, and treatment-related mortality were 40%, 58%, and 5%, respectively. De Witte and colleagues also presented a comparison in 184 patients with MDS or tAML who received either allogeneic or autologous HCT after induction chemotherapy, dependent on sibling donor availability. The overall survival and relapse-free survival rates in the autologous group were 33% and 27%, compared with 36% and 31% in the allogeneic group, respectively. In a prospective study assessing feasibility of autologous HCT after conditioning with BU/CY, Wattel et al showed that among 24 patients who were in complete remission after induction chemotherapy, 50% were alive at 8 to 55 months; median disease-free survival was 33 months.[115] These data suggest that autologous HCT can result in long-term remission in some patients and can be considered as an option for transplant candidates without HLA-matched allogeneic donors.

Autoimmune Disorders

Proof that HCT may offer effective treatment for severe autoimmune disorders came from observations in patients who received HCT for other indications, and were also cured of concurrent autoimmune disorders, eg, rheumatoid arthritis.[116] Subsequently, Yasumizu et al showed that diabetes in NOD mice was curable by allogeneic HCT from an autoimmune resistant donor strain, but not by syngeneic HCT.[117] Other groups presented similar results in mice with autoimmune encephalomyelitis and renal disorders.[118,119] However, HCT

Algorithm for Treatment Decisions in Patients With Aplastic Anemia

Experimental HCT may be from HLA-nonidentical donors or with cord blood.
HCT, hematopoietic cell transplantation; IST, immunosuppressive therapy

was effective only if given at an early stage of the disease, when there was no significant end-organ damage.[120]

Autologous HCT

Systemic sclerosis (SSc): The European cooperative (EBMT) group reported results of a multicenter phase I/II trial of autologous HCT in 41 patients with SSc.[121] Patients had predominantly diffuse skin disease, and various transplant regimens (mainly CY/ATG/TBI based) were used. Twenty of 29 evaluable patients (69%) had improvements in skin scores of more than 25%. Disease progression occurred in seven patients (19%) at a median followup of 67 (range 49–255) days. Eleven patients (27%) died, seven apparently from treatment-related toxicity. The probability of survival at one year was 73%. Lung function and pulmonary hypertension did not improve significantly, but stabilized. Nash et al recently reported results of a phase II, single arm North American study of high-dose immunosuppressive conditioning therapy and autologous CD34-selected HCT in 34 patients with diffuse cutaneous SSc.[122] Conditioning included TBI (800 cGy) with lung shielding, cyclophosphamide (120 mg/kg) and equine ATG (90 mg/kg). Neutrophil and platelet counts recovered by 9 (7–13) and 11 (7–25) days after HCT, respectively. Seventeen of 27 (63%) evaluable patients who survived at least 1 year after HCT had sustained responses at a median follow-up of 4 (range 1–8) years. Major improvement was noted in skin (modified Rodnan skin score −22.08; $P < 0.0001$) and overall function ($P < 0.0001$). Importantly, skin biopsies showed a statistically significant decrease in dermal fibrosis compared to baseline ($P < 0.0001$). Lung, heart, and kidney function remained clinically stable. There were 12 deaths during the study (8 transplant-related and 4 related to SSc). The estimated progression-free survival at 5 years was 64%. Thus, sustained responses, including decrease in dermal fibrosis, were observed exceeding those reported with other therapies. Prospective randomized trials are planned.

Multiple sclerosis (MS): MS may have a relative benign course or may progress rapidly with devastating clinical effects. Earlier data suggested that these patients may benefit from high-dose immuno-

suppressive therapy and autologous HCT.[123,124] Several updates have been published recently. A retrospective analysis of results in 183 patients by the EBMT group showed stabilization or improvement in 63% of patients at a median follow-up of 42 months.[124] Treatment-related mortality was 5% among patients transplanted before 2000. Subsequently, no toxic deaths were observed in patients conditioned with a BEAM (carmustine, etoposide, cytosine-arabinoside, melphalan)/ATG regimen. Progression-free survival rates of 60% to 65% at 4 to 5 years have also been reported by others.[125] T-cell depletion did not offer an advantage.[126] One among 26 patients who were treated at other major centers died with a post-transplant lymphoproliferative disorder.[127] All reports indicate some EDSS improvement. Because of concern about neurological flare-up during G-CSF stem cell mobilization, administration of either cyclophosphamide or prednisone has been added to G-CSF. Overall, these results suggest that autologous HCT has some efficacy in stabilizing progressive MS. Results may be comparable or superior to currently available alternative treatment options. Randomized studies are underway.

Systemic lupus erythematosus (SLE): SLE in many patients is a crippling disease and great hopes have been placed on HCT.[128] A recent report summarizes results in 50 patients.[129] All patients were refractory to "standard" therapy and had life-threatening organ involvement. Patients were conditioned with cyclophosphamide, 200 mg/kg, and equine ATG, 90 mg/kg, and given $CD34^+$ selected autologous cells that had been harvested after mobilization with cyclophosphamide and G-CSF. Among 48 evaluable patients, one died from treatment-related toxicity, and with a median follow-up of 29 months, the projected 5-year survival was 84%, "disease-free" survival 50%. Renal function stabilized and various parameters, including carbon monoxide diffusion improved. These data suggest that controlled prospective trials should be conducted.

Rheumatoid arthritis: Rheumatoid arthritis was one of the first autoimmune disorders shown to improve with HCT albeit with allogeneic cells.[116] Subsequent studies showed that autologous HCT were also beneficial. Compared to other autoimmune diseases, the mortality of autologous HCT for rheumatoid arthritis has been as low as 1%. The EBMT registry reported the largest cohort of 70 patients with rheumatoid arthritis who received autologous HCT. This study showed that while most patients responded initially, relapses occurred in at least 50% of patients.[130] Generally, the conditioning regimens involved CY only, or BU/CY.

Autologous HCT has been carried out for additional autoimmune/inflammatory disorders, such as Crohn disease, resulting in remissions and prolonged disease quiescence.[131]

Allogeneic HCT

Allogeneic HCT for the treatment of autoimmune diseases was mainly a by-product of treatment for other hematological disorders. Many of these cases involved patients with rheumatoid arthritis who developed gold therapy-related aplastic anemia, and subsequently were cured by allogeneic HCT.[116] However, many patients with severe autoimmune diseases, such as SLE, SSc, already have extensive vital organ damage, and are not good candidates for such treatment. Nevertheless, Nash et al recently reported on two patients with SSc who were conditioned with busulfan, cyclophosphamide, and equine ATG and transplanted with marrow cells from HLA-identical siblings.[132] Although one patient died at 17 months with GVHD and infections, one is alive and well at 5 years with nearly complete resolution of dermal fibrosis and marked improvement in physical function.

AIDS

The initial experience with allogeneic HCT in patients with AIDS was with AIDS related lymphoma.[133,134] While short term eradication of HIV was observed, there were no long-term survivors. Vilmer and colleagues reported on three patients who had developed AIDS at 8 to 56 months after marrow transplantation for aplastic anemia or leukemia,[135] who were given six sequential lymphocyte infusions from the original marrow donor combined with interferon IFN-α and later IFN-γ. All three patients showed hematologic and immunologic improvement. Numerous additional attempts were reported,[136] but overall HCT has not been successful.

The introduction of highly active antiretroviral therapy (HAART) has improved the prognosis of patients with AIDS, including those who have developed lymphoproliferative disorders.[137] A report summarizing results in 62 patients with AIDS-related lymphoma indicates that 38 achieved complete remissions with autologous HCT, and overall survival ranged from 50% to 85% at 9 to 32 months.[137]

Ho et al proposed to use stem cells transfected with retroviral vectors containing the gene for a hairpin ribozyme capable of cleaving HIV-1 RNA. In vitro studies showed, indeed, that transfected cells were resistant to infection by HIV.[138] Ongoing studies are exploring the possibility of combining a hematopoietic stem cell transplant with cytotoxic T cells specific for HIV-1.[139]

Langerhans Cell Histiocytosis (LCH)

LCH, formerly called histiocytosis X, is an uncommon disorder of childhood. Children whose disease progresses to the disseminated form have a poor prognosis. Since the originator cell of the disease is thought to be marrow-derived, marrow-ablative therapy and transplantation should provide effective therapy. Both autologous and allogeneic HCTs have been carried out.[140,141] After conditioning with chemotherapy (eg, etoposide and cyclophosphamide) and TBI engraftment is achieved, with about half of the patients surviving free of disease.[142]

POSTTRANSPLANT COMPLICATIONS AND THERAPEUTIC INTERVENTIONS

Graft-Versus-Host Disease (GVHD)

GVHD is the most frequent complication of allogeneic HCT.[48] Methods of GVHD prevention are listed in Table 99–6. With a combination of CSP (given daily) and MTX (given on days 1, 3, 6, and 11) as prophylaxis, acute GVHD occurs in 10% to 50% of patients after HLA-identical transplants and in 50% to 90% of patients transplanted from alternative donors. The corresponding figures for chronic GVHD are 20% to 50% and 30% to 60%, respectively. Acute GVHD is the single most important risk factor for the development of chronic GVHD.[143] In patients prepared with conventional conditioning regimens, acute GVHD usually presents within a month of transplantation. With HLA-nonidentical transplants, the presentation may be "hyperacute" within days of HCT. In patients prepared with nonmyeloablative regimens, clinical manifestations of typical acute GVHD may develop 4 to 5 months (or even later) after transplantation. Conversely, clinical and histologic features of chronic GVHD may be present as early as 50 to 60 days after HCT. A new classification of GVHD has recently been presented.[144]

The main target organs of GVHD are the immune system, skin, liver and intestinal tract, although other organs can be involved. The result of interactions between donor and host cells is an activation and clonal expansion of donor T cells (afferent phase of the graft-versus-host reaction/GVHD), leading to a complex pattern of cytokine release, recruitment of secondary effector cells, and destruction of recipient target cells and tissues (efferent phase). These interactions occur not only in recipients who differ from the donor for MHC class I or class II antigens, but even between HLA-matched individuals, because of differences for non-HLA or "minor" antigens encoded for by genes outside of but presented by the MHC. The chronic GVHD syndrome has prominent features of autoreactivity, and T

HCT for Patients with MDS Is an Evolving Field.

The algorithm provides some guidance regarding consideration of patient age, comorbid conditions, disease stage (and the possible advisability of induction therapy) when deciding upon a conditioning regimen. For patients with high-risk disease and with reduced-intensity/nonmyeloablative transplant regimens, G-CSF mobilized peripheral blood progenitor cells (G-PBMC) are currently the preferred source of stem cells. Posttransplant manipulations depend on the type of transplant, the degree of donor cell chimerism that is achieved, and the remission status.

lymphocytes with abnormal cytokine profiles (secreting, eg, IL-4 and IFN-γ) may be present.[48]

In patients with malignant disorders, graft-versus-host reactivity may be beneficial in the form of a GVL effect. In nonmalignant disorders, however, GVHD is undesirable. Methods of GVHD prophylaxis are summarized in Table 99–6. Combination regimens of MTX and CSP or MTX and tacrolimus offer the most effective currently available prophylaxis.[49,145] Other promising agents, such as mycophenolate mofetil (MMF) and rapamycin (sirolimus), are under active investigation. In vivo administration of monoclonal antibodies (murine, humanized or human) against the interleukin-2 (IL-2) receptor or antibodies neutralizing TNF-α have only been of transient benefit.[146] Gnotobiosis (treatment in a sterile environment) has been effective in some trials.

T-cell depletion of donor marrow by 2–4 log, clearly effective in reducing the incidence of GVHD, is complicated by an increased incidence of graft failure.[147,148] Since failure of sustained engraftment is a potential problem in patients with aplastic anemia even with unmanipulated marrow, T-cell depletion has generally not been applied to this patient group. Of note is the observation in several studies that the incidence of GVHD was lowest in patients who showed "mixed chimerism," ie, the coexistence, at least transiently, of donor and host lymphohematopoietic cells postgrafting.[149] The mechanism is not clear. Recent studies aimed at inducing mixed chimerism by design, in particular in the setting of nonmyeloablative transplants, have shown a reduction of GVHD incidence in some, but not in other studies, although GVHD manifestation may be less severe.[150]

GVHD is the most important risk factor for long-term morbidity and mortality after HCT. Therefore, if GVHD develops, it requires aggressive therapy for both the acute and chronic form. Current therapy for acute GVHD includes glucocorticoids, CSP, monoclonal antibodies, immunotoxins, and cytokine blockade.[146]

Graft Failure

Graft failure and rejection may be due to allosensitization of the recipient, HLA disparities between patient and donor,[151] or defects in the recipient microenvironment. This may be the case in about 5% of patients with aplastic anemia; it also occurs in MDS. Certain anti–human monoclonal antibodies (eg, Campath IG), or immune-globulin conjugates, thymoglobulin (rabbit ATG) administered during the peritransplant period may reduce the graft failure rate without increasing toxicity.[148,152]

Infections

Infections in recipients of HCT are a major cause of transplant-related morbidity and mortality. In the peritransplant phase, neutropenia is the most important risk factor, particularly for bacterial infections. All patients receive broad-spectrum antibiotics (eg, ceftazidime or quinolone) when the neutrophil count declines to <500/μL. In addition, acyclovir and fluconazole are given as prophylaxis. As hematopoiesis recovers, GVHD may develop and viral, eg, CMV, respiratory virus, and invasive fungal infections (*Candida, Aspergillus*) may occur. Iron overload of the patient may increase the risk of invasive fungal infections.[41] Close monitoring for reactivation of organisms or new infections is important to allow prompt institution of (preemptive) therapy, especially in patients with GVHD. All patients should receive trimethoprim/sulfamethoxazole for *P. jiroveci* prophylaxis.

Delayed Complications

The longest surviving HCT recipients have now been followed for almost four decades, and many are leading normal lives; some, however, have developed late complications (Table 99–7). Complications are related either to pretransplant events, the conditioning regimen (irradiation) or transplant-associated events (chronic GVHD, immunodeficiency).[153] Potentially life-threatening problems include infections and pulmonary dysfunction, particularly bronchiolitis obliterans which is usually associated with chronic GVHD.[154] Autoimmune disorders may develop due to adoptive transfer (from a donor who is affected), may be related to GVHD, or may be idiopathic.[155]

The omission of high-dose TBI as part of the conditioning regimen has reduced the frequency and severity of transplant-related complications such as interstitial pneumonitis, cataracts, impairment of growth and development.[63] It is desirable to avoid irradiation completely, at least in very young children, in whom growth and development of the skeleton and the central nervous system occur at an exponential rate.

Systematic psychosocial studies investigating the effects of HCT on personal development, family dynamics and partner-relationships are only now being pursued. Active rehabilitation is necessary in many instances.

SUMMARY

HCT has been developed into curative therapy for many nonmalignant disorders. Best results are achieved with HLA-identical sibling transplants. However, there has been considerable progress with molecular HLA typing, also allowing for close matching of patients and unrelated donors. Selection of donors on that basis has significantly improved transplantation outcome for these patients. For example, outcome in patients with aplastic anemia and MDS who received transplants from molecularly matched unrelated donors is comparable to that in patients who were transplanted from HLA-identical sibling donors. A major problem in all patients is GVHD, especially with its chronic manifestations, which are also responsible for systemic or organ-specific late complications. Because with nonmalignant diseases, there is no potential benefit of GVHD in the form of a GVL effect, every effort must be directed at preventing GVHD. There is limited data on a graft-vs-tumor effect in patients with MDS. To what extent the application of nonmyeloablative conditioning to patients with nonmalignant disorders and MDS will improve outcome, remains to be determined.

CHAPTER 100

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR IMMUNE DEFICIENCIES AND GENETIC DISORDERS

Sarita A. Joshi and Stella M. Davies

The first successful studies of hematopoietic cell transplantation for treatment of any disease were performed for treatment of the genetic disorder severe combined immunodeficiency (SCID).[1] This transplantation established proof of principle that engraftment of hematopoietic stem cells was possible and could correct a genetic disorder. Children with immunodeficiencies were obvious subjects for these investigations because they have a limited capacity to reject a graft, and the early successes were a result of an emerging understanding of human leukocyte antigen (HLA) typing.

Use of hematopoietic cell transplantation therapy for indications other than immunodeficiencies has required the development of immunosuppressive and myeloablative therapies. These strategies have extended the applicability of hematopoietic cell transplantation to individuals with intact immune systems. It has been shown that achievement of engraftment from related and unrelated HLA-matched donors is possible in that setting. Currently, most hematopoietic cell transplantations are performed for treatment of hematologic malignancies. Over the last 20 years, however, a growing body of literature has described the application of allogeneic transplantation for correction of inborn errors of metabolism. In these disorders, a single gene defect leads to the absence of a key protein, which causes the clinical phenotype of disease. Allogeneic hematopoietic cell transplantation provides a means for replacing the missing protein, potentially improving the clinical phenotype. The most significant experience has been with treatment of mucopolysaccharidoses (MPS) and leukodystrophies, although case reports have described transplantation therapy for many other genetic disorders.

This chapter reviews the development and current status of hematopoietic cell transplantation for genetic immunodeficiencies, MPS, and leukodystrophies, discusses use of hematopoietic cell transplantation for less frequent disorders, and describes future directions for the field.

IMMUNE DEFICIENCIES

Severe Combined Immunodeficiency

SCID is a rare syndrome of profoundly impaired cellular and humoral immune system function (see Chapter 51).[2] Although both X-linked recessive and autosomal recessive forms of SCID are recognized, the X-linked form is the most frequent. Patients with X-linked SCID typically have very low numbers of T cells and natural killer (NK) cells, whereas B cells are often found in relatively high numbers even though specific antibody responses are deficient (B^+ SCID). A less common variant of SCID in which the numbers of T and B cells are low (B^- SCID) has an autosomal recessive inheritance. The true incidence of SCIDs is not known; however, they are estimated to occur in approximately one of every 10,000 live births. Infants with SCID have lymphopenia, and recognition of this abnormality can lead to early diagnosis. The lymphocytes of these babies are functionally abnormal and fail to proliferate in vitro or on challenge with mitogens, antigens, or allogeneic cells. Typically, levels of immunoglobulin are low or undetectable, thymus-dependent areas of the spleen are devoid of lymphocytes, and lymph nodes and tonsils usually are absent. SCID requires immediate treatment. Unless hematopoietic cell transplantation or, in a small number of cases, gene therapy succeeds, death occurs during infancy. Early reports of transplantation for treatment of SCID involved the use of HLA-matched family member donor cells, and current data indicate excellent outcomes with this therapy. A review of hematopoietic cell transplantation therapy for immunodeficiencies at Duke University covering a period of more than 16.5 years demonstrated that all 12 recipients of HLA-identical donor grafts were surviving.[3]

Use of Alternative Donors

The majority of patients with SCID do not have an HLA-matched related donor available. Alternative approaches (e.g., T-cell–depleted HLA-haploidentical parental hematopoietic cell transplantation and identification of unrelated donors from registries) have been used aggressively. Use of haploidentical grafts has the advantage of almost immediate availability and availability for essentially all infants because the mother or father of the child can be a donor. This strategy has the disadvantage of delayed, sometimes incomplete, immune system recovery as a consequence of the aggressive T-cell depletion that is needed to reduce the risk of graft-versus-host disease (GVHD). Buckley et al.[3] reported outcomes in 77 infants with SCID receiving T-cell–depleted HLA-haploidentical parental grafts at Duke University. Sixty of the 77 patients (78%) were surviving 3 months to 16.5 years after transplantation. T-cell function became normal approximately 3 to 4 months after transplantation, and the majority of long-term survivors had normal T-cell function, with all T cells in the blood being of donor origin. B-cell function remained abnormal in many of the recipients of haploidentical marrow, and most of these patients continue to receive intravenous immunoglobulin as support.

A large multicenter series of hematopoietic cell transplantation therapy for immunodeficiencies has been reported from Europe.[4] This study included data from 37 centers in 18 countries that participated in a European registry for stem cell transplantation for SCID and other immunodeficiency disorders. The registry includes 1082 transplantations performed in 919 patients; 566 transplantations were performed in 475 SCID patients. One hundred four SCID patients receiving an HLA-identical related donor transplantation were included in this series, and the survival rate was 77%. Of note, the analysis showed that similarly positive outcomes could be achieved with unrelated donor cells, with a survival rate of 81% in recipients of genotypically identical related donor cells, 72% in phenotypically matched related donors, and 63% in phenotypically matched unrelated donors. Significant improvements in survival after HLA-identical and HLA-nonidentical hematopoietic cell transplantations have occurred over time (Fig. 100–1). Cox regression multivariate analysis of risk factors for mortality showed only the age at the time of transplantation and use of trimethoprim-sulfamethoxazole prophylaxis had a significant effect on survival after transplantation from a related HLA-identical donor. Younger age was associated with an improved prognosis, with survival of 85% at 3 years in patients who underwent transplantation at an age less than 6 months. Survival of patients receiving an HLA-mismatched graft was 54%. SCID phenotype had an effect on survival after HLA-nonidentical stem cell transplantation. SCID patients without B cells had a poorer prognosis than did SCID patients with B cells, in accordance with a previous report.[5] In

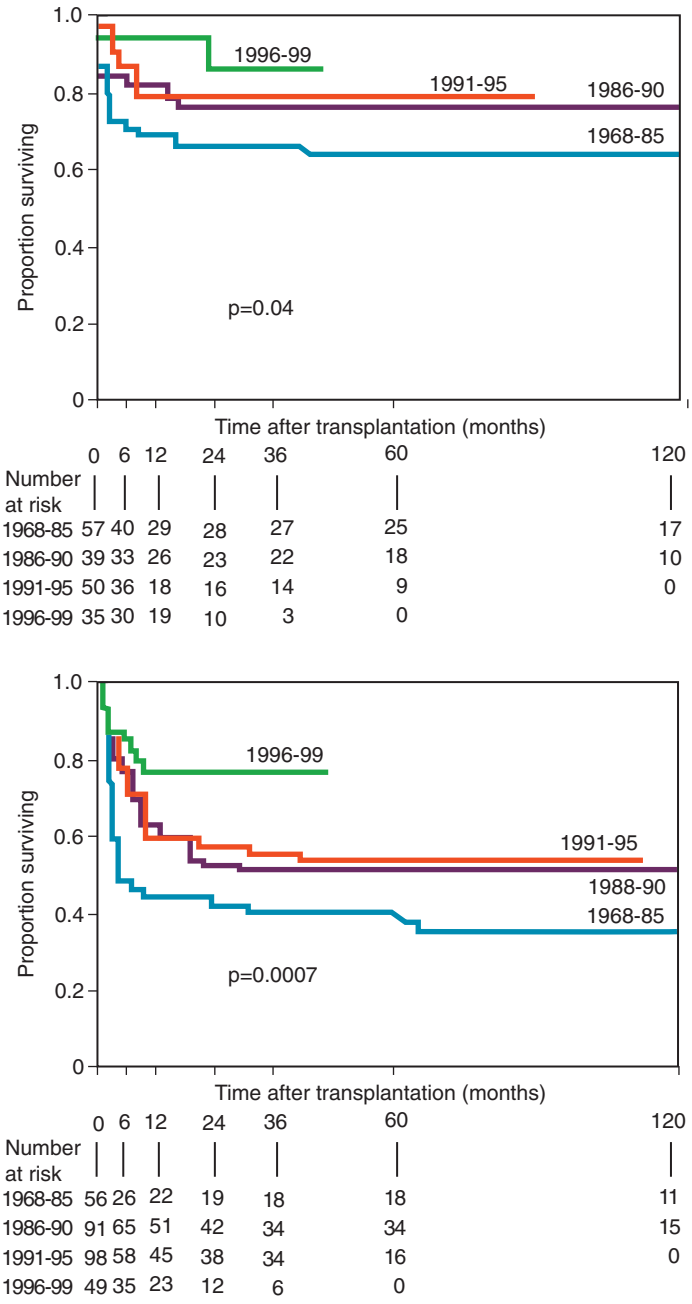

Figure 100–1 Cumulative probability of survival after transplant in patients with severe combined immunodeficiency disease, according to donor source (related or unrelated) and human leukocyte antigen matching and year of transplantation. (From Antoine C, Muller S, Cant A, et al: Long-term survival and transplant of haemopoietic stem cells for immunodeficiencies: Report of the European experience, 1968–99. Lancet 361:553, 2003.)

the HLA-nonidentical setting, use of a myeloablative conditioning regimen had a positive effect on survival in SCID patients without B cells but did not reach significance in other SCID groups. Independent predictors of increased mortality in SCID patients given a graft from a related HLA-mismatched donor included the SCID without B-cell phenotype, absence of a protected environment, and presence of pulmonary infection before transplantation.

The study of Antoine et al.[4] explored a center-size effect, segregating data from experienced centers (at least 50 procedures). In the more experienced centers, the survival rate after HLA-nonidentical transplantation was significantly better (57% vs 43%; $P = 0.009$). Moreover, the frequency of acute GVHD decreased over time after haploidentical transplantation, from 35% to 40% before 1996 to 22% thereafter ($P < 0.009$), perhaps because more effective methods of T-cell depletion are now used. This might contribute to the observed improvements in survival over time.

Debate continues regarding the relative merits of transplantation using haploidentical stem cells, commonly immediately available from the child's parents, or conducting an unrelated donor search to find perhaps more closely HLA-matched stem cells from an unrelated donor. Data from two transplant centers (Hospital for Sick Children, Toronto, Canada, and University of Brescia Spedali Civili, Brescia, Italy) were combined in a study designed to address this question.[6] This study showed improved survival with matched unrelated donor stem cells compared with mismatched family member stem cells (80.5% vs 52.5%; $P = 0.03$). In addition, long-term reconstitution of a full T-cell repertoire was achieved more frequently after unrelated donor transplant compared with mismatched family member donor transplantation (94% vs 61.1%; $P = 0.02$).

Use of Cord Blood

Umbilical cord blood, from either siblings or unrelated donors, stored in cord blood banks is being used increasingly for hematopoietic cell transplantation therapy for immunodeficiencies. Cord blood is an attractive stem cell source because recipients with immunodeficiencies typically are small; therefore, cell doses likely will be adequate. In addition, search commonly can be completed and a suitable unit identified in a period of a couple of weeks.[7]

Knutsen and Wall[8] reported the outcomes of umbilical cord blood transplantation in eight children with severe primary T-cell immunodeficiency disorders. Three patients had SCID, one had reticular dysgenesis, one had Nezelof syndrome, two had combined immunodeficiency, and one had Wiskott-Aldrich syndrome (WAS). In this series, all patients received a preparative regimen of busulfan and cyclophosphamide, and all achieved complete donor chimerism, although one child required a second transplantation after rejecting the initial graft. In this study, the early appearance of T-cell immunocompetence was observed, likely due to engraftment of memory T cells. In addition, proliferative responses to mitogens and alloantigens were normal. Similarly, Bhattacharya et al.[9] reported results of umbilical cord transplants in 14 children ((two from siblings, 12 from unrelated donors) with immune deficiency, including eight children with SCID. Outcomes were excellent; all children achieved donor cell engraftment, and 12 of 14 children were surviving at the time of the report. Although these results are encouraging, continuing followup of these patients is necessary to evaluate long-term outcomes and determine the optimal stem cell source for treatment of patients with SCID. It remains possible that umbilical cord blood stem cells, typically not exposed to prior viral infections, may be inferior in achieving rapid control of viral pathogens in children with infection acquired before or during transplantation.

Timing of Transplant

A number of studies have shown that the best outcomes in children with SCID are achieved with transplantation performed as early as possible. Kane et al.[10] performed a retrospective review of patients with SCID who underwent transplantation in the neonatal period between 1987 and 1999 at a center in the United Kingdom and described excellent outcomes. Thirteen patients received 18 hematopoietic cell transplantations. Stem cell sources included marrow (n = 4), umbilical cord blood (n = 1), parental T-cell–depleted haploidentical marrow (n = 10), and T-cell–depleted unrelated donor marrow (n = 3). Patients were conditioned with busulfan and cyclophosphamide. All patients were surviving 6 months to 11.5 years after transplantation. Of note, five patients required additional hematopoietic cell infusions to achieve adequate and stable immune system recovery. Multiple hematopoietic cell infusions are not infrequent in transplantation therapy for SCID, particularly if grafts are given without a

preparative regimen. Myers et al.[11] also addressed the value of early transplantation in a report describing a subset of the Duke University experience reported by Buckley. This study compared immune system function in 21 SCID infants receiving transplantations in the neonatal period with function in 70 SCID infants undergoing transplantations at an older age. Lymphocyte phenotypes, response to mitogens, immunoglobulin levels, and T-cell receptor circles were evaluated before transplantation and sequentially thereafter. Of the 21 SCID patients who underwent transplantation in the neonatal period, 95% were surviving. The infants who underwent transplantation in the neonatal period developed higher lymphocyte responses to phytohemagglutinin and higher numbers of $CD3^+$ and $CD45RA^+$ T cells in the first 3 years of life than those who received transplantations later. T-cell receptor circles peaked earlier and with higher values in the neonatal transplants than in the later transplants. These authors proposed that improved outcomes for SCID could be achieved with universal newborn screening for lymphopenia so that children with SCID would be diagnosed early and transplantation performed under the most favorable circumstances.

In Utero Transplant

A logical extension of the reports describing improved outcome with younger age at the time of transplantation has been the investigation of in utero transplantation for treatment of SCID. Flake et al.[12] reported successful treatment of a fetus with X-linked SCID by in utero transplantation of paternal marrow cells enriched with hematopoietic cell progenitors by $CD34^+$ cell selection. Three transabdominal injections of hematopoietic stem cells were given to the fetus in utero. At birth, the patient had no evidence of GVHD, and hematologic and immune system function appeared normal. Notwithstanding the success of this case, the clinical experience with in utero hematopoietic stem cell transplantation has been otherwise disappointing, and in most cases engraftment was not achieved. Touraine et al.[13,14] reported the treatment of one patient with bare lymphocyte syndrome and another patient with SCID by in utero transplantation of hematopoietic cells from fetal liver. Multiple prenatal and postnatal fetal liver transplantations were performed, and the evidence of engraftment in these two patients was limited. Whether benefit was gained from the in utero component of the therapy was unclear. Additional work in this field is needed before in utero transplantation becomes an accepted therapy.

Reduced-Intensity Regimens

The need for a preparative regimen prior to transplantation therapy for SCID is variable. Many patients with little residual NK cell or lymphocyte function will achieve engraftment without a preparative regimen. Avoiding use of a preparative regimen significantly reduces the late effects of transplantation. No clinical test can categorically predict graft rejection. A common approach is to attempt engraftment in the absence of a preparative regimen but to resort to hematopoietic cell infusion with a preparative regimen if engraftment fails. The greater the degree of HLA mismatch between donor and recipient, the more difficult will be achieving engraftment and the greater the likelihood of needing a preparative regimen. An alternative to a full preparative regimen, particularly suitable for children with significant organ dysfunction, is use of a nonmyeloablative regimen. Rao et al.[15] reported 33 consecutive unrelated donor transplants in children with primary immune deficiencies, including six children with SCID, using a reduced-intensity preparative regimen that included fludarabine, melphalan, and antilymphocyte globulin or alemtuzumab (Campath). All patients had successful initial engraftment with predominantly donor chimerism, and early toxicity was low. Thirty-one of 33 children were surviving 1 year after transplantation. Mixed chimerism occurred at later time points, with 55% of children full donor chimeras at 1 year, and 39% with likely adequate levels of donor chimerism. Two of the 33 children had low-level chimerism requiring prophylactic medication and likely retransplantation. The authors of this study compared these results with those of ablative transplants performed for a similar patient population at the same institution. Incidences of engraftment and GVHD were similar between the two groups. Overall survival was notably superior in the reduced-intensity preparative regimen group (94% vs 53%; $P = 0.014$) compared with the myeloablative group, although it should be noted that the majority of the myeloablative transplants were performed in earlier years. Viral reactivation was common after reduced-intensity conditioning but was controllable with careful monitoring and preemptive treatment.

Reduced-intensity preparative regimens likely will provide an attractive option for transplantation for SCID in the future. Transplantation with no conditioning regimen has been used widely because late adverse effects are reduced in children who can achieve adequate immune reconstitution. However, this approach may result in graft failure, and the time course of T-cell reconstitution may be prolonged or recovery limited in some patients.[16,17] Use of a conditioning regimen appears to improve cell recovery in particular SCID phenotypes, and it is anticipated that better tolerated reduced-intensity regimens may increase enthusiasm for use of preparative therapy.[18]

Wiskott-Aldrich Syndrome

WAS is a lethal hematologic disease characterized by platelet and lymphocyte dysfunction, microthrombocytopenia, and a tendency to autoimmunity and lymphoreticular malignancies (see Chapter 51). WAS has a worldwide distribution, with an estimated incidence between one and 10 per million live male births. In the past it was diagnosed based on the triad of microthrombocytopenia, eczema, and recurrent infections. WAS is a consequence of mutation in the WAS (also called WASP) gene at Xp11.22–11.23.[19] *WASP* encodes a 502-amino-acid protein that is selectively expressed in hematopoietic stem cell-derived lineages and is a key regulator of cell signaling and cytoskeletal reorganization. Mutations in the WASP gene can result in classical WAS or in a less severe form of X linked thrombocytopenia that may present at birth or during the first few months of life with petechiae, bruising, and bloody diarrhea. Excessive hemorrhage after circumcision is an early diagnostic sign, particularly when associated with eczema during infancy and childhood. Correlation of genotype with phenotype has shown that complete absence of expression of WASP protein is associated with greater susceptibility to infection, severe eczema, tendency to hemorrhage, and malignancy.[20] Children who expressed some WASP protein have a less severe phenotype, and commonly these children have missense mutations.[21] Boys with deletions or insertions commonly have the more severe WASP-negative phenotype.

The current mainstays of supportive care for WAS are splenectomy and intravenous immunoglobulin infusion.[22,23] With these treatments, patients with WAS remain at high risk for overwhelming sepsis due to an inherent deficiency of antibody production to polysaccharide antigens in combination with splenectomy. In addition, boys who do not achieve safe platelet counts are restricted in their activities. Immune system complications of WAS are commonly managed by long-term corticosteroid therapy or, in extreme cases, by palliative organ transplantation for end-stage renal failure or liver disease.[24,25] Development of lymphoma, which occurs frequently in the second decade of life in untransplanted boys, is associated with poor outcomes.

Transplant Outcome

Two large registry series have described the outcome of hematopoietic cell transplantation for patients with WAS. Filipovich et al.[26] analyzed outcomes reported to the International Bone Marrow Transplant Registry (IBMTR) and the National Marrow Donor Program (NMDP). This study included 170 hematopoietic cell

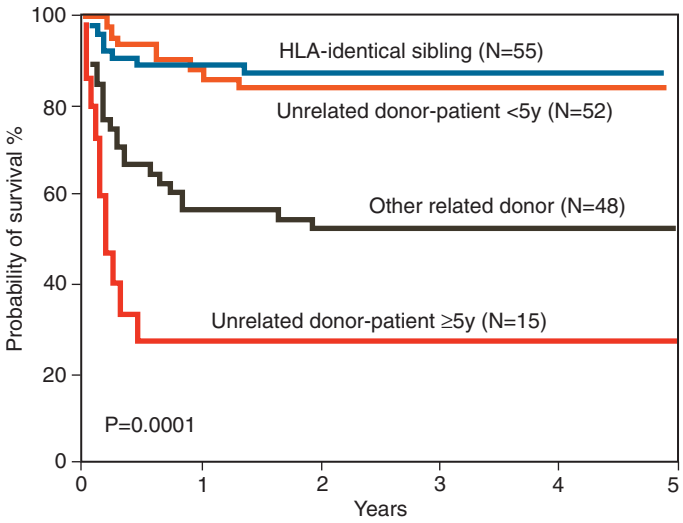

Figure 100–2 Probabilities of survival by donor type and recipient age for 170 patients receiving hematopoietic cell transplantations for treatment of Wiskott-Aldrich syndrome. There was no significant difference in the risk of mortality after human leukocyte antigen (HLA)-matched sibling–donor transplantations and after unrelated-donor transplantations in children younger than 5 years. A significantly worse rate of survival was associated with use of related donors other than HLA-identical siblings, regardless of recipient age, and with use of unrelated donors in patients older than 5 years. (From Filipovich AH, Stone JV, Tomany SC, et al: Impact of donor type on outcome of bone marrow transplant for Wiskott-Aldrich syndrome: Collaborative study of the International Bone Marrow Transplant Registry and the National Marrow Donor Program. Blood 97:1598, 2001.)

transplantations for patients with WAS performed between 1968 and 1996. Fifty-five were from HLA-identical sibling donors, 48 from other relatives, and 67 from unrelated donors. The 5-year probability of survival for all subjects was 70%. Probabilities differed by donor type: 87% of recipients of HLA-identical sibling donor grafts survived compared with 52% of recipients of other related donor grafts. Seventy-one percent of patients who received unrelated donor transplantations survived. Multivariate analysis indicated that boys older than 5 years had significantly lower survival rates when receiving transplants from related donors other than HLA-identical donors or from unrelated donors compared with transplantations from HLA-identical sibling donors. Boys receiving unrelated-donor transplantation before age 5 years had survival rates similar to boys receiving HLA-identical transplantation (Fig. 100–2). Detailed data regarding chimerism and immune system reconstitution were not available in this multicenter registry series. Other studies have indicated that early mixed chimerism in patients with WAS often is stable because of a survival advantage for stem cells and hematopoietic precursors bearing the normal WAS gene.[27]

European registry data indicate similarly good results with genotypically identical transplantations.[4] This study included 32 patients with WAS who received a genotypically identical graft, and 81% were surviving. Survival was inferior for recipients of HLA-mismatched related grafts, with 45% surviving (n = 43). Although data for WAS cases were not shown separately for non-SCID immunodeficiency patients, there was no difference in survival between recipients of genotypically HLA-identical and HLA-matched unrelated-donor transplantations. In this study, 75% of patients with unrelated donors were considered "HLA-identical" to their donors. The level of resolution of HLA typing and the loci included to define "identical" were not stated in the report. A case series of 57 boys with WAS transplanted in a number of centers in Japan also describes excellent outcomes for young patient transplanted with related or matched unrelated donor stem cells.[28] This study includes transplants performed between 1985 and 2004 and included 11 boys transplanted from HLA-matched related donors, 10 from mismatched related donors, 21 from unrelated bone marrow donors, and 15 from unrelated cord blood units. The overall 5-year survival rate for patients receiving bone marrow from unrelated donors and those receiving cord blood from unrelated donors was 80% in both groups. Univariate factors associated with poorer survival included age over 5 years, transplantation from an HLA-mismatched donors, and use of a preparative regimen other than busulfan, and cyclophosphamide, with or without antithymocyte globulin. Only the preparative regimen remained significant in a multivariate analysis. Similar observations have been reported by investigators from the University of Brescia, Italy, who described their single-center experience of 23 transplants for WAS, spanning the years 1990 to 2005.[29] This report described similar excellent outcomes in recipients of unrelated donor marrow stem cells, with 81.2% (13/16) surviving; deaths occurred only in recipients of mismatched related stem cells or in children with severe symptomatology at the time of transplantation.

Taken together, these data show that early hematopoietic cell transplantation using genotypically or phenotypically matched donor–recipient pairs is excellent therapy for boys with WAS. Transplantation before age 5 years is associated with the best outcome. These data should encourage earlier referral of suitable candidates for transplantation.

Table 100–1 Classification and Underlying Conditions of Hemophagocytic Lymphohistiocytosis

Genetic HLH
Familial HLH (Farquhar disease[a])
Known gene defects (perforin, Munc13-4, syntaxin 11)
Unknown gene defects
Immune deficiency syndromes
Chédiak-Higashi syndrome
Griscelli syndrome
X-linked lymphoproliferative syndrome
Acquired HLH
Exogenous agents (infectious organisms, toxins)
Infection-associated hemophagocytic syndrome
Endogenous products (tissue damage, metabolic products)
Rheumatic diseases
Macrophage activation syndrome
Malignant diseases

[a]Familial hemophagocytic lymphohistiocytosis (HLH) was first described by Farquhar and Claireaux in 1952.

Adapted from Janka G, zur Stadt U: Familial and acquired hemophagocytic lymphohistiocytosis. Hematology 2005 American Society of Hematology Education Book, 82, 2005.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a life-threatening immune system disorder characterized by fever, massive hepatosplenomegaly, pancytopenia, hypertriglyceridemia, hypofibrinogenemia, and central nervous system disease, commonly manifested as seizures and encephalopathy (see Chapter 52).[30] Historically, HLH has been categorized as primary or secondary. The primary form, also known as *familial erythrophagocytic lymphohistiocytosis*, typically has a symptomatic presentation at infancy. Inheritance usually is autosomal recessive. Secondary HLH often is associated with Epstein-Barr virus infections and typically manifests at an older age. Clinical findings similar to those seen in HLH also occur in children with Chédiak-Higashi syndrome, Griscelli syndrome, and X-linked lymphoproliferative disorder (Table 100–1). Children with these genetic disorders who manifest HLH will generally require prompt transplant for disease control.

Table 100–2. Gene Mutations Identified in Hemophagocytic Lymphohistiocytosis.

Disease	Chromosome Location	Associated Gene	Gene Function
FHLH1	9q21.3–22	Unknown	Not known
FHLH2	10q21–22	PRF1	Induction of apoptosis
FHLH3	17q25	UNC13D (Munc)	Vesicle priming
FHLH4	6q24	STX11	Vesicle transport; t-SNARE
GS-2	15q21	RAB27A	Vesicle transport; small GTPase
CHS-1	1q42.1–q42.2	LYST	Vesicle transport, not further defined
XLP	Xq25	SH2D1A	Signal transduction and activation of lymphocytes

CHS, Chédiak-Higashi syndrome; FHLH, familial hemophagocytic lymphohistiocytosis; GS, Griscelli syndrome; XLP, X-linked lymphoproliferative syndrome.

Adapted from Janka G, zur Stadt U: Familial and acquired hemophagocytic lymphohistiocytosis. Hematology 2005 American Society of Hematology Education Book, 82, 2005.

Most patients with familial HLH have complete lacking of or impaired NK cell function. The specific underlying genetic cause can now be discerned in approximately 50% to 60% of cases. The most common genetic defects in patients with FHL involve the perforin gene (*PRF1*) on chromosome 10q21 and the *Munc13-4* gene on chromosome 17q25 (Table 100–2).[31,32] Mutations of *PRF1* account for approximately 30% to 40% of patients, defined as the FHL2 subtype, and *MUNC13-4* mutations are identified in an additional 25% to 30% of cases (FHL3). The proteins encoded by both genes are implicated in the killing machinery of cytotoxic lymphocytes.[32,33] Perforin is a protein expressed in the cytoplasmic granules of cytotoxic T lymphocytes and NK cells. Perforin may be principally responsible for translocation of granzyme B from cytotoxic cells into target cells. Granzyme B then can migrate to the target cell nucleus and participate in triggering of apoptosis.[34]

Munc13-4, a protein essential for cytolytic granule fusion to the cell surface membrane, is a direct partner of rab27a.[32,33] The two proteins are highly expressed in cytotoxic T lymphocytes and mast cells, where they colocalize on secretory lysosomes. This complex is an essential regulator of secretory granule fusion with the plasma membrane in hematopoietic cells.

More recently, mutations in the syntaxin11 gene (6q24) have been reported in a small group of patients (FHL4) of common Kurdish origin.[35] This defect is thought to alter intracellular vesicle trafficking of the phagocytic system, but the exact functions are unknown. In addition, a small number of male patients with the clinical syndrome of HLH have germline mutations in SH2D1A/SAP, the gene associated with X-linked lymphoproliferative disorder.[36]

The clinical features of HLH are due to widespread infiltration of the liver, spleen, marrow, and central nervous system with activated lymphocytes and macrophages. Expansion of these cells represents a failure of regulation of the immune system response, particularly by NK cells. NK cells primarily use the perforin/granzyme pathway to eliminate virus-infected or transformed cells and achieve cytotoxicity. Flow cytometric analyses of intracytoplasmic perforin expression and surface CD107a, a marker of granule exocytosis (expressed at the surface of NK cells after their interaction with suitable target cells), as a surrogate for Munc13-4 defects have been used to identify cases with these mutations.[37] Therapeutic options have evolved along t he principles of control of exaggerated clinical manifestations of inflammation, eradication of pathogen-infected antigen-presenting cells, and stem cell transplantation to replace the defective immune system.

Transplant Outcomes

An analysis of 122 HLH patients treated with chemotherapy alone revealed a very poor 5-year survival rate of 10.1%.[38] In contrast, the 5-year survival rate for allogeneic hematopoietic cell transplantation recipients was 66%. The majority of patients in this report received transplants from HLA-matched sibling donors. As with any genetic disease, use of matched sibling donor marrow cells for transplantation raises the concern that the sibling donor also might have HLH. Differences in age at onset of at least 3 years between siblings have been described. Potential donors from affected families should be studied carefully for evidence of latent HLH. In light of the emerging genes being associated with HLH, every effort must be made to identify these mutations in probands so that similar mutations can be sought in sibling donors prior to transplantation. If similar outcomes can be achieved with unrelated donor hematopoietic cell transplantation, this might be a more attractive option that avoids this uncertainty in families without a defined gene mutation. A survival rate of 44% was reported in HLH patients receiving unrelated-donor hematopoietic cell transplantation (n = 16) treated at two institutions.[39] This report also noted that survival was poor in patients not in clinical remission at the time of transplantation, with only one of six patients surviving. These data emphasize the need to make the best possible attempt to achieve a remission prior to transplantation.

An international study of the treatment of HLH with a uniform chemotherapy and transplantation protocol (HLH 94) supports the value of hematopoietic cell transplantation for patients with HLH.[40] In 1994, the Histiocyte Society initiated a prospective international collaborative therapeutic study aimed at improving survival. One hundred thirteen patients younger than 15 years with persistent, recurring, or familial disease received a chemotherapy regimen of etoposide, corticosteroids, cyclosporine, and, in selected patients, intrathecal methotrexate, followed by hematopoietic cell transplantation. All patients either had an affected sibling or fulfilled the Histiocyte Society diagnostic criteria for HLH. At a median followup of 3.1 years, the estimated overall 3-year probability of survival was 55%, and in familial cases the probability of survival was 51%. The 3-year probability of survival in patients who underwent transplantation was 62%.

A separate report dissected in detail the transplant outcomes of children receiving transplantation according to the HLH 94 study.[41] Eighty-six children, 29 with familial HLH, were included in the report. Overall 3-year survival post transplant was 64%, with similar outcomes in recipients of matched related or matched unrelated donor stem cells (71% and 70%, respectively) and inferior survival in recipients of family haploidentical donors or mismatched unrelated donors (50% and 54%, respectively). Outcomes were improved in children with inactive disease at the time of transplant, although some children with persistent active disease were survivors post-transplant.

Reduced-Intensity Regimens

The majority of deaths posttransplant in HLH 94 were due to regimen-related toxicity, raising interest in less toxic preparative regimens. The Great Ormond Street Hospital team reported outcomes of reduced-intensity conditioning transplants in 12 children with HLH, using a variety of fludarabine-based regimens and stem cell sources.[42] Nine of 12 children were surviving, three of whom had mixed chimerism ranging from 2% to 84% donor cells. The patient with 2% donor cell engraftment remains in clinical complete remission 73 months from transplantation; however, the adequacy of such low-level chimerism for long-term disease control remains uncertain. A proportion of children transplanted for HLH will have graft failure

(i.e., completely absent donor chimerism), particularly when mismatched or haploidentical stem cells are used, raising the question of whether a second attempt at transplant is indicated in children with quiescent disease. Ardeshna et al.[43] reported three children with HLH and graft rejection. After a period of disease quiescence lasting 4 months to 8 years, disease recurrence and subsequent death occurred in each case, suggesting that further transplantation should be offered in such cases. Further long-term followup is needed to define the level of mixed chimerism that is acceptable in HLH, and this number may vary in different children with different genetic and infectious etiologies of disease.

Control of CNS Disease

An important challenge in the management of HLH is the control of CNS disease. Thirty-two percent of children enrolled in HLH 94 had neurologic alterations at onset, secondary to an inflammatory meningoencephalopathy. CNS involvement with HLH can lead to severe and perhaps permanent CNS dysfunction. As survival improves, CNS impairment is being increasingly identified as a long-term sequela of HLH. In the HLH 94 protocol, early intensification with systemic chemotherapy as well as intrathecal methotrexate was recommended for children with CNS involvement. Sixty-seven percent of children receiving intrathecal methotrexate achieved resolution of CNS symptoms, but a similar proportion of children with CNS disease who did not receive IT therapy had resolution of symptoms, leaving uncertainty regarding the importance of IT therapy.[40] Of note, patients with HLH-related CNS insults who underwent stem cell transplantation did not generally have radiologic resolution of CNS lesions; however, there was a suggestion of disease stabilization by magnetic resonance imaging with functional and cognitive correlates. Other reports cite stabilization of neurologic function and frequent reversal of neurologic deficits within 1 to 3 years after a successful graft.[44] Ouachee-Chardin et al.[45] reported 48 patients with HLH treated between 1982 and 2004. The report highlights a 28% incidence of veno-occlusive disease (VOD) among younger recipients of haploidentical grafts and antithymocyte globulin during conditioning. The overall survival of patients followed for a median of 5.8 years was 58.5 %. A sustained remission was noted in all patients, and donor chimerism greater than 20% was seen in these patients. In contrast to the development of myglodysplastic syndrome and acute myelogenous leukemia (MDS/AML) in three patients with HLH treated with the HLH 94 protocol, none of the patients treated with combination immunotherapy and hematopoietic stem cell transplantation in the French study developed this phenomenon.[45] Patients studied here also demonstrated stabilization of neurologic disease without development of new lesions or CNS reactivation.

MUCOPOLYSACCHARIDOSES

MPS I (Hurler Syndrome)

MPS comprises a group of recessively inherited lysosomal storage diseases characterized by specific enzyme deficiencies, tissue accumulation of glycosaminoglycans leading to musculoskeletal deformities, organ involvement, and mental retardation of varying severity (see Chapter 53).[46] Experience with hematopoietic cell transplantation therapy is greatest in cases of Hurler syndrome (MPS I), the prototypical MPS disease. MPS I is caused by deficiency of lysosomal α-L-iduronidase. Affected children appear normal at birth but subsequently develop coarse facial features, hepatosplenomegaly, short stature, persistent rhinitis, corneal clouding, claw hands, coronary artery stenosis, hydrocephalus, progressive mental retardation, and a variety of well-defined musculoskeletal abnormalities known as *dysostosis multiplex*. Untreated patients will have progressive mental retardation with development of severe kyphosis. Such patients typically die of cardiopulmonary insufficiency and/or complications of progressive mental retardation.

Transplant Outcomes

A 9-month-old boy was the first child treated with hematopoietic cell transplantation for MPS I in 1980.[47] This patients is surviving 20 years later, fully engrafted with cells from his mother's marrow; he has stable intelligence in the low-to-normal range.[48] This initial favorable experience has encouraged further investigation of transplantation therapy for MPS I. In the largest series to date, Peters et al.[49] reported outcomes of hematopoietic cell transplantation for MPS I in 54 children using data collected by the Storage Disease Collaborative Study Group. The patients in this study had a median age of 1.8 years at the time of transplantation (range 0.4–7.9 years). Transplantations were performed between 1983 and 1995. Thirty-nine of the 54 patients (72%) had engraftment after the first hematopoietic cell transplantation. This is a much lower frequency of engraftment than would be expected in other disorders and indicates that patients with MPS I have particular difficulty perhaps with stem cell homing or adhesion. The actuarial probability of 5-year survival was 75% for recipients of genoidentical grafts and 53% for recipients of related HLA-mismatched donor grafts. Survival for all patients who achieved engraftment was 53%.

This large study provided the opportunity for the authors to examine cognitive outcomes. Baseline and posthematopoietic cell transplantation neuropsychological data were available for 26 of 30 engrafted survivors. Of 14 patients who underwent transplantation before age 24 months, nine demonstrated developmental trajectories that were normal or somewhat slower than normal. In contrast, only three of 12 patients who underwent transplantation after age 24 months showed developmental trajectories that were normal or somewhat slower than normal ($P = 0.01$). For children with a baseline Mental Developmental Index (MDI) greater than 70, there was a significant correlation between the MDI at followup study and leukocyte α-L-iduronidase enzyme activity ($P = 0.02$). Children were more likely to maintain normal cognitive development if they received transplants from a donor with homozygous normal leukocyte α-L-iduronidase enzyme activity compared with a heterozygous carrier of MPS I. These data indicate the importance of early transplantation in children with MPS I (typically before age 2 years) to optimize cognitive outcome.

A companion paper described the outcome of 40 children with MPS I who received unrelated-donor hematopoietic cell transplantations.[50] The children in this report had a median age of 1.7 years (range 0.9–3.2 years) and underwent transplantation between 1989 and 1994. Only 25 of the 40 patients achieved donor cell engraftment, again emphasizing the difficulty in engraftment in this patient population. An estimated 49% percent of patients were alive at 2 years. Sixty-three percent had evidence of allogeneic donor engraftment, and 37% had recovery of autologous hematopoiesis. When graft failure occurs in this population, recovery of autologous hematopoiesis is usual, rather than aplasia. Higher hematopoietic cell dose correlated with both improved donor cell engraftment and superior survival. Neither T-cell depletion of the marrow nor inclusion of irradiation as part of the conditioning regimen influenced the incidence of engraftment, although the power of the study to identify an effect was modest. Similar results were reported in a large single-center study from France describing transplantation in 27 children with MPS I, using mostly unrelated donors, 23 of whom were surviving, 21 with functional grafts.[51] Similar to other reports, the incidence of primary graft failure was high (16%).

Use of Cord Blood

The rapid availability of umbilical cord blood units for transplantation makes cord blood an attractive therapeutic option. Staba et al.[52] reported outcomes of 20 consecutive children with MPS I who received unrelated cord blood transplants after a chemotherapy-based preparative regimen. They described survival rates similar to those reported with bone marrow as a stem cell source (17/20 alive) and amelioration of the disease phenotype. Umbilical cord blood trans-

plantation allows rapid transplantation to halt substrate deposition in MPS I. An alternative approach is active substrate depletion with enzyme replacement therapy prior to transplantation. Commercial availability of enzyme (Aldurazyme; Genzyme) is allowing many transplant centers to explore this approach. Early reports indicate that this strategy is well tolerated, although the optimal duration of replacement prior to transplantation and the value of posttransplant therapy remain unclear.[53,54] Children with MPS I have a high incidence of pulmonary hemorrhage after transplantation, and use of enzyme for substrate depletion from the lungs might reduce this clinically very significant toxicity, although data are still early.[55,56] Use of reduced-intensity conditioning therapy is also being explored and might similarly reduce pulmonary toxicity.[57]

Assessment of Transplant Outcomes

Assessment of cognitive outcomes is a vital component of evaluating the success of transplantation for genetic disorders. Peters et al.[49,50] assessed the MDI before and after transplantation in 11 engrafted survivors. Eight children had a baseline MDI of greater than 70 at the time of transplantation. Of these cases, six patients showed stability in the age equivalence scores; two patients were too early to evaluate. Four of the children were acquiring skills at a pace equal to or slightly below age peers, and two children had shown either a plateau in their learning or extreme slowing in their learning process. Posttransplantation evaluation of engrafted children with baseline MDI less than 70 (typically older children) indicated that two children had shown deterioration in their developmental skills, whereas the remaining three children maintained their skills and were adding to them at a variable rate. The authors concluded from this study that MPS I patients with baseline MDI greater than 70 who achieve engraftment will have favorable long-term outcomes, with cognitive function close to or within the normal range. A further report of adaptive functions in a cohort of 41 posttransplant children with MPS I examined communication, daily living skills socialization, and motor skills and described long-term slow improvement in functional outcomes, with best outcomes in children with good cognitive function before transplant.[58] Again, these data emphasize the need for early transplantation in MPS I patients before the occurrence of significant loss of cognitive function.

Biochemical studies have shown a close correlation between mean posttransplant enzyme level and residual substrate, indicating that higher levels are likely to yield better functional outcomes.[59] This observation is of particular importance in families with an HLA-matched sibling donor who is a heterozygote and has reduced levels of α-L-iduronidase. Results of well-matched unrelated donor transplants have improved due to better HLA typing, larger registries, and better supportive care, making this a potentially better donor source than a heterozygous sibling donor.

The low frequencies of engraftment described in these studies are a common feature of transplantation for MPS I cases. A proportion of children who fail to engraft can be rescued with a second allogeneic transplantation. Grewal et al.[60] described outcomes in 11 MPS I patients who received a second transplantation after initial graft failure. The median age at second transplantation was 25 months (range 16–45 months), and the median time from the first transplantation was 8 months (range 4–18.5 months). The conditioning regimen consisted of cyclophosphamide and total body irradiation, with or without antithymocyte globulin. The source of hematopoietic cells was an unrelated donor in six cases, an HLA-matched sibling in four cases, and an HLA-mismatched related donor in one case. Five of the 11 grafts were T-cell–depleted prior to infusion. Actuarial survival was 50% over 4 years. All surviving patients show sustained donor engraftment with normalization of α-L-iduronidase levels. Neuropsychological function stabilized after the second transplantation in three of five evaluable patients.

Long-term followup after transplantation for MPS I has shown that although donor cell engraftment can stabilize neurocognitive decline, continuing complications secondary to accumulation of glycosaminoglycans occur as the children mature. In particular, orthopedic abnormalities, including acetabular dysplasia, kyphoscoliosis, carpal tunnel syndrome, trigger finger, and genu valgum, tend to progress. Typically, multiple surgeries are required in the first decade after transplantation.[61,62]

The management of children with MPS during transplantation can be complex. Cardiac involvement due to deposition of glycosaminoglycan in coronary arteries causing stenosis can lead to sudden death during anesthesia or cardiac failure secondary to cardiomyopathy.[63–65] These manifestations improve significantly after engraftment is achieved. However, as the children grow, deposition of glycosaminoglycan in the poorly vascularized cardiac valves continues despite the presence of donor enzyme. Some long-term transplantation survivors have required cardiac valve replacement. Patients with MPS commonly have deposition of glycosaminoglycan in the upper airway and can be particularly difficult to intubate.[64,66] Belani et al.[64] described 141 episodes of anesthesia in children with MPS. In children with MPS I, the incidence of odontoid dysplasia was 94%, and 38% demonstrated anterior C1–2 subluxation, illustrating the need for great care during anesthesia. Intubation was noted to be more difficult, with the vocal cords frequently not visible, and there was a high frequency of airway obstruction after extubation. Two children required reintubation to support their airway. In this series, two deaths occurred secondary to severe and extensive coronary obstruction, and the study noted that cardiac catheterization could underestimate the degree of coronary stenosis. Ocular abnormalities associated with MPS may progress after successful transplantation, and careful efforts to optimize vision with surgery or refraction are important to optimizing developmental progress.[67,68] Lifelong observation of all aspects of the child's growth and development is essential to achieve the highest possible level of function. Significant improvements can be achieved with frequent and aggressive speech, physical, and occupational therapy.

MPS VI (Maroteaux-Lamy Syndrome)

MPS VI (Maroteaux-Lamy syndrome) is characterized by defective degradation of dermatan sulfate due to deficiency of *N*-acetylgalactosamine IV sulfatase.[69] The clinical severity of MPS VI is highly variable, with a continuum from mildly affected to severely affected patients.[70] Affected individuals typically have bony dysplasia hepatosplenomegaly, airway narrowing, deposition of dermatan sulfate on cardiac valves, and deposition in subcutaneous tissues leading to restriction in movement. MPS VI patients typically have a normal intellect, although cognitive deterioration, perhaps in association with hydrocephalus, can occur later in life. Patients usually die in their teens or early adult life, often of cardiopulmonary failure. Experience with transplantation in MPS VI is limited because of the rarity of this disease and the variable phenotype. The first human hematopoietic cell transplantation for MPS VI was reported in 1984, when Krivit et al.[71] described the outcome of sibling donor transplantation in a 13-year old girl with a severe form of MPS VI. This patient had severe life-threatening upper airway obstruction leading to obstructive sleep apnea. A subsequent report of her clinical status 40 months later described resolution of the sleep apnea, improvement in hepatosplenomegaly, and improvement in range of motion due to resolution of soft-tissue changes.[72] Of note, no radiographic improvement in bone pathology and no increase in height were observed. The patient had severe corneal clouding that did not resolve and required corneal transplantation.

Subsequent case reports have observed that some aspects of the MPS VI phenotype will be improved by transplantation.[73,74] Herskhovitz et al.[74] described four patients who underwent transplantation for MPS VI, with followup periods ranging between 1 and 9 years. The indications for transplantation were cardiomyopathy in three patients and severe obstructive sleep apnea in one. In all engrafted patients, facial features have become less coarse. Cardiac manifestations improved or remained stable, and three of the four patients were being educated in mainstream schools. However, skel-

etal changes persisted or even progressed, although posture and joint stability improved, and all patients remained ambulatory and active. These data support the role of transplantation therapy in prolonging survival and improving quality of life in MPS VI patients. However, careful selection of patients whose condition is most likely to improve with transplantation is necessary.

MPS II (Hunter Syndrome)

MPS II (Hunter syndrome) is an X-linked disorder caused by deficiency of iduronate sulfatase enzyme activity.[70] MPS II has a wide range of clinical severity, from the early-onset severe form (MPS IIA) to the milder later onset form (MPS IIB). Boys with MPS IIA exhibit significant somatic features, such as coarse facial features, progressive hearing loss, hepatosplenomegaly, cardiomyopathy, dysostosis multiplex, macrocephaly, central nervous system deterioration, and neuropsychological impairments. As in cases of MPS I, clinical features of the disease are due to deposition of storage material. Neuropsychological consequences of MPS IIA are similar to those of MPS I, except that behavioral abnormalities may be more marked. In general, male subjects with MPS IIB experience milder signs and symptoms with great variability in age of onset and severity, with survival as long as 40 years reported. The variable phenotype and life expectancy of patients with MPS II make the decision to submit a patient to the risks of transplantation very difficult. In addition, some cases of children who underwent transplantation for MPS II and who suffered continuing neurologic deterioration despite achievement of adequate engraftment have been reported.[75,76] Vellodi et al.[76] described a series of 10 patients who underwent transplantation as treatment for Hunter syndrome. The donor was an HLA-identical sibling in two cases, an HLA-nonidentical relative in six cases, a volunteer unrelated donor in one case, and unknown in one case. Only three of the 10 patients survived more than 7 years posttransplantation. In two of these cases, patients experienced steady progression of physical disability and mental handicap, although one patient maintained normal intellectual development with only mild physical disability. These authors and others have suggested a role for transplantation in carefully selected boys with Hunter syndrome.[77–80] This issue is controversial. If such transplantations are undertaken, careful attention should be given to the process of informed consent and to long-term followup to document the benefits achieved.[81–83]

MPS VII (Sly Syndrome)

MPS VII (Sly syndrome) is an autosomal recessive disorder caused by an inherited defect in the lysosomal hydrolase β-glucuronidase. The enzyme defect causes accumulation of undegraded glycosaminoglycans. Approximately 40 cases of MPS VII have been reported worldwide, and there is considerable experience in transplantation of mouse models in this disease.[84–86] Animal models have also been used in an investigation of brain-directed gene therapy, with encouraging preliminary results.[87] One detailed case report of transplantation in a 12-year-old girl with Sly syndrome has been reported.[88] This child had significant improvement in mobility and in apnea associated with upper airway obstruction after engraftment. Of note, the patient's mental retardation was not reversed by transplantation, which is in agreement with the findings in animal models.[89]

LEUKODYSTROPHIES

Adrenoleukodystrophy

X-linked adrenoleukodystrophy (ALD) is a demyelinating disorder of the central nervous system with highly variable clinical presentation.[90–93] The gene responsible for ALD encodes for the peroxisomal membrane protein adrenoleukodystrophy protein (ALDP), which is a member of the ABC (ATP-binding cassette) transporter superfamily.[94] Individuals with ALD are deficient in lignoceroyl-CoA ligase, an enzyme needed for degradation of very-long-chain fatty acids. Elevated levels of very-long-chain fatty acids in blood, particularly C24 and C26, are useful for diagnosing ALD. Approximately half of individuals with a mutation in this gene have the rapidly progressive childhood cerebral form of the disease, which is associated with an inflammatory response in the brain. Boys with childhood-onset cerebral adrenoleukodystrophy (COCALD) commonly experience rapid neurologic deterioration progressing to death 2 to 3 years after diagnosis, although a minority survive for a prolonged period in a semivegetative state. Within the same kindreds, however, 25% or more of individuals have a milder form of the disease called adrenomyeloneuropathy. Adrenomyeloneuropathy progresses slowly, involves the spinal cord, and shows little or no inflammatory response. Adrenomyeloneuropathy is compatible with a near-normal lifespan. In addition, within the same kindred, individuals can be carriers of a gene mutation but be asymptomatic or they can have Addison disease in isolation.[90] The phenotypic variability of ALD and the discordance in severity even within families make the decision to offer a therapy that is associated with significant morbidity and mortality, such as hematopoietic cell transplantation, a difficult one.[91] In addition, in symptomatic boys with COCALD, the rapid, often stepwise progression of the disease and the deterioration that can occur after transplantation may lead to severe disability, even in children who are successfully engrafted. Identifying the benefits that can be achieved with hematopoietic cell transplantation for COCALD and identifying the optimal patients for with transplantation remain a challenge. It is desirable to identify boys destined to manifest COCALD at the earliest stage of their disease and offer transplantation. It is not desirable to offer transplantation to those destined to have adrenomyeloneuropathy or isolated Addison disease. Data suggest that neuropsychological testing may predict early progression of a symptomatic case of COCALD.[95] In addition, monitoring progression of lesions detected by magnetic resonance imaging, with scoring according to the Loes scale, may assist in patient selection.[96]

The largest experience with transplantation for COCALD reported pooled data from 43 transplant centers worldwide, including transplants performed between 1982 and 1999.[97] One hundred twenty-six boys were included in the report, and complete data were available for 94 transplants. Overall survival was 56%, and the leading cause of death was disease progression. Neurologic function prior to transplantation was a key predictor of outcome, with 92% survival in boys with no or one neurologic deficit and a low magnetic resonance imaging severity score prior to transplant. Similar findings were reported in a single-center study of 12 transplants for COCALD, with poor outcomes in boys with poor or rapidly progressing neurologic function prior to transplantation.[98]

A single-center study described late neurologic outcomes in 12 patients with COCALD who were followed for 5 to 10 years after transplantation.[99] The findings indicated variable levels of improvement. Magnetic resonance imaging showed complete reversal of abnormalities in two patients and improvements in one. All patients who showed continued radiologic demyelination early after transplantation were stabilized and remained unchanged thereafter. Motor function remained normal or was improved after transplantation in 10 patients, verbal intelligence remained within the normal range for 11 patients, and performance abilities were improved or were stable in seven patients. The authors concluded that hematopoietic cell transplantation had long-term beneficial effects when the procedure was performed at an early stage of the disease. Identifying boys with known ALD based on elevated levels of very-long-chain fatty acids at the start of the decline that will lead to symptomatic COCALD is an important goal in the continuing investigation of transplantation for ALD.

Early diagnosis of ALD is commonly not possible for the first affected child in a family. Boys commonly present with behavioral difficulties and a decline in school performance that is mistaken for attention deficit disorder, and diagnosis is commonly delayed until gait abnormalities appear. Immunosuppressive approaches are currently being explored in boys with neurologic disease too far advanced

to allow successful transplantation. Future transplantation series should continue careful monitoring of short- and long-term complications to ensure that the therapy gives maximum benefit and least harm.

Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD) is an autosomal recessive inherited disorder caused by a deficiency of arylsulfatase A activity, which leads to accumulation of galactosyl sulfatide. Clinical symptoms vary depending on the patient's age at onset of the disease.[100] MLD can be classified clinically as infantile (onset at 6 months to 2 years), early juvenile (onset at 4–6 years), late juvenile (onset at 6–16 years), and adult (onset after 16 years of age). The juvenile- and early-onset presentations are characterized by progressive mental regression, loss of speech, quadriplegias, peripheral neuropathy, and death within a few years of onset. The adult-onset forms are more typically associated with psychiatric symptoms, particularly in the early stages of the disease.[101] Presentation commonly includes a change in personality, poor school or job performance, emotional instability, disorganized thinking, and impairment of memory. Diagnoses of hypomania, depression, or psychosis are common until additional clinical signs prompt magnetic resonance imaging examination, which will show diagnostic white matter changes.[102] Late-onset MLD can manifest as polyneuropathy because a progressive peripheral neuropathy is an important cause of morbidity in this disorder.

In 1985, Bayever et al.[103] reported transplantation for late infantile MLD using an HLA-identical sibling donor. In the 33 months after the procedure, progression of the patient's neurologic deterioration appeared to be halted. In 1990, Krivit et al.[104] reported a second case of late infantile MLD with transplantation from a matched sibling donor. In this case, progression of neurologic deterioration appeared to be delayed. Subsequent case reports support the belief that transplantation can retard the progression of disease in early cases.[105–115] However, the peripheral neuropathy associated with MLD appears likely to progress even in the presence of full donor engraftment. Experience with transplantation in cases of adult-onset MLD remains limited. Case reports of this disorder also suggest a halting of neurologic deterioration, although there is no evidence of any gain in function after successful engraftment.

Investigators are studying the role of umbilical cord blood transplantation for treatment of early-onset rapidly progressive infantile MLD. Identification and procurement of suitable donor cells can proceed more quickly with an umbilical cord blood source than with an adult volunteer unrelated donor. Determination of the degree of specific and measurable benefit of the umbilical cord blood transplantation approach and appropriate patient selection will require long-term followup.

Globoid Cell Leukodystrophy (Krabbe Disease)

Globoid cell leukodystrophy (Krabbe disease) is an autosomal recessive disease caused by diminished or absent activity of the lysosomal enzyme glucocerebrosidase.[100,116] Globoid cell leukodystrophy is characterized by progressive loss of central and peripheral myelin and by spasticity, dementia, and peripheral neuropathy.[117] Globoid cell leukodystrophy typically progresses to a chronic vegetative state and premature death. The most frequent form of globoid cell leukodystrophy has onset in early infancy and is rapidly progressive, typically leading to death within 2 years. The late-onset form, which begins in later childhood, has a more insidious onset and progresses over several years to death. Data describing the outcome of transplantation therapy for patients with globoid cell leukodystrophy are sparse. Krivit et al.[118] described five children with globoid cell leukodystrophy treated with allogeneic hematopoietic cell transplantation. Four of the patients received marrow from an HLA-identical sibling, and one was treated with unrelated umbilical cord blood with one HLA DR mismatch. Engraftment of donor-derived hematopoietic cells occurred in all patients and was followed by a return to normal glucocerebrosidase levels. In the four patients with later-onset disease, central nervous system deterioration was halted. In the patient with the infantile form of the disease, which was diagnosed biochemically prior to development of symptoms, signs and symptoms of neurologic deterioration had not appeared by the time of reporting. Of note, some of the patients in this series achieved significant reversal of symptoms of globoid cell leukodystrophy. This observation contrasts with the findings of most transplantation studies of metabolic disease in which halting of deterioration is achieved but few, if any, patients show gain in function.

Transplantation in children with the rapidly progressive infantile form of globoid cell leukodystrophy is controversial.[119,120] Early transplantation reports described difficulty in achieving engraftment and early death from GVHD without reversal of symptomatic disease. Prompt transplantation in the immediate postnatal period or even in utero offers the possibility of reversal or control of disease. Umbilical cord blood allows rapid transplantation once the diagnosis has been made. An initial report of cord blood transplantation in 11 asymptomatic newborns and 14 symptomatic infants with infantile globoid cell leukodystrophy showed that although engraftment could be achieved, no substantial improvement was seen in children treated after onset of symptoms.[121] In contrast, some benefit was seen in asymptomatic children, some of whom retained normal cognitive and motor skills while others had mild-to-moderate delays in expressive language and mild-to-severe delays in gross motor function. The long-term results of this therapy remain to be determined, and such investigations should be performed within the context of a carefully monitored clinical investigation because the long-term benefits and risks currently are unknown.

OTHER RARE DISEASES

Case reports have described the role of hematopoietic cell transplantation in the treatment of patients with a range metabolic disorders. Successful outcomes of transplantation have been reported for patients with diseases such as α-mannosidosis, Wolman disease, and Niemann-Pick type 1A disease.[122–126] In light of the small number of cases reported for these diseases, it is difficult to make firm recommendations about therapy. In addition, positive outcomes are more likely to be reported than are negative outcomes. There is a continuing role for registries such as the IBMTR and disease-specific registries for reporting the outcomes of consecutive series of cases.

FUTURE DIRECTIONS

Partial correction of a clinical phenotype (e.g., patients with MPS I) is a significant limitation to the success of hematopoietic cell transplantation as therapy for metabolic diseases. Transplantation fails to deliver adequate levels of enzyme to areas of the body that are poorly vascularized, such as cardiac valves, bone, and cartilage. A potential strategy to address this problem is use of mesenchymal as well as hematopoietic stem cells. Mesenchymal stem cells are cells with the potential to differentiate into mesodermal cells, such as cartilage and bone. Data have shown that after a hematopoietic cell transplantation, the stromal cells of the marrow remain of host origin.[127] The addition of mesenchymal stem cells cultivated ex vivo might achieve donor cell engraftment, improve delivery of enzyme to bone and cartilage, and improve disease course. Additionally, animal models suggest that coinfusion of mesenchymal stem cells can facilitate engraftment of allogeneic cells and reduce GVHD.[128,129] Although these studies are in their early stages, they have shown that it is possible to grow mesenchymal stem cells ex vivo and infuse them without toxicity. Krivit et al.[130] infused mesenchymal stem cells into children with MLD who had previously successfully undergone transplantation. In these children, peripheral neuropathy had progressed despite successful halting of central nervous system disease by hematopoietic

cell transplantation. Preliminary data indicate improvement in nerve conduction times after infusion of mesenchymal stem cells grown from the original hematopoietic cell donor. There likely will be significant continuing efforts in this area, using genetically modified and unmodified mesenchymal stem cells to an attempt to optimize correction of the phenotype.

An additional limitation of transplantation as therapy for metabolic disorders is, in general, the inability to reverse central nervous system damage that occurred before transplantation. A potential and likely feasible approach to solving this problem is newborn screening for storage disorders to enable transplantation at the earliest possible time. Newborn screening programs performed using heel-stick cards currently used to screen for other disorders have been proposed.[131–134] Such programs would identify affected patients in the first month of life and allow early transplantation before severe central nervous system damage has occurred.

Significant morbidity is associated with the intensive myeloablative conditioning regimens used for bone marrow transplantation. Reduced-intensity preparative therapies that combine powerful immunosuppression with fludarabine with moderate myeloablation with alkylating agents have been explored. Preliminary results suggest that the approach may achieve adequate engraftment with reduced regimen-related toxicity and may improve long-term outcomes.[135,136]

An exciting alternative approach to hematopoietic cell transplantation for treatment of genetic disorders is use of gene therapy, in which autologous cells are transduced with a normal copy of the defective gene. This approach is attractive because the issues of donor identification and GVHD are removed. A large amount of preclinical work has been performed addressing the use of this strategy. Significant issues and technical questions remain to be addressed, however, before gene therapy is a viable option in humans. Chief among these are the relative inefficiency of gene transduction and the challenges related to regulation and durability of gene expression using these strategies. An additional challenge has arisen recently because one of the examples of successful use of human gene therapy, treatment of children with γ-chain SCID, has been associated with insertional leukemogenesis in a significant number of patients.[137,138] However, analysis of the insertion sites and better understanding of the biology of this event may show that the phenomenon is specific to this particular transgene or therapeutic approach.[139–142] Similar studies using vectors and transduction strategies with relatively minor differences have not shown the same tendency for leukemogenesis.[143] Further understanding of the mechanism by which this occurred is essential for the development of future gene therapy studies (see Chapter 110).

CHAPTER 101

OUTCOMES OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES IN ADULTS

Parameswaran Hari and Mary Horowitz

BACKGROUND

Allogeneic hematopoietic cell transplantation (HCT) offers the potential for cure in many hematologic malignancies. Thomas et al.[1,2] were the first to report long-term leukemia-free survival (LFS) after HLA (human leukocyte antigen)-identical sibling transplantation in patients with refractory acute leukemia. Better outcomes subsequently were demonstrated in patients transplanted in first complete remission (CR1) or second complete remission (CR2).[3–6] Durable cytogenetic remissions and long-term LFS after identical twin and allogeneic bone marrow transplantation for chronic myelogenous leukemia (CML) were reported in the late 1970s and early 1980s.[7–9] Use of allogeneic HCT for treatment of leukemia increased dramatically in the 1980s. By 1985, approximately 75% of allogeneic transplantations were performed for leukemia, with approximately equal numbers for CML, acute myelogenous leukemia (AML), and acute lymphoblastic leukemia (ALL). In the 1990s, allogeneic HCT was increasingly considered an effective salvage treatment strategy for patients with lymphoma or myeloma that failed to respond to conventional chemotherapy and/or autologous HCT.

Allogeneic transplantation involves administration of a preparative regimen of chemotherapy, immunosuppressive drugs, and/or radiation followed by infusion of donor hematopoietic cells. Most patients receive prolonged (≥3 months) therapy with immunosuppressive drugs posttransplant to prevent or treat graft-versus-host disease (GVHD). The purpose of the preparative or conditioning regimen is twofold: to eradicate malignant cells and to eliminate host immune cells capable of rejecting donor cells. The ability to restore hematopoiesis with donor hematopoietic stem cells permits administration of substantially higher (myeloablative) doses of cytotoxic therapy than is otherwise possible. Although originally regarded primarily as a way of rescuing patients from therapy-induced marrow aplasia, it now is accepted that graft-versus-tumor effects conferred by alloreactive donor cells contribute substantially to cancer eradication.

PATIENT POPULATION

Accompanying the growth of HCT has been a coordinated international effort to collect and analyze data on transplant outcomes through the International Bone Marrow Transplant Registry (IBMTR), which was established in 1972. The IBMTR affiliated with the United States (U.S.) National Marrow Donor Program (NMDP) in 2004 to become the Center for International Blood and Marrow Transplant Research (CIBMTR). CIBMTR currently collects data on HCT outcomes from more than 400 transplant centers worldwide and received information on more than 7000 allogeneic HCTs in 2006. These data show that hematologic malignancies (and premalignant conditions) are the most common indications for allogeneic HCTs (Fig. 101–1). In 2006, AML accounted for 33% of allogeneic HCTs, ALL 16%, CML 6%, other leukemias and preleukemias 18%, Hodgkin lymphoma and non-Hodgkin lymphoma (NHL) 12%, and multiple myeloma 3%. Use of allogeneic HCT for hematologic malignancies in the 1980s and early 1990s was largely restricted to young patients ≤45 years with an HLA-identical sibling donor. Less intensive conditioning regimens and improved GVHD prophylaxis and supportive care have increased use of allogeneic HCT in older patients. Only 4% of allogeneic HCT recipients in 1987 to 1992 were older than 50 years. In 2006, 33% were older than 50 years and 11% were older than 60 years. Application of HCT in patients without HLA-identical siblings was facilitated by establishment of large unrelated donor registries. In 1987 to 1992, less than 10% of HCTs for hematologic malignancies used unrelated donors; in 2006, this figure was greater than 40%.

CONDITIONING REGIMENS

The purpose of the preparative or conditioning regimen is to eradicate malignant cells and to suppress host immune competent cells. Historically, these regimens included myeloablative doses of cytotoxic drugs with or without radiation. Myeloablative regimens used for hematologic malignancies often involve a combination of cyclophosphamide (commonly 60 mg/kg/day for 2 days) and total body irradiation (TBI; 8–15 Gy, single or fractionated doses).[3] Many regimens use busulfan (typically 4 mg/kg/day for 4 days if given orally or 3.2 mg/kg/day if given intravenously) in place of TBI in combination with cyclophosphamide (most commonly 60 mg/kg/day for 2 days). Reported posttransplant survival rates with cyclophosphamide and TBI and with cyclophosphamide and busulfan are similar, although some data suggest advantages for TBI-containing regimens in ALL.[10–12] Other drugs have been added to or substituted for cyclophosphamide and/or busulfan, including etoposide, melphalan, and cytarabine, in a variety of regimens to provide better, generally disease-specific, antineoplastic activity.[13–23] Large trials comparing efficacy of these regimens are lacking. A CIBMTR study suggested better outcomes for patients with ALL in CR2 with either higher doses of TBI or substitution of cyclophosphamide by etoposide in a standard-dose TBI regimen.[24] Table 101–1 lists the most commonly used myeloablative conditioning strategies by disease. Table 101–2 lists doses and schedules for the most frequently used myeloablative conditioning regimens.

High-dose conditioning regimens are associated with significant risks of regimen-related toxicity. An important strategy for decreasing early regimen-related morbidity and mortality is reduced-intensity conditioning. This approach uses immunosuppressive but submyeloablative doses of drugs and radiation to allow donor cell engraftment. It relies primarily upon immune-mediated effects of donor cells to eradicate malignancy (see Chapter 106). Reduced-intensity regimens are designed to cause less host tissue damage and less inflammatory cytokine secretion, with the intent of lowering the risk of transplant-related mortality (TRM) and, possibly, severe GVHD.[25,26] The intensity of these regimens varies considerably, ranging from low (200 cGy) doses of TBI that do not induce cytopenia to combinations of fludarabine, busulfan, and/or melphalan that induce significant (although reversible) cytopenia.[27–33] A list of common reduced-intensity regimens, grouped in general order of intensity, is given in Table 101–3.

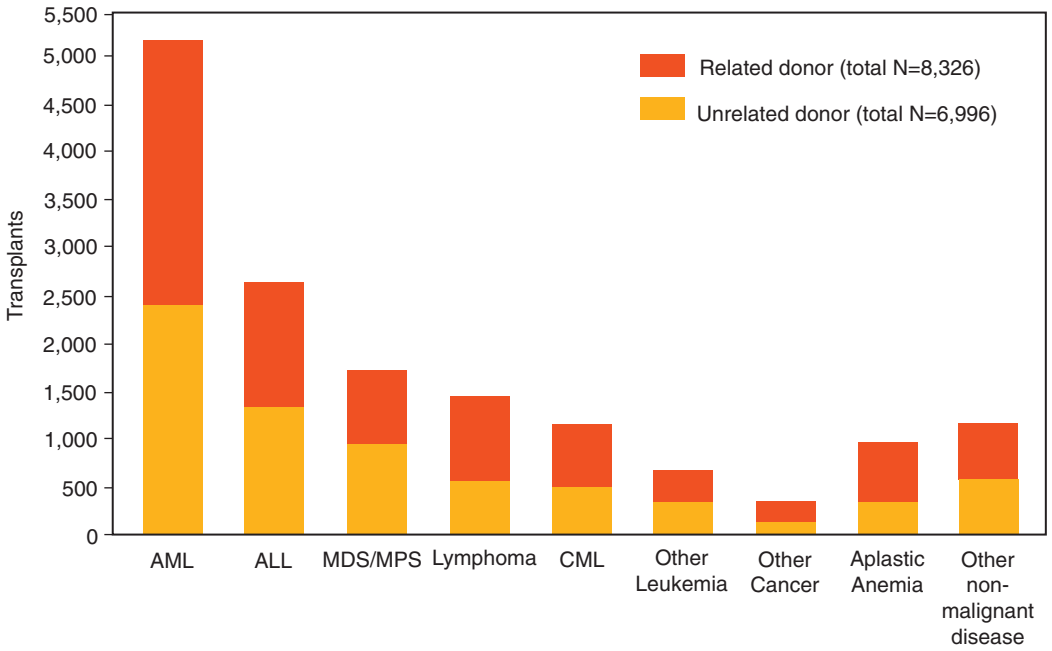

Figure 101–1 Indications for allogeneic hematopoietic cell transplants by donor type and disease status from 2005–2006.

Table 101–1 Common Myeloablative Conditioning Regimens by Disease

Disease	Regimens Used in Order of Frequency Reported to Center for International Blood and Marrow Transplant Research
Acute myelogenous leukemia	Busulfan + cyclophosphamide TBI + cyclophosphamide Other TBI combinations Other busulfan combinations
Acute lymphoblastic leukemia	TBI + cyclophosphamide Busulfan + cyclophosphamide TBI + other agents (not cyclophosphamide) TBI + cyclophosphamide + other agents
Chronic myelogenous leukemia	TBI + cyclophosphamide Busulfan + cyclophosphamide TBI + other agents
Non-Hodgkin lymphoma	TBI + cyclophosphamide Busulfan + cyclophosphamide

For chronic lymphocytic leukemia and multiple myeloma, the majority of allogeneic transplants currently are performed after reduced-intensity conditioning protocols.
See Table 101–2 for details of the regimens used.
TBI, total body irradiation.

Reduced-intensity regimens have less antitumor activity than conventional myeloablative regimens. However, they also induce less immune compromise as the duration and depth of neutropenia are reduced and host-derived immunocompetent cells are not immediately eliminated. They also may facilitate faster recovery of a T-cell repertoire that is more complex and robust than the early T-cell repertoire of patients receiving myeloablative regimens.

Less peritransplant immune compromise, neutropenia, and organ toxicity make reduced-intensity regimens attractive for use in patients not eligible for conventional high-dose regimens because of advanced age or comorbidities.[31,34,35] Whether these benefits outweigh the risks of reduced antitumor effects in patients eligible for traditional conditioning regimens remains an important research question. However, reduced-intensity regimens are increasingly used in patients of all ages receiving both related and unrelated donor transplants, as is shown in Fig. 101–2 depicting data from the CIBMTR.[36–38]

GRAFT SOURCES

Historically, hematopoietic cells for transplantation were collected directly from the marrow, and marrow is still the graft source used for many allotransplants. Collection of hematopoietic cells from peripheral blood by leukapheresis after administration of hematopoietic growth factors was introduced in 1981.[39] Use of umbilical cord blood as a source of hematopoietic stem cells was introduced in 1988.[40] Grafts from marrow, peripheral blood, and cord blood differ in the total numbers of cells available, the proportion of pluripotent stem cells to lineage-committed late progenitor cells, and the characteristics of immune reactive cells.[41] Marrow is the primary source (approximately 55% of transplants) of allogeneic donor cells for transplantation in children; peripheral blood is the main source (80% of transplants) in adults. Among patients receiving grafts from unrelated donors, umbilical cord blood is used for 40% of transplants in children (younger than 20 years) and 5% of transplants in adults.

The CIBMTR, in collaboration with the European Group for Blood and Marrow Transplantation (EBMT), examined long-term outcomes after peripheral blood and marrow transplantation in adults with acute and chronic leukemia. The first report,[42] with a median followup of 1 year, showed higher chronic GVHD rates in patients receiving peripheral blood grafts. Among patients transplanted for advanced leukemia, those receiving peripheral blood grafts had lower TRM and higher LFS rates. Long-term followup data (median followup >6 years) were obtained for the patients who were alive at the time of the initial report.[43] Consistent with the initial report, chronic GVHD was more frequent after peripheral blood transplantation than after bone marrow transplantation; relapse rates were similar in the two groups. An LFS advantage for peripheral blood was seen in patients receiving HCT for advanced CML (33% vs 25%) but a disadvantage in those with CML in first chronic phase (41% vs 61%). Long-term LFS was similar with peripheral blood and bone marrow transplants in patients with acute leukemia. The Stem Cell Trialists collaborative group conducted a meta-analysis using data from nine randomized trials of related donor peripheral blood versus bone marrow transplants enrolling 1111 adult patients.[44] Patients receiving

Table 101–2 Commonly Used Myeloablative Conditioning Regimens for Hematologic Malignancies

Drugs and Total Doses	Schedule (days)	Comments and References
Classic Regimens		
"Cy/TBI"		Used in myeloid and lymphoid malignancies
Cyclophosphamide 120 mg/kg	-6, -5	Extensive experience over 30 years[309,310]
TBI 12–14.4 Gy	-3, -2, -1	
"BU/Cy"		Developed as an alternative nonradiation regimen
Busulfan 16 mg/kg PO	-9, -8, -7, -6 q6h	Used primarily for myeloid malignancies[10]
Cyclophosphamide 200 mg/kg	-5, -4, -3, -2	
"BU/Cy-2"		Derived from Bu/Cy above
Busulfan 16 mg/kg PO	-7, -6, -5, -4 q6h	Most common current nonradiation regimen used for wide variety of myeloid and lymphoid malignancies[11]
Cyclophosphamide 120 mg/kg	-3, -2	
Other Standard Regimens		
"TBI/VP"		Alternative to Cy/TBI
Etoposide 60 mg/kg	-3	Randomized study showed no differences in advanced leukemia outcomes[311,312]
TBI 12–13.2 Gy	-7, -6, -5, -4	
"Ara-C/TBI"		Used for myeloid and lymphoid leukemias[18]
Ara-C 36 g/m^2	-9, -8, -7, -6, -5, -4	
TBI 12 Gy	-3, -2, -1	
"Bu/MEL"		Active in a wide variety of myeloid and lymphoid malignancies as well as myeloma[17,21]
Busulfan 16 mg/kg PO	-5, -4, -3, -2	
Melphalan 140 mg/m^2	-1	
"Thiotepa/Cy"		Active against advanced leukemia and hematologic malignancies[14]
Thiotepa 15 mg/kg	-7, -6	Thiotepa has also been combined with busulfan
Cyclophosphamide 120–150 mg/kg	-4, -3, -2	
Intensified Regimens With Additional Agents Added to the Standard		
"Cy/TBI/VP"		Primarily used in acute leukemia to improve therapeutic efficacy of Cy/TBI but no randomized comparisons[15]
Cyclophosphamide 120 mg/kg	-6, -5	
Etoposide 30–60 mg/kg	-4	
TBI 12–13.75 Gy	-3, -2, -1	
"TBI/Thiotepa/Cy/ATG"		Used in acute leukemias in an attempt to increase conditioning intensity
TBI 13.75 Gy	-9, -8, -7, -6	Current multicenter acute myelogenous leukemia trial explores this regimen with T-cell–depleted grafts[23]
Thiotepa 10 mg/kg	-5, -4	
Cyclophosphamide 120 mg/kg	-3, -2	
± ATG (dose depends on type used)	-5, -4, -3, -2	
"BU/Cy/VP"		Used in advanced hematologic malignancy[22]
Busulfan 16 mg/kg PO	-7, -6, -5, -4 q6h	
Cyclophosphamide 120 mg/kg	-3, -2	
Etoposide 60 mg/kg	-3	
"Cy/TBI/Ara-C"		Intensified combination used in advanced leukemia and with T-cell–depleted grafts[16,19]
Ara-C 18–36 g/m^2	-14, -13, -12, -11, -10, -9	
TBI 12–14 Gy	-7, -6, -5, -4, -3	
Cyclophosphamide 60–90 mg/kg	-2	
"Bu/Cy/Ara-C" (BAC)		Primarily used in high-risk myeloid malignancies for dose intensity[13]
Busulfan 16 mg/kg PO	-7, -6, -5, -4 q6h	
Cyclophosphamide 120 mg/kg	-3, -2	
Ara-C 8 g/m^2	-5, -4	
"CBV"		Used in non-Hodgkin lymphoma, chronic lymphocytic leukemia[20]
Cyclophosphamide 6 g/m^2	-6, -5, -4, -3	
BCNU 450 mg/m^2	-6, -5, -4, -3	
Etoposide 1600 mg/m^2	-6, -5, -4, -3	

Ara-C, cytosine arabinoside; ATG, antithymocyte globulin; BCNU, carmustine; BU, busulfan; Cy, cyclophosphamide; Gy, Gray; MEL, melphalan; TBI, total body irradiation; VP, etoposide.

peripheral blood grafts had faster neutrophil and platelet engraftment, a lower relapse rate if transplanted for hematologic malignancy, and higher overall and disease-free survival if transplanted for late-stage disease. However, peripheral blood was associated with a significantly increased risk of extensive chronic GVHD and conferred no survival advantage for patients with early-stage disease. In the unrelated donor setting, a CIBMTR analysis of 917 transplants facilitated by the NMDP suggests that survival is similar with bone marrow and peripheral blood grafts but that chronic GVHD is more frequent with peripheral blood.[45] A large randomized trial of unrelated bone marrow versus peripheral blood HCT for hematologic malignancies is being conducted by the United States Blood and Marrow Transplant Clinical Trials Network (BMT CTN).

One important obstacle to allografting is identifying a donor for the 70% of patients without an HLA-identical sibling (see Chapter 103). Despite increasing numbers of volunteer HLA typed donors available through national and international donor registries, many patients, especially non-Caucasian patients, do not find suitable donors.[46,47] Also, the unrelated donor search process can be time consuming, raising the risk of disease progression before transplanta-

Table 101–3 Commonly Used Reduced-Intensity Conditioning Regimens

Regimen	Disease(s)	Donor	Graft-versus-Host Disease Prophylaxis	Comments	References
Low-Dose TBI Based					
TBI 2 Gy	Hematologic malignancies	MRD	CsA/FK + MMF	Widely used in HLA-identical sibling transplants More immunosuppressive than myeloablative	90, 228
TBI 2 Gy ± Flu 90 mg/m^2	Hematologic malignancies	MUD, MRD	CsA/FK + MMF	Widely used More immunosuppressive than myeloablative	30, 32
TBI 4–5.5 Gy ± Cy 80–120 mg/kg	Hematologic malignancies	MUD	CsA ± MMF ± MTX ± steroid	Used in advanced malignancies with unrelated donor HCT TRM 19% in good-risk patients and 42% in poor-risk patients at 2 years	313
TBI 8 Gy + Flu 120 mg/m^2 ± ATG	AML	MUD, MRD	CsA ± MTX	Increasing myeloablation and immunosuppression Used in AML with TRM 8% in good-risk patients	314
TBI 8 Gy + Cy 80–120 mg/kg + Flu 120 mg/m^2 ± ATG	CML	MUD, MRD	CsA + MTX	Reported in early-phase CML in elderly patients, with TRM 29% at 1 year	315
Thymic radiation + Cy 150–200 mg/kg + ATG	Hematologic malignancies	MRD	CsA	33% disease-free survival at 1 year in refractory hematologic malignancies	316
Fludarabine and Cyclophosphamide Based					
Flu 90–125 mg/m^2 + Cy 2–3.6 g/m^2	NHL, HL, AML, CML	MUD, MRD	FK/CsA ± MMF/rapamycin ± MTX	Reduced-intensity regimen with more chemotherapy-related toxicity TRM 0%–30% at 1 year	317–319
Flu 90–125 mg/m^2 + Cy 2–2.5 g/m^2 + rituximab ± ATG	NHL, indolent lymphoma	MUD, MRD	FK + MTX	Popular reduced-intensity regimen for NHL CD20-expressing NHL	28, 268
Busulfan (IV or PO) Based					
Flu 120–150 mg/kg + BU 3.2–10 mg/kg	AML, MDS, hematologic malignancies	MUD, MRD	CsA/FK + MTX	Increasingly used combination for myeloid malignancies Busulfan IV equivalent used commonly	320
Flu 120–180 mg/kg + BU 8 (PO) or 6.4 (IV) mg/kg ± ATG	AML, MDS	MUD, MRD	CsA ± MMF + MTX	TRM 3%–8% at 2 years Busulfan IV also dosed at 130 mg/m^2/day × 4 Primarily used in AML and MDS	27, 33, 321
Flu 150–180 mg/kg + BU 8 mg/kg + Campath	AML, MDS, hematologic malignancies	MUD, MRD	CsA ± MTX	TRM 12.5%–33% at 1 year	322, 323
Flu 200 mg/kg + BU 8 (PO) mg/kg + TBI	AML, MDS	MUD, MRD	CsA + MMF	Increasing myeloablation TRM 25% at 1 year	324
Flu 125–240 mg/kg + BU 6.6–12 mg/kg ± Ara-C	CML including advanced phase	MUD, MRD	CsA ± MMF ± MTX	Least immunosuppressive and most ablative 41% disease-free at 562 days	325
Melphalan Based					
Flu 90–180 mg/m^2 + MEL 70–180 mg/m^2 ± ATG	Hematologic malignancies	MRD, MUD	CsA/FK + MTX	TRM 18%–26% at 1 year Significant myeloablation from MEL	29, 282, 326
Flu 150 mg/m^2 + MEL 140 mg/m^2 ± Campath	Hematologic malignancies	MUD, MRD	CsA/FK + MTX	TRM 11%–38% at 1 year Used in lymphoid and myeloid malignancies	327, 328
Cladribine 60 mg/m^2 + MEL 140–180 mg/m^2	Hematologic malignancies	MUD, MRD	FK + MTX	Excessive toxicity reported and used only in clinical trials	329

AML, acute myelogenous leukemia; Ara-C, cytosine arabinoside; ATG, antithymocyte globulin; BU, busulfan; CML, chronic myelogenous leukemia; CsA, cyclosporine; Cy, cyclophosphamide; FK, tacrolimus; Flu, fludarabine; Gy, Gray; HCT, hematopoietic cell transplantation; HLA, human leukocyte antigen; MEL, melphalan; MMF, mycophenolate; MRD, matched related donor; MTX, methotrexate; MUD, matched unrelated donor; NHL, non-Hodgkin lymphoma; TBI, total body irradiation; TRM, transplant-related mortality. HL, Hodgkin lymphoma; MDS, myelodysplastic syndrome.

tion can be performed.[48] Umbilical cord blood offers several advantages as a source of hematopoietic stem cells for unrelated donor transplantation (see Chapter 105). It is readily available and entails little or no risk to the donor. Current data also indicate that HLA-matching criteria for cord blood transplantation need not be as stringent as for adult donor transplantation, greatly increasing the likelihood of finding a suitably matched graft for most patients.[49,50] The major drawback of cord blood transplants is the limited number of cells in each cord blood unit leading to slow rates of hematopoietic recovery relative to bone marrow or peripheral blood transplants. Numbers of cord blood transplants have increased steadily over the past decade (Fig. 101–3). Few controlled comparisons of cord blood and marrow grafts in hematologic malignancies and no randomized trials are available. A CIBMTR analysis compared HLA-matched (at the allele level for A, B, C, and DR) marrow transplants with matched and mismatched (intermediate resolution for A and B, allele level for DR) cord blood transplants in children with leukemia.[51] The highest survival was seen in children receiving HLA-matched cord blood, although this group was small. No difference in outcome between HLA-matched marrow and 5/6 HLA-locus matched cord blood

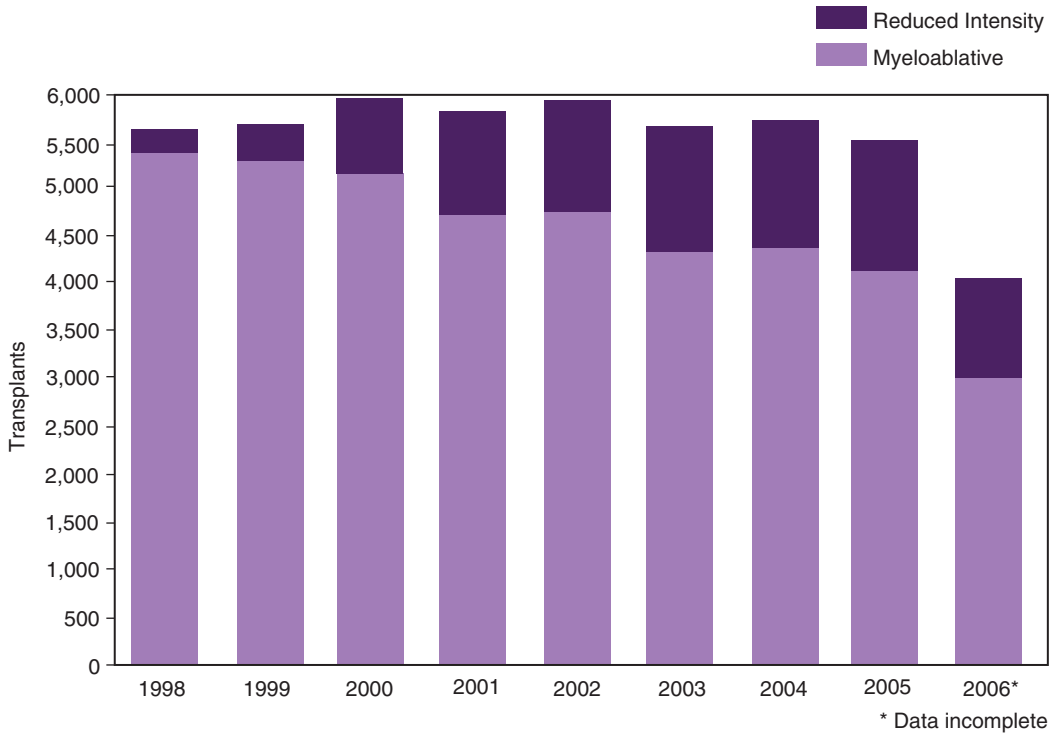

Figure 101–2 Proportion of myeloablative and reduce-intensity constitioning regimens a year.

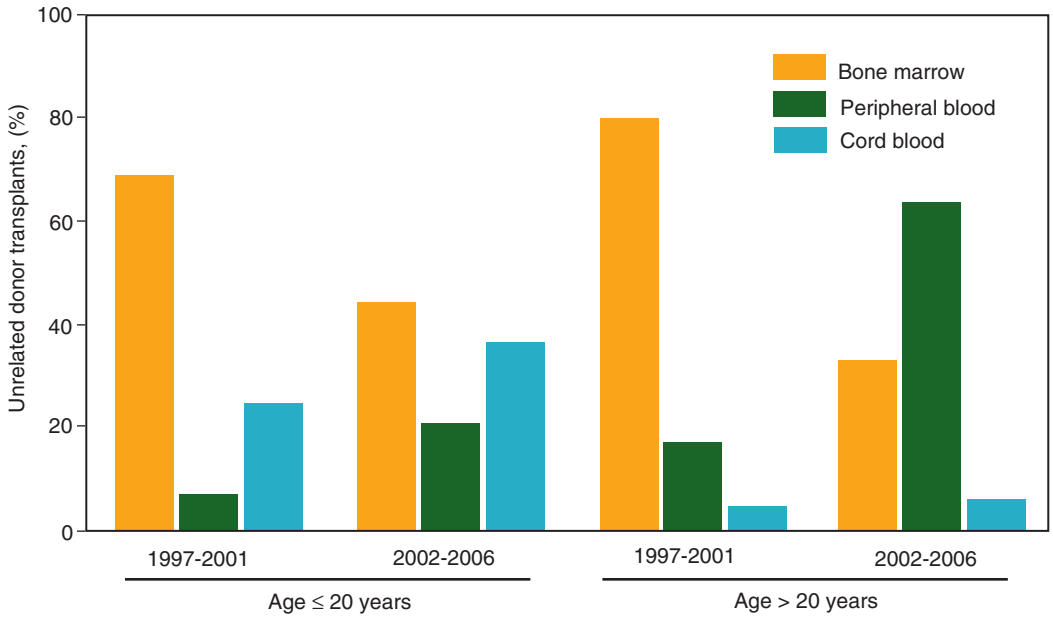

Figure 101–3 Allogeneic stem cell sources by donor type versus recipient age from 1997–2006.

transplants was observed, provided the cord blood cell dose was greater than 3×10^7 kg. Several studies have compared bone marrow transplants and cord blood transplants in adults.[52–56] Results are mixed; some show similar survival between HLA-mismatched cord blood units and HLA-matched bone marrow and some show an advantage for HLA-matched marrow. The data consistently show slower hematopoietic recovery but less GVHD with cord blood grafts. Results from all studies indicate that a one or two HLA-antigen mismatched cord blood transplant may be an acceptable alternative for patients with hematologic malignancies who need HCT but do not have an HLA-identical adult donor, assuming a unit of adequate cell dose can be identified. Studies developing approaches to facilitate engraftment with limited cord blood cell doses, including use of multiple units and cell expansion techniques, are in progress.

GRAFT-VERSUS-MALIGNANCY EFFECTS

Substantial laboratory and clinical evidence indicate that alloreactive cells exhibit potent anticancer activity (see Chapter 107). Barnes et al.[57] studied leukemic mice treated with high-dose TBI and com-

pared those receiving syngeneic and allogeneic bone marrow infusions. Mice receiving syngeneic marrow died quickly of leukemia, whereas those receiving allogeneic cells survived longer but eventually developed fatal GVHD. Importantly, the allografted mice had no evidence of leukemia at death. Several canine and murine experiments have reproduced these results.[58–60] Mathé et al.[61] proposed the term *adoptive immunotherapy* for the antitumor effect of allogeneic cells. Antitumor effects could be specific, that is, after sensitization of the donor or the donor's cells to antigens present on malignant cells, or nonspecific, that is, associated with GVHD, an immune reaction of donor lymphocytes against normal and malignant host cells presumably triggered by differences in histocompatibility antigens.[62–65] Bortin et al.[58,66] coined the term *graft versus leukemia* (GVL) to indicate the adoptive immunotherapeutic effect of transplanted allogeneic hematopoietic cells against leukemia cells. In some animal models, the GVL effect could not be distinguished from GVHD, whereas in others the two were separable.[58,59,67–70] Clinical evidence for the importance of GVL in eradicating tumor includes the following: (a) lower incidence of leukemia relapse in allograft recipients with acute and/or chronic GVHD than in those without GVHD[60,63–65,71–75]; (b) higher relapse rates after identical twin versus allogeneic HCT[65,76,77]; (c) high relapse rates after T-cell–depleted transplants[65,78–82]; (d) durable cytogenetic and molecular remissions induced after posttransplant relapse by infusion of donor leukocytes without other antileukemia therapy[83–89]; and (e) durable remissions achieved after very low doses of conditioning agents (e.g., 200-cGy TBI) and allogeneic HCT.[90,91] Graft–versus-tumor effects are associated with GVHD, and measures that prevent or suppress GVHD may allow more relapse, but significant anticancer effects are demonstrable even in the absence of clinically significant GVHD, especially in AML and CML.[92,93] The efficacy of immune-mediated antitumor effects vary by disease but are most evident in myeloid leukemias and some subtypes of lymphoma.[87,89,94–102]

PROGNOSTIC FACTORS

Although allogeneic HCT has efficacy in hematologic malignancies, the procedure itself carries a substantial risk of morbidity and mortality. TRM may result from toxicity of the pretransplant conditioning regimen to lung, liver, and other organs, bleeding related to cytopenias, GVHD, and infection related to delayed immune reconstitution, especially in the setting of GVHD or its treatment. Additionally, many patients have recurrence of malignancy despite intensive conditioning and GVL. Primary causes of death after allogeneic transplantation for hematologic malignancy are shown in Fig. 101–4. The prognosis of transplant recipients is influenced by several factors associated with risk of TRM and/or cancer recurrence or progression. Many of factors these are disease specific and discussed in later sections of this chapter.

Donor Factors: TRM rates are lower after HLA-identical sibling than after other related or unrelated donor transplants because of less graft failure, faster immune reconstitution, and less GVHD.[103–111] Among alternative donor transplants, those from more closely HLA-matched donors tend to have lower risks of GVHD and TRM.[105,108–111] Donor-recipient HLA mismatching is associated with increased risk of posttransplant complications, including graft rejection, acute and chronic GVHD, and mortality. Risks increase progressively with multiple HLA mismatches (see Chapter 103). With modern molecular HLA typing techniques (which allow selection of more closely HLA-matched donors) and current GVHD prevention strategies, the difference in TRM between HLA-matched sibling and unrelated donor transplantation has narrowed.[112] Using data reported to the CIBMTR for 2005 to 2006, day 100 TRM rates for patients with acute leukemia receiving allografts from HLA-identical sibling donors were 5%, 7%, and 9% for patients transplanted in first complete remission (CR1), CR2 or subsequent CR, or not in CR, respectively. Corresponding rates after unrelated donor transplantation were 8%, 10%, and 12%.

Timing of Transplantation: In general, HCT outcomes are better when transplantation is performed earlier in the course of a malignancy (see box on Timing of Hematopoietic Stem Cell Transplantation and Transplant Referral). Transplantation for advanced disease is associated with higher risks of both relapse and TRM. High TRM in the setting of advanced disease likely reflects the poorer clinical status and more extensive prior treatment of these patients. Because some hematologic malignancies have excellent prognosis with nontransplant therapy (e.g., children with standard-risk ALL or adults with acute promyelocytic leukemia), appropriate timing of transplantation requires consideration of likely outcomes with transplant and nontransplant therapies. However, even when not used as first-line therapy, transplants should not be inordinately delayed because patients with refractory disease or severe complications from extensive prior therapy are unlikely to benefit. For patients with diseases potentially curable by allografting, appropriate timing of transplantation should be considered early in planning management strategies. This includes determining the availability of suitable related or unrelated donors.[113] The American Society for Blood and Marrow Transplantation (ASBMT) and the NMDP have developed joint guidelines based upon current clinical practice and literature review, including evidence-based reviews (see box on NMDP-ASBMT Guidelines for Transplant Consultation).[114]

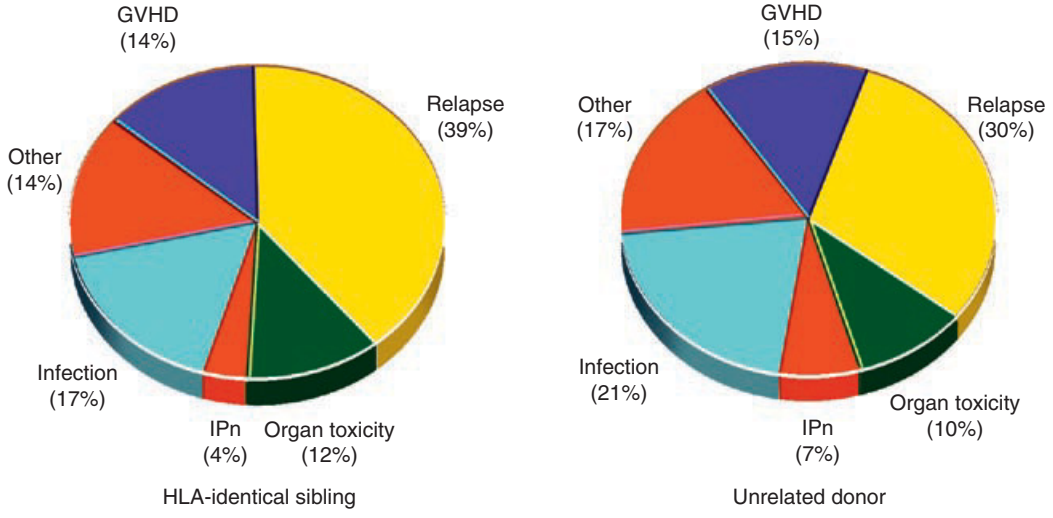

Figure 101–4 Causes of death after transplants performed in 1998–2004.

Timing of Hematopoietic Cell Transplantation and Transplant Referral

General Principles

- HCT outcomes are better when performed earlier in the course of hematologic malignancies.
- HCT for advanced disease is associated with higher TRM and relapse.
