- Appropriate timing of HCT requires consideration of likely outcomes with nontransplant and transplant therapies.
- Even when not considered as front-line therapy, inordinate delay in HCT is to be avoided.
- For patients who are potentially curable by allogeneic HCT, consideration of HCT should be addressed early in the treatment plan. This includes HLA typing and identification of suitable donors.

NMDP-ASBMT Guidelines for Transplant Consultation

Adult Acute Myelogenous Leukemia

High-risk acute myelogenous leukemia, including

- Antecedent hematologic disease (e.g., myelodysplasia)
- Treatment-related leukemia
- Induction failure
  - CR1 with poor-risk cytogenetics (see text for details)
  - CR2 and beyond

Adult Acute Lymphoblastic Leukemia

High-risk acute lymphoblastic leukemia, including

- Poor-risk cytogenetics (see text for details)
- High white blood cell count (>30,000–50,000) at diagnosis
- Central nervous system or testicular leukemia
- No CR within 4 weeks of initial treatment
- Induction failure
  - Second complete remission or beyond

Non-Hodgkin Lymphoma

Follicular lymphoma

- Poor response to initial therapy
- Initial remission duration <12 months
- Second relapse
- Transformation to diffuse large B-cell lymphoma
  - Diffuse large B-cell lymphoma
- First or subsequent relapse
- CR1 for patients with high or high–intermediate IPI
- No CR with initial treatment
  - Mantle cell lymphoma
- Following initial therapy

Hodgkin Lymphoma

No initial CR
- First or subsequent relapse

Multiple Myeloma

After initiation of therapy
- At first progression

Chronic Myeloid Leukemia (European LeukemiaNet Guidelines)[211]

Imatinib as first-line therapy in all cases

Allogeneic HCT to be considered in the following scenarios:
- For patients in early chronic phase
- Intolerance/excess toxicity from imatinib
- Failure on imatinib *or* "warning features" at presentation (defined in Baccarani et al.[211])
- Accelerated phase or early blast crisis
- Initial imatinib therapy followed by HCT

Available online at http://www.asbmt.org/policystat/policy.htm.

Patient- and Disease-Related Factors: TRM is lower and, consequently, survival is higher in patients who are young, are cytomegalovirus negative, and have good performance scores and no active infection.[115–117] Age poses a significant barrier to application of allogeneic HCT, as older patients are at significantly higher risk for regimen-related toxicity and GVHD. Consequently, the median age of transplant recipients is substantially lower than the median age at diagnosis of the diseases for which transplantation is performed (Table 101–4). In most settings, factors associated with increased likelihood of relapse or progression after conventional therapy also predict increased risk of posttransplant relapse or progression. Importantly, patients whose disease does not respond to conventional therapy are significantly less likely to have durable remissions after transplantation than those with responsive disease. However, HCT may cure a significant proportion of patients with diseases considered incurable with nontransplant therapy.

ACUTE MYELOID LEUKEMIA

The incidence of AML increases with age, varying from 12 per million in persons 20 to 44 years old to 150 per million in persons older than 65 years.[118] Median age at diagnosis is 67 years, with only approximately 33% of patients younger than 55 years at diagnosis and 15% between the ages of 55 and 65 years.[119] Although 50% to 75% of adults with AML achieve CR, only 20% to 30% achieve long-term LFS with conventional chemotherapy approaches.[120,121] The curative potential of allogeneic HCT in AML is well established, and AML currently is the most common indication for allogeneic HCT, accounting for approximately one third of allografts in 2006. However, variation is considerable among countries and physicians with regard to the timing of and the strategy for applying HCT, that is, consolidation versus salvage therapy.[122–125] In the United States, approximately 25% of AML patients younger than 70 years undergo an allogeneic HCT. Median age at transplantation is 45 years; 75% of HCT recipients are younger than 55 years.

Approximately 2400 allogeneic transplantations for AML were registered with the CIBMTR in 2006; approximately 40% were from unrelated donors.[126] Sixty percent of HLA-identical sibling transplants were performed as consolidation therapy in patients in CR1, 15% in CR2 or subsequent CR, and 25% in patients with active disease (induction failure or relapse). Thirty percent of unrelated donor transplants were done in CR1, 30% in CR2 or subsequent CR, and 37% in patients with active disease. Myeloablative conditioning regimens were used for 75% of transplants in patients younger than 55 years and in 60% of transplants in patients older than 55 years; the remainder received a variety of reduced-intensity regimens.

Major predictors of HCT outcome in AML are remission state at the time of transplantation, donor type, and age. The CIBMTR has data on approximately 10,000 recipients of allogeneic HCT for AML performed between 1998 and 2004. Among 6092 patients receiving transplants from HLA-identical siblings, 5-year probabilities of relapse, LFS, and overall survival were 34%, 44%, and 47%, respectively. Patients in CR1 have the best posttransplant outcomes; those with more advanced disease have higher risks of both relapse and TRM. Among adults who received HLA-identical sibling transplants following myeloablative conditioning between 1998 and 2004, 5-year probabilities of survival were 55% for 2369 patients transplanted in CR1, 42% for 611 patients transplanted in CR2 or subsequent CR, and 21% for 1,113 patients transplanted with active disease (Fig. 101–5A). Among children (younger than 20 years), 5-year probabilities of survival were 59% for 804 children transplanted in CR1, 56% for 174 transplanted in CR2 or subsequent CR, and 25% for 165 transplanted with active disease (Fig. 101–5B). Nine hundred sixteen

Table 101–4 Impact of Age at Diagnosis on Allogeneic Hematopoietic Stem Cell Transplantation

Disease	Proportion of Patients Aged >65 Years at Diagnosis	Matched Sibling HCT Recipients Aged >65 Years	Unrelated Donor HCT Recipients Aged >65 Years
Acute myelogenous leukemia	23%	2%	1%
Acute lymphoblastic leukemia	2%	<1%	<1%
Chronic myeloid leukemia	35%	<1%	<1%
Chronic lymphocytic leukemia	71%	3%	0%
Non-Hodgkin lymphoma	50%	1%	1%
Hodgkin lymphoma	10%	0%	2%
Multiple myeloma	60%	1%	0%

Bethesda, MD. http://seer.cancer.gov/csr/1975_2003/, based on November 2005 SEER data submission, posted to the SEER web site, 2006. Accessed August 1, 2007; and CIBMTR database.

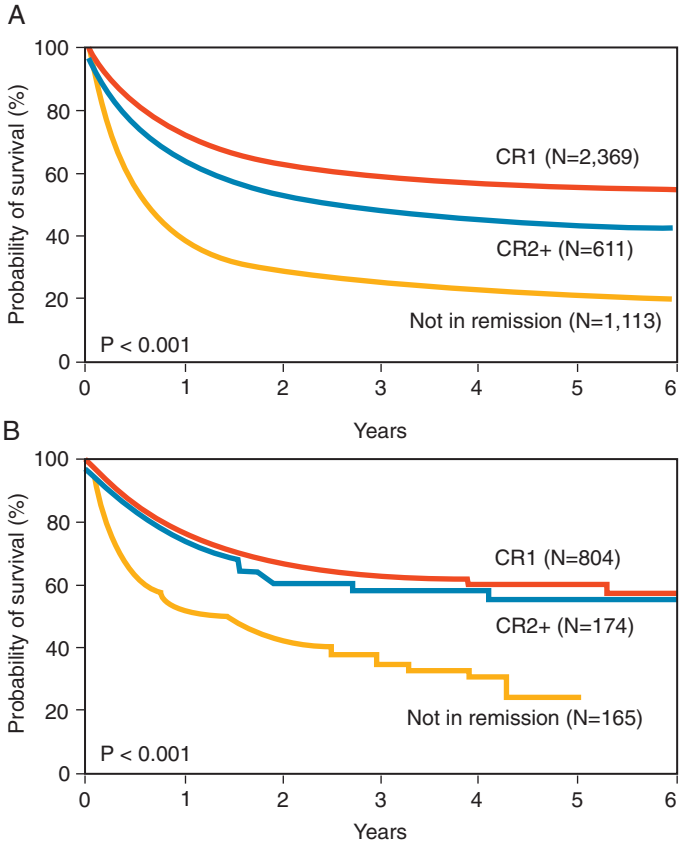

Figure 101–5 Probability of survival after human leukocyte antigen (HLA)-identical sibling transplants with myeloablative conditioning for acute myelogenous leukemia (AML), age ≥ 20 years, 1998–2004, by disease status. **B**, Probability of survival after HLA-identical sibling transplants with myeloablative conditioning for AML, age <20 years, 1998–2004, by disease status.

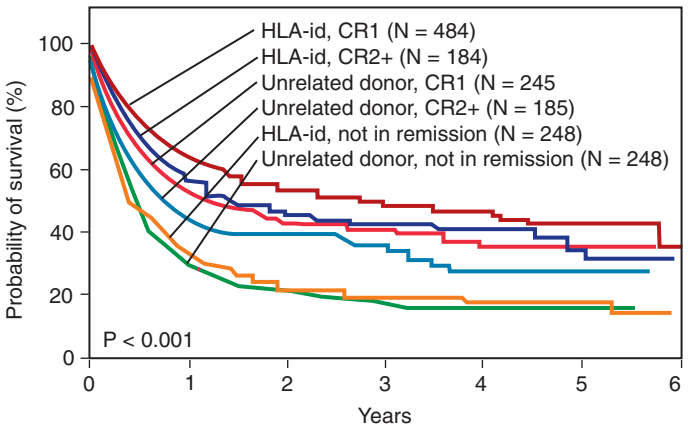

Figure 101–6 Probability of survival after allogeneic transplants with reduced-intensity conditioning for acute myelogenous leukemia, age ≥ 20 years, 1998–2004, by donor type and disease status.

transplants for AML reported to the CIBMTR in 1998 to 2004 used reduced-intensity conditioning. These patients were older and more likely to have significant comorbidities than patients receiving myeloablative regimens. Among adults receiving HLA-identical sibling transplants with reduced-intensity conditioning, 5-year probabilities of survival were 42% for 484 patients transplanted in CR1, 35% for 184 patients transplanted in CR2 or subsequent CR, and 17% for 248 patients transplanted in relapse (Fig. 101–6).

Unrelated donor transplantation is associated with higher TRM but somewhat lower relapse rates than HLA-identical sibling transplantation. Among 4097 recipients of unrelated donor transplants reported to the CIBMTR between 1998 and 2004, 5-year probabilities of relapse, LFS, and overall survival were 34%, 29%, and 30%, respectively. Among adults receiving unrelated donor transplants following myeloablative conditioning, 5-year probabilities of survival were 41% for 833 patients transplanted in CR1, 36% for 733 transplanted in CR2 or subsequent CR, and 16% for 1015 transplanted with active disease (Fig. 101–7A). Among children (younger than 20 years), 5-year probabilities of survival were 38% for 345 children transplanted in CR1, 47% for 427 transplanted in CR2 or subsequent CR, and 21% for 293 transplanted with active disease (Fig. 101–7B). Reduced-intensity conditioning is also used for unrelated donor HCT for AML, again more commonly in older patients with significant comorbidities. Among adults receiving unrelated donor HCT following reduced-intensity conditioning in 1998 to 2004, 5-year probabilities of survival were 35% in 245 patients transplanted in CR1, 27% in 185 transplanted in CR2 or subsequent CR, and 15% in 248 transplanted with active disease (see Fig. 101–6).

One of the most powerful prognostic indicators in conventional therapy of AML is the cytogenetic profile.[127–129] The commonly used Southwest Oncology Group (SWOG)/Eastern Cooperative Oncology Group (ECOG) classification[130] identifies three risk groups for cytogenetic abnormalities:

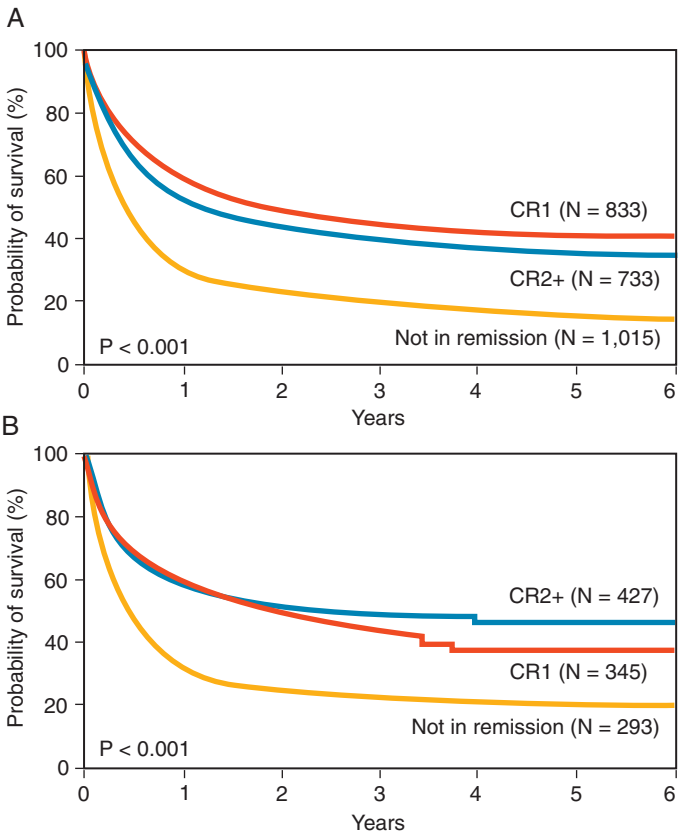

Figure 101–7 **A**, Probability of survival after unrelated donor transplants with myeloablative conditioning for acute myelogenous leukemia (AML), age ≥ 20 years, 1998–2004, by disease status. **B**, Probability of survival after unrelated donor transplants with myeloablative conditioning for AML, age <20 years, 1998–2004, by disease status.

- Favorable: inv[16]t(16;16)/del(16q) with or without other chromosome anomalies and t(8;21) without either del(9q) or as part of a complex karyotype
- Intermediate: +8, −Y, +6, del(12p) and normal karyotype
- Unfavorable: −5/del(5q), −7/del(7q), inv(3q)/t(3;3), abnormal 11q, 20q, or 21q, del(9q), t(6;9), t(9;22), abnormal 17p, and complex karyotype (>3anomalies)

Several new cytogenetic and molecular characteristics (FLT-3 mutations, NPM mutations, and c-kit mutations) are also associated with prognosis of AML treated with chemotherapy.[131]

Disease factors, such as cytogenetics, that predict prognosis with conventional chemotherapy may or may not affect HCT outcomes. Cytogenetics appears to be important in the HLA-matched related donor HCT setting.[127,132,133] An EBMT analysis of 500 recipients of sibling allografts for AML in CR1 showed that adverse cytogenetics had a strong impact on the risk of relapse and survival in multivariate analysis.[133] An earlier IBMTR study of 708 patients transplanted in CR1 from sibling donors also demonstrated similar increased risks of relapse and treatment failure for patients with poor prognosis cytogenetic abnormalities.[127] However, given the possibility of varying susceptibility of different cytogenetic risk groups to the immune effects of HCT, the current cytogenetic risk grouping schemes may not be ideal for patients undergoing HCT. A large single-center study suggested the utility of a novel transplant-specific risk classification scheme based on cytogenetics over other disease- or transplant-related factors.[134]

In contrast to these studies, among 560 patients receiving unrelated donor transplants for AML in CR1 or CR2 between 1988 and 2002, LFS rates were not significantly associated with cytogenetic profile.[135] Among 261 patients transplanted in CR1, 5-year LFS rates were 29%, 30%, and 27% for patients with favorable, intermediate, and unfavorable cytogenetics, respectively. Among 266 patients transplanted in CR2, corresponding 5-year LFS rates were 42%, 38%, and 37%. The outcome for patients with unfavorable cytogenetics is superior to that reported with conventional consolidation chemotherapy; these patients should be considered for allogeneic transplantation early in their treatment course.

Posttransplant Relapse

The optimal therapy for patients whose AML recurs after allogeneic HCT is not defined, and most therapies have limited utility. Although combination chemotherapy can induce remission in 30% to 40% of patients, the remissions usually are of short duration.[136,137] Some patients may be successfully treated with donor lymphocyte infusions (DLI), with or without prior chemotherapy, to induce a GVL effect, although DLI alone rarely results in long remissions.[87,88,99] Second allogeneic transplantation with myeloablative conditioning is associated with very high TRM, ranging from 40% to 50%.[138,139] Relapse rates are high, and the procedure is generally not considered useful unless the initial posttransplant remission is longer than 1 year. The role of second HCT with reduced-intensity conditioning is uncertain.

Timing of HCT for AML

Despite numerous studies, the question of whether allogeneic HCT is superior to consolidation chemotherapy or autologous transplantation for AML in CR1 is controversial. Five cooperative group trials have compared allogeneic BMT to other postremission therapies for AML in CR1.[140–144] Despite large numbers of enrolled patients, interpretation of results is difficult for several reasons: biologic rather than random assignment to the allogeneic transplant arm (based on availability of an HLA-matched donor), poor compliance with transplant assignment, absence of studies specifically designed to address the question in high-risk patients, ongoing redefinition of high-risk subgroups as new markers are discovered, and variation in analytical approaches.[145–148] There is general agreement that most patients younger than 55 years who do not respond to conventional therapy and who have good performance status are best treated with allogeneic transplantation if an appropriate related or unrelated donor is available.[149–152]

The National Comprehensive Cancer Network (NCCN) guidelines, widely used to guide cancer therapy in the United States, endorse allogeneic HCT with HLA-identical sibling or unrelated donors as consolidation therapy for patients with poor-risk cytogenetics, therapy-related AML, or AML with antecedent myelodysplasia.[149] However, the NCCN AML panel did not reach consensus on a single preferred postremission strategy for patients without poor-risk cytogenetics. A risk-based approach was recommended using factors such as patient age, comorbid conditions, features of the disease at diagnosis, and number of cycles of induction therapy needed to achieve remission to guide selection of chemotherapy versus transplant approaches. The long-term toxicities of allogeneic HCT were considered prohibitive for patients with good-risk cytogenetics; the panel recommended reserving this option for patients who relapsed after initial nontransplant treatment. Transplant-based options using either sibling or autologous stem cell sources were recommended for patients with intermediate-risk cytogenetics. The joint NMDP and ASBMT guidelines recommend a transplant evaluation for all patients with high-risk AML (defined as AML preceded by another hematologic disorder, treatment-related leukemia, and primary induction failure) and for patients in CR2 or beyond.[114]

ACUTE LYMPHOBLASTIC LEUKEMIA

The incidence of ALL is 1.5 per 100,000 persons. Median age at diagnosis is 13 years. Approximately 60% of patients are younger

than 20 years and 15% are older than 55 years at diagnosis.[119] More than 70% of children with ALL are cured with chemotherapy regimens. The outcome of adults with ALL has improved in recent years, with more than 75% achieving initial CR,[153–155] but long-term survival of adults is less than 40%.[156–163] Prognosis is influenced by patient and disease characteristics such as age, performance status, phenotype, and genotype. Allogeneic HCT for ALL is generally reserved for patients who do not respond to conventional therapy, that is, they relapse or are in CR2 or subsequent CR. It also is an option for patients in CR1 with factors predicting a high risk of failure.[155,164] In the United States, approximately 15% of ALL patients younger than 70 years receive an allogeneic HCT (CIBMTR, unpublished data).

In 2006, approximately 1300 allogeneic HCTs for ALL were registered with the CIBMTR; about half were from unrelated donors. Median age at transplantation was 22 years; only 15% were performed in patients older than 55 years. Among patients younger than 20 years receiving HLA-identical sibling transplants, 40% were performed in CR1, 50% in CR2 or subsequent CR, and 10% in children with active disease. Corresponding probabilities for children receiving unrelated donor transplants were 30%, 60%, and 10%. Among adults 20 years or older receiving HLA-identical sibling transplants, 60% were performed in CR1, 20% in CR2 or subsequent CR, and 20% in patients with active disease. Corresponding probabilities for adults receiving unrelated donor transplants were 40%, 30%, and 30%. Most (90%) transplantations were done using myeloablative conditioning.

Major predictors of HCT outcome in ALL are remission state at time of transplantation, donor type, and age. The CIBMTR has data on approximately 6000 recipients of allogeneic HCT for ALL between 1998 and 2004. Among patients receiving transplants from HLA-identical siblings, 5-year probabilities of relapse, LFS, and overall survival were 39%, 37%, and 42%, respectively. Among adults receiving HLA-identical sibling transplants, 5-year probabilities of survival were 42% for 879 patients in CR1, 29% for 323 in CR2 or subsequent CR, and 16% for 360 with active leukemia (Fig. 101–8A). Among children receiving HLA-identical sibling HCT, 5-year probabilities of survival were 56% for 589 children transplanted in CR1, 48% for 880 children transplanted in CR2 or subsequent CR, and 27% for 185 with active leukemia (Fig. 101–8B).

Among 3212 patients receiving unrelated donor transplants between 1998 and 2004, 5-year probabilities of relapse, LFS, and overall survival were 31%, 29%, and 31%, respectively. Among adults receiving unrelated donor transplants, 5-year probabilities of survival were 36% for 519 patients transplanted in CR1, 24% for 380 in CR2 or subsequent CR, and 8% for 392 transplanted with active disease (Fig. 101–9A). Five-year probabilities for children receiving unrelated donor transplants were 45% for 466 children transplanted in CR1, 36% for 1221 children in CR2 or subsequent CR, and 17% for 244 transplanted with active disease (Fig. 101–9A).

The major cause of mortality after allogeneic transplantation for ALL is TRM, which is higher with unrelated donor transplants. The reported TRM in prospective trials ranges from 15% to 26% after HLA-identical sibling transplants and from 30% to 37% after unrelated donor transplants.[165–167] The ECOG/Medical Research Council (MRC) study reported 5-year overall survival of 55% for HLA-identical sibling and 46% for unrelated donor HCT (restricted to patients with bcr-abl–positive ALL).[166] In the German Multicentre ALL study 6/99, survival at 2 years was 53% with HLA-identical sibling donor and 44% with unrelated donor HCT.[167] CIBMTR data also indicate higher TRM with unrelated versus HLA-identical sibling transplants (approximately 40% vs approximately 25%.) Although some of this difference derives from a tendency for delayed transplantation in the unrelated donor setting, TRM rates differ even after stratification by disease state. Among patients transplanted in CR1, 5-year TRM rates are 19% with HLA-identical sibling and 34% with unrelated donor transplants. Corresponding rates for patients transplanted with advanced disease are 30% and 47%.

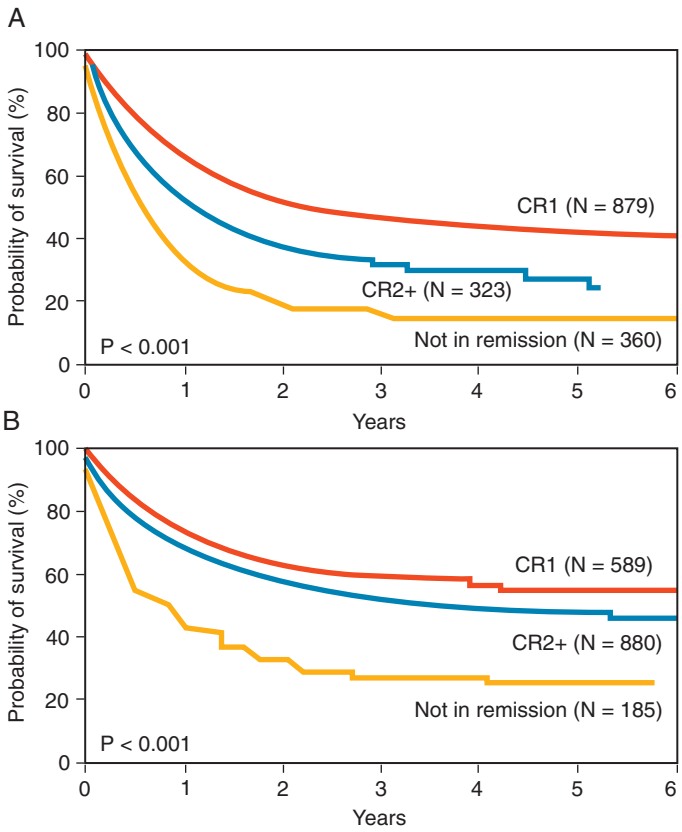

Figure 101–8 **A**, Probability of survival after human leukocyte antigen (HLA)-identical sibling transplants for acute lymphoblastic leukemia (ALL), age ≥ 20 years, 1998–2004, by disease status. **B**, Probability of survival after HLA-identical sibling transplants for ALL, age <20 years, 1998–2004, by disease status.

As in AML, prognosis in ALL is influenced by cytogenetic profile. In the most definitive study of cytogenetic risk in adult ALL, the outcomes of 1522 patients enrolled in the UKALLXII/ECOG 2993 study were analyzed.[168] The Philadelphia chromosome [t(9;22)(q34;q11.2)]/*BCR-ABL* fusion [Ph^+, t(4;11)(q21;q23), t(8;14)(q24.1;q32)], complex karyotype (five or more chromosomal abnormalities), or high hypodiploidy/near triploidy were associated with inferior rates of event-free and overall survival. In contrast, patients with high hyperdiploidy or a del(9p) had significantly better outcome. Multivariate analysis demonstrated that the prognostic relevance of t(8;14), complex karyotype, and low hypodiploidy/near triploidy was independent of sex, age, white blood cell count, and T-cell status among Philadelphia chromosome–negative (Ph^-) patients. Too few patients in the prognostically relevant cytogenetic subgroups underwent allogeneic HCT in the study to assess the impact of cytogenetics on transplantation. In Philadelphia chromosome–positive (Ph^+) ALL, long-term remissions are rare with chemotherapy despite CR rates of up to 90%. Related or unrelated HCT in CR1 is recommended. Although adverse cytogenetics are also associated with increased risk of relapse after HCT, allogeneic transplantation cures 20% to 40% of patients with Ph^+ and other high-risk cytogenetic abnormalities.[169–172]

Posttransplant Relapse

Overall, few patients who relapse after allogeneic HCT are long-term survivors.[136,137] In a series of 130 patients who relapsed after HCT for treatment of ALL, 94 patients underwent salvage therapy.[136] Relapse more than 1 year after HCT and isolated extramedullary relapses were associated with a higher probability of subsequent

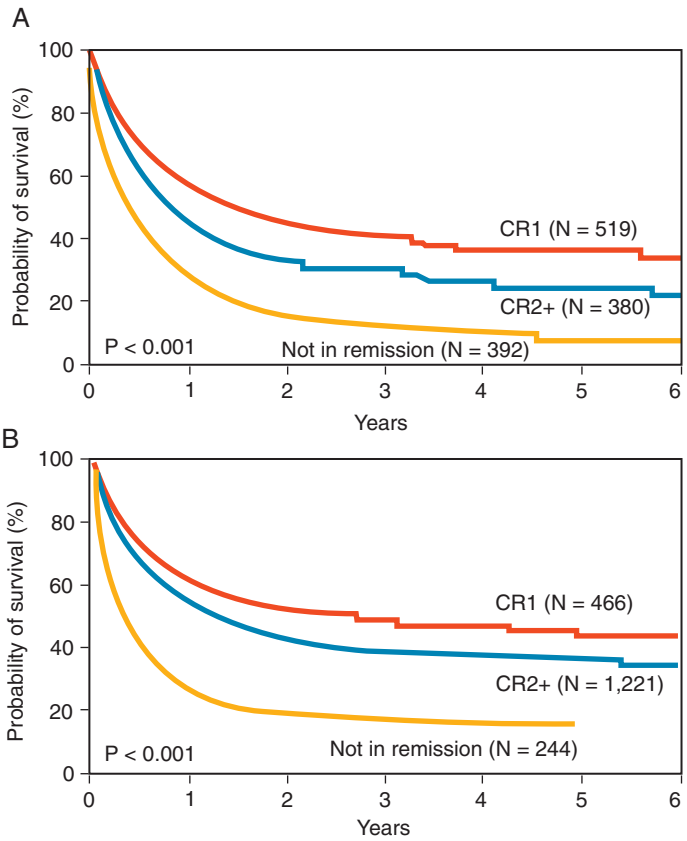

Figure 101–9 **A**, Probability of survival after unrelated donor transplants for acute lymphoblastic leukemia (ALL), age ≥ 20 years, 1998–2004, by disease status. **B**, Probability of survival after unrelated donor transplants for ALL, age <20 years, 1998–2004, by disease status.

remission. However, of the 52 patients who achieved a remission, only three became long-term leukemia-free survivors. DLIs and second HCT also are considerations in patients who relapse late after HCT. In a series of 15 patients who relapsed after HCT, a second allogeneic HCT was associated with TRM of 36% at day 100, and only 8% had long-term disease-free survival.[173] DLIs rarely produce long-term disease-free survival in ALL.[87]

Timing of Allogeneic HCT in ALL

Allogeneic HCT in CR1 from related or unrelated donors is generally accepted as the most effective available therapy for patients with Ph^+ ALL.[169–172] In children with standard-risk ALL, HCT is an accepted therapy for those in CR2.[174] For adults with Ph^- ALL, the appropriate timing of HCT is more controversial. Some prospective and retrospective comparative studies fail to show a significant advantage for allogeneic HCT in adults, with lower relapse rates offset by high TRM.[175,176] Two studies showed an advantage for allogeneic HCT in specific subsets of patients: one in patients with high-risk features [t(9;22), null or undifferentiated phenotype, high leukocyte count, age >30 years at onset, and >4 weeks to achieve first remission] and the other in adults younger than 50 years at the time of treatment.[163,177] The combined ECOG/MRC International ALL study compared postremission strategies in adult ALL.[178] Patients with HLA-matched sibling donors had higher overall and event-free survival and lower relapse rates than did patients assigned to other therapies. However, this advantage was confined to standard-risk patients (defined as bcr-abl negative, age <35 years, and without high leukocyte counts at presentation). In high-risk patients, high TRM abrogated the reduction in relapse risk. Two-year probability of TRM was 39% in high-risk patients and 20% in standard-risk patients. Despite these findings, allogeneic transplantation currently is considered by expert consensus[164] as the best curative therapy for adult patients with high-risk features such bcr-abl–positive ALL or those with a poor response to initial induction therapy[177,179] and among adults with t(4;11) ALL.[180]

No published comparisons of unrelated donor HCT with conventional therapy for ALL are available. In an analysis performed by the German Multicentre ALL Study group, patients with ALL in CR1 receiving HLA-identical sibling and unrelated donor transplants had similar LFS.[181] Other studies have shown superior LFS with unrelated donor transplants compared to autotransplants in high-risk subgroups of patients, particularly those beyond first remission.[182,183] A CIBMTR comparison of unrelated donor and autologous transplantation in ALL showed similar survival rates (40% and 32%, respectively), although the unrelated donor recipients included more patients with high-risk features such as unfavorable karyotype and high white blood cell count at diagnosis.[183] High TRM (>40%) offset the benefit of lower leukemia relapse in the unrelated donor cohort. In practice, most unrelated donor transplants are reserved for patients who do not respond to conventional therapy or with poor prognosis cytogenetic abnormalities such as bcr-abl–positive ALL.

The NMDP and ASBMT joint committee recommends transplant evaluation in patients with ALL in CR2 and at diagnosis in patients with high-risk ALL, such as patients with poor-risk cytogenetics (Ph chromosome or 11q23 abnormalities), high leukocyte count (>30,000–50,000), CNS or testicular leukemia, or patients who do not achieve CR within 4 weeks of initial induction treatment.[164]

CHRONIC MYELOID LEUKEMIA

The incidence of CML is 1.5 per 100,000 persons per year. Median age at diagnosis is 67 years; approximately 33% of patients are younger than 55 years at diagnosis and 14% are between 55 and 64 years old.[119] Allogeneic HCT is an established curative therapy for CML. Thousands of patients have been followed for more than 10 years (many for more than 15 and 20 years) after allogeneic HCT, with sustained hematologic and molecular remissions noted.[184–186] However, dramatic changes in practice occurred after targeted tyrosine kinase inhibitors were introduced for CML treatment. From 1999 to 2003, the numbers of allogeneic HCTs for CML decreased by approximately 40% in Europe[186] and by approximately two thirds in the United States.[187] CML accounted for more than 25% of allogeneic HCTs performed in the United States in 1998 to 1999 but fewer than 10% in 2006. Despite these changes, there is consensus that HCT is a valuable treatment for some patients with CML, affording the possibility of cure in patients with high-risk disease or those not responding to imatinib or other tyrosine kinase inhibitor therapy.[149]

Approximately 500 allogeneic transplantations for CML were registered with the CIBMTR in 2006; approximately 40% were from unrelated donors. Median age at HCT was 35 years; approximately 10% were older than 55 years and 10% younger than 20 years. Fifty-five percent were performed in patients in first chronic phase, 35% in patients in a subsequent chronic phase or in accelerated phase, and 10% in patients in blast phase. More than 80% had received imatinib prior to HCT. Myeloablative conditioning regimens were used for 85% of transplants in patients younger than 55 years and in 60% of transplants in patients older than 55 years; the remainder received a variety of reduced-intensity conditioning regimens. As in acute leukemia, major predictors of HCT outcome in CML are disease status, donor type, and age. Additionally, among patients transplanted in chronic phase, disease duration is important. The CIBMTR has data on 5229 patients receiving HLA-identical sibling transplants for CML performed from 1998 to 2004. Five-year probabilities of relapse, LFS, and overall survival were 24%, 52%, and 63%, respectively. Among patients receiving HLA-identical sibling transplants after myeloablative conditioning, 5-year probabilities of survival were

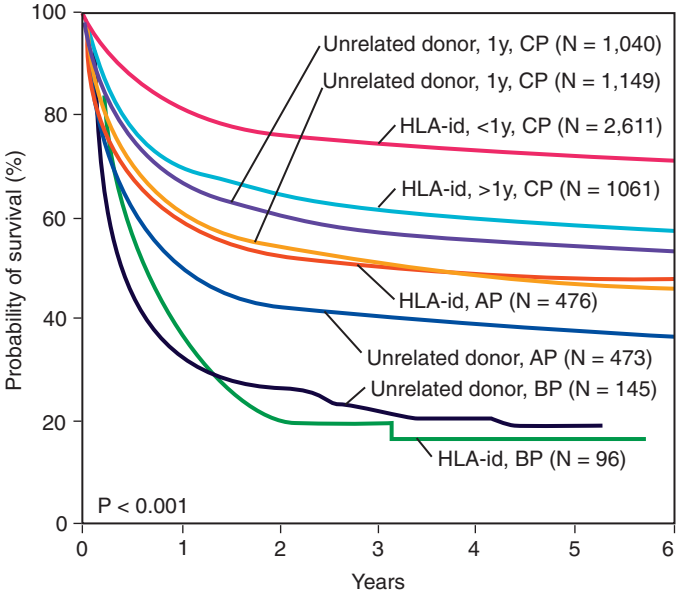

Figure 101–10 Probability of survival after allogeneic transplants with myeloablative conditioning for chronic myelogenous leukemia, 1998–2004, by disease status and donor type.

72% for 2611 patients transplanted in first chronic phase within 1 year of diagnosis, 58% for 1061 transplanted in first chronic phase but more than 12 months after diagnosis, 47% for 476 transplanted in accelerated phase, and 19% for 476 transplanted in blast phase (Fig. 101–10). Seven hundred one transplants for CML reported to the CIBMTR from 1998 to 2004 used reduced-intensity conditioning regimens. Among those receiving HLA-identical sibling transplants with reduced-intensity conditioning, 5-year probabilities of survival were 73% for 183 transplanted in first chronic phase within 1 year of diagnosis, 48% for 147 transplanted in first chronic phase but more than 12 months after diagnosis, and 46% for 63 transplanted in accelerated phase. The EBMT has reported outcomes in 187 patients who received reduced-intensity conditioning followed by allogeneic HCT for CML between 1994 and 2002.[188] Median age was 50 years; 61% received a transplant from an HLA-identical sibling, 25% from an unrelated donor, and the remainder from HLA-mismatched related donors. TRM was only 6% at 100 days but rose to 23% by 2 years posttransplant. Grade II to IV acute GVHD occurred in 32% of patients and chronic GVHD in 43%. Among patients transplanted in first or second chronic phase, overall survival rate and LFS rate at 3 years were 69% and 57%, respectively. Two-year probabilities of survival for patients transplanted in accelerated or blast phase were only 24% and 8%, respectively. Progressive CML was the major cause of death.

Overall survival rates of 35% to 45% 3 years after unrelated donor HCT for CML are reported.[16,105,106,108,189–193] In a series of 1423 transplants for CML facilitated by the NMDP, 3-year LFS was 43% in 914 patients transplanted in first chronic phase.[193] Although severe acute GVHD rates were high (43% grade II–IV, 33% grade III–IV), relapse rates were low at 6%, indicating a strong GVL effect. Among patients receiving unrelated donor HCT for CML after myeloablative conditioning from 1998 to 2004 and reported to the CIBMTR, 5-year probabilities of survival were 54% for 1040 transplanted in first chronic phase within 1 year of diagnosis, 48% for 1149 transplanted in first chronic phase but more than 12 months after diagnosis, 37% for 473 transplanted in accelerated phase, and 19% for 145 transplanted in blast phase (see Fig. 101–10). The largest single-center series of HCT for CML, including 196 patients transplanted at the Fred Hutchinson Cancer Center in Seattle, Washington, reported 5-year survival rates of 57%.[108] In that study, among patients 50 years or younger who received HCT within 1 year of diagnosis from an HLA-A, HLA-B, and HLA-DRB1 matched unrelated donor, 5-year survival was 74%, similar to that observed after HLA-matched sibling transplants at the same center. The CIBMTR has data on 231 unrelated donor transplants for CML using reduced-intensity conditioning. Five-year probabilities of survival were 55% for 47 transplanted in first chronic phase within 1 year of diagnosis, 50% for 128 transplanted in first chronic phase but more than 12 months after diagnosis, 43% for 39 transplanted in accelerated phase, and 6% for 17 transplanted in blast phase.

The EBMT has developed a risk scoring system for outcome after allogeneic HCT for CML. The system considers patient age, interval between diagnosis and transplant, disease phase, donor–recipient sex match, and donor relationships.[115] This scoring scheme was validated in a subsequent CIBMTR study[194] and by other groups.[195] Posttransplant survival also has been correlated with cytomegalovirus serostatus of the recipient, degree of donor–recipient HLA match, frequency of cytotoxic T-lymphocyte precursors in donor blood,[105,196] and total nucleated cell dose of infused marrow.[193]

Depleting the donor graft of T lymphocytes before infusion can decrease the incidence of GVHD, but at the cost of an increased risk of relapse, especially in patients with advanced disease.[16,189,197–200] This effect is particularly evident in CML. In a randomized trial of T-cell–depleted versus non–T-cell–depleted transplants from an unrelated donor, patients receiving T-cell–transplants had lower risks of acute GVHD but higher risks of relapse.[189] In that study, the 3-year probability of relapse was 20% with T-cell–depleted transplants but less than 10% with non–T-cell–depleted grafts. Overall survival and LFS did not differ significantly either for the entire cohort or for patients with CML.

Posttransplant Relapse

The probability of relapse at 5 years is approximately 20% for patients receiving HLA-identical sibling transplants for CML in first chronic phase.[65,74,77,82,201,202] The risk is higher for patients transplanted in accelerated or blast phase. Therapeutic options for patients who relapse following allogeneic HCT include DLI, second transplants with reduced-intensity or myeloablative conditioning, and imatinib or other tyrosine kinase inhibitor or interferon-α. Numerous studies support use of DLI to exploit GVL effects for inducing complete molecular remissions.[84,86–88,97,98,203,204] Durable complete remission can be established in up to 75% of patients, especially when DLI is performed in early cytogenetic relapse. In an analysis reported by Collins et al.,[87] complete responses were seen in 76% of patients receiving DLI for molecular or chronic phase hematologic relapse compared to 33% in patients with accelerated phase relapse and 17% in patients with blast phase relapse. Although response rates are higher in patients with GVHD, durable molecular responses occur in many patients without clinically evident GVHD. Second HCT with full or reduced-intensity conditioning is sometimes used for posttransplant relapse but is associated with high rates of TRM, especially if the interval between the first and second transplant is less than 1 year. This approach is generally reserved for young patients who have accelerated or blast phase relapse more than 1 year after a first transplant.

Imatinib is reported to be effective for treatment of posttransplant CML relapse in small case series.[205–209] Olavarria et al.[208] reported outcomes in 128 patients receiving imatinib after relapsing after allogeneic HCT. Fifty-one patients were in chronic phase, 31 in accelerated phase, and 46 in blast crisis. Fifty patients had not responded to treatment with DLI prior to imatinib. The overall hematologic response rate was 84%. The complete cytogenetic response rate was 58% for patients in chronic phase, 48% for those in accelerated phase, and 22% for those in blast crisis. Twenty-five (26%) patients had complete molecular responses. With median followup of 9 months, the estimated probabilities of 2-year survival were 100%, 86%, and 12% for patients treated in chronic phase, accelerated phase, and blast crisis, respectively. These results are encouraging, but longer followup is necessary. It is likely that the newer tyrosine kinase inhibitors will also be used in the posttransplant relapse setting, although efficacy data are not available.

Timing of Transplantation

As recently as 1999, CML treatment guidelines recommended early HCT within 1 to 2 years of diagnosis in young patients with an HLA-identical donor.[210] Imatinib is now the initial therapy of choice for CML, although national[149] and international guidelines[211] recommend consideration of allogeneic transplantation in some newly diagnosed patients. An early consultation with a transplant physician is important to evaluate the potential role of HCT (including performing a preliminary related and unrelated donor search), to formulate a strategy for HCT in the event of imatinib failure or discovery of resistant bcr-abl mutations, and to agree upon a strategy for monitoring the patient's progress. Early HCT is indicated for patients whose initial presentation is in blast phase and should be considered for those with a suboptimal response to imatinib. HCT is also a consideration for patients whose CML progresses after an initial response or have bcr-abl mutations that predict for nonresponse to tyrosine kinase inhibitors. A monitoring plan for early signs of progression is indicated because outcomes are significantly better if HCT is performed prior to transformation to accelerated or blast phase. Definitions of suboptimal response and failure with imatinib, guidelines for monitoring patients receiving imatinib, and indications for initiating alternative therapy, including HCT, have been developed and published by a consensus panel sponsored by the European LeukemiaNet[211] and the United States NCCN consensus panel.[149]

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is the most common leukemia in the Western world, affecting 3.8 per 100,000 population in the United States.[119] It is primarily a disease of older adults. Median age at onset is 72 years; only approximately 10% of patients are younger than 55 years at diagnosis and 20% between 55 and 65 years. Many patients have prolonged survival with observation alone or conservative therapy. The role and timing of allogeneic transplantation are controversial. Patients requiring therapy can achieve good responses and prolonged survival with a variety of modalities, such as chemotherapy, monoclonal antibodies, or autologous transplantation.[212–216] However, these approaches are not curative.[216] Allogeneic transplantation is a consideration for younger patients with high-risk features predicting short survival, such as patients with Rai stage II to IV disease or those not responding to or relapsing after fludarabine-based therapy.[217] Currently CLL accounts for approximately 4% of allogeneic HCTs.

Biologic predictors of high-risk disease in CLL include specific cytogenetic abnormalities (e.g., 17p13 abnormalities), ZAP-70 expression, high CD38 expression, and unmutated immunoglobulin heavy chain variable (Ig V_H) gene status of the tumor clone (see Chapter 83).[218–222] Poor-risk CLL is characterized by resistance to conventional chemotherapy, including fludarabine-based regimens and, typically, short duration of responses.[223–226] Allogeneic HCT can induce long-term clinical remissions in patients with CLL even in the presence of fludarabine resistance and some biologic risk factors and in these patients may offer the best option for long-term disease control.[227–229] In contrast to other CLL therapies, late relapses are uncommon after allografting.[217,230] T-cell depletion of the donor graft is associated with increased risk of relapse, whereas development of chronic GVHD is associated with reduced relapse risk.[214,231] The latter data as well as the efficacy of DLI[229,232] in inducing durable molecular responses after allotransplant relapse suggest that GVL plays a role in the efficacy of allogeneic HCT in CLL.

Approximately 260 allogeneic transplantations for CLL were registered with the CIBMTR in 2006; approximately 40% were from unrelated donors. Median age at transplantation was 55 years. Approximately 70% were in patients older than 50 years; only 30% were in patients older than 60 years. Median interval between diagnosis and transplantation was 5.5 years. Ten percent of patients had their disease for more than 10 years before transplantation. Most transplants for CLL used reduced-intensity conditioning regimens; only 45% of patients younger than 55 years and 25% of patients older than 55 years received myeloablative conditioning in 2006.

A review of 54 myeloablative HLA-identical sibling transplants for CLL performed in 1984 to 1992 reported to the IBMTR or the EBMT showed 46% survival at 3 years.[233] TRM was high at 46%. Most of these patients had long-standing or advanced disease with multiple courses of chemotherapy. The authors concluded that transplantation should be considered for young patients with poor prognosis with chemotherapy. The Fred Hutchinson Cancer Center reported their early experience in 25 patients with CLL transplanted in 1980 to 1999.[234] TRM at day 100 was unacceptably high at 57% for patients receiving busulfan and cyclophosphamide conditioning but only 17% for those receiving TBI regimens. Five-year survival was 32%. Results of HCT with myeloablative conditioning in 38 patients receiving unrelated donor transplants in 1993 to 1999 were reported by the NMDP/CIBMTR.[235] Twenty-one of the patients were chemotherapy refractory, and 89% had received fludarabine. Conditioning included TBI in 92% of patients. Five-year survival, TRM, and relapse rates were 33%, 32%, and 38%, respectively.

Data suggest that reduced-intensity conditioning regimens are effective and less toxic than myeloablative regimens in allogeneic HCT for CLL. A report describing heavily pretreated patients with advanced CLL receiving reduced-intensity conditioning demonstrated 2-year overall and disease-free survival rates of 60% and 52%, respectively.[228] In another study of 30 patients with advanced CLL who received allogeneic HCT after reduced-intensity regimens, 4-year survival, TRM, and relapse rates were 69%, 15%, and 30%, respectively.[229] The EBMT compared the outcomes of 73 patients with CLL transplanted with reduced-intensity regimens with 82 similar patients transplanted after standard myeloablative conditioning during the same time period.[231] The patients who received reduced-intensity conditioning had 2-year survival, TRM, and relapse rates of 70%, 19%, and 28%, respectively. Corresponding rates for patients who received myeloablative conditioning were 70%, 26%, and 11%. Although reduced-intensity regimens were associated with significantly less TRM, no difference in event-free or overall survival between the two groups was observed given the higher incidence of relapse in the reduced-intensity group.

Among 684 patients receiving HLA-identical sibling transplants for CLL in 1998 to 2004, 5-year probabilities of survival were 46% for 318 patients receiving myeloablative conditioning and 45% for 366 receiving reduced-intensity regimens. Corresponding LFS rates were 29% and 8%. Among 317 patients receiving unrelated donor transplants during this period, 5-year probabilities of survival were 26% for 138 patients receiving myeloablative conditioning and 29% for 179 receiving reduced-intensity regimens (Fig. 101–11). Corresponding LFS rates were 19% and 19%. For older patients or those

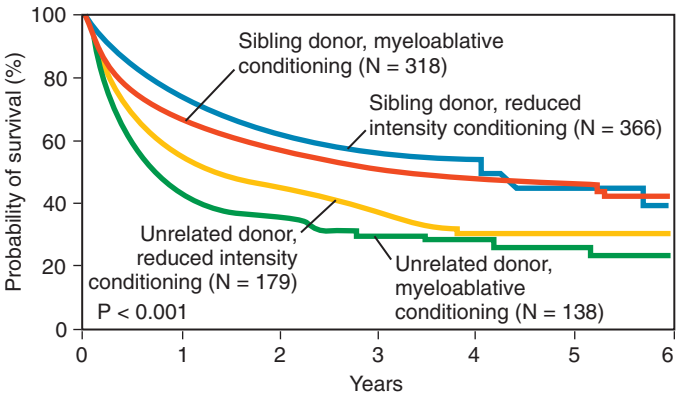

Figure 101–11 Probability of survival after allogeneic transplants for chronic lymphocytic leukemia, 1998–2004, by donor type and regimen intensity.

with significant comorbidities that increase the risk of TRM, reduced-intensity regimens appear to be an appropriate choice, especially if the CLL is chemosensitive. Whether myeloablative regimens is preferable in younger patients with poorly controlled disease is not clear.[236]

Current NCCN or ASBMT guidelines do not address the role of HCT in CLL. However the EBMT consensus group has recommended allogeneic HCT as a reasonable treatment option for younger patients with nonresponse or early relapse (within 12 months) after purine analogue therapy.[237] Patients who relapse within 24 months after having responded to purine analogue-based combination therapy or autologous transplantation and patients with p53 abnormalities requiring treatment are also considered candidates for transplant evaluation.

NON-HODGKIN LYMPHOMA

The NHLs are a heterogeneous group of malignancies with an incidence of 19.1 per 100,000 persons (see Chapter 80). Median age of onset is 67 years, with only 30% younger than 55 years at diagnosis.[119] Treatment choices, prognosis, and the role of allogeneic HCT in NHL depend on histologic subtype as well as patient characteristics such as age and comorbidities. Although nontransplant therapies are the mainstay of treatment for follicular NHL, these treatments rarely cure the disease. Autologous HCT cures a substantial proportion of patients with relapsed or high-risk diffuse large cell lymphoma but is less effective for follicular, mantle cell, and lymphoblastic lymphomas.[238] A tumor-free graft and the potential for immune-mediated graft-versus-lymphoma effects are the major advantages of allogeneic over autologous HCT in NHL. Disadvantages are the risks of TRM, GVHD, and donor restrictions.[239] Fewer than 700 allogeneic HCTs were performed for NHL in the United States in 2006, much fewer than the 3000 autologous HCTs performed for NHL and considerably less than the more than 50,000 cases of NHL diagnosed each year. Autologous HCT is an accepted therapy for patients who do not respond to nontransplant treatment or as initial consolidation therapy in patients with a high risk of failure. Allogeneic HCT is generally reserved for patients with a high likelihood of relapse after autografting or from whom an adequate autologous graft cannot be obtained.[238,240,241] This includes patients with follicular or lymphoblastic NHL, patients with lymphoma refractory to conventional chemotherapy, and patients with extensive marrow involvement, coexisting myelodysplasia, poor marrow reserve, or prior pelvic irradiation. Some patients relapsing after an autograft for NHL can achieve long-term disease-free survival with allogeneic transplantation.[242]

Graft-versus-lymphoma effects are less well defined in lymphoma than in leukemia but may play a role in preventing relapse after transplants for NHL.[243–246] Relapse rates are lower after allogeneic than autologous HCT, although this may be due in part to reinfusion of lymphoma cells in autologous grafts. Among allograft recipients, patients with GVHD have lower relapse rates than those without GVHD.[244] Donor leukocyte infusions are only occasionally effective in persons whose NHL recurs after an allograft.[87,247] Bierman et al.[248] compared the outcomes of syngeneic, allogeneic, and autologous transplants for NHL reported to the CIBMTR. Lower relapse rates were not observed in the allogeneic group compared to syngeneic transplants, suggesting that the graft-versus-lymphoma effect was not clinically significant. This analysis also suggested that lymphoma contamination of the graft was a major contributor to relapse after autografts, as autograft recipients had a fivefold higher relapse risk than did syngeneic transplant recipients. The most compelling evidence for graft-versus-lymphoma activity comes from reports of prolonged remissions achieved with reduced-intensity preparative regimens followed by allografting, where disease control would not be expected from the conditioning regimen alone. The effect appears to be strongest in follicular and mantle cell lymphoma.[30,249,250]

Diffuse Large Cell Lymphoma

The most common lymphoma subtype is diffuse large B-cell (non-Hodgkin) lymphoma (DLBCL). Population-based studies indicate that DLBCL is curable in approximately 50% of cases in the current era.[251] Among patients who relapse, those with chemosensitive lymphoma have a 40% to 50% chance of long-term disease-free survival with autologous HCT.[252,253] No randomized studies have compared allogeneic with autologous transplants in relapsed DLBCL. An EBMT study comparing allogeneic and autologous transplants in NHL failed to show a difference in progression-free survival or relapse in the intermediate-grade NHL subset.[244] A CIBMTR study comparing patients receiving HLA-identical sibling allografts for DLBCL with patients matched on disease- and patient-related risk factors who received autotransplants showed higher TRM and no beneficial effect on risk of progression with allografting.[254] Allografts are often recommended for patients who relapse after an autograft.[242] Several single-center studies with small numbers of patients give conflicting results for allogeneic HCT in this setting.[25,255,256] A CIBMTR analysis of 114 patients who received a myeloablative allograft for treatment of relapse following autologous transplantation between 1990 and 1999 showed 5-year survival of 24% and disease-free survival of 5%.[257] TRM was high in all of these studies, and current approaches increasingly use reduced-intensity conditioning to ameliorate this problem.[258–260] Long-term data on outcome are lacking.

Forty-five percent of the 250 allografts for DLBCL registered with the CIBMTR in 2006 were in patients who never achieved first remission; only half of these patients had chemotherapy-sensitive disease. Fifteen percent of transplants were performed as consolidation therapy for DLBCL in first or subsequent remission, 20% in resistant or untreated relapse, and 20% in chemosensitive relapse. Thirty percent of patients had a prior autograft. Median age at HCT was 50 years. Reduced-intensity conditioning was used in 40% of transplants. Among 440 recipients of HLA-identical sibling transplants for DLBCL performed in 1998 to 2004, 3-year probabilities of actuarial survival were 39% for 323 patients with chemotherapy-sensitive disease and 21% for 117 with resistant disease. Corresponding progression-free survival rates were 33% and 15%. Among 129 recipients of unrelated donor transplants for DLBCL performed in this period, the 3-year probabilities of actuarial survival were 28% for 86 patients with chemotherapy-sensitive disease and 14% for 43 with resistant disease. Corresponding progression-free survival rates were 25% and 6%.

Follicular Lymphoma

Follicular lymphoma is the second most common lymphoma in the United States (see Chapter 79).[261] The natural history of this disease is marked by repeated chemosensitive relapses of progressively shorter duration and ultimately death from progressive disease.[262] Currently no nontransplant options are considered curative, but prolonged survival with good quality of life is possible for most patients. Autologous and allogeneic HCT are alternative approaches aimed at long-term survival and potential cure in patients for whom nontransplant therapy fails.[263] Although none of the trials were randomized, multiple studies show substantially lower risks of relapse with allogeneic compared to autologous HCT.[246,264,265] A CIBMTR analysis compared the outcomes of 131 patients with follicular NHL who underwent myeloablative allogeneic HCT with 597 who received autologous HCT (n = 597).[265] The risk of relapse was significantly lower in the allogeneic HCT group ($P < 0.001$): 19% at 1 year with very few relapses thereafter versus 36% at 1 year and 58% at 5 years after autografting. However, the benefit of lower relapse rates was offset by higher TRM; 5-year probabilities of overall survival were similar after allogeneic and autologous transplantation (52% and 55%, respectively). These results are very similar to a large single-center report from the University of Nebraska.[266]

The low recurrence rate with allogeneic HCT shows the potential for cure of follicular lymphoma. However, the toxicity of allogeneic

HCT is a major barrier to the general applicability of this approach to most patients with follicular lymphoma. Current clinical practice recommends allogeneic HCT for younger patients with recurrent follicular lymphoma who have suitable sibling donors because they may tolerate treatment-related toxicity better.[267] There is also considerable interest in using reduced-intensity regimens for follicular lymphoma because of an apparent greater graft-versus-lymphoma effect for this histology.[240] The best reported outcomes with reduced-intensity regimens have been demonstrated in single-center studies in patients with chemotherapy-sensitive relapses.[268] An EBMT study of 52 patients with low-grade NHL receiving allografts reported 2-year progression free and overall survival rates of 54% and 65%, respectively, with a 2-year TRM rate of 31%.[250]

Of the approximately 250 allogeneic transplants for follicular lymphoma registered with the CIBMTR in 2006, 81% were performed in patients with chemotherapy-sensitive disease. Sixty-percent were performed using a reduced-intensity conditioning regimen. Among 747 HLA-identical sibling transplants for follicular lymphoma performed in 1998 to 2004, 5-year probabilities of survival were 58% in 426 patients receiving standard myeloablative conditioning and 66% in 321 receiving reduced-intensity conditioning. Corresponding probabilities of progression-free survival were 42% and 44%. Among 209 recipients of unrelated donor transplants for follicular lymphoma performed during this period, 5-year probabilities of actuarial survival was 39% for 99 patients receiving myeloablative conditioning and 47% for 110 receiving reduced-intensity conditioning. Corresponding progression-free survival rates were identical at 34%.

Mantle Cell Lymphoma

Mantle cell lymphoma accounts for 6% of cases of adult NHL and is primarily a disease of older men (median age at onset 65 years).[269,270] The natural history of the disease is characterized by response to initial chemotherapy followed by refractory relapse and median survival of approximately 3 years. The role of autologous and allogeneic HCT is poorly established, although common clinical options include combination chemotherapy followed by autologous HCT in first remission and autologous or allogeneic HCT in relapse.[149] Among 175 allogeneic HCTs registered with the CIBMTR in 2006, 20% were performed in first remission; 20% of patients had a prior autograft. Seventy percent were performed using a reduced-intensity conditioning regimen. Reduced-intensity conditioning regimens are increasingly used in mantle cell NHL. Because autologous transplants are not curative, most patients are of advanced age at diagnosis, and a graft-versus-tumor effect appears to exist.[271] Two-year overall survival of 64% and disease-free survival of 60% were demonstrated using reduced-intensity conditioning allogeneic HCT in a single-center study.[30] Relapse and TRM rates were 9% and 24%, respectively. Among 488 patients receiving allogeneic HCT for mantle cell NHL in 1998 to 2004 reported to the CIBMTR, 3-year probabilities of survival were 50% and 34% after 375 HLA-identical sibling transplants and 113 unrelated donor transplants, respectively. Reduced-intensity conditioning was used in 40% of cases and yielded similar survival outcomes to myeloablative conditioning.

Current U.S. NCCN guidelines recommend consideration of allogeneic HCT as an adjunct to initial therapy, preferably on a clinical trial.[149]

Rare Subtypes of NHL

The lymphoblastic lymphomas account for only approximately 2% of NHLs.[269] They usually are of precursor T-cell origin and occur most commonly in children and young adults. Both autologous and allogeneic HCTs have been used in patients with lymphoblastic lymphoma; reported overall survival rates are 56% to 80% for patients who received transplants in CR1.[157,244,272,273] In a CIBMTR analysis, HLA-identical sibling allogeneic HCT for lymphoblastic lymphoma was associated with fewer relapses than autologous HCT, but higher TRM of allogeneic HCT abrogated any survival benefit.[274]

The role of allogeneic HCT in relapsed or chemotherapy-refractory anaplastic large cell lymphoma is not defined. In case reports, allogeneic HCT has been shown to be effective in patients with multiple relapses of ALK-positive anaplastic large cell lymphoma or even with chemotherapy-refractory disease.[275] The existence of a graft-versus-anaplastic large cell lymphoma effect also has been postulated. Fewer than 150 allogeneic HCTs for anaplastic large cell lymphoma were reported to the CIBMTR between 1989 and 2006.

HODGKIN LYMPHOMA

The incidence of Hodgkin lymphoma is 2.7 per 100,000 persons in the United States. Median age at onset is 37 years, and 75% of patients are younger than 55 years at diagnosis.[119] There is a bimodal peak in the incidence of HD, with most patients between the ages of 15 and 30 years, followed by another peak in adults older than 55 years. Most patients with Hodgkin lymphoma are cured with conventional chemotherapy (with or without radiation).[276,277] Autologous HCT is an accepted and effective salvage therapy for the 20% to 30% patients who do not respond to conventional chemotherapy. Two randomized studies and several retrospective studies support the use of autologous HCT in relapsed and refractory Hodgkin lymphoma, especially in chemotherapy-sensitive patients.[278,279] In 2006, 928 autologous transplants for Hodgkin lymphoma were registered with CIBMTR but only 240 allogeneic HCTs. About half of the allogeneic transplants were in patients who had relapsed after a prior autotransplant. Median age was 33 years; 70% used reduced-intensity conditioning regimens. Potential advantages of allogeneic transplants in advanced Hodgkin lymphoma are that donor hematopoietic cells have not been exposed to chemotherapy, there is no risk of lymphoma cells contaminating the graft, and there may be a graft-versus-lymphoma effect. However, relatively few allogeneic transplants for Hodgkin lymphoma are performed; 80% are from related donors. As in NHL, most are performed in heavily pretreated and often chemotherapy-refractory patients.[280]

An IBMTR analysis of 100 HLA-identical sibling transplants for Hodgkin lymphoma performed between 1982 and 1992 showed high TRM (61%) and 3-year disease-free survival of 15%.[280] A matched pair analysis of autologous and allogeneic transplants for Hodgkin lymphoma showed fewer relapses but more transplant-related deaths with allografts; survival was similar.[281] Reduced-intensity conditioning regimens for reducing TRM have been explored. An early single-center study reported TRM of 22% at 18 months in 40 heavily pretreated patients.[282] Overall survival at 18 months was 61%, with progression-free survival of 32%.

Three hundred eighty allogeneic HCTs for Hodgkin lymphoma were reported to the CIBMTR between 1998 and 2004. Among patients receiving HLA-identical sibling transplants, 3-year probability of survival was identical (38%) in 141 patients receiving myeloablative conditioning and 93 patients receiving reduced-intensity conditioning. The outcomes of 146 unrelated donor transplant recipients for Hodgkin lymphoma using reduced-intensity conditioning and reported to the CIBMTR between 1999 and 2004 have been evaluated.[283] Overall survival, progression-free survival, and TRM rates were 38%, 20%, and 33% at 2 years. Most (90%) of these patients had relapsed after a prior autograft, and 50% had chemotherapy-resistant disease at transplantation. A comparison with 38 unrelated donor transplants using myeloablative conditioning did not show statistically significant differences in TRM, survival, or relapse risk.

National consensus guidelines do not currently recommend allogeneic HCT in relapsed or refractory Hodgkin lymphoma; therefore, this treatment should ideally be performed as part of a clinical trial.[149]

MULTIPLE MYELOMA

Multiple myeloma is a disease of older adults. Median age at onset is approximately 70 years.[119] Two thirds of patients are 65 years or older; only 15% are younger than 55 years. The most common treatment strategy for multiple myeloma involves initial therapy with corticosteroid-based combination regimens followed by single or planned tandem autologous peripheral blood stem cell transplantation in transplant-eligible patients. Currently, myeloma is the most common indication for HCT in the United States, although most HCTs use autologous cells. Approximately 4000 autologous and 350 allogeneic HCTs for myeloma were performed in the United States in 2006. Approximately 20% of allogeneic HCTs were from unrelated donors. Median ages of autologous and allogeneic HCT recipients were 58 and 54 years, respectively; fewer than 10% of allograft recipients were older than 60 years. Eighty percent of the allogeneic HCTs were in patients who had a prior autotransplant.

Two prospective randomized clinical trials have shown that high-dose therapy with autologous HCT is superior to conventional chemotherapy in prolonging survival.[284,285] Unfortunately, the vast majority of patients eventually relapse after autologous HCT, including after planned sequential autotransplant.[286] Several studies show that allogeneic HCT produces durable molecular remissions in myeloma, with a significantly lower risk of relapse than autologous HCT.[274,287–289] Other evidence for a graft-versus-myeloma effect of allogeneic HCT include reports of lower relapse rates in patients developing GVHD and the success of DLI in reinducing remission in some patients who relapse after allogeneic transplantation.[102,290–292] Unfortunately, TRM rates after allogeneic HCT done with conventional myeloablative conditioning have been high, leading to significantly inferior overall survival rates compared to autotransplants.[293,294] Nevertheless, some allotransplant recipients have prolonged disease-free survival and may be cured of their myeloma.[295] The allotransplant arm of the U.S. Intergroup S9321 study demonstrated a long-term (7-year) plateau in the survival curve at 39%, although the very high initial TRM (40%) led to premature termination of this arm.[295] Data from the EBMT indicate that TRM after myeloablative HCT decreased significantly to approximately 20% over the past 10 years; the change was attributed to improved supportive care and better patient selection.[296]

In practice, most allogeneic HCTs for myeloma now use reduced-intensity conditioning. An analysis by the EBMT of 320 patients is the largest reported experience with reduced-intensity conditioning in multiple myeloma.[297] Most of the patients had undergone a prior autograft (23% as a planned tandem procedure), were in a complete or partial response (72%) prior to transplant, had HLA-matched sibling donors (82%), and had received fludarabine-based conditioning (86%) with the addition of melphalan, busulfan, or TBI. Compared to 196 patients who received myeloablative conditioning for myeloma, patients who received reduced-intensity conditioning were older and more likely to have progressive disease. TRM rates at 2 years in the reduced intensity and myeloablative groups were 24% and 37%, respectively. Three-year probabilities of survival were similar at 38% and 50%, whereas progression-free surviva1 was lower in the reduced-intensity group (19% vs 34% in the myeloablative group). In multivariate analysis, progressive disease at transplantation and use of alemtuzumab were associated with worse outcomes. Current studies do not indicate that lower early TRM with reduced-intensity conditioning translates into a survival plateau, with relapse risks as high as 60% in the first 3 years, especially in patients with high-risk disease (e.g., adverse cytogenetics).[298–300] The best results with reduced-intensity conditioning seem to occur in patients with chemosensitive disease[301] without adverse markers such as chromosome 13 abnormalities[302] or high β_2-microglobulin levels[300] or in patients who had an autotransplant in the preceding year.[303]

Allogeneic HCT with reduced-intensity conditioning can be performed may as an initial transplant approach, for relapse after autologous transplantation, or after autologous transplantation in a planned sequential approach. The Seattle group who pioneered the latter approach reported initial results in three groups of patients[304,305]: relapsed patients who had not responded to prior autologous HCT (n = 14), relapsed patients who had not received prior autotransplant (n = 19), and patients who had received planned sequential autologous allogeneic transplants (n = 84). Four-year overall survival probabilities were 40%, 35%, and 70%, respectively. TRM was 2% at day 100 and 17% overall. The strategy of initial autologous transplantation for tumor reduction followed by allogeneic HCT from related and unrelated donors after reduced-intensity conditioning to provide a graft-versus-myeloma effect is increasingly used. A study from Italy indicates significantly higher progression-free and overall survival rates with sequential auto-allotransplants (using HLA-identical sibling donors) versus tandem autologous transplants.[306] A large trial testing this strategy is underway in the United States.

Among 1152 HLA-identical sibling HCTs for multiple myeloma performed in 1998 to 2004 and reported to CIBMTR, 5-year probabilities of survival were 38% for 532 patients receiving myeloablative conditioning and 39% for 620 receiving reduced-intensity conditioning. Among 340 unrelated donor HCTs performed during the same time period, 5-year probabilities of survival were 16% for 130 patients receiving myeloablative conditioning and 21% for 210 patients receiving reduced-intensity conditioning. Twenty-five percent of those receiving myeloablative conditioning and 64% of those receiving reduced-intensity conditioning had undergone a prior autotransplant (Fig. 101–12).

The NCCN guidelines do not distinguish between myeloablative and nonmyeloablative allogeneic HCT in myeloma. All indications are considered a category 2A recommendation (reflecting uniform NCCN consensus, based on lower-level evidence including clinical experience, that the recommendation is appropriate).

LATE EFFECTS IN SURVIVORS OF ALLOGENEIC TRANSPLANTS

Patients who survive the first 5 years after HCT are likely to survive long term, with mortality rates eventually approaching that of the general population.[184,307] However, some survivors experience late complications of HCT. Baker et al.[307] studied the long-term risks and benefits of HCT for CML. Two hundred forty-eight recipients of HCT for CML who had survived at least 2 years post-HCT were compared to 317 normal siblings. Subjects completed a 238-item survey on medical late effects. Compared with sibling controls, survivors had higher risks of ocular, oral health, endocrine, gastrointestinal, musculoskeletal, neurosensory, and neuromotor impairments. Chronic GVHD is a major risk factor for hypothyroidism, osteoporosis, cardiopulmonary, neurosensory, and neuromotor impairments and late deaths.[184,307] These data show the need for continued monitoring and medical intervention in these patients.

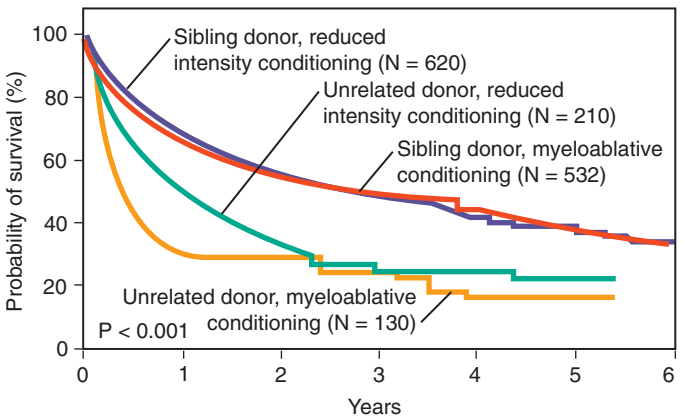

Figure 101–12 Probability of survival after allogeneic transplants for multiple myeloma, 1998–2004, by donor type and regimen intensity.

Disappointingly, HCT survivors do not seem more likely than the general population to seek regular medical care or follow routine personal health guidelines. Education on the importance of such followup should be an integral part of posttransplant care. The CIBMTR and EBMT have published guidelines for long-term followup of transplant recipients.[308]

CHAPTER 102

AUTOLOGOUS TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES

Jeffrey R. Schriber, Amrita Krishnan, and Stephen J. Forman

In the last 30 years, combination chemotherapy regimens have been developed for treatment of the majority of hematologic malignancies and solid tumors. These regimens typically utilize agents with relatively nonoverlapping toxicities and different mechanisms of action to decrease the potential for drug resistance.[1] Such regimens are designed to maximize objective clinical responses while minimizing toxicity.

Although most malignancies demonstrate significant disease responsiveness to conventional dose chemotherapy, many such responses are incomplete or not durable. One strategy to overcome the lack of response is dose intensification. In laboratory models, delivery of the highest possible doses of chemotherapy is a frequent requirement for achieving long-term disease control.[2] These studies also indicate that disease resistance to a variety of cytotoxic agents can, in some tumor systems, be overcome with a 5- to 10-fold escalation in drug dose. The ability to overcome drug resistance by dose intensification is one of the fundamental requirements for autologous transplantation to be successful.

The second fundamental requirement is the ability to overcome the toxicity of dose-intensive therapy. By choosing agents where the primary dose limiting toxicity is hematologic, it is possible to harvest either marrow or peripheral blood stem cells to shorten or eliminate the duration of hematologic toxicity. Table 102–1 shows the list of commonly used chemotherapy drugs used in autologous transplant regimens with the organ-limiting toxicity when autologous stem cell support is provided.

RATIONALE FOR HIGH-DOSE THERAPY

Hyriniack and Bush introduced the concept of dose intensity (drug dose administered in mg/m²/week) for the purposes of being able to quantify the dose–response effect.[3] The dose–response effect is defined as the correlation of the effect of a drug with increasing doses. It was their hypothesis that dose intensity correlated with response, which in turn correlated with survival. Several assumptions are inherent in this hypothesis and include the following:

1. All drugs in a given regimen are therapeutically equivalent.
2. Synergy and cross-resistance between drugs do not play an active role.
3. The area under the curve is more important than peak drug concentrations.
4. Scheduling has no importance other than what is reflected in total dose intensity.

This suggests that chemotherapy regimens should be designed to maximize dose intensity and focus on the overall dose administered over time rather than achieving the highest peak dose. Laboratory models and clinical observations have demonstrated a dose–response relationship against a variety of tumors, leading to the concept that the highest possible doses should be incorporated into the design of the regimen.[4,5] Where possible, combinations of active, non-cross-resistant agents should be used to decrease the emergence of drug resistance. This latter consideration is based on studies by Skipper that estimate a spontaneous rate of mutation conferring resistance to a single drug to be in the order of 1 in 10^6 or 1 in 10^7 cancer cell.[2] The implication of this is that spontaneous mutations are highest in patients at diagnosis or at relapse (high tumor burden). The agents used in the regimen need to have different dose-limiting toxicities to avoid dose reduction and prevent additive toxicity. This would facilitate the delivery of full single-dose therapies of the drug. To minimize the rapid emergence of resistance, combinations of drugs in high-dose regimens with different mechanisms of action would limit the emergence of cross resistance.

Table 102–2 lists the malignant hematologic diseases for which utilizing high-dose chemotherapy or chemoradiotherapy and autologous transplant have been studied and showed improved outcome for patients. Unlike allogeneic transplant, where the high-dose preparatory regimen provides both cytoreduction to reduce or eliminate the tumor burden and immunosuppression to facilitate engraftment and a graft-versus-tumor effect, the regimen used for autologous transplant is designed to provide maximal antitumor activity limited only by the nonhematologic toxicity of the regimen.

CONTRIBUTION OF THE GRAFT TO RELAPSE

Despite the success of transplantation, the major cause for failure following autologous transplantation continues to be disease relapse. Relapsed disease can theoretically be due to the inability of the chemotherapy to eliminate the tumor burden that had remained in the body or due to tumor cells that may reside in the reinfused stem cell product. Even when there is no potential for the graft to be responsible for relapse, that is, a syngeneic (identical twin) graft, the cure rate is far from 100% and emphasizes that it is the tumor burden and its sensitivity to treatment that is responsible for the majority of relapses.[6]

In diseases where the bulk of the disease resides in the marrow, such as acute myelogenous leukemia (AML) and myeloma, the high likelihood of reinfusing tumor cells has led to the development of methods designed to eradicate tumor cells with the goal of achieving results comparable to syngeneic transplantation. Intuitively it would seem that all sources of autologous stem cells from patients with hematologic malignancies might contain cells that contribute to relapse, and studies of stem cell products have documented the presence of tumor cells in the grafts, including leukemia, myeloma, lymphoma, and breast cancer.[7–10]

Although tumor cells can be found in the stem cell product, what is critical is whether these cells are in fact clonogenic. Brenner et al have provided direct evidence that infusion of autologous tumor cells contributes to relapse following autologous transplantation. They incubated a third of harvested marrow from two children undergoing hematopoietic cell transplantation (HCT) for AML with the L and L-6 retroviral vector.[11] This vector contained the selectable neomycin resistance gene, which marked approximately 5% of cultured progenitor cells. Patients underwent transplantation with infusion of both marked and unmarked marrow cells. At the time of the relapse, some of the leukemia cells contained the neomycin resistance gene, demonstrating that these leukemia cells were present in the reinfused graft and could be detected at relapse.

Most of the phase II trials that have purged the graft use either chemotherapeutic agents (AML), monoclonal antibodies against differentiation antigens on B cell hematopoietic tumor cells (B-cell lymphoma), or enrichment devices that enrich stem cells and reduce tumor cell contamination of the graft. These studies suggest that

Table 102–1 Agents Used in Autologous Transplant Regimens and Their Dose-Limiting Toxicity

Etoposide	Mucositis, dermatitis
Cyclophosphamide	Cardiac failure, pulmonary failure, hemorrhagic cystitis
Cisplatinum	Renal failure, hearing loss
Carmustine (BCNU)	Interstitial pneumonitis, seizures
Total body irradiation	Interstitial pneumonitis, enteritis, mucositis
Melphalan	Mucositis
Busulfan	Venoocclusive disease of the liver Interstitial pneumonitis Seizures
Thiotepa	Mucositis
Mitoxantrone	Cardiac failure
Taxol	Neuropathy
Carboplatin	Neuropathy

Table 102–2 Autologous Transplantation for Hematologic Malignancy

1.	Acute myelogenous leukemia: First and second remission
2.	Hodgkin lymphoma: Induction failure, second remission and relapse
3.	Non-Hodgkin lymphoma: Intermediate with high-risk features in first remission, chemoresponsive relapse
4.	Low grade B-cell lymphoma: Second remission or chemosensitive relapse
5.	Mantle cell lymphoma: First remission, mantle cell in second, complete remission
6.	Peripheral T-cell lymphoma: First or second remission
7.	Multiple myeloma: Chemosensitive, responsive disease
8.	Chronic lymphocytic leukemia: In remission

purging reduces the number of clonogenic cells but often delays engraftment.[12–14]

Studies in lymphoma patients have correlated the ability to deplete contaminating malignant lymphoma cells from the graft with overall disease-free survival following transplant.[15] What is not clear is whether purging itself in this instance reduces the relapse rate or if the ability to purge the tumor is simply an indication of lower tumor burden, which may correlate with improved disease survival. In addition, strategies such as treatment of the patient with monoclonal antibody prior to peripheral blood stem cell collection reduce tumor cell contamination and in some circumstances such as B-cell lymphoma obviate the need for in vitro purging.[17,18]

Laboratory studies have shown purging to reduce tumor cell contamination in vitro. The benefit of purging of tumor cells in human transplant studies however has remained controversial and unproven. Retrospective analyses give some indication as to the potential value of purging; however, no prospective randomized trials addressing the efficacy of ex vivo purging have been reported.[12,14] Although tumor contamination clearly can play a role in relapse, the relative contribution compared to the total body burden of tumor cells appears to be low and definitive randomized trials would require huge numbers of patients and are impractical to consider at this time.

AUTOLOGOUS TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCY

The first successful case of autologous HCT was reported in 1959. The case described a 2-year-old girl with recurrent acute lymphoblastic leukemia (ALL) who received total body irradiation (TBI) and followed by reinfusion of marrow, which had been obtained while she was in a remission. At the time of her therapy she was bedridden and a marrow showed 98% lymphoblasts.[18] Despite her advanced stage, she eventually recovered and 3 months later remained in remission. Since this case, tens of thousands of patients have undergone this therapy for a variety of diseases. This chapter summarizes the currently understood benefits and limitations of autologous transplant for hematopoietic malignancy.

ACUTE MYELOGENOUS LEUKEMIA

Initially, autologous transplant applied the same clinical approach previously utilized for patients undergoing allogeneic transplant. Patients with advanced disease were treated with high-dose chemotherapy and then received infusion of their own marrow, typically collected during remission rather than marrow from a human leukocyte antigen (HLA)-identical sibling. Although this approach produced a high remission rate, there were few, if any, cures. Similar to the strategy that evolved with allogeneic transplant, autologous HCT was subsequently used earlier in the clinical course of the disease (first complete remission), for those who lacked a histocompatible sibling donor or who were ineligible for allogeneic transplantation. The high-dose chemoradiotherapy regimens used for autologous HCT in AML are generally derived from those utilized for allogeneic transplant, the most common of which include TBI and cyclophosphamide, TBI, etoposide and cyclophosphamide, busulfan and etoposide, or busulfan and cyclophosphamide.[19–23]

Studies utilizing unpurged marrow, purged marrow, and peripheral blood stem cells have reported disease-free survivals for patients with AML transplanted in first remission ranging between 34%–70%, 41%–76%, and 35%–80% respectively.[24] Although these trials demonstrate the efficacy of autologous transplant, they have been criticized for including patients with a mixture of disease subtypes, cytogenetic risk factors, and pretransplant therapy. In addition, differences in the stem cell product source, manipulation, and in preparative regimens make comparisons between trials and conventional therapy difficult.

Despite the differences, numerous phase II and phase III trials have shown that autologous HCT is a useful alternative for patients who are not allogeneic HCT candidates, especially those with normal cytogenetics. Currently patients with AML with good-risk cytogenetics (8:21; inversion 16) do relatively well with repeated doses of high-dose ARA-C, whereas patients with poor-risk cytogenetics are best treated with an allogeneic approach. Many trials show a similar outcome for autologous HCT compared with allogeneic HCT and a higher cure rate compared with chemotherapy.[25] In one such trial, the European Organization for Research and Treatment of Cancer (EORTC) conducted a prospective randomized trial comparing three postremission treatment strategies in patients who were in a complete remission (CR) after induction therapy.[26] After receiving intensive consolidation therapy, patients with HLA-identical siblings were assigned to the allogeneic transplant arm. The remainder were randomized to receive high-dose treatment followed by autologous BMT or a second course of intensive chemotherapy. Two hundred fifty-four patients were randomized to autologous BMT using cyclophosphamide and either TBI or busulfan or to intensive therapy with high dose ARA-C and daunorubicin. Figure 102–1 shows the Kaplan–Meier estimates of disease-free survival by group. Patients who received intensive therapy had a predicted 4-year disease-free survival of 30% versus 48 and 55% for the autologous and allogeneic bone marrow transplantation (BMT) groups.

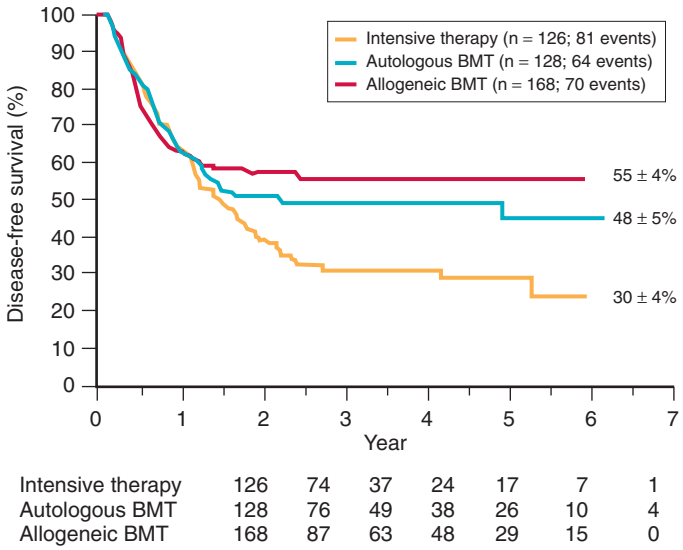

Figure 102–1 Kaplan–Meier estimates of disease-free survival for patients assigned to allogeneic bone marrow transplantation (BMT) (dotted line, $n = 168$), autologous BMT (dashed line, $n = 128$), or intensive consolidation chemotherapy (solid line, $n = 126$). Percentages represent estimated disease-free survival rates ± standard error. (Data from Zittoun RA, Mandelli F, Willemze R, et al: Autologous or allogeneic bone marrow transplantation compared with intensive chemotherapy in acute myelogenous leukemia. European Organization for Research and Treatment of Cancer (EORTC) and the Gruppo Italiano Malattie Ematologiche Maligne dell'Adulto (GIMEMA) Leukemia Cooperative Groups. N Engl J Med 332:217, 1995.)

Despite the apparent improvement over conventional therapy with autologous HCT, the most common cause for failure is relapse. Better definition of the risk factors that predict patients who will relapse and studies that examine patients prospectively based on these factors will further define the role of autologous HCT in patients who are in first remission. The detection of quantifiable minimal residual disease after achieving a remission is one approach being studied to determine the need and timing of transplant.[27]

The role of autologous HCT in second remission is better defined than in first remission as the cure rate with conventional therapy—regardless of the initial leukemic cell characteristics—for such patients is extremely low.[28] Patients have undergone transplant utilizing either chemically or immunologically purged marrow, or utilizing stem cells collected in first remission after achieving second remission. One study comparing autologous transplantation to unrelated donor transplant for advanced leukemia showed that although relapse rates were lower with unrelated donor transplantation, disease-free survival was not significantly different between the two types of transplant.[29]

For patients with acute promyelocytic leukemia in second remission, an analysis of the quantity of leukemic cells in the stem cell product can predict the outcome following autologous transplant. Those patients whose stem cells remain positive for the 15;17 translocation by polymerase chain reaction (PCR) have a high likelihood of relapse, whereas those patients whose reinduction therapy allowed the collection of a PCR-negative stem cell product are often cured by the autologous transplant. These studies indicate that autologous transplant with a PCR-negative stem cell product is a reasonable alternative for patients who do not have a suitable donor and for older patients who achieve a second remission and may not be candidates for allogeneic transplantation.[30]

Patients with newly diagnosed AML have significantly higher chances of long-term disease-free survival presently than two decades ago, largely as a result of better induction and consolidation chemotherapy regimens, supportive care, and the selective use of allogeneic and autologous transplantation. Importantly, knowledge of the cytogenetic and molecular biological characteristics of the patient's leukemia can be used to determine the appropriate therapy and whether the transplant should be performed during first or subsequent remission.

ACUTE LYMPHOBLASTIC LEUKEMIA

Improvements in induction and consolidation therapy for both adults and children with ALL have resulted in improved disease-free survival, particularly those with certain subgroups of disease.[31–33] For those patients with high-risk features, including the Philadelphia chromosome, high white count at diagnosis, and longer time to achieve remission, allogeneic transplantation has also been successfully utilized to prevent disease recurrence.[34] However, many patients with high-risk ALL or those with second CR do not have a readily available histocompatible related or unrelated donor and are candidates for autologous transplant. Despite this, the experience of autologous transplant, both in single institutional studies and larger randomized trials, has been disappointing.[35] At present, there is no clear role for autologous HCT for patients with ALL outside of a clinical trial designed to reduce relapse.

CHRONIC LYMPHOCYTIC LEUKEMIA

Although a large number of patients have undergone autologous transplant for acute leukemia, myeloma, lymphoma, and Hodgkin lymphoma, there have been relatively few studies addressing the issue of autologous transplant in CLL.[36–38] The role of transplant has been limited by the older age of the patient population, and difficulty collecting sufficient stem cells that are not contaminated with leukemic cells. Therefore, patients undergoing transplant represent a highly selected group who have had a very good response to therapy. Although the complete response rate after transplant is high, the overall impact on disease-free survival is difficult to ascertain, with no studies showing a disease-free survival plateau.[39] Nevertheless, studies suggest that it is feasible to perform in selected patients and may extend the duration of remission.[40,41] Recent progress in the initial treatment of CLL, particularly with the addition of anti-CD20 monoclonal antibodies, has increased the number of patients who achieve a complete morphologic remission and may expand the possibility of successful autologous transplant in patients with CLL.

HODGKIN LYMPHOMA

Hodgkin lymphoma, even when advanced, can often be cured with standard doses of combination chemotherapy. However, patients who relapse can achieve further remissions with chemotherapy or radiation treatment but rarely are cured with standard therapy alone. The use of high-dose therapy followed by autologous transplant can produce long-term disease-free survival in selected patients with advanced Hodgkin lymphoma.[42] Reports from single institutions and cooperative group trials indicate that between 30% and 65% of selected Hodgkin lymphoma patients can become long-term disease-free survivors after autologous transplant,[43–49] including some patients with primary refractory disease.[50,51]

A large randomized phase III trial comparing high-dose chemotherapy and stem cell rescue versus standard salvage chemotherapy in patients with relapsed Hodgkin lymphoma was conducted to determine the role of dose intensity on disease response and survival.[52] In this trial, 161 patients with relapsed Hodgkin lymphoma were randomized to receive two cycles of Dexa-BEAM followed by either two subsequent courses of Dexa-BEAM or high dose BEAM and stem cell rescue for all patients with evidence for chemosensitive disease. One hundred seventeen patients were deemed chemosensitive and 56

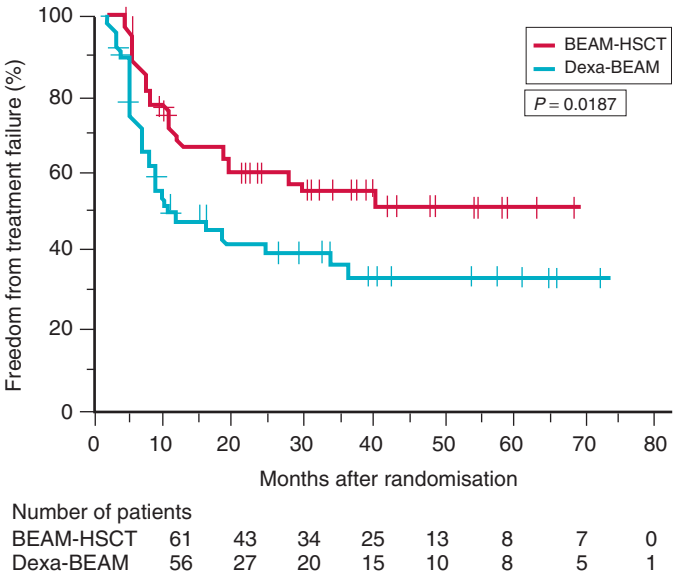

Figure 102–2 Freedom from progression for patients with relapsed chemosensitive Hodgkin lymphoma randomized to conventional therapy (Dexa BEAM) or high dose therapy and autologous stem cell rescue (BEAM HSCT). (Data from Schmitz N, Pfistner B, Sextro M, et al: Aggressive conventional chemotherapy compared with high-dose chemotherapy with autologous haematopoietic stem-cell transplantation for relapsed chemosensitive Hodgkin's disease: A randomised trial. Lancet 359:2065, 2002.)

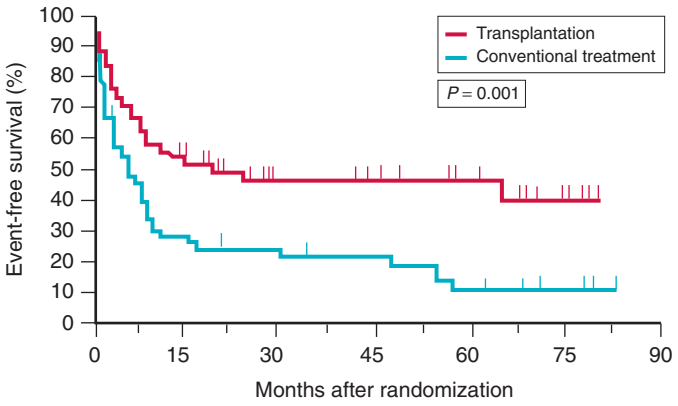

Figure 102–3 Event-free survival in 109 patients with recurrent, chemotherapy-sensitive non-Hodgkin lymphoma (NHL) randomized to high-dose therapy and autologous bone marrow transplantation ($n = 55$) or conventional treatment ($n = 54$). Tick marks represent censored data. (Data from Philip T, Guglielmi C, Hagenbeek A, et al: Autologous bone marrow transplantation as compared with salvage chemotherapy in relapses of chemotherapy-sensitive non-Hodgkin's lymphoma. N Engl J Med 333:1540, 1995.)

underwent standard therapy, with 61 randomized to the high-dose chemotherapy arm. Freedom from treatment failure as shown in Fig. 102–2 was significantly better (55 vs 34%) for patients who underwent autologous transplantation ($P < 0.019$). This treatment advantage was maintained for patients who had early or late relapses. The median time to treatment failure for those patients who received standard chemotherapy was 12 months and has not been reached for the high-dose arm (median follow-up 39 months). There were however no differences as yet in overall survival between the two groups. Of note, 8 of the 17 relapses that occurred following standard chemotherapy had since proceeded to autologous transplantation. This report confirmed the results of a smaller randomized trial performed by the British National Lymphoma group.[53]

An international effort analyzing a large number of patients with Hodgkin lymphoma suggested that there are disease characteristics that predict a high likelihood of relapse after conventional therapy. Several factors were identified, each of which reduced tumor control by 7% to 8%.[54] Among these poor prognostic factors at diagnosis are anemia (Hb < 10.5 g/dL), stage IV disease, male sex, age over 45, albumin less than 4 mg/dL, WBC greater than 15,000/μL, lymphocyte count less than 600/μL (or <8%). Patients with four or more of these features have a poor prognosis and could potentially benefit from early autologous transplantation. Pilot trials for the use of high-dose chemotherapy and transplantation as part of the initial management of Hodgkin lymphoma have been conducted with very optimistic results.[55] To date, no randomized trials comparing early versus late transplant have been performed to answer this question in this group of patients at high risk for relapse.

The preparative regimens used in autologous transplantation for Hodgkin lymphoma have depended on combination chemotherapy, most commonly combinations of Carmustine (BCNU), VP-16 with either cyclophosphamide (CBV) or cytarabine and melphalan (BEAM).[44–52] Augmented CBV regimens have been shown to improve long-term disease control in phase II trials. Given its known effectiveness in the treatment of Hodgkin lymphoma, some programs have also used TBI or total lymphoid irradiation.[48] However, many patients who require transplant have had prior mediastinal mantle radiation, thus precluding the use of TBI as a component of the treatment regimen. The combination of TBI and prior mantle radiation increases prohibitively the risk of cardiac and pulmonary toxicity and likely increases the risk for subsequent development of myelodysplastic syndrome (MDS) or AML. In some cases, irradiation directed to site of bulky or refractory disease can be used following transplantation, to help reduce the chance of relapse in those areas.

NON-HODGKIN LYMPHOMA

Like other tumors, the basis for high-dose chemotherapy and autologous stem cell transplant in non-Hodgkin lymphoma (NHL) is that resistance to standard therapy can be overcome by escalation of doses of drugs or radiation beyond limiting marrow toxicity. The initial reports of successfully incorporating high-dose therapy with autologous transplant were from the National Cancer Institute, where BACT (carmustine, cytarabine, cyclophosphamide and thioguanine) chemotherapy followed by autologous bone marrow transplantation eradicated lymphoma in some patients with "high grade" lymphoma previously considered incurable.[56] These observations led to the development of several trials, including a randomized trial documenting the efficacy of autologous transplant in patients with lymphoma.

INTERMEDIATE GRADE B CELL LYMPHOMA

Several investigations have reported a cure rate of 35% to 40% of patients with chemotherapy-sensitive diffuse aggressive non-Hodgkin lymphoma with high-dose therapy and autologous transplant.[57] These studies were received with great enthusiasm because under ordinary circumstances, less than 10% of patients with relapsed lymphoma can be cured with conventional salvage therapy. Eventually an international randomized trial demonstrated that second-line chemotherapy with cisplatin, cytarabine, and decadron (DHAP) followed by consolidation with high-dose chemotherapy with carmustine, etoposide, cytarabine, and cyclophosphamide (BEAC) and autologous transplant was more effective than continued conventional chemotherapy alone.[58] Patients randomized to the transplant arm had significantly higher CR rates (84% vs 44%). At 5 years, event-free survival (46% vs 12%; $P = .001$) and OS (53% vs 32%; $P = .038$) were significantly superior in transplanted patients (Fig. 102–3). This study was limited to patients under the age of 60 who had achieved a CR after primary therapy and who had no known

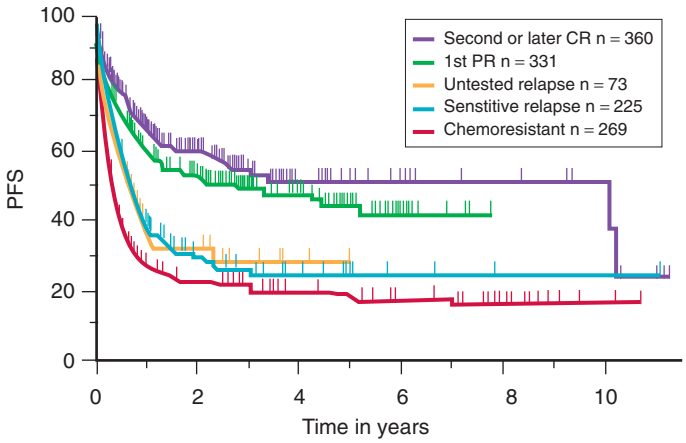

Figure 102–4 Progression-free survival of all adult non-Hodgkin lymphoma (NHL) patients after HDC by status at time of HDC. (Data from Armitage JO: Bone marrow transplantation. N Engl J Med 330:827, 1994.)

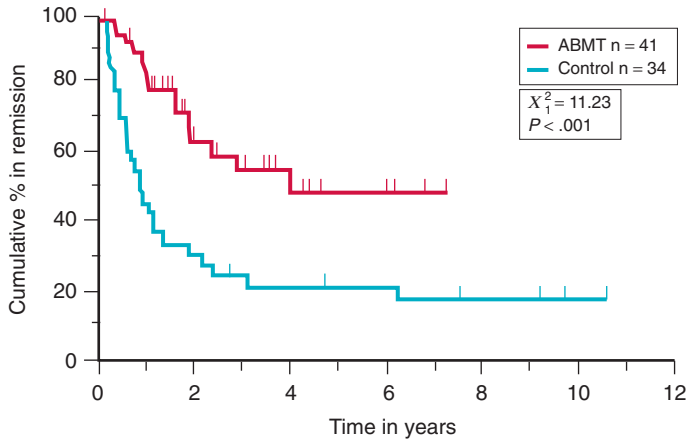

Figure 102–5 Freedom from progression curve in 41 patients with follicular lymphoma in second remission treated with CY/TBI plus autologous bone marrow transplantation compared with 34 historical control patients treated with chemotherapy at St. Bartholomew's Hospital. (Data from Rohatiner AZ, Johnson PW, Price CG, et al: Myeloablative therapy with autologous bone marrow transplantation as consolidation therapy for recurrent follicular lymphoma. J Clin Oncol 12:1177, 1994.)

marrow or CNS involvement and had responded to second-line therapy.

The issue of chemosensitivity appears to play an important part in the overall long-term disease-free survival of patients with lymphoma who undergo autologous transplant. Patients refractory to initial therapy often responded to transplant but suffered a relapse relatively quickly.[59] In addition, those patients with lymphoma who had responded to primary treatment but proved resistant to second-line treatment also had a relatively low response rate. In contrast, patients responding to conventional therapy did well after subsequent autologous transplant. Figure 102–4 shows the long-term disease-free survival for patients with advanced lymphoma depending upon the remission status and sensitivity to chemotherapy.

Some investigators have attempted to identify patients who had poor prognostic features at diagnosis and who were at high risk for relapse even with achievement of a complete remission. These phase II studies showed that early transplant while in first remission resulted in high disease-free survival in patients who would be expected to have had a greater chance of relapse with standard therapy.[60] A large phase III trial comparing chemotherapy alone to chemotherapy followed by transplant in patients with intermediate high-grade lymphoma who had one or more unfavorable prognostic features did not show a significant difference in event-free overall survival in the study arms.[61] However, an analysis limited to poor risk subsets demonstrated significant benefit in disease-free survival for patients with high-dose therapy and autologous transplant.[62] The transplant arm had significantly higher disease-free (55% vs 39%; $P < .02$) and overall survival rates (64% vs 49%; $P < .04$) compared to the sequential chemotherapy arm. Another smaller study randomized high-risk patients to MACOP B for 12 weeks versus high-dose sequential (HDS) therapy and autologous transplantation.[63] At a median 55-month follow-up, the CR rate was 96% in the HDS group, compared with 70% in the MACOP-B group ($P = .001$). Rates of freedom from disease progression (84% vs 49%; $P < .001$), freedom from relapse (88% vs 70%; $P = .055$), and event-free survival (76% vs 49%; $P = .004$) were all significantly superior in the HDS group. Overall survival at 7 years favored the HDS group (81% vs 55%; $P = 0.09$). Currently a large national trial is being conducted to determine if patients with high-risk lymphoma undergoing treatment in the era of rituxan treatment have improved survival if transplanted early or at the time of relapse.[64]

Patients with primary refractory NHL represent a very difficult subset to treat. Fortunately, true refractoriness is relatively rare. Kewalramani et al[65] examined the outcomes of 85 patients who underwent second-line chemotherapy with ICE following failure with first-line induction therapy. Patients were classified as induction partial responders (IPR) or induction failures (IF) according to their response to initial therapy. Forty-three (51%) had chemosensitive disease with no difference in response seen between those who were IPR or IF. Of 42 patients who ultimately underwent ABMT, the 3-year OS and EFS rates were 53% and 44%, respectively, suggesting that even patients with induction failure, as long as they remain chemosensitive, can be cured with transplantation. An analysis of the Autologous Blood and Marrow Transplant Registry study led to similar conclusions.[66]

LOW GRADE B-CELL LYMPHOMA

A number of phase II trials have been conducted to determine the curative potential of high-dose therapy and autologous transplant in patients with "low grade" lymphomas.[67–70] Even if the approach was noncurative, the prolongation of remission itself would be a worthwhile goal for this group of patients. Similar to diffuse aggressive high-grade lymphoma, selection of appropriate patients is key for the success of high-dose therapy and autologous transplant in low-grade lymphoma. The long natural history of patients with low-grade lymphoma makes it difficult to determine if a proportion of patients are cured or had their survival prolonged by high-dose therapy and autologous transplant. Figure 102–5 illustrates what is considered to be the best available historical comparison for patients with recurrent low-grade lymphoma. This analysis from St. Bartholomew's Hospital in London showed that freedom from recurrence and survival for patients treated with CY and FTBI plus purged autologous marrow were improved compared with chemotherapy controls matched for remission status. Although there was a statistically significant advantage in disease control with a high-dose approach, this did not translate into a survival benefit.[67]

Similar to large-cell lymphoma, several groups have attempted to identify patients with low-grade lymphoma with poor-risk features who should undergo transplant during first remission. Disease-free survival in these studies was extended compared to remission durations expected with chemotherapy, and overall survivals to date have been excellent.[71,72] However, based on available data, patients with low-grade lymphoma who have brief initial remission (less than 1 year) and who are responsive to chemotherapy with standard treatment represent a group of patients with very short survivals after relapse and are the most appropriate candidates for high-dose therapy and autologous transplant.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma is a relatively newly recognized disease with a unique phenotype and characteristic genetic abnormality leading to increased expression of cyclin D_1, which accounts for only approximately 6% of cases of adult NHL (see Chapters 79 and 80).[73,74] The median age of onset is 65 years, and the disease predominates in men. Although the disease often responds well to initial chemotherapy, remissions are short, with a median survival of 3 to 4 years. No chemotherapeutic regimen has been shown to be curative, which leads to further investigations of high-dose chemotherapy followed by autologous HCT in first or subsequent remission.[73,74]

There have been a number of single-center trials that have studied autologous HCT in first and subsequent remissions.[75–77] Studies at the University of Nebraska evaluated clinical outcomes and prognostic factors in a group of 40 patients who underwent high-dose chemotherapy and autologous HCT for mantle cell lymphoma between 1991 and 1998.[76] In this report with a median follow-up of 24 months, the 2-year EFS was 36% and the OS was 65%. The only factor that was associated with the poor EFS rate was the number of prior chemotherapy regimens, similar to the prognostic features observed in transplantation for low-grade lymphoma. Those patients who had received 3 or more prior therapies had a 2-year EFS of 0% as compared to 45% for those who had received fewer than 3 therapies ($P = .004$).[76]

A larger, retrospective analysis was performed using data from the EBMT and ABMTR registries on the outcome of 195 mantle cell lymphoma patients who had received an autologous HCT.[78] After a median follow-up of 3.9 years, the 2-year and 5-year PFS rates were 55% and 33%, and OS rates were 76% and 50%, respectively. Patients with chemosensitive disease who were not in a first CR were 2.99 times more likely to succumb to their disease over time than patients transplanted in first CR ($P < .001$), confirming the results observed by many institutions. These reports suggest that patients treated with autologous HCT in first CR have better outcome than patients receiving autologous HCT in subsequent relapses, because of better disease control and decreased disease relapse.

On the basis of these observations, the European Mantle Cell Lymphoma Network performed a prospective randomized trial comparing myeloablative radiochemotherapy followed by autologous HCT to an interferon-α maintenance program in patients in first CR. In their study, 122 patients were assessable; 62 proceeded to autologous HCT and 60 received interferon-α. The patients who underwent the transplantation had a significantly longer PFS, with a median of 39 months compared with 17 months in the interferon arm ($P = .01$). In a subset analysis, patients undergoing transplantation in CR had the greatest benefit. Although longer follow-up is required to determine the difference in OS, collectively, the data suggest that autologous HCT may improve prognosis when performed as part of a first-line treatment strategy in patients with mantle cell lymphoma. However, many patients continue to relapse and as a result autologous HCT does not appear to be curative in the majority of patients. The apparently strong GVL affect seen in mantle cell lymphoma has led to the consideration of reduced-intensity allogeneic transplant in patients in relapse or who fail to achieve a CR with initial therapy.[79,80]

RITUXIMAB AND AUTOLOGOUS STEM CELL TRANSPLANT

Rituximab, a chimeric IgG1 monoclonal antibody that targets CD20, has revolutionized the treatment of B-cell NHL. Two randomized trials have shown that rituximab improves the response rate and survival in patients with advanced-stage DLCL-B when administered in combination with standard chemotherapy (see Chapters 89 and 90). Given its efficacy in depleting B cells with limited toxicity, rituximab has been incorporated into HDT and autologous HCT for DLCL-B as in vivo purging, as part of a high-dose regimen or as maintenance therapy posttransplant to prevent relapse.[82–84]

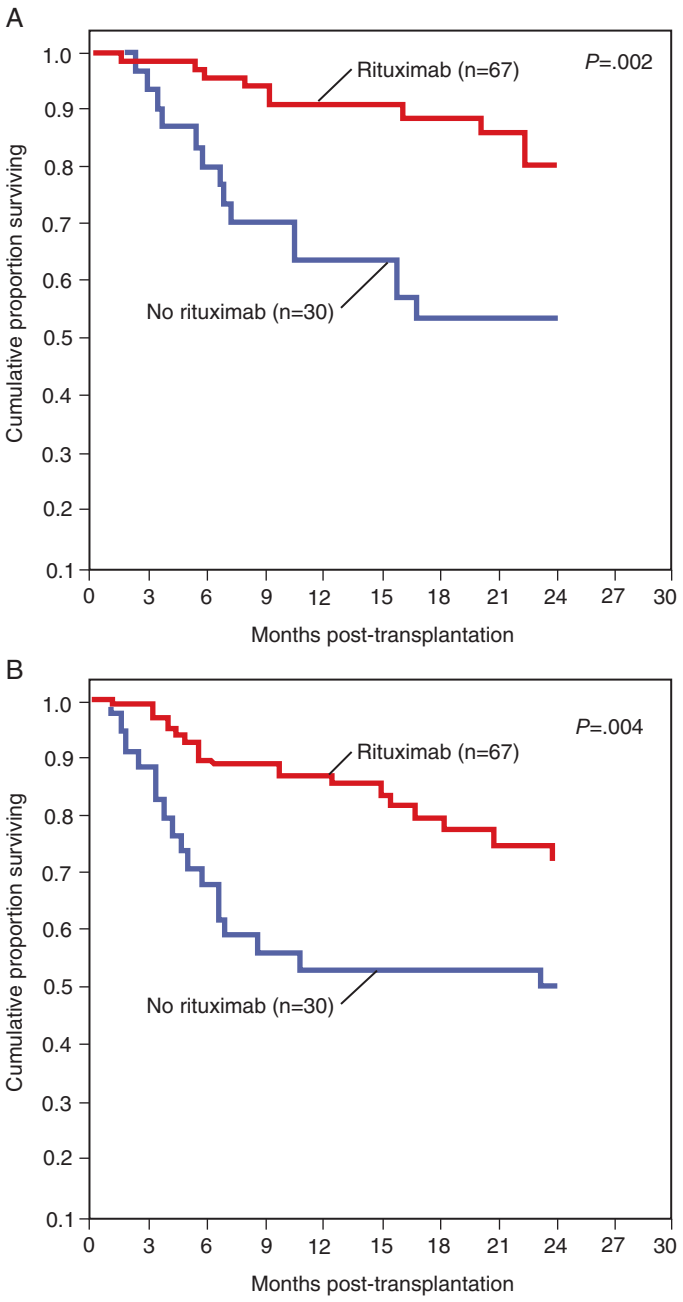

Figure 102–6 Kaplan–Meier estimates of survival (A) and disease free suivival (B) for patients with non-Hodgkin lymphoma by treatment group. (Data from Khouri IF, Saliba RM, Hosing C, et al: Concurrent administration of high-dose rituximab before and after autologous stem cell transplantation for relapsed aggressive B cell non-Hodgkin's lymphomas. J Clin Oncol 23:2240, 2005.)

Khouri et al evaluated the efficacy and safety of administering high-dose rituximab in combination with high-dose BEAM and autologous HCT in 67 patients with recurrent aggressive B-cell NHL.[84] Rituximab was administered during stem cell mobilization at 375 mg/m^2 1 day before chemotherapy and 1000 mg/m^2 7 days after chemotherapy and on days 1 and 8 after transplant. The results of this treatment were retrospectively compared with a historical control group receiving the same preparative regimen without rituximab. With the median follow-up time for the study group of 20 months, the 2-year OS was 80% for the study group compared with 53% for the control group ($P = .002$). The 2-year disease-free survival rates were 67% and 43%, respectively, for the study group and the control group ($P = .004$) (Fig. 102–6). The median time to neutro-

phil recovery of more than 500 cells/μL was 11 days in the rituximab group and 10 days for the matched control group ($P = .001$).

Horwitz et al evaluated the feasibility and toxicity of rituximab post autologous HCT in 35 patients with B-cell NHL (25 DLCL-B) who underwent HDT followed by refulling a purged autologous graft.[85] Rituximab schedule was 4 weekly infusions (375 mg/m^2) starting on day 42 and repeated for a second course at 6 months after transplant. With a median follow-up of 30 months, the 2-year EFS rate was 83% and the OS rate was 88%. For 21 patients with relapsed or refractory DLCL-B, the EFS and OS rates were 81% and 85%, respectively. Grade 3 to 4 neutropenia occurred in 54% of patients; however, the incidence of infection was not increased. Delayed B-cell recovery was observed in all patients and suppressed immunoglobulin G level and low pneumococcal titer were observed in a subset of patients. These results are promising and further studies are required to establish whether posttransplant rituximab can improve cure rates in patients with relapsed or refractory DLCL-B.

RADIOIMMUNOTHERAPY-BASED TRANSPLANT FOR B-CELL LYMPHOMA

Recently, radioimmunotherapy (RIT) has been utilized to improve disease control in patients with B-cell lymphoma. Radioisotope-labeled monoclonal antibodies provide a mechanism by which radioactivity can be directly targeted to tumor sites while sparing normal tissues (see Chapter 82). B-cell lymphomas are attractive targets for RIT because of their radiosensitivity, their well-defined surface antigens, and the availability of multiple monoclonal antibodies to those antigens. There are two US Food and Drug Administration-approved radioisotope-labeled monoclonal antibodies for treatment of relapsed or refractory B-cell NHL: the yttrium 90-labeled ibritumomab tiuxetan (^{90}Y-Zevalin, Biogen Idec, San Diego, CA) and the iodine 131-labeled tositumomab (Bexxar, Corixa, Seattle, WA). In an attempt to deliver target radiation to tumor sites, RIT has been evaluated in myeloablative trials with and without high-dose chemotherapy. Press et al pioneered the use of high-dose RIT in conjunction with autologous HCT in two different trials.[86,87] The first trial used high-dose ^{131}I-tositumomab with autologous bone marrow rescue in 43 patients with B-cell lymphoma in relapse.[86]

Nineteen patients received therapeutic infusions of 234 to 777 mCi of ^{131}I-labeled antibodies followed by autologous marrow infusion. Sixteen patients achieved a CR, two a partial response, and one a minor response. Nine of 16 complete responders have remained in CR for 3 to 53 months. Toxicities included myelosuppression, nausea, infection, and two episodes of cardiopulmonary toxicity. The second study was a phase I/II trial of high-dose ^{131}I-tositumomab, etoposide, and cyclophosphamide and autologous HCT in 52 (38 indolent, 14 aggressive) NHL patients.[87] The maximum tolerated dose of ^{131}I-tositumomab that could be safely combined with high-dose etoposide and cyclophosphamide delivered 25 Gy to critical normal organs. The regimen was well tolerated, with a 15% incidence of grades III and IV toxicity. The estimated OS and PFS at 2 years were 83% and 68%, respectively. The results compared favorably with those in a nonrandomized control group of patients who underwent autologous HCT using TBI, etoposide, and cyclophosphamide during the same period (53% OS and 36% PFS at 2 years) (Fig. 102–7).

Nademanee et al[88] evaluated high-dose ^{90}Y-ibritumomab tiuxetan in combination with high-dose etoposide 40 to 60 mg/kg and cyclophosphamide 100 mg/kg in 31 patients with poor-risk or relapsed B-cell NHL, including 14 patients with DLCL-B.[88] The median number of prior chemotherapy regimens was two (range, 1–6). All but two had received rituximab either alone ($n = 8$) or in combination with chemotherapy ($n = 21$). The median ^{90}Y-ibritumomab tiuxetan dose delivered was 72 mCi (range, 37–105) to deliver a target dose of 1000 cGy to the highest normal organ. The treatment was well tolerated, with mucositis and neutropenic fever being the most

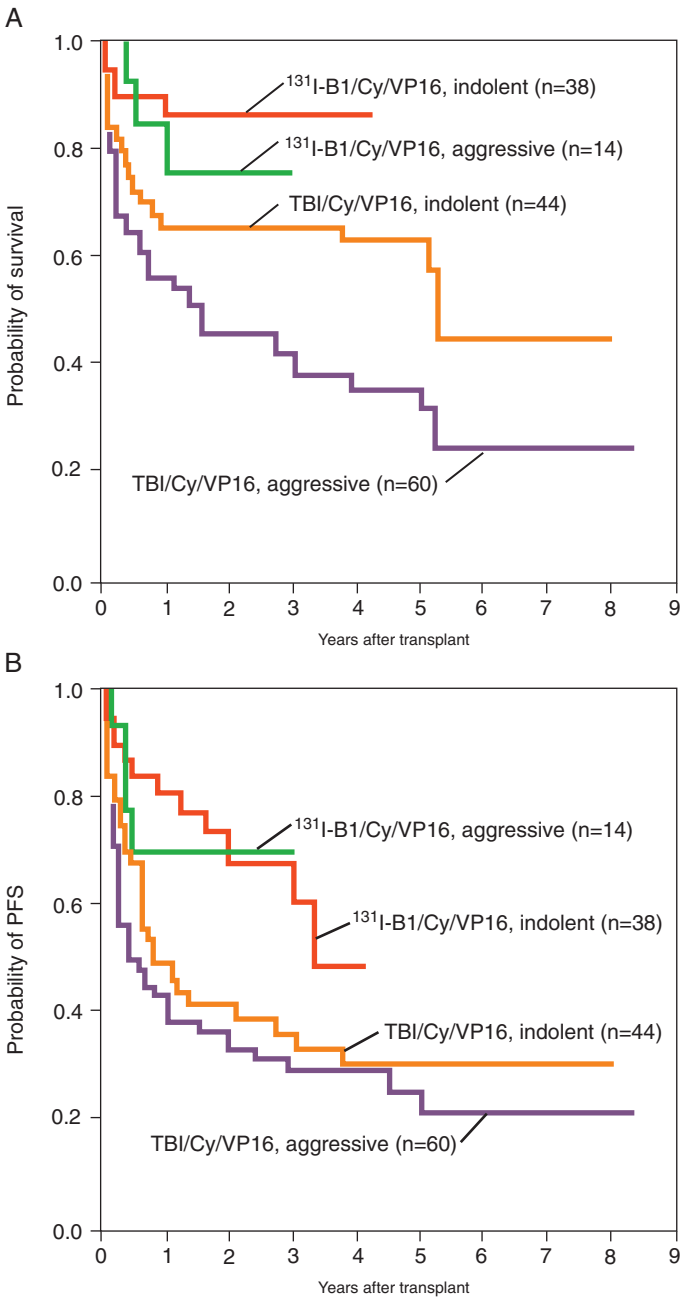

Figure 102–7 Survival analyses according to type of lymphoma. **A**, Overall survival in 38 patients with relapsed indolent lymphomas and 14 patients with relapsed aggressive lymphomas treated with ^{131}I-tositumomab, etoposide, cyclophosphamide, and ASCT and in 44 patients with relapsed indolent lymphomas and 60 patients with relapsed aggressive lymphomas treated with external-beam TBI (1.5 Gy twice a day for 4 days), etoposide (60 mg/kg), cyclophosphamide (100 mg/kg), and ASCT. **B**, Progression-free survival in 38 patients with relapsed indolent lymphomas and 14 patients with relapsed aggressive lymphomas treated with ^{131}I-tositumomab, etoposide, cyclophosphamide, and ASCT and in 44 patients with relapsed indolent lymphomas and 60 patients with relapsed aggressive lymphomas treated with external-beam TBI (1.5 Gy twice a day for 4 days), etoposide (60 mg/kg), cyclophosphamide (100 mg/kg), and ASCT. (Data from Press OW, Eary JF, Gooley T, et al: A phase I/II trial of iodine-131-tositumomab (anti-CD20), etoposide, cyclophosphamide, and autologous stem cell transplantation for relapsed B-cell lymphomas. Blood 96:2934, 2000.)

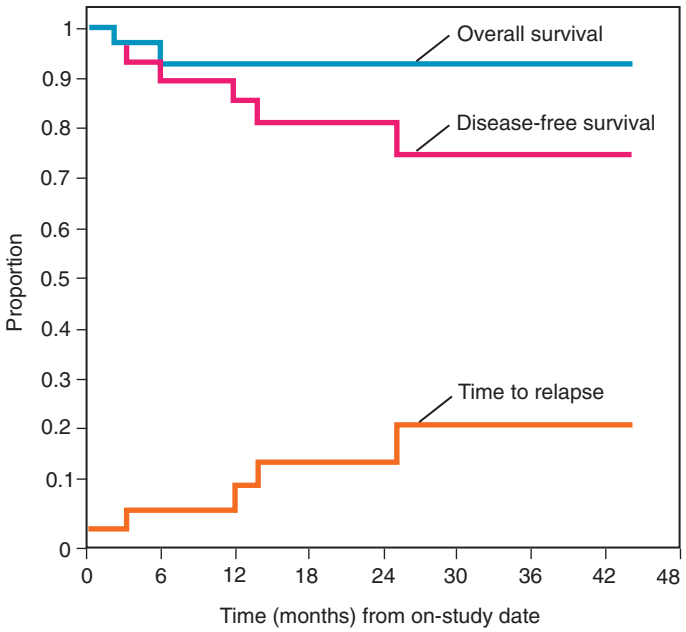

Figure 102–8 Kaplan–Meier estimated 2-year overall survival, disease-free survival, and relapse for 31 patients who received high-dose ^{90}Y-ibritumomab tixetan etoposide and cyclophosphamide plus ASCT in NHL. (Data from Nademanee A, Forman S, Molina A, et al: A phase 1/2 trial of high-dose yttrium-90-ibritumomab tiuxetan in combination with high-dose etoposide and cyclophosphamide followed by autologous stem cell transplantation in patients with poor-risk or relapsed non-Hodgkin's lymphoma. Blood 106:2896, 2005.)

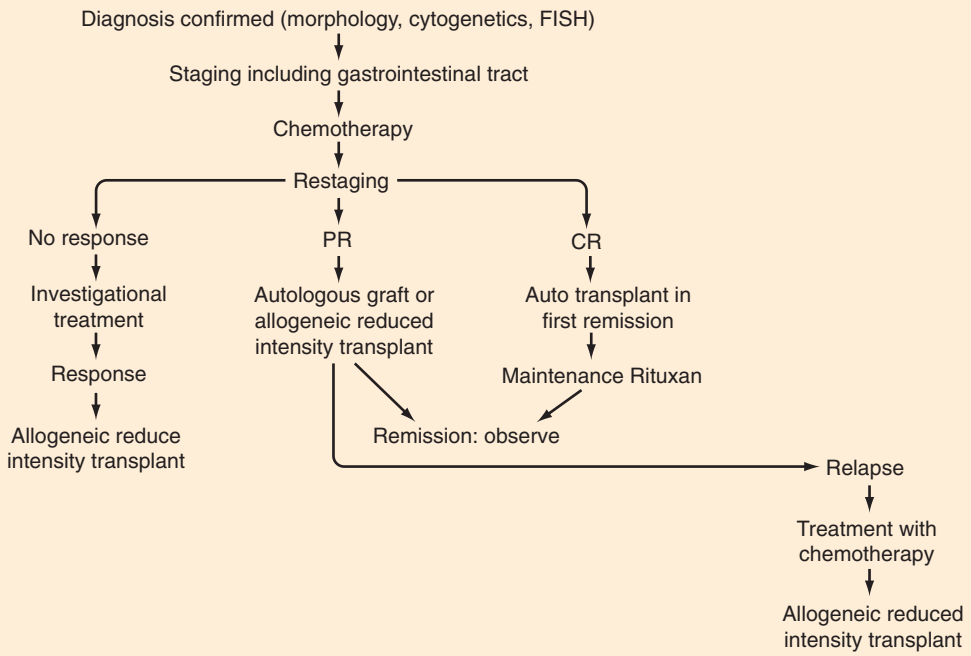
common acute toxicities. There was no delay in engraftment. All patients with active disease at transplant achieved remission, although five patients relapsed. At a median follow-up of 22 months, the 2-year estimated OS and disease-free survival rates were 92% and 78%, respectively (Fig. 102–8). These results indicate the feasibility of delivering high-dose RIT, either ^{90}Y-ibritumomab tiuxetan or ^{131}I-tositumomab, in combination with high-dose chemotherapy in an autologous HCT setting for B-cell NHL.

Given the complexity of delivering high-dose RIT, several investigators have chosen to add conventional doses or lower doses of ^{131}I-tositumomab or ^{90}Y-ibritumomab tiuxetan to high-dose BEAM regimen followed by autologous HCT. Vose et al conducted a phase I/II study evaluating the addition of a standard outpatient dose of ^{131}I-tositumomab in four doses cohorts (30, 45, 60, and 75 cGy) to the BEAM regimen in 23 patients with chemotherapy-refractory or multiply relapsed aggressive B-cell NHL.[89] The treatment was well tolerated without additional toxicity. The CR rate after transplantation was 57% and the overall response rate was 65%. At a median follow-up of 38 months, the 3-year EFS was 39% and OS was 55%. Winter et al evaluated escalating doses of ^{90}Y-ibritumomab tiuxetan to deliver 100, 300, and up to 1300 cGy to normal organs followed by high-dose BEAM and autologous HCT.[90] Thirty-five patients with B-cell NHL were treated, including 16 with DLCL-B and 7 with transformed NHL. The median number of chemotherapy regimens was three. All patients received individualized RIT doses, which ranged from 100 to 1300 cGy. Thirteen patients received ^{90}Y-ibritumomab tiuxetan doses of 0.5 mCi/kg or higher. There was no delay in hematopoietic recovery. One patient experienced asymptomatic decreases in diffusion capacity less than 50% and one had grade IV hepatotoxicity. At a median follow-up of 14 months, the median survival had not been reached. Three-year OS and PFS were 65% and 42%, respectively. Krishnan et al evaluated the combination of standard-dose ^{90}Y-ibritumomab tiuxetan 0.4 mCi/kg and high-dose BEAM followed by autologous HCT in 24 older patients (median age 60 years) with relapsed aggressive B-cell NHL (10 DLCL, three transformed).[91] Median granulocytes and platelet engraftment occurred at days 11 and 13, respectively. At a median follow-up of 13 months, OS and PFS were 98% and 74%, with a relapse rate of 21%. The regimen was well tolerated even in these older patients and toxicity was similar to high-dose BEAM. These studies suggest that a standard dose of RIT can be added to high-dose chemotherapy in the autologous HCT setting without additional toxicity. Additional studies with RIT and autologous HCT are ongoing and preliminary results suggest that these approaches may be superior to conventional high-dose regimens.



PERIPHERAL T-CELL LYMPHOMA

Mature T- and natural killer cell lymphomas constitute a rare and heterogeneous group of neoplasms. Their incidences vary according to the geographic region and ethnic origin of the population. In general, peripheral T-cell lymphomas are defined by their postthymic origin, in comparison to precursor T-cell lymphomas, which includes lymphoblastic lymphoma. The importance of the T-cell phenotype as well as the other subtypes of the disease is being increasingly recognized as separate clinical-pathologic entities, with the primary chemotherapy and transplant approaches being evaluated in light of this new knowledge. The revised European/American Lymphoma Classification utilizes information regarding morphology, phenotype, and molecular and clinical information to provide a more unified scheme for all lymphoid malignancies, and included peripheral T-cell lymphoma. This provided the basis for the recently published WHO classification with the important separation of cutaneous, systemic, and anaplastic types of T lymphomas. Reports based on earlier classifications did not distinguish prognosis among B- and T-cell lymphomas. However comprehensive studies in recent years demonstrated that the T-cell phenotype has a negative impact in overall survival. (See Chapters 78–80 for details of treatment and classification of peripheral T-cell lymphoma).

Similar to research work in distinguishing the various histologies and molecular characteristics of B-cell lymphomas and their impact on treatment, the same approach has now been conducted in the analysis of peripheral T-cell lymphomas. For example, anaplastic large-cell lymphoma, identified by its very pleomorphic appearance and expression of CD30 on tumor cells, can be separated into those that demonstrate overexpression of the anaplastic lymphoma kinase (ALK) and those that do not. The abnormal expression is due to a characteristic acquired genetic abnormality that leads to overexpression of the ALK gene on chromosome 2. This results in a different clinical outcome with a 5-year overall survival for patients with ALK-positive, systemic anaplastic T-cell lymphoma, between 65% and 90% compared with 30% to 40% for a group of patients whose tumor was ALK-negative. In addition, the International Prognostic Index (IPI) utilized to define prognosis among patients with B-cell lymphoma is also applicable to patients with T-cell lymphoma. Given the varying prognosis among patients with these diseases, transplantation has also been utilized in patients who present with poor prognosis disease and with patients with relapsed disease.

With the poor outcome in most patients with peripheral T-cell lymphomas utilizing CHOP-type treatment, several studies have been conducted to study autologous HCT as consolidation therapy with patients with peripheral T-cell lymphoma, including anaplastic large-cell lymphoma.[92–94] In one study made up of predominantly young patients, an encouraging 5-year overall survival of 80% was reported after initial chemotherapy followed by autologous transplant.[93] A recent study of patients with advanced disease and a high IPI showed the 2-year overall survival and disease-free survival at 83% for patients transplanted after achievement of remission, compared with 45% for those patients transplanted beyond first remission, with little differences between the various types of T-cell lymphoma, including anaplastic large-cell lymphoma, peripheral T-cell lymphoma, and angioimmunoblastic lymphadenopathy.[95] Patients with relapsed peripheral T-cell lymphoma who demonstrate chemosensitivity appear to have approximately a 35% disease-free survival rate.

Transplant approach to mantle cell lymphoma

Patients with refractory disease have much less favorable outcome, very similar to what is seen in relapsed B-cell lymphoma. Although the studies are smaller than have been conducted with B-cell lymphoma and randomized trials are limited, the data suggest that those patients with peripheral T-cell lymphoma with a high IPI or ALK-negative disease are reasonable candidates for treatment with autologous HCT early in the course of disease. For patients with relapsed disease, a transplant may be the only curative option.

MULTIPLE MYELOMA

Multiple myeloma is part of a spectrum of disorders referred to as plasma cell dyscrasias that includes benign conditions such as monoclonal gammopathy (see Chapter 87) and accounts for approximately 10% of hematologic tumors with a median presentation age of approximately 65 years. Symptomatic multiple myeloma (MM) requires initiation of systemic therapy utilizing combination chemotherapy, most commonly with thalidomide and dexamethasone, with new combination therapy showing improved response and depth of remission using agents such as thalidomide, lenalidomide and bortezomib.[96] Very few patients achieve a true complete remission and the median survival is approximately 36 months.

High-dose cytotoxic therapy combined with autologous transplant was first considered for MM in 1986, resulting in some patients' having prolonged survival with minimal disease activity.[97] In 1983, investigators from the Royal Marsden Hospital explored high-dose melphalan alone at a dose of 140 mg/m².[98] The observation of true complete remissions following this procedure performed without hematopoietic growth factor and stem cell support led to the introduction of autologous transplant in the mid-1980s initially in support of higher-dose melphalan or melphalan combined with TBI.[99,100] An underlying hypothesis in these trials was that the reinfusion of typically hypoproliferative tumor cells with low in vitro clonogenic potential would not contribute significantly to disease recurrence despite their presence in the marrow graft. This led to studies focused on high-dose therapy given during the early phase of disease as well as the exploration of multiple cycles of high-dose therapy, each supported by stem cells.

A number of phase II studies indicated a high response rate as well as apparent improved disease-free survival in patients undergoing high-dose therapy for MM.[101–103] These studies have achieved a 40% to 50% complete remission rate with a median duration of progression-free survival of 24 to 36 months.[104] Patients with chemosensitive tumor cells or who are less heavily pretreated have the most favorable outcome. The major favorable prognostic features associated with EFS and OS after autologous HCT include low levels of β2M and CR prior to transplantation; the absence of "unfavorable cytogenetics" (ie, abnormalities of chromosomes 11 and 13); less than 12 months of standard therapy preceding transplantation; and non-IgA myeloma. Combinations of these important prognostic variables allow a risk-based therapeutic approach of MM patients.[105]

In 1995 Attal et al published a French trial of 200 patients with MM, demonstrating the efficacy of high-dose therapy in improving the outcome of patients with myeloma.[106] In this trial, patients received two courses of vincristine, melphalan, cyclophosphamide, and prednisone (VMCP) alternating with vincristine, carmustine, doxorubicin, and prednisone (VBAP) and were then randomized to receive either conventional chemotherapy (eight additional courses of VMCP/VBAP) or high-dose therapy (melphalan and TBI) followed by autologous transplant. The transplant patient demonstrated significantly higher response rates, event-free survival (EFS), and overall survival (OS) compared with conventional therapy. Response rates in the high-dose and conventional arms were 81% and 57%, respectively. The 5-year probability of EFS and OS was 28% and 52% in recipients of high-dose therapy, and only 10% and 12% in patients treated with conventional therapy: the treatment-related mortality was comparable between the two groups (Fig. 102–9). Attempts to improve on this outcome including the use of autologous either depleted of tumor cells or processed to select normal hematopoietic progenitor cells have not improved outcomes although several log tumor depletion is obtained. This and other similar trials make

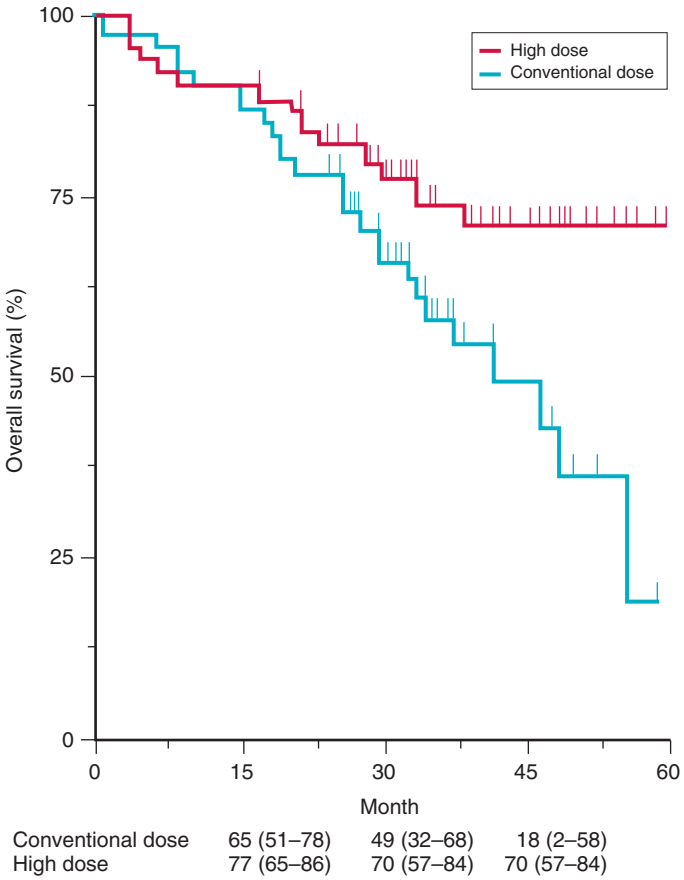


Figure 102–9 Overall survival according to treatment group in patients with multiple myeloma 60 years old or less who were treated with either conventional dose or high dose chemotherapy. (Data from Attal M, Harousseau JL, Stoppa AM, et al: Autologous bone marrow transplantation versus conventional chemotherapy in multiple myeloma: A prospective, randomized trial. N Engl J Med 335:91, 1996.)

autologous transplantation part of the standard of care for most patients with symptomatic myeloma, even with high-risk features.[107] At many centers it is now the most common indication for autologous transplantation.

There are still a number of issues that remain regarding transplant for MM. One key issue is the timing of transplantation. One study collected stem cells upfront on patients and then randomized them to early versus late (at time of disease progression) transplantation.[108] The patients in the late-transplant arm received chemotherapy with VMCP and were transplanted if they had disease progression or relapse following a plateau phase. One important characteristic is that patients did not have further therapy to ensure disease sensitivity but rather went directly to transplantation. In this trial, there was no difference in the median survival rates between the two groups.

Myeloma, like many malignancies, tends to be more common in older patients. Importantly, several studies have now demonstrated that patients over the age of 60 have comparable outcomes to younger patients.[109–111] In addition, it appears that patients with renal failure on the basis of myeloma also show similar benefits from high-dose therapy.[112]

Several centers have been utilizing a tandem autologous transplant approach in attempts to improve the overall disease-free survival in patients with myeloma. An update of one trial suggested that patients who undergo a second transplant have increased the 7-year event-free survival to 20% and the overall survival to 42%, representing a doubling of the results obtained with a single transplant (Table 102–3).[113] A recent update of a study of single versus double transplant suggested that the double cycle was most effective in those patients who did not have a very good partial response after undergoing one transplant (Fig. 102–10)[114]—a result that has been confirmed in another prospective trial.[115] Some studies now suggest a role for maintenance treatment to extend the duration of the remission.[116] Other studies have suggested that a single transplant with a second one at the time of early relapse may be as efficacious.[117] Although transplant may improve the outcome for many patients with myeloma, there are many important questions that are being studied, including the following:

1. Benefit of one versus two autologous transplants and in upfront treatment
2. Timing of autologous transplant (early vs late)
3. Impact of remission prior to or after first transplant on the need for a second autologous transplant
4. Role of maintenance therapy after autologous transplant—which regimens, and for how long?
5. Does maintenance therapy obviate the need for a second autologous transplant?
6. Impact of gene array and cytogenetic analysis on the benefits of transplant or maintenance therapy.
7. Optimal transplant regimen
8. Potential for immunotherapy after transplant.

Table 102–3 Final Results of IFM Trial of Single vs Double Transplant in Multiple Myeloma Patients Under 60 Years of Age

Outcome	Single Transplant	Double Transplant	*P*
CR or good PR	42%	50%	.15
Events	87%	79%	.03
Median EFS	25 months	30 months	.05
7-Year EFS (estimated)	10%	20%	<.03
Deaths	72%	56%	.001
Median OS	48 months	58 months	.01
7-Year OS	21%	42%	<.01

IFM, intergroup francophone du myélome; CR, complete remission; PR, partial remission; EFS, event-free survival; OS, overall survival.

AMYLOIDOSIS

Primary amyloidosis is a clonal plasma-cell dyscrasia in which systemic disease results from extracellular deposits of proteinaceous material in end organs such as the heart, kidneys, and the peripheral nervous system (see Chapter 89). In contrast to myeloma, the percentage of plasma cells in the bone marrow tends to be low. Owing to its pattern of end-organ damage, autologous HCT for amyloid has been associated with a 4 to 8 times higher mortality than for myeloma. The presence of cardiac amyloid contributes most significantly to the mortality. The amyloid protein can diffusely infiltrate the GI tract and, therefore, GI bleeding is also a significant cause of transplant-related mortality. Attempts to reduce mortality have included a risk-adapted approach, with stratification based on the extent of end-organ involvement, although this may be at the cost of lower response rates.[118–120]

LONG-TERM COMPLICATIONS OF AUTOLOGOUS TRANSPLANTATION

Most patients will recover from the acute effects of the high-dose regimens used in the treatment of the disease. This has been facilitated by the use of mobilized stem cells, growth factors and optional use of antibiotics, antifungal agents and transfusion support. However,

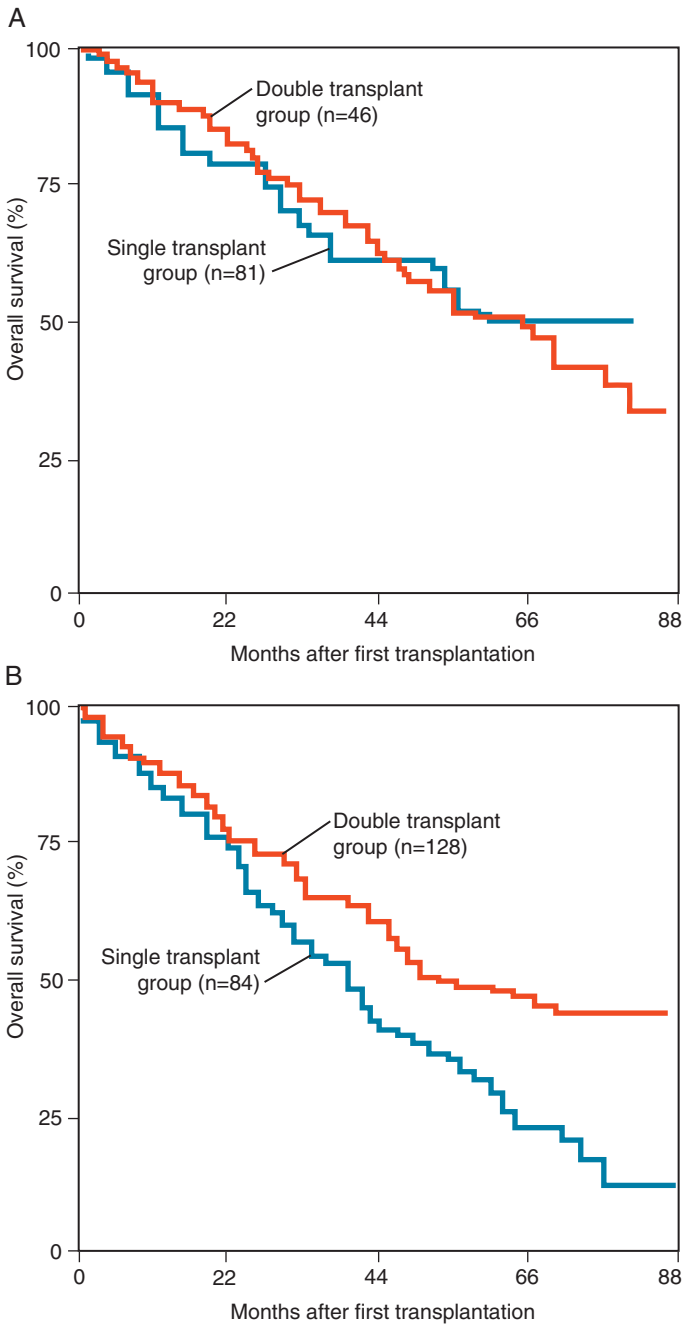

Figure 102–10 Single vs double HCT for multiple myeloma. (Data from Attal M, Harousseau JL, Facon T, et al: Single versus double autologous stem-cell transplantation for multiple myeloma. N Engl J Med 349:2495, 2003.)

all patients are at risk for long-term problems that require follow-up and care.[121]

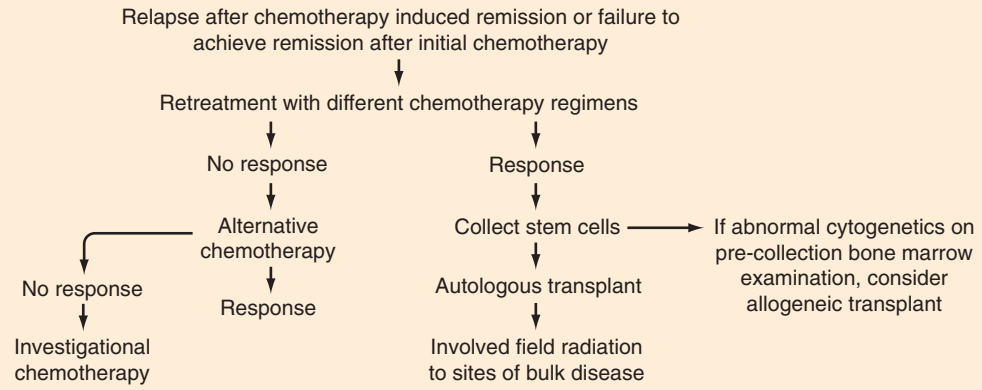
Cataracts

Cataracts are usually a complication that results from the use of TBI in the preparatory regimen. An analysis from the European Bone Marrow Transplant Registry indicated that cataracts developed only in those patients who received TBI.[122,123] Depending on the degree of impairment of visual acuity, lens replacement can be performed with excellent results.

Secondary Malignancies

The most important long-term complication of autologous HCT is the development of MDS or secondary leukemia.[124–126] The incidence of secondary acute leukemia and MDS, although difficult to assess, appears to be substantially lower in patients undergoing transplant for AML than those receiving similar preparative regimens for lymphoma and Hodgkin lymphoma. This finding has been attributed to the type of prior therapy that is utilized in patients with Hodgkin lymphoma, lymphoma, and myeloma (alkylating agents, topoisomerase I and II inhibitors) as opposed to patients with acute leukemia whose therapy is built around the use of anthracycline and cytosine arabinoside. MDS is reported to occur in 6% to 15% of patients undergoing autologous HCT for lymphoma or Hodgkin lymphoma.[127,128] A second factor that has been implicated has been the type of stem cells (marrow versus peripheral blood) that are reinfused. Some studies have suggested that patients who receive peripheral blood cells rather than marrow grafts have higher incidences of MDS, as well as patients who had their stem cells mobilized using VP16 and have the 11q23 abnormality that is seen following topoisomerase exposure. The third factor that has been implicated as a potential risk factor for the development of MDS in many studies is the use of a TBI-based transplant regimen.[128]

Further investigation is still necessary and it is clear that patients who have had high previous alkylator exposure should be carefully evaluated for the presence of MDS prior to proceeding with autologous transplantation. For patients who are noted to have abnormalities prior to transplant or those who develop this complication secondary to transplant, allogeneic HCT is the best option for treatment.



Infertility

One of the major complications of high-dose chemoradiotherapy for the treatment of hematologic malignancy is infertility, a frequent concern expressed by young patients who are being evaluated for transplant.[129] With current methods, men are sometimes able to collect viable sperm for future use and women are able, under some circumstances, to cryopreserve fertilized ova for implantation following transplantation. New techniques involving the harvesting of and storage of ova prior to fertilization will further expand the possibilities for female patients. Despite these technical advances, the expense is often limiting and there is not always sufficient time to collect sperm or fertilized eggs prior to proceeding to urgently needed antitumor therapy. For patients who wish to consider a family, it is imperative that this is addressed early in the course of their disease well before transplant is anticipated because often the therapy prior to transplantation can reduce the quality and quantity of viable sperm necessary for storage.

Impairment of ovarian function after radiation depends on the radiation dose and the patient's age.[130] Patients who are young and receive TBI can, on rare occasions, recover ovarian function and fertility. Nevertheless, for the vast majority of patients receiving high-dose radiotherapy-containing regimens, infertility is a long-term problem.

For men given TBI, more than 90% of patients are azoospermic and have elevated follicle-stimulating hormone levels. There is less effect on testosterone levels, with some patients having normal luteinizing hormone levels and normal levels of testosterone. However, some patients demonstrate hypogonadism requiring replacement therapy (transdermal testosterone patches or intramuscular injections). Women who develop an early menopause can usually be treated with hormone replacement therapy to avoid secondary problems of osteoporosis and sexual dysfunction. The effect of these therapies on sexual satisfaction is also an important one. As the number of long-term survivors undergoing autologous transplant increases, the issues of fertility and normal sexual function are becoming increasingly important problems that require sensitive attention.[129,131]

Clinical approach to autologous transplant for Hodgkin Lymhoma

FUTURE DIRECTIONS

Although autologous HCT represents an important component of cancer care, relapse continues to be the major cause for failure regardless of the underlying disease. It is likely that in the future, rather than being seen as a treatment that stands alone autologous HCT be seen as part of an overall treatment plan for individual malignancies, with both pretransplant and posttransplant strategies affecting the outcome. Because its main efficacy is derived by tumor debulking, it may be possible to activate the immune system using combinations of growth factors (IL 2, GM CSF), tumor-based vaccines, and dendritic cells or other immune-based or -targeted therapy that may be most effective when there is a low tumor burden, such as monoclonal antibodies, antiangiogenic factors, and genetically modified T cells. Another possibility that is being actively explored is combining the relative safety of autologous transplant to largely debulk tumors and then utilizing nonmyeloablative allogeneic transplants with less toxicity to derive the benefit of a graft-versus-tumor effect, as has been reported in MM.[132] Some combination of these or similar approaches will enable continued improvement in survival to these devastating illnesses.

CHAPTER 103

UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

Effie W. Petersdorf and Claudio Anasetti

The outcomes of unrelated donor hematopoietic cell transplantation (HCT) have greatly improved as a result of better understanding of the diversity of genes that give rise to host-versus-graft (HVG) and graft-versus-host (GVH) allorecognition. Development of robust typing methods that define functional variation of human leukocyte antigen (HLA) and killer immunoglobulin-like receptor (KIR) genes have greatly accelerated understanding of gene–gene interactions that lead to graft failure, graft-versus-host disease (GVHD), and graft-versus-leukemia (GVL). Elucidation of which HLA molecules are the ligands for KIR receptors of natural killer (NK) cells and discovery of the pivotal role played by NK alloreactivity are opening up new avenues for potential antitumor therapy. Continued growth of registries of volunteer donors worldwide now provides the potential for identifying suitable donors for up to 80% of Caucasian patients in need of a transplant. The major challenges are to increase the safety and efficacy of unrelated donor HCT therapy through improved prevention and treatment of GVHD, while leveraging control of leukemia through GVL effects. For unrelated HCT to be more widely applied to patients of diverse ethnic and racial background, more information on permissible HLA mismatches is needed so that mismatched donors can be safely used when matched donors are not available. This chapter chronicles genotyping methods used for donor selection and the clinical results of unrelated donor HCT in the era of DNA typing for HLA and KIR genes.

VOLUNTEER REGISTRIES

The field of allogeneic transplantation has witnessed a rapid growth in the use of unrelated donors over the last 15 years. In an European Group for Bone Marrow Transplantation (EBMT) survey, unrelated donor transplants accounted for the largest increase among allogeneic transplants in Europe.[1] A total of 24,168 first transplants were performed yearly, of which 37% were allogeneic and 14% from unrelated donors. The primary indications for unrelated donor HCT were leukemia (acute myeloid leukemia [AML], acute lymphoblastic leukemia [ALL], chronic myeloid leukemia [CML], chronic lymphocytic leukemia) 63%, myelodysplastic syndrome (MDS) 10%, lymphoma 9%, and nonmalignant disorders 8%. In the United States, unrelated donor transplants are performed for treatment of leukemia (65%), MDS (8%), lymphoma (10%), and nonmalignant disorders (9%) (http://www.marrow.org). In 2006 alone, more than 1000 transplants were performed in patients 50 years and older.

Unrelated HCT has been made feasible by the establishment of registries of volunteer donors worldwide. The Anthony Nolan Appeal was the first effort to demonstrate the feasibility of donor recruitment.[2] Now known as the Anthony Nolan Research Institute, this registry was the first to promote access to HLA-matched marrow donors for patients around the world. In the United States, early efforts for donor recruitment were spearheaded by individual centers.[3] Growing interest in unrelated donor HCT led the U.S. Congress to authorize the creation of a national registry comprising a network of donor centers, transplant centers, and a national coordinating center through the Transplant Act of 1984. Two years later, a federal contract to establish a national registry was awarded to the National Marrow Donor Program (NMDP) (http://www.nmdp.org).[4] In the Netherlands, Professor Jon J. van Rood led the Europdonor Foundation in the collection of HLA data from donor registries around the world and in the formation of a database of HLA phenotypes known as Bone Marrow Donors Worldwide (BMDW) (http://www.bmdw.org).[5] Continued growth in registry size worldwide has increased the chances that well-matched donors can be identified. The NMDP registers 25,500 new donors each month and more than 300,000 each year (www.marrow.org). Today, more than six million donors are available through the NMDP, and more than five million donors are available through international cooperative agreements with registries around the world. With this database of 11 million donors, the average likelihood of identifying a potential donor for bone marrow (BM) or peripheral blood stem cells (PBSC) is 84%.

The median time from initiation of a formal unrelated donor search to a request for a donation is 51 days (http://www.marrow.org). Although more than half of all U.S. patients who initiate a search will have 10 or more suitably matched NMDP donors, efficiency of the search process is highly dependent on the racial and ethnic background of the recipient and the composition of the registry.[6] A Dutch study of 549 unrelated donor searches conducted between 1987 and 2000 showcased the differences between median search times for patients of Northwestern and non-Northwestern European descent.[7] Whereas almost 60% of Northwestern European patients received a transplant within a median time of 4.4 months from the start of the search, only 32% of non-Northwestern European patients were able to identify suitable donors, and half did not have a compatible donor. For all patients, the efficiency with which the unrelated donor search is conducted is critical, and guidelines for planning transplantation as well as approaches for surmounting the unique challenges of finding donors are available (http://www.asbmt.org/policystat/policy.html).[7,8]

DONOR EVALUATION AND SELECTION

Selection of unrelated donors includes consideration for the level of the HLA tissue type match with the recipient and the presence of recipient antidonor antibodies, which place the patient at high risk for nonengraftment.[9,10] Criteria other than HLA are considered for donor selection when more than one HLA-identical match is available for a given patient. An NMDP analysis designed to study donor variables associated with transplant outcome examined 6978 transplants performed between 1987 and 1999.[11] Improved recipient survival and disease-free survival (DFS) were observed with use of young BM donors; these transplant recipients experienced lower risks of both acute and chronic GVHD. With each increasing decade of donor age, the risk of acute and chronic GVHD increased by 10%. This study did not find any effects of donor gender on engraftment, acute GVHD, or survival. However, transplantation from parous female BM donors was associated with increased risk of chronic GVHD. Among female parous donors, the relative risk was 1.19 with a history of a single pregnancy and increased to 1.40 with two or more pregnancies. In general, larger (male) donors provide larger BM and PBSC cell doses compared to smaller (female) donors.[6,12] Donor ABO blood type does not affect the risk of GVHD or mortality. In an updated NMDP analysis of 7043 transplants performed between 2000 and 2004, the donor–recipient HLA match status and younger

Table 103–1 Common Definitions in HLA Genetics

Term	Definition	Example
Allele	Unique sequence of an HLA gene defined by molecular methods	DRB1*0401 allele is a unique sequence defined as DR4 by serologic methods
Antigen	Antibody-defined protein	DR4 antigen is a serologically defined protein product of an HLA gene
Haplotype	HLA genes inherited as a chromosomal unit	HLA-A1, HLA-B8, HLA-DR3 is a common haplotype among white populations
Genotype	Molecularly defined HLA allele or sequence	Genotypically matched donor and recipient are identical for the HLA alleles at a given HLA gene (e.g., HLA-DRB1*0401)
Phenotype	Serologically defined HLA protein or antigen	Phenotypically matched donor and recipient share the same HLA antigen (e.g., HLA-DR4)

HLA, human leukocyte antigen.

donor age were the two variables significantly associated with clinical outcome.[6]

Evaluation of unrelated donors includes a screening medical history, physical examination, and laboratory testing for risks associated with transmissible elements akin to blood transfusion donors. Special focus is placed on risks of transmission of hepatitis, human immunodeficiency virus (HIV), malaria, West Nile virus, transmissible spongiform encephalitis (Creutzfeldt-Jacob disease), and Chagas disease. Donor screening includes blood tests for human immunodeficiency virus 1 and 2, hepatitis B virus, hepatitis C virus, *Treponema pallidum*, human T-cell lymphotrophic virus I and II, and cytomegalovirus.

The importance of a "backup" donor has been increasingly recognized.[8] In a Dutch study of 502 unrelated donor evaluations, 46 were canceled, 78% were deferred due to medical reasons, and 22% were deferred due to nonmedical reasons. In half of the cases for which a backup donor was already identified, the delay in scheduling the transplant was less than 2 weeks. However, when no backup donor was available, the median delay to transplant was 18 weeks. Identification of backup donors is particularly important for patients with high-risk hematologic malignancies, whose disease tempo does not afford delays in transplantation.

PROCESS OF IDENTIFYING A SUITABLE UNRELATED DONOR

HLA Typing and Donor Matching in the DNA Era: Genetics of the HLA Complex

The advent of molecular techniques has made possible the definition of unique sequence variants (alleles) that encode each HLA molecule that is recognized by an antibody (antigen; Table 103–1). Polymorphism ensures that a large array of foreign peptides can be presented to the immune system by HLA molecules.[13] As of April 2007, more than 469 HLA-A, 794 HLA-B, 244 HLA-C, 525 HLA-DRB1, 71 HLA-DQB1, and 124 HLA-DPB1 alleles have been defined in diverse human populations (http://www.ebi.ac.uk/imgt/hla; Table 103–2).[14] DNA genotyping was adopted as standard technique for selection of HLA-matched unrelated donors because unrelated individuals who are matched for HLA antigens may not necessarily share the same HLA sequences. If HLA alleles can be expressed in any combination and if inheritance of alleles were random, then the total estimated number of possible five-locus HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1 genotypes would be more than 1×10^{23}. Clinical experience demonstrates that some patients have been able to find a matched donor even in a relatively small file of unrelated donors. Donor identification is successful because HLA alleles are found in association with each other at an observed frequency that exceeds their expected frequency, a phenomenon known as *linkage disequilibrium* (LD).[15,16] The probability of identifying a matched donor for a given patient is higher when the patient and donor share a similar ethnic background.[5,17–27] Linked HLA genes are inherited from each parent as a haplotype in classical Mendelian fashion (see Assessment of HLA Haplotypes below). HLA gene and haplotype frequencies provide important data for estimating optimal registry size and composition (www.allelefrequencies.net).[18,19,24]

Given the polymorphism of allele sequences that encompass variants of a single serologically defined antigen, it is not surprising that antigen-matched donor and patient pairs may differ for their alleles (Table 103–3).[28–32] A study by the NMDP defined the extent of allele mismatching among serologically typed recipients and their transplant donors.[33] Among HLA-A, HLA-B, HLA-DRB1 serologically matched pairs, as many as 29% encoded allele mismatches at HLA-A, HLA-B, or HLA-DRB1; 89% of HLA-A, HLA-B, HLA-DRB1

Table 103–2 Polymorphism of HLA Genes

	Antigens	Alleles
HLA-A	24	469
HLA-B	50	794
HLA-C	9	244
HLA-DRB1	15	525
HLA-DQB1	9	71
HLA-DPB1	6	124

HLA, human leukocyte antigen.

HCT, hematopoietic cell transplantation; HLA, human leukocyte antigen; HTC, homozygous typing cells; KIR, killer immunoglobulin-like receptor; MHC, major histocompatibility complex; NK, natural killer; PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism; SNP, single nucleotide polymorphism.

allele-identical pairs encoded additional mismatches at HLA-C and HLA-DP. Early donor selection criteria did not include consideration for HLA-C, so many donors who were serologically or even sequence matched for HLA-A and HLA-B antigens were later found to be mismatched at the HLA-C locus.[30] The overall frequency of allele mismatching is lower if the recipient has a common haplotype.[31] Because the frequencies of HLA alleles and haplotypes reflect the ethnicity and race of the patient and donor population, donor–recipient HLA mismatches can be ethnogeographically distinct (www.allelefrequencies.net).[29,34–36] In Caucasian transplant populations, for example, donor–recipient allele disparity is frequent for the A2, B27, B35, B39, and DR4 antigens.[29,31]

HLA TYPING METHODS

Serology and Cellular Assays

Serologic reagents have served as the gold standard for HLA antigen typing since the early 1960s.[37–39] Development of standardized tissue typing reagents and methods of nomenclature for HLA genes have been facilitated by a series of 14 international histocompatibility workshops (Table 103–4).[40–51] Serologic typing methods use a complement-dependent microcytotoxicity assay with alloantisera containing antibodies against polymorphic HLA specificities.[37] A public specificity is shared by distinct HLA molecules, whereas a private specificity is unique to a single HLA molecule. HLA molecules can share one or more public epitopes and differ for private epitopes. The combination of HLA antigens of an individual defines their phenotype, and the alleles define their genotype. All serologically defined alloantigens have been characterized at the allele level; however, not all sequenced-defined alleles have an equivalent phenotype studied by serology. Hence, a nomenclature has been developed to translate serologically defined antigens and DNA-defined alleles.[52]

The most commonly used cellular assay for the class II region is the mixed lymphocyte culture (MLC), in which disparity between the donor and the recipient for the antigens encoded by HLA class II region genes (also known as the HLA-D region) leads to lymphocyte activation and proliferation.[53,54] Although the strength of the proliferation measured in an MLC correlates roughly with the degree of HLA-D region incompatibility,[55] MLC is poorly predictive of GVHD and therefore has limited clinical utility for donor selection.[56–58]

The limiting dilution assay is a technique for determining the frequency of donor antihost cytotoxic T-lymphocyte precursors and helper T-lymphocyte precursors. These assays have proved useful in predicting the risk of GVHD and mortality prior to transplantation in some reports and may provide a means for selecting a suitable unrelated donor when more than one equally matched donor is available.[21,59–67] High frequencies of cytotoxic T-lymphocyte precursors have been observed with class I donor–recipient mismatching; helper T-lymphocyte precursor has been shown to detect class II disparity.[21,60,61,65] The frequency of donor cytotoxic T-lymphocyte precursor reactivity against recipient targets is correlated with the risk of

acute GVHD after unrelated donor HCT when ex vivo or in vivo T-cell depletion is used for GVHD prophylaxis.[59,62,64,66,67] In T-cell–replete transplantation, significant associations between frequency of cytotoxic T-lymphocyte precursors and acute GVHD have not been identified.[68–70]

DNA Methods

The advent of polymerase chain reaction (PCR) in the 1980s revolutionized donor typing and matching and has greatly accelerated understanding of the HLA barrier in transplantation. Guidelines for typing volunteer donors using DNA-based methods are available.[71–73] To transition from serologic to DNA-based methods, development of dictionaries of HLA alleles and antigen equivalents has become a necessity because many donors in the registries have been typed only by serologic assays.[74] Interpretation and use of molecular typing data for donor search and selection has required the development of informatics programs.[75,76]

Low-resolution DNA-based typing methods can define groups of alleles that are serologic equivalent (e.g., HLA-A*02 is DNA defined and is equivalent to HLA-A2 that is serologically defined). Intermediate-resolution DNA typing methods provide additional information, but not to the level of the complete DNA sequence that distinguishes one allele from another (e.g., the information is sufficient to delineate one group of alleles that include HLA-A*0201 and another that include HLA*0205, but cannot definitely assign the allele). High-resolution typing defines the unique DNA sequence of an allele (e.g., HLA-A*0201). The term "6/6" matched refers to recipients and donors who share the same low-resolution-defined HLA-A, HLA-B, and HLA-DR genes. The term "8/8" refers to high-resolution matching at the four loci HLA-A, HLA-B, HLA-C, and HLA-DRB1. When HLA-DQB1 is added, "10/10" refers to high-resolution matching at the five loci. When HLA-DPB1 is added, "12/12" refers to donor–recipient pairs that are allele matched at all six genetic loci.

Several PCR-based HLA typing approaches are widely used by clinical tissue typing laboratories in support of unrelated HCT programs. The sequence-specific primer method uses a panel of primers to amplify the HLA locus or alleles.[77–82] The PCR products are electrophoresed on a gel, and assignment of an HLA type is made by examining the composite pattern of positive and negative PCR reaction methods.

The sequence-specific oligonucleotide probe hybridization (SSOPH) method uses a solid phase support[83–95] to immobilize PCR-amplified products. Nonradioactive-labeled oligonucleotide probes are allowed to hybridize to the support. Probes with sequences complementary to the target DNA will hybridize, whereas probes with as few as one nucleotide difference will fail to hybridize. Alternatively, SSOPH methods can use probes that are immobilized to the solid phase support and allow PCR-amplified target DNA to hybridize to the support.

A variation of the SSOPH method is oligonucleotide array technology.[96] Arrays can simultaneously query multiple regions of polymorphisms in many HLA genes. Oligonucleotide probes can be designed to all four potential nucleotides, thereby enabling detection of new sequence polymorphisms with the same sensitivity and specificity as sequencing-based typing. Redundancy of probe sequences allows combinations of alleles to be distinguished in heterozygous individuals. Finally, sequencing methods provide high resolution of HLA alleles and are the definitive method for characterizing novel HLA sequences.[97–102]

ASSESSMENT OF THE VECTOR OF MISMATCHING

The "vector" or "direction" of HLA compatibility between a donor and a recipient has biologic relevance in defining the risks of graft failure and GVHD. The concept of the vector was first demonstrated in cases of haploidentical related mismatched transplantation and defines HVG and GVH alloreactivity.[103] The presence of donor alleles not shared by the recipient determines HVG allorecognition, whereas the presence of recipient alleles not shared by the donor provides the immunologic basis for GVH allorecognition (Table 103–5). "Bidirectional" mismatching refers to the situation in which both HVG and GVH vectors are present at a given HLA locus. "Unidirectional" mismatching describes the situation in which either the donor or the recipient is homozygous for the same allele at the mismatched locus. A unidirectional GVH vector mismatch occurs when the donor is homozygous and the recipient is heterozygous and shares one allele with the donor (e.g., patient DRB1*0101, *0410 vs donor DRB1*0101, *0101). A unidirectional HVG vector mismatch occurs when the patient is homozygous and the donor is heterozygous and shares one allele with the patient (e.g., patient DRB1*0101, *0101 vs donor DRB1*0101, *0401). Clinical outcomes analyses that evaluate the association between HLA disparity and risk of graft failure or GVHD should specify the vector of incompatibility that is used to define the comparison groups.

Table 103–5 Vector of Mismatch

Vector	Definition	Examples	
		Donor	***Recipient***
HVG	Presence of donor alleles not present in the recipient	DRB1*0101,0401[a]	DRB1*0101,0410
		DRB1*0101,0401[b]	DRB1*0101,0101
GVH	Presence of recipient alleles not present in the donor	DRB1*0101,0401[a]	DRB1*0101,0410
		DRB1*0101,0101[b]	DRB1*0101,0410

[a]These combinations contain bidirectional (both HVG and GVHD) mismatch vectors.
[b]Unidirectional mismatches.
GVH, graft versus host; HVG, graft versus graft.

ASSESSMENT OF HLA HAPLOTYPES

Patients who are candidates for allogeneic transplantation undergo a pedigree analysis to determine the availability of potential HLA genotypically identical siblings who could serve as a donor. The family study, which includes typing of the propositus' mother, father, and all full siblings, provides an internal verification of the patient's HLA haplotypes. Because HLA genes segregate in classical Mendelian fashion, the probability that a sibling inherits the same parental haplotypes is 25% (genotypically identical). The probability that a sibling inherits one identical paternal or maternal haplotype plus one nonshared haplotype is 50% (haploidentical). The probability of inheriting neither of the same haplotypes is 25% (complete mismatch).

When no related donor is available or suitable, a search for an unrelated donor is initiated. A search of all available international registries today includes consideration of more than 11 million donors worldwide (www.nmdp.org; www.worldmarrow.org). In the assessment of every unrelated donor, matching for each HLA genetic locus allele is considered. However, gene-by-gene identity for HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ between two unrelated individuals does not necessarily signify that the HLA alleles are linked on the same chromosomal haplotype.[104] Hence, it is possible for two unrelated individuals who share the same HLA genotype to have different HLA haplotypes. The clinical significance of haplotype matching is described next.

CLINICAL IMPORTANCE OF DONOR HLA MATCHING IN CASES OF UNRELATED DONOR HCT

The first successful human allogeneic marrow transplantations were performed in 1968.[105,106] Early clinical experience in allogeneic transplantation identified both HLA and non-HLA factors as important in defining posttransplantation complications. Donor HLA mismatching was identified as a risk factor for graft failure after HCT from relatives.[9] Non-HLA factors associated with an increased risk of graft failure included transplantation of a lower marrow cell dose,[107] use of T-cell–depleted marrow,[108] and transplantation of marrow from a cross-match–positive donor (presence of antidonor lymphocyte antibodies in the patient's serum pretransplant).[103] HLA mismatching was also shown to increase the incidence and severity of acute GVHD.[109]

Use of HLA-matched unrelated donors as the source of marrow was first applied in the case of a patient with severe aplastic anemia.[110] Durable engraftment and immunologic reconstitution were early barriers to successful unrelated donor HCT.[111–115] As clinical experience matured and tissue typing methods became more robust, unrelated donor HCT was established as a therapeutic approach for treatment of hematologic disorders when an HLA-identical sibling is not available. DNA-based methods have become established as the gold standard for HLA testing, as serologically identical recipients and potential unrelated donors can be mismatched for one or more alleles that are identified by DNA testing methods.[30,32,116]

Retrospective analysis of transplant donors and recipients that test the hypothesis that allele disparity confers biologic significance on transplant outcome should include examination of pairs that are fully typed for HLA-A, HLA-B, HLA-C, HLA-DRB, HLA-DQB1, and HLA-DPB1 at the sequence level. Many non-HLA variables have an impact on the same clinical endpoints that are also affected by HLA disparity. Hence, multivariable models should adjust for all clinical variables that are known to affect outcome. Finally, the study should have sufficient statistical power to detect a significant difference in outcome when one truly exists. Very large numbers of transplants are required to adjust for HLA and non-HLA variables (see box on Criteria for an Interpretable Study on the Role of HLA Matching in Cases of Unrelated Donor Transplantation). Studies meeting these criteria have demonstrated that patients had superior DFS after HLA-matched unrelated HCT.[117–123] When allele-matched donors are not available, the criteria for prioritization of mismatched donors come into focus. The current criteria for donor selection are as follows. (i) When feasible, "8/8" HLA-A, HLA-B, HLA-C, and HLA-DRB1 matching predicts for best patient survival. (ii) When a matched donor cannot be identified, use of a donor mismatched for a single allele can be considered. Under these circumstances, matching for HLA-DQB1 should also be considered, as mismatch for DQB1 alone seems forgiving, but mismatch for DQB1 plus another locus appears to increase mortality.[124,125] (iii) Multiple mismatches are less well tolerated and should be limited, (iv) Permissible HLA mismatches have been proposed as defined by polymorphism for selected HLA class I residues that participate in peptide repertoire or direct contact with the T-cell receptor. (v) HLA haplotype matching between donors and recipients may lower the risk of severe acute GVHD. (vi) Polymorphisms outside of the classical HLA loci may be clinically significant (Table 103–6).

Criteria for an Interpretable Study on the Role of HLA Matching in Cases of Unrelated Donor Transplantation

DNA-based methods have become established as the gold standard for HLA testing. It now is evident that serologically identical recipients and potential unrelated donors can be mismatched for one or more alleles that are identified by DNA testing methods. Therefore, retrospective analysis of transplant donors and recipients that test the hypothesis that allele disparity confers biologic significance on transplant outcome should include examination of pairs that are fully typed for HLA-A HLA-B, HLA-C, HLA-DRB1, HLA-DQB1, and HLA-DPB1 at the sequence level. In this way, the relative risks of HLA disparity on a given clinical endpoint can be more accurately measured. Many non-HLA variables have an impact on the same clinical endpoints that are also affected by HLA disparity; hence, multivariable models should adjust for all clinical variables that are known to affect outcome. Finally, the study should have sufficient statistical power to detect a significant difference in outcome when one truly exists. Very large numbers of transplants are required to adjust for HLA and non-HLA variables.

HLA-MATCHED UNRELATED DONOR HCT

The impact of more complete and precise donor HLA matching is dramatic. Overall survival after transplantation for treatment of AML, MDS, ALL, and CML from an 8/8 matched unrelated donor can approach the results observed after HLA-identical sibling transplantation (http://www.marrow.org).[117–119,123,126–130] For all modalities, the underlying disease diagnosis, and stage of disease at transplantation remain the most important prognostic features that affect DFS. The impact of HLA mismatching with respect to these clinical variables is coming into better focus.[125] The development of reduced-intensity conditioning regimens has expanded the clinical indications of HCT to patients of older age or patients who have underlying medical conditions that preclude the use of myeloablative regimens.[131,132]

In an analysis of patients transplanted for treatment of acute or chronic leukemia or NHL from HLA-identical siblings, patients positive for HLA-DR15 had lower recurrence of disease posttransplant and improved survival compared to patients who were DR15 negative.[133] Additional reports of HLA-A3 and HLA-DR1 and GVHD risk after sibling transplantation suggest that the immunogenicity of the specific alleles may directly influence GVHD risk.[134–136] Because the siblings were HLA identical, these observations cannot be explained by HLA disparity. These data have significance not only in the setting of HLA-identical related HCT but also for unrelated and mismatched related donor HCT. In addition to HLA allele mismatch-specific risk after unrelated HCT, new evidence suggests that risk can arise from mismatching for HLA haplotypes (see Importance of MHC Haplotypes later). The risk associated with haplotype mismatching after unrelated donor HCT can be assessed with haplotyping tools.

Table 103–6 Principles of Donor HLA Matching Using High-Resolution DNA Typing Methods

1.	When feasible, four-locus HLA-A, HLA-B, HLA-C, and HLA-DRB1 matching is optimal.
2.	When a matched donor cannot be identified, use of a single allele or single antigen mismatched donor can be considered. Avoid double mismatches including HLA-DQB1.
3.	Multiple mismatches are less well tolerated and should be limited.
4.	Permissible HLA mismatches can be defined by specific class I and class II residues that participate in peptide repertoire or direct contact with the T-cell receptor.
5.	Haplotype matching of HLA-A, HLA-B, HLA-C, HLA-DRB1 allele-identical donors and recipients may lower posttransplant risks of clinically severe acute graft-versus-host disease.

HLA, human leukocyte antigen.

SINGLE-LOCUS MISMATCHED UNRELATED HCT

Early studies of patients receiving HLA antigen-matched, MLC-compatible unrelated donor HCT uniformly reported a relatively high incidence of acute GVHD and transplant-related mortality (TRM) compared with transplantations from HLA-identical siblings.[137–140] The possibility that undetected donor–recipient mismatching for HLA allele variants could be responsible for increased complications in cases of unrelated donor HCT suggested that the safety and success of unrelated donor transplantations could be improved by further advances in HLA typing and donor matching and prompted close examination of serologically identical unrelated transplant pairs using DNA typing methods. The HLA variation that is identifiable using DNA methods is functional.[29,36,131,141,142] DNA-based methods can detect differences in allele sequences among serologically identical unrelated donor–recipient pairs, and the risk of mortality is increased with mismatching for a single HLA allele. Most posttransplant complications associated with donor HLA mismatching occur within the first 6 months after transplantation,[29,36,141,143,144] but some occur quite late.[145]

The risks of graft failure, GVHD, and mortality associated with mismatching were not contributed equivalently by all HLA loci. Because DNA-based laboratory methods were first developed for class II genes, clinical information on donor mismatching for HLA-DRB1, HLA-DQB1, and HLA-DPB1 preceded that for HLA-A, HLA-B, and HLA-C. As a result, donor selection criteria included consideration for donor class II matching in the early 1990s, followed by refined criteria inclusive of class I (see box on HLA Selection Criteria for Unrelated Donors). Early studies of class II allele matching were performed in study populations typed by serology for class I antigens. As a result, the risks attributed to DRB1 or DQB1 mismatching may have included the risk related to additional undetected class I disparities. In one of the earliest studies of patients with hematologic malignancy transplanted from HLA-A, HLA-B, HLA-DR serologically matched unrelated donors, DRB1 and DQB1 allele mismatching was associated with increased risk of severe acute GVHD.[146] Several large studies extended the findings of class II disparity and risk of clinically significant acute GVHD.[141,147–150] An NMDP analysis of 831 CML transplants found that the HLA-DRB1 effects were significant when class II allele matching was evaluated in a good-risk subset of patients transplanted during the first chronic phase from class I serologically matched unrelated donors.[150]

HLA Selection Criteria for Unrelated Donors

DNA typing can uncover additional allele disparity between HLA-A, HLA-B, HLA-DR phenotypically matched unrelated donors and recipients. Both GVHD and mortality are increased with use of phenotypically matched unrelated donors compared with related donor–recipient pairs. The difference in outcome can be attributed in part to the effects of mismatching for HLA-A, HLA-B, HLA-C, and HLA-DRB1 alleles and to the degree of HLA-A, HLA-B, HLA-DRB1 haplotype identity between the donor and recipient. Routine testing of potential donors should include DNA typing for HLA-A, HLA-B, HLA-C, and HLA-DRB1 at the intermediate resolution (antigen-equivalent) level. After the best-matched unrelated donors are identified, routine testing should include allele (sequence)-level typing for these genes. When a matched donor is not available, then the number of mismatches should be limited to one or two, with a single HLA-DQB1 mismatch being the best tolerated.

HLA-C: Discovery of a Classical Transplantation Antigen

Among the earliest clinical observations implicating class I was the demonstration that HLA-C is capable of eliciting an alloantibody immune response.[151] HLA-C antigens could be recognized by cytotoxic T lymphocytes and present peptides to T cells.[152–154] Demonstration of HLA-C as a classical transplantation antigen did not occur until the 1990s.[155,156] HLA-C mismatching was identified as an independent risk factor for graft failure, particularly in patients receiving myeloablative conditioning regimens followed by T-cell–replete transplantations for treatment of CML.[156] Increased risk of graft failure was also associated with HLA-A and/or HLA-B mismatching and low marrow cell dose.

The importance of unrelated donor matching for HLA-C was confirmed by two large analyses from the Japan Marrow Donor Program (JMDP)[36] and the NMDP (Table 103–7).[141] In the JMDP study, both HLA-C and HLA-A allele disparities were independent risk factors for severe acute GVHD, and HLA incompatibility for HLA-C was associated with reduction of leukemia relapse after HCT, a so-called GVL effect. Mismatching at the HLA-C locus in combination with mismatching at HLA-A/B and/or HLA-DR/DQ was associated with a lower 3-year relapse rate compared with mismatching at HLA-A/B or HLA-DR/DQ alone. In an expanded dataset, the JMDP demonstrated that HLA-A, HLA-B, HLA-C, and HLA-DRB1 are each independent risk factors for grade III and IV acute GVHD.[143] In the NMDP study, DNA from donors and recipients were typed for HLA-A, HLA-B, HLA-C, HLA-DRB, HLA-DQA1, HLA-DQB1, HLA-DPA1, and HLA-DPB1 alleles using high-resolution methods.[141] After accounting for clinical variables and mismatching at HLA-A, HLA-B, and HLA-DR, multivariate analysis revealed that HLA-C allele disparity conferred a statistically significantly increased relative risk on mortality (see Table 103–7). These data demonstrate that prospective evaluation of unrelated donors should include consideration for compatibility at HLA-C.

Models for Understanding Alloreactivity

HLA-B and HLA-DP have served as models for understanding the structural basis for allorecognition, where specific amino acids residues of class I and II molecules contribute to eliciting the immune response.[157–159] Donor-derived cytotoxic T lymphocytes isolated from a patient with graft rejection selectively recognized the patient-mismatched HLA-B44 allele (B*4402 vs B*4403),[160] indicating that class I allele differences may evoke donor–antihost responses and

Table 103–7 Mortality by HLA Mismatch

Locus	Relative Risk	95% Confidence Interval	*P* Value
A[a]	1.3	1.2–1.6	0.0002
B[a]	1.2	1.1–1.4	0.007
C[b]	1.2	1.1–1.4	0.005
DR[a]	1.2	1.0–1.5	0.01

From Flomenberg N, Baxter-Lowe LA, Confer D, et al: Impact of HLA class I and class II high resolution matching on outcomes of unrelated donor bone marrow transplantation: HLA-C mismatching is associated with a strong adverse effect on transplant outcome. Blood 104:1923, 2004.

supporting the hypothesis that allelic variants of the same HLA antigen can be functionally relevant. A parallel story emerged for HLA-DP.[36,141,161–167] Population studies have shown that HLA-DP is unique among other HLA genes because of very weak LD between HLA-DP and HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ. As a result, less than 20% of HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1–matched unrelated donor pairs are also matched for HLA-DP. Retrospective examination of HLA-DP has required very large transplant populations so that sufficient numbers of HLA-DP matched pairs could be compared with mismatched pairs. Furthermore, the measured effects attributed to single loci in early studies likely measured additive effects of HLA-DP with HLA-A, HLA-B, and HLA-DR. HLA-DP does function as a classical transplantation antigen with respect to GVHD.[161,166–168] Mismatching for two DPB1 allele increases the risk of acute GVHD compared to one or no HLA-DP mismatch.[161] Analysis of the structural basis of HLA alloreactivity shed light on specific epitopes encoded by HLA-DP exon 2 that are responsible for increased GVHD risk.[158] This study showcases the importance of functional studies side-by-side genetic analysis to better understand the residues that define alloreactivity.

The hypothesis that donor-recipient mismatching at certain amino acid substitutions in the class I HLA molecule may be associated with higher post-transplant risks compared to mismatching at other residues was first tested by Ferrara et al.[157] Amino acid mismatching at residue 116 was found to be associated with significantly increased risks of acute GVHD and transplant-related mortality compared to matching at this residue. Recently, the JMDP has evaluated 5210 Japanese recipients of unrelated donor transplants to identify mismatched residues of HLA-A, -B, -C, -DRB1, -DQB1 or -DPB1 molecules that correlate with clinical outcome.[149] Analysis of each allele-defined mismatch yielded 4 HLA-A, 1 HLA-B, 7 HLA-C, 2 HLA-DR/DQ, and 2 HLA-DP mismatch combinations to be significantly associated with increased post-transplant complications. Each allele was subsequently defined by its putative amino acid sequence, and all polymorphic donor-recipient mismatched positions at each locus were individually analyzed for associations. Donor-recipient mismatching for Tyr9–Phe9 of HLA-A and for Tyr9–Ser9, Asn77–Ser77, Lys80–Asn80, Tyr99–Phe99, Leu116–Ser116, and Arg156–Leu156 of HLA-C were identified to be clinically significant. When the study group was restricted to pairs matched at HLA-C for positions 77 and 80 that define KIR ligands, donor-recipient mismatching at positions 9, 99, 156, and 163 were found to correlate strongly with GVHD risk. This study demonstrates that mismatching for positions of HLA-A or C that participate in peptide binding is functional and provides a basis for defining non-permissive HLA allele mismatches. Statistical models have been developed to predict peptide binding of HLA molecules as an approach to predict those HLA alleles that lead to diverse binding of peptide and which may consequently affect T cell recognition of HLA and its minors.[170]

DOES MISMATCH FOR ALLELES OR ANTIGENS POSE THE SAME RISKS?

With the availability of molecular methods for defining the HLA alleles of transplant recipients and donors, it now is possible to evaluate the impact of the location and number of mismatched amino acid residues as potential factors defining the permissibility of a mismatch. In a single-center study of graft failure after myeloablative unrelated HCT, donor–recipient mismatching for HLA-A, HLA-B, or HLA-C antigens conferred greater risk for graft failure than did single allele mismatches at these loci.[142] Recipient homozygosity for alleles or antigens was also significantly associated with graft failure among patients with a single class I antigen mismatch. Graft failure occurred in one of two homozygous recipients and in none of 47 heterozygous recipients mismatched for a single allele ($P = 0.04$), whereas graft failure occurred in four of five homozygous recipients and in seven of 51 heterozygous recipients mismatched for a single antigen ($P = 0.004$). The allele and antigen mismatches represented in this study population differed in the number of nonsynonymous substitutions and in the location of the mismatch in the α_1 and α_2 domains of the molecule. Single class I allele disparity encoded from 0 to 14 (median 2) substitutions in the α_1 and α_2 domains. In contrast, single antigen mismatched pairs had involvement of 1 to 27 (median 13) substitutions. These data series, highly enriched for mismatches at HLA-C, suggest that multiple mismatches for residues that affect peptide binding and T-cell receptor contact might have been instrumental in evoking T-cell responses that led to graft failure in these patients.

Table 103–8 Impact of HLA-A, B, C, DR Matching on Mortality: 8/8 Model

	N	RR	95% CI	P Value
Matched	1840	1.00	—	—
HLA-A, Mismatch	274	1.36	1.17–1.59	<0.0001
HLA-B, Mismatch	116	1.16	0.92–1.47	0.20
HLA-C, Mismatch	478	1.19	1.05–1.35	0.006
HLA-DR, Mismatch	117	1.48	1.19–1.85	0.0005

HLA, human leukocyte antigen; N, number; RR, relative risk; CI, confidence interval. (From Lee SJ, Klein J, Haagenson M, et al: High-resolution donor-recipient HLA matching contributes to the success of unrelated donor marrow transplantation. Blood 110:4576, 2007.)

Two studies have examined allele and antigen mismatches in large populations and the risks conferred by each kind of mismatch on TRM and survival. A single-center analysis from Seattle indicated that an isolated allele or antigen mismatch was similarly detrimental to survival.[125] Among low-risk patients, no single-locus mismatch with the exception of HLA-DQ appeared tolerable. HLA-C mismatches were particularly detrimental, whether patients had low- or high-risk malignancy. An analysis by the NMDP measured risks associated with single-locus mismatches in a large population of HLA allele-typed pairs (Table 103–8).[124] Each HLA-A, HLA-B, HLA-C, or HLA-DRB1 mismatch was found to confer a 9% to 10% lower overall survival compared to a baseline of 8/8 allele matches. Among all single-locus mismatches, disparity for HLA-A or HLA-DRB1 was associated with higher mortality than disparity at HLA-B or HLA-C. Mismatching at HLA-A, HLA-B, and HLA-C each was associated with increased risk of GVHD. As in the previous NMDP analysis,[141] allele and antigen mismatches were similarly detrimental except for the case of HLA-C, where allele disparities did not contribute to the risk. These data are consistent with the graft failure study discussed earlier,[142] in which a predominance of HLA-C mismatches and allele disparities did not contribute to increased risk. These studies demonstrate that when measuring the effects of HLA mismatching, large well-characterized populations are needed, and variables known to affect clinical outcome should be accounted for. Avoidance of HLA-A, HLA-B, HLA-C, and HLA-DRB1 allele mismatches may lower risks of posttransplant complications.

MULTILOCUS MISMATCHED UNRELATED DONOR HCT

The effects of HLA disparity on risk of graft failure, GVHD, and mortality can be measured by the total number of detectable mismatches. As the number of HLA disparities increases, so does risk for these complications. In the JMDP study of 1298 patients,[143] the overall incidence of graft failure increased with increasing numbers of mismatched HLA loci: 1.7% matched; 4.8%, 4.1%, and 4.8% of single HLA-A/B, HLA-C, and HLA-DR/DQ, respectively; 10.4%, 8.9%, and 6% in two-locus HLA-A/B plus HLA-C, HLA-A/B plus HLA-DR/DQ, and HLA-C plus HLA-DR/DQ, respectively; and 10.6% in three-locus incompatible transplants. In patients who received unrelated donor HCT for treatment of CML,[29] single allele mismatch at HLA-A, HLA-B, or HLA-C did not increase the risk of

Table 103–9 Three-Year Survival after Unrelated Donor Hematopoietic Cell Transplantation for Standard Risk Diseases: The Japan Marrow Donor Program Experience

Match Status	Survival (%)	*P* value
Matched	65.4	—
A/B	39.9	<0.001
C Mismatch	68.9	NS
DR/DQ	70.9	NS
A/B + C	51.5	0.10
A/B + DR/DQ	50.0	0.09
C + DR/DQ	50.6	0.06
A/B + C + DR/DQ	39.1	<0.001

From Morishima Y, Sasazuki T, Inoko H, et al: The clinical significance of human leukocyte antigen (HLA) allele compatibility in patients receiving a marrow transplant from serologically HLA-A, HLA-B, and HLA-DR matched unrelated donors. Blood 99:4200, 2002.

graft failure compared to matched recipients (2%); however, multiple HLA-A, HLA-B, and/or HLA-C allele mismatches were associated with a 29% incidence of graft failure.

Quantitative effects of multiple class I, multiple class II, or simultaneous class I and II mismatching can be associated with acute GVHD risk.[36,141,143,146–148,171] Pronounced effects of two-locus HLA-DRB1, HLA-DQB1 mismatching on risk of grade III and IV acute GVHD can be discerned (22% matched; 43% single-locus mismatches; 64% two-locus mismatches).[148] In HLA-A, HLA-B, HLA-DR serologically matched unrelated pairs who received unmodified grafts,[147] matching for both HLA-DRB1 and HLA-DQB1 reduced the rate of GVHD from 73% (any mismatch) to 38% (matched for both genes; $P = 0.02$).

JMDP data provide information on the quantitative effects of HLA mismatching on GVHD risk.[143] Not only were multiple class I disparities a risk factor for GVHD, but HLA-C disparity in the presence of mismatching at any other HLA locus (class I and/or class II) was associated with significantly increased incidence of grades II through IV GVHD: 60.9%, 55.7%, and 64.3% for HLA-C plus HLA-A/B, HLA-C plus HLA-DR/DQ, and HLA-C plus HLA-A/B and HLA-DR/DQ, respectively, compared with 34.5%, 54.9%, 42.7%, and 34.4% for matched, HLA-A/B mismatched, HLA-C mismatched, and HLA-DR/DQ mismatched, respectively. The JMDP experience demonstrates that multilocus mismatching is associated with a decreased rate of survival (Table 103–9). In some pediatric series, children tolerate higher degrees of disparity with use of certain immunosuppressive regimens.[172]

IMPORTANCE OF MHC HAPLOTYPES

The MHC is the most diverse region in the human genome known to date.[173] The MHC is residence of the classical HLA and nonclassical genes, including HLA-E, HLA-F, HLA-G, MICA, and MICB. Of the known genes, data suggest a role for HLA-E in transplant outcome.[174,175] Increased risk for bacterial infections and corresponding TRM at day 180 posttransplant were found in recipients transplanted from HLA-E*0101,0101 homozygous unrelated donors.[174] HLA-E*0103,0103 homozygosity among HLA-identical siblings conferred protection against acute GVHD and TRM, leading to increased overall survival. These data point to the potential involvement of the innate immune system in GVHD.

In addition to the nonclassical HLA genes, more than 100 loci within the extended 7.6 megabase (Mb) MHC region have immune function.[173] One approach that has been taken to discover putative novel transplantation determinants is LD mapping. The MHC is characterized by LD of discrete segments or blocks of sequences that reside between HLA genes.[176–179] Although the specific content of these blocks is under investigation, donor–recipient matching for these regions is associated with superior clinical outcome.[179,180] If these data point to the importance of non-HLA MHC variation in transplantation, then new approaches for querying the MHC that take advantage of the strong LD would be immensely helpful in localizing functional variation. Currently, gene-by-gene matching between recipients and unrelated donors is performed to approximate the haplotype matching that is feasible between genotypically identical sibling pairs. However, HLA-matched unrelated donors and recipients are not related to one another, and given the extreme diversity of the MHC, haplotype-associated variation among HLA-matched transplant pairs may exist. To test the hypothesis that the HLA haplotype serves as a tool for querying such areas outside of classical loci, a novel long-range phasing technique has been developed.[104] By physically linking HLA-A with HLA-B with HLA-DR on the same strand of DNA, this technique has been applied to test the hypothesis that HLA-identical unrelated donors and recipients encode different HLA haplotypes, and, furthermore, haplotype mismatching is associated with increased posttransplant risks conferred by variation that is linked to the different haplotypes.[181] In this study, a homogeneous population of HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1 allele-matched unrelated transplants were characterized using the phasing method. Of these pairs, 20% were found to have different physical linkage of HLA-A, HLA-B, and HLA-DR. Haplotype mismatching was associated with significantly increased risk of grade III to IV acute GVHD. The increased risk of GVHD was offset by lower relapse, leading to similar overall survival. This study demonstrates that variation linked to the haplotype is functional and that the HLA haplotype can be used as a surrogate marker for GVHD risk. Prospective donor matching for HLA haplotypes in addition to HLA genes may lower risks of acute GVHD.

In the future, haplotypes can be used to map putative transplantation determinants, as the map of the MHC continues to be refined for single nucleotide polymorphisms, the most common kind of variation in the human genome (http://www.sanger.ac.uk/HGP/Chr6?MHC). If such variation is functional, it may explain the increased risks of GVHD observed after HLA-matched unrelated donor HCT compared to sibling transplantation. Laboratory approaches for capturing MHC diversity include direct sequencing and high-throughput platforms for single nucleotide polymorphism genotyping. Traditionally, microsatellite (Msat) markers have been a robust tool for mapping disease-causing variation in many model systems, including autoimmunity and cancer.[182–184] Msats provide indirect information because Msats themselves are not functional. Their LD with putative functional genes, however, provides the basis for its application in estimating optimal donor registry size and composition[185,186] and for donor selection.[187] Two studies have used Msats to query the MHC region for novel determinants.[184,185] Tumor necrosis factor (TNF) variation within the class III region of the HLA complex was associated with lower survival among patients who developed GVHD.[185] These studies provide the impetus for further exploration of the MHC.

KIR RECEPTORS

Elucidation of the genetic diversity of the *KIR* family of genes and their functional role as receptors for HLA class I offers a novel approach for use of HLA class I mismatched donors to decrease risks of GVHD and relapse.[188–193] KIRs are inhibitory or activating. Both types are expressed on NK cells and other cell types, including T cells; however, inhibitory KIRs are dominant. HLA and KIR genes are encoded on chromosomes 6 and 19, respectively, and segregate independently. However, HLA serves a dominant role in selection of the peripheral repertoire of NK cell inhibitory KIRs. Thus, HLA-mismatched siblings, haploidentical relatives, and mismatched unrelated donors have different repertoires of NK cell inhibitory KIRs. In some HLA-mismatched pairs, the recipient is missing the appropriate ligands for donor NK cell inhibitory KIR. A recipient who lacks the

appropriate HLA ligand for the donor KIR will trigger NK-mediated killing of host target cells.[194] In HCT for malignancy, such a combination is desirable, as killing of target host leukemia cells would lead to lower risk of relapse after transplantation. Some pairs of HLA-identical individuals encode distinct KIR sequences and can express distinct KIR on their peripheral NK cells. Recipients lacking the specific HLA ligand for donor KIR could enjoy enhanced antitumor activity after HCT.

The specificity of the dominant inhibitory KIR receptors for its ligand is governed by residues 77 and 80 of HLA-C and by the HLA-Bw4 epitope present on some HLA-B and HLA-A molecules.[195] For HLA-C, ligands are classified into two groups, named C1 and C2. Inhibitory KIR2DL2 and 2DL3 receptors recognize Ser77 and Asn80 present in the following C1 ligands: HLA-Cw1; Cw3 (except Cw*0307, 0310, 0315); Cw7 (except Cw*0707, 0709); Cw8; Cw12 (except Cw*1205,12041/2); Cw13; Cw14 (except Cw*1404); Cw*1507; and Cw16 (except Cw*1602). The KIR2DL1 receptor recognizes Asn at position 77 and Lys at position 80 of the following C2 ligands: HLA-Cw2; Cw*0307; Cw*0315; Cw4; Cw5; Cw6; Cw*0707, Cw*0709; Cw*1205 Cw*12041/2; Cw15 (except Cw*1507); Cw*1602; Cw17; and Cw18. The HLA-Bw4 epitope serves as a ligand for the inhibitory KIR3DL1 receptor. The following HLA-B antigens and alleles are Bw4 positive: B5, B13, B17, B27, B37, B38, B44, B47, B49, B51, B52, B53, B58, B59, B63, B77, B*1513, B*1516, B*1517, B*1523, and B*1524. Based on high-resolution typing of HLA class I alleles of the recipient, the presence or absence of ligands and whether the recipient is C1/C2 heterozygous, C1/C1 homozygous, or C2/C2 homozygous is determined.

The concept of donor NK-mediated killing of recipient antigen-presenting cells was demonstrated in mice and suggested by a study in patients who underwent HLA haplotype-incompatible T-cell–depleted mismatched transplantation for high-risk AML or ALL.[188] These patients received a high $CD34^+$ cell dose and no postgrafting immunosuppression, a regimen that promotes rapid NK recovery.[193] AML patients who received transplants from KIR ligand–mismatched donors had significantly improved 5-year survival rates compared with patients who received KIR ligand–matched transplants (60% vs 5%; $P = 0.0005$). Donor KIR ligand mismatching was associated with no graft failure, no acute GVHD, and a 0% 5-year probability of relapse in cases of transplantation for AML. Relapse of ALL was not associated with KIR mismatching, presumably because NK cells do not express adhesion receptors to LFA-1–deficient ALL cells. In contrast, KIR ligand mismatching was an independent risk factor for poor transplantation outcome (15.5% incidence of graft failure, 13.7% incidence of acute GVHD, and 75% 5-year probability of relapse). Patients carrying the diagnosis of ALL were not protected against relapse with use of KIR ligand–mismatched donors (90% in KIR ligand matched vs 85% in KIR ligand mismatched at 5 years).

These original observations have been reproduced in some but not all studies.[188,196,197] Extension of the original concepts of KIR ligand mismatch in the haploidentical transplant model to HLA-matched sibling donor and unrelated donor populations has yielded heterogeneous results and may reflect the vastly different conditioning and immunosuppressive regimens that promote T-cell and NK-cell reconstitution early after transplantation.[194,196,198–204] In one study, HLA genotypes were analyzed in a large population of T-replete unrelated donor transplants.[202] Lower posttransplant relapse was observed among HLA-mismatched recipients who were homozygous for HLA-Bw6 and HLA-C KIR ligand groups. This association was not observed among HLA-matched recipients. A population of T-replete allografts for ALL, AML, MDS, and CML was examined, and three groups were established based on HLA genotypes ligand and 14 KIR genes: HLA class I antigen matched (KIR ligand matched), class I antigen mismatched but KIR ligand matched, mismatch at both HLA class I and inhibitory KIR-ligand mismatched.[205] The overall survival at 1 year posttransplant for these three groups differed significantly (59%, 49%, and 30%, respectively). The mismatched groups had lower overall survival and event-free survival compared to the matched group. Furthermore, the group with both HLA and KIR mismatching had higher relapse and TRM than the other groups. A detrimental effect was observed for patients who lacked inhibitory KIR receptors. Among HLA-matched cases, those who lacked C1 or C2 HLA ligand had lower overall survival compared to patients with either present. Patients who lacked C1 or C2 had higher TRM compared to patients who had all ligands present. Therefore, for T-replete unrelated donor HCT, inhibitory KIR ligand mismatching and missing inhibitory KIR ligands confer higher risk to patients.

A large analysis by the JMDP sheds further light on the importance of KIR ligand matching.[206] This study included 1790 T-replete unrelated donor transplants. Donor–recipient HLA-C disparity was associated with reduced relapse among patients with ALL. HLA-DPB1 mismatches were associated with lower relapse among CML transplants. Mismatching for the KIR2DL ligand in the GVH vector was associated with an increased risk of relapse for ALL. An increased risk of rejection was observed for KIR2DL ligand mismatches in the HVG vector. The risk of acute GVHD was increased with disparity for HLA-A, HLA-B, HLA-C, HLA-DPB1, and KIR ligand mismatching in the GVHD vector. Mismatching for HLA-A, HLA-B, HLA-DQB1, and KIR ligand in the GVH vector increased mortality. In summary, this analysis demonstrated an important role for HLA-C, HLA-DPB1, and KIR ligand mismatching in GVHD vector on posttransplant relapse. As a whole, KIR ligand mismatching had adverse effects on acute GVHD and rejection and had no survival benefit for patients undergoing T-replete unrelated HCT.

The KIR family of genes displays allelic and haplotypic polymorphism. KIR genes are organized into two broad groups of haplotypes known as "group A" and "group B" haplotypes.[195,207–213] Group A haplotypes encode primarily inhibitory receptors and the activating KIR2DS4 gene. Group B haplotypes tend to exhibit more diversity, encoding more activating genes including KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5, and KIR3DS1. The clinical relevance of KIR haplotypes has been explored and reveals that the number of activating KIR genes is a determinant of relapse and DFS.[214] In this analysis, patients received myeloablative in vivo antithymocyte globulin T-cell–depleted unrelated transplants. The study population was evaluated according to the presence of donor Group A haplotypes (inhibitory receptors with one activating KIR2DS4) and donor Group B haplotypes (more activating KIRD KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5, and KIR3DS1). KIR ligand mismatching was associated with significantly higher TRM, lower overall survival, and lower DFS compared to ligand matching. Transplantation from donors with group A KIR haplotypes or donors with lower numbers of activating KIR genes was associated with reduced relapse and improved DFS among AML/MDS recipients and to lesser extent among CML patients. No haplotype effects were observed in patients with ALL. This study indicates not only that the HLA ligand is an important factor but that the composition of donor KIR haplotypes (i.e., group A KIR haplotypes) influences risk of relapse and improved DFS. These observations point to the potential usefulness of prospective integration of recipient and donor KIR genotype information into donor selection to fully maximize NK-driven antileukemic effects.

UNRELATED DONOR TRANSPLANTATION FOR SELECTED HEMATOLOGIC MALIGNANCIES

Acute Leukemia

Historical clinical experience with use of unrelated donor HCT for treatment of acute leukemia demonstrated superior DFS when HCT was performed for patients in remission or early first relapse.[140,215–220] In early studies of patients receiving transplants for AML or ALL in relapse, the presence of circulating blasts in the peripheral blood and the presence of more than 30% blasts in the marrow both were associated with poor outcome.[216] For patients carrying the diagnosis of AML, a higher marrow cell dose was associated with improved DFS of 54% at 5 years.[221] An analysis from Japan illustrated the

importance of disease stage at transplantation as a important variable influencing DFS. Patients with ALL in first complete remission (CR1), second complete remission (CR2), third complete remission (CR3), and no complete remission (CR) had DFS of 56%, 33%, 22%, and 12%, respectively. Rates for patients with AML were 71%, 55%, 43%, and 12%, respectively.[222] Similar results demonstrating lower relapse and higher DFS with transplantation for early disease provided the basis for recommendations for initiation of an unrelated donor search as soon as possible after the diagnosis of high-risk leukemia is made if a suitable family donor is not identified.[223–225] Furthermore, these data demonstrated that if an HLA-matched unrelated donor is found, transplantation should be carried out during remission or early after relapse. A much larger worldwide experience has provided the opportunity to refine indications for allogeneic transplantation for acute leukemia and specific approaches to optimize transplant results for patients with AML and ALL. For patients with active leukemia, the availability of high-throughput HLA typing laboratory support has decreased the time required to identify well-matched donors. Depending on the recipient's genotype, it currently is feasible to offer transplantation for high-risk patients within 3 months.

Acute Myeloid Leukemia

Allogeneic transplantation for patients with high-risk AML might improve survival compared to chemotherapy alone or autologous transplantation, but prospective trials of unrelated donor HCT are lacking.[226] When an HLA-identical sibling is available to serve as donor, high-risk patients with unfavorable cytogenetics have improved survival after HCT compared to chemotherapy alone.[227] If a matched related donor is not available, CIBMTR data demonstrate that transplantation for high-risk CR1 disease yields survival rates at least as good as those observed after related donor HCT (http://www.cimbtr.org). Cytogenetics are predictive of remission rates, remission duration, and long-term DFS,[228–230] but heterogeneity of data merits further longitudinal analysis.[231] After transplantation in CR1 from matched or mismatched unrelated donors, patients with unfavorable cytogenetics had a 28% 5-year survival rate, 26% DFS, and 25% relapse rate.[229] These outcomes compare favorably with the 5% to 15% survival observed for high-risk CR1 patients who receive chemotherapy only and with outcome after sibling transplantation. This clinical experience indicates that transplantation in CR1 for patients with unfavorable cytogenetics should be considered if possible. Delay of transplantation for patients with "good-risk" cytogenetics may be reasonable until there is evidence of disease recurrence with careful molecular monitoring of marrow function. In these patients, initiation of an unrelated donor search in CR1 would prevent delay in scheduling transplantation when disease recurs. Patients with intermediate-risk cytogenetics remain the most challenging and require both careful assessment of comorbidities and close monitoring of disease for planning the appropriate time for transplantation.

Three-year DFS greater than 40% can be achieved when unrelated HCT for high-risk patients can be performed in remission.[232] The combination of busulfan and melphalan for conditioning has yielded 3-year DFS of 61% for advanced leukemia.[233] For patients with chromosome 5 or 7 abnormalities, relapse remains the primary reason for transplant failure, with higher rates of relapse observed after related donor compared to unrelated donor HCT; however, 3-year survival rates of 25% are observed.[234] Higher nonrelapse mortality has been observed after related donor transplantation for pediatric AML/ALL compared to unrelated donor HCT.[235] Strategies for lowering regimen-related toxicity have included the development of safer myeloablative conditioning regimens using pharmacokinetics-targeted busulfan[236] and intravenous busulfan.[237–239] For older patients and patients with coexisting medical issues that preclude the use of myeloablative conditioning, the availability of reduced-intensity and nonmyeloablative regimens for AML patients has provided high-risk AML patients the option for cure.[132,240–259] For patients transplanted in CR1, overall survival at 2 years may exceed 60%.[132] Primary causes of failure after transplant are relapse and infectious complications.[260] For patients at high risk for disease recurrence, prophylactic donor lymphocyte infusions after transplantation has yielded superior outcomes: 87% overall survival with a cumulative incidence of leukemic death of 8% and nonrelapse mortality of 17% at 1 year.[259]

Acute Lymphoblastic Leukemia

The most common stage of ALL patients referred for unrelated donor HCT is CR2, but mounting evidence indicates that high-risk patients should be considered early for transplantation in CR1. Factors associated with poorer outcome after chemotherapy include high-risk cytogenetic abnormalities including t(9;22) and t(4;11) translocation and hypodiploid DNA. For patients in CR1 with such high-risk features and no HLA-identical sibling donor, striking a balance between the increased TRM associated with unrelated HCT and the probability of survival with conventional chemotherapy alone is required for each patient.[260–265] For Philadelphia chromosome–positive (Ph^+) ALL, use of donors with limited HLA mismatches has been shown to be acceptable and is associated with decreased leukemic relapse post-transplant, indicating the presence of GVL effects, albeit with higher rates of acute GVHD, which obviates any advantages for survival.[215] More recently, a survival advantage favoring related HCT has been shown for Ph^+ recipients in either CR1 or CR2 and a potential benefit of unrelated HCT with a 37% to 49% DFS at 2 years.[266,267] For Ph chromosome–negative (Ph^-) ALL, the probability of cure is 30% with chemotherapy alone. Transplantation in CR1 for high-risk patients may afford DFS of 56%.[261]

When an HLA genotypically identical sibling is not available, transplantation from unrelated donors has been associated with a 44% to 46% overall survival compared to 53% to 55% after sibling transplantation.[268–270] The overall outcomes between these two populations in some series are becoming more similar to one another.[271,272] In an evidence-based review, transplantation for high-risk ALL in CR1 was recommended, but not for standard-risk ALL.[273] Striking a balance between the toxicities associated with unrelated donor transplantation and the beneficial GVL feasible with alternative donors remains a major clinical challenge.[274,275] For high-risk T-cell ALL in one series, overall survival was comparable after sibling, unrelated donor, or mismatched related donor transplantation.[276] DFS was 67% for CR1 compared to 42% for patients receiving chemotherapy alone. Overall survival 5 years after HCT was 67% compared to 47% for patients receiving chemotherapy only. Relapse remained the major cause of failure after sibling HCT; TRM was the major cause of failure after unrelated donor/mismatched related donor transplantation. In a study of high-risk patients with t(1;19)- and t(4;11)-positive ALL, allogeneic transplantation in CR1 provided opportunity for DFS.[277]

Compared to autologous transplantation, unrelated donor HCT provides a greater antileukemic effect (40% 3-year overall survival for unrelated donor vs 32% for autologous transplantation) and is the treatment of choice in patients with CR2 at high risk for relapse.[275] In an analysis of a large Medical Research Council/Eastern Cooperative Oncology Group trial, autologous transplantation was no better than standard chemotherapy for ALL.[278] In a series of Ph^+ ALL adults, a 34% overall survival rate for CR1 and 21% rate for CR2 or beyond was achieved. Improved survival was associated with younger age, CR at HCT, use of total body irradiation, and a sibling donor.[279] Severe acute GVHD increased TRM but did not lower the relapse rate. Chronic GVHD was associated with lowered relapse and did not increase TRM. New approaches to optimizing transplant and immunosuppressive regimens through lower regimen-related toxicity and increased GVL are promising. The addition of rituximab to a cyclophosphamide–total body irradiation regimen in adults with ALL was well tolerated and resulted in 30% DFS, 24% TRM, and 47% overall survival at 2 years.[280] Full donor chimerism and GVL can be achieved with use of reduced-intensity conditioning, and this modality has provided a transplant option to patients who otherwise are not candidates for standard regimens.[281]

Transplantation for pediatric ALL suggests greater tolerability of HLA mismatching in this population.[282,283] Overall outcome for patients transplanted in CR3 showed 3-year event-free survival of 35%, 42% relapse, and 23% TRM.[283] No significance differences in outcomes between mismatched unrelated and matched unrelated donors were observed. Both short CR1 and extramedullary relapse at first relapse were identified as poor risk factors. In an analysis by the CIBMTR that included transplants for AML or ALL from sibling and unrelated donors, TRM was 6% for siblings and 15% for unrelated donors.[284] DFS at 3 years for these two groups was 49% and 54% for patients in CR1, respectively, and 20% and 30% for patients with advanced disease. The risks of relapse, mortality, and DFS were associated with disease stage at the time of transplant. Relapse was lowest after unrelated donor HCT for CR1, but overall survival and DFS were similar after sibling and unrelated HCT.

Myelodysplastic and Myeloproliferative Syndromes

There has been an increased appreciation of the considerable heterogeneity of disorders formally classified as MDS and their multifactorial etiologies.[285–287] New information on the significance of the Jak2 mutation provides the basis for considering myeloproliferative syndromes including polycythemia vera, essential thrombocythemia, and chronic idiopathic myelofibrosis as clinical diseases distinct from refractory anemia (RA) and RA with excess blasts in transformation (RAEB-t).[288,289] Criteria used in the evaluation of MDS include extent and nature of peripheral blood cytopenia, evidence for dysplasia on marrow morphology, and presence and kind of cytogenetic abnormalities.[290,291]

Allogeneic transplantation is the only known cure for MDS and myeloproliferative disorders, including chronic myelomonocytic leukemia.[140,292–294] Transplantation outcome is related to disease morphology, blast count, neutrophil count, disease duration, patient age, and cytomegalovirus serostatus.[294] The International Prognostic Scoring System (IPSS) stage at transplantation, which includes cytogenetics, and therapy-related MDS strongly correlate with risk of posttransplant disease recurrence and is useful for determining patients who might benefit from HCT early after diagnosis.[295] Given the average unrelated donor search time, consideration of HCT should be made for patients with RAEB or RAEB-t at the time of diagnosis because of the short median survival and high incidence of transformation to AML among patients with blasts. Decision analysis algorithms suggest that transplantation is indicated for patients with MDS diagnoses carrying higher risk according to IPSS definitions.[296] In general, patients with MDS are older and often have accompanying medical issues that potentially can increase morbidity. These factors frequently require additional medical evaluation and treatment and must be taken into account when planning transplantation.

In general, improved DFS is associated with good-risk cytogenetic markers and shorter disease duration,[297] whereas longer disease duration and lower neutrophil count at the time of HCT are associated with increased risk of nonrelapse mortality. Unrelated donor HCT for higher-risk MDS or secondary AML is an option, particularly for younger patients.[298] In a single-center study of patient transplanted for RAEB using targeted busulfan-cyclophosphamide conditioning, 40% DFS was achieved; DFS for more advance diseases was 33% for RAEB-t and 17% for transformed AML; and lower IPSS scores were associated with the highest DFS and lowest relapse rates.[299] Overall transplant outcome may be optimized with use of pretransplant chemotherapy for secondary MDS.[300,301]

Use of busulfan-cyclophosphamide is associated with higher survival than with other myeloablative regimens.[302] Compared to regimens containing total body irradiation, transplant outcome after busulfan-cyclophosphamide conditioning is effective,[303] with DFS at 3 years approaching 70% for unrelated transplants with early-stage (or low-risk) MDS.[297] Fludarabine in combination with targeted oral busulfan has yielded an overall survival rate of 42% and DFS of 35% at 18 months in advanced MDS, and a modified fludarabine-busulfan regimen up to 74% DFS for AML in remission.[236] Intravenous busulfan-fludarabine has been shown to be an effective regimen with low toxicity for conditioning patients with AML or MDS.[304] Transplantation for chronic myelomonocytic leukemia (CMML) after myeloablative conditioning has achieved 41% 4-year DFS and 23% incidence of relapse.[305] Little difference in overall survival was observed between unrelated and related recipients after treosulfan-fludarabine conditioning for secondary AML/MDS.[257]

Attempts to increase the intensity of the conditioning regimen in order to lower the relapse rate have led to increased regimen-related toxicity and nonrelapse mortality. Because TRM remains a major cause of failure for low-risk MDS,[299,306] new approaches to reduce toxicity from the transplant procedure have been explored.[297,299,307] Reduced-intensity regimens lower regimen-related toxicity while providing beneficial GVL effects.[308–314] The combination of the anti-CD52 antibody alemtuzumab with reduced-intensity conditioning has demonstrated a 43% 3-year overall survival rate, with a 22% incidence of chronic extensive GVHD.[315] In an analysis of patients with AML in remission, RA, RAEB, RAEB-t or refractory/untreated AML, DFS of 75%, 46%, 33%, and 11%, respectively, were observed after conditioning with 550-cGy total body irradiation with cyclophosphamide. The overall incidence of relapse was 7%, and TRM was 37%.[251] An optimal conditioning regimen has not been determined.[309,316,317]

Chronic Myeloid Leukemia

With the availability of specific bcr-abl targeting agents capable of producing clinical and cytogenetic remissions for CML, HCT has moved to second-line therapy. The efficacy of tyrosine kinase inhibitors (imatinib) to induce CR and, in some patients, durable remission has been shown in phase I, II, and III clinical trials.[318–322] This has led to a decline in the number of allogeneic transplants performed for good-risk early CML.[323] Although imatinib as front-line therapy for CML in chronic phase appears to be more efficacious than transplantation within the first 2 years of disease diagnosis,[324] some patients who develop resistance to imatinib may be salvaged with allogeneic transplantation.[325] Given that allogeneic transplantation remains a proven curative modality for CML,[326] the availability of imatinib and other targeting agents opens the question about optimal timing of HCT. An expert panel convened by the European LeukemiaNet put forward recommendations for the preferred upfront treatment of newly diagnosed CML, developed criteria for monitoring hematologic, cytogenetic, and PCR-defined responses, and provided considerations for optimal timing of allogeneic transplantation.[327] When an HLA genotypically matched sibling is not available, balancing the risks and benefits of unrelated donor HCT is required, with careful attention to the time required for the donor search. With increasingly more patients deferring allogeneic transplantation in favor of upfront bcr-abl tyrosine kinase targeted therapy, an area of active investigation is the impact of the time from diagnosis to HCT on overall transplant outcome. Several studies provide evidence that pretransplant imatinib therapy does not adversely affect the outcome of subsequent allogeneic transplantation.[328–331] Comparison of transplant results between patients receiving imatinib for at least 3 months before HCT and patients who did not receive imatinib demonstrated no increase in early hepatotoxicity, delay in engraftment, or differences in overall survival, DFS, relapse, or nonrelapse mortality. However, patients who had a suboptimal response or loss of response to imatinib had a higher hazard of mortality compared to patients who achieved a complete cytogenetic remission or a major cytogeneic response.[331]

The historic transplant experience in the era before imatinib demonstrated a 45% 2-year DFS rate for patients with chronic phase disease who underwent transplantation within 1 year of diagnosis, 36% for patients who underwent transplantation more than 1 year from diagnosis, 27% for patients who underwent transplantation in the accelerated phase of disease, and 0% for patients who underwent transplantation in the blast phase of disease.[332] An expanded analysis

of 1423 unrelated donor HCT showed that graft failure occurred in 9.9% of patients and grade III to IV acute GVHD occurred in 33%.[333] For patients receiving HCT in chronic phase, 5.7% developed hematologic relapse 3 years posttransplantation. Factors identified as associated with improved DFS included disease phase (chronic phase) at transplantation within 1 year of diagnosis, recipient age younger than 35 years, cytomegalovirus seronegative recipient, and development of no or mild acute GVHD. Such patients had a 63% DFS rate at 3 years. Single-institution results of unrelated donor transplantation for CML patients receiving T-cell–depleted BM with anti-CD52 monoclonal antibody (alemtuzumab [Campath])[334] showed that the probability of graft failure was 16%, probability of grade III and IV acute GVHD was 24%, and probability of clinically extensive chronic GVHD at 1 year was 38%. Clinical relapse occurred in 20% of patients who underwent transplantation in the first chronic phase. Survival and DFS rates were 52% and 41%, respectively, at 3 years for patients who underwent transplantation in chronic phase, and 28% and 26% for patients who underwent transplantation in accelerated phase. Patients with chronic phase disease who were younger than 40 years who underwent transplantation from HLA-matched donors had survival and DFS rates of 73% and 49%, respectively. Two-year survival rates of 77% have been achieved for patients 35 years and younger in early chronic phase.[335] Similar results were reported by the NMDP in a matched-cohort comparison of unrelated donor and HLA-identical sibling donor transplantations.[336] When unrelated donor HCT was performed in chronic phase (within 1 year from diagnosis), the 5-year DFS rates of unrelated versus matched sibling donors were 61% and 68% for patients younger than 30 years, 57% and 67% for patients 30 to 40 years, and 46% and 57% for patient older than 40 years. Compared to patients receiving a transplant for CML prior to 1997, current patients have a 10% to 15% overall better outcome.[120,336–344] Good-risk patients have achieved the greatest improvement in transplant outcome, with an overall survival rate of 80% and TRM of 17%. Updated outcomes confirm that disease phase at the time of transplantation remains the single most important predictor of relapse and DFS,[336,345] and transplantation in cytogeneic remission remains highly favorable for long-term survival.[346]

The extent of donor–recipient matching for HLA has historically correlated with transplant outcome. Comprehensive donor matching for class I and II HLA alleles is associated with increased survival after unrelated donor HCT for CML. In an NMDP study of 831 donor–recipient pairs, survival rates for HLA-A, HLA-B serologically matched transplantations were significantly better with HLA-DRB1 allele matching of the donor than with HLA-DRB1 mismatching.[150] Other transplantation centers have reported similar results, with an estimated cumulative incidence of clinical or cytogenetic relapse at 5 years of 10% for patients transplanted in chronic phase.[344] Overall 3-year survival rates for chronic phase, accelerated phase, blast phase, and blast phase/second chronic phase patients who underwent transplantation from an HLA-A, HLA-B, HLA-DRB1–matched donor were 62%, 34%, 9%, and 27%, respectively. Among patients younger than 50 years old who underwent transplantation from an HLA-A, HLA-B, HLA-DRB1–matched donor less than 1 year or more than 3 years from diagnosis, the probability of surviving 5 years was 74% and 50%, respectively. Among patients who underwent transplantation in chronic phase, the risk of acute GVHD was significantly higher across an HLA-DR serologic mismatch, with a trend for a higher incidence of grade II to IV acute GVHD with use of an HLA-A or HLA-B cross-reactive group (CREG) antigen-mismatched donor. The cumulative incidence of clinically extensive chronic GVHD was 67% among patients surviving disease free for more than 100 days. No significant difference in the risk of clinically extensive chronic GVHD between HLA-matched and HLA-mismatched cases was noted.

Reduced-intensity and nonmyeloablative conditioning for patients with CML is better tolerated, sustained engraftment is feasible, and overall survival statistics are approaching 65% for good-risk patients.[1,347–353] An EBMT review of clinical outcome following allogeneic transplantation has shown that the results of reduced-intensity conditioning (fludarabine, busulfan, antithymocyte globulin) approach those of conventional transplants.[351]

With the lowered up-front toxicity of reduced-intensity and nonmyeloablative conditioning, the risk of posttransplant disease recurrence and the role of donor lymphocyte infusion and posttransplant imatinib remain important questions.[354,355] Furthermore, potential differences in outcome between BM and PBSC sources demonstrate the need to balance potential up-front benefits with long-term morbidities.[341,356–359] PBSC has been associated with faster engraftment; however, its use increased the risks of grade III to IV acute GVHD, chronic and chronic extensive GVHD, which led to lower relapse, higher DFS, and higher overall survival.[358] In a CIBMTR analysis,[357] a higher incidence of acute and chronic GVHD with PBSC compared to BM did not lead to different relapse risks. TRM in the first 9 months was similar among PBSC and BM recipients. However, among patients who survived 9 months, TRM was higher with PBSC than with BM, which led to poorer overall survival with PBSC, especially in good-risk patients. This CIBMTR analysis suggests that the early advantages of PBSC should be put into the context of potential late risks stemming from chronic GVHD.

Strategies for monitoring disease recurrence after transplantation for CML remain important for identifying patients at high risk for relapse who would benefit from ancillary antileukemic therapy.[360–363] Posttransplant monitoring of bcr-abl transcripts using quantitative reverse transcriptase PCR (RT-PCR) after transplantation has been used to measure risk of relapse.[363] Ongoing research into the mechanisms leading to new mutations[364] and development of new laboratory tools[365] remain important questions.

CONCLUSION

The HLA and KIR genetic systems regulate the transplantation barrier. Clinical outcome after unrelated donor transplantation can be achieved with donor matching for the highly polymorphic HLA loci. When HLA disparity cannot be avoided, judicious selection of a donor with the fewest HLA mismatches and avoidance of certain loci may provide patients with the opportunity for lifesaving transplantation. Disease stage remains a strong predictor of overall transplant outcome, and expediency in timing of transplantation for patients with high-risk disease is paramount. New research avenues include identification of novel MHC resident genetic variation that may contribute to risks of GVHD and TRM and the precise role of the KIR systems in preventing transplant complications and disease relapse.

CHAPTER 104

HAPLOIDENTICAL HEMATOPOIETIC CELL TRANSPLANTATION

Bimalangshu R. Dey and Thomas R. Spitzer

PRINCIPLES AND RATIONALE

The complex innate and adaptive human immune systems are well equipped to withstand major antigenic challenges. Transgressing major histocompatibility barriers has been a particularly severe challenge, and the experience of haploidentical hematopoietic cell transplant (HCT) has underscored the problems of this approach. Our understanding of the basic immunobiology of HCT across major histocompatibility complex (MHC) barriers has increased dramatically over the past 2 to 3 decades; however, the translation of those discoveries into clinical practice has evolved more slowly. The most formidable complications of HCT across human leukocyte antigen (HLA) barriers, namely, graft rejection and graft-versus-host disease (GVHD), have been more effectively prevented and treated with modern pharmacologic interventions and manipulations of the hematopoietic graft.

Restoration of competent immunity remains a major obstacle to the long-term success of haploidentical HCT. With vigorous ex vivo depletion of a graft containing a high number of $CD34^+$ progenitor cells (the "megadose" approach) and sufficiently immunosuppressive conditioning, high rates of sustained engraftment with minimal GVHD have been achieved.[1] However, severe, potentially fatal opportunistic infections and recurrent malignancy are impediments to the successful application of this approach to many patients.

Realization of the potential of allogeneic HCT has one major limitation: the lack of an HLA-matched related donor in the majority of families. The HLA genes are tightly linked and inherited in a genetic unit called a *haplotype*. Haplotypes can be determined by testing for alleles at three loci: HLA-A, HLA-B, and HLA-DR. Every child inherits one haplotype from each parent. Two siblings have a 25% chance of inheriting the same two parental haplotypes and thus of becoming HLA-*genotypically* identical. There is always an excellent chance of finding a family member who shares with the patient at least one HLA haplotype but differs in the second haplotype. If the donor's different haplotype is by chance *phenotypically* identical for HLA-A, HLA-B, and HLA-DR to the recipient's, the results of transplantation following HLA-phenotypically matched related donors are comparable to that after HLA-genotypically identical related donors. However, only approximately 30% of patients have an HLA-genotypically or phenotypically matched related donor. In approximately 60% of cases without a family donor, an HLA-matched unrelated donor can be identified. In reality, in a substantial proportion of situations an unrelated, HLA-compatible adult donor cannot be identified in the needed time frame. Related donors matched for one haplotype but mismatched for the alleles of the other haplotype (haploidentical donors) are virtually always readily available.

The successful performance of haploidentical HCT would mean that most patients will have an immediately available donor both for the transplant and potentially for future modulation of the cellular environment by administration of selected donor cell populations. At least in preclinical animal models, a stronger graft-versus-tumor (GVT) effect has been demonstrated when MHC barriers are crossed.[2] A primary reason for treatment failure after HCT for advanced hematologic malignancies, particularly with use of reduced-intensity conditioning, is recurrent malignancy.[3–5] One way to address the risk of relapse would be to capture the potentially more potent GVT effect of a haploidentical transplant. Finally, the lessons of haploidentical HCT will be important for strategies to induce donor specific tolerance through mixed lymphohemapoietic chimerism.[6,7]

COMPLICATIONS OF HAPLOIDENTICAL HCT

Although the theoretical rationale for haploidentical HCT is clear, the application of this strategy has been limited by three major complications: GVHD, graft rejection, and prolonged immunodeficiency. These problems are discussed as a prelude to the historical clinical experience of haploidentical HCT and the attempts that have been made to overcome these complications.

Graft-Versus-Host Disease

Not surprisingly, the risk of acute (and perhaps chronic) GVHD is substantially higher after T-cell–replete haploidentical HCT than HLA-matched related donor transplantation.[8–10] The frequency and severity of a "hyperacute GVHD" syndrome with pharmacologic prophylaxis was well demonstrated by Powles et al. [8] in an early experience with T-cell replete haploidentical bone marrow transplantation (BMT) for advanced acute leukemia. Powles et al. reported 35 patients with advanced acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL) who received 1–3 HLA antigen-mismatched related BMT following cyclophosphamide/total body irradiation (TBI) or cyclophosphamide/melphalan conditioning and cyclosporine with or without methotrexate GVHD prophylaxis. Twelve of these patients died of a syndrome consisting of pulmonary edema, seizures, intravascular hemolysis, and/or acute renal failure. Ten patients had primary graft failure requiring a second transplant from the same donor. This life-threatening syndrome probably reflects an inflammatory cytokine cascade associated with a potent graft-versus-host alloresponse (or, in some cases, possibly graft rejection) and illustrates the potentially catastrophic consequences of crossing HLA barriers with pharmacologic GVHD prophylaxis alone.

Beatty et al.[9] at the Fred Hutchinson Cancer Research Center also showed in an early retrospective analysis of transplant outcomes that the incidence of acute GVHD was significantly higher after 1–3 HLA antigen-mismatched BMT compared to HLA-genotypically identical sibling donor transplants. Despite a higher incidence of GVHD, however, overall survival was not significantly different following HLA-matched and single antigen-mismatched donor BMT, likely due to a stronger GVT effect of single antigen-mismatched BMT balancing the harmful effects of acute GVHD. Although the number of patients who received a 2 or 3 HLA antigen-mismatched transplant was too small to reach meaningful conclusions, the survival of those patients was poor and indicated that the mortality risk of transplants was unacceptably high in donor–recipient pairs with more than a single antigen mismatch.

Use of ex vivo T-cell depletion of the haploidentical hematopoietic graft can result in a substantially lower incidence of GVHD, albeit in some experiences with a greater risk of engraftment failure.[11] With "megadose" peripheral blood stem cells (PBSCs) obtained by stimulation of the donor with high-dose granulocyte colony-stimulating factor (G-CSF) and vigorous ex vivo T-cell depletion, the prob-

ability of sustained engraftment after haploidentical transplant was high (100/101 patients in one series),[1] and the probability of acute GVHD was very low (8 %) in that same series. However, the complications of severe opportunistic infection and disease relapse, reflecting inadequate immune reconstitution, persist with this approach.[12,13]

Graft Rejection

A strong association between the degree of HLA incompatibility and graft failure was well demonstrated by Anasetti et al[14] in an analysis of 269 myeloablative BMTs for leukemia or lymphoma. The overall rate of graft failure for transplants from haploidentical donors was 12.3% compared to 2.0% for transplants from genotypically identical sibling donors. The graft failure rate also correlated with the degree of histocompatibility with 9% and 21% graft failure rates for transplants from single locus mismatched and two loci mismatched donors, respectively. Incompatibility at both the B and D loci and a positive cross-match for antidonor lymphocytotoxic antibody independently predicted graft failure.

With T-cell depletion of bone marrow grafts, graft failure rates after haploidentical HCT have been very high.[15] The problem of graft failure has been overcome in large part by the use of very-high-dose G-CSF–mobilized PBSC, as discussed in the Principles and Rationale section.[1] A "veto" function of $CD34^+$ cells and selected $CD8^+$ cells likely has contributed to the high rate of sustained engraftment with this strategy.[16,17]

Nonmyeloablative haploidentical HCT approaches have been explored more recently. Higher rates of graft failure have been observed with T-cell–replete bone marrow versus T-cell–depleted G-CSF–mobilized PBSC.[18,19] Posttransplant high-dose cyclophosphamide also has been used to deplete alloreactive (in both the GVH and host-versus-graft directions) T cells with a high rate of sustained engraftment following nonmyeloablative haploidentical BMT.[20]

Prolonged Immunodeficiency

The well-known serious consequences of haploidentical HCT, including relapse and delayed immune recovery with resultant risk of fatal infectious complications, are complicated by the rigorous T-cell depletion that is necessary to prevent fatal GVHD. Delayed immune recovery after T-cell–depleted haploidentical HCT has been associated with a very high risk for bacterial, fungal, viral, and other opportunistic infections.[21,22] With refinements in transplant strategy, including the use of "megadose" $CD34^+$ cells, the rate of donor engraftment has improved with a very low incidence of GVHD, but infectious complications have remained a substantial problem.[23] In this important study, the mortality from causes other than leukemic relapse was 40%. The high incidence of infectious complications, which occurred despite the use of antibacterial, antifungal, and antiviral prophylaxis, resulted in 59% of all nonleukemic deaths. Of note, $CD4^+$ T-cell counts were below 200/μL for as long as 16 months. Immune recovery was faster in patients who received 10 times as many T cells, but that resulted in an increased incidence of GVHD.[24]

Delayed immune recovery results from the degree of HLA disparity, the low numbers of T cells infused, the use of T-cell–depleting serotherapy (e.g., antithymocyte globulin [ATG]), the intensity of the conditioning regimen, and impaired thymic function.[25,26] Development of a fully functional immune system requires recovery of both innate and adaptive immune responses. Whereas the innate system, represented by natural killer (NK) cells, neutrophils, dendritic cells, monocytes, and macrophages, is restored relatively rapidly, the recovery of the adaptive system, represented by a broad functional T- and B-cell repertoire, is markedly delayed following T-cell–depleted haploidentical-HCT. T-cell reconstitution occurs through two main pathways: *early reconstitution* via a thymic-independent pathway known as *homeostatic peripheral expansion*, which involves expansion of mature T cells that survive the conditioning and/or are retained within the allograft, and *late reconstitution* via a thymic-dependent pathway. Although a broad T-cell repertoire presumably resulting from donor precursor cells emigrating from the thymus (i.e., via thymopoiesis) provides optimal T-cell reconstitution, effective immune reconstitution can occur relatively early through homeostatic peripheral expansion alone conferring protection against disease progression and infectious pathogens. However, this recovery is effectively eliminated by T-cell depletion in the haploidentical HCT setting. Impaired thymic function as a result of toxicity of the conditioning regimen or GVHD further contributes to delayed immune recovery.[26–28] Lamb et al.[22] demonstrated NK cell recovery as early as 1 month posttransplant, with B- and T-cell recovery at 6 months and more than 2 years, respectively, in patients who received T-cell–depleted haploidentical HCT.

HISTORICAL CLINICAL EXPERIENCE OF HAPLOIDENTICAL HCT

The first reported successful allogeneic transplants were performed in children with primary immunodeficiency syndromes who received HLA-matched sibling donor bone marrow.[29,30] Based on this initial encouraging experience, T-cell–depleted parental donor haploidentical BMT was attempted. This strategy subsequently was shown to be successful in a number of primary immunodeficiency disorders, including severe combined immunodeficiency disease and Wiskott-Aldrich syndrome.[31,32] Despite the early successes of HLA-matched BMT and the realization that only sustained lymphoid chimerism was necessary for functional cure of these diseases, it was quickly learned that more aggressive conditioning was required to overcome HLA barriers in the haploidentical BMT setting.[33,34]

The early clinical experience with myeloablative T-cell–replete BMT with pharmacologic GVHD prophylaxis for treatment of hematologic malignancies was remarkable for a significantly higher incidence of GVHD compared to HLA-matched related donor transplants[9] and a high incidence of early and severe ("hyperacute") GVHD.[8] The comparable survival of patients in the Beatty report who received an HLA-matched versus a single antigen–mismatched donor BMT despite a higher incidence of acute GVHD in the latter patient population was believed to result from a stronger GVT effect of HLA single antigen–mismatched BMT balancing the harmful effects of acute GVHD. Too few patients received a 2 or 3 HLA antigen-mismatched transplant to reach meaningful conclusions, but the poor outcomes of those patients suggested that the mortality risk of transplants involving donors who were more than a single antigen mismatch with their recipient was unacceptably high.

An International Bone Marrow Transplant Registry (IBMTR) analysis of transplant outcomes following HLA-matched and HLA-mismatched related and unrelated donor BMT for AML, ALL, and chronic myeloid leukemia (CML) added to our understanding of transplant outcomes according to degree of histocompatibility. In this analysis, transplant-related mortality was significantly higher after a 1 or 2 HLA antigen-mismatched related or matched or single antigen-mismatched unrelated donor BMT than after HLA-matched sibling BMT.[10] The large number of patients also permitted an analysis of outcomes according to leukemia status at the time of transplant. Among patients with early leukemia (AML or ALL in first complete remission or CML in chronic phase), transplants from non–HLA-matched related donors were associated with a higher risk for transplant-related mortality than were matched donor transplants. The risk of treatment failure also was higher following alternative donor BMT. For patients with more advanced leukemia, treatment failure risk was similar for HLA-matched donor transplants and single antigen-mismatched related donor transplants and lower than the treatment failure risk following matched unrelated donor and 2 HLA antigen-mismatched related donor BMT. Although this study demonstrated

the importance of leukemia status and the impact of HLA matching on treatment failure risk and survival outcomes, the analysis was limited by the heterogeneous groups of patients (including, for example, both T-cell–depleted and T-cell–replete transplants) and the exclusive use of serologic methods of HLA typing (thus underestimating the HLA disparity that now can be identified by molecular methods).

Drobyski et al.[35] compared the transplant outcomes of 139 patients with hematologic malignancies who underwent T-cell–depleted BMT from HLA-matched unrelated, single antigen-mismatched unrelated and related haploidentical donors. No significant differences in rates of engraftment or cumulative incidences of acute or chronic GVHD were observed among the three groups. Surprisingly, a higher 2-year cumulative relapse probability was observed after haploidentical BMT, and transplant-related mortality risk was higher in both the haploidentical and single antigen-mismatched unrelated donor groups. Overall survival was significantly higher in the HLA-matched unrelated donor group.[35]

RECENT HAPLOIDENTICAL HCT APPROACHES

In an effort to overcome the complications of haploidentical HCT and to improve disease-free and overall survival, a number of strategies have been developed (Table 104–1). Both myeloablative and nonmyeloablative (reduced-intensity) conditioning regimens have been evaluated. The most successful approaches have been those that address and modulate the T-cell content (or function) of the graft and provide sufficient immunosuppression to allow for sustained engraftment.

Table 104–1 Relent Haploidentical HCT Stratreles

Center	Disease	Conditioning *GVHD Prophylaxis*	GVHD (%) *Acute*	*Chronic*	NRM	EFS or DFS/OS
Non-Ex Vivo T-cell–Depleted Haploidentical Hematopoietic Cell Transplantation						
Royal Marsden[8] (N = 35)	AML/ALL	TBI/CY or TBI/MEL CYA ± MTX	80%	18%	34%	NS/31% at 6 months to3 years

[a]AML/ALL in remission, EFS only.

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; ARA-C, cytarabine; ATG, antithymocyte globulin; BMT, bone marrow transplantation; BU, busulfan; CML, chronic myeloid leukemia; CR, complete remission; CY, cyclophosphamide; CYA, cyclosporine; DFS, disease-free survival; EFS, event-free survival; FLU, fludarabine; GVHD, graft-versus-host disease; HM, hematologic malignancy; Mab, monoclonal antibody; MDS, myelodysplastic syndrome; MECCNU, methyl-CCNU; MEL, melphalan; MMF, mycophenolate mofetil; MP, methylprednisone; MTX, methotrexate; NHL, non-Hodgkin lymphoma; NIMA, noninherited maternal antigen; NMD, nonmalignant disease; NRM, nonrelapse mortality; NS, not stated; OS, overall survival; PBSC, peripheral blood stem cell; SCT, stem cell transplantation; TBI, total body irradiation; TCD, T-cell depletion; TT, thiotepa; VP-16, etoposide; XRT, irradiation.

Myeloablative Haploidentical HCT: Ex Vivo T-cell Depletion

An abundant preclinical experience[36] and an early randomized clinical trial in patients undergoing HLA-matched BMT[37] showed that GVHD could be effectively prevented following ex vivo T-cell depletion of the graft. However, increased rates of graft failure and disease recurrence showed important limitations of this strategy.

Henslee-Downey et al.[38] in a series of haploidentical BMT clinical trials evaluated TBI-based myeloablative conditioning with partial (1–1.5 log reduction) T-cell depletion of the allograft and posttransplant cyclosporine-based pharmacoprophylaxis. Ex vivo T-cell depletion was accomplished with either a T10B9 (anti-αβ T-cell receptor) monoclonal antibody or OKT3 (anti-CD3) monoclonal antibody. Sustained engraftment occurred in more than 90% of their transplants, which was attributable to an intensified conditioning regimen and the incomplete T-cell depletion. The incidence of acute GVHD was low in one report (13% grade > I GVHD), and an encouraging long-term survival probability of 20% in patients with advanced hematologic malignancy was observed.

Using high numbers of PBSC to address the problem of graft loss and more vigorous T-cell depletion to prevent GVHD, Aversa et al.[23] demonstrated a very low incidence of GVHD and impressive event-free and overall survival probabilities following myeloablative haploidentical HCT in patients with acute leukemia. Conditioning therapy consisted of TBI, thiotepa, fludarabine, and ATG. Ex vivo T-cell depletion was performed using $CD34^+$ cell selection (most recently with a Miltenyi CD34 cell selection device). With "megadose" PBSC containing a median of 13.6×10^6 (range $5.1–29.7 \times 10^6$) $CD34^+$ cells/kg, sustained engraftment was reliably achieved with minimal acute or chronic GVHD. In a published experience, 104 patients with AML (n = 67) or ALL (n = 37) received a haploidentical T-cell–depleted HCT using this regimen. Engraftment ultimately was achieved in 100 of 101 evaluable patients. Eight patients had grade II or higher acute GVHD, whereas five of 70 patients developed chronic GVHD. A 38% nonrelapse mortality risk, predominantly due to opportunistic infection, occurred. Killer cell immunoglobulin-like receptor (KIR) ligand mismatching in the GVH direction was shown to be associated with strikingly less relapse following transplantation for AML.[39] No difference in relapse probability was observed for ALL, according to KIR ligand compatibility.

Several pediatric experiences have demonstrated high rates of sustained engraftment and a low incidence of GVHD following vigorously T-cell–depleted HCT for nonmalignant hematologic disorders and hematologic malignancy.[40–42] Using positive selection of stem cells with $CD34^+$- or $CD133^-$-coated magnetic microbeads or, more recently, depletion of T and B cells using $CD3^-$- and $CD19^-$-coated microbeads, Lang et al. reported primary engraftment in greater than 70% of their patients. 41 of 63 patients transplanted with $CD34^+$- or $CD133^+$-selected cells, 83% achieved stable primary engraftment (which increased to 98% after retransplant). Grade II to IV acute GVHD occurred in less than 10% of patients. Disease-free and overall survival probabilities for patients with nonmalignant disease and hematologic malignancy (non-Hodgkin lymphoma or ALL in complete remission) were 60% and 48%, respectively. A less than 10% incidence of fatal viral infections in recently transplanted patients was observed, suggesting favorable immune reconstitution in this population of pediatric patients.

Marks et al. [43] treated 34 children having acute leukemia and other hematologic malignancies with TBI/cyclophosphamide and alemtuzumab or ATG followed by T-cell–depleted (either by $CD34^+$ cell selection or ex vivo treatment with alemtuzumab) megadose PBSC transplantation. Cyclosporine as sole GVHD prophylaxis was used only for children who did not receive $CD34^+$ cell-selected grafts. Twenty-four patients (71%) died of relapse or infection. Actuarial overall survival at 2 years was 26%. Of the nine patients with refractory AML, there were no long-term survivors.

The experience with myeloablative ex vivo T-cell–depleted (by $CD34^+$ cell selection) "megadose" PBSC transplantation for hematologic malignancy has not been universally favorable. High early nonrelapse mortality rates due to impaired immune reconstitution (resulting in a high incidence of opportunistic infections or recurrent malignancy) have been reported with this approach. Waller et al.[13] reported a mortality rate of 93% (26/28 patients), mostly due to infection or relapse, following ATG-based myeloablative conditioning and high dose $CD34^+$ cell-selected PBSC. In a Canadian multicenter trial using myeloablative conditioning and $CD34^+$ cell-selected PBSC grafts, 10 (91%) of 11 patients died of infection or recurrent leukemia.[12] The reasons for the inferior survival outcomes in these trials are unclear but may reflect patient selection (i.e., transplantation of patients with more advanced disease) or modifications of the treatment regimen.

Ex Vivo T-cell Anergization

Given the impaired reconstitution following nonselective T-cell–depleted HCT and based on experiments showing ex vivo induction of alloantigen-specific anergy by coculturing of host and donor bone marrow mononuclear cells in the presence of cytotoxic T lymphocyte antigen 4 immunoglobulin (CTLA4Ig), Guinan et al.[44] conducted a trial of ex vivo anergized haploidentical BMT in an attempt to induce alloantigen specific tolerance. Anergy was demonstrated by measuring precursor T-cell frequencies before and after ex vivo treatment of the marrow graft. A multiple log decrease in antirecipient precursor helper T-cell frequency was demonstrated after ex vivo anergization. Anti–third party precursor helper T-cell frequency was not significantly changed by ex vivo treatment of the graft. Twelve patients with advanced hematologic malignancy received TBI-based myeloablative conditioning and ex vivo anergized BMT. Three patients developed acute gastrointestinal GVHD. Five of 12 patients were alive and disease free from 4.5 to 29 months following transplant.

Myeloablative Haploidentical HCT with In Vivo T-cell Depletion

Because of the very high incidence of GVHD and transplant-related mortality following non–T-cell–depleted haploidentical HCT, most of the recent efforts in this field have focused on ex vivo T-cell or T-cell subset depletion. Recently, however, several groups have reported impressive, acceptably low transplant-related mortality and favorable survival probabilities following non–T-cell–depleted PBSC transplantation. Common to these strategies, however, has been the use of polyclonal ATG for in vivo T-cell depletion.

Lu et al.[45] treated 135 patients having a variety of hematologic malignancies with busulfan, cytarabine, cyclophosphamide, rabbit ATG (on days −5 through −2), and non ex vivo T-cell–depleted bone marrow and/or PBSC transplantation. GVHD prophylaxis consisted of mycophenolate mofetil, cyclosporine, and methotrexate. All patients had full donor chimerism at day 30 posttransplant. The cumulative incidence of grades II to IV acute GVHD was 40%, and the 2-year incidence of transplant-related mortality was 22%. The probability of relapse at 2 years was 18%. Infectious complications included cytomegalovirus virus (CMV) interstitial pneumonitis and hemorrhagic cystitis in 17% and 35% of patients, respectively. Two-year leukemia-free and overall survival probabilities were 64% and 71%, respectively.

Ogawa et al.[46] used reduced-intensity conditioning (busulfan, fludarabine, and rabbit ATG) as preparation for 2–3 HLA antigen-mismatched non–ex vivo T-cell–depleted PBSC transplantation in 26 patients with high-risk hematologic malignancies. GVHD prophylaxis consisted of tacrolimus and corticosteroids. Serum soluble interleukin-2 receptor (sIL-2R) levels were followed, and tapering of corticosteroids was based partly on the results of these assays. Twenty-five of the 26 patients achieved full donor chimerism. Five patients developed grade II acute GVHD, and five of 20 evaluable patients developed chronic GVHD. Transplant-related mortality was 15%

(4/26 patients). $CD4^+$ cell recovery was slow, with a median count greater than 100/μL at 9 months. Fifteen (58%) of the 26 patients were alive and in complete remission at a median of 664 days posttransplant.

The surprisingly low incidence of GVHD in these series compared to historical experiences of non–ex vivo T-cell–depleted HCT likely reflects the use of ATG for in vivo T-cell depletion, improved GVHD prophylaxis strategies, and better prevention and treatment of opportunistic infections. The importance of genetic factors (i.e., heterogeneity of the population) and other factors, such as use of donors mismatched for noninherited maternal antigens, remains to be determined in future clinical trials of non–ex vivo T-cell–depleted haploidentical transplant.

Nonmyeloablative Conditioning for Haploidentical HCT

Nonmyeloablative (reduced-intensity) conditioning for HCT is associated with significantly less transplant-related morbidity and mortality than is myeloablative conditioning, thus permitting the transplantation of older patients and patients with significant pretransplant comorbidity.[3–5,47] A variety of postulated mechanisms, including less proinflammatory cytokine production and preservation of host "regulatory" cellular elements observed after nonmyeloablative transplants, may account for less clinical evidence of GVHD.[48] A potent GVT effect may be achieved, following either spontaneous or donor lymphocyte infusion (DLI)-induced conversion of mixed to full donor lymphohematopoietic chimerism.[4,49]

Nonmyeloablative Haploidentical HCT Strategies Using In Vivo T-cell Depletion

Pelot et al.[49] showed in murine MHC-mismatched transplant models that mixed lymphohematopoietic chimerism can be reliably induced following nonmyeloablative conditioning, in vivo T-cell depletion with anti-CD4 and anti-CD8 monoclonal antibodies, and thymic irradiation. Remarkably, these mixed chimeric mice are resistant to in-duction of GVHD following delayed DLI, despite a potent lymphohematopoietic graft-versus-host response, which converts their mixed chimerism to full donor hematopoiesis. A more potent GVT effect has been demonstrated in mixed chimeric mice that convert to full donor chimerism after DLI, compared to full donor chimeras given DLI (with the enhanced antitumor effect shown to result from the preservation of host professional antigen-presenting cells).[50,51]

Based on these murine models, a series of haploidentical nonmyeloablative HCT clinical trials have been conducted at the Massachusetts General Hospital. The initial trials involved cyclophosphamide, equine ATG for in vivo T-cell depletion, and pretransplant thymic irradiation.[52] Cyclosporine was given as GVHD prophylaxis and was tapered and discontinued by 5 weeks posttransplant in the absence of GVHD. DLIs were given to patients with mixed chimerism and without GVHD in an attempt to maximize the GVT effect. Because of a high incidence of severe acute GVHD in the initial group of patients, the monoclonal anti-CD2 antibody MEDI-507 was substituted for ATG in an effort to effect a more complete T-cell depletion.[18] A series of protocol changes have since been made, including the use of ex vivo T-cell depleted G-CSF–mobilized PBSC (rather than bone marrow), changes in the dose and schedule of MEDI-507, and the addition of fludarabine to address the problems of GVHD and graft failure. Mixed "split lineage" lymphohematopoietic chimerism has been achieved in all of the patients treated with ex vivo T-cell–depleted PBSC, with an early predominance of donor granulocyte chimerism and a much lower percentage of donor T-cell chimerism. In the majority of these patients, mixed chimerism in all lineages has converted to full or nearly full donor chimerism, either with tapering of immunosuppression or following DLI. Although GVHD has occurred in the majority of patients following conversion to full donor chimerism, it has been manageable in most cases. Striking antitumor responses in selected patients with chemorefractory aggressive lymphomas also have been achieved.

An unexpected observation in these clinical trials as well as HLA-matched nonmyeloablative HCT trials at the Massachusetts General Hospital was that durable antitumor responses in some patients with chemorefractory hematologic malignancies occurred despite loss of the hematopoietic graft.[53] Nine (41%) of 22 patients who received an HLA-matched or haploidentical nonmyeloablative HCT achieved a response after loss of their graft. Six patients were alive from 2.5 to 5.5 years posttransplant; four of these patients were in a sustained complete remission. The observation of ongoing tumor regression following serial DLI in a patient who lost his graft, accompanied by "spikes" in circulating host $CD8^+$ T cells, raised the intriguing possibility that a host specific antitumor response was induced. In an effort to elucidate the mechanism of these antitumor responses, Rubio et al.[54,55] established a murine nonmyeloablative transplant model in which recipient lymphocyte infusions were administered in order to cause rejection of the graft, followed by tumor challenge with host strain-specific malignant cells. A survival benefit was observed in the mice that developed mixed chimerism followed by recipient lymphocyte infusion–induced graft rejection compared to mice that received conditioning only, conditioning and transplant, or conditioning and recipient lymphocyte infusions alone. The antitumor response has been shown to be mediated by recipient lymphocyte infusion–derived interferon-γ–producing $CD8^+$ cells and recipient $CD4^+$ cells.

Rizzieri et al.[56] at Duke University Medical Center have used anti-CD52 monoclonal antibody therapy (alemtuzumab) for both ex vivo and in vivo T-cell depletion in a clinical trial of haploidentical nonmyeloablative HCT for hematologic malignancies and selected solid tumors. Conditioning consisted of fludarabine, cyclophosphamide, and alemtuzumab, followed by infusion of alemtuzumab-treated PBSC. GVHD prophylaxis consisted of mycophenolate mofetil with or without cyclosporine. DLI were given to patients with persistent disease. Of 49 patients, 8 (16%) developed grade II to IV acute GVHD, and 7 (8%) developed chronic GVHD. Three patients (6%) experienced primary graft failure, and 4(8%) had secondary graft failure. The complete remission rate was 75%; relapse-free and overall survival probabilities at 1 year were 43% and 31%, respectively.

Nonmyeloablative Haploidentical HCT with Posttransplant High-Dose Cyclophosphamide

Based on canine experiments in which high-dose posttransplant cyclophosphamide was effective in depleting alloreactive T cells in both the GVH and host-versus-graft directions, O'Donnell et al.[20] performed a phase I trial to determine the minimal conditioning needed to achieve stable engraftment after 1–3 HLA antigen-mismatched BMT. Thirteen patients with hematologic malignancy received low-dose TBI, fludarabine with or without cyclophosphamide conditioning, and high-dose cyclophosphamide on day +3 posttransplant. Nine of 13 patients achieved sustained engraftment. Six of 13 patients developed acute GVHD. Six of 13 patients were alive, five in complete remission, at a median of 191 days posttransplant.

In an updated report of their experience of 84 patients treated with this protocol, 16 (19%) patients experienced graft rejection; 14 of those patients recovered autologous hematopoiesis. Seven of the 16 patients who had graft loss achieved an antitumor response, including three of 6 patients with myelodysplastic syndrome, two of three patients with CML, and both patients with chronic myelomonocytic leukemia.[57]

Selective Allodepletion

Nonselective depletion of T cells from the allograft prior to transplantation effectively prevents severe acute GVHD but invariably

predisposes the recipient to loss of the graft, disease relapse, and an increased incidence of infectious complications. Unmanipulated T-cell add-backs likely will not be effective in preventing these problems without causing GVHD because the frequency of alloreactive T cells in the peripheral blood is far greater than that of either specific antiviral or antileukemic T cells. One approach to overcoming these adverse outcomes is to selectively deplete the graft of the GVHD-causing alloreactive T cells identified by upregulation of activation markers while conserving cells mediating GVT and antimicrobial immune responses. Several methods of selective removal of alloreactive T-cells have been reported that rely on ex vivo stimulation of donor T cells by recipient peripheral blood mononuclear cells in a unidirectional mixed lymphocyte reaction culture. Host-reactive donor T cells can be identified by their expression of activation markers (CD25, CD69, CD71), proliferative potential, or preferential retention of photoactive dyes. They subsequently can be targeted for depletion using a variety of methods, including an immunotoxin,[58,59] immunomagnetic bead separation,[60–63] fluorescence-activated cell sorting,[64,65] photodynamic purging,[66,67] or Fas–Fas ligand-mediated apoptosis.[68] These selective allodepletion methods have yielded 70% to 95% reductions in alloreactivity in vitro, with retention of immune responses against third-party and infectious organisms. Several methods even allow retained alloreactivity against leukemia cells.[66,69–71] Although this promising approach has been shown to be feasible in clinical trials,[72,73] several concerns have been raised, including contamination of recipient peripheral blood mononuclear cells by leukemic cells, loss of antileukemic activity, and induction of clinically significant GVHD. In a clinical trial, Amrolia et al.[74] used different cell doses for allodepleted (via immunotoxin) T-cell add-back. At a dose level of 10^5 $CD3^+$ cells/kg, patients exhibited significantly more rapid recovery of T cells at 3 to 5 months after haploidentical HCT than did patients who received 10^4 $CD3^+$ cells/kg. The incidence of GVHD was very low, and the median time to reach a $CD4^+$ cell count greater than 300/μL was 4 months in patients at dose of 10^5 $CD3^+$ cells/kg compared with more than 6 months in patients at a dose of 10^4 $CD3^+$ cells/kg and 8 months in the series by Eyrick et al.[75] without allodepleted T-cell add-back. A similar improvement in immune reconstitution without GVHD has been demonstrated by another group that used photodynamic therapy for selective depletion of alloreactive T cells.[76] Bear in mind that however small the alloreactive T-cell subset of the total T-cell population (<0.1% in the HLA-matched sibling setting; 1%–5% in the HLA-mismatched setting), their complete elimination may be difficult, and doses of unmanipulated T cells as low as 3×10^4 kg can be associated with severe GVHD following haploidentical HCT. Mielke et al.[77] at the National Institutes of Health demonstrated that selective depletion of alloreactive T cells preserves a $CD25^-CD4^+Foxp3^+$ fraction of T cells that is capable of undergoing marked expansion posttransplant to T regulatory cells (Tregs), which can provide protection against GVHD.

CHOICE OF DONORS FOR HAPLOIDENTICAL HCT: SPECIAL CONSIDERATIONS

Exploiting KIR Ligand Mismatching in the GVH Direction

NK-cell alloreactivity in the GVH or host-versus-graft direction can be a powerful means of optimizing the efficacy and safety of haploidentical HCT. NK cells are a unique $CD56^+CD3^-$ cell population composing approximately 10% of peripheral blood lymphocytes[78,79] and are involved in innate antiviral and antitumor immune responses.[80–83] They compose a heterogeneous population of different cell subsets with distinct phenotypic and functional characteristics. The majority (90%) are highly cytotoxic $CD56^{dim}$ cells likely functioning as efficient effector cells, whereas a minority (10%) are immunoregulatory $CD56^{bright}$ cells producing cytokines.[84,85] Following HCT, including haploidentical transplant with selected $CD34^+$ cells, NK cells recover as early as 2 to 3 weeks posttransplant by rapid differentiation from engrafted $CD34^+$ cells.[14,22,86]

The "missing self" recognition concept was hypothesized 2 decades ago by Klas Karre. He suggested that, unlike T and B cells, NK cells are activated by the absence of self MHC class I molecules on the surface of target cells.[87–90] Expression of self MHC molecules on target cells delivers an inhibitory signal to NK cells via inhibitory KIRs. In the absence of this inhibitory signal, NK cell alloreactivity, manifested by NK cell-mediated target cell lysis, proceeds by default. When NK-cell inhibitory receptors are engaged by KIR-specific epitopes, killing is inhibited, whereas killing of target cells occurs when NK-cell inhibitory receptors are not engaged, due to either absence of MHC class I or MHC mismatch. Because virally infected cells and tumor cells downregulate MHC expression to escape adaptive immune surveillance, the ability of NK cells to identify "missing self" is critical in (innate) immune response against viruses and tumor cells.[91,92] Essentially all NK cells express at least one inhibitory receptor that is specific for a self MHC class I epitope, thereby preventing autoreactivity.[93] NK cells also have activating receptors, most notably NKG2D and NKp46, which can trigger NK-cell alloreactivity when they are engaged by appropriate antigens on virally infected cells and tumor cells.[94–97] Although inhibitory signals are believed to dominate over activating signals, NK cell activity is regulated by quantitative differences in cumulative inhibitory and activating signals transmitted via KIRs. Therefore, the presence or absence of the respective ligands on recipient cells determines if NK cells will be primed to be alloreactive and kill the targets.[79,98]

By selecting haploidentical stem cell donors whose NK cells are not fully inhibited by recipient MHC class I ligands, that is, there is a KIR ligand mismatch in the GVH direction, the graft NK-cell alloreactivity may be used to optimize a GVT effect. As discussed in the Myeloablative Haploidentical HCT: Ex Vivo T-cell Depletion section, Ruggeri et al.[39,99] found that HLA (KIR ligand) mismatching in the GVH direction following T-cell–depleted haploidentical HCT is associated with strong NK-cell alloreactivity leading to (a) a dramatically reduced relapse in patients with AML, (b) a lower rate of graft rejection, and (c) a reduction in GVHD. As supported by their animal studies, the reduction in GVHD is due to donor NK-mediated depletion of host antigen-presenting cells that are crucial in priming alloreactive donor T cells and hence in the pathogenesis of GVHD, and donor NK cells that attack host hematopoietic cells and spare epithelial GVHD target tissues.[39,99,100] The lower rates of graft rejection were shown to be due to donor NK-mediated lysis of host residual T cells, thereby preventing them from rejecting the graft. Furthermore, in their murine transplant model they showed that pretransplant transfer of NK cells into mice improved engraftment after transplantation, allowing durable full donor chimerism following reduced-intensity conditioning. This NK-cell conditioning prevented GVHD well enough to allow for safe infusion of otherwise lethal doses of allogeneic T cells, which were given to facilitate immune reconstitution.

Fetomaternal Microchimerism

Several transplant centers have developed haploidentical HCT strategies based on the principle of tolerance induction as a result of in utero exposure to maternal antigens and the development of long-lasting fetomaternal microchimerism.[101] A large IBMTR analysis by van Rood et al.[102] showed that the incidence of grade II or higher acute GVHD following non–T-cell–depleted haploidentical HCT was related to haplotype inheritance. Transplants from a noninherited maternal antigen-mismatched sibling were associated with significantly less acute GVHD. Moreover, transplant-related mortality was significantly higher in transplants from a maternal or a paternal donor. Several Japanese transplant centers have performed non–T-cell–depleted transplants following either myeloablative or nonmye-

loablative conditioning from microchimeric noninherited maternal antigen-mismatched donors.[103–106] Although the overall incidence of grade II or higher acute GVHD incidence was high (56% of 34 evaluable patients) in one series, a significantly lower risk of acute GVHD was observed in patients who received a transplant from a donor who was noninherited maternal antigen mismatched in the GVH direction.

IMMUNE RECONSTITUTION FOLLOWING HAPLOIDENTICAL HCT

Transfer of a functional lymphohematopoietic system from donor to recipient in a timely fashion determines in large part the eventual success of HCT. Given the problem of delayed immune reconstitution with resultant risk of infectious complications and disease relapse following haploidentical transplantation, particularly after ex vivo T-cell–depleted HCT, new strategies are required to limit the severity and duration of this immunodeficiency. Both adoptive cellular therapy approaches and strategies using soluble factors are being investigated.

Immunotherapy involving both cellular and soluble factors can be guided by two distinct concepts: (a) enhancement of general immune reconstitution relative to enhancement of antigen specific responses, and (b) expansion of beneficial cell subsets and depletion of harmful effectors cells. New approaches aimed at facilitating engraftment and reducing GVHD while preserving GVT effects have been developed using regulatory T cells and mesenchymal stem cells (MSCs). In mice, two types of regulatory T cells, $CD4^+CD25^+$ T cells (Tregs) and NK T cells (NK/Tregs), have been shown to prevent acute GVHD.[107–111]

Tregs represent approximately 5% to 10% of peripheral $CD4^+$ T-cells in mice and humans and are identified by their capacity to suppress both $CD4^+$ and $CD8^+$ T-cell activation. Tregs have been shown to promote engraftment and reduce acute GVHD without loss of GVT effects.[107,108,112] In murine models, Tregs can be successfully expanded ex vivo by in vitro stimulation with allogeneic splenocytes plus IL-2. When added to the donor inoculum containing alloreactive T cells, the Treg population can prevent GVHD, enhance immune reconstitution, and reduce the risk of infection while the GVT effect is well preserved.[113] Preliminary experience with expanded Tregs in humans is promising,[114] although clinically meaningful expansion of this small effector cell population and its beneficial use outside of acute GVHD[115] are not defined. Composing only 1% to 3% of all T cells in the spleen in normal mice, NK/Tregs of either donor or host type have the unique capacity to prevent acute GVHD in mice by secreting IL-4, which prompts donor T cells to acquire an antiinflammatory, IL-4–secreting helper T cell 2 (T_H2) phenotype.[110,111,116] NK/Tregs-mediated GVHD prevention strategy was evaluated clinically by Lowsky et al.,[117]who showed an apparent reduction in the rate of acute GVHD in patients with lymphohematopoietic malignancies while permitting GVT effects after HLA-matched HCT. Preliminary evidence also suggests that this strategy may be effective in the haploidentical HCT setting.[118] MSCs, which are multipotential nonhematopoietic progenitors and constitute only 0.001% of nucleated cells in human bone marrow,[119] have been extensively evaluated for their regenerative and immunomodulatory properties. Human MSC have a high in vitro proliferative potential and have the capacity to differentiate into a number of mesenchymal tissues, such as bone, cartilage, and fat. MSCs have been demonstrated to inhibit T-cell alloreactivity[120–124] and prolong skin allograft survival.[121] In addition, ex vivo expanded MSCs have the potential to prevent and treat acute GVHD when used after HLA-matched or HLA-mismatched HCT.[125,126] Although the exact mechanism of immune modulation by MSC is not clearly defined, they appear to mediate their immunomodulatory effects by inhibiting interferon-γ secretion from T_H1 and NK cells, increasing IL-10 secretion from Tregs and increasing IL-4 secretion from T_H2 cells, thereby promoting a $T_H1 \rightarrow T_H2$ shift.[123]

Cytokines and Chemokines

A number of cytokines and chemokines and their associated monoclonal antibodies can be applied to influence effector cell development, activation, trafficking, and thereby transplant outcomes, including engraftment, GVHD, immune reconstitution, and antitumor effects.[127–129] Use of G-CSF posttransplant accelerates neutrophil recovery, but studies have shown deleterious effects on immune restoration, namely, by inhibition of NK-cell and T-cell function.[130–132] Given their excellent capacity to enhance in vivo expansion of NK and T cells after T-cell–depleted HCT, IL-2[133–136] and IL-18[137] potentially could improve immune reconstitution after haploidentical transplant. However, caution must be taken because, depending on the timing of administration of these cytokines, unfavorable outcomes such as exacerbation of GVHD may occur.[138,139] In one murine model, IL-7 improved immune reconstitution by enhancing thymopoiesis in addition to expanding peripheral T cells, NK cells, NK/Tregs, B cells, monocytes, and macrophages.[140] However, in another model this cytokine enhanced the development of acute GVHD.[141] Keratinocyte growth factor has been shown in a murine model to improve thymic and peripheral T-cell recovery after transplant.[142] Monoclonal antibodies specific for selective cytokines and chemokines to prevent GVHD[44,143,144] and optimize GVT effects are being evaluated.[128]

Enhancement of Antigen-Specific Immune Responses

Prevention and treatment of opportunistic viral, fungal, bacterial, and parasitic infections remain formidable challenges after haploidentical HCT. For example, the failure to successfully treat viral infections, which is partly due to the limited number of nontoxic antiviral drugs, constitutes a major cause of treatment failure following haploidentical transplant. Both $CD4^+$ and $CD8^+$ cells are critical in maintaining CMV, Epstein-Barr virus, adenovirus, polyomavirus, and herpes virus in their latent phase. Therefore, adoptive immunotherapy with ex vivo expanded virus-specific cytotoxic T lymphocytes (CTLs) is being explored. Infusion of donor-derived allogeneic CMV-specific T-cell clones into recipients for prevention or treatment of CMV-related disease, without causing GVHD, has shown promising potential.[145–148] These studies also demonstrated that CMV-specific $CD4^+$ cells are important for reconstitution and maintenance of $CD8^+$ CTL responses. Encouraging early results have been achieved when ex vivo expanded allogeneic CTL clones specific for Epstein-Barr virus were used for prophylaxis and management of Epstein-Barr virus–associated diseases, including posttransplant lymphoproliferative disorder.[149–152] The identification of antigens that are specifically expressed by leukemia cells, such as PR1 by CML and AML cells, and can be recognized by T cells has led to successful ex vivo generation of leukemia-specific donor T cells (PR1-CTL) that may promote a GVT effect.[153–155] Notwithstanding the promise of these novel approaches, the large-scale therapeutic potential of adoptive transfer of ex vivo expanded antigen-specific effector cells has not yet been fully realized for a number of reasons. One reason is the short survival of the effector cells, which likely is due to factors intrinsic to the cells themselves or to the host environment into which the cells are infused.

OPTIMIZATION OF GVT EFFECT: ADOPTIVE CELLULAR THERAPY VIA DLI

Adoptive cellular immunotherapy using DLI has been shown experimentally and clinically to be a potent means of inducing a GVT effect by converting mixed to full donor chimerism after allogeneic transplant.[156–158] In patients with recurrent CML after HLA-matched HCT, complete clinical and molecular remissions are achieved in the majority of patients following unmodified DLI.[159,160] A high incidence of GVHD (and marrow aplasia) has tempered the use of this approach and has led to a revision of DLI strategies, such as lowering the dose of infused T cells or giving T-cell subsets such as $CD8^+$–

depleted DLI.[161] The GVHD risk likely is higher after alternative donor transplantation, and considerably smaller doses of T-cells have been used in the haploidentical HCT setting.[162,163] Lewalle et al.[162] reported the outcomes of escalating DLI doses after haploidentical transplantation. $CD3^+$ T-cell doses greater than 1×10^4 kg every 3 months (given to convert mixed to full chimerism) caused significant GVHD in recipients of T-cell– and B-cell–depleted myeloablative haploidentical HCT. Or et al.[163] treated 28 patients (six prophylactic and 22 therapeutic) with HLA-mismatched DLI. The dose range of T cells in the DLI was 1×10^2 to 1.5×10^9 kg. GVHD (median peak grade 2) occurred in 13 of the 28 patients. A higher incidence of GVHD unexpectedly occurred in recipients of 5/6 HLA-matched DLI compared to recipients of a 3/6 HLA-matched DLI. In our nonmyeloablative HCT trial, in which vigorous ex vivo and in vivo T-cell depletion are used, $CD3^+$ T-cell doses greater than 1.0×10^6 kg were given in some circumstances. Because GVHD occurred in the majority of cases (most often skin-limited GVHD), future strategies will use a smaller initial DLI dose.[18] Additional dose finding studies are required to establish the safest and most effective DLI T-cell dose and schedule following haploidentical HCT. Critical to the success of HCT will be the identification of specific cellular populations that can be administered as adoptive cellular immunotherapy (e.g., pathogen- or tumor-specific CTL) and that are capable of optimizing the separation of GVHD and GVT.

HAPLOIDENTICAL HCT: NEW APPLICATIONS

Combining Haploidentical PBSCs with Umbilical Cord Blood for Facilitation of Engraftment

Umbilical cord blood transplantation has been complicated by slow hematologic recovery and delayed immune reconstitution due in part to the relatively low number of hematopoietic progenitor cells collected and transplanted. In an attempt to facilitate hematologic recovery and reduce the complications associated with impaired immune recovery, Fernandez et al. cotransplanted 11 patients with umbilical cord blood cells and $CD34^+$ cell-selected haploidentical PBSC.[164] Rapid neutrophil recovery occurred at a median of 10 days (range 9–17 days) days. Chimerism studies showed a predominance of the haploidentical genotype in the granulocyte and mononuclear lineages early posttransplant, followed by progressive replacement by cells of umbilical cord donor origin. Grade II or higher GVHD occurred in 4 (36%) of the 11patients. Five of the 11 patients were alive and in complete remission 6 to 43 months posttransplant. Evaluation of immune reconstitution in this patient population demonstrated early recovery of NK cells and B cells and delayed but eventually complete recovery of $CD4^+$ and $CD8^+$ cells.[165]

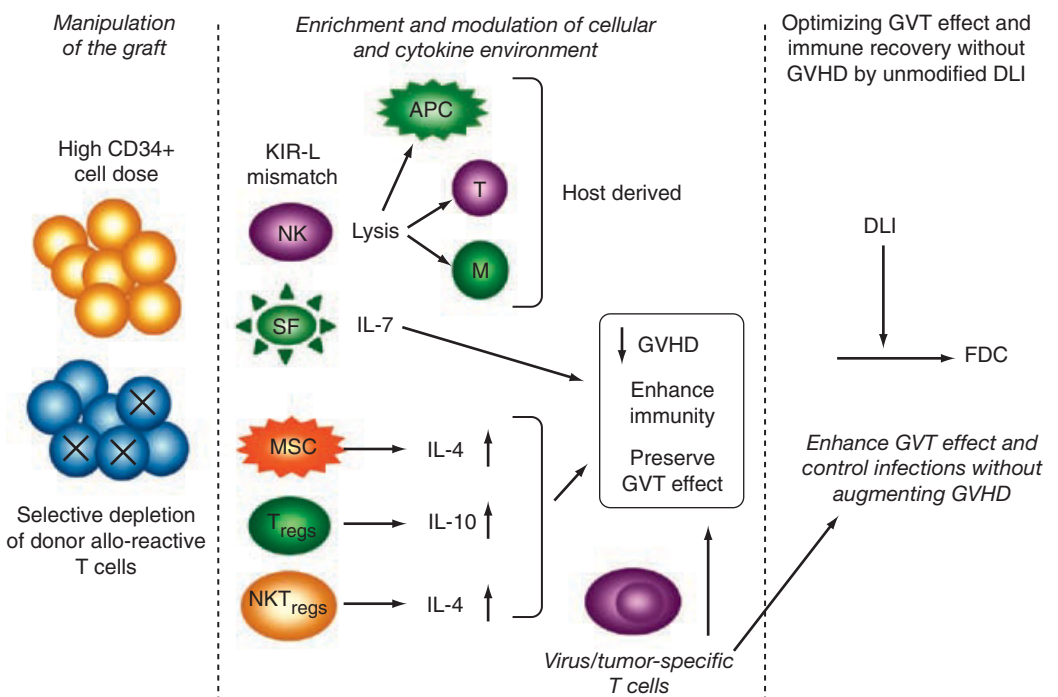

Figure 104–1 Schema of a strategy for optimizing outcomes of haploidentical HCT. Graft Manipulation: High $CD34^+$ cell dose likely will improve donor engraftment by overcoming host-mediated resistance. Selective ex vivo depletion of donor alloreactive T cells may reduce the incidence of severe acute graft-versus-host disease (GVHD) while preserving graft-versus-tumor (GVT) effect and improving immune recovery. Enrichment and Modulation of Cellular and Cytokine Environment: KIR ligand mismatching in the graft-versus-host (GVH) direction will prompt donor natural killer (NK) cells to promote engraftment by attacking host T cells (T), diminish acute GVHD by depleting host antigen-presenting cells (APC) while eliminating host-derived malignant cells (M). Ex vivo expanded NK cells, mesenchymal stem cells (MSCs), T regulatory cells (Tregs), NK Tregs, and soluble factor (interleukin-7) will further augment donor engraftment, innate and adaptive immune responses, and reduce GVHD while not impairing GVT effects. MSC and NK Tregs, via IL-4 production, will skew donor T cells toward an antiinflammatory T_H2 phenotype that is associated with reduced GVHD. Optimizing GVT Effect and Immune Recovery Without GVHD by unmodified Donor Leukocyte Infusion (DLI): Ex vivo engineered tumor antigen- and pathogen (virus)-specific donor-derived T cells (both cytotoxic T lymphocytes [CTLs] and CD4 cells) can be used to prevent and/or treat relapse of an underlying malignancy and opportunistic infections, respectively. In some circumstances, unmodified DLI may be used to convert mixed chimerism to full donor chimerism (FDC), probably enhancing a GVT effect without augmenting GVHD.

Specific Tolerance Induction

Induction of donor-specific tolerance has important implications for the field of organ transplantation, which currently is limited by the complications of lifelong immunosuppressive therapy. Multiple preclinical small and large animal models have shown that sustained specific tolerance can be induced after induction of even transient mixed lymphohematopoietic chimerism.[166,167] Based on these preclinical discoveries, we have conducted clinical trials of combined related donor bone marrow and kidney transplantation for patients with end-stage renal disease. In the first of these trials, combined HLA-matched bone marrow and kidney transplantation was performed in patients with multiple myeloma and end-stage renal disease. This experience was notable for the achievement of complete remissions in four of six patients and the occurrence of renal graft rejection (transient and reversible) in only one patient. All six patients were alive from approximately 3 to 8 years posttransplant.[7,168]

In order to broaden the application of this strategy, we initiated a trial of combined haploidentical bone marrow and kidney transplantation for patients with end-stage renal disease but no associated malignancy. The preparative therapy is one that we used in earlier trials of haploidentical HCT for hematologic malignancies and was notable for the uniform development of transient mixed chimerism followed by graft rejection.[18] Of the first five patients who received a combined haploidentical bone marrow and kidney transplant, four are no longer receiving immunosuppressive therapy. In vitro evidence of specific tolerance also has been demonstrated.[169]

The proof of principle of sustained donor-specific tolerance induction through mixed lymphohematopoietic chimerism has been demonstrated clinically. Future trials will include the transplantation of other organs, including cadaveric organs, and the inclusion of fully HLA-mismatched related donors.

FUTURE DIRECTIONS

The promise of haploidentical HCT, specifically the opportunity to offer allogeneic transplantation to virtually everyone who requires it and to take advantage of the powerful GVT effect that it affords, has yet to be fully realized. Although the complications of severe GVHD and graft rejection have been overcome in large part by the use of "megadose" T-cell–depleted hematopoietic progenitor cells, prolonged immunodeficiency remains a formidable problem. Reduced-intensity conditioning has ameliorated early transplant-related morbidity and perhaps mortality but has been associated with a higher relapse probability and no clear advantage in terms of restoration of effective immunity. Vigorous pan–T-cell depletion of the graft dramatically reduces the incidence of acute GVHD but delays immune reconstitution, resulting in a high incidence of opportunistic infections and disease relapse.

The future of haploidentical HCT relies on the ability to modulate the cellular content of the graft and the posttransplant cellular environment, to separate GVHD and GVT, and to rapidly restore effective immunity (shown schematically in Fig. 104–1). Strategies such as selective allodepletion of the graft or enrichment for (or addition of) cell populations such as Tregs or MSC to the graft may achieve effective protection from GVHD while imparting effective antitumor and antiinfective immunity.

Following the transplant, administration of specific cellular populations or soluble factors may affect the separation of GVHD and graft-versus-malignancy effect. Unmanipulated DLI may still be considered at certain time points to convert the mixed chimerism to full donor hematopoiesis in an effort to achieve an early GVT effect and facilitate early reconstitution. The adoptive transfer of allogeneic cytotoxic T cells that are specific for viral or tumor antigens may be other strategies for addressing the problems of infection and disease relapse. Other cellular populations, such as NK or NK T cells or MSC, may favorably influence the balance of GVHD and immune reconstitution. The future of haploidentical transplant depends on our expanding knowledge of the cellular populations and soluble factors that determine the separation of GVHD and GVT effect and our ability to modulate the cellular content of the graft and the posttransplant environment to improve disease-free and overall survival probabilities.

CHAPTER 105

UMBILICAL CORD BLOOD TRANSPLANTATION

Claudio G. Brunstein and John E. Wagner, Jr.

Transplantation of allogeneic hematopoietic stem cells (HSC) derived from bone marrow (BM) or peripheral blood has been used successfully to treat high-risk or relapsed hematologic malignancies, marrow failure syndromes, selected hereditary immunodeficiency states, and metabolic disorders. However, the availability of suitable donors remains a major limitation, often preventing the application of hematopoietic cell transplantation (HCT). Because only 30% of patients have an HLA-matched sibling donor, adult volunteer unrelated donor (URD) registries have been created.[1] Currently more than 11 million donors are registered worldwide, with more than eight million donors typed at the HLA-A, B, and DR loci and approximately 870,000 typed by high-resolution molecular techniques *(www.bmdw.org)*. The National Marrow Donor Program (NMDP) has more than six million registered donors, with approximately 410,000 having undergone high-resolution HLA-A, B, and DR typing (S. Spellman and D. Weisdorf, Personal Communication, May 2007). However, only 40% of caucasians and a far greater proportion of those of racial and ethnic minority descent are able to find a suitable HLA-matched donor.[1,2] Furthermore, data from marrow donor registries have consistently reported a 3- to 4-month median interval from initiation of the search to transplantation. During the search process, transplant candidates may die of disease progression or related complications (i.e., infections, treatment toxicities) or become ineligible for HCT. Although great efforts have been made to improve donor availability,[3,4] there remains a need to investigate alternative sources of HSCs to alleviate the shortage of suitable URDs and reduce the length of the donor search process. New strategies are needed to reduce the high risk of mortality that currently limits the successful application of adult volunteer URD HCT therapy intended to replace a diseased or damaged hematopoietic compartment and immune system.

The concept of using umbilical cord blood (UCB) as a clinical source of HSC was first considered in the late 1960s. Recognizing the potential value of UCB, Ende and Ende[5] were among the first to apply UCB to the treatment of a child with leukemia. In the first published report, freshly procured UCB samples from eight donors were infused over a 17-day period in a 16-year-old boy with acute lymphocytic leukemia who previously had been treated with 6-mercaptopurine and prednisone. Although long-term reconstitution was not demonstrated, Ende and Ende documented a transient alteration in red cell antigens in the peripheral blood, suggesting a transient mixed chimerism from at least one if not several of the units. Additional studies performed by Koike[6] and Vidal[7] in the late 1970s and early 1980s suggested that UCB may contain sufficient numbers of hematopoietic progenitor cells for transplantation. Preclinical studies compared numbers of hematopoietic progenitors in UCB and marrow. The authors concluded that if a sufficient volume of cord blood could be collected, the number of BM progenitors would be adequate to reconstitute hematopoiesis in transplant recipients.[6,7] In anticipation of possible clinical application, Koike[6] subsequently showed that UCB progenitors could be cryopreserved without significant loss of viability and proliferative capacity. The conclusion was that "(cryopreserved) cord blood cells . . . may be useful as a source of hemopoietic progenitor cells for marrow transplantation."

Hal Broxmeyer, Ted Boyse, Gordon Douglas, and Lewis Thomas in collaboration with Pablo Rubinstein were instrumental in further development of the concept that UCB could be a clinically applicable source for HSCs and progenitors useful for transplantation. The Broxmeyer laboratory systematically evaluated the hematopoietic potential of human UCB in vitro and developed practical and efficient methods for large-volume collections and storing UCB in anticipation of its clinical use.[8–11] This work ultimately led to a collaboration between Henry Friedman, Joanne Kurtzberg, and Arleen Auerbach, who cared for a child with Fanconi anemia, Hal Broxmeyer and Gordon Douglas who collected and stored the cord blood unit from the patient's sibling, and Eliane Gluckman, Agnes Devergie, Hélène Esperou, Gérard Socie, and Pierre Lehn, the transplant team. The first human UCB transplant took place on October 6, 1988 in Paris.[12] Complete chimerism was sustained long term after transplantation in both myeloid and lymphoid lineages. Thus, these investigators were the first to demonstrate that pluripotent HSC existed in human UCB. The recipient of this first UCB HCT remains alive and well with complete chimerism 19 years later (J. Kurtzberg, Personal Communication, June 2007).

After this initial report, several investigators started to explore the potential of UCB as a source of HSC for transplantation. At first many questions were raised: Would this HSC source engraft larger recipients or patients with diseases other than Fanconi anemia? Would lethal graft-versus-host disease (GVHD) occur because of maternal lymphocyte contamination, previously shown to occur in some neonates with congenital immunodeficiency? Would naive lymphocytes in the UCB unit really be less likely to cause GVHD? Would these naive UCB lymphocytes mount an effective graft-versus-leukemia (GVL) response? Could UCB be used as a source of HSC in the URD setting, rather than in the relatively rare situation of sibling HCT? Some of these questions would not be resolved for another decade.

Based on the early successes with sibling donor UCB transplantation,[12–15] public cord blood banks (CBBs) were created. The first was founded in 1992 by Pablo Rubinstein at the New York Blood Center. Today, at least 38 CBBs collecting UCB units for public use worldwide. As of May 2007, more than 260,000 HLA-A, B, and DRB1 typed UCB units were registered with Bone Marrow Donors Worldwide (www.bmdw.org). However, a significant proportion of the UCB units, particularly those collected in the early years, have limited usefulness based on the number of cells stored and the quality controls (i.e., infectious disease screen) applied at the time. Despite these limitations, UCB from siblings and URDs has been used to reconstitute hematopoiesis in at least 7000 patients with malignant and nonmalignant disorders, including more than 2500 adult recipients. This chapter reviews the current state of knowledge regarding UCB biology as well as clinical results with UCB transplantation and current research initiatives with this unique source of HSC.

ATTRIBUTES OF UMBILICAL CORD BLOOD HEMATOPOIETIC PROGENITOR CELLS

Recognition of the potential clinical utility of UCB prompted numerous laboratory studies to reassess the biologic characteristics of the primitive hematopoietic progenitors found in UCB. Ontologically, hematopoiesis begins in the ventral aspect of the fetal aorta and primitive yolk sac early after conception. Following a brief hepatic

phase, at the end of the second trimester it enters the marrow space, where it remains throughout adulthood. It has long been recognized that human UCB contains a high frequency of hematopoietic progenitor cells, at least equal to that of colony-forming unit granulocyte-macrophage (CFU-GM) progenitor cells in adult BM.[8–10,16] The reason for the presence of these cells in the circulation is not known but may relate to growth factors released by the placenta. Within hours of birth, however, the progenitors leave the neonatal circulation and subsequently are present only at very low frequency in unmobilized peripheral blood.

Primitive hematopoietic progenitor cells in UCB express both CD34 and HLA-DR, suggesting that they are phenotypically distinct from those of adult BM.[17] In contrast to HLA-DR, Hao et al.[18] and Cardoso et al.[19] found that CD38 distinguishes subpopulations of hematopoietic progenitor cells in UCB. The $CD34^+CD38^-$ immunophenotype defines a rare, quiescent $CD34^+$ subpopulation in both UCB and adult BM that can be distinguished functionally from the $CD34^+CD38^+$ population by sustained clonogenicity in extended long-term culture assay (>8 weeks). However, in comparison to $CD34^+CD38^-$ cells in adult marrow, Hao et al.[18] showed that UCB $CD34^+CD38^-$ cells continue to proliferate well beyond 8 weeks. In addition, UCB $CD34^+CD38^-$ cells proliferate more rapidly in response to cytokine stimulation in vitro, and each $CD34^+$ cell generates a significantly greater number of progeny compared to adult marrow counterparts.

Lansdorp et al.[20] compared the proliferative responses of purified candidate stem cell populations in adult marrow, fetal liver, and UCB. When cells with the $CD34^+CD45RA^{lo}CD71^{lo}$ phenotype were cultured in serum-free media supplemented with a mixture of cytokines including interleukin (IL)-3, IL-6, stem cell factor, and erythropoietin, striking differences were observed. Throughout the culture period, the number of $CD34^+$ BM cells remained relatively constant, whereas $CD34^+$ UCB cells increased several hundred-fold, and $CD34^+$ fetal liver cells increased several thousand-fold. Additionally, Carow et al.[21] demonstrated that UCB CFU-granulocyte, erythrocyte, megakaryocte, macrophage (GEMM) progenitors had extensive replating capacity, which contrasts with that of adult marrow. Addition of UCB plasma to the culture medium resulted in extensive secondary replating potential, suggesting that other factors were present in UCB plasma not found in adult plasma or in artificial media supplemented with recombinant growth factors. These properties suggest that UCB may be more amenable than BM to in vitro manipulation for the purposes of genetic manipulation or ex vivo expansion.

Broxmeyer et al.[10] assessed the potential suitability of UCB as a graft for adult recipients. Although the numbers of nucleated cells (NC) and progenitors in UCB specimens were substantially lower than that of allogeneic marrow grafts, they postulated that the progenitors in UCB had a greater capacity for expansion than did BM. Work performed in this laboratory and others supported this claim. Cardoso et al.[19] showed that the total CFU-GM production of UCB $CD34^+CD38^-$ cells was 7.6-fold greater than that in a corresponding population in adult marrow. Similarly, Lewis and Verfaillie[22] demonstrated a higher frequency of both myeloid and lymphoid progenitors at day 0 and enhanced proliferative capacity at 5 weeks in both contact and noncontact culture conditions with UCB compared to mobilized adult peripheral blood.

Consistent with these in vitro findings, UCB was also found to have a higher engrafting capability in vivo using a murine model than did cells derived from adult marrow.[23] Although no validated in vitro or animal model in vivo assay for true pluripotential HSC exists, it is clear that UCB $CD34^+$ cells contain a higher frequency of mouse severe combined immunodeficient (SCID) repopulating cells (SRC). Through limiting dilution analysis, the frequency of SRC in UCB is 1 in 9.3×10^5 cells, in marked contrast to 1 in 3×10^6 found in adult BM and 1 in 6×10^6 found in mobilized adult peripheral blood. Although there is one SRC per 660 $CD34^+CD38^-$ UCB cells, Yahata et al.[24] demonstrated an SRC frequency of 1 in 44 $CD34^+CD38^-$ cells using the technique of intrabone marrow injection rather than conventional tail vein injection. Using the same technique, Wang et al.[25] also demonstrated that UCB contains $CD34^-$ cells that have SCID-repopulating activity.

In summary, UCB appears to contain an increased concentration of primitive hematopoietic progenitors with greater proliferative capacity compared to adult marrow. These unique biologic features may explain in part the higher than expected rate of engraftment observed in UCB transplant recipients despite the low absolute numbers of $CD34^+$ cells and CFU-GM infused. Interestingly, other studies suggest that UCB progenitors may also be "less mature" by virtue of telomere length.[26] How these attributes affect engraftment or the capacity of UCB stem and progenitor cells to be expanded or genetically modified in ex vivo culture remains to be determined.

ATTRIBUTES OF THE NEONATAL IMMUNE SYSTEM

Adult URD marrow transplantation is limited by the lack of suitable donors, particularly in certain ethnic and racial minorities, and by the risk of life-threatening complications such as GVHD and opportunistic infection, particularly when donor and recipient are not HLA matched. To address this problem, efforts over the last 3 decades have focused on enlarging the URD pool and developing new immunosuppressive drugs. However, although a reduction in T-cell number can reduce the incidence of severe acute GVHD, T-cell depletion (TCD) increases the risks of graft failure, viral infection, and relapse.[27,28] These complications offset the advantage of reduced GVHD. Other strategies are required to improve survival in the setting of URD HCT.

In this context, the unique neonatal immune system associated with UCB may be advantageous. Clinical results with UCB transplantation show a less than expected incidence of GVHD given the use of HLA-disparate grafts. The precise explanation for the reduced alloreactive response is unclear. The median $CD3^+$ cell dose of approximately 8×10^6/kg in UCB grafts[29,30] compares to 30 to 40×10^6 $CD3^+$ cells/kg recipient body[28] weight in a typical marrow allograft and can be equated with a BM graft after modest TCD. Because a $CD3^+$ cell dose less than 0.1×10^6 $CD3^+$ cells/kg is required to eliminate the risk of severe acute GVHD, the T-cell dose delivered in UCB should be capable of inducing significant GVHD, particularly in the setting of HLA mismatch. Therefore, the more likely explanation for the reduced incidence of GVHD with UCB transplant is qualitative and functional differences found with UCB lymphoid cells.

Rainaut et al.[31] reported that, compared to adult peripheral blood, UCB has (a) a significantly greater absolute number of lymphocytes per milliliter (two to threefold greater), (b) a significantly lower percentage of $CD8^+$ T cells, and (c) a significantly greater CD4/CD8 ratio.[31] Hannet et al.[32] further characterized UCB lymphocytes, reporting phenotypic characteristics suggestive of T-cell "immaturity". These authors found that the majority of $CD4^+$ UCB lymphocytes coexpressed CD45RA (91% vs 40% of adult $CD4^+$ lymphocytes), fewer $CD3^+$ T cells expressed IL-2 receptors (8% vs 18%), and fewer $CD3^+$ T cells expressed the activation marker HLA-DR (2% vs 10%). Clement et al.[33] found that virtually all UCB $CD4^+$ T cells coexpress CD38 (95%) and CD45RA (>90%).[33] They also demonstrated that $CD4^+CD45RA^+$ UCB T cells have no detectable helper function and that their dominant immunoregulatory activity is suppression.

Roncarolo et al.[34] reported investigations of the functional immunologic properties of UCB lymphocytes. Purified UCB T cells were found to proliferate vigorously when activated by allogeneic antigens in primary mixed lymphocyte reactions, indicating that UCB cells respond normally to activation by alloantigens. In addition, strong proliferative responses were observed when UCB T cells were activated by cross-linked anti-CD3 monoclonal antibodies. However, UCB cells had a reduced capacity to stimulate allogeneic cells in primary mixed lymphocyte reactions, suggesting reduced antigen-presenting capacity. UCB cells are impaired in their capacity to generate allogeneic cytotoxic activity in primary mixed lymphocyte reactions. Whether this defect is intrinsic to cytotoxic T cells or due

to other factors preventing the generation of alloantigen-specific cytotoxic T cells is not known.

The alloreactive T-cell repertoire present in UCB is composed of unprimed cells, compared to the repertoire of T cells in adult BM or peripheral blood in which more than 50% of alloreactive T cells are of the primed memory phenotype. Studies by Roncarolo et al.[34] indicate that repeated activation of unprimed UCB T cells with alloantigens in vitro results in the inability of these cells to proliferate or produce cytokines following restimulation with the same antigens. Furthermore, although these authors showed that the natural killer (NK) activity of purified $CD56^+$ UCB NK cells against NK-sensitive targets is comparable to that observed with adult NK cells, El Marsafy et al.[35] showed that UCB NK cells can exhibit suppressor activity inhibiting autologous UCB T-cell responders in mixed lymphocyte cultures.

Roncarolo et al.[34] demonstrated that IL-2, IL-6, and tumor necrosis factor-α production by UCB mononuclear cells following activation was comparable to that observed with adult peripheral blood mononuclear cells. However, in contrast, interferon-γ and IL-10 production was significantly decreased, and IL-4 and IL-5 were absent. Granulocyte-macrophage colony-stimulating factor levels were generally higher in the supernatants of UCB cells.

In addition, Godfrey et al.[36] demonstrated a high frequency of regulatory T cells in UCB. These cells, characterized by coexpression of CD4, CD25, and FOXP3, have already been shown to be critically important in self-tolerance and prevention of autoimmunity.[37–42] Numerous investigators have shown that regulatory T cells markedly impair the activation and expansion of alloreactive $CD4^+$ and $CD8^+$ T cells and GVHD lethality.[37–41] Whether these cells are responsible for the reduced risk of severe GVHD typically observed in recipients of UCB, even when highly HLA mismatched, is not known. This T-cell subpopulation is under active investigation.

Of interest is the finding that fetal immune cells are tolerant to noninherited maternal HLA antigens and that this tolerance is reduced over the first year of life.[43] At birth, UCB cells were observed to be immunologically nonreactive with cells from mother and minimally reactive with cells from father. Although the neonatal blood was capable of mediating NK lysis, the infant did not develop the ability to generate an alloantigen-specific cytotoxic response until sometime between birth and 6 months of age. The concept of partial fetal tolerance to the noninherited maternal allele (NIMA) was first proposed on the basis of outcomes observed in recipients of parental renal allografts.[44,45] How such "tolerance" develops is unknown, but this phenomenon is particularly intriguing in view of the clinical results observed in haploidentical sibling donor–recipient pairs. If the immune cells in the UCB graft are partially tolerant to HLA antigens on NIMA, this finding could have significant implications in defining what is an "acceptable" donor in both the related and URD setting, which heretofore has not been explored.

Today, the unique attributes of the neonatal immune system permit the clinical application of HLA-mismatched UCB without increased risk of GVHD. Although the mechanisms remain to be discovered, work is ongoing to isolate and expand unique lymphocyte populations to enhance engraftment, reduce GVHD, or augment the GVL response.

SIBLING DONOR UMBILICAL CORD BLOOD TRANSPLANTATION

The first multiinstitutional registry report detailing the transplant outcomes after UCB transplantation from HLA-matched and HLA-mismatched sibling donors was published in 1995[13] and updated in 1998.[15] For the 74 patients transplanted with sibling donor UCB, the median recipient age was 4.9 years (range 0.5–16.3 years). Of these patients, 56 received a 0–1 HLA antigen-mismatched graft and 18 a 2–3 HLA antigen-mismatched graft. Prophylaxis for acute GVHD most often consisted of cyclosporine alone or in combination with methylprednisolone or an anti–T-cell antibody. The median cell dose infused was 4.7 (range 1.0–33.0), with half of patients receiving prophylactic granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor. For recipients of 0–1 HLA antigen-mismatched sibling donor UCB grafts, the probability of neutrophil recovery (defined as absolute neutrophil count $>5 \times 10^8$/L) was 91% (±2%) at 60 days posttransplantation at a median of 22 days (range 9–46 days). Platelet recovery after transplantation (defined as platelet count $>5 \times 10^{10}$/L untransfused for 7 days) was achieved at a median of 51 days (range 15–117 days). Although the engraftment rate was high for the group as a whole, there was a trend toward a greater risk of graft failure in recipients with a history of a marrow failure syndrome, hemoglobinopathy, or storage disease. All patients receiving transplant as therapy for a malignancy engrafted. Of note, use of hematopoietic growth factor was not associated with more rapid myeloid recovery or better engraftment. This first analysis led to several critical conclusions in terms of engraftment: (a) UCB appears to be a reliable source of HSC at least for children, (b) hematopoietic growth factor has no clear effect upon rate or durability of engraftment, and (c) no clear cell dose effect suggested that the number of hematopoietic cells infused was still above the threshold number of cells needed for consistent engraftment.

Gluckman et al.[46] on behalf of the Eurocord Transplant Registry subsequently reported transplant outcomes in 74 recipients of related donor UCB. The median age of the population was 5 years (range 0.2–20 years); 46 patients had malignancy, 17 BM failure syndromes, eight hemoglobinopathy, and seven inborn errors of metabolism. Sixty of the 74 patients received HLA-identical grafts. In contrast to the report by Wagner et al,[15] the probability of neutrophil engraftment was 79%, and platelet engraftment was 62% by day 60. Myeloid recovery and engraftment were favorably influenced by younger recipient age ($P = 0.02$), lower recipient body weight ($P = 0.02$), and HLA identity ($P = 0.04$), with a trend toward better outcome in those with a higher NC dose ($P = 0.06$). Furthermore, in univariate analysis platelet recovery was favorably influenced by lower recipient body weight ($P = 0.04$) and HLA identity ($P < 0.001$). In the setting of related donor UCB transplantation, this was the first report suggesting a possible relationship between NC dose of the UCB graft and speed and likelihood of myeloid engraftment. This finding for the first time suggested that a lower threshold might be identifiable for which the risk of graft failure or markedly delayed myeloid recovery might be considered excessive.

In terms of acute GVHD, the incidence has been consistently low in recipients of 0–1HLA antigen-mismatched sibling donor UCB transplants. In the first report by Wagner et al,[13,15] the probability of grade II to IV and grade III to IV GVHD was only 3% (±2%) and 2% (±2%), respectively, by day 100 after UCB transplantation. Of the cohort of patients with a 0–1 HLA antigen-disparate sibling donor, chronic GVHD was reported in only three patients; no patient had extensive disease. Interestingly, severe GVHD was observed infrequently in the 15 evaluable patients with haploidentical sibling donors.[15] Of the 15 evaluable patients, two were mismatched at two HLA antigens and 13 were mismatched at three HLA antigens. Although patient numbers were small, donor–recipient pairs mismatched at the NIMA appeared to be less likely to develop grade II to IV acute GVHD than donor–recipient pairs mismatched at the paternal allele. This observation supported the hypothesis that partial tolerance to the NIMA might develop during gestation, as suggested by van Rood et al.[47] and subsequently supported by other reports in recipients of haploidentical BM. Gluckman et al.[46] also observed a low incidence of acute GVHD, with 18% of the entire cohort having grade II to IV disease. In this study, the probability of acute GVHD was 9% in recipients of HLA-matched UCB and 50% in recipients of HLA-mismatched units ($P < 0.001$). Chronic GVHD was observed in eight of 56 patients surviving beyond day 100 after transplantation.

Wagner and Kurtzberg[15] reported a survival rate of 61% (±12%) in recipients of 0–1HLA antigen-mismatched UCB grafts at median followup of 2 years. Causes of death were multifactorial, including graft failure, relapse, organ failure, infection, and bleeding. For the entire cohort, GVHD was listed as a cause of death in only one

patient with an HLA 3 antigen-mismatched donor graft. The probability of disease-free survival (DFS) in those treated for malignancy was 41% (±11%). Similarly, Gluckman et al.[46] reported a survival of 63% at 1 year. Factors that favorably influenced survival were younger age ($P < 0.001$), lower recipient body weight ($P < 0.001$), HLA identity ($P < 0.006$), and negativity of recipient cytomegalovirus (CMV) serology ($P = 0.002$). Lower body weight was associated with improved outcome, but cell dose had yet to be identified as a key factor in terms of survival.

These observations led to a comparison of sibling UCB transplants and marrow transplants using BM from HLA-matched sibling donors. Therefore, in a joint study of the International Bone Marrow Transplant Registry and Eurocord, Rocha et al.[48] reported the results of an analysis comparing outcomes in 2052 recipients of HLA-matched marrow and 113 recipients of HLA-matched UCB from sibling donors. UCB recipients were transplanted between 1990 and 1997 and received grafts containing a median cell dose of 4.7×10^7 NC/kg. Myeloid recovery after UCB transplantation (median 26 days, 89% by day 60) was inferior to that observed after BM (median 18 days, 98% by day 60; $P < 0.001$). However, UCB transplantation was associated with a significantly lower incidence of grade II to IV acute GVHD (14% vs 24%, $P = 0.02$), with less frequent grade III to IV acute GVHD and less chronic GVHD. Importantly, survival rates after UCB and BM transplantation were similar at 3 years (64% vs 66%, $P = 0.93$). Causes of death between the two cohorts were similar, with no significant differences in the number of deaths from relapse, suggesting that risk of relapse may be similar. Although only suggestive, these data indicated that the GVL effect of the allograft still might be intact despite the apparent reduction in risk of acute and chronic GVHD.

In summary, these data suggested that survival after sibling UCB transplantation was comparable to that observed with sibling donor BM. Although the rate of hematopoietic recovery and probability of engraftment were inferior to those of marrow, risks of acute and chronic GVHD were superior. The data supported the routine use of sibling donor UCB when available. More importantly, these data supported the development of both private and public CBBs, as it was becoming increasingly clear that directed UCB collections (i.e., for a sibling with a disease amenable to hematopoietic cell transplantation) would obviate the need for harvesting marrow from an appropriately HLA-matched sibling. Investigators speculated that UCB might offer significant advantages over marrow or peripheral blood as a source of HSCs and progenitor cells for both children and adults in need of URD HCT. The stage was set for large-scale banking of UCB and UCB transplantation using partially HLA-matched URDs.

UNRELATED DONOR UMBILICAL CORD BLOOD TRANSPLANTATION: OUTCOMES IN CHILDREN

As a result of the early successes with sibling donor UCB transplantation, programs for the banking of URD UCB were initiated in many countries around the world. Currently CBBs are located throughout North America, South America, Europe, Asia, and Australia. Known benefits of banked UCB include (a) rapid availability, (b) absence of donor risk, (c) absence of donor attrition, and (d) very low risk of transmissible infectious diseases, such as CMV and Epstein-Barr virus (EBV). The attributes of UCB compared with BM are summarized in Table 105–1.

The literature on the use of URD UCB transplantation in children is summarized in Table 105–2. The first two reports of URD UCB transplantation in children were published simultaneously in 1996.[49,50] These two studies demonstrated that hematopoietic recovery and sustained engraftment could be expected in the majority of patients. Furthermore, risk of acute GVHD was low, a particularly striking finding given the use of HLA 1 and 2 antigen-mismatched units in the majority of patients. Gluckman et al.[46] subsequently reported the outcomes of 65 patients (median age 9 years; 49 with hematologic malignancy) transplanted with URD UCB. The probability of myeloid recovery was 87%. Notably, recipients of an UCB unit containing greater than 3.7×10^7 NC/kg were more likely to have faster myeloid recovery (25 days vs 35 days) and higher probability of myeloid recovery (94% vs 76%), more clearly demonstrating the importance of NC dose compared to prior reports with sibling donors. More recent analyses of the Eurocord dataset, including more than 500 patients, reported a 74% incidence of myeloid recovery by day 60 after UCB transplantation.[51] In multivariate analysis, neutrophil engraftment was positively influenced by HLA-matched, cryo-

Table 105–1 Comparison of Umbilical Cord Blood and Bone Marrow as Hematopoietic Stem Cell Sources for Unrelated Donor Transplantations

Factor	Bone Marrow Graft	Umbilical Cord Blood Graft
Available pool	Adult volunteer donors Estimated 11 million	Cryopreserved Estimated 260,000
Typing in database	68% HLA A, B, DRB1	100% HLA A, B, DRB1
Current standard for HLA match	8/8 A, B, C, DRB1 (allele level)	4–6/6 A, B, DRB1 (A and B antigen level, DRB1 allele level)
Median search time	4 months	1 month
Major factors limiting availability	HLA match Donor attrition	Cell dose
Minimum total nucleated cell needed for transplantation	~2.0×10^8/kg	~2.5×10^7/kg
Ease of changing transplantation date	Difficult	Flexible
Access to additional stem cells or lymphocytes	Yes	No
Potential disease transmission CMV or EBV Congenital disease	 Yes No	 No Yes
Risk to donor	Uncommon (potential complications related to anesthesia, surgery, growth factor, or needed for central access) Median time to return to normal activity: 7 days	None

preserved NC dose 4×10^7/kg or greater and administration of hematopoietic growth factors.[51]

Rubinstein et al.[52,53] subsequently summarized the results using UCB facilitated by the CBB at the New York Blood Center. In this study, patients had a hematologic malignancy (n = 581 [67%]), genetic disease (n = 209 [24%]), or acquired BM failure (n = 79 [9%]); the majority of patients (79%) were children. In contrast to the report by Gluckman et al., engraftment was 93% overall. One of the most important aspects of this report was identification of the cell dose threshold. Although a stepwise increase in graft NC dose was associated with a progressively shortened time to myeloid recovery, the incidence of myeloid recovery did not significantly change once the NC dose exceeded 2.5×10^7/kg. For the first time, the clinical data clearly established a cell dose threshold of 2.5×10^7/kg recipient body weight (based on the number of cells cryopreserved). In addition, HLA match (HLA 0 vs >1 mismatch) was associated with improved engraftment. The median time to myeloid recovery in recipients of 6/6 HLA-matched UCB unit was 23 days compared to 28 days in those transplanted with HLA-mismatched units ($P = 0.0027$).

Several studies failed to detect any association between HLA match and risk of acute GVHD,[51,54] but Rubinstein et al.[53] discerned a relationship. In the latter analysis, 3 (8%) of 36 recipients of 6/6 HLA-matched UCB, 42 (19%) of 227 recipients of 5/6 HLA-matched UCB, and 92 (28%) of 323 recipients of less than 4/6 HLA-matched UCB transplants developed severe acute GVHD ($P = 0.006$). Gluckman et al.[51] reported survival in 34% of patients at 1 year, with older recipient age, female gender of recipient, and advanced disease stage being adverse risk factors for survival. Notably, neither degree of HLA mismatching nor cell dose was shown to influence survival in this study. Rubinstein and Stevens[53] reported 3-year survival for each disease category, with 48% (95% confidence interval [CI] 40–55) of patients with genetic disease alive and 27% (95% CI 40–55) of patients with hematologic malignancy alive. Risk factors for adverse transplant-related events (defined as autologous reconstitution, requirement for a second graft, and death) were low cell dose and HLA mismatch.[53] Risk factors for relapse were advanced stage of disease at time of transplant and absence of acute GVHD after UCB transplantation.

In addition to registry analyses, several single-institution series have been reported. Between 1994 and 2001, outcomes in the first 102 consecutive patients (median age 7.4 years) transplanted at the University of Minnesota have been reported.[55] All patients received a myeloablative preparative regimen for treatment of malignant (n = 65) or nonmalignant (n = 37) disease. UCB grafts contained a median infused NC dose of 3.1×10^7/kg, CD34 cell dose 2.8×10^5/kg, and CD3 cell dose of 8.0×10^6/kg. Eighty-six percent of the UCB units were 1–3 HLA antigen-mismatched with the recipient. Median time

to myeloid recovery (absolute neutrophil count >5 × 10^8/L) was 23 days (range 9–54 days), with 88% of patients recovering by day 42. Of note, $CD34^+$ cell dose less than 1.7 × 10^5 cells/kg was associated with markedly inferior engraftment, higher treatment-related mortality (TRM), and lower probability of survival compared to higher cell doses. In Cox regression, HLA match, higher $CD34^+$ cell dose, and absence of grade III-IV acute GVHD after transplantation were associated with improved survival.

Results of the Cord Blood Transplantation (COBLT) study, a national trial in the United States sponsored by the National Heart, Lung, and Blood Institute, have been reported.[29] This prospective, multiinstitutional study benefited by the use of standardized eligibility criteria, treatment plan, and evaluation criteria. Similar to prior reports, this cohort was primarily pediatric, and most patients had a malignancy. Of the 191 patients with malignancy in the pediatric age range (<18 years), the median age was 7.7 years (range 0.9–17 years), the median weight 25.9 kg (range 7.5–118.4 kg); 40% were Caucasian. The UCB units contained a median NC, CD34, and CD3 cell dose of 5.1 × 10^7/kg, 1.9 × 10^5/kg, and 7.9 × 10^6/kg, respectively. Although 9% of donor–recipient pairs were 6/6 HLA-matched (at antigen level HLA-A and B, and allele level HLA-DRB1), 30% and 58% were matched at 5/6 and 4/6 loci, respectively. In this report, engraftment was observed in 79.9% (75–85) at a median of 27 days (range 11–90 days). In Cox regression, HLA match and higher NC dose were favorable risk factors. In terms of acute and chronic GVHD, grade II to IV disease was observed in 41.9% (95% CI 34%–49%) and grade III to IV disease in 19.5% (95% CI 14%–26%) by day 100, and chronic GVHD was observed in 20% at 1 year. Of note, more closely matched pairs (6/6 and 5/6) were less likely to have acute GVHD. Of the 191 patients with malignancy, overall survival was 57.3% (50–64) at 1 year. In Cox regression, negative recipient CMV, male gender, ABO match, and higher NC dose were favorable risk factors.

As the experience with URD UCB transplantation widened, analyses of outcomes within specific disease categories became possible. Acute leukemia represents the single largest group for which children require allogeneic HSC transplantation. DFS rates range from 35% to 60% after UCB transplantation (Table 105–3).[56–62] Locatelli et al.[63] analyzed risk factors potentially influencing outcomes in children with acute leukemia who received UCB from either related (n = 42) or unrelated BM (n = 60) donors. In this study, 66 patients were defined as good risk (transplant in first or second complete remission), whereas 36 were transplanted in more advanced stages and were considered poor risk. Overall, the probability of event-free survival (EFS) at 2 years was 30%, with 49% survival for good-risk patients and 8% in those with more advanced disease. As expected for recipients of BM, multivariate analysis demonstrated that disease status at the time of transplant was the most significant risk factor. Similarly, Michel et al.[59] reported 2-year leukemia-free survival (LFS) of 42% and overall survival of 49% in children with acute myeloid leukemia undergoing UCB transplantation. Again, multivariate analysis only found disease status as a risk factor for both outcomes. Wagner et al.[30] observed a probability of survival of 50% at 2 years specifically for patients with acute leukemia in remission. In contrast, survival was 30% at 2 years for those with more advanced disease. Regardless of risk group, outcomes were similar for patients with acute lymphoblastic leukemia and acute myeloid leukemia.

Several reports have focused on acute lymphocytic leukemia. A report from the Eurocord Registry revealed a 36% DFS rate at 2 years for children in complete remission and 15% for those in relapse.[64] More recently, Sawczyn et al.[61] reported results in 26 children with acute lymphocytic leukemia undergoing myeloablative UCB trans-

The column labeled "No./Source of HSC" reflects all patients reported in the study regardless of diagnosis. The column labeled "Disease/No." reflects only patients with different forms of acute leukemia and its respective number in that cohort.

[a]Some reports included in this table reported on cohorts of patients, which included diseases other than acute leukemias.

[b]Outcome for all patients.

[c]The 95 patients with acute myelogenous leukemia are reported in both references.

[d]Study compared outcomes of UCB with other hematopoietic stem cell sources.

[e]For patients with ALL, relapse at 2 years was 10% for patients with standard-risk disease (n = 14) and 43% for high-risk disease (n = 14).

For patients with high-risk AML (n = 22), the incidence of relapse was 47%, and one of four patients with standard-risk disease relapsed. In patients with ALL, the survival rate was 55% for standard-risk patients and 32% for high-risk patients. For patients with AML, the survival rate was 33% for high-risk patients, and two of four with standard-risk disease survived.

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CR, complete remission; EFS, event-free survival; HSC, hematopoietic stem cell; LFS, leukemia-free survival; NA, not available; OS, overall survival; REL, related; RFS, relapse-free survival; TRM, transplant-related mortality; UCB, umbilical cord blood; URD, unrelated donor.

Table 105–4 Umbilical Cord Blood Transplantation for Children with Nonmalignant Diseases

[a]Of the patients reported in Martin et al.81 2006, 14 with Hurler's syndrome and 4 with Krabbe's disease previously had been reported in Staba et al. 2004 and Escolar et al. 2005, respectively.

[b]Study describes experience of the Sibling Donor Cord Blood Program, which includes hematologic malignancies that are not included in this table.

ALEN, Alemtuzumab; ATG, antithymocyte globulin; β-thal, β-thalassemia; BU, busulfan; chemo, chemotherapy; CsA, cyclosporine; CY, cyclophosphamide; FLU, fludarabine; ID, immunodeficiency disease; MA, myeloablative; MEL, melphalan; MMF, mycophenolate mofetil; MTX, methotrexate; NMA, nonmyeloablative; REL, related; SCD, sickle cell disease; SCID, severe combined immunodeficiency disease; S-D, Shwachman-Diamond; TLI, total lymphoid irradiation; URD, unrelated donor; VP-16, VePesid (etoposide); WAS, Wiskott-Aldrich syndrome.

plantation. Survival was 62% with a median follow-up of 36 months for the surviving patients. In multivariate analysis NC dose was the only independent predictor of EFS. In this analysis, disease stage and HLA match were not significant variables bearing on outcome. EFS in recipients of a UCB unit containing greater than 3×10^7 NC/kg was 90% compared to 15% for recipients of $\leq 3 \times 10^7$/kg.[61]

More recently are reports on the use of UCB for treatment of nonmalignant diseases such as metabolic diseases, hemoglobinopathies, and immune deficiencies. Most of these transplants were performed in children. Outcomes are summarized in Table 105–4.[65–78] Reports of UCB transplantation for treatment of children with sickle cell disease and β-thalassemia have shown high rates of engraftment and encouraging survival.[67,69,74–76] Walters et al.[79] reported that engraftment and survival rates are similar in patients transplanted with UCB and BM from HLA-matched donors. This work has supported the further development of directed donor UCB banking efforts, particularly for ethnic and racial minorities at higher risk for hemoglobinopathies.[79]

Allogeneic HCT has been successfully applied to treatment of selected metabolic diseases.[80] In contrast to other transplant indications, the goal in this setting is adoptive transfer of missing or defective enzymes. As hematopoietic elements circulate throughout the body, including the central nervous system, partial or complete chimerism often is associated with stabilization (and in some cases improvement) in the central and peripheral manifestations of these disorders. In the COBLT study, which included a patient population with lysosomal and peroxisomal storage diseases, 1-year survival was 72%.[81] However, results vary with stage of disease and age of the recipient.[68,70] Escolar et al.[68] reported outcomes of UCB transplantation in infants with Krabbe disease diagnosed in utero or during the early neonatal period and transplanted shortly after birth. Early results suggest very high survival rates. Similarly, Staba et al.[70] reported high survival rates in children with Hurler syndrome if UCB transplant occurred early in the course of the disease.

Experience with UCB HCT for treatment of relatively rare immune deficiency states is growing. Early reports are promising,

with high rates of engraftment and survival in excess of 80%.[66,71,72,77] Importantly immunologic recovery was observed in the majority of patients.[66,72]

Larger numbers of patients and longer followup are needed to determine the true benefit of UCB in the setting of nonmalignant disease. Comparative studies are required to determine how outcomes after UCB transplant compare to those after BM transplant. Whether UCB offers advantages remains to be proven. However, it is unequivocally clear that UCB is (a) associated with less GVHD, which has no beneficial effect in this setting (in contrast to the setting of malignant disease), and (b) more rapidly available, which is particularly critical for rapidly progressive neurologic diseases. However, bear in mind that graft rejection does occur after UCB transplantation, and the donor is not available for reharvesting or donor lymphocyte collection.[69] However, data increasingly demonstrate the impact of HLA match and cell dose on engraftment,[82] such that better selection of units may reduce the risk of graft failure in the future (see Umbilical Cord Blood Graft selection below). Overall, the available clinical data support use of UCB as a source of HSC for transplantation in children with nonmalignant diseases.

In summary, increasing body of evidence supports front-line use of URD UCB in children. In a report by the Institute of Medicine of the U.S. National Academy of Sciences, UCB use now matches that of BM as a source of HSCs for URD transplantation in children.[83]

UNRELATED DONOR UMBILICAL CORD BLOOD TRANSPLANTATION: OUTCOMES IN ADULTS

After the initial success in children, URD UCB transplant was explored in adults. The literature on use of URD UCB transplantation in adults is summarized in Table 105–5. The first reports of URD UCB transplantation in adults were published in 1996.[49,50,84] Laporte et al.[84] reported on a case of a 26-year-old patient with chronic myelogenous leukemia who had not responded to interferon and was in second chronic phase after myeloid blast crisis. The patient received cyclophosphamide, antithymocyte globulin (ATG), and total body irradiation (TBI) conditioning followed by infusion of a 5/6 HLA-matched unrelated UCB unit with NC dose of 1×10^7/kg. The patient had myeloid recovery by day 23 and platelet recovery by day 48. At the time of the report, the patient was 8 months from transplantation with donor-derived hematopoiesis, with no cytogenetic evidence of the Philadelphia chromosome. Wagner et al.[50] reported on two 21-year-old patients, one with Fanconi anemia and refractory anemia and another with adrenoleukodystrophy. The patient with Fanconi anemia received a 3/6 HLA-matched UCB graft with NC dose of 2×10^7/kg. The conditioning regimen consisted of cyclophosphamide and TBI as well as GVHD immunoprophylaxis with cyclosporine and prednisone. The patient died shortly after transplant. The other patient with adrenoleukodystrophy received a 5/6 HLA-matched graft with a cell dose of 1.7×10^7/kg. The conditioning regimen consisted of busulfan, cyclophosphamide, and TBI. GVHD immunoprophylaxis included cyclosporine and prednisone. The patient had myeloid recovery at day 24 with full chimerism but remained platelet transfusion dependent and had developed grade II acute GVHD at the time of the report. Kurtzberg et al.[49] described a 23-year-old patient with Fanconi anemia and untreated acute myeloid leukemia. The patient received a 5/6 HLA-matched UCB unit with NC dose of 3.7×10^7/kg. The conditioning regimen consisted of cyclophosphamide, TBI, and ATG with cyclosporine immunoprophylaxis. The patient engrafted, developed grade III acute GVHD, and was alive for more than 1 year at the time of the report. These studies were the first to demonstrate the potential of hematopoietic recovery and sustained engraftment in adults after URD UCB transplant.

In 2001, the first series on the use of URD UCB for treatment of adults was reported.[85,86] Laughlin et al.[85] described 68 adult patients (median age 31 years, range 17–58 years) with hematologic diseases who received 3/6 to 6/6 HLA-matched UCB grafts. The median NC dose was 1.6×10^7/kg. The probability of myeloid recovery was 90%, at a median time to neutrophil and platelet recovery of 27 and 99 days, respectively. The incidence of grade II to IV acute GVHD was 60% and grade III to IV was of 16%. There was no association between the development of acute GVHD and HLA match, CMV seropositivity, or conditioning regimen. Thirty-three percent of evaluable patients developed chronic GVHD. The 100-day TRM was 50%, and EFS was 26%. Patients who received $CD34^+$ cell dose $\geq 1.2 \times 10^5$/kg had better EFS. Neither age nor HLA match was a predictor of EFS. Rocha et al.[86] reported on 108 adult patients (median age 26 years, range 15–53 years) with hematologic malignancies who underwent URD UCB transplantation. Median NC dose infused was 1.7×10^7/kg. Median time to neutrophil and platelet recovery were 32 and 129 days, respectively. Grade II to IV acute GVHD was observed in 41% of patients and chronic GVHD in 26%. TRM was 54%, and the 1-year survival rate was 27%.

These and other early reports on the efficacy of UCB transplant in adults generally demonstrated poor engraftment and high TRM. Reasons for poor outcomes included patient selection and low UCB graft cell dose. During the early period of UCB transplantation in adults, 1×10^7 NC/kg was frequently cited as the lower acceptable dose limit.[85–88] However, markedly delayed time to myeloid recovery was consistently noted with median durations of neutropenia up to 32 days.[85–88] In addition, graft failure was a common event, with rates as high as 40%.[86,87,89] Acute GVHD also tended to be higher than typically reported in pediatric populations (30%–70% grade II–IV acute GVHD).[85–88] The reasons for higher GVHD in adult UCB recipients included older recipient age, greater use of HLA-mismatched UCB units, and higher proportion of patients with CMV-positive serostatus.[90] Delayed hematopoietic recovery, higher incidence of graft failure, and GVHD contributed to TRM incidences reported to be as high as 50%.[85–88] However, patient selection may have played an important role, as UCB transplant candidates had experienced delay in transplantation (failed a prior marrow donor search), had extensive prior therapy, and had advanced disease. In the COBLT study[89] performed between 1999 and 2000, 15% of patients were in relapse at the time of UCB transplant, and 12% died during the preparative therapy prior to UCB infusion. Survival rates ranged from 20% to 30%.[85–88]

Since the first successful URD UCB transplant in an adult with chronic myelogenous leukemia in 1996,[84] an estimated 2500 UCB transplants have been performed in adults older than 18 years. Most adult recipients of UCB have had acute leukemia.[85,87–89,91–97] For patients with acute leukemia, EFS is between 15% and 50%[85,87–89,91,92,94,95,97]; some small series report EFS up to 70%[93,96] and overall survival between 17% and 45%.[85,88,89,91,92] Better outcomes are associated with younger age,[87,88] higher CFU-GM, CMV-negative serostatus,[92] and leukemia in complete remission.[91,98]

Results of URD UCB transplant used as therapy for other hematologic diseases in adults are starting to emerge. Overall survival for UCB transplant therapy of chronic myeloid leukemia ranges from 20% to 50%.[91,99,100] For lymphoma, 1-year progression-free survival (PFS) ranges from 50% to 63%. Of note, most patients with lymphoma typically received a nonmyeloablative conditioning regimen in contrast to patients with leukemia. Reasons for use of a nonmyeloablative regimen include extensive prior therapy, failed prior autologous HCT, and older age.[101–103] One study in patients with Hodgkin lymphoma reported PFS of 25%.[103]

In summary, interest in use of UCB as a source of HSC for URD transplantation in adults has been growing. Limited availability of units with adequate cell doses has been the principal obstacle. New strategies for addressing the cell dose limitation are detailed in Strategies for Augmenting Cell Dose section.

UMBILICAL CORD BLOOD VERSUS OTHER HEMATOPOIETIC STEM CELL SOURCES

Hematopoietic cell transplant using BM or peripheral blood from HLA-matched related and URDs as a source of stem cells has

AML, acute myeloid leukemia; ANC, absolute neutrophil count; CFU-GM, colony-forming unit granulocyte-macrophage; CML, chronic myelogenous leukemia; COBLT, Cord Blood Transplantation study; DFS, disease-free survival; EFS, event-free survival; GVHD, graft-versus-host disease; LFS, leukemia-free survival; MDS, myelodysplastic syndrome; NA, not available; OS, overall survival; sAML, secondary acute myeloid leukemia; TRM, treatment-related mortality.

represented the standard of care for patients with various hematologic diseases, cancers, BM failure syndromes, and metabolic disorders. UCB has gradually emerged over the past decade as an alternative source for hematopoietic cells for use in transplant of patients unable to identify a suitably matched marrow or peripheral blood donor. Increasing use of UCB is principally due to the favorable results in children, increased availability of units with larger cell doses, rapid donor identification and cell acquisition, and less restriction of donor/recipient HLA matching. Because use of UCB as a source of stem cells for transplant may have certain advantages, comparison of UCB transplant outcome with that of more conventional marrow or peripheral blood HCT is of interest.

Umbilical Cord Blood Versus Related Donor Hematopoietic Cell Transplantation

Analyses comparing outcomes after unrelated UCB transplant and HLA-matched and HLA-mismatched related donor HCT have been reported (Table 105–6).[60,103–106] Comparing results of recipients of UCB (n = 26) and related donor grafts (n = 23) after myeloablative conditioning, Jacobsohn et al.[60] reported prolonged time to myeloid recovery in recipients of UCB (median 29 vs 16 days, $P < 0.001$), similar incidences of acute and chronic GVHD, and similar TRM, EFS, and overall survival rates. In multivariate analysis the authors were unable to find any independent predictors of short- and long-term outcomes, suggesting that UCB transplant had outcomes comparable to related donor HCT.

In another single-institution study, Takahashi et al.[106] compared outcomes in recipients of unrelated UCB transplant (n = 100) and HLA-matched (n = 54) or HLA-mismatched (one locus: n = 11; two loci: n = 6) related donor HCT after a myeloablative preparative regimen. All UCB grafts were HLA mismatched (one locus: n = 16; two loci: n = 54; three loci: n = 28; four loci: n = 2). Recipients of related donor grafts received either BM (n = 55) and/or peripheral blood stem cells (n = 21). Except for the degree of HLA matching, pretransplant characteristics between the two groups were similar. Despite longer time to neutrophil and platelet recovery after UCB transplantation, engraftment was comparable (UCB 94% vs 98% related donor). As reported by Jacobsohn et al.,[60] incidences of acute and chronic GVHD, TRM, and relapse and probability of survival were similar between cohorts.

In a registry-based retrospective study,[105,107] Rocha et al. compared outcomes in patients with advanced acute myeloid and lymphocytic leukemia who received unrelated UCB or haploidentical, related donor T cell depleted (TCD) marrow grafts. Again, time to myeloid recovery was longer (23 vs 13 days, $P < 0.001$) and incidence of grade II to IV acute GVHD was higher (23% vs 5%, $P < 0.001$) in recipients of UCB. TRM was similar between groups regardless of diagnosis. Interestingly, LFS in patients with acute myeloid leukemia was similar (UCB 30% vs haploidentical TCD marrow 24%, $P = 0.39$). However, in patients with acute lymphoblastic leukemia, LFS was statistically higher in those transplanted with UCB (36% vs 13%, $P = 0.01$).

Investigators at the University of Minnesota have studied the use of reduced-intensity conditioning (RIC) regimens in UCB transplant. They compared outcomes in recipients of unrelated UCB and HLA-matched sibling donors for adult patients with (a) advanced Hodgkin lymphoma[103] and (b) acute myeloid leukemia.[104] In both studies, no significant differences could be discerned between the UCB and the sibling donor groups with regard to incidence of myeloid recovery, acute GVHD, or TRM. In the series of heavily pretreated patients with Hodgkin lymphoma, neither PFS (UCB 25% vs sibling 20%, $P = 0.67$) nor survival (UCB 51% vs sibling 48%, $P = 0.93$) was significantly different.[103] Among patients with de novo or secondary acute myeloid leukemia, only disease status at the time of transplantation and preexisting comorbidities affected outcome, with no significant difference between the two HSC sources. Relapse rates (UCB 35% vs sibling 35%, $P = 0.72$) and survival (UCB 31% vs sibling 32%, $P = 0.62$) were similar for the two cohorts.

Umbilical Cord Blood Versus Unrelated Donor Hematopoietic Stem Cells: Children

Several studies have compared outcomes of UCB and unrelated marrow transplants in pediatric recipients (Table 105–7). One of the first reports was a matched-pair analysis (matching age, diagnosis, and disease stage) at the University of Minnesota that compared the outcomes in pediatric patients transplanted with either 0–3 HLA-A, B, DRB1-mismatched UCB or HLA-A, B, DRB1-matched BM.[108] Recipients of UCB received cyclosporine and methylprednisolone as GVHD prophylaxis. BM recipients received either cyclosporine and methotrexate (BM-MTX) or T-cell depletion (BM-TCD). Although myeloid recovery was significantly slower after UCB transplantation, incidence of recovery by day 45 was similar (UCB 88% vs BM-MTX 96%, $P = 0.41$; UCB 85% vs BM-TCD 90%, $P = 0.32$). Likewise, incidences of platelet recovery and acute and chronic GVHD were similar. Overall, the probability of survival after UCB transplantation was 53% versus 41% in BM-MTX recipients ($P = 0.40$) and 52% after UCB transplantation versus 56% in BM-TCD recipients at 2 years ($P = 0.80$). This study suggested that despite increased HLA disparity in recipients of UCB, survival rates were similar to rates of recipients of HLA-matched URD BM.

Rocha et al.[109] similarly performed a comparative study in pediatric patients with acute leukemia transplanted with UCB (n = 99), unmanipulated BM (n = 262), or TCD BM (n = 180). In their study, UCB recipients were more likely to have high-risk features (e.g., history of early relapse, short interval from diagnosis to transplant, and prior transplantation). Compared to outcomes in recipients of unmanipulated BM, UCB recipients had delayed neutrophil and platelet recovery ($P < 0.01$) and increased TRM prior to day +100 ($P < 0.01$). UCB and TCD BM recipients both had decreased incidences of acute GVHD. Recipients of TCD BM (but not recipients of UCB) had an increased incidence of relapse. After day 100, compared to recipients of unmanipulated BM, both UCB ($P = 0.002$) and TCD recipients ($P = 0.0001$) had a decreased incidence of chronic GVHD, with risk of relapse and mortality higher only in TCD BM recipients. Differences in patient characteristics (not accounted for in adjusted analysis) as well as differences in supportive care and transplant center effect could have contributed to the findings of this study.

A collaboration of the New York Blood Center and the Center for International Blood and Marrow Transplant Research (CIBMTR) compared the outcomes of children receiving HLA-matched and HLA-mismatched UCB (n = 503) or allele-matched URD BM (n = 116), which is the current standard of care worldwide.[110] All patients had acute leukemia, were younger than 16 years, and were undergoing myeloablative transplantation. In this study, the UCB recipient pairs were HLA matched at A and B loci at the antigen level and DRB1 at the allele level, whereas URD BM recipient pairs were HLA matched at A, B, C, and DRB1 loci at the allele level (n = 116). For the purpose of analysis, UCB patients were segregated into those that had HLA-matched units (n = 35), one-locus HLA-mismatched units (n = 201), or two-locus HLA-mismatched units (n = 267). TRM was lowest (6%) and LFS highest (60%) in recipients of HLA-matched UCB. Relapse rates were statistically lower in recipients of HLA-mismatched UCB (20%), with lowest rates in UCB recipients mismatched at two loci. Five-year LFS was similar in recipients of UCB mismatched at one or two loci to that of allele-matched BM transplants. Outcome was superior in recipients of HLA-matched UCB. For recipients of 8/8 allele HLA-matched marrow, 6/6 antigen HLA-matched UCB, 5/6 antigen HLA-matched UCB (cell dose >3.0 × 10^7 NC/kg), and 4/6 antigen HLA-matched UCB (any cell dose), adjusted LFS rates were 38%, 60%, 45%, and 33%, respectively (Fig. 105–1).

[d]Multivariate analysis with matched marrow as reference group. *Acute GVHD grades II–IV*: Matched marrow vs mismatched marrow RR 1.51 (1.08–2.13), P = 0.01; matched marrow vs matched UCB RR 0.45 (0.22–.96), P = 0.04. No other significant differences. *Chronic GVHD*: Matched marrow vs mismatched marrow RR 1.90 (1.14–3.17), P = 0.01. No other significant differences. TRM: $5/6^{low}$ UCB vs matched marrow RR 1.88 (1.01–3.47), P = 0.05; 4/6 UCB vs matched marrow RR 2.31 (1.47–3.62), P = 0.0003. No other significant differences. *Relapse*: 4/6 UCB vs matched marrow RR 0.54 (0.36–0.83), P = 0.0045. No other significant differences.

ANC, absolute neutrophil count; DFS, disease-free survival; GVHD, graft-versus-host disease; HSC, hematopoietic stem cell; NA, not available; NCD, nucleated cell dose; NS, not significant; RR, relative risk; TCD, T-cell depleted; TRM, treatment-related mortality; UCB, umbilical cord blood; URD, unrelated donor.

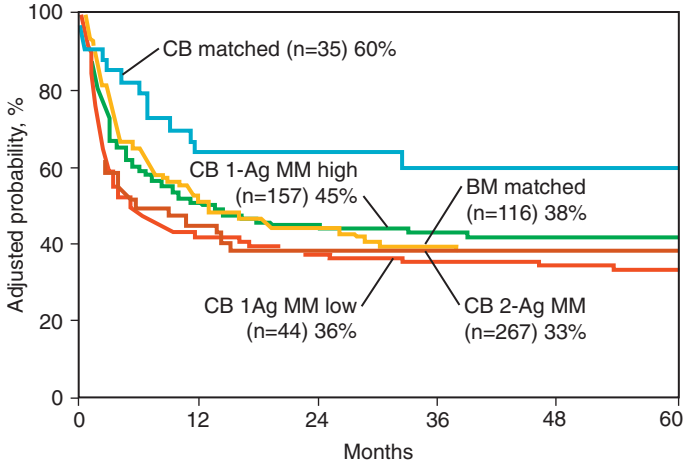

Figure 105–1 Leukemia-free survival (LFS) rates were highest after transplantation of matched cord blood (CB): 60% at 5 years. LFS rates were similar after transplantation of 1- and 2-antigen mismatched (Ag MM) CB and allele-matched bone marrow (BM). Five-year probabilities of LFS rates were 38% after matched BM; 45% after 1-AG MM CB, high cell dose; 36% after 1-AG MM CB, low cell dose; and 33% after 2-AG MM CB.

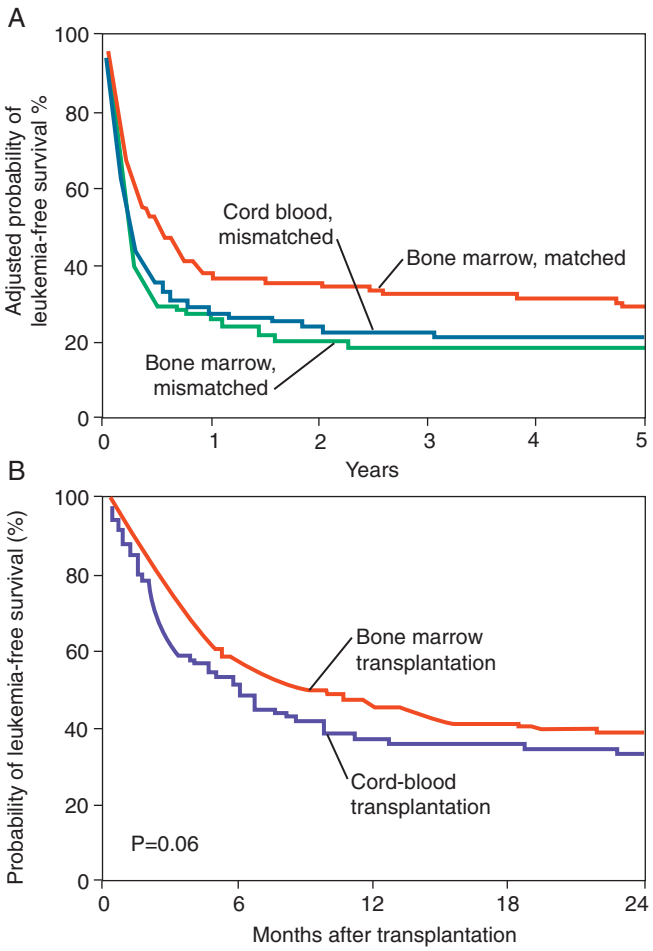

Figure 105–2 Registry-based analysis probability of leukemia-free survival for adult patients after myeloablative conditioning with unrelated umbilical cord blood versus matched or mismatched unrelated donor transplantation. (*From Laughlin MJ, et al: Outcomes after transplantation of cord blood or bone marrow from unrelated donors in adults with leukemia. N Engl J Med 351:2265, 2004, and Rocha V, et al: Transplants of umbilical-cord blood or bone marrow from unrelated donors in adults with acute leukemia. N Engl J Med 351:2276, 2004.*)

Umbilical Cord Blood Versus Unrelated Donor Hematopoietic Cell Transplantation: Adults

More recently, registry and single-institution studies have compared outcomes after UCB and unrelated marrow or peripheral blood transplantation in adult recipients (Table 105–8). Rocha et al.[111] reported a matched-pair analysis comparing outcomes in adult acute leukemia patients receiving UCB (n = 81) or BM (n = 162) transplants. In their study, patients were matched for variables including age, diagnosis, status of disease at transplant, and use of TBI. All BM grafts were matched at HLA-A, B (antigen level), and DRB1 (allele level), whereas 90% of UCB grafts were mismatched at one to three HLA antigens. As previously observed in children, myeloid recovery was significantly delayed after UCB transplantation (median 28 days vs 19 days), and duration of neutropenia after UCB transplantation could be correlated with the cryopreserved cell dose. UCB transplantation was associated with less acute GVHD (31% vs 41%, $P = 0.05$). Incidences of chronic GVHD, TRM, and relapse were comparable between groups. DFS was 26% in recipients of UCB and 33% in recipients of BM ($P = 0.28$). The authors concluded that UCB units matched at 4/6 to 6/6 HLA antigens and with a cell dose at least 1.0×10^7 NC/kg should be considered an acceptable alternative to HLA-matched URD BM for transplant of adults with acute leukemia.

Two seminal registry reports[112,113] and one single-center study[114] comparing outcomes in adult recipients of URD UCB and unrelated marrow transplant were published in 2004 (Table 105–9). All three studies demonstrated delayed neutrophil and platelet recovery after UCB transplantation.[112–114] Despite a higher degree of HLA mismatch for recipients of UCB grafts, all three studies demonstrated lower or similar incidences of grade II to IV acute GVHD after UCB transplantation.[112–114] However, survival rates differed among the three studies. Whereas survival and LFS after UCB transplantation was inferior to HLA-matched marrow in the report by Laughlin et al.[112] (Fig. 105–2A), survival and LFS were similar or superior for recipients of UCB in the reports by Rocha et al.[113] (Fig. 105–2B) and Takahashi et al.,[114] respectively. Hwang et al.[115] performed a meta-analysis and suggested that the differences in survival could not be entirely explained by HLA match, as most of the subjects in the report by Takahashi et al.[114] were 4/6 matched. Of note, Rocha et al.[113] included only patients transplanted after 1998 because they wished to avoid the "learning curve" with lower survival rates prior to 1998. Whether this influenced the outcomes reported by Laughlin et al.[112] is unknown.

In summary, these three reports support the general use of URD UCB transplant in adults. UCB transplant is particularly suited to patients for whom a suitably HLA-matched unrelated volunteer donor cannot be identified in the time interval mandated by the individual patient's disease status.

STRATEGIES FOR AUGMENTING CELL DOSE

Achievement of an adequate cell dose is one of the limiting factors that prevents increased use of UCB for transplantation. Furthermore, data from many clinical studies suggest that low cell dose compounds the deleterious effect of HLA mismatch and contributes to delayed hematopoietic recovery, poor engraftment, high TRM, and poor survival. Therefore, novel strategies are needed to augment the cell dose of the UCB graft. Several possible approaches can be considered, the most obvious being ex vivo expansion culture. Clinical trials with expanded UCB products have not yet demonstrated any obvious impact on time to neutrophil or platelet recovery. Alternative strategies being explored to enhance rate of hematopoietic recovery include (a) use of two partially HLA-matched UCB units, (b) ex vivo expansion of UCB progenitors, (c) coinfusion of mesenchymal stem cells

[a]The 22 patients who receive Cy/FLU/TBI in the series by Barker et al. are included in the series by Brunstein et al.

[b]Study included patients receiving multiple-unit UCB grafts.

[c]The incidence of grade II–IV acute GVHD for patient who received tacrolimus/sirolimus posttransplantation immunosuppression was 29%.

[d]Cy/FLU/TBI 2 Gy (TBI) was given to 33 patients, FLU/Cy or MEL in 11, FLU + busulfan (<8 mg/kg) associated or not to other drugs in 13, FLU/TBI (2 Gy) in 3, and other regimens in 5.

Antithymocyte globulin/antilymphocyte globulin was added in 26% of cases. The probability of neutrophil recovery was 88% of the 33 patients who received the Cy/FLU/TBI conditioning regimen and 65% for patients receiving other regimens ($P < 0.01$).

ANC, absolute neutrophil count, BU/FLU/TBI, busulfan, fludarabine, and total body irradiation; Cy/FLU/TBI, cyclophosphamide, fludarabine, and total body irradiation; FLU/MEL/TBI, fludarabine, melphalan, and total body irradiation; GVHD, graft-versus-host disease; NCD, nucleated cell dose; TRM, treatment-related mortality. NR, not reported; ATG, rabbit anti-thymocyte globulin.

or regulatory T cells to suppress graft resistance, and (d) strategies to reduce nonspecific losses of UCB HSC and enhance homing to the marrow microenvironment (e.g., intrabone marrow injection, treatment with parathyroid hormone [PTH]).

Multiple Unit Umbilical Cord Blood Transplantation

Among the many strategies currently being explored to enhance engraftment is the use of two partially HLA-matched UCB units as the graft source (Tables 105–5, 105–6, and 105–9).[98,116–118] Despite initial concerns regarding the possibility of bidirectional immunologic rejection between the two UCB units from two immunologically functional, HLA-mismatched donors, engraftment was consistently observed in practice. This strategy, initially pioneered at the University of Minnesota, has been studied in both the myeloablative and reduced-intensity settings.

In the myeloablative setting, a pilot study of 23 patients demonstrated the safety and feasibility of "double UCB transplantation."[98] In the first report, the conditioning regimen consisted of cyclophosphamide 120 mg/kg, fludarabine 75 mg/m^2, and fractionated TBI 1320 cGy. The median recipient age was 24 years (range 13–53 years), median weight was 73 kg (range 48–120 kg), and median infused NC dose of the two units was 3.5×10^7 (range 1.1–6.3 NC/kg). Median time to myeloid recovery was 23 days, and all patients who survived more than 21 days achieved sustained engraftment (Fig. 105–3). Interestingly, nearly one third of patients demonstrated "double chimerism" at day 21 (i.e., evidence of engraftment from each donor), with one donor predominating over time. Cell dose, HLA match, ABO match, and order of infusion does not predict which unit will predominate. Analysis clearly indicates that adult recipients of double UCB transplantation have engraftment rates similar to or better than the rates observed in children despite significantly higher median weight and greater use of HLA-mismatched units.[119] An update of 58 patients treated with this strategy reveals a median time to engraftment of 22 days and an overall incidence of myeloid recovery of 91% at 42 days. Although engraftment using double UCB transplant appears to have improved engraftment, risk of grade II to IV acute GVHD may be higher (57% at 100 days). The incidence of grade III to IV acute GVHD is 16% and TRM at 6 months is low at 18%. At 2 years, overall survival is 57% and DFS is 55%. Other investigators also considered the use of double UCB transplantation, with similar results.[120] Pilot studies using more than two UCB units have been reported.[121,122]

In addition to evaluating the impact on engraftment and GVHD, Verneris et al.[123] evaluated the impact of double UCB transplantation on the risk of relapse in patients with acute leukemia. As the use of two units was restricted to patients with an inadequate single UCB unit, recipients of a double UCB graft were significantly older (median age 24 years vs 8 years) and heavier (median weight 70 kg vs 32 kg). In 80% of double UCB transplants, at least one unit was mismatched at two HLA antigens with the recipient. Compared to recipients of a single UCB unit, double UCB recipients with acute leukemia transplanted in first or second complete remission experienced a 10-fold lower incidence of relapse. Although risk of grade II to IV acute GVHD was higher in recipients of two units, no other factor could be associated with relapse risk other than the use of two units.

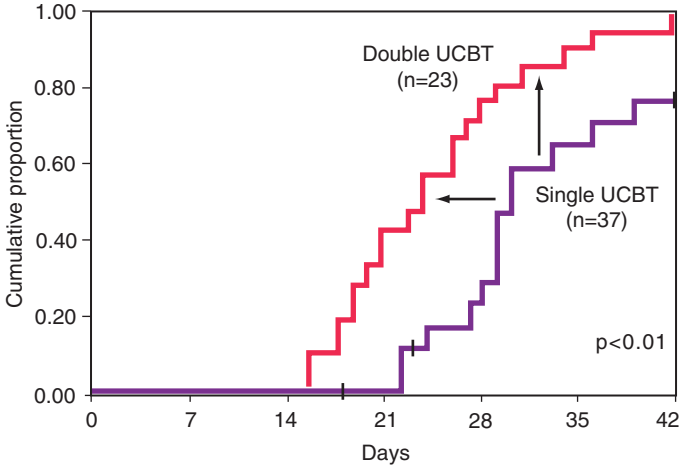

Figure 105–3 Time to neutrophil engraftment after myeloablative transplantation for adult patients with hematologic malignancy who received one (historical controls) or two umbilical cord blood units at the University of Minnesota.

Based on these results, the BMT Clinical Trials Network (CTN) initiated two phase II trials of double UCB transplantation in adults and one prospective phase III clinical trial in children comparing single versus double UCB transplantation. Although the primary endpoint of the phase II trials in adults is hematopoietic recovery, the primary endpoint of the phase III trial in children is 1-year LFS. In each of these trials, incidences of GVHD, TRM, and leukemia relapse as well as pace of immune recovery are among the secondary endpoints that will be assessed.

In summary, the data suggest that use of two partially HLA-matched UCB units in the myeloablative setting is safe as measured by the high incidence of donor engraftment, timely myeloid recovery, and low incidences of severe acute GVHD and TRM.

Ex Vivo Expansion of Umbilical Cord Blood Stem and Progenitor Cells

Because the cell dose contained in a single unit has been the single most important limitation of UCB, particularly for adult patients,[116] various ex vivo expansion culture strategies have been the evaluated over the past 10 years.[124–129] Although these studies have not shown any significant toxicity related to infusion of ex vivo expanded cells, they also have not yet shown clear evidence of clinical benefit. This may be due in part to treatment design. In most studies, a single UCB unit was used both as a graft and as a source of HSC for ex vivo expansion. After thawing, a portion of the UCB was sent for ex vivo expansion for periods of up to 2 weeks, whereas the remaining proportion of the unit was administered unmodified on day 0. This study design led to two major problems in interpretation of the results: (a) because the ex vivo expanded units were infused at a later time, there was reduced chance of observing an impact on myeloid recovery, and (b) it was not possible to determine if the engrafted cells were derived from the unmodified or the ex vivo expanded portion of the graft (because there was no genetic marker to distinguish unexpanded from expanded cells).

In an attempt to identify potentially efficacious ex vivo expansion culture strategies, new trial designs are being considered, including (a) use of UCB units that have been divided prior to cryopreservation so that one portion of the of the unit can be expanded and infused together with the unexpanded portion, (b) use of the double UCB model with coinfusion of expanded product from one UCB and unexpanded product from the other UCB, and (c) infusion of an expanded product alone, with one or two UCB units as a backup to be infused at a preestablished time in the event of graft failure.

In summary, trials with ex vivo expanded UCB cells have failed to demonstrate clear impact upon engraftment. New expansion strategies are promising and are under development and testing.[130–132] Combined with newer trial designs, identification of promising strategies for expanding the number of UCB stem and progenitor cells will be forthcoming.

Intrabone Marrow Injection

Considering that cell dose is the most significant limitation for UCB transplantation, injection of the graft directly into the BM space

theoretically could lead to improved homing and avoid trapping of hematopoietic progenitors in tissues that do not support hematopoiesis.[24,25,133–135] Murine models have shown that less than 20% of HSC infused intravenously ultimately reach the BM space; most are trapped in organs with extensive capillary beds such as the lungs.[136] In addition, when hematopoietic progenitors are injected directly into the BM space, better donor engraftment at the site of injection and improved colonization of other bones occur.[25,135] Clinical data on this approach are limited.[137,138] However, one small clinical trial randomized patients undergoing related donor allogeneic transplants to receive the grafts either intravenously or through intrabone marrow injection.[137] Although well tolerated, no demonstrable impact on clinical outcome was observed. Raiola et al.[139] reported on 12 adult patients who received a single UCB transplantation through direct intrabone marrow injection after myeloablative conditioning. The median NC dose infused was 2.7×10^7/kg (range 1.6–3.5/kg). All patients engrafted at a median of 20 days for neutrophils and 30 days for platelets. Only two patients developed grade II acute GVHD. The finding of rapid repopulation and differentiation at the site of injection is intriguing.

At the University of Minnesota, a phase I to II clinical trial evaluating the safety and potential efficacy of intrabone marrow injection is underway. In this study, two partially HLA-matched UCB units are transplanted with one randomly assigned to intrabone marrow injection and the other administered intravenously. Because of genetic differences between units, it will be possible to discern a competitive advantage to cells administered by intrabone marrow injection. To date, nine patients have been enrolled. Although all patients have engrafted, median time to myeloid recovery is 22 days. In contrast to the report by Raiola et al., GVHD has been observed in five of five patients who are at least 100 days after transplantation. The study remains open.

Coinfusion of Mesenchymal Stem Cells

An alternative approach to enhancing engraftment is coinfusion of mesenchymal stem cells that actively participate in normal hematopoiesis through production of growth factors and cytokines and provision of direct cell–cell interactions.[140,141] In NOD/SCID mouse transplant models, mesenchymal stem cells have been shown to facilitate engraftment of human UCB hematopoietic cells.[142,143] Early clinical reports suggest that mesenchymal stem cells may suppress immune reactions and indirectly enhance engraftment (inhibition of host resistance) in addition to preventing GVHD.[144–146] A report suggests that the immune modulation of MSC is mediated at least partly through regulatory T cells.[147]

One clinical study at the University of Minnesota has explored coinfusion of parental haploidentical ex vivo expanded MSC with unrelated UCB.[148] No serious adverse events were observed. Although neutrophil and platelet recoveries appeared to be more rapid, a randomized trial with a larger numbers of patients would be required to provide definitive proof that use of MSC is beneficial in this unrelated UCB transplant setting.

Coinfusion of Purified Partially Hematopoietic Progenitors

A novel approach for shortening the period of neutropenia after UCB transplantation is coinfusion of partially HLA-matched, T-cell–depleted peripheral blood stem cells from related donors.[149,150] The goal is to promote a transient myeloid recovery derived from these partially HLA-matched cells as a bridge before permanent recovery and engraftment from the UCB unit. This approach has markedly shortened the time to an absolute neutrophil count greater than 0.5 × 10(9)/L to 10 days, with no obvious deleterious effect on UCB engraftment.[149] Chimerism studies reveal an initial predominance of cells derived from the haploidentical cells in both the granulocyte and mononuclear cell fractions but progressive replacement by cells derived from the UCB graft.

Parathyroid Hormone Treatment

Osteoblastic cells are a regulatory component of the hematopoietic stem niche.[151] Coinfusion of osteoblasts purified from murine long bones promoted engraftment and provided long-term survival in fully ablated mice.[152] Osteoblast function and proliferation may be regulated by many different pathways, including Notch1 and BMP.[151,153–155] Calvi et al.[153] showed that stimulation with PTH increased the number of osteoblasts, with high expression of the Notch ligand jagged1. The authors showed both in vitro and in vivo that PTH stimulation led to expansion of the number of HSC. In an allogeneic transplant murine model, PTH treatment led to an increased number of primitive hematopoietic cells and markedly improved survival.[153] The same group showed that administration of PTH to mice increased the number of circulating HSC and protected HSC from repeated exposure to cyclophosphamide.[156] A phase II clinical trial studying administration of PTH to enhance engraftment after UCB transplantation is being initiated (K. Ballen, Personal Communication, December 2007).

UMBILICAL CORD BLOOD TRANSPLANTATION AND REDUCED-INTENSITY CONDITIONING

Because the median age of diagnosis in patients with hematologic malignancies is the fifth and sixth decades of life,[157] regimen-related toxicities and, consequently, TRM are high.[158,159] In addition, older age is associated with increased incidence of comorbidities at the time of transplant, further increasing the risk of morbidity and mortality.[160] Together with a history of extensive therapy and use of autologous or allogeneic transplant comes a need to develop less toxic therapies for patients not able to tolerate a conventional myeloablative conditioning regimen.[161–163] Therefore, experience with using RIC regimens prior to related and unrelated blood and BM transplantation is rapidly growing, and results have been encouraging.[164169]

UCB is an adequate source of cells with sufficient numbers of HSC and alloreactive T cells to mediate sustained donor engraftment after an RIC regimen.[170–177] Results with UCB transplantation after RIC are summarized in Table 105–9. Although original series used single UCB units in the context of RIC,[173,174,176,177] experience with double UCB transplantation after RIC is growing.[171,178] In these series, the median age at transplantation typically is older (range 47–59 years) than in reports of myeloablative UCB transplantation. The median infused NC dose is 2.4 to 4.0×10^7/kg, with higher cell doses reflecting increased availability of larger UCB units and use of the double UCB platform. Notably, the median time to myeloid recovery has ranged from 9.5 to 26 days and platelet recovery (>20 × 109/L) from 32 to 43 days. The time to myeloid recovery is affected by the intensity of the conditioning regimen used, with shorter periods of neutropenia observed in recipients undergoing less intense regimens. Graft failure overall has been observed in 10% to 20% of patients.

Reported rates of acute and chronic GVHD after RIC and UCB transplantation vary widely (Table 105–9). The incidence of grade II to IV acute GVHD has been reported between 20% and 60% and chronic GVHD between 20% and 50%.[171,173–177] Grade II (and not grade III–IV) acute GVHD may be higher among recipients of double UCB grafts, although this remains to be proven.[179] In terms of TRM, the risk in the setting of UCB transplant and RIC relates primarily to the intensity of conditioning and presence of comorbidities and not the age of recipients. Overall, TRM in available reports has ranged from 14% to 46%.[171,173–177] Reported rates of relapse have ranged from 5% to 30%.[171,173,175] In one study of recipients of RIC and single UCB transplantation, favorable risk

factors for DFS were greater HLA match, higher NC dose (>2.4 × 10^7/kg), use of cyclophosphamide/fludarabine/TBI 200 cGy conditioning, and diagnosis of lymphoma.[177] Overall, survival rates after RIC and single UCB transplant have ranged from 33% to 37%.[173,174] Studies that included patients receiving double UCB unit grafts have reported overall survival rates ranging from 44% to 74%.[171,178]

At the University of Minnesota, more than 170 UCB transplants after RIC have been performed, primarily in older adults. The first 110 patients received a single conditioning regimen that consists of fludarabine 40 mg/m^2/day for 5 days, cyclophosphamide 50 mg/kg/day for 1 day, and low-dose TBI (200 cGy) in a single fraction without shielding.[171] For this cohort, the median patient age was 51 years. Patients were eligible for a single UCB unit graft if the cell dose exceeded 3.0 × 10^7/kg; otherwise, they were eligible for two partially HLA-matched UCB units. Ninety-three (84%) patients received double UCB graft in order to achieve the minimum target cell dose. The median total infused NC dose was 3.7 × 10^7/kg and CD34 cell dose was 4.7 × 10^5/kg, with no significant differences between recipients of single and double UCB grafts. Sixty-five percent of patients transplanted with one UCB received a two-locus HLA-mismatched unit compared to 78% of patients transplanted with two UCB units in which one or both units were mismatched at two loci. For this cohort, the incidence of primary myeloid recovery was 92% at a median of 12 days (range 0–32 days). The incidence of platelet recovery (>50 × 10^9/L) was 65% (95% CI 54%–76%) by day 180 and occurred at a median of 49 days (range 0–134 days). Sustained donor engraftment was achieved in 85% (95% CI 77%–92%). Logistic regression analysis showed a significantly higher risk of graft failures among patients who received at least one unit with a two-locus HLA-mismatched. Notably, no influence of total NC dose or number of units used on neutrophil engraftment was observed. Similar to observations in the myeloablative setting,[98] only one unit contributed to long-term hematopoiesis in all patients. However, early recovery was most often host in origin, with gradual switch to donor-derived hematopoiesis over 100 days. Incidences at day 100 of grade II to IV acute GVHD was 59% (95% CI 49%–69%) and grade III to IV acute GVHD 22% (95% CI 14%–30%). In Cox regression analysis, patients who received double-unit UCB grafts and those who did not receive ATG treatment experienced a higher relative risk of grade II to IV acute GVHD, consistent with reported findings in a larger cohort.[179] Overall cumulative incidence of TRM was 19% (95% CI 12%–26%) at day 180. The only risk factor for TRM in Cox regression analysis was the presence of comorbidities. For this heterogeneous group of older adults or patients with comorbidities or extensive prior therapy, the probability of survival was 45% and PFS was 38% (95% CI 28%–248%). In multivariate analysis, presence of comorbidities adversely influenced PFS, and use of two UCB units was associated with a trend toward improved PFS (P = 0.06; Fig. 105–4).

Since the introduction of nonmyeloablative UCB transplantation is recent, a few series on disease-specific outcomes are available.[102–104] One study included 20 patients with advanced Hodgkin lymphoma and non-Hodgkin lymphoma.[102] In this study, the median age was 47 years, and six of 20 patients had previously undergone autologous transplant. The incidence of TRM was 40%; 1-year PFS was 50%. In another analysis of 16 patients with chronic lymphocytic leukemic (CLL), mantle cell lymphoma, or follicular lymphoma, 1-year PFS was 60%.[101] As noted elsewhere in Umbilical Cord Blood versus Related Donor Hematopoietic Cell Transplantation section, two reports of UCB transplantation after RIC in patients with Hodgkin lymphoma and acute myeloid leukemia demonstrated 2-year survival of 25% and 31%, respectively.

In summary, UCB appears to be an effective HSC source in the setting of RIC. Fludarabine is a typical part of the conditioning regimen.[170,171,173,174,177,180] Based on the report by Rocha et al.[177] to date the combination of cyclophosphamide/fludarabine/TBI 200 appears to be the most effective in terms of engraftment and survival. Additional treatment strategies need to be explored, but combined use of UCB and RIC markedly extends the availability of transplant therapy.

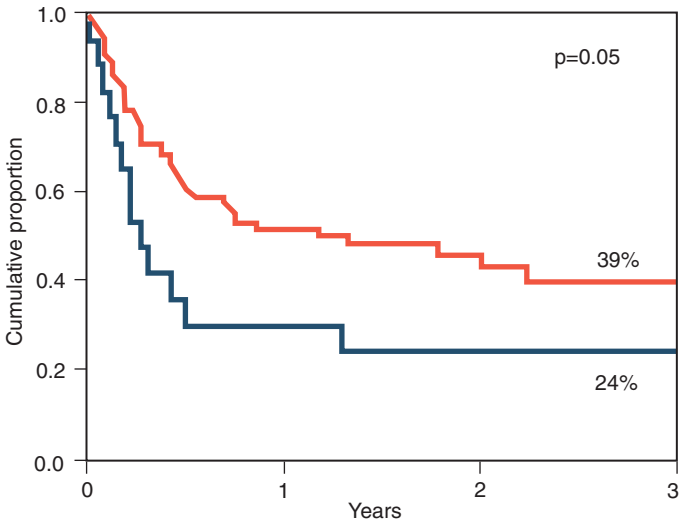

Figure 105–4 Progression-free survival after nonmyeloablative transplantation with one (n = 17) or two (n = 93) umbilical cord blood unit grafts at the University of Minnesota.

IMMUNE RECONSTITUTION AFTER UMBILICAL CORD BLOOD TRANSPLANTATION

Thomson et al.[181] reported on the immune reconstitution of 27 children receiving URD UCB transplantation. Lymphocyte recovery occurred at 2 months for NK cells, 6 months for B cells, 9 months for $CD8^+$ T cells, and 12 months for $CD4^+$ T cells. Similar findings were reported by Niehues et al.[182] in 63 pediatric UCB transplantation recipients (14 related, 49 unrelated; median age 4 years; median cell dose 6.1 × 10^7 NC/kg). Recovery occurred at 3 months for NK cells, 6 months for B cells, 8 months for $CD8^+$ T cells, and 12 months for $CD3^+$ and $CD4^+$ T cells. Factors favoring T-cell recovery were related donor, higher NC dose, and positive recipient CMV serology, whereas recovery was delayed by acute GVHD. As a further measure of T-cell recovery, new thymic emigrants, as measured by T-cell receptor excision circles (TREC), were detected at normal levels starting at 12 months after UCB transplantation.[183] In contrast, TRECs were not detected in adults until 18 months after UCB transplantation and then only at a threefold lower level than expected for age.

Moretta et al.[184] compared immune reconstitution after UCB transplant with 23 matched BM transplant recipient controls. Donors were either sibling (n = 11) or unrelated (n = 12). UCB transplant recipients showed a marked increase in the number of B lymphocytes than did BM transplant recipients. The absolute number of $CD3^+$, $CD8^+$ T cells, and NK cells as well as T-cell proliferative response to mitogens recovered similarly in UCB transplant and BM transplant recipients, with URD UCB transplant showing superior recovery of $CD4^+$ T cells. Similarly, Talvensaari et al.[185] reported on T-cell recovery in related donor transplantation by comparing 10 UCB transplant recipients to 19 age- and GVHD-matched BM transplant controls. During the first year after transplant, both TREC values and T-cell repertoire were low in both groups. However, at 2 years TREC values and T-cell repertoire were higher in UCB transplant recipients than in BM transplant recipients. In contrast, Hamza et al.[186] reported that, compared to matched URD BM transplant, lymphocyte counts recovered slower in the first 2 months after UCB transplantation. However, by 1 year after UCB transplantation lymphocyte counts were in the normal range, whereas for matched URD BM transplant lymphocyte counts still were below normal. They reported a significantly higher risk of bacterial infection during the first 50 days after UCB transplant than in matched URD BM transplant, but without significant difference between the two groups

beyond 50 days. No difference was observed between the two groups with regard to the incidence of fungal or viral infections at any time after transplantation.

Weinberg et al.[187] reported that the greatest determinant of thymic function after HCT is the occurrence of GVHD. In their study, serial $CD4^+$ and $CD8^+$ TREC levels were measured in 12 UCB transplant recipients. In the 12 to 24 months after transplant, TREC levels rose to normal or above normal levels for age in many of the recipients and were similar to the values seen with BM. As with BM the presence of GVHD suppressed thymic output in UCB transplant recipients. However, TREC levels rose in three patients even though immunosuppression was continued for at least 6 months after transplant in the absence of GVHD. This finding suggested that active GVHD is a more potent suppressor of thymic output than is immunosuppressive therapy.

Giraud et al.[188] studied the lymphocyte subset recovery and immunoglobulin levels of eight children after unrelated UCB transplantation. They reported recovery of absolute B-cell numbers at 9 months. T cells were delayed until 12 months, particularly the subset of $CD3^+CD8^+$ compared to $CD3^+CD4^+$. The relative number of NK cells was elevated in the first 6 months, but the absolute number remained in the normal range. IgA and IgM levels returned to normal by 6 months, whereas IgG levels required 9 months. Finocchi et al.[189] reported on six children after unrelated UCB transplantation and showed recovery of T-cell, B-cell, and NK-cell absolute number by 12 months. Remarkably, three fourths of patients had a diversified polyclonal T-cell population. However, $CD4^+$ T-cell receptor diversity recovered faster than that of $CD8^+$ T cells.

Cohen et al.[190] studied the development of antigen-specific lymphocytes in 153 children who participated in the COBLT study. They found that antigen-specific T cells against herpesviruses (CMV, varicella zoster virus, and herpes simplex virus) could be detected as early as 1 to 2 months after UCB transplantation. Overall, 66 children were able to develop responses to one or more herpesvirus during the evaluation period. The probability of developing an antigen-specific response was not different for patients who were serologically positive or negative for the three viruses studied. No association was found between the development of antigen-specific T-cell and immunophenotypic reconstitution, NC dose, primary disease, or development of acute and chronic GVHD. In a smaller study that included 16 children who received either a related or unrelated UCB graft, Montagna et al.[191] found that despite a low absolute number of $CD3^+$ cells T cells, this population recovered proliferative capacity in response to an anti-$CD3^+$ monoclonal antibody, CMV, and *Candida albicans* antigens as early as 3 to 5 months after transplantation. In addition, T-cell polyclonal responses were documented. Interestingly, recipient-derived T cells were found to contribute to the observed response.[191] However, the limited number of patients does not allow firm conclusions regarding differences between recipients of sibling or unrelated UCB donor grafts.

Additional studies are needed to determine quantitative and qualitative differences in immune recovery between UCB and other sources HSCs for transplantation. In addition, correlation between immune reconstitution and susceptibility to infections would be instructive. Life-threatening infection is a significant risk after allogeneic transplantation, and approaches to augment immune reconstitution without increasing the incidence of GVHD are of great interest.

INFECTIOUS COMPLICATIONS AFTER UMBILICAL CORD BLOOD TRANSPLANTATION

Immune recovery after UCB transplant has been postulated to be delayed or incomplete, and such inadequate immune reconstitution might predispose recipients to inordinate risk of infection.[192] Reports regarding the incidence of infections after UCB transplantation can be largely grouped into case reports, reports of infections present at the time of death, retrospective small series focusing on a specific type of infection, and retrospective reports comparing prevalence of infections in UCB and in other stem cell sources.[193]

Bacterial infections are the most frequent source of serious infections after UCB transplantation, and the risk is higher for patients with graft failure.[27,186,194] However, serious and life-threatening infections were not clearly higher in patients with delayed myeloid recovery. Before 100 days, bacterial infections were more frequent after UCB transplantation compared to URD BM transplant, primarily caused by coagulase-negative staphylococci and gram-negative bacilli.[194] Among gram-negative bacteria, the most frequent were Pseudomonas, Acinetobacter, and *Escherichia coli*. Among gram-positive bacteria, the most frequent were coagulase-negative Staphylococci, Enterococcus, and *Staphylococcus aureus*.[27,194,195] Mycobacterial infections were rare events, and UCB graft recipients do not appear to be at particularly high risk.[27,194,196,197] Other case reports of rare bacterial infections after UCB transplantation are reported in the literature.[198–201]

Fungal infections have been reported to occur in 30% to 40% of patients transplanted with UCB. Aspergillus species were responsible for approximately 50% to 70% of fungal infections; Candida species represent most of the remaining fungal infections.[27,194] Development of severe acute GVHD, delayed myeloid recovery, and use of ATG for treatment of GVHD have been reported to be risk factors for fungal infections.[194]

Herpesvirus infections have been frequently observed after UCB transplantation. Among patients who are seropositive for herpes viruses prior to UCB transplantation, the incidence of reactivation rate is approximately 25% for herpes simplex,[202] 63% for varicella,[203] 80% for human herpesvirus type 6 (HHV-6),[204–206] and 30% to 100% for CMV.[194,207,208]

Whereas most of these infections tend to occur after engraftment and are associated with development of GVHD, HHV-6 reactivations occur early after UCB transplantation.[204–206] Guidelines for HHV-6 monitoring and treatment are not yet established.

The importance of CMV lies in its reported adverse effect on TRM and survival after UCB transplantation.[30,46,58] One comparative study reported earlier onset of CMV viremia after UCB transplantation compared to URD grafts, although no significant difference in the incidence of CMV reactivation or disease between HSC sources was observed.[194] Others report that CMV reactivation may be more frequent among recipients of UCB compared to other adult HSC sources,[207,208] suggesting CMV-specific immunity may be delayed after UCB transplantation.[207] CMV disease, although infrequent, is associated with pretransplantation positive serostatus and prior viremia.[194]

Review of the literature indicates the incidence of EBV viremia is between 29% and 65% in the standard (non-UCB) allogeneic HCT setting.[209–214] The incidence of EBV-associated posttransplant lymphoproliferative disease is 2% to 4% after UCB transplantation.[215,216] However, a significantly higher risk of EBV-associated posttransplant lymphoproliferative disease has been reported after UCB when a nonmyeloablative regimen including ATG was used. At the University of Minnesota, the incidence of EBV reactivation or posttransplant lymphoproliferative disease in recipients of RIC with and without ATG and with myeloablative conditioning with and without ATG has been reported as 21%, 2%, 3.3%, and 0%, respectively.[216] Others have also observed a higher risk of EBV complications after administration of ATG.[210,217] In the subset of patients who undergo UCB transplantation after a nonmyeloablative conditioning and ATG, EBV viremia monitoring should be considered with plans for therapy should EBV reactivate.[216]

UMBILICAL CORD BLOOD AS A SOURCE OF EFFECTOR CELLS

Umbilical Cord Blood–Derived Regulatory T Cells

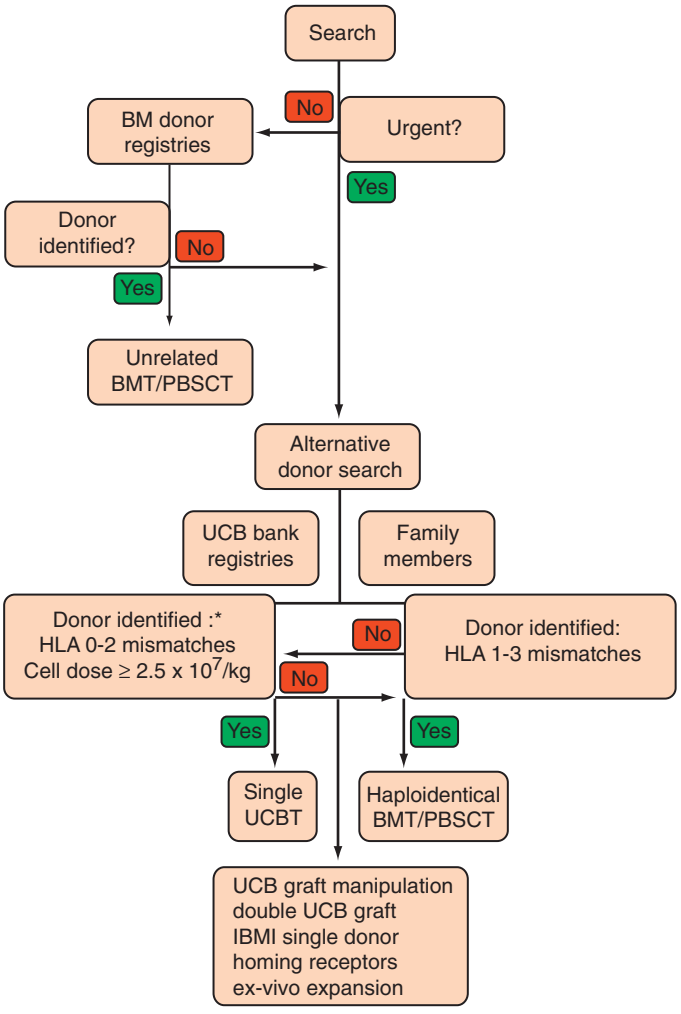
Regulatory T cells are a subset of $CD4^+$ T cells that coexpress CD25 (IL-2Rα chain) and high levels of FOXP3.[36] Regulatory T cells are

dependent on IL-2 despite the fact that they do not produce it like other T cells.[218] Regulatory T cells have been shown to be involved with self-tolerance and prevention of autoimmunity.[37–42] Infusion of ex vivo expanded regulatory T cells prevents development of GVHD and suppresses established GVHD.[37,38,40,42,219,220] In addition, $CD4^+CD25^+$ T cells promote hematopoietic engraftment after allogeneic transplantation.[41,221] In murine models, a graft-versus-tumor effect against most acute myeloid leukemia and leukemia/lymphoma cell lines persists after infusion of regulatory T cells.[42,219,220]

The frequency of $CD25^+$ cells appears to be lower in adult human blood (2%–5% of $CD4^+$ T cells) compared to mouse lymph node T cells (5%–10% of CD4's).[222,223] Moreover, delineation of a clear population of $CD4^+CD25^+$ cells is more difficult in humans. FOXP3 transcriptional activation and expression appears to be crucial to human regulatory T-cell function.[36,224,225] The isolation and functional properties of UCB regulatory T cells have been reported.[36,224,226–228] UCB provides a highly reproducible source of potently suppressive regulatory T cells.[36] UCB-derived regulatory T cells appear to be functionally mature despite a naive phenotype.[226] Compared with thymic regulatory T cells, UCB-derived regulatory T cells have broader suppressive activity, perhaps due to further maturation in the circulation.[224]

Ex vivo expanded and activated UCB-derived regulatory T cells are being tested in humans undergoing UCB transplant in order to determine the safety and efficacy of these cells in promoting engraftment and reducing the risk and/or severity of GVHD. If results of these early clinical trials suggest that infusion of UCB regulatory T cells is safe, it is possible that UCB-derived regulatory T cells will be used for treatment of autoimmune diseases or in the setting of solid organ transplantation as a means to ameliorate immune response.

UCB-Derived Natural Killer Cells



Treatment options for advanced and particularly refractory acute myeloid leukemia are limited. NK cells have been shown to contribute to the antitumor effect after allogeneic transplantation.[229] Miller et al.[230,231] studied the administration of ex vivo expanded and activated NK cells for treatment of advanced leukemia. They observed a 25% complete remission for patients with chemotherapy-refractory acute myeloid leukemia who received haploidentical NK cells after immunosuppressive chemotherapy.[230] Compared to peripheral blood, UCB is rich in NK precursors. This led to the development of a new strategy involving ex vivo expansion and activation of UCB-derived NK cells for treatment of chemotherapy-refractory acute myeloid leukemia in the context of a myeloablative double UCB transplant.[232] After a myeloablative conditioning regimen containing cyclophosphamide 120 mg/kg, fludarabine 125 mg/m^2, and TBI 1320 cGy starting at day −19, patients subsequently receive a CD3-depleted UCB-derived NK cell product from one UCB unit, followed by six doses of IL-2. The UCB-derived NK cells are KIR ligand mismatched whenever possible. On day 0, patients receive a double UCB unit transplant followed by cyclosporine and mycophenolate mofetil immunosuppression for GVHD prophylaxis. Early results suggest that patients will tolerate NK infusion without major toxicity. The effect of UCB-derived NK infusion on short- or long-term suppression of leukemia is not known.

Umbilical Cord Blood–Derived Pluripotent Stem Cell Populations

Reports suggest that progenitors with pluripotent capacity are present in UCB.[233–236] A population of $CD45^-$ UCB-derived cells has been shown to differentiate into osteoblast, chondroblasts, adipocytes, hematopoietic cells, and neural cells, with tissue reconstitution and long-term engraftment in murine models.[234,236] These pluripotent unrestricted somatic cells have been shown not only to be a potential source of cellular therapy for tissue repair[233] but also to support expansion of hematopoietic progenitors.[235]

UMBILICAL CORD BLOOD GRAFT SELECTION

Insufficient information is available to make definitive recommendations guiding the choice of BM versus UCB as a source of hematopoietic stem and progenitor cells for URD transplantation. However, observations on the feasibility and efficacy of UCB transplantation suggest that a simultaneous search for unrelated BM and UCB donors should be performed for transplant candidates who do not have an HLA-matched sibling donor. Donor selection should be based on the underlying diagnosis, urgency of transplant, availability of an HLA A, B, C, and DRB1-matched BM donor(s), NC dose of UCB unit(s), and degree of HLA-disparity between UCB unit(s) and recipient HLA type (Fig. 105-5). Data still support the first use of an HLA-matched BM donor for specific diseases, such as Fanconi anemia and severe aplastic anemia, based on (a) track record and experience with BM and (b) ability to wait out the donor search in most cases. Use of an unrelated adult BM or peripheral blood donor also may be favored in nonurgent chronic myelogenous leukemia cases because of the potential availability of donor lymphocyte infusions following transplantation. However, the majority of URD HCT candidates do not have a suitably matched adult volunteer URD, and many patients

*Refer to figure 6 for umbilical cord blood graft selection strategy

Figure 105–5 Search strategy for unrelated donor grafts: unrelated volunteer donor versus umbilical cord blood.

cannot wait 3 to 4 months for completion of a donor search. For these patients, UCB transplant often is a reasonable option. At the University of Minnesota, we have been able to identify suitable UCB donors in 93% of cases; however, this reflects the institutional practice of using two partially HLA-matched UCB units for patients who do not have a single unit with an adequate cell dose.

Currently, there is no uniform approach for selecting the "optimal" UCB graft. HLA match and cell dose are the most important factors. Disease type also may play a role in UCB donor selection. The analysis by Eapen et al.[110] demonstrates a higher TRM with every increment in HLA mismatch; however, it also demonstrates greater GVL in pediatric patients with malignancy, resulting in comparable LFS rates in patients with one-locus and two-locus mismatches. Although a two-locus mismatch may be perfectly acceptable for a child with leukemia in whom a GVL effect may be important, these data suggest that a two-locus HLA mismatch should be avoided if possible in a child with nonmalignant disease.

Historically, HLA A and B mismatches have been preferentially selected over mismatches at HLA DRB1, and two mismatches at the same antigen have been avoided. (Rocha et al. personal Communication, March 2008) have shown that mismatches at both DR antigens result in poorer results. Conversely, improved engraftment and survival have been observed in cases where the mismatches have occurred only in the rejection vector.[237]

Despite differences in unit selection preferences, most experienced UCB transplant teams would agree that the minimum graft cell dose

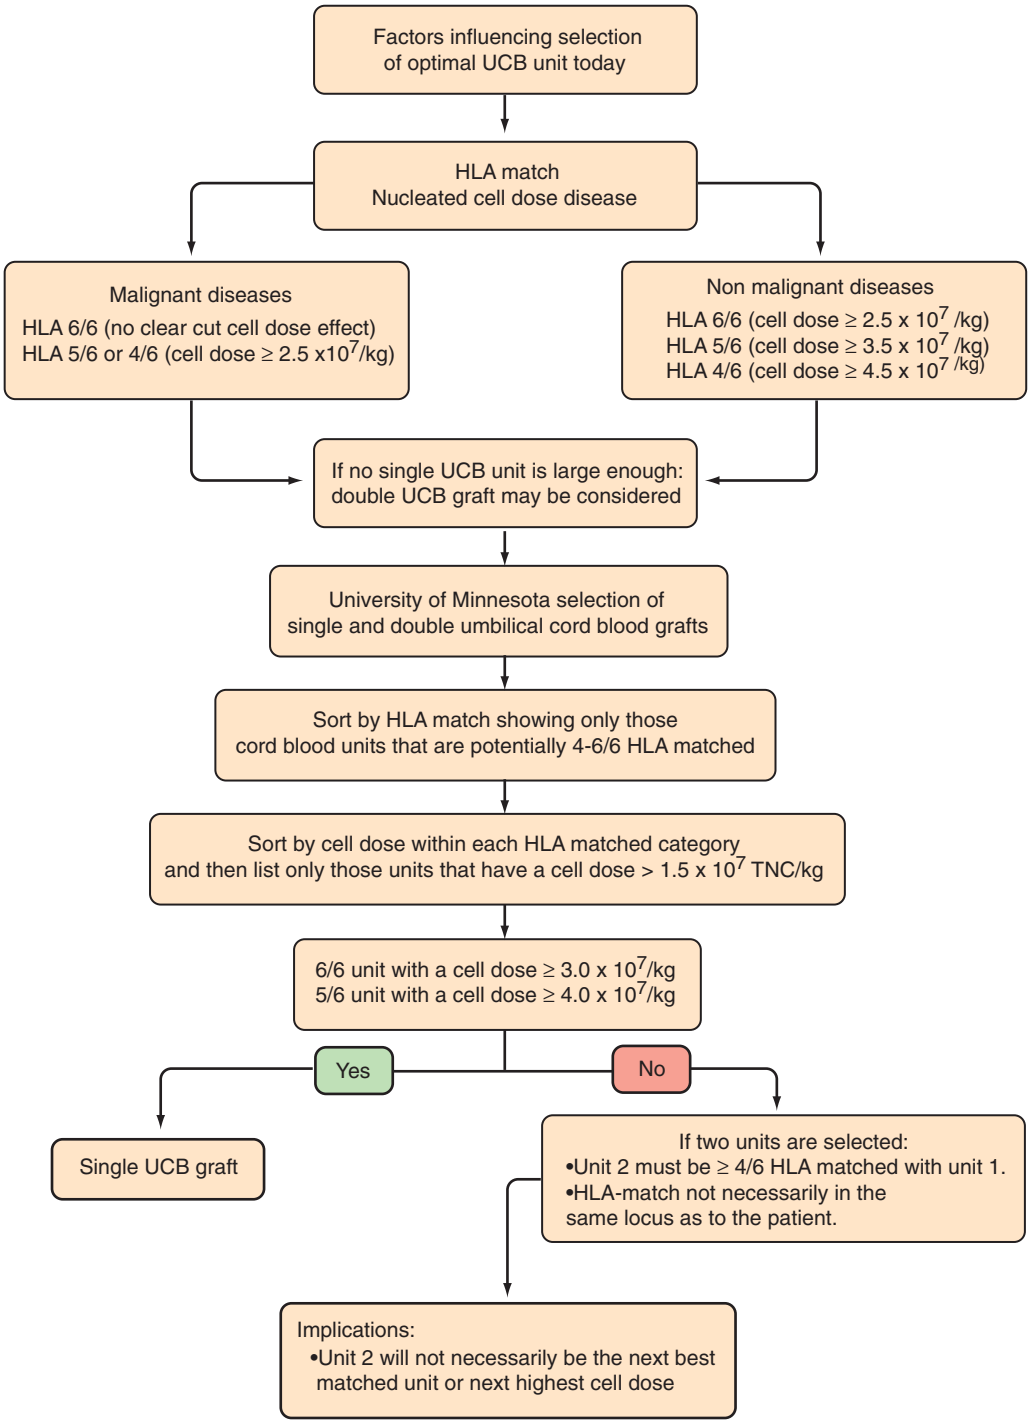


Figure 105–6 Factors influencing selection of optimal umbilical cord blood units today.

is 2.5×10^7 NC/kg actual recipient body weight, and the minimum HLA match is four of six antigens for "routine" transplant (HLA "match" is based on antigen level A and B typing and allele level DRB1 and no matching requirement for C, DP, or DQ). However, the question still remains how to balance cell dose and HLA match. Higher cell doses can ameliorate the negative effect of HLA mismatch, but the doses have to be substantially higher. In a study by Rubinstein et al,[238] an increase of 30×10^6/kg NC/kg would be needed to make a 4/6 matched graft comparable to a 5/6 matched graft. Numerous factors that play a role in UCB graft selection, and the authors have proposed a selection algorithm (Fig. 105–6). Points to consider are also shown because they may alter the general recommendations

Unit selection is even more complicated for programs considering double UCB transplantation. Although even less data on how to choose the two best units are available, the algorithm shown in Fig. 105–6 details how the units are selected at the University of Minnesota. Although the principles are the same (choose UCB units with best donor–recipient HLA match and highest cell doses), we have arbitrarily required partial HLA match between the two units. It is important to realize that in approximately 20% of cases, a less well-matched unit or lower cell dosed unit must be selected in order to fulfill this "arbitrary" requirement.

CHAPTER 106

PREPARATIVE REGIMENS FOR HEMATOPOIETIC CELL TRANSPLANTATION

Marcos de Lima, Amin Alousi, and Sergio Giralt

The combination of chemical and physical agents used as antineoplastic or as immunosuppressive agents prior to autologous or allogeneic hematopoietic cell transplant (HCT) is known as the preparative or conditioning regimen. The preparative regimen is the sole provider of antineoplastic activity in the autologous transplant setting and, in addition, provides most of the immunosuppressive activity in allogeneic transplants. Preparative regimens vary among institutions, and comparison of safety and efficacy is difficult (Table 106–1). Furthermore, differences in supportive care, graft-versus-host disease (GVHD) prophylaxis, donor–recipient human leukocyte antigen (HLA) compatibility, and source of hematopoietic cells also should be considered when analyzing outcomes achieved after transplant with different preparative regimens. The lack of standardization makes comparisons of published results difficult. Frequently the choice of a preparative regimen is made on the basis of institutional and personal experience. Here we review the development of commonly used preparative regimens for hematopoietic cell transplant.

CLASSIFICATION OF PREPARATIVE REGIMENS

In the allogeneic transplant setting, the preparative regimen provides treatment for the underlying disease and provides the immunosuppression needed to prevent graft rejection. The intensity of immunosuppression required depends on the immunocompetence of the recipient, donor–recipient histocompatibility, and the composition of the transplanted hematopoietic cell product. Delivery of high-dose therapy is the major purpose of the preparative regimen in autologous transplant. Rescue from marrow suppression induced by the high-dose preparative regimen is provided by previously procured and stored autologous hematopoietic cells.

Preparative regimens may be classified by the use of total body irradiation (TBI), as chemotherapy-only, or as TBI-based (either TBI alone or combined with chemotherapy). If the preparative regimen is "myeloablative," patients generally do not resume normal marrow function unless rescued by autologous or allogeneic hematopoietic cell transplant. Alternatively, the preparative regimen may be "nonmyeloablative." Nonmyeloablative regimens allow for autologous recovery of hematopoiesis in most patients even if autologous or allogeneic hematopoietic cells are not administered. As proposed by Champlin and colleagues, a nonmyeloablative regimen should not eradicate host hematopoiesis and should allow hematopoietic recovery in less than 28 days without hematopoietic cell transplant.[1] On engraftment, mixed chimerism should be present. If there is graft rejection, autologous hematopoiesis should occur. The nonmyeloablative preparative regimen does not completely eliminate host malignant cells, and will rely on an allogeneic graft-versus-tumor effect to eradicate the disease. A myeloablative regimen requires hematopoietic cell transplant, and donor cells should persist after engraftment. Finally, a "reduced intensity ablative" regimen requires a transplant for hematologic reconstitution, and if rejection occurs, prolonged aplasia will be observed, particularly in heavily pretreated patients or those with marrow involvement.

Outcomes after transplant are influenced by a variety of factors other than the preparative regimen. Recipient's age, extent of prior treatments, and disease stage, for example, may affect regimen-related mortality after transplant (Table 106–2).

LANDMARKS IN THE DEVELOPMENT OF HEMATOPOIETIC CELL TRANSPLANTATION

Evidence that animals could be protected from otherwise lethal doses of radiation by shielding hematopoietic tissues emerged in the 1920s. In most cases, marrow was used as a hematopoietic cell source. Interestingly, the first (unsuccessful) attempt to perform hematopoietic cell transplant in a human was in 1939, to treat gold-induced marrow aplasia.[2] In the 1940s and early 1950s, a rapid evolution in the knowledge of radiation effects occurred, and the development of hematopoietic cell transplant concepts paralleled the investigations on radiation. Jacobson and colleagues demonstrated that shielding the spleen protected mice against radiation-induced aplasia. In 1952, it was observed that marrow aplasia could be prevented by injection of spleen cells from syngeneic mice.[3,4] In 1955, Barnes and Loutit reported that leukemia-bearing mice exposed to lethal doses of radiation and treated with isologous myeloid tissue died after 1 month with overt leukemia. Animals treated with homologous marrow cells, however, survived for longer periods without leukemia but died of a wasting syndrome with diarrhea. The wasting syndrome was more intense and occurred earlier among recipients of marrow and spleen cells, as opposed to recipients of marrow cells alone. They proposed that an immune antitumor effect could be present (graft-versus-leukemia), associated with the wasting syndrome (later defined as GVHD).[5] The secondary disease or runting syndrome (as opposed to primary disease, caused by radiation, which induced effects such as skin and gastrointestinal damage) was further characterized in the late 1950s, including the documentation that T lymphocyte-mediated GVHD targeted lymphoid organs, skin, gut, and liver.[6–8] Mixed chimerism (the coexistence of hematopoietic cells from the donor and recipient) was also characterized using erythrocyte antigens, mononuclear cell sex chromatin and sex chromosomes, and specific tolerance to donor skin grafts.

Thomas and coworkers took these concepts to the clinic and used allogeneic hematopoietic cell transplant after preparation with radiation and chemotherapy to treat end-stage patients with malignancies.[9] In 1958, five Yugoslav victims of an atomic reactor accident were treated with marrow transplant by Mathe and colleagues. Four survivors had evidence of transitory chimerism without GVHD. Mathe and colleagues also documented complete engraftment, development of acute and chronic GVHD, and survival of more than 1 year in a patient after allogeneic bone marrow transplant from six different donors in the early 1960s.[10]

The possibility of rescuing dogs exposed to lethal doses of TBI with previously collected and cryopreserved autologous stem cells was elegantly demonstrated in the early 1960s.[11] Studies in dogs also showed that progressively higher TBI doses are needed in order to engraft related, unrelated, or mismatched donors.[12] Furthermore, canine investigations provided insights into histocompatibility issues and on the use of immunosuppressants for GVHD prophylaxis.[13–16]

The description of the HLA system and the realization of the importance of immunologic matching provided another cornerstone for the development of hematopoietic transplant.[17] Children with severe combined immunodeficiency and a patient with Wiskott–Aldrich syndrome were successfully transplanted in 1968. The patient with Wiskott–Aldrich syndrome received immunosuppressive therapy

Table 106–1 Preparative Regimens for Hematopoietic Cell Transplantation

Regimen	Indications	Autologous Transplants	Allogeneic Transplants	Regimen Intensity	References
Cyclophosphamide and TBI (CyTBI)	Acute leukemias, lymphoid malignancies, CML, myelodysplastic syndromes	Yes	Yes	Ablative	40, 50, 87
Melphalan and TBI	Multiple myeloma	Yes	Less often used	Ablative	62
Etoposide and TBI	Acute (mostly ALL) and chronic leukemias	Yes	Yes	Ablative	88
Cyclophosphamide, etoposide, and TBI (CyVPTBI)	Leukemias, lymphomas	yes	Yes	Ablative	89
Busulfan (PO 16 mg/kg) and cyclophosphamide (BuCy2)	Myeloid leukemias, myelodysplastic syndromes	Yes	Yes	Ablative	29
Busulfan (IV, 3.2 mg/kg daily × 4 days) and cyclophosphamide (IV BuCy)	Myeloid leukemias and myelodysplastic syndromes; less often used for lymphoid malignancies	Yes	Yes	Ablative	33
Cyclophosphamide ± ATG	Aplastic anemia (HLA-identical sibling donors; ideal regimen for engraftment of unrelated donor stem cells is unclear). Recent results of randomized trial investigating role of ATG did not indicate benefit.	No	Yes	Ablative	90, 91
Carmustine, etoposide, cytarabine, melphalan (BEAM) ± rituximab	Non-Hodgkin lymphoma and Hodgkin lymphoma (autologous transplants)	Yes	Yes, but less often used	Ablative	92
High-dose melphalan	Multiple myeloma (autologous transplants)	Yes	No	Ablative	93
Cyclophosphamide, carmustine, etoposide (CBV)	Non-Hodgkin lymphoma and Hodgkin lymphoma (autologous transplants)	Yes	No	Ablative	94,95
Fludarabine and IV busulfan 130 mg/m^2 (4 doses)	Myeloid malignancies, other malignancies	No	Yes	Ablative	38, 34, 38
Thiotepa, fludarabine and melphalan ± ATG	Myeloid and lymphoid malignancies	Less often used	Yes. Donors: related matched and haploidentical, unrelated (including UCB)	Ablative	96
Fludarabine and cyclophosphamide (FC) ± rituximab or campath	Lymphoid malignancies	No	Yes	Nonmyeloablative	85, 97
Low-dose TBI ± fludarabine	Myeloid and lymphoid malignancies	No	Yes	Nonmyeloablative	84
Total-lymphoid irradiation (TLI)	Myeloid and lymphoid malignancies	No	Yes	Reduced intensity	86
Fludarabine and melphalan (FM) ± ATG or campath	Myeloid malignancies, multiple myeloma	No	Yes	Reduced intensity	98, 99, 100
Fludarabine, busulfan (8 mg/kg total dose) and ATG	Myeloid malignancies	No	Yes	Reduced intensity	101
Low-dose TBI, fludarabine, cyclophosphamide or oral busulfan and ATG	Myeloid and lymphoid malignancies	No	Yes; highly immunosuppressive; UCB transplants	Reduced intensity	102

ALL, acute lymphocytic leukemia; ATG, anti-thymocyte globulin; UCB, umbilical cord blood; CML, chronic myelogenous leukemia; HLA, human leukocyte antigen; TBI, total body irradiation. Adapted from Mangan KF: Choice of conditioning regimens. In Ball ED, Lister J, Ping L (eds.): Hematopoietic Stem Cell Therapy, 1st ed. New York, Churchill Livingstone, 2000, p 403, ch 35.[103]

before marrow infusion.[18,19] Incorporation of methotrexate, and subsequently the combination of cyclosporine and methotrexate as standard GVHD prophylaxis, allowed patients with malignant and nonmalignant diseases to be considered for allogeneic transplant. In 1977, the Seattle group reported a series of cases of refractory acute leukemia treated successfully with allogeneic hematopoietic cell transplant.[20–22]

CYCLOPHOSPHAMIDE AND THE COMBINATION OF BUSULFAN AND CYCLOPHOSPHAMIDE

Animal models were used extensively in the development of chemotherapy regimens for hematopoietic cell transplant. Cyclophosphamide emerged as an effective preparative agent that allowed successful

Table 106–2 Factors Other Than the Preparative Regimen That May Influence Outcomes Post–Hematopoietic Cell Transplants

Patient-related factors
Age (increased treatment-related mortality with older age), comorbid conditions, performance status
Disease-related factors
Diagnosis (malignant versus nonmalignant disease, for example), susceptibility to the graft-versus-tumor effect, stage of disease (increased treatment-related mortality with advanced stage), responsiveness to salvage treatment, duration of first remission (AML, non-Hodgkin lymphomas), time from diagnosis to transplant
Donor–recipient factors
Donor-recipient HLA compatibility (also, sibling versus nonsibling), number of pregnancies
Peritransplant period
GVHD prophylaxis regimen, other prophylactic drugs
Graft
Source of stem cells, graft engineering (T-cell depletion increases the relapse and rejection rates), cell dose
Posttransplant
Duration of follow-up, median follow-up, further immune manipulations (donor lymphocyte infusion, for example)
Study design
Degree of censoring in the data analysis, type of study (randomized or nonrandomized, etc)

engraftment of transplanted allogeneic hematopoietic cells. Furthermore, incorporation of antilymphocyte globulin to chemotherapy regimens decreased the engraftment failure rate. The addition of busulfan to cyclophosphamide resulted in better engraftment in the rat with lower doses of cyclophosphamide.[23–26]

Santos and coworkers investigated the optimal dose of cyclophosphamide and busulfan as a non-TBI-containing preparative regimen for allogeneic hematopoietic cell transplants. The combination of busulfan (16 mg/kg) and cyclophosphamide (200 mg/kg) (BuCy) was effective but carried a high treatment-related mortality. The combination of busulfan (16 mg/kg) and cyclophosphamide (120 mg/kg) (BuCy2) was developed to minimize toxicity and quickly became a popular preparative regimen for allogeneic hematopoietic cell transplant and an alternative to cyclophosphamide and TBI-containing regimens (Cy-TBI).[27–29]

Oral administration of busulfan, however, is limited by the erratic absorption of the drug. High plasma levels are associated with increased incidence of hepatic venoocclusive disease (VOD) and other toxicities, whereas low levels are associated with loss of therapeutic efficacy. The use of careful and frequent monitoring of drug levels after oral administration minimizes this problem.[30] Deeg and collaborators reported on 109 patients with myelodysplastic syndrome prepared with oral busulfan targeted to plasma concentrations of 800 to 900 ng/mL and cyclophosphamide 120 mg/kg followed by related (n = 45) or unrelated (n = 64) donor hematopoietic cell transplants. Three-year relapse-free survival was 56% for related and 59% for unrelated recipients, and nonrelapse mortality at 100 days was 12% for related and 13% for unrelated recipients.[31] Improved results of allogeneic transplant therapy for patients with chronic myelogenous leukemia (CML) receiving a preparative regimen consisting of oral busulfan at doses targeted to achieve effective plasma levels and intravenous cyclophosphamide were also reported by the Seattle group.[32]

Recently, the development of an intravenous busulfan formulation has circumvented most of the problems generated by unpredictable plasma drug levels associated with oral administration. An equivalence rate of 0.8 mg of intravenous busulfan to 1 mg given orally has been proposed and is widely used. Preliminary results suggest a decreased rate of hepatic VOD, possibly by elimination of the "first pass" effect in hepatic sinusoids.[33–35] Busulfan and one of the final metabolites of cyclophosphamide, acrolein, are metabolized by glutathione-S-transferase conjugation. Exchanging cyclophosphamide for fludarabine may improve the safety margin of the combination.[36] Furthermore, there is evidence that the nucleoside analog, fludarabine, potentiates alkylator-induced cell killing through inhibition of DNA-damage repair. A preparative regimen using fludarabine and single daily dosing of intravenous busulfan (130 mg/m^2) appears to be effective and safe. There is no interdose accumulation and the single daily dosing schedule delivers a higher systemic peak concentration of busulfan without additional toxicity (median daily AUC of 4871 μmol/min). Patients with acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS) (n = 96) treated with this regimen had a low regimen-related mortality rate of 3% at 1 year, with only two cases of moderate, reversible hepatic VOD. The MD Anderson Cancer Center experience also suggests that there is a reduction in acute GVHD rates with this combination, which has improved survival for patients with AML and MDS transplanted in complete remission, when compared to historic controls that received IV BuCy2.[37,38]

TOTAL BODY IRRADIATION-BASED REGIMENS

In 1977, Thomas and coworkers reported results of allogeneic transplant therapy in 54 patients with acute myelogenous leukemia (AML) and 46 with acute lymphoblastic leukemia (ALL). Patients received hematopoietic cells obtained from the marrow of an HLA-identical sibling. A combination of cyclophosphamide (120 mg/kg) and TBI (10 Gy) was used as a preparative regimen in these heavily pretreated patients. Of the 94 patients engrafted, only 1 patient rejected the graft. Thirteen patients became long-term leukemia-free survivors. Survival was superior among patients with a better performance status at the time of transplant. This study demonstrated that hematopoietic cell transplant could be considered earlier in the management of patients with acute leukemia who have an HLA-matched sibling donor.[39] Thomas and colleagues also investigated preparative regimens containing TBI given in fractions (fractionated TBI) to minimize extramedullary toxicity, especially interstitial pneumonia. Patients who received 2 Gy/day for 6 days had a better outcome than subjects who were treated with 10 Gy in a single dose (Fig. 106–1).[40]

Studies of allogeneic hematopoietic cell transplant therapy for AML in first complete remission and CML in chronic phase demonstrated that increasing the dose of TBI decreased the leukemia relapse rate; higher transplant-related mortality and toxicity were observed.[41,42] When compared to patients receiving 12-Gy TBI in their preparative regimen, patients treated with 15.75 Gy had a higher incidence of hepatic VOD, interstitial pneumonia, renal failure, mucositis, and death. The incidence of grade II or greater acute GVHD was also higher after 15.75 Gy of TBI (Figs. 106–2 and 106–3). The complex interaction between preparative regimen, patient age, disease stage, and donor–recipient compatibility is also illustrated in a report by Cornelissen and associates.[43] They analyzed 127 adult patients with high-risk ALL receiving matched unrelated donor hematopoietic cell transplants reported to the National Marrow Donor Program. Sixty-four patients were transplanted in first remission, 16 in second or third remissions, and 47 patients had relapsed ALL or primary induction failure. All but 12 patients received cyclophosphamide and TBI-based preparative regimens. One-year treatment-related mortality was 50% for patients in first remission, and more than 60% for the others. Survival of patients in first remission was 40% at 2 years, and results were better for donor–recipient pairs matched at *HLA-DRB1* loci using high-resolution typing. Accordingly, better HLA typing is affecting treatment-related mortality, and incorporation of high-resolution molecular typing for class I alleles is expected to improve results further in the unrelated donor transplant setting.

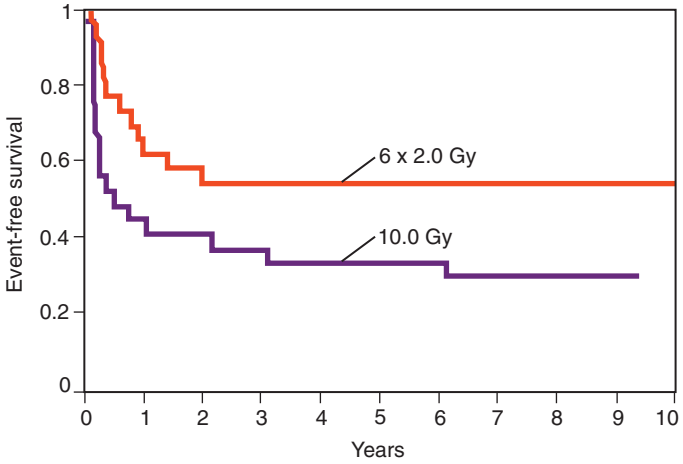

Figure 106–1 Kaplan–Meier product limit estimates for event-free survival of patients with acute myelogenous leukemia in first remission, given 60 mg/kg cyclophosphamide on each of 2 days, randomized to receive 2 Gy total body irradiation (TBI) on each of 6 days ($n = 26$) or 10 Gy TBI ($n = 27$) in one exposure followed by an infusion of hematopoietic stem cells from an HLA-identical sibling. Fractionated TBI elicited improved event-free survival. (Data from Thomas ED: Total body irradiation regimens for marrow grafting. Part 1. J Radiat Oncol Biol Phys 19:1286, 1990.)

The reader is urged to keep in mind that there is significant heterogeneity in the delivery of TBI. These include different energy sources, dissimilar shielding practices, schedules and concomitant chemotherapy. However, some form of fractionation is used at most US centers.

A preparative regimen containing cyclophosphamide (120 mg/kg) and TBI (920–1575 cGy) provides enough immunosuppression for engraftment of hematopoietic cells obtained from HLA-identical siblings, HLA-matched unrelated donors, and unrelated donor umbilical cord blood.[44] Addition of antithymocyte globulin to the preparative regimen may improve engraftment and contribute to the prevention of GVHD after transplant of hematopoietic cells from donors other than HLA-identical siblings.[45] The combination of TBI and cyclophosphamide is the most frequently used regimen for the treatment of ALL. There is little evidence, however, for or against the use of busulfan and cyclophosphamide for this disease.

RANDOMIZED COMPARISONS OF PREPARATIVE REGIMENS CONTAINING BUSULFAN AND CYCLOPHOSPHAMIDE (BuCy) VERSUS TOTAL BODY IRRADIATION AND CYCLOPHOSPHAMIDE (Cy-TBI) FOR THE TREATMENT OF LEUKEMIAS WITH ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

The choice of the ideal preparative regimen for hematopoietic cell transplant therapy of myeloid leukemias has been an ongoing issue since busulfan and cyclophosphamide (BuCy) was developed as an alternative to TBI-containing regimens. Several randomized studies have been published, comparing outcomes after TBI and cyclophosphamide (Cy-TBI) and BuCy preparation for HLA-identical sibling hematopoietic cell transplants. The Nordic group enrolled patients receiving allogeneic hematopoietic cell transplant therapy for AML, lymphoid malignancies, and CML, and found improved disease-free survival with less toxicity among patients with advanced-stage disease receiving a Cy-TBI-containing preparative regimen. A long-term analysis of the Nordic study showed an increased risk of chronic GVHD, obstructive bronchiolitis, hemorrhagic cystitis, and hepatic VOD after transplant with the BuCy preparative regimen.[46] Blaise

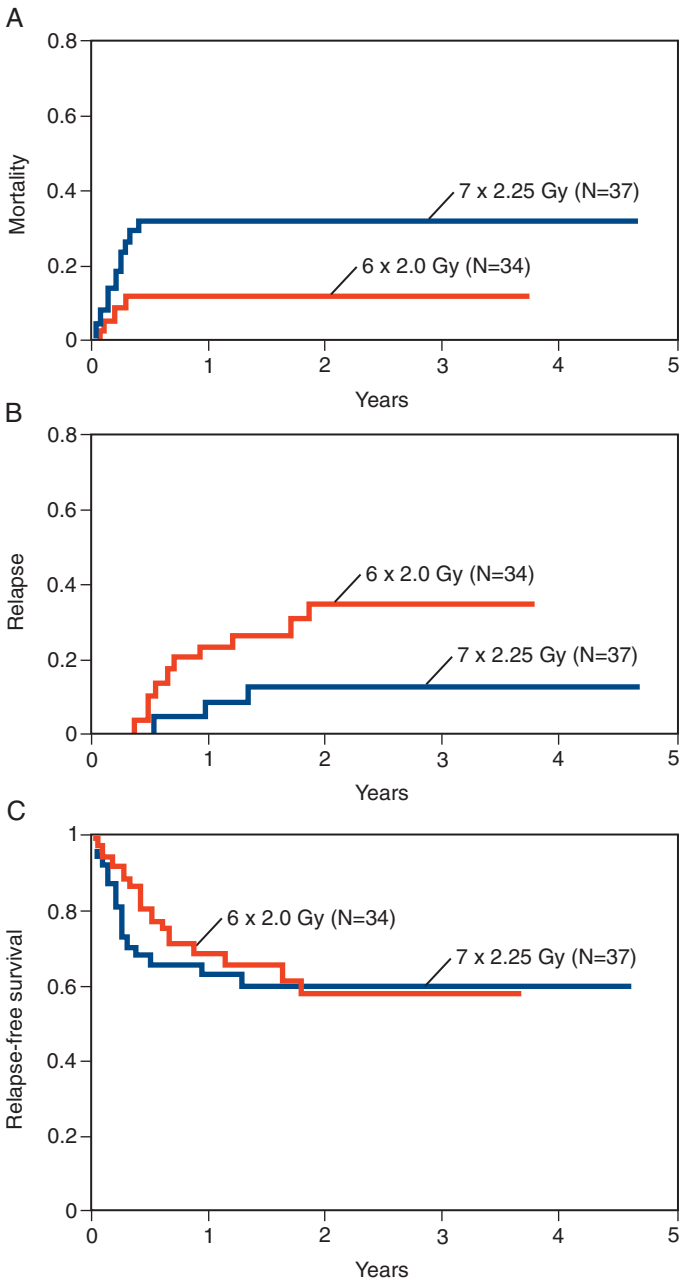

Figure 106–2 The preparative regimen with higher doses of total body irradiation (TBI) reduced probability of relapse at the expense of increased mortality. **A**, Mortality in patients not relapsing after stem cell transplantation ($P = .04$). Patients who relapsed were censored at the time of relapse. **B**, Probability of relapse ($P = .06$). **(C)** Probability of surviving relapse-free after transplantation. (Data from Clift R, Buckner C, Appelbaum F, et al: Allogeneic marrow transplantation in patients with acute myeloid leukemia in first remission: A randomized trial of two irradiation regimens. Blood 76:1869, 1990.)

and colleagues reported a study with AML patients in first remission. They found better disease-free and overall survival and decreased treatment-related mortality and relapse rate in hematopoietic cell transplant recipients prepared with Cy-TBI rather than with BuCy. In 2001, Blaise published extended follow-up data from the 1992 study of AML patients in first remission. The BuCy preparative regimen was associated with poorer outcome than the Cy-TBI regimen. Failure in the early post-transplant period, including more transplant-related deaths and relapses, occurred in the BuCy group. Late events, such as secondary cancers, had a similar incidence in

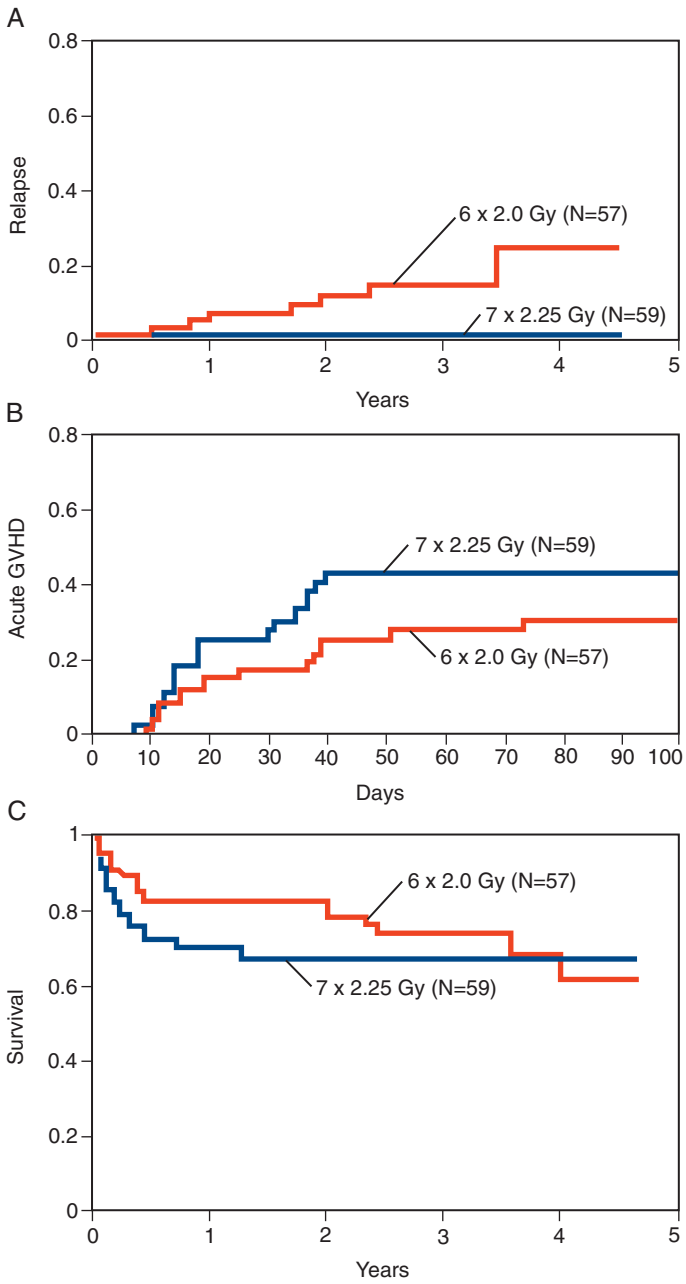

Figure 106–3 Increasing the dose of total body irradiation (TBI) reduced the relapse rate, but was associated with higher acute graft-versus-host disease (GVHD) and toxicity rates. **A**, Probability of relapse after transplantation during the chronic phase of chronic myelogenous leukemia (CML) for patients receiving 12 Gy or 15.75 Gy TBI ($P = .08$). **B**, Probability of developing grade II or worse acute GVHD after transplantation in the chronic phase of CML for patients receiving 12 Gy or 15.75 Gy TBI ($P = .15$). **C**, Probability of survival after transplantation during chronic phase of CML for patients receiving 12 Gy or 15.75 Gy TBI. (Data from Clift R, Buckner C, Appelbaum F, et al: Allogeneic marrow transplantation in patients with acute myeloid leukemia in the chronic phase: A randomized trial of two irradiation regimens. Blood 77:1663, 1991.)

both groups of patients. Interestingly, a French multicenter study showed that these preparative regimens were equivalent for the treatment of patients with CML in chronic phase.[47–50] A major weakness of these reports is that the researchers did not monitor busulfan blood levels. It is possible that at least some of the differences in toxicity and diminished efficacy of the busulfan-containing regimen could be related to undetected high or low blood levels, respectively. Clift and colleagues reported a long-term analysis of outcomes that confirmed that the two regimens had similar efficacy and nonrelapse mortality. BuCy, however, was better tolerated than Cy-TBI.[48] A Southwest Oncology Group study compared VP-16 (etoposide) and TBI with BuCy for the treatment of patients with AML not in first remission.[51] No difference in disease-free survival was documented.

Socie and associates reported consolidated long-term follow-up results of the studies described above for patients with AML ($n = 172$) and CML ($n = 316$).[52] Among patients with CML, no statistically significant difference in overall and disease-free survival was detected. Ten-year survival estimates were 65% and 63% with BuCy and Cy-TBI, respectively. In patients with AML, a 10% lower survival rate was observed after BuCy (10-year actuarial survival of 51% and 63% with BuCy and Cy-TBI, respectively); however, this difference was not statistically significant. Long-term complications, such as avascular necrosis of the femur, were associated with chronic GVHD and steroid use, and to a lesser extent with the preparative regimens.

These studies illustrate the inherent differences in response of various leukemias to the preparative regimens, as well as the need for pharmacokinetic studies and long-term follow-up when comparing preparative regimens.

AUTOLOGOUS TRANSPLANTS

Choice of Agents for Autologous Hematopoietic Cell Transplantation

The alkylating agents are the most commonly used class of antineoplastic agents in the preparative regimen for hematopoietic cell transplant. Other agents are not considered for dose escalation due to extramedullary toxicity occurring at lower doses or at the same dose levels where myelosuppression occurs. The maximum tolerated dose with autologous hematopoietic cell transplant support may be as high as 30 times the standard dose for the alkylating agent thiotepa.[53]

Tumors are heterogeneous in terms of chemotherapy or radiation sensitivity, and preparative regimens containing chemotherapy combinations may provide a way to act at different sites within cancer cells. Choice of chemotherapeutic agents is generally based on relative lack of overlapping toxicity or cross-resistance, effectiveness, and achievable fold dose escalation. Most of the preparative regimens used in autologous transplant employ combination chemotherapy or chemotherapy and radiation. More recently, the explosion of new biologic knowledge has led to the development of new classes of agents with anticancer properties. Monoclonal antibodies are becoming part of preparative regimens designed to target diseases expressing a wide range of epitopes, such as CD20 (non-Hodgkin lymphomas), as discussed below. It is to be expected that the regimens will progressively change in order to incorporate these novel agents.

Mobilization Regimens

Collection of peripheral blood stem cells for hematopoietic cell transplant in the steady state is ineffective because of the small number of hematopoietic progenitors in the peripheral blood. Several regimens for mobilization of autologous hematopoietic cells have been proposed, based on the observation that the number of these cells increase in the circulation during hematologic recovery after chemotherapy and that hematopoietic growth factors increase the numbers of circulating stem cells. Combinations of chemotherapy and growth factors are used successfully in a variety of regimens and doses.[54,55–57] Allogeneic donors are mobilized with growth factors alone whereas autologous donors may receive chemotherapy followed by growth factors.[59] AMD3100, a CXCR4 antagonist may become part of future mobilization strategies.[58] There are few formal comparisons of mobilization regimens, and various regimens have been used.

Preparative Regimens for Autologous Transplant in Multiple Myeloma

Multiple myeloma is one of the few hematologic malignancies for which there is a series of randomized studies comparing different preparative regimens for autologous transplant. It is instructive to review the results of some of these comparisons.

Response rate after conventional therapy such as oral melphalan and prednisone is 50% to 60%, with a 5% complete remission rate. Responders have a median survival of 3 years, and prognosis is based on a variety of features identified at diagnosis. Evidence has accumulated showing a dose–response relationship in the treatment of this disease. High-dose TBI-based preparative regimens coupled with autologous hematopoietic cell transplant were shown to be superior to standard dose chemotherapy in randomized trials. A French study reported complete remission and 5-year survival rates of 22% and 52% in the autologous transplant arm versus 5% and 12% in the standard therapy arm.[59] Increasing the dose of melphalan from 100 mg/m^2 to 400 mg/m^2 (200 mg/m^2 for each transplant procedure), which is delivered in some tandem transplant programs, increases the complete remission rate from 6% to 15%–25% in refractory patients, and to 20%–45% in recently diagnosed individuals. Early harvesting of mobilized peripheral blood progenitor cells (preferably during the first year of chemotherapy) allows for the collection and storage of more cells that can be used to support tandem transplants.

Moreau and colleagues reported a randomized comparison of melphalan (200 mg/m^2) versus melphalan (140 mg/m^2) plus TBI (8 Gy) as the preparative regimen for autologous transplant in patients with newly diagnosed disease.[61] All patients received four cycles of vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD) prior to the high-dose preparative regimen and autologous hematopoietic cell transplant.[60] Patients treated without TBI had less toxicity, shorter hospitalization, and faster recovery than those receiving melphalan and TBI. Whereas event-free survival was similar, 45-month survival was 46% in the TBI arm and 66% in the non-TBI arm. Moreau and colleagues pointed out that although better salvage regimens were probably responsible for the difference in survival, toxicity was significantly reduced in the non-TBI arm. Barlogie and colleagues employed tandem transplants preceded by three cycles of VAD chemotherapy, cyclophosphamide (6 gm/m^2) with GM–CSF for peripheral blood stem cell harvesting, and EDAP (etoposide, dexamethasone, cytosine arabinoside, cisplatin) for one cycle.[61] The high-dose preparative regimen consisted of melphalan (200 mg/m^2) in the first transplant. Patients achieving at least a partial remission received a second transplant with the same preparative regimen, whereas nonresponders were prepared with melphalan (140 mg/m^2) and TBI. All patients received interferon maintenance until relapse. Among the 231 patients treated (median age 51 years), more than half had Durie–Salmon stage III disease and 30% had β2 microglobulin levels greater than 3 mg/L, strong predictors of poor prognosis. Seventy-one percent of the patients received the second transplant as intended. The complete remission rate increased from 5% after VAD, to 30% after the first transplant and to 41% after completion of two autologous transplants. Treatment-related mortality was 1% after the first and 4% after the second transplant, respectively. Median actuarial 5-year survival was 58 months. The role of double autologous transplants was investigated in a protocol of the Intergroupe Francophone du Myelome. Attal and coworkers randomized 399 untreated patients younger than 60 years to receive a single transplant after a preparative regimen consisting of melphalan (140 mg/m^2) and TBI (8 Gy) or tandem transplant after preparation with melphalan (140 mg/m^2) followed by the TBI–melphalan regimen, respectively.[62] Response rate was similar, but overall and event-free survival were significantly improved in the tandem transplant arm. Seven-year postdiagnosis probability of overall and event-free survival was 42% and 20% in the tandem transplant group and 21% and 10% in the single transplant group. Patients that did not achieve a very good partial remission within 3 months after the first transplant had a probability of survival at 7 years of 11% in the single transplant group. This probability was 43% in the double transplant arm. Based on these results, patients younger than 60 years treated with the autologous hematopoietic cell transplant approach should receive tandem transplants, and every effort should be performed to store autologous stem cells early in the course of the disease.

Toxicity of Preparative Regimens

The analysis of toxicity data after hematopoietic cell transplant has to take into account the variability of regimens used by different groups and the scoring system used to describe the results. Drugs used to prevent GVHD or infectious complications may alter toxicity, and prophylaxis practices may differ from institution to institution, or at the same institution over time. Methotrexate used for GVHD prevention is such an example. The use of reduced doses of the drug ("mini" methotrexate, 5 mg/m^2 on days 1, 3, 6, and 11 posttransplant) may produce less mucositis and other toxicities than more traditional dosing of this agent.[63]

Regimen-related toxicity may be arbitrarily defined as adverse event secondary to the preparative regimen occurring during the first 30 days after transplant.[64] Several regimen-related toxicities, however, may occur beyond 30 days (such as pulmonary toxicity). Autologous transplants are usually associated with less toxicity (Fig. 106–4), whereas increasing age (Fig. 106–5), advanced disease (Fig. 106–6) and unrelated donor transplants (Fig. 106–7) are generally linked to increased rates of adverse reactions and decreased survival probability.

Several improvements in the field of supportive care have minimized many of the acute toxicities associated with HCT. Examples include the incorporation of selective type three 5-hydroxytryptamine (5-HT3) receptor antagonists for prevention and treatment of nausea, palifermin (recombinant human keratinocyte growth factor) to prevent and minimize the severity of radiation-induced mucositis[65] and mesna (2-mercaptoethane sodium sulfonate) to decrease the

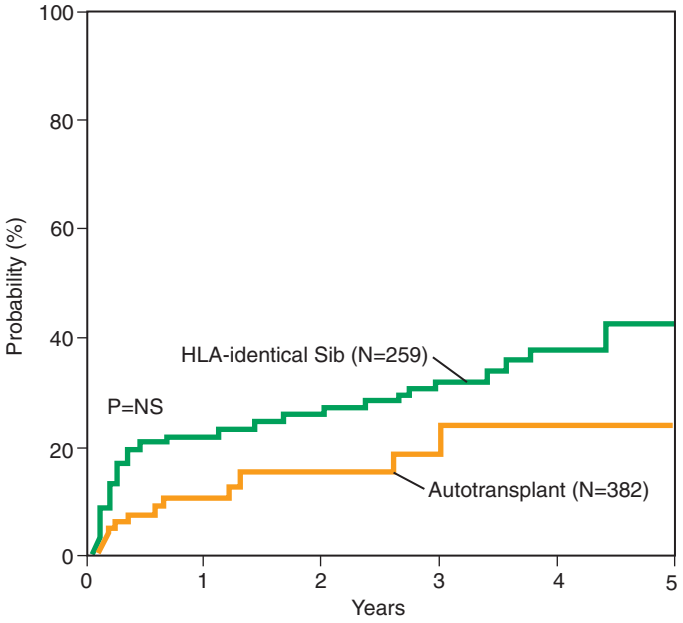

Figure 106–4 Probability of transplant-related mortality after allogeneic hematopoietic stem cell transplantation for acute myelogenous leukemia (AML) patients in second complete remission. Patients receiving autologous transplantations tend to have lower rates of treatment-related mortality than recipients of allogeneic transplants, as exemplified here by patients with AML treated with busulfan and cyclophosphamide. (Cases reported to the International Bone Marrow Transplant Registry (IBMTR), unpublished data, courtesy of the IBMTR.)

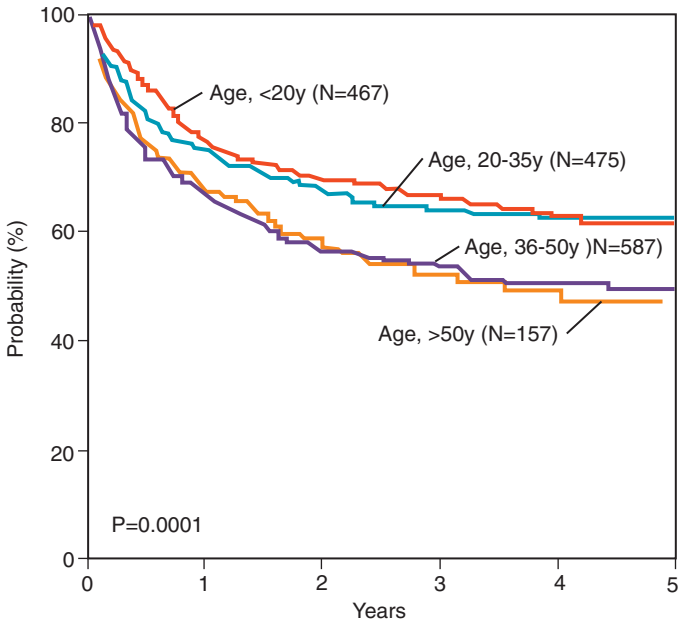

Figure 106–5 Probability of survival after human leukocyte antigen (HLA)-identical sibling transplants for patients with acute myelogenous leukemia (AML) in remission is affected by recipient's age. Kaplan–Meier survival curves of patients that received busulfan and cyclophosphamide as conditioning regimen show decreased survival probability for older patients. (Data from the International Bone Marrow Transplant Registry (IBMTR), on cases reported from years 1996–2000, unpublished data, courtesy of the IBMTR.)

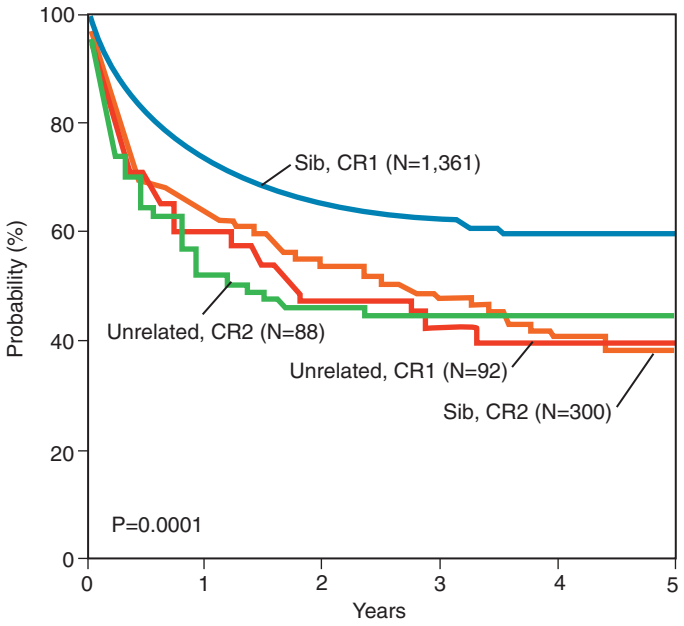

Figure 106–7 Donor type influences survival after allogeneic hematopoietic transplantations: probability of survival after matched unrelated donor and human leukocyte antigen (HLA)-identical sibling bone marrow transplant for acute myelogenous leukemia (AML). All patients received busulfan and cyclophosphamide and were treated from 1996 to the year 2000. Sib = sibling. (Cases reported to the International Bone Marrow Transplant Registry, unpublished data, courtesy of the IBMTR.)

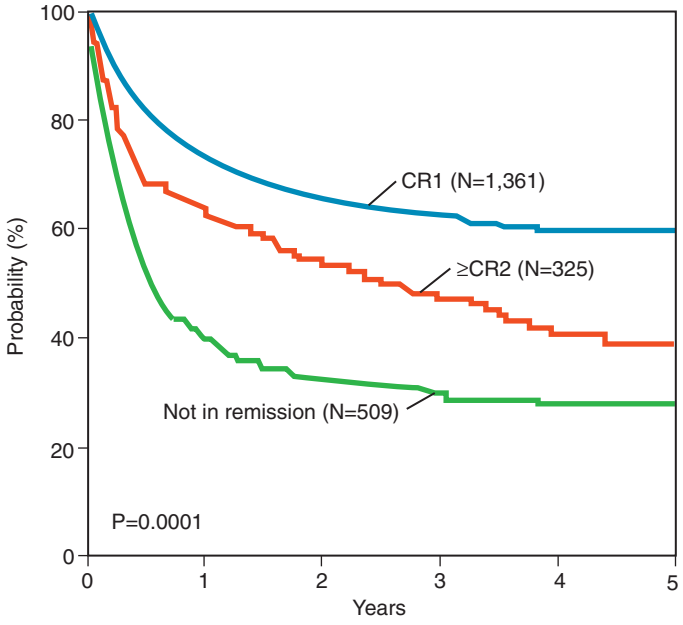

Figure 106–6 Probability of survival after allogeneic human leukocyte antigen (HLA)-identical sibling transplants for acute myelogenous leukemia (AML) is affected by the disease status at transplant. Probability of survival for patients treated with busulfan and cyclophosphamide is shown as a function of remission status. CR1 = first complete remission; CR2 = second complete remission. (Cases reported to the International Bone Marrow Transplant Registry (IBMTR) from years 1996–2000, unpublished data, courtesy of the IBMTR.)

occurrence of regimen-related hemorrhagic cystitis. Long-term toxicities are generally more difficult to prevent, and increased awareness and surveillance are highly recommended (such as for hypothyroidism after TBI). An intervention that is likely to be of benefit for selected individuals is the use of biphosphonates to prevent bone loss after transplant, although long-term benefits are largely assumed but not proven, and some serious side effects have been reported.

Second malignancies may occur following hematopoietic cell transplants, and are more common in patients conditioned with TBI-based regimens.[66] The risk of secondary cancers was 6.7% at 15 years posttransplant among 3,200 patients who survived for at least 5 years after HCT.[67] Incidence of cancers of the brain, thyroid, liver, bone, oral cavity and connective tissue were significantly increased. Incidence increased with the dose of radiation and decreased with non-TBI-containing regimens.

Posttransplant lymphoproliferative disorder represents a group of Epstein–Barr virus-related clinical syndromes that may include very aggressive non-Hodgkin lymphoma. HLA-mismatching, T-cell depletion of the graft, use of antilymphocyte antibodies in the conditioning regimen, and use of potent or multiple immunosuppressive treatments for GVHD are well-recognized risk factors. Tables 106–3 and 106–4 describe commonly reported regimen-related toxicities.

MONOCLONAL ANTIBODIES

The feasibility and efficacy of supplementing high-dose chemotherapy protocols with rituximab, an anti-CD20 mouse/human chimeric monoclonal antibody (MAb) active against various lymphoid malignancies has been documented by several groups. The goal is to achieve in vivo purging during mobilization and to eliminate minimal residual disease after transplant.[68,69] The MD Anderson Cancer Center experience using high-dose rituximab (1000 mg/m^2) after mobilization chemotherapy and on days 1 and 8 post–autologous transplant was reported by Khouri and colleagues.[70] Forty-two patients with CD20 expressing non-Hodgkin lymphoma were

Table 106–3 Acute Toxicity of Preparative Regimens

Toxicity	Causative Agents	Incidence and Comments
Interstitial pneumonitis	Total body irradiation (TBI), carmustine, busulfan, cyclophosphamide	Higher in patients who received radiation to the chest prior to bone marrow transplantation. Allogeneic transplants > autologous transplants. Fractionated doses of TBI minimize extramedullary toxicity. Busulfan (IV, 3.2 mg/kg) and cyclophosphamide (IV) (BuCy) < TBI. Acute and chronic forms. Idiopathic pneumonia syndrome classically described as occurring at a median of 50 days posttransplant.
Diffuse alveolar hemorrhage	TBI	May occur with different regimens. Allogeneic transplants > autologous transplants.
Hemorrhagic cystitis	Cyclophosphamide, TBI, etoposide, ifosfamide, holmium	Higher in cyclophosphamide-containing regimens. May lead to chronic urinary tract strictures and severe bladder dysfunction.
Hepatic venoocclusive disease (VOD)	Busulfan, cyclophosphamide, tbi, carmustine	Possibly higher incidence among patients with active viral hepatitis and iron overload. High mortality with severe forms (ascites, severe weight gain, jaundice, painful hepatomegaly) Fractionated doses of TBI minimize extramedullary toxicity. Use of IV formulation of busulfan appears to reduce the risk (better control of area under the concentration curve versus time).
Mucositis	Melphalan, TBI, busulfan, cyclophosphamide, etoposide, thiotepa, methotrexate	Higher among heavily pretreated patients, and patients who received prior radiation to the cervical and mediastinal areas. Methotrexate used for graft-versus-host disease (GVHD) prophylaxis may worsen mucositis.
Diarrhea	Melphalan, TBI, cyclophosphamide	
Seizures	Busulfan	Prophylactic use of anticonvulsants minimizes the risk. Incidence higher in children than in adults
Renal failure	TBI, carmustine, ATG, ifosfamide	Often multifactorial
Encephalopathy	Carmustine, ifosfamide	Often multifactorial

Acute GVHD and its treatment may worsen regimen-related toxicities.

Table 106–4 Delayed Toxicity of Preparative Regimens

Side effect	Regimen	Incidence / Comments
Hypothyroidism	TBI	Single fraction TBI, up to 73% incidence of thyroid dysfunction; fractionated TBI, 15%–25% (mean time to development of hypothyroidism, 49 months)[104,105]
Growth/development delay	TBI	Steroid use may worsen growth delay.
Sterility	TBI, chemotherapy-containing regimens	Women receiving TBI in doses greater than 10 cGy have higher incidence of permanent ovarian damage. Older age increases the likelihood of menopause post-BMT.[106] Sperm production is usually severely decreased post-TBI, but less so after busulfan-based regimens.
Chronic pulmonary damage	TBI, carmustine-containing regimens	Bronchiolitis obliterans caused by chronic GVHD may cause severe pulmonary dysfunction in the allogeneic setting.
Cataracts	TBI, Busulfan	Fractionated TBI, incidence of >30%. Steroid use also a factor
Osteoporosis	TBI, chemotherapy-containing regimens	Prevalence unknown (probably underestimated)
Myelodysplasia	Cyclophosphamide/TBI, etoposide containing regimens, other chemotherapy-ontaining regimens	Rare occurrence after allogeneic BMT (eg, represents disease relapse). Incidence after autologous transplant may be as high as 18% ± 9% at 6 years post-BMT. Contribution of hematopoietic stem cell damage by previous therapy is important and frequently chromosomal abnormalities are detected in the bone marrow prior to transplant.[107–109]
Alopecia	BuCy, cyclophosphamide/TBI and other regimens	Alopecia was more common after BuCy than after CyTBI in one randomized study.[110]

Development of chronic GVHD and its treatment may overlap with, precipitate, or worsen regimen-related toxicities. For explanation of abbreviations, see Table 106–1.

treated, using high-dose chemotherapy with the BEAM regimen. Two-year survival was 80% (there were no treatment-related deaths) versus 53% for a historical control group. The use of high-dose rituximab, however, remains controversial, and most groups use lower doses.

Similarly, MAb may contribute to the treatment of myeloid leukemias. A phase I/II study was conducted at the MD Anderson Cancer Center adding gemtuzumab ozogamicin (Mylotarg) 2 or 4 mg/m^2 to the reduced-intensity preparative regimen of fludarabine and melphalan 140 mg/m^2. Gemtuzumab ozogamicin is a monoclonal antibody that targets the CD33 antigen commonly present in myeloid cells. A group of 52 patients received allogeneic transplantation with this regimen (49 with refractory and/or refractory CD33-positive myeloid leukemias). The lower dose was safely added to the regimen, and a comparison with historic controls indicated a prolongation of survival.[71]

The CD52 MAb alemtuzumab (Campath) targets a glycoprotein that is highly expressed on normal T- and B-lymphocytes and on a significant proportion of malignant lymphoid cells. Graft T cell depletion using this MAb prevents acute and chronic GVHD, but it is unclear if this benefit is offset by increased relapse rates. Alemtuzumab is under intense investigation as part of the preparative regimen in several centers worldwide, especially in the context of mismatched-related, haploidentical, or unrelated donor transplants.[72]

RADIOIMMUNOTHERAPY

The principle of attaching radioactive particles to MAb is referred to as radioimmunotherapeutics (RIT). It is expected to increase both efficacy and safety by delivering irradiation directly to the target on the tumor cell with relative sparing of normal tissue. In addition, high-energy particles can kill surrounding tumor cells that do not directly bind the antibody through a bystander effect. Currently two radioimmunoconjugates (RICs) are approved by the U.S. Food and Drug Administration for the treatment of CD20+ expressing lymphoma: iodine-131 (I-131) tositumomab and yttrium-90 (Y-90) ibritumomab tiuxetan. Ibritumomab tiuxetan (Zevalin) is a murine anti-CD20 IgG1 kappa monoclonal antibody linked to tiuxetan and to the beta-emitting radioisotope Ytrium-90 (therapeutic) or to Indium-111 (for imaging). A phase I/II trial using etoposide (40–60 mg/kg on day −4), cyclophosphamide (100 mg/kg on day −2), and Zevalin has been reported.[73] Dosimetry was performed on day −21 with 5 mCi ^{111}In-ibritumomab tiuxetan, followed by Zevalin (40–100 mCi) with ytrium ibritumomab tiuxetan. Eighteen patients received hematopoietic cells when the radiation dose was estimated to be less than 5 cGy. There were no treatment-related deaths and median time to engraftment of neutrophils was 10 days, illustrating the safety of this approach.

The first phase 1 RIT study with stem cell support was conducted by Press and coworkers in 1993 with I-131-labled anti-CD20 (B1, 1F5) and anti-CD37 (MB-1) to treat relapsed lymphoma.[74] The anti-CD20 antibody was found to be superior to the anti-CD37 antibody in terms of dosing, distribution, and toxicity. Patients treated with 23.75 Gy or less to normal organs experienced minimal nonhematologic toxicity. Two patients experienced grade 3 cardiopulmonary complications after receiving doses that resulted in 27.25 and 30.75 Gy to the lung. A subsequent phase 2 study by the same investigators and trials performed by other groups confirmed the activity of regimens combining chemotherapy and RIT. A relatively common long-term toxicity has been a rise in thyroid-stimulating hormone, although acute toxicities have been similar to those observed without the RIC. I-131-tositumomab has been administered in a standard total body dose (rather than dosimetry determined) combined with the BEAM regimen, again without excessive side effects.[75] Clinical trials are underway investigating RIT as part of preparative regimens for allogeneic transplants to treat lymphoma.

Targeting radiation to the marrow is an attractive approach to minimize the toxic effects of γ radiation. Radionuclides that emit β radiation have a particle emission range that is much greater than the size of the cells, with the potential for more side effects and the need for higher doses of radioactivity. The α-emitting radionuclides may be a suitable alternative to target the hematopoietic system because of the high-energy particles that distribute the irradiation over smaller distances. In a canine model of nonmyeloablative allogeneic transplantation, a preparative regimen consisting of bismuth 213, an α-emitting radionuclide, combined to an anti-CD45 monoclonal antibody (CD45 is a broadly expressed hematopoietic surface antigen) was well tolerated and produced stable mixed chimerism.[76]

Three different antibodies have been tested—anti-CD33, -CD45, and -CD66—attached to one of four radionuclides (^{131}I, ^{90}Y, ^{188}Re, or ^{213}Bi). Various phase 1 and 2 trials have investigated the addition of one of these RIC either to fully ablative (Cy-TBI or BuCy2) or reduced-intensity conditioning regimens and are reviewed elsewhere by Kotzerke and collaborators.[77]

Matthews and coworkers reported the use of an anti-CD45 antibody incorporated into a conditioning regimen for patients with advanced acute leukemia and MDS. A total of 34 patients received the ^{131}I- anti-CD45 antibody administered in a dose estimated to deliver an absorbed dose of radiation to the liver (the highest uptaking normal organ in all but one patient) ranging from 3.5 Gy (dose level 1) to 12.25 Gy (level 6). The RIC was combined with Cy (120 mg/kg) and TBI (12 Gy divided into six fractions) followed by autologous or allogeneic transplant. The MTD (mucositis) was determined to be 10.5 Gy. This strategy resulted in supplemental doses of radiation of 24 and 50 Gy to the marrow and spleen. DFS was 29% with nonrelapse mortality and relapse rate of 18% and 50%, respectively. A phase 1/2 trial was then conducted in 46 patients with intermediate or poor risk cytogenetics AML in first remission using the ^{131}I- anti-CD45 antibody combined with targeted oral Bu (AUC of 600–900 ng/mL) and Cy 120 mg/kg, followed by matched related donor transplant.[78,79] Four patients safely received a dose at level 1 that targeted 3.5 Gy to normal organs, with all subsequent patients receiving dose level 2 of 5.25 Gy. This resulted in mean doses of 11.3 and 29.7 Gy to the bone marrow and spleen, respectively. Grade II mucositis occurred in all patients and 71% of evaluable patients developed hypothyroidism. The estimated 3-year DFS and nonrelapse mortality was 61% and 21%, respectively. These results reported by the Seattle group indicate the potential of RIC to increase the intensity of the conditioning regimen without added toxicity.

The use of skeletal targeted therapy with ^{166}HoDOTMP (Holmium), a tetraphosphonate radiotherapeutic agent that emits beta particles, was investigated by Giralt and colleagues in a group of 83 patients with multiple myeloma. Holmium was used in combination with melphalan 140 mg/m^2, 200 mg/m^2, or melphalan 140 mg/m^2 with TBI (800 cGy). Nominal doses of radiation delivered to the bone marrow ranged from 20 to 40 Gy. Autologous transplant was performed 7 to 10 days after the radioisotope was given. There were two early deaths and 23 patients developed hemorrhagic cystitis, and thrombotic microangiopathy occurred in 7 patients who were treated at 40 Gy. The kidney is the excretion organ of ^{166}HoDOTMP. Complete responses occurred in 38% of the patients, whereas 31% achieved a partial remission. The authors recommended a dose of 30 Gy or less with bladder irrigation to prevent hemorrhagic cystitis. The response rate compared favorably with that observed after other preparative regimens for autologous transplants in multiple myeloma.[80] Logistics and costs of RICs however are potential obstacles for the widespread use of these promising agents in HSCT.

NONMYELOABLATIVE HEMATOPOIETIC CELL TRANSPLANTATION

Many of the treatment failures after allogeneic hematopoietic cell transplant are due to the intensive preparative regimens traditionally used for myeloablation and immunosuppression. Furthermore, the

RATIONALE APPROACH TO CHOOSING A CONDITIONING REGIMEN

Case 1: 66-year-old woman with 2ry acute myeloid leukemia (AML) in first complete remission (CR1) has a human leukocyte antigen (HLA)-compatible unrelated donor. History of prior autologous transplant for lymphoma, compensated diabetes, and hypertension. Performance status is 1 and she is independent in activities of daily living	Questions to ask Is she a transplant candidate? Yes, phase 2 data suggests benefits for these patients. No phase 3 data available. Should she receive a reduced intensity regimen? Yes, high comorbidity score would suggest lower nonrelapse mortality (NRM) and improved survival with a reduced intensity conditioning (RIC) regimen. Is a specific regimen recommended? No, no randomized trials have been performed comparing different RIC regimens. Registry analysis has not shown a benefit of one regimen over another in the unrelated donor setting (Giralt et al).
Case 2: 55-year-old man with myelodysplastic syndrome (MDS) and an HLA-compatible sibling donor. No comorbidities.	Is he a transplant candidate? Yes, phase 2 data suggests benefits for these patients. No phase 3 data available Should he receive a reduced-intensity regimen? No, comorbidity score would suggest similar NRM for RIC and ablative regimens in this setting. Standard of care would be full-dose busulfan-based regimen with pharmacologic monitoring.

incidence of GVHD is, to some extent, related to the intensity of the regimen. Thus allogeneic hematopoietic cell transplant has been restricted to younger patients with good performance status. Many candidates are excluded because of advanced age or comorbid conditions. The peak incidence of most hematologic malignancies for which allogeneic transplant is used is in patients in their 60s and 70s; therefore, most of the patients who might benefit from hematopoietic cell transplant are ineligible.

The existence of a graft-versus-tumor (GVT) effect in humans is supported by indirect evidence, such as the lower rate of relapse in patients who develop GVHD or the higher relapse rates after syngeneic transplants or among recipients of T cell-depleted allografts. Direct evidence comes from the observation that donor lymphocytes can induce remission in patients relapsing after allogeneic transplant.[81] A less intensive preparative regimen that is sufficiently immunosuppressive to prevent graft rejection may be used to explore the graft-versus-tumor effect. In addition, achievement of stable mixed or complete hematopoietic donor chimerism may be curative for several nonmalignant genetic diseases without resorting to complete marrow ablation.[82]

Diseases that can be classified as highly sensitive to the graft-versus-tumor effect include CML, low-grade lymphoma, mantle cell lymphoma, and chronic lymphocytic leukemia. AML, intermediate-grade lymphoma, multiple myeloma, and Hodgkin lymphoma can be classified as of intermediate sensitivity, whereas ALL and the high-grade lymphomas are relatively insensitive.[1] Accordingly, the likelihood of success after nonmyeloablative transplants is highly influenced by the diagnosis and disease stage. The low intensity of the preparative regimen and the relatively delayed time for the graft-immune effect to be effective render rapidly progressing malignancies less likely to benefit from nonmyeloablative hematopoietic cell transplant.

Truly nonmyeloablative preparative regimens include fludarabine–cyclophosphamide, fludarabine–idarubicin–cytarabine, and 2-Gy TBI-based regimens, whereas reduced-intensity ablative regimens include combinations of fludarabine with intermediate doses of melphalan or busulfan (see Table 106–1 and Fig. 106–8).[83–85]

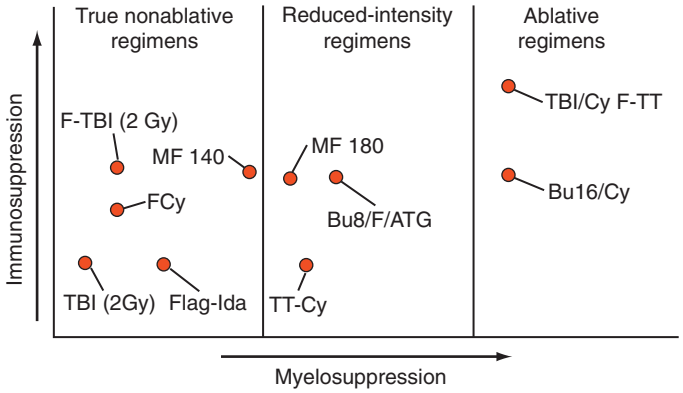

Figure 106–8 Commonly used nonablative or reduced-intensity regimens. Nonablative regimens do not completely eradicate host hematopoiesis; autologous recovery occurs if the graft is rejected. Many reduced-intensity regimens are ablative, as only donor-derived cells are generally detected posttransplant, and graft rejection results in prolonged pancytopenia. Progenitor cells from donors other than HLA-identical siblings will require greater immunosuppression to prevent rejection. Rapidly progressing malignancies generally require increased degree of myelosuppression. Bu16/Cy, busulfan (16 mg/kg)/cyclophosphamide; FCy, fludarabine/cyclophosphamide; Flag-Ida, fludarabine, cytarabine–idarubicin; F-TBI, fludarabine–total body irradiation; Bu8/F/ATG, busulfan (8 mg/kg)/fludarabine/antithymocyte globulin; MF, melphalan–fludarabine (with melphalan 140 or 180 mg/m^2); TBI/Cy F-TT, fludarabine/thiotepa; TT-Cy, thiotepa/cyclophosphamide. (Data from Champlin R, Khouri I, Anderlini P, et al: Nonmyeloablative preparative regimens for allogeneic hematopoietic transplant. Biology and current indications. Oncology [Huntingt] 17[1]:94, 2003.)

Furthermore, the intensity of the preparative regimen may be reduced if enough cytoreduction and some degree of immunosuppression is achieved by a preceding autologous transplant. This strategy of "auto-allo" transplant is under investigation in the therapy of multiple myeloma, non-Hodgkin lymphoma, and Hodgkin lymphoma.

Another less myelotoxic approach was reported by Lowsky and colleagues, using a conditioning regimen with 10 doses of total lymphoid irradiation (80 cGy each) plus antithymocyte globulin. Thirty-seven patients with lymphoid malignancies or acute leukemia were treated, and only two had acute GVHD. Antitumor effects were documented in patients with lymphoid malignant diseases.[86]

CONCLUSION

Incorporation of new drugs, antibodies, and radioimmunoconjugates in the preparative regimen, as well as graft engineering, is likely to modify the way we perform hematopoietic cell transplant. Further improvements in supportive care and the prophylaxis of GVHD will most certainly contribute to the evolution of the knowledge and practice of hematopoietic cell transplant. Pharmacogenetics data will allow individualization of doses and guide the choice of less toxic agents. The foundations of autologous and allogeneic transplant have been established over the last 50 years. The role of this form of treatment will most certainly change in the next decade to incorporate the advances in the field of immunology, cellular biology, pharmacology, and genetics.

CHAPTER 107

GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-LEUKEMIA RESPONSES

Pavan Reddy and James L. M. Ferrara

INTRODUCTION

The ability of allogeneic hematopoietic cell transplantation (HCT) to cure certain hematologic malignancies is widely recognized. An important therapeutic aspect of HCT in eradicating malignant cells is the graft-versus-leukemia (GVL) effect. The importance of the GVL effect in allogeneic HCT has been recognized since the earliest experiments in stem cell transplantation. Forty years ago, Barnes and colleagues noted that leukemic mice treated with a subtherapeutic dose of radiation and a syngeneic (identical twin) graft transplant were more likely to relapse than mice given an allogeneic hematopoietic cell transplant.[1,2] They hypothesized that the allogeneic graft contained cells with immune reactivity necessary for eradicating residual leukemia cells. They also noted that recipients of allogeneic grafts, though less likely to relapse, died of a "wasting syndrome" now recognized as graft-versus-host disease (GVHD). Thus, in addition to describing GVL, these experiments highlighted for the first time the intricate relationship between GVL and GVHD. Since these early experiments, both GVHD and the GVL effect have been studied extensively.[3] This chapter reviews the pathophysiology, clinical features, and treatment of GVHD and summarizes current understanding of the relationships between GVHD and the GVL effect.

GRAFT-VERSUS-HOST DISEASE: CLINICAL AND PATHOLOGIC ASPECTS

Ten years after the work of Barnes and Loutit, Billingham formulated the requirements for the development of GVHD: the graft must contain immunologically competent cells, the recipient must express tissue antigens that are not present in the transplant donor, and the recipient must be incapable of mounting an effective response to destroy the transplanted cells.[4] According to these criteria, GVHD can develop in various clinical settings when tissues containing immunocompetent cells (blood products, bone marrow, and some solid organs) are transferred between persons. The most common setting for the development of GVHD is following allogeneic HCT; without prophylactic immunosuppression, most allogeneic HCTs will be complicated by GVHD. GVHD occurs secondary to mismatches in histocompatibility antigens between the donor and recipient. Matching of the major histocompatibility complex (MHC) antigens speeds engraftment and reduces the severity of GVHD.[5] The MHC contains the genes that encode tissue antigens and were first identified functionally in murine models as transplantation antigens responsible for rejection of tissue grafts. In humans, the MHC region lies on the short arm of chromosome 6 and is called the human leukocyte antigen (HLA) region.[6] The HLA region includes many genes, not all of which are involved in immune activation. It is divided into two classes, Class I and Class II, each containing numerous gene loci that encode a large number of polymorphic alleles. MHC class I molecules are involved in the presentation of peptides to $CD8^+$ T cells, and class II molecules present peptides to $CD4^+$ T cells.[6]

Each MHC antigen is composed of two polypeptide chains. Class I antigens are made up of a heavy chain that contains the polymorphic regions and the nonpolymorphic light chain, beta-2 microglobulin. The class I HLA antigens include HLA A, B, and C antigens. These are expressed on almost all cells of the body at varying densities,[6] Both chains of class II antigens contain polymorphic regions and are encoded in the MHC. The class II antigens are further divided into DR, DQ, and DP antigens. Class II antigens are expressed on B cells, dendritic cells and monocytes and their expression can be induced on many other cell types following inflammation or injury.[6,7] The determination of HLA types has become much more accurate with molecular techniques that replace earlier serologic or cellular methods. In patients whose ancestry involves extensive interracial mixing, the chances of identifying an HLA-identical unrelated donor are diminished.[8]

Despite HLA identity between a patient and donor, substantial numbers of patients still develop GVHD as a result of differences in minor histocompatibility antigens that lie outside the HLA loci. Most minor antigens are expressed on the cell surface as degraded peptides bound to specific HLA molecules, but the precise characterization of many human minor antigens is yet to be accomplished.[9] In the United States, the average patient has a 25% chance of having an HLA match among his biological full siblings.[8] Patients who lack a suitably HLA-matched related donor may seek unrelated adult unrelated or umbilical cord blood (UCB) donors.

ACUTE GRAFT-VERSUS-HOST DISEASE

Acute GVHD can occur within days (in recipients who are not HLA-matched with the donor or in patients not given any GVHB prophylaxis) or as late as 2 months after transplantation. The incidence ranges from less than 10% to more than 80%, depending on the degree of histoincompatibility between donor and recipient, the number of T cells in the graft, the patient's age, and the GVHD prophylactic regimen.[10] The principal target organs include the immune system, skin, liver, and intestine. GVHD occurs first and most commonly in the skin as a pruritic maculopapular rash, often involving the palms, soles, and ears; it can progresses to total-body erythroderma, with bullae formation, rupture along the epidermal–dermal border, and desquamation in severe cases.[10] Gastrointestinal (GI) and liver manifestations often appear later and rarely represent the first and only findings. Intestinal symptoms include anorexia, nausea, diarrhea (sometimes bloody), abdominal pain, and paralytic ileus.[10] Liver dysfunction includes hyperbilirubinemia and increased serum alkaline phosphatase and aminotransferase values. Coagulation studies may become abnormal, and hepatic failure with ascites and encephalopathy may develop in severe cases.[10–12] Hepatic GVHD can be distinguished from hepatic venoocclusive disease (VOD) by weight gain or pain in the right upper quadrant in the latter.[12] Acute GVHD also results in the delayed recovery of immunocompetence.[10] The clinical result is profound immunodeficiency, and susceptibility to infections, often further accentuated by the immunosuppressive agents used to treat GVHD.[10]

Pathologically, the sine qua non of acute GVHD is selective epithelial damage of target organs.[13,14] The epidermis and hair follicles are damaged and sometimes destroyed. Small bile ducts are profoundly affected, with segmental disruption. The destruction of intestinal crypts results in mucosal ulcerations that may be either patchy or diffuse. Other epithelial surfaces, such as the conjunctivae, vagina, and esophagus, are less commonly involved. A peculiarity of GVHD

histology is the frequent paucity of mononuclear cell infiltrates; however, as the disease progresses the inflammatory component may be substantial. Recent studies have identified inflammatory cytokines as soluble mediators of GVHD and have suggested that direct contact between target cells and lymphocytes may not be required for target cell destruction (see following sections). GVHD lesions are not evenly distributed in the target tissues. In the skin, damage is prominent at the tip of rete ridges; in the intestine, at the base of the crypts; and in the liver, in the periductular epithelium. These areas contain a high proportion of stem cells, giving rise to the idea that GVHD targets may be undifferentiated epithelial cells with primitive surface antigens.[15]

The histologic severity of a given lesion is at best semiquantitative, and consequently the severity of pathologic findings is not used in the grading of GVHD. As it is often difficult to obtain an adequate tissue biopsy, the physician is left to use clinical judgment. It can be very difficult to distinguish GVHD from other post-BMT complications such as drug eruptions and infectious complication by histologic criteria.

A recent multicenter phase 3 trial used an independent committee to assess the presence and severity of GVHD. The incidence of GVHD as determined by investigators was substantially higher than the review committee could confirm.[16] Nevertheless, for an experienced clinician a combination of physical and laboratory findings in the appropriate context provides a working diagnosis of GVHD that is satisfactory to produce a meaningful prognostic scale based on the clinical grading system. [12,17] Standard grading systems generally include clinical changes in the skin, GI tract, liver, and performance status (Table 107–1).[18] Although the severity of GVHD is sometimes difficult to quantify, the overall grade correlates with disease outcome. Whereas mild GVHD (grade I or II) is associated with little morbidity and almost no mortality, higher grades are associated with significantly decreased survival.[18,19] With grade IV GVHD, the mortality is almost 100%.[19]

Table 107–1 Glucksberg Criteria for Staging of Acute Graft-Versus-Host Disease[a]

Overall grade	Skin	Liver		Gut
I	1–2	0		0
II	1–3	1	and/or	1
III	2–3	2–4	and/or	2–3
IV	2–4	2–4	and/or	2–4

[a]See this table for individual organ staging. Traditionally, individual organs are staged without regard to attribution. The overall grade of graft-versus-host disease (GVHD), however, reflects the actual extent of GVHD.

Clinical Features of Acute Graft-Versus-Host Disease

The clinical features and staging and grading of acute GVHD are summarized in Tables 107–1 and 107–2.

In a comprehensive review of patients receiving therapy for acute GVHD, Martin et al[20] found that 81% had skin involvement, 54% had GI involvement, and 50% had liver involvement at the initiation of GVHD therapy. After high-intensity (conventional) conditioning, acute GVHD generally occurs within 14 to 35 days of stem cell infusion. The time of onset may depend upon the degree of histocompatibility, the number of donor T cells infused, and the prophylactic regimen for GVHD. A "hyperacute" form of GVHD may occur in patients with severe HLA mismatches and in patients who receive T-cell replete transplants without or with inadequate in vivo GVHD prophylaxis.[21] It is, however, important to note that this hyperacute form is pathophysiologically distinct from the hyperacute rejection after solid organ allografting. This form of GVHD is manifested by fever, generalized erythroderma and desquamation, and often edema. It typically occurs about one week after stem cell infusion and may be rapidly fatal. In patients receiving more conventional (in vivo) GVHD prophylaxis, such as a combination of cyclosporine (CSP) and methotrexate, the median onset of GVHD is typically 21 to 25 days after transplantation; however, after in vitro T cell depletion of the graft the onset may be much later.[21] Thus, the findings of rash and diarrhea by one week after transplantation would very likely be hyperacute manifestations of GVHD if minimal or ineffective prophylaxis were administered; the same kinetics would be very unlikely with the use of calcineurin inhibitors or in vitro T cell depletion of the stem cell inoculum. A less ominous syndrome of fever, rash, and fluid retention occurring in the first 1 to 2 weeks after stem cell infusion is the "engraftment syndrome." These manifestations may be seen with either allogeneic or autologous transplantation. Although the pathophysiology is poorly understood, it is thought to be due to a wave of cytokine production as the graft starts to recover. This is related to, but distinct from, the "cytokine storm"[21,22] that is thought to contribute to acute GVHD in that there is no concomitant T cell-mediated attack. This syndrome responds immediately to steroids in most patients and it typically presents earlier than acute GVHD.[16] In autologous transplantation the differential diagnosis is of little relevance, but in allogeneic transplant recipients it must be distinguished from the hyperacute manifestations of GVHD. A prompt response to steroids would argue in favor of an engraftment syndrome, although some patients with GVHD will also respond.

Table 107–2 Clinical Manifestations and Staging of Acute GVHD

Organ	Clinical Manifestations	Staging
Skin	Erythematous, maculopapular rash involving palms and soles. May become confluent. Severe disease: bullae	Stage 1: <25% rash Stage 2: 25%–50% rash Stage 3: generalized erythroderma Stage 4: bullae
Liver	Painless jaundice with conjugated hyperbilirubinemia and increased alkaline phosphatase	Stage 1: bili 2–3 mg/dL Stage 2: bili 3.1–6 mg/dL Stage 3: bili 6.1–15 mg/dL Stage 4: bili > 15 mg/dL
Gastrointestinal (GI) tract	Upper: nausea, vomiting, anorexia Lower: diarrhea, abdominal cramps, distention, ileus and bleeding	Stage 1: diarrhea > 500 mL/day Stage 2: diarrhea > 1000 mL/day Stage 3: diarrhea > 1500 mL/day Stage 4: ileus, bleeding

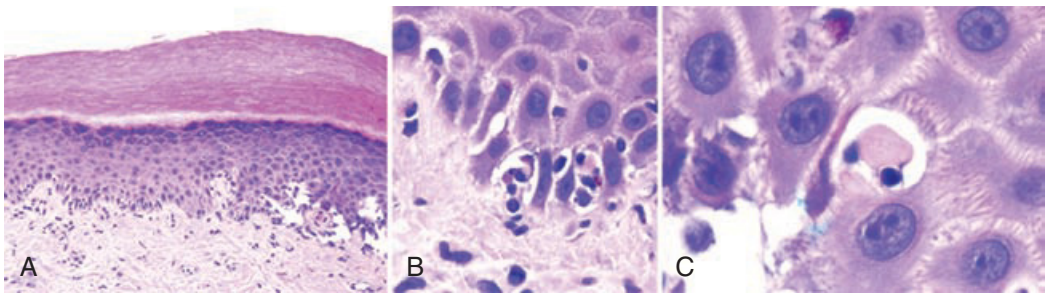

Figure 107–1 Graft-versus-host disease, skin biopsy (**A**–**C**). This 40-year-old man with a history of relapsed Hodgkin lymphoma was status-post allogeneic stem cell transplant with donor lymphocyte infusion. He developed painful oral ulcers, and a macular-papular rash on the arms, hand, and chest. The skin biopsy is from the palmar surface of the hand (**A**). It shows a scant lymphoid infiltrate in the dermis with a developing subepithelial blister (*right*). There is basal vacuolar change (**B**) with single lymphocytes in the epithelium, and apoptotic keratinocyte accompanied by lymphocytes (**B**, and detail, **C**). (*Case courtesy of Drs. Vesna Petronic-Rosic and Mark Racz, University of Chicago.*)

Skin

Skin is the most commonly affected organ (Fig. 107–1). In patients receiving transplants after myeloablative conditioning, the skin is usually the first organ involved, and GVHD often coincides with engraftment. However, the presentation of GVHD is more varied following nonmyeloablative transplants or donor lymphocyte infusions.[23] The characteristic maculopapular rash can spread throughout the rest of the body but usually spares the scalp, and is often described as feeling like a sunburn, with tight or pruritic skin. In severe cases the skin may blister and ulcerate.[24] Histologic confirmation is critical to rule out drug reactions or viral infections. Apoptosis at the base of dermal crypts is a characteristic histologic finding. Other features include dyskeratosis, exocytosis of lymphocytes, satellite lymphocytes adjacent to dyskeratotic epidermal keratinocytes, and dermal perivascular lymphocytic infiltration.[23,25]

Gastrointestinal Tract

Gastrointestinal (GI) tract involvement of GVHD may present as nausea, vomiting, anorexia, diarrhea, and/or abdominal pain.[25] It is a panintestinal process, often with differences in severity between the upper and lower GI tracts. Gastric involvement gives rise to postprandial vomiting that is not always preceded by nausea. Although gastroparesis is seen after hematopoietic cell transplant, it is usually not associated with GVHD. The diarrhea of GVHD is secretory. Significant GI blood loss may occur as a result of mucosal ulceration and is associated with a poor prognosis.[26] In advanced disease, diffuse, severe abdominal pain and distention is accompanied by voluminous diarrhea (>2 L/day).[19,27]

Radiologic findings of the GI tract include lumenal dilatation with thickening of the wall of the small bowel and air/fluid levels suggestive of an ileus on abdominal flat plates or small bowel series. Abdominal computed tomography may show the "ribbon" sign, of diffuse thickening of the small bowel wall.[24] Little correlation exists between the extent of disease and the appearance of mucosa on endoscopy, but mucosal sloughing is pathognomonic for severe disease.[28] Nevertheless, some studies have shown that antral biopsies correlate well with the severity of GVHD in the duodenum and in the colon even when the presenting symptom is diarrhea.[28] Histologic analysis of tissue is imperative to establish the diagnosis. The histologic features of GI GVHD are the presence of apoptotic bodies in the base of crypts, crypt abscesses, crypt loss, and flattening of the surface epithelium.[27,29]

Liver

Liver function test abnormalities are common after hematopoietic cell transplant and occur secondary to venoocclusive disease, drug toxicity, viral infection, sepsis, iron overload, and other causes of extrahepatic biliary obstruction.[12] The exact incidence of hepatic GVHD is probably underreported because many patients do not undergo liver biopsies. The development of jaundice or an increase in the alkaline phosphatase and bilirubin are the initial features of acute GVHD of the liver. The histologic features of hepatic GVHD are endothelialitis, lymphocytic infiltration of the portal areas, pericholangitis and bile duct destruction and loss.[19,30]

Other Organs

Whether GVHD affects organs other than the classic triad of skin, liver, and gut has remained a matter of debate. However, numerous reports suggest additional organ manifestations. The most likely candidate is the lung. Lung toxicity, including interstitial pneumonitis and diffuse alveolar hemorrhage, may occur in 20% to 60% of allogeneic transplant recipients but in fewer autologous transplant recipients. Causes of pulmonary damage other than GVHD include engraftment syndrome, infection, radiation pneumonitis, and chemotherapy-related toxicity (eg, methotrexate, busulfan).[21,31] At least one retrospective analysis failed to link severe pulmonary complications to clinical acute GVHD.[32] The mortality due to pneumonia increases with the severity of GVHD, but this association does not necessarily imply that GVHD, as opposed to immunosuppression given for therapy, is causative.[21] A particular histopathologic syndrome of lymphocytic bronchitis has been attributed directly to GVHD,[31] although this association has not been confirmed by others.

Despite the fact that kidneys and heart can be targets for allogeneic damage, as evidenced by their rejection after renal and cardiac transplants, respectively, there is no convincing evidence for direct renal or cardiac damage from acute GVHD that is not secondary to drugs or infection. Similarly, neurologic complications are also common after transplantation but most can be attributed to drug toxicity, infection, or vascular insults.

Differential Diagnosis

Acute GVHD must be distinguished from any process that causes a constellation of fever, erythematous skin rash, and pulmonary edema that may occur during neutrophil recovery. This picture may reflect the dysregulated production of inflammatory cytokines and cellular responses to these molecules, and has been termed *engraftment* or *capillary leak syndrome*.[33,34] The picture is most clearly recognized after autologous transplantation where, theoretically, GVHD should not occur. In allogeneic transplant recipients, distinction from acute GVHD is difficult. This engraftment syndrome is thought to reflect cellular and cytokine activities during early recovery of (donor-derived) blood cell counts and/or homeostatic proliferation of lymphocytes, but a precise delineation of the offending cells

and mechanisms has not been accomplished. Engraftment syndromes may be associated with increased mortality, primarily from pulmonary failure but also (other) multiorgan dysfunction. Corticosteroid therapy may be effective particularly for the treatment of pulmonary manifestations.[35] The differential diagnosis of skin rashes, diarrhea and liver function abnormalities can be difficult to resolve. Skin rashes may reflect delayed reactions to the conditioning regimen, antibiotics, or infections and furthermore histopathologic skin changes consistent with acute GVHD can be mimicked by chemoradiotherapy and drug reactions.[21,36] Diarrhea can be a consequence of TBI, viral infections, especially with CMV and other herpes viruses, parasites, *Clostridium difficile*, nonspecific gastritis, narcotic withdrawal, and drug reactions: all of which mimic GVHD of the gut. Liver dysfunction can be due to parenteral nutrition, venoocclusive disease, viral or drug-induced hepatitis, or mechanical obstruction of the biliary tract.

PATHOPHYSIOLOGY OF ACUTE GRAFT-VERSUS-HOST DISEASE

It is helpful to remember two important principles when considering the pathophysiology of acute GVHD. First, acute GVHD represents exaggerated but normal inflammatory responses against foreign antigens (alloantigens) that are ubiquitously expressed in a setting where they are undesirable. The donor lymphocytes that have been infused into the recipient function appropriately, given the foreign environment they encounter. Second, donor lymphocytes encounter tissues in the recipient that have been often profoundly damaged. The effects of the underlying disease, prior infections, and the intensity of conditioning regimen all result in substantial changes not only in the immune cells but also in the endothelial and epithelial cells. The allogeneic donor cells rapidly encounter not only a foreign environment but one that has been altered to promote the activation and proliferation of inflammatory cells. Thus, the pathophysiology of acute GVHD may be considered a distortion of the normal inflammatory cellular responses that, in addition to the absolute requirement of donor T cells, involves multiple other innate and adaptive cells and mediators.[37] The development and evolution of acute GVHD can be conceptualized in three sequential phases (Fig. 107–2) to provide a unified perspective on the complex cellular interactions and inflammatory cascades that lead to acute GVHD: (a) activation of the antigen-presenting cells (APCs), (b) donor T cell activation, differentiation and migration and (c) effector phase.[37] It is important to note that the three-phase description as discussed below allows for a unified perspective in understanding the biology. It is, however, not meant to suggest that all three phases are of equal importance or that

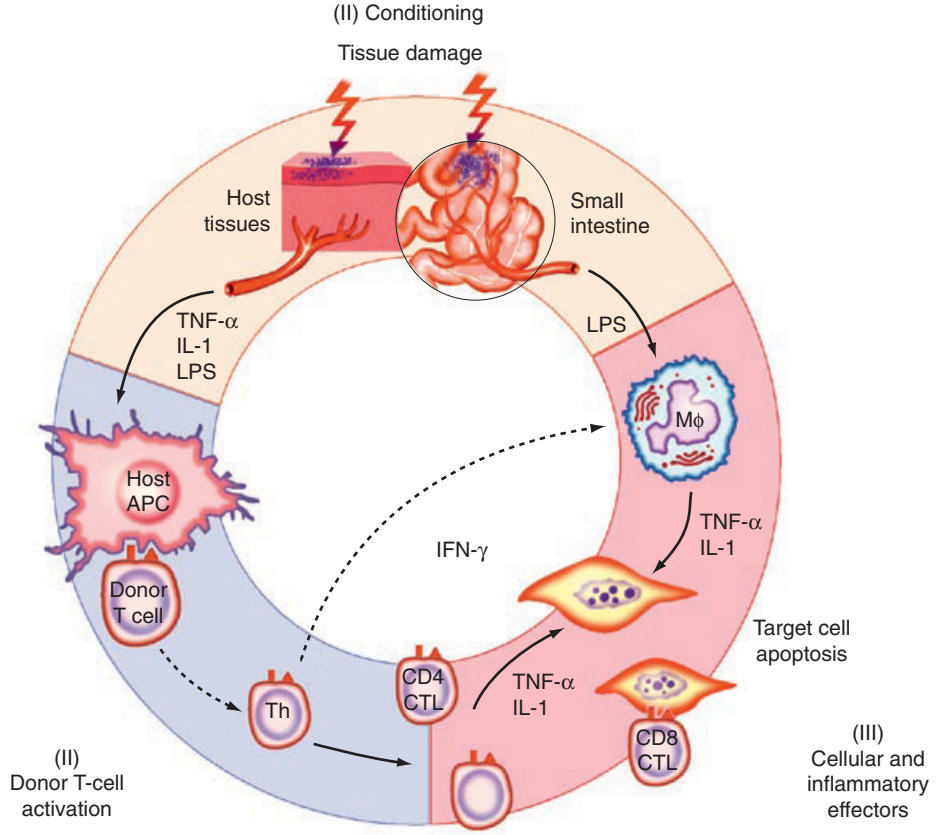

Figure 107–2 Pathophysiology of graft-versus-host disease (GVHD). During step 1, irradiation and chemotherapy both damage and activate host tissues, including intestinal mucosa, liver, and the skin. Activated cell hosts then secrete inflammatory cytokines (eg, TNF-α and IL-1), which can be measured in the systemic circulation. The cytokine release has important effects on antigen-presenting cells (APCs) of the host, including increased expression of adhesion molecules (eg, ICAM-1, VCAM-1) and of MHC class II antigens. These changes in the APCs enhance the recognition of host MHC and/or minor antigens by mature donor T cells. During step 2, donor T-cell activation is characterized by proliferation of GVHD T cells and secretion of the Th1 cytokines IL-2 and IFN-γ. Both of these cytokines play central roles in clonal T-cell expansion, induction of CTL and NK cell responses, and the priming of mononuclear phagocytes. In step 3, mononuclear phagocytes primed by IFN-γ are triggered by a second signal such as endotoxin (LPS) to secrete cytopathic amounts of IL-I and TNF-α. LPS can leak through the intestinal mucosa damaged by the conditioning regimen to stimulate gut-associated lymphoid tissue or Kupffer cells in the liver; LPS that penetrate the epidermis may stimulate keratinocytes, dermal fibroblasts, and macrophages to produce similar cytokines in the skin. This mechanism results in the amplification of local tissue injury and further production of inflammatory effectors such as nitric oxide, which, together with CTL and NK effectors, leads to the observed target tissue destruction in the transplant host. CTL effectors use Fas/FasL, perforin/granzyme B, and membrane-bound cytokines to lyse target cells.

GVHD occurs in a stepwise and sequential manner. The spatiotemporal relationships between the biological processes described below, depending on the context, are more likely to be chaotic and of varying intensity and relevance in the induction, severity and maintenance of GVHD.

Phase 1: Activation of Antigen-Presenting Cells

The earliest phase of acute GVHD is initiated by the profound damage caused by the underlying disease and infections and further exacerbated by the BMT conditioning regimens (which include total body irradiation [TBI] and/or chemotherapy) that are administered even before the infusion of donor cells.[38–42] This first step results in activation of the APCs.[7] Specifically, damaged host tissues respond with multiple changes, including the secretion of proinflammatory cytokines, such as TNF-α and IL-1, described as the cytokine storm.[40,41,43] Such changes increase expression of adhesion molecules, costimulatory molecules, MHC antigens and chemokines gradients that alert the residual host and the infused donor immune cells.[41] These danger signals activate host APCs.[44,45] Damage to the GI tract from the conditioning is particularly important in this process. Such damage results in systemic translocation of immunostimulatory microbial products such as lipopolysaccharide that further enhance the activation of host APCs. The secondary lymphoid tissue in the GI tract is probably the initial site of interaction between activated APCs and donor T cells.[41,46,47] Of interest, an increased risk of GVHD is associated with intensive conditioning regimens that cause extensive injury to epithelial and endothelial surfaces with a subsequent release of inflammatory cytokines and increases in expression of cell surface adhesion molecules.[41,42] The relationship among conditioning intensity, inflammatory cytokine, and GVHD severity has been supported by elegant murine studies.[43] Furthermore, the observations from these experimental studies have led to two recent clinical innovations to reduce acute GVHD: (a) reduced intensity conditioning (RIC) to decrease the damage to host tissues and thus limit activation of host APC and (b) natural killer (NK) cell killer immunoglobulin receptor (KIR) mismatches between donor and recipients to eliminate host APCs by the alloreactive NK cells.[48,49]

Host type APCs that are present and have been primed by conditioning, are critical for the induction of this phase; recent evidence suggests that donor type APCs exacerbate GVHD, but, in certain experimental models, donor type APC chimeras also induce GVHD.[45,50–52] In clinical situations, if donor-type APCs are present in sufficient quantity and have been appropriately primed, they too might play a role in the initiation and exacerbation of GVHD.[53–55] Among the cells with antigen-presenting capability, dendritic cells (DCs) are the most potent and play an important role in the induction of GVHD.[56] Experimental data suggest that GVHD can be regulated by qualitatively or quantitatively modulating distinct DC subsets.[57–62] Langerhans cells were also shown to be sufficient for the induction of GVHD when all other APCs were unable to prime donor T cells, although the role for Langerhans cells when all APCs are intact is unknown.[63] Studies have yet to define roles for other DC subsets. In one clinical study persistence of host DC after day 100 correlated with the severity of acute GVHD, whereas elimination of host DCs was associated with reduced severity of acute GVHD.[54] The allostimulatory capacity of mature monocyte-derived DCs (mDCs) after reduced-intensity transplants was lower for up to 6 months compared to the mDCs from myeloablative transplant recipients, thus suggesting a role for host DCs and the reduction in danger signals secondary to less intense conditioning in acute GVHD.[64] Nonetheless, this concept of enhanced host APC activation explains a number of clinical observations such as increased risks of acute GVHD associated with advanced-stage malignancy, conditioning intensity, and histories of viral infections.

Other professional APCs such as monocytes/macrophages or semiprofessional APCs might also play a role in this phase.[7] For example, recent data suggest that host-type B cells might play a regulatory role under certain conditions.[65] Also host- or donor-type nonhematopoietic cells, such as mesenchymal stem cells or stromal cells, when acting as APCs have been shown to reduce T cell allogeneic responses, although the mechanism for such inhibition remains unclear. The relative contributions of various APCs, professional or otherwise, remain to be elucidated.

Phase 2: Donor T-Cell Activation, Differentiation and Migration

The infused donor T cells interact with the primed APCs, leading to the initiation of the second phase of acute GVHD. This phase includes antigen presentation by primed APCs, and the subsequent activation, proliferation, differentiation, and migration of alloreactive donor T cells. After allogeneic HCT, both host- and donor-derived APCs are present in secondary lymphoid organs.[66,67] The T-cell receptor (TCR) of the donor T cells can recognize alloantigens either on host APCs (direct presentation) or donor APCs (indirect presentation).[68,69] In direct presentation, donor T cells recognize either the peptide bound to allogeneic MHC molecules or allogeneic MHC molecules without peptide.[69,70] During indirect presentation, T cells respond to the peptide generated by degradation of the allogeneic MHC molecules presented on self-MHC.[70] Experimental studies demonstrated that APCs derived from the host, rather than from the donor, are critical in inducing GVHD across MiHA mismatch.[7,68] Recent data suggest that presentation of distinct target antigens by the host- and donor-type APCs might play a differential role in mediating target organ damage.[7,71,72] In humans, most cases of acute GVHD developed when both host DCs and donor DCs are present in peripheral blood after HCT.[54]

Costimulation

The interaction of donor lymphocyte TCR with the host allopeptide presented on the MHC of APCs alone is insufficient to induce T-cell activation.[7,73] Both TCR ligation and costimulation via a second signal through interaction between the T-cell costimulatory molecules and their ligands on APCs are required to achieve T-cell proliferation, differentiation, and survival.[74] The danger signals generated in phase 1 augment these interactions and significant progress has been made on the nature and impact of these second signals.[75,76] Costimulatory pathways are now known to deliver both positive and negative signals, and molecules from two major families, the B7 family and the TNF receptor (TNFR) family, play pivotal roles in GVHD.[77] Interruption of the second signal by blockade of various positive costimulatory molecules (CD28, ICOS, CD40, CD30, 4–1BB, and OX40) reduces acute GVHD in several murine models, whereas antagonism of the inhibitory signals (PD-1 and CTLA-4) exacerbates the severity of acute GVHD.[78–84] The various T cell and APC costimulatory molecules and the impact on acute GVHD are summarized in Table 107–3. The specific context and the hierarchy in which each of these signals play a dominant role in the modulation of GVHD remain to be determined.

T-Cell Subsets

T cells consist of several subsets whose responses differ according to antigenic stimuli, activation thresholds, and effector functions. The alloantigen composition of the host determines which donor T-cell subsets proliferate and differentiate.

$CD4^+$ and $CD8^+$ Cells

CD4 and CD8 proteins are coreceptors for constant portions of MHC class II and class I molecules, respectively.[85] Therefore MHC class I (HLA-A, HLA-B, HLA-C) differences stimulate $CD8^+$ T cells and MHC class II (HLA-DR, HLA-DP, HLA-DQ) differences

Table 107–3 T Cell–APC Interactions

T cell	APC
Adhesion	
ICAMs	LFA-1
LFA-1	ICAMs
CD2 (LFA-2)	LFA-3
Recognition	
TCR/CD4	MHC II
TCR/CD8	MHC I
Costimulation	
CD28	CD80/86
CD152 (CTLA-4)	CD80/86

CD134 (OX 40)	CD134L (OX40L)
CD137 (4–1BB)	CD137L (4–1BBL)
HVEM	LIGHT

HVEM, HSV glycoprotein D for herpesvirus entry mediator; LIGHT, homologous to lymphotoxins, shows inducible expression, and competes with herpes simplex virus glycoprotein D for herpes virus entry mediator (HVEM), a receptor expressed by T lymphocytes.

stimulate $CD4^+$ T cells.[85–88] But clinical trials of $CD4^+$ or $CD8^+$ depletion have been inconclusive.[89] This perhaps is not surprising, because GVHD is induced by MiHAs in the majority of HLA-identical HCT, which are peptides derived from polymorphic cellular proteins that are presented by MHC molecules.[90] Because the manner of protein processing depends on genes of the MHC, two siblings will have many different peptides in the MHC groove.[90] Thus in the majority of HLA-identical transplants, acute GVHD may be induced by either or both $CD4^+$ and $CD8^+$ subsets in response to minor histocompatibility antigens.[89] The peptide repertoire for class I or class II MHC remains unknown and might even be different in different individuals.[91] But it is plausible that only a few of these peptides might behave as immunodominant "major minor" antigens that can potentially induce GVHD. In any event, such antigens remain to be identified and validated in a large patient population.

Naïve and Memory Subsets

Several independent groups have found that the naïve (CD62L(+)) T cells were alloreactive and caused acute GVHD but not the memory (CD62L(–)) T cells across different donor/recipient strain combinations.[92–95] Furthermore, expression of naïve T cell marker CD62L was also found to be critical for regulation of GVHD by donor natural regulatory T cells.[96] By contrast, another recent study demonstrated that alloreactive memory T cells and their precursor cells (memory stem cells) caused robust GVHD.[97,98] It remains as yet unknown whether the reduced GVHD potential of memory type T cells from a naïve murine donor, in contrast to their ability to cause greater solid organ allorejection,[99] is due to a consequence of the intense conditioning regimen and/or altered trafficking or from a restricted repertoire and/or from T-cell intrinsic defect.

Regulatory T Cells

Recent advances indicate that distinct subsets of regulatory $CD4^+D25,^+$ $CD4^+D25^-L10^+$ Tr cells, DN^- T cells, NK, T cells and regulatory DCs control immune responses by induction of anergy or active suppression of alloreactive T cells.[58,59,100–108] Several studies have demonstrated a critical role for the natural donor $CD4^+D25^+$ Foxp3+ regulatory T (Treg) cells, obtained from naïve animals or generated ex vivo, in the outcome of acute GVHD. Donor $CD4^+D25^+$ T cells suppressed the early expansion of alloreactive donor T cells and their capacity to induce acute GVHD without abrogating GVL effector function against these tumors.[109,110] $CD4^+D25^+$ T cells induced or generated by immature or regulatory host-type DCs and by regulatory donor-type myeloid APCs were also able to suppress acute GVHD.[58] One of the clinical studies that evaluated the relationship between donor $CD4^+D25^+$ cells and acute GVHD in humans after matched sibling donor grafts found that in contrast to the murine studies, donor grafts containing larger numbers of $CD4^+CD25^+$ cells developed more severe acute GVHD.[111] These data suggest that coexpression of $CD4^+$ and $CD25^+$ is insufficient because an increase in $CD25^+$ T cells in donor grafts is associated with greater risks of acute GVHD after clinical HCT. Another recent study found that Foxp3 mRNA expression (considered a specific marker for naturally occurring CD4(+)$CD25^+$regs) was significantly decreased in peripheral blood mononuclear cells from patients with acute GVHD.[112,113] But Foxp3 expression in humans, unlike mice, may not be specific for T cells with a regulatory phenotype.[114] It is likely that the precise role of regulatory T cells in clinical acute GVHD will therefore not only depend upon identification of specific molecular markers in addition to Foxp3 but also on the ability for ex vivo expansion of these cells in sufficient numbers. Several clinical trials are under way in the United States and Europe with attempts to substantially expand these cells ex vivo and use for prevention of GVHD.

Host $NK1.1^+$ T cells are another T-cell subset with suppressive function that has been shown to suppress acute GVHD in an IL-4-dependent manner.[107,108,115] By contrast, donor NKT cells were found to reduce GVHD and enhance perforin mediated GVL in an IFN-γ dependent manner.[116,117] Recent clinical data suggest that enhancing recipient NKT cells by repeated TLI conditioning promoted Th2 polarization and dramatically reduced GVHD.[108] Experimental data also show that activated donor NK cells can reduce GVHD through the elimination of host APCs or by secretion of transforming growth factor-β (TGF-β) secretion.[117] A murine HCT study using mice lacking SH2-containing inositol phosphatase (SHIP), in which the NK compartment is dominated by cells that express two inhibitory receptors capable of binding either self or allogeneic MHC ligands, suggests that host NK cells may play a role in the initiation of GVHD.[118]

T-Cell Apoptosis

Deletional mechanisms of tolerance fall into two categories: (a) central (thymic) deletion and (b) peripheral deletion.[119] Central deletion is an effective way to eliminate continued thymic production of alloreactive T cells. To this end, lymphoablative treatments have been used as a condition to create a mixed hematopoietic chimeric state in murine transplant models.[120] In this strategy, donor cells seed the thymus and maturing donor-reactive T-cell clones are deleted through intrathymic apoptosis.[121,122] The proportion of the peripheral T-cell repertoire that can respond to allogeneic MHC antigens can play a critical role in the development of tolerance.[123] In the case of MHC-mismatched transplantation, the frequency of alloreactive T cells is at least five orders of magnitude greater than the frequency of peptide-specific T cells responding to a nominal antigen.[123,124] The pathways of T cell apoptosis by which peripheral deletion occurs can be broadly categorized into activation-induced cell death (AICD) and passive cell death (PCD).[123] An important mediator of AICD in T cells is the Fas receptor.[125] Activated T cells expressing the Fas molecule undergo apoptotic cell death when brought into contact with cells expressing Fas ligand. A critical role for Fas mediated AICD has been clearly demonstrated in attenuation of acute GVHD by several Th1 cytokines.[126–130]

PCD or "death by neglect" illustrates the exquisite dependence of activated T cells upon growth factors (eg, IL-2, IL-4, IL-7, and/or IL-15) for survival; apoptotic cell death in this instance is largely due to rapid downregulation of Bcl-2.[131–133] Transplantation of Bcl-xL T cells into nonirradiated recipients significantly exacerbates GVHD; however, no difference in GVHD mortality is observed in animals that have been lethally irradiated.[134] Selective elimination of donor T cells in vivo after HCT using transgenic T cells in which a thymidine kinase (TK) suicide gene is targeted to T cells has also been shown to attenuate the severity of acute GVHD.[134–137] Another recent approach to prevent GVHD is the selective depletion of alloantigen-specific donor T cells by a photodynamic cell-purging process wherein donor T cells are treated with photoactive 4,5-dibromorhodamine[123] and subsequently exposed to visible light.[138] Thus several deletional mechanisms have been shown to reduce acute GVHD but the conditions under which one or another of these deletional mechanisms plays a predominate role remain to be determined.

Cytokines and T-Cell differentiation

APC and T cell activation result in rapid intracellular biochemical cascades that induce transcription of many genes including cytokines and their receptors. The Th1 cytokines (IFN-γ, IL-2 and TNF-α) have been implicated in the pathophysiology of acute GVHD.[139–141] IL-2 production by donor T cells remains the main target of many current clinical therapeutic and prophylactic approaches. Such approaches include administration of cyclosporine, tacrolimus, and monoclonal antibodies (mAbs) against IL-2 and its receptor.[142,143] Of note, emerging data indicate an important role for IL-2 in the generation and maintenance of $CD4^+D25^+$ Foxp3+ Tregs, suggesting that prolonged interference with IL-2 may inadvertently hinder the development of long-term tolerance after allogeneic HCT.[144–147] Similarly the role of other Th1 cytokines as regulators or inducers of GVHD severity depends on the degree of allomismatch, the intensity of conditioning, and the T-cell subsets that are involved after HCT.[148–150] Thus, although the cytokine storm initiated in phase 1 and amplified by the Th1 cytokines correlates with the development of acute GVHD, early Th1 polarization of donor T cells to HCT recipients can attenuate acute GVHD, suggesting that physiological amounts of Th1 cytokines are critical for GVHD induction whereas inadequate production (extremely low or high) could modulate acute GVHD through a breakdown of negative feedback mechanisms for activated donor T cells.[130,141,150–152] Th2 polarization by cytokines as well as by rapamycin and the secretion of IL-4 by $NK1.1^+$ T cells can reduce acute GVHD.[153–160] But Th1 and Th2 subsets cause injury to distinct acute GVHD target tissues and some studies failed to show a beneficial effect of Th2 polarization on acute GVHD.[161] Thus the Th1/Th2 paradigm of donor T cells in the immunopathogenesis of acute GVHD has evolved over the last few years and its causal role in acute GVHD is complex and incompletely understood. IL-10 plays a key role in suppression of immune responses, and its role in regulating experimental acute GVHD is unclear.[162] Recent clinical data demonstrate an unequivocal association of IL-10 polymorphisms with the severity of acute GVHD.[163] TGF-β, another suppressive cytokine, was shown to suppress acute GVHD but to exacerbate chronic GVHD.[164] The roles of some other cytokines, such as IL-7 (that promotes immune reconstitution) and IL-13, remain unclear.[165–168] The role for Th17 cells, a recently described novel T-cell differentiation in many immunologic processes, is not yet known.[169] In any case, experimental data collectively suggest that the timing of administration, the production of any given cytokine, the intensity of the conditioning regimen, and the donor–recipient combination may all be critical to the eventual outcome of acute GVHD.

Leukocyte Migration

Donor T cells migrate to lymphoid tissues, recognize alloantigens on either host or donor APCs, and become activated. They then exit the lymphoid tissues and traffic to the target organs and cause tissue damage.[170] The molecular interactions necessary for T-cell migration and the role of lymphoid organs during acute GVHD have recently become the focus of a growing body of research. Chemokines play a critical role in the migration of immune cells to secondary lymphoid organs and target tissues.[171] T-lymphocyte production of macrophage inflammatory protein-1 alpha is critical to the recruitment of $CD8^+$ but not $CD4^+$ T cells to the liver, lung, and spleen during acute GVHD.[172] Several chemokines such as CCL2–5, CXCL2, CXCL9–11, CCL17, and CCL27 are overexpressed and might play a critical role in the migration of leukocyte subsets to the target organs liver, spleen, skin, and lungs during acute GVHD.[170,173] $CXCR3^+$ T and $CCR5^+$ T cells cause acute GVHD in the liver and intestine.[170,174–176] CCR5 expression has also been found to be critical for Treg migration in GVHD.[177] In addition to chemokines and their receptors, expression of selectins and integrins and their ligands also regulates the migration of inflammatory cells to target organs.[171] For example, interaction between α4β7 integrin and its ligand MadCAM-1 are important for homing of donor T cells to Peyer patches and in the initiation of intestinal GVHD.[46,178] αLβ2/ICAM-1, -2, -3 and α4β1/VCAM-2 interactions are important for homing to the lung and liver after experimental HCT.[170] The expression of CD62L on donor Tregs is critical for their regulation of acute GVHD, suggesting that their migration in secondary tissues is critical for their regulatory effects.[67] The migratory requirement of donor T cells to specific lymph nodes (eg, Peyer patches) for the induction of GVHD might depend on other factors such as the conditioning regimen and the inflammatory milieu.[46,179] Furthermore, FTY720, a pharmacologic sphingosine-1-phosphate receptor agonist, inhibited GVHD in murine but not in canine models of HCT.[180,181] Thus, there might also be significant species differences in the ability of these molecules to regulate GVHD.

Phase 3: Effector Phase

The effector phase that leads to GVHD target organ damage consists of a complex cascade of multiple cellular and inflammatory effectors that simultaneously or sequentially modulate each other's responses. Effector mechanisms of acute GVHD can be grouped into cellular effectors (eg, cytotoxic T lymphocytes or CTLs) and inflammatory effectors such as cytokines. Inflammatory chemokines expressed in inflamed tissues upon stimulation by proinflammatory effectors such as cytokines are specialized for the recruitment of effector cells, such as CTLs.[182] Furthermore, the spatiotemporal expression of the cytochemokine gradients might determine not only the severity but also the unusual cluster of GVHD target organs (skin, gut, and liver).[170,183]

Cellular Effectors

Cytotoxic T cells are the major cellular effectors of GVHD.[184,185] The Fas–Fas ligand (FasL), the perforin–granzyme (or granule exocytosis) and TNFR-like death receptors (DR), such as TNF-related apoptosis-inducing ligand (TRAIL: DR4, 5 ligand) and TNF-like weak inducers of apoptosis (TWEAK: DR3 ligand) are the principal CTL effector pathways that have been evaluated after allogeneic BMT.[185–190] The involvement of each of these molecules in GVHD has been tested by using donor cells that are unable to mediate each pathway. Perforin is stored in cytotoxic granules of CTLs and NK cells, together with granzymes and other proteins. Although the exact mechanisms remain unclear, following the recognition of a target cell through the TCR–MHC interaction, perforin is secreted and inserted into the cell membrane, forming "perforin pores" that allow granzymes to enter the target cells and induce apoptosis through various downstream effector pathways such as caspases.[191] Ligation of Fas results in the formation of the death-inducing signaling complex and also activation of caspases.[192,193]

Transplantation of perforin deficient T cells results in a marked delay in the onset of GVHD in transplants across MiHA disparities only, both MHC and MiHA disparities,[126] and across isolated MHC I or II disparities.[185,194–198] However, mortality and clinical and histologic signs of GVHD were still induced even in the absence of perforin-dependent killing in these studies, demonstrating that the perforin–granzyme pathway plays a minor role in target organ damage. A role for the perforin–granzyme pathway for GVHD induction is also evident in studies employing donor-T cell subsets. Perforin- or granzyme B-deficient $CD8^+$ T cells caused less mortality than wild-type T cells in experimental transplants across a single MHC class I mismatch. This pathway, however, seems to be less important compared to the Fas–FasL pathway in CD4-mediated GVHD.[197–199] Thus, it seems that $CD4^+$ CTLs preferentially use the Fas–FasL pathway, whereas $CD8^+$ CTLs primarily use the perforin–granzyme pathway.

Fas, a TNF-receptor family member, is expressed by many tissues, including GVHD target organs.[200] Its expression can be upregulated by inflammatory cytokines such as IFN-γ and TNF-α during GVHD, and the expression of FasL is also increased on donor T cells, indicating that FasL-mediated cytotoxicity may be a particularly important effector pathway in GVHD.[185,201] FasL-defective T cells cause less GVHD in the liver, skin and lymphoid organs.[196,199,201] The Fas–FasL pathway is particularly important in hepatic GVHD, consistent with the keen sensitivity of hepatocytes to Fas-mediated cytotoxicity in experimental models of murine hepatitis.[185] Fas-deficient recipients are protected from hepatic GVHD but not from other organ GVHD, and administration of anti-FasL (but not anti-TNF) MAbs significantly blocks hepatic GVHD damage occurring in murine models.[185,202,203] Although the use of FasL-deficient donor T cells or the administration of neutralizing FasL MAbs had no effect on the development of intestinal GVHD in several studies, the Fas–FasL pathway may play a role in this target organ, because intestinal epithelial lymphocytes exhibit increased FasL-mediated killing potential.[204] Elevated serum levels of soluble FasL and Fas have also been observed in at least some patients with acute GVHD.[205,206]

The utilization of a perforin–granzyme and FasL cytotoxic double-deficient (*cdd*) mouse provides an opportunity to address whether other effector pathways are capable of inducing GVHD target organ pathology. An initial study demonstrated that *cdd* T cells were unable to induce lethal GVHD across MHC class I and class II disparities after sublethal irradiation.[195] However, subsequent studies demonstrated that cytotoxic effector mechanisms of donor T cells are critical in preventing host resistance to GVHD.[189,207] Thus when recipients were conditioned with a lethal dose of irradiation, *cdd* $CD4^+$ T cells produced similar mortality to wild-type $CD4^+$ T cells.[189] These results were confirmed by a recent study demonstrating that GVHD target damage can occur in mice that lack alloantigen expression on the epithelium, preventing direct interaction between CTLs and target cells.[190]

The participation of another death ligand receptor signaling pathway, TNF/TNFRs, has also been evaluated. Experimental data suggest that this pathway is crucial for GI GVHD (discussed more below). Recently, several additional TNF family apoptosis-inducing receptors/ligands have been identified, including TWEAK, TRAIL, and LTβ/LIGHT, that have been proposed to play a role in GVHD and GVL responses.[78,208–214] However whether these distinct pathways play a more specific role for GVHD mediated by distinct T-cell subsets in certain situations remains unknown. Intriguingly, recent data suggest that none of these pathways might be critical for mediating the rejection of donor grafts.[208,215] Thus it is likely that their role in GVHD might be modulated by the intensity of conditioning and by the recipient T-cell subsets. Existing experimental data suggest that perforin and TRAIL cytotoxic pathways are associated with $CD8^+$ T cell-mediated GVL.[185] The available experimental data are strongly skewed toward $CD8^+$ T cell-mediated GVL based on the dominant role of this effector population in most murine GVT models; however, $CD4^+$ T cells can mediate GVL and might be crucial in clinical BMT depending on the type of malignancy and the expression of immunodominant antigens.

Taken together, experimental data suggest that different lytic pathways may be implicated in the development of GVHD in specific target organs and for the generation of a GVL effect. However, the clinical importance of these observations is not known.

Inflammatory Effectors

Inflammatory cytokines synergize with CTLs, resulting in the amplification of local tissue injury and further promotion of inflammation, which ultimately leads to the observed target tissue destruction in the transplant recipient.[22] Macrophages, which had been primed with IFN-γ during step 2, produce inflammatory cytokines TNF-α and IL-1 when stimulated by a secondary triggering signal.[216] This stimulus may be provided through Toll-like receptors (TLRs) by microbial products such as lipopolysaccharide and other microbial particles, which can leak through the intestinal mucosa damaged by the conditioning regimen and gut GVHD.[217,218] It is now apparent that immune recognition through both TLR and non-TLRs (such as NOD) by the innate immune system also controls activation of adaptive immune responses.[217,219] Recent clinical studies of GVHD suggested the possible association with TLR/NOD polymorphisms and severity of GVHD.[220–222] Lipopolysaccharide and other innate stimuli may stimulate gut-associated lymphocytes, keratinocytes, dermal fibroblasts, and macrophages to produce proinflammatory effectors that play a direct role in causing target organ damage. Indeed experimental data with MHC mismatched HCT suggest that under certain circumstances these inflammatory mediators are sufficient in causing GVHD damage even in the absence of direct CTL induced damage.[50] The severity of GVHD appears to be directly related to the level of innate and adaptive immune cell priming and release of proinflammatory cytokines such as TNF-α, IL-1, and nitric oxide (NO).[50,218,223–225]

The cytokines TNF-α and IL-1 are produced by an abundance of cell types during processes of both innate and adaptive immunity; they often have synergistic, pleiotrophic, and redundant effects on both activation and effector phases of GVHD.[141] A critical role for TNF-α in the pathophysiology of acute GVHD was first suggested over 20 years ago when mice transplanted with mixtures of allogeneic BM and T cells developed severe skin, gut, and lung lesions that were associated with high levels of TNF-α mRNA in these tissues.[226] Target organ damage could be inhibited by infusion of anti-TNF-α MAbs, and mortality could be reduced from 100% to 50% by the administration of the soluble form of the TNF-α receptor (sTNFR), an antagonist of TNF-α.[40,43,224] Accumulating experimental data further suggest that TNF -a is involved in a multistep process of GVHD pathophysiology. TNF-α can (a) cause cachexia, a characteristic feature of GVHD; (b) induce maturation of DCs, thus enhancing alloantigen presentation; (c) recruit effector T cells, neutrophils, and monocytes into target organs through the induction of inflammatory chemokines; and (d) cause direct tissue damage by inducing apoptosis and necrosis. TNF-α is also involved in donor T-cell activation directly through its signaling via TNFR1 and TNFR2 on T cells. TNF–TNF1 interactions on donor T cells promote alloreactive T-cell responses and TNF–TNFR2 interactions are critical for intestinal GVHD.[211,227] TNF-α also seems to be an important effector molecule in GVHD involving skin and lymphoid tissue.[226,228] Additionally, TNF-α might also be involved in hepatic GVHD, probably by enhancing effector cell migration to the liver via the induction of inflammatory chemokines.[229] An important role for TNF-α in clinical acute GVHD has been suggested by studies demonstrating elevated serum levels of TNF-α or elevated TNF-α mRNA expression in peripheral blood mononuclear cells in patients with acute GVHD and other endothelial complications, such as hepatic venoocclusive disease (VOD).[229–232] Phase 1–2 trials using TNF-α antagonists reduced the severity of GVHD, suggesting that it is a relevant effector in causing target organ damage.[233,234]

The second major pro-inflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1.[235] Secretion of IL-1 appears to occur predominantly during the effector

phase of GVHD of the spleen and skin, two major GVHD target organs.[236] A similar increase in mononuclear cell IL-1 mRNA has been shown during clinical acute GVHD. Indirect evidence of a role for IL-1 in GVHD was obtained with administration of this cytokine to recipients in an allogeneic murine HCT model. Mice receiving IL-1 displayed a wasting syndrome and increased mortality that appeared to be an accelerated form of disease. By contrast, intraperitoneal administration of IL-1ra starting on d 10 posttransplant was able to reverse the development of GVHD in the majority of animals, providing a significant survival advantage to treated animals.[237] However, the attempt to use IL-1ra to prevent acute GVHD in a randomized trial was not successful.[238]

As a result of activation during GVHD, macrophages also produce NO, which contributes to the deleterious effects on GVHD target tissues, particularly immunosuppression.[225,239] NO also inhibits the repair mechanisms of target tissue destruction by inhibiting proliferation of epithelial stem cells in the gut and skin.[240] In humans and rats, the development of GVHD is preceded by an increase in serum levels of NO oxidation products.[241–244]

Existing data demonstrate important role for various inflammatory effectors in GVHD. The relevance of currently studied or as yet unknown specific effectors might however be determined by other factors, including the intensity of preparatory regimens, the type of allograft, the T cell subsets and the duration of HCT. In any event, both experimental and clinical data suggest an important role for both the cellular and inflammatory mediators in GVHD induced target organ damage.

Prevention of Acute Graft-Versus-Host Disease

Elimination of T cells with monoclonal antibodies, immunotoxins, lectins, CD34 columns, or physical techniques are effective at reducing GVHD. A typical unmanipulated marrow transplant entails the infusion of ~10^7 T cells per kg of recipient weight. A reduced T cell dose of <10^5 per kg has been associated with complete control of GVHD.[245] More recently the combination of very high stem cell numbers and <3×10^4 CD3 cells/kg allowed haploidentical transplantation without GVHD.[246] Presumably host immune cells that survive the initial conditioning are responsible for graft rejection. When the stem cell source contains a large numbers of T cells, the GVH reaction further reduces the residual population capable of alloreactivity, thus decreasing graft rejection. To some degree the higher graft failure rates may be controlled by increasing the intensity of the immunosuppression of the conditioning regimen,[247,248] or adding back T cells.[249] Overall there been no improvement in survival that can be definitively attributed to T cell depletion.

Treatment of established GVHD with specific T cell antibodies has produced mixed results. Although antithymocyte globulin has definite activity in established GVHD, the nonspecific clearance of T cells may result in increased opportunistic infections and no improvement in survival.[20,250,251] More specific therapy with humanized anti-IL-2 receptor antibody, daclizumab[252,253] or the humanized anti-CD3 antibody, visilizumab[254,255] are promising, because they offer selective removal of T cell subsets. However, an increased risk of infection may still be observed.[256]

The first generally prescribed GVHD preventive regimen was the administration of intermittent low dose methotrexate as developed in a dog model by Thomas and Storb.[257] The principle of this approach was to administer a cell-cycle specific chemotherapeutic agent immediately after the transplant, when the T cells have started to divide in response to allogeneic antigens. Subsequently, the addition of antithymocyte globulin, prednisone or both resulted in incremental improvement in the GVHD rate but no improvement in survival.[258,259] Ultimately the course of methotrexate was abbreviated and combined with a T cell activation inhibitor, such as cyclosporine or tacrolimus. The introduction of cyclosporine in the late 1970's was a significant advance in GVHD prevention. A similar agent, tacrolimus, has been shown to control GVHD.[260] As a single agent cyclosporine was about as effective as methotrexate.[261] However, in combination with methotrexate, there was a significant reduction in the incidence of GVHD and an improvement in survival.[262] Subsequent trials of tacrolimus and methotrexate compared with cyclosporine and methotrexate showed no advantage for either combination.[260] The addition of prednisone to the conventional two-drug regimen resulted in similar rates of GVHD and no improvement in survival.[263]

Sirolimus (rapamycin) is a macrocyclic lactone immunosuppressant that is similar in structure to tacrolimus and cyclosporine. All three drugs bind to immunophilins; however, sirolimus complexed with FKBP12 inhibits T cell proliferation by interfering with signal transduction and cell cycle progression and can prevent GVHD.[264] Because Sirolimus acts through a separate mechanism from the tacrolimus-FKBP complex (and cyclosporine-cyclophilin complex), it is synergistic with both tacrolimus and cyclosporine. More recently, mycophenolate mofetil (MMF) has been studied. It is the prodrug of mycophenolic acid (MPA) a selective inhibitor of inosine monophosphate dehydrogenase, an enzyme critical to the de novo synthesis of guanosine nucleotide. Because T lymphocytes are more dependent on such synthesis than myeloid or mucosal cells, MPA preferentially inhibits proliferative responses of T cells.[265]

One hypothesis that flows from the three step model of GVHD is that reduction of intestinal colonization with bacteria could prevent GVHD. Animal studies in germ free environments support this notion, where GVHD was not observed until mice were colonized with gram negative organisms.[266] Later, gut decontamination and use of a laminar air flow environment was associated with less GVHD and better survival in patients with severe aplastic anemia.[267] Similarly, studies of intestinal decontamination in patients with malignancies have shown less GVHD in some[268,269] but not all studies.[270] Finally, another recent approach to GVHD prevention has been the use of nonmyeloablative conditioning transplants. A less intensive preparative regimen decreases the tissue toxicity and subsequent release of cytokines in animal models.[43,271] Patients generally experience mild toxicity in the initial peritransplant period and develop little or no GVHD, although many develop GVHD later, especially after donor lymphocyte infusions. In fact, the rates of GVHD are often higher than with conventional transplants, and GVHD is associated with a significant portion of the GVL effect.[272,273]

An important role for TNFα in clinical acute GVHD has been suggested by studies demonstrating elevated levels of TNFα in the serum of patients with acute GVHD and other endothelial complications such as venoocclusive disease.[274–277] Therapy of GVHD with humanized anti-TNFα (infliximab)[278,279] or a dimeric fusion protein consisting of the extracellular ligand-binding portion of the human TNFα receptor (TNFR) linked to the Fc portion of human IgG1 (etanercept)[280] have shown some promise. The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1. Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD in the spleen and skin, two major GVHD target organs.[281] IL-1 receptor antagonist (IL-1RA) is a naturally occurring pure competitive inhibitor of IL-1 that is produced by monocytes/ macrophages and keratinocytes. Interestingly, the IL-1RA gene is polymorphic and the presence in the donor of the allele that is linked to higher secretion of IL-1RA was associated with less acute GVHD.[282] Two phase 1–2 trials showed promising data that specific inhibition of IL-1 with either the soluble receptor or IL-1RA could result in remissions in 50% to 60% of patients with steroid-resistant GVHD.[283,284] But a subsequent randomized trial of the addition of IL-1RA or placebo to cyclosporine and methotrexate beginning at the time of conditioning and continuing through day 14 after stem cell infusion did not show any protective effect of the drug, despite the attainment of very high plasma levels.[238,285] Thus, at least as administered in this study, IL-1 inhibition was insufficient to prevent GVHD in humans. IL-11 was also able to protect the GI tract in animal models and prevent GVHD, but it did not prevent clinical GVHD.[285] Thus, not all preclinical strategies successfully translate to new therapies.

Therapy for Acute GVHD

Glucocorticoid steroids are the initial therapy for acute GVHD. The mechanisms by which steroids work are multifactorial; they act as lympholytic agents and inhibit the release of inflammatory cytokines such as IL-1, IL-2, IL-6, gamma interferon, and TNF-α. Because of its intravenous availability, methylprednisolone is the steroid most commonly given for acute GVHD. Various dosing regimens have been used, none of which is clearly superior. High-bolus doses (10–20 mg/kg or 500 mg/m^2) have higher initial response rates, but flares on tapering and opportunistic infections are common. Both the Seattle and Minnesota transplant groups have found that treatment with steroids was as effective as, or more effective than, other therapies or combination of therapies, with 20% to 40% of patients having durable long-term responses.[286,287] Long-term salvage rates for patients who did not respond to steroids were 20% or less; most patients eventually died from infection, acute GVHD, and/or chronic GVHD. More recently, a randomized trial demonstrated that topical therapy with oral budosenide can have prednisone sparing effects and is efficacious in treatment of GI GVHD.[288] Clinically, two types of failure of corticosteroid treatment of acute GVHD can be distinguished: true steroid resistance, that is, progression of GVHD symptoms and manifestations while patients are receiving full-dose corticosteroid treatment, and steroid dependence, that is, reoccurrence (or flare) of GVHD during or after tapering of steroid treatment.[289] In general, the prognosis with true steroid-resistant GVHD is worse than the prognosis of steroid-dependent patients.[289] A comparison of trials dealing with steroid-resistant GVHD is hampered by variable inclusion of both patient groups in many of these trials. A variety of agents has been tested, including chemical immunosuppressants such as MMF, ATG, anti-CD3 anti-T cell antibodies as well as more specific agents directed against activation or adhesion molecules anti-CD25, anti-CD147, cytokines or extracorporeal photopheresis.[289,290] To date, there are no randomized trails testing one versus the other in this clinical situation.

Other Supportive Approaches

Infections are the main cause of death in patients with steroid-refractory acute GVHD, and careful surveillance and control of infections is mandatory in patients with acute GVHD. Fungal infections, especially aspergillosis, are the leading complication. Prophylaxis and early aggressive treatment should be facilitated by the introduction of new azoles (voriconazole and posaconazole) or echinocandins (caspofungin, micafungin), which broaden therapeutic efficacy with acceptable toxicity. A variety of further supplementary approaches have been suggested; for example, large volumes of diarrhea might be controlled by the use of octreotide[291] and oral beclomethasone (or budesonide).[288]

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD was initially defined as a GVHD syndrome presenting more than 100 days after transplant; its onset occurred either as an extension of acute GVHD (progressive), after a disease-free interval (quiescent), or with no precedent (de novo).[292,293] Chronic GVHD may be limited or extensive (Table 107–3). Any grade of acute GVHD increases the probability of chronic GVHD, although no singular pathologic feature of the former predicts the development of the latter. Its incidence ranges from 30% to 60% after transplantation with the bone marrow, although it may be higher after peripheral blood progenitor transplants.[294]

As with acute GVHD, the immune system appears to be affected in all patients, who are highly susceptible to bacterial, viral, fungal, and opportunistic infections. Specific abnormalities of cellular immunity include decreases in the production of antibodies against specific antigens, defects in the number and function of CD4$^+$ T cells, and increases in the number of nonspecific suppressor cells, which further diminish lymphocyte responses. Eighty percent of patients have skin changes resembling widespread lichen planus with papulosquamous dermatitis, plaques, desquamation, dyspigmentation, and vitiligo.[273,295] Destruction of dermal appendages leads to alopecia and onychodysplasia. Severe chronic GVHD of the skin can resemble scleroderma, with induration, joint contractures, atrophy, and chronic skin ulcers. Chronic cholestatic liver disease occurs in 80% of patients and often resembles acute GVHD; it rarely progresses to cirrhosis. Severe mucositis of the mouth and esophagus can result in weight loss and malnutrition. Intestinal involvement, however, is infrequent.[273,295] Chronic GVHD also produces a sicca syndrome, with atrophy and dryness of mucosal surfaces caused by lymphocytic destruction of exocrine glands, usually affecting the eyes, mouth, airways, skin, and esophagus.[24,295,296] The hematopoietic system may also be affected, and thrombocytopenia is an unfavorable prognostic factor in patients with chronic GVHD.[273] Important predictors of unfavorable outcome are progressive onset, lichenoid skin changes, elevated serum bilirubin level, continued thrombocytopenia, and failure to respond to 9 months of therapy.[273,297–299] Among patients with none of these risk factors, 70% are expected to survive, compared with less than 20% with two or more of these risk factors.[299]

Histologic examination of the immune system reveals involution of thymic epithelium, disappearance of Hassall corpuscles, depletion of lymphocytes, and absence of secondary germinal centers in lymph nodes.[300] Pathologic skin findings include epidermal atrophy with changes characteristic of lichen planus and striking inflammation around eccrine units. Sclerosis of the dermis and fibrosis of the hypodermis subsequently develop. GI lesions include localized inflammation of the mucosa and stricture formation in the esophagus and small intestine.[295] Histologic findings in the liver are often similar to those that occur in acute GVHD but are more intense, with chronic changes such as fibrosis with hyalinization of portal triads, obliteration of bile ducts, and hepatocellular cholestasis.[273] The endocrine glands of the eyes, mouth, esophagus, and bronchi show destruction focused on centrally draining ducts, with secondary involvement of alveolar components.[300] Findings of bronchiolitis obliterans, similar to those that occur in rejection of lung transplants, are now generally considered a pulmonary manifestation of chronic GVHD, although the pathogenesis of this process remains unclear.[300]

Clinical Manifestations of Chronic GVHD

Chronic GVHD can present with a plethora of clinical manifestations. Because of its unpredictable pattern and the late onset when patients are no longer receiving care at their transplant center, the diagnosis is often delayed or not recognized. The staging of chronic GVHD is summarized in Table 107–4. However, the recently developed NIH Consensus Criteria, upon validation, might soon become the standard for diagnosing and evaluating responses for chronic GVHD.[301,302]

Dermatologic

Skin involvement in chronic GVHD presents with varied features. Lichenoid chronic GVHD presents as an erythematous, papular rash that resembles lichen planus with no typical distribution pattern.[24] Sclerodermatous GVHD may involve the dermis and/or the muscular fascia and clinically resembles systemic sclerosis. The skin is thickened, tight, and fragile, with very poor wound healing. Either hypopigmentation or hyperpigmentation may occur. In severe cases, the skin may become blistered and ulcerate. Hair changes can include increased brittleness, premature graying, and alopecia. Fingernails and toenails may also be affected by chronic GVHD. Destruction of sweat glands can cause hyperthermia.[303]

Table 107–4 Commonly Administered Drugs for GVHD Prophylaxis and Treatment

Drug	Mechanism	Adverse Effects
Corticosteroids	Direct lymphocyte toxicity, suppress pro-inflammatory cytokines such as TNF-α	Hyperglycemia, acute psychosis, severe myopathy, neuropathy, osteoporosis, cataract development
Methotrexate (MTX)	Antimetabolite, inhibits T cell proliferation	Significant renal, hepatic, and gastrointestinal toxicities
Cyclosporine (CSP)	IL-2 suppressor, blocks Ca^{2+}-dependent signal transduction distal to TCR engagement	Renal and hepatic insufficiency, hypertension, hyperglycemia, headache, nausea and vomiting, hirsutism, gum hypertrophy, seizure with severe toxicity
Tacrolimus (FK506)	IL-2 receptor, blocks Ca^{2+}-dependent signal transduction distal to TCR engagement	Similar to CSA
Mycophenolate mofetil (MMF)	Inhibits de novo purine synthesis	Body aches, abdominal pain, nausea and vomiting, diarrhea, neutropenia
Sirolimus	mTOR inhibitor	Thrombocytopenia, hyperlipidemia, TTP
Antithymocyte globulin (ATG)	Polyclonal immunoglobulin	Anaphylaxis, serum sickness

Ocular

Ocular GVHD usually presents with xerophthalmia or dry eyes. Irreversible destruction of the lacrimal glands results in dryness, photophobia, and burning. Local therapy with preservative-free tears and ointment or the placement of punctal plugs by an ophthalmologist might be required. Conjunctival GVHD, a rare manifestation of severe chronic GVHD, has a poor prognosis.[24,303]

Oral

Oral GVHD causes xerostomia and/or food sensitivity.[303] More advanced disease may cause odynophagia as a result of esophageal damage and strictures, although esophageal involvement occurs rarely without oral disease. Physical examination may reveal only erythema with a few white plaques, prompting a misdiagnosis of thrush or herpetic infections. Lichenoid changes in advanced disease can cause extensive plaque formation.[24]

Gastrointestinal

Patients with chronic GVHD have GI complaints that mimic other disease states, including acute GVHD, infection, dysmotility, lactose intolerance, pancreatic insufficiency, and drug-related side effects. In one retrospective review of the intestinal biopsies of patients with chronic GVHD and persistent GI symptoms, a majority of patients had evidence of both acute and chronic GVHD, and only 7% of the patients had isolated chronic GVHD.[24,295] Thus although chronic GVHD may involve the GI tract alone, it may be difficult to diagnose in those circumstances without concurrent acute GVHD.

Hepatic

Hepatic disease typically presents as cholestasis with elevated serum levels of alkaline phosphatase and bilirubin. Isolated hepatic chronic GVHD has become more common with the increasing use of donor lymphocyte infusions.[11] Liver biopsy is required to confirm the diagnosis of chronic hepatic GVHD in patients with no other target organ involvement.

Pulmonary

Bronchiolitis obliterans is a late and serious manifestation of chronic GVHD. Patients typically present with a cough or dyspnea.[303] Severe sclerotic disease of the chest wall may also give rise to similar symptoms, with no intrinsic pulmonary disease. Pulmonary function tests demonstrate obstructive physiology and a reduction in DLCO. Chest computed tomography results may be normal or may show hyperinflation with a ground glass appearance. Overall, patients with bronchiolitis obliterans have minimal response to therapy and a very poor prognosis. Patients with chronic GVHD are also at risk for chronic sinopulmonary infections but symptoms may be minimal.[24]

Hematopoietic

Cytopenias in chronic GVHD are common. This may be a result of stromal damage, but autoimmune neutropenia, anemia, and/or thrombocytopenia are also seen. Thrombocytopenia at the time of chronic GVHD diagnosis is associated with poor prognosis. However, thrombocytopenia posttransplant is a poor prognostic factor regardless of GVHD and eosinophilia is occasionally seen with chronic GVHD.[303]

Immunologic

Chronic GVHD is inherently immunosuppressive. Functional asplenia with an increased susceptibility to encapsulated bacteria is common, and circulating Howell–Jolly bodies can be seen on peripheral blood smear. Patients are also at risk for invasive fungal infections and *Pneumocystis carinii* pneumonia.[303] Hypoglobulinemia is common and patients with levels below 500 mg/dL should be supplemented with intravenous immunoglobulin.[303]

Musculoskeletal

Fascial involvement in sclerodermatous GVHD is usually associated with skin changes. Fasciitis in joint areas can cause severe restriction of range of motion. Muscle cramps are a common complaint in patients with chronic GVHD, but myositis with elevated muscle enzymes is rare. Many patients with chronic GVHD are on steroid therapy and have low levels of sex hormone posttransplant. Avascular necrosis, osteopenia, and osteoporosis are also frequent complications.[303]

Whether kidneys, which are primary targets in some animal models of chronic GVHD, are also involved in the human syndrome is yet to be determined in large studies.[304] Among the myriad clinical features of chronic GVHD, three definitive signs appear to be risk factors for increased mortality: (a) extensive skin GVHD involving more than 50% of the body surface area; (b) platelet count of more than 100,000/μL; and (c) progressive onset and acute GVHD that continues uninterrupted beyond day 100.[305] Historically, it has been

difficult to make a definitive diagnosis of chronic GVHD. Recent criteria established by NIH consensus conference might prove to be beneficial in establishing uniform criteria for diagnosis, treatment, and response.[302] The NIH consensus criteria are currently in the process of being evaluated.

Differential Diagnosis

The distinction between chronic and acute GVHD has been traditionally based on the time of onset. The NIH Working Group has added two subcategories to the two main categories of GVHD. The broad category of acute GVHD includes (a) classic acute GVHD (maculopapular rash, nausea, vomiting, anorexia, profuse diarrhea, ileus, or cholestatic hepatitis) occurring within 100 days after transplantation or DLI (without diagnostic or distinctive signs of chronic GVHD) and (b) persistent, recurrent, or late acute GVHD: features of classic acute GVHD without diagnostic or distinctive manifestations of chronic GVHD occurring beyond 100 days of transplantation or DLI (often seen after withdrawal of immune suppression). The broad category of chronic GVHD includes (a) classic chronic GVHD without features characteristic of acute GVHD and (b) an overlap syndrome in which features of chronic and acute GVHD appear together. In the absence of histologic or clinical signs or symptoms of chronic GVHD, the persistence, recurrence, or new onset of characteristic skin, GI tract, or liver abnormalities should be classified as acute GVHD regardless of the time after transplantation. With appropriate stratification, patients with persistent, recurrent, or late acute GVHD or overlap syndrome can be included in clinical trials with patients who have chronic GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE: PATHOPHYSIOLOGY

The pathophysiology of chronic GVHD is less well understood than that of acute GVHD and has undergone less intensive experimental modeling.[24] It is important to recognize that chronic GVHD was originally defined as a temporal rather than a clinical or pathophysiological entity. The initial clinical reports of chronic GVHD described abnormalities that occurred at least 150 days after stem cell infusion.[306,307] By convention, day 100 after stem cell infusion is used as an arbitrary divider between acute and chronic GVHD. But some manifestations of acute GVHD occur after day 100 and some manifestations of chronic GVHD may occur before day 100.[24,303] Thus it is preferable to consider the clinical symptoms and signs per se rather than their timing of the onset.

Relatively little is known about the pathophysiology of chronic GVHD. This is due in part to the absence of appropriate animal models that can capture the kinetics and the protean manifestation of chronic GVHD.[308] On the basis of certain clinical features, chronic GVHD has been considered to be an autoimmune disease. Some experimental data suggest that chronic GVHD results from defective central negative selection, leading to the generation of autoreactive clones that escape tolerogenic mechanisms operating in the periphery.[309,310] This would suggest that the nonpolymorphic antigens expressed in both the donor and recipient rather than MiHA antigens are the likely targets. In contrast to T cells from animals with acute GVHD that are specific for host alloantigens, T cells from animals with chronic GVHD are specific for a public (common) determinant of MHC class II molecules.[311,312] These T cells are considered autoreactive because they recognize public MHC class II determinants that are common to both donor and recipient rather than polymorphic histocompatibility antigens that are specific for the host. The autoreactive cells of chronic GVHD are associated with a damaged thymus, which can be injured by several mechanisms including acute GVHD, the conditioning regimen, or age-related involution and atrophy. In chronic GVHD, the ability of the thymus to delete autoreactive T cells (negative selection) and to induce tolerance is impaired.[24,313,314] However, no clear data exist on the isolation of autoreactive donor-derived T-cell clones that equally recognize nonpolymorphic antigens from the donor and recipient cells. This, however, does not directly preclude the existence or a causative role for autoreactive T cells. Chronic GVHD could also be a product of T cells that have undergone relatively chronic antigen stimulation owing to the presence of inexhaustible and ubiquitous MiHA antigens. Allo-T cells under circumstances of chronic MiHA antigen stimulation can induce syndromes resembling those induced by the chronic antigen stimulation in autoimmune diseases. This concept is also consistent with the proposal of acute GVHD as a risk factor for chronic GVHD. The antigens targeted in chronic GVHD could be the same dominant ones targeted in acute GVHD, but the reactive T cells could be different; for example, they may secrete transforming growth factor-β. But antigens other than those that were initially immunodominant, even those not initially targeted but introduced through epitope spread could be important. It is also conceivable that regulatory mechanisms may frequently fail in allo-HCT, resulting in activation and expansion of T cells that recognize both nonpolymorphic and MiHA epitopes. One recent murine study suggested that development of a chronic GVHD-like syndrome is target antigen-dependent.[71] Furthermore, chronic GVHD pathogenesis could, in part, be a consequence of T cell priming by donor-derived APCs.[72] In some patient subsets, responses to rituximab, presence of MiHA-specific antibodies, and the presence of chronic GVHD after T-cell depletion allo-BMT would indicate that in addition to donor T cells, donor B cells might either have a direct effector role or prime T cells as APCs.[315,316] It is important to understand that given the many clinical presentations of chronic GVHD that tend to occur at variable time after HCT, it is possible that separate pathogenic mechanisms might be involved in causing distinct manifestations and that no single mechanism is sufficient to cause chronic GVHD.

THERAPY FOR CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD has a major impact on both quality of life (QOL) and survival, frequently involves multiple organs, and necessitates prolonged immunosuppressive therapy.[317] One report noted that 15% of cancer-free transplant recipients were still receiving immunosuppressive therapy after 7 years.[318] The more severe forms of chronic GVHD are clearly associated with a lower disease-free survival. Thus, the potential benefit of a graft-versus-leukemia effect is shadowed by significant treatment-related mortality.[318]

Current therapies for chronic GVHD are of limited efficacy, and there is no long-term satisfactory regimen for patients who fail front-line steroid-based therapy. Indeed, there is no Food and Drug Administration (FDA)-approved medication for use in chronic GVHD. The lack of standardized response criteria to measure therapeutic efficacy poses a major obstacle to pursuing therapeutic trials in chronic GVHD. Overall survival and / or discontinuation of systemic immunosuppression are accepted long-term endpoints in chronic GVHD trials. The recent National Institutes of Health (NIH)-sponsored consensus project provided for the first time a set of standardized measures and definitions to use as response criteria in chronic GVHD.[301,302] Nonetheless, these recommendations are yet be tested and validated in prospective studies. The NIH Consensus Conference has defined response measures classified in 2 main groups: clinician-assessed and patient-reported (see next page).[308]

The prevention of acute GVHD has not consistently resulted in a lower incidence of chronic GVHD. A clear example is the use of reduced-intensity transplants, consistently associated with a lower incidence of acute GVHD but with no a major impact on chronic GVHD.[319,320] The extended use of GVHD prophylaxis with cyclosporine, or variations in the cyclosporine dosage used, showed no beneficial effects on the incidence of chronic GVHD.[317,321] The addition of thalidomide to cyclosporine and methotrexate prophylaxis, the administration of IV Ig, or early treatment based on biopsy findings of subclinical GVHD in an attempt to treat chronic GVHD preemptively were unsuccessful.[317] The most commonly used thera-

Measure	Clinician-Assessed	Patient-Reported
I. Chronic GVHD-specific core measures		
Signs	Organ-specific measures	Not applicable
Symptoms	Clinician-assessed symptoms	Patient-reported symptoms
Global rating	Mild, moderate, or severe	Mild, moderate, or severe
	0 to 10 severity scale	0 to 10 severity scale
	7-point change scale	7-point change scale
II. Chronic GVHD nonspecific ancillary measures		
Function	Grip strength	Patient-reported function
	2-minute walk time	
Quality of life	—	Patient-reported health-related quality of life

From the NIH consensus Conference.[308]

pies to treat chronic GVHD are cyclosporine and prednisone. Sullivan et al[322] reported that prednisone alone is superior to prednisone plus azathioprine for primary treatment of patients with chronic GVHD. However, in patients classified as high-risk on the basis of platelet counts below 100,000/μL, treatment with prednisone alone resulted in only 26% 5-year survival. When a similar group of patients was treated with alternating-day cyclosporine and prednisone, 5-year survival exceeded 50%.[323] A recent randomized study of 287 patients with extensive GVHD found no statistically significant difference in nonrelapse death at 5 years or in cumulative incidence of secondary therapy at 5 years when prednisone alone was compared to prednisone plus cyclosporine.[24] For chronic GVHD that recurs or fails to respond to initial therapy, there is no standard treatment. Experimental therapies currently under evaluation include psoralen plus ultraviolet light, MMF, thalidomide, total lymphoid irradiation, plaquenil, extracorporeal photopheresis, pentostatin, and acetretin.[297] Table 107–4 lists the commonly used GVHD drugs and their common side effects.[324]

SYNGENEIC GRAFT-VERSUS-HOST DISEASE

A GVHD-like syndrome that is usually self-limited and predominantly affects the skin can occur in recipients of syngeneic or autologous transplants.[325] It is also possible that some of the cases of syngeneic GVHD reflected a mistaken assumption that the donor was syngeneic without extensive molecular confirmation. It is primarily manifest as a rash that usually responds promptly to corticosteroid therapy. Although the level of severity may be grade II or III, the disease generally resolves promptly with the administration of glucocorticoids and is not life-threatening. Virtually all patients in whom a GVHD-like syndrome develops after syngeneic transplantation have been prepared with intensive conditioning regimens, usually involving irradiation. Experimental studies suggest that such conditioning is essential for the induction of thymic dysfunction, which is necessary for the development of the disease. Generation of autoreactive cells (a defect in thymic negative selection) as well as elimination of regulatory cells appear to be the requirements for the development of this disease.[314] An additional hypothesis is that in some individuals, maternal cells transmitted to them during their fetal development remain present throughout adult life.[326] These observations suggest the possibility that in some instances small numbers of HLA incompatible cells (derived from the donor's mother) may be transmitted with HLA-identical transplants. Transplacentally transferred maternal cells may also play a role in the development of neonatal GVHD.[326]

Transfusion-Associated Graft-Versus-Host Disease

Most blood products administered to immunocompromised patients are now irradiated or at least leukocyte depleted to avoid the transfusion of viable alloreactive T cells. With most homologous blood products, the MHC incompatibility between donor and recipient results in rapid clearance of transfused T cells by the recipient's immune system. However, occasionally transfusions from donors who are homozygous for one of the recipient's MHC haplotypes are not recognized as foreign by the recipient.[327–329] These cells can survive, "engraft," and may mount an immunologic attack against the unshared haplotype in the patient, resulting in transfusion-induced GVHD.[329] This syndrome of transfusion-associated GVHD differs from GVHD occurring after transplantation in regard to its kinetics but also in regard to its manifestations insofar as the recipient marrow is a major target.[328] Because the number of stem cells in the offending blood product is inadequate, there is no hematopoietic recovery from donor cells. This syndrome is generally fatal owing to refractory pancytopenia in addition to other organ involvement.

GRAFT-VERSUS-LEUKEMIA RESPONSES

The GVL response after allogeneic HCT comes from the immunologic attack of the host tissue and, by extension, the leukemia/tumor. This response represents a potent form of immunotherapy that circumvents some of the immunoediting mechanisms used by tumor cells to develop in the hosts. The power of the alloimmune response to eliminate malignancy was first reported more than 50 years ago in experimental models by Barnes and Loutit.[1] However, the entity GVL and its close association with GVHD was not established another 15 years.[330]

CLINICAL FEATURES

Clinical evidence that the donor graft mediates important antileukemic effect comes from higher relapse rates for recipients of syngeneic stem cells than recipients of HLA-matched sibling grafts.[331] These findings have also been confirmed in a multicenter analysis of HCT recipients with acute myelogenous leukemia (AML) in first remission and subsequent retrospective analyses by the International Bone Marrow Transplant Registry (IBMTR).[332–334] The second IBMTR analysis also showed that the magnitude of this GVL effect is greater for patients with CML and AML and not statistically significant for patients with ALL in first remission.[335,336]

Several case reports of patients with relapse of leukemia after allogeneic HCT noted remissions of the malignancy either after abrupt withdrawal of immunosuppression or during a flare of acute GVHD.[337–340] Patients who develop GVHD after allogeneic HCT experience relapse less frequently than similar patients who do not develop clinical disease. GVHD is protective against relapse both for HCT recipients with advanced leukemia[341–343] and for patients who receive transplants in earlier stages of malignancy.[344] Additional analyses also suggest that the magnitude of the GVL effect appears to be disease and stage specific.[344–346] Initial reports suggested that chronic GVHD was most protective against relapse,[343] but other analyses demonstrate that acute GVHD is also protective.[344] On the basis of these reports, newer trials of immunotherapy are designed to include cessation of immunosuppressive therapy (without taper) to induce a GVL reaction for patients whose malignancy has relapsed after HCT. Furthermore, Childs et al demonstrated that the graft-versus-tumor effect also plays an important role in inducing remissions from a nonhematologic malignancy, renal cell carcinoma.[347]

Another line of clinical evidence regarding the GVL effect of allogeneic HCT and its tight linkage to GVHD comes from the studies employing T-cell depletion of the donor graft. Donor T cells included in the stem cell graft are critical for acute GVHD, and T-cell depletion by various strategies is one of the most successful means of reducing the incidence and severity of GVHD after allogeneic HCT.[348–354] Unfortunately, although T-cell depletion results in less treatment-related morbidity and mortality, improved overall survival rates have not been reliably demonstrated. This failure is due in large part to a reciprocal increase in the subsequent relapse rate after T-cell depletion, as well as to graft failure and other complications.[346,355,356]

T-cell depletion increases relapse rates particularly in CML.[344,346,357] This observation provides further strong, albeit indirect, evidence that allogeneic donor T cells are important mediators not only of GVHD but also of the GVL properties of the allogeneic stem cell graft. Finally the most compelling evidence of donor T cells in mediating GVL comes from the observations made from donor lymphocyte infusions.

Genetic Basis

The immunotherapeutic effect that occurs in an allo-BMT setting is primarily mediated by allogeneic donor T or NK cells directed against the alloantigens shared by the recipient tumor and target tissues and/or tumor-specific antigens that have the advantage of not being subjected to tolerance mechanisms by the host tumor.[358–360] Understanding of the exquisite specificity of T-cell responses led to attempts to identify specific antigens that are responsible for the GVL effect. Much of the focus has been on the identification of (a) certain oncogenic viral proteins because these are absent in normal cells but expressed by transformed tumor cells (certain EBV peptides such as EBNA-1, LMP-1, LMP, and LCL), (b) antigens that are expressed in a tissue-specific fashion (melanoma-specific proteins), and (c) proteins that are overexpressed in tumors (*WT1*, *proteinase 3*, survivin, telomerase reverse transcriptase, CYPB1 and Her-2/neu).[90,359] Although these antigens are specific, most T-cell responses to these antigens are limited because of the poor immunogenicity of these proteins, expression on normal cells, defects in the processing or presentation of tumor antigens or by production of factors that disable T-cell responses. Thus, clinical attempts to obtain high specificity of T-cell responses have been offset with difficulties in obtaining enough sensitivity and vice versa. Furthermore, given the current concepts of stem cell origins of leukemia and cancers, identification of the immunogenic proteins that are specifically expressed in the malignant stem cells and harnessing T-cell responses to those antigens will be needed for the optimal GVL effect to cure malignancy.[361,362]

In contrast to the tumor-specific or associated antigens discussed above, alloantigens are not subjected to tolerance mechanisms. Vaccination strategies with autologous T cells utilizing tumor-associated or -specific antigens have yielded disappointing clinical antitumor responses.[363] By contrast, allogeneic HCT has met with remarkable GVL responses, perhaps because of recognition of minor alloantigens in addition to the tumor-associated antigens.[364] This concept has been demonstrated by recent murine studies, which showed that alloantigen on the tumor cells is required for GVL responses and that the principal targets of GVL are the immunodominant allogeneic MiHAs rather than the tumor-associated antigens.[52,365] Thus T cells specific for MiHA antigens could provide a potent GVL effect. Significant progress has been made in the identification of MiHAs that are specifically expressed in the host hematopoietic tissues and therefore might allow for a GVL response without causing GVHD.[90] Together, these results suggest that, in addition to tumor-specific proteins, expression of alloantigens and cognate interactions between donor T cells and the tumor tissues are required for the effective induction of the majority of GVL responses. However, T cells specific for some MiHAs are also responsible for GVHD, and a means of consistently separating the beneficial GVL effect from GVHD has not yet been clinically achieved.

KIR Polymorphisms

Two competing models—mismatched and missing ligand models—for HLA-KIR allorecognition have been supported by clinical observations of GVL responses in different patient and transplant populations.[49,366] The former model has been shown to separate GVL and GVHD responses in the context of T-cell depleted (TCD) haploidentical HCT for AML.[367,368] Even though this model is supported by elegant laboratory studies, it was found to be invalid for ALL and also for AML after unrelated donor HCT with immunosuppression.[367] Recent retrospective clinical data suggest that GVHD and GVL can be separated by the "missing ligand" model in CML/AML and MDS patients after TCD HLA-identical sibling HCT.[366,368,369] Further validation of either models by clinical prospective studies and the a better understanding of the balance between the inhibitory and activating receptor - ligand interaction of the NK cells are needed to adequately exploit the interface between HLA - KIR genetics to separate GVHD from GVL.[370,371]

IMMUNOBIOLOGY OF GRAFT-VERSUS-LEUKEMIA RESPONSES

Given the tight association of clinical GVHD and GVL and the common biological principles governing these responses after allogeneic HCT, we will discuss below the similarities and distinctions between them in the context of the three cellular phases of GVHD.[372]

Phase 1: Activation of Antigen-Presenting Cells

The concept that tumor eradication after allogeneic HCT might not require toxic chemoradiotherapy and could be achieved primarily by the immunotherapeutic effect from the GVL responses has led to the clinical development of non-myeloablative HCT for hematologic and nonhematologic malignancies.[373] Phase 1 is characterized by the development of 'cytokine storm' generated 'danger signals' from the conditioning regimen and the subsequent activation of APCs.[372] Experimental data suggested that the reduction in conditioning would attenuate the 'cytokine storm', lead to the development of mixed donor-host chimerism and confine the GVH response primarily to secondary lymphoid organs, thus cause less severe GVHD without impairing GVL responses.[374–376] However, non-myeloablative HCT has delayed the kinetics but did not reduce the overall incidence of GVHD and a significant numbers of patients either failed to respond or relapsed.[21] Furthermore, recent murine and human studies have suggested that homeostatic expansion of T cells in a lymphopenic environment induced by conditioning (as opposed to mere immunosuppression) improves the antitumor efficacy of adoptively transferred syngeneic or autologous T cells by increasing the availability of space, enhancing the memory responses and reducing the competition for homeostatic cytokines (such as IL-7 and IL-15) for transferred T cells while eliminating regulatory T cells.[377–379] Thus low intensity HCT clearly demonstrate the principle of GVL effect, but the role of 'cytokine storm', and homeostatic expansion of allogeneic T cells in shaping the intensity of GVL responses is not known.

Host and donor APCs are critical for the induction and severity of GVHD.[7] Activation of APCs is the key step in Phase 1 of GVHD.[372] Significant progress has been made in understanding the role of APCs in GVL. Recent experimental evidence demonstrate a crucial role for professional host APCs in the induction of GVL responses mediated by donor T cells even when the tumor cells showed some features of APCs.[52,380] Tumors that merely express costimulatory molecules may still be unable to stimulate an effective immune response because of their various 'immunoediting' processes that cause ineffective antigen presentation.[381] However, when the tumor cell itself functions as a professional APC, as with CML, it can generate an effective GVL response.[382,383] By contrast, cancers such as acute leukemias that seldom differentiate into APCs generate poor GVL responses. Data also demonstrated that given sufficient time and a low tumor burden, cross-presentation of tumor-associated antigens and/or alloantigens by professional donor APCs can occur, and may promote or sustain GVL responses by maintaining or expanding alloreactive T cells after initial priming on host APCs.[52,383] This concept is consistent with clinical GVL responses in CML in which the final stage of a GVL response to CML may be the result of donor T cells responding not directly to the small number of CML stem cells or progenitors (which

would be undifferentiated and therefore poor APCs) but to tumor antigens cross-presented on professional donor APCs. But it is unclear if such cross-presentation is sufficient to elicit effective GVL responses against acute or advanced leukemia. These data, however, suggest that GVL responses generated after low intensity conditioning may not be as robust as those after full intensity HCT and highlight the need for a clearer understanding of the effects of 'cytokine storm' and lymphopenia generated danger signals on the activation of APCs in mediating GVL.

Phase 2: Donor T-Cell Activation

The core of GVL responses, as with GVHD, is also dependent on the activation of appropriate numbers of T cells. The 'second signals' from professional APCs (or certain tumor cells that function as effective APCs) are critical for generating an effective GVL response.[78] Several of the costimulatory pathways that modulate GVHD have also been evaluated in mediating GVL responses.[78] Blockade of CD28 costimulation preserved GVL responses but reduced GVHD in murine studies.[384] However, when the tumor cells also expressed B7 molecules, such blockade reduced the GVL responses.[382] Ex vivo blockade of CD40-CD40L interaction has been shown to reduce GVHD by generating Tregs but preserve GVL.[78,100,385] By contrast blockade of the 4–1BB pathway reduced both GVHD and GVL.[82] The other costimulatory molecules (OX40 and ICOS) and the inhibitory molecules (CTLA-4 and PD-1) also modulate antitumor responses.[83,84] A better understanding of the context (ie, low intensity or DLI) and of the hierarchy of timing, duration and extent of costimulatory requirements of donor T cell subsets might result in approaches which balance the intensity of GVL and GVHD responses. Clinical and experimental evidence suggest that donor T cells numbers correlate with the severity of GVHD and GVL responses. TCD grafts have reduced GVHD but increased disease relapse suggesting a role for T cell numbers in GVL responses as well.[386] Clinical attempts to separate GVHD and GVL by regulating allogeneic T cell dose have met with limited success. For example, administration of 1×10^5 T cells/kg after HLA-matched sibling transplantation did not mediate GVL effects and yet was associated with a measurable incidence of GVHD. Thus infusion of adequate numbers of donor T cell effectors is crucial for GVL responses.[386] This has been demonstrated by durable responses that are observed in CML and other malignancies after donor leukocyte infusion (DLI, see later) despite the experimental evidence that host APCs stimulate a stronger GVL response than donor APCs.[52,383] The lack of immunosuppression after DLI increases the likelihood of a GVH response, and DLI are almost always associated with clinical GVHD. The delivery of additional allogeneic effector cells in DLI also increases the effector: target ratio compared to the time of initial HCT. This is underscored by a more effective GVL response to DLI against minimal residual disease (bcr-abl positivity by PCR) compared to the response against high leukemic burden (e.g., blast crisis) in CML patients.[383] Thus DLI provides the proof in principle for the concepts that sufficient T cell numbers and appropriate antigen presentation are required for both GVHD and an effective GVL response.

T-Cell Subsets

Most experimental studies have implicated donor $CD8^+$ T cells as the primary mediators of GVL, but there are no clinical data for $CD8^+$ mediated GVL responses in the absence of CD4 T cells.[185,359,383] Moreover, some clinical data suggest a role for greater CD4 mediated GVL responses without an increase in GVHD after allogeneic HCT and DLI.[380,387–390] But it is unclear whether $CD4^+$ T-cell–initiated GVL responses occur in the absence of generation of MiHA specific $CD8^+$ T cells. Given the critical requirement of alloantigens for most GVL responses, the specific requirement of either CD4 and/or CD8 T cells for GVL and GVHD is likely to be determined by the expression of the relevant immunodominant MiHAs and/or tumor associated proteins. Therefore it is unlikely that GVHD and GVL responses can be separated under all circumstances merely by depletion of either subset of alloreactive T cells. However, experimental data suggest it might be possible to separate GVHD and GVL when certain donor T cell subsets are either depleted or infused (DLI) at the appropriate interval after transplant.[380] But the optimal interval for such infusions has not been identified.

Because of recent identification and understanding of the role of various T cell subsets in mediating immune responses, depletion of specific T cell subsets to separate GVHD and GVL remains an area of active investigation. For example, recent experimental data suggest that CD62L expressing naïve T cells home to secondary lymph nodes and are critical for initiating GVHD.[93] By contrast, CD62L negative effector memory T cells with enhanced reactivity to recall antigens mediated GVL responses with minimal GVHD.[93] An important caveat to these data is that the lack of *a priori* knowledge of the repertoire of human memory T cells would make it difficult to predict if these cells might cross-react only with tumor associated antigens and/or with recipient's alloantigens. Using CD62L status alone as determinant of GVHD potential can also have other unintended consequences as recent studies have demonstrated that its expression is critical for the regulation of GVHD by Tregs (see later). Moreover it is not known whether the behavior of human memory T cells parallels that of murine memory T cells in their migratory, functional and cytolytic capabilities. Although Tregs reduce antitumor immunity in murine models and in human subjects experimental data suggest that administration of donor type Tregs either at the time of HCT or when delayed reduced GVHD but preserved $CD8^+$ mediated perforin dependent GVL responses.[109,391] Similar preservation of experimental GVL was also observed by harnessing donor NKT function with GCSF analogues.[116,117] However, whether these observations are valid after clinical HCT when the GVL responses might not be entirely dependent on CD8 T cells remains unclear.

T-Cell Migration

It is conceivable that manipulation of these interactions to focus the alloimmune response to lymphohematopoietic tissues would enhance GVL responses but not GVHD. For example, blockade of CCR9 ligand TECK or CCR5, and CCL17 may prevent the migration of donor T cells to GI tract and skin respectively, but preserve GVL.[170] Pharmacologic manipulation with the immunosuppressive agent FTY720 has recently provided the proof in principle for this approach.[180] Given the redundancy, strategies to modulate the chemokine biology for separation of GVHD and GVL will require greater understanding of these networks in modulating the migration of not only specific T cell subsets but also of the other immune cells in the context of different conditioning regimens.

Phase 3: Effector Phase of Graft Versus Leukemia

The effector arm of GVL is also characterized primarily by the antigen specific cellular and less by the inflammatory components of alloresponse. Experimental data demonstrate that neutralization of IL-1-a reduced GVHD preserved GVL.[281] By contrast donor TNF-α secretion contributes to both GVHD and GVL effects and in some cases, antagonism of TNF-α, reduced GVHD and GVL responses.[224,392,393] Nonetheless antagonism of non-specific inflammatory effectors such as either IL-1 or TNF-α appears to regulate GVHD to a greater extent than GVL responses after experimental allogeneic HCT.[393]

Several lines of experimental and clinical data demonstrate that antigen specific donor T cell subsets and NK cells are the key effectors of GVL.[359] The cytotoxic pathways that are operative in the NK and T cell mediated antitumor responses have been well characterized.[359] Fas ligand mediated CTL of tumor targets is utilized by both NK and T (mostly Th1) cells. But most murine experiments with FasL deficient donor T cells suggested that FasL is a key effector molecule

for causing GVHD but not for GVL.[185] However one study found that FasL is required for CD4+ mediated GVL against myeloid leukemia.[394,395] By contrast, even though perforin mediated CTL pathways are also utilized by T (mostly Th2) and NK cells, experimental data with perforin deficient donor T cells demonstrated a loss of GVL with a diminution in the severity of GVHD.[185] In some other experimental models, perforin was required only for GVL but not GVHD.[185] Recent data showed that TRAIL mediated CTL had no effect on GVHD severity but was required for optimal GVL.[209] Therefore strategies that increase donor T cell TRAIL expression or enhance the susceptibility of tumors to TRAIL mediated CTL (such as HDAC inhibitors) may promote a robust GVL effect without exacerbating GVHD.[396–398] Thus significant progress has been made in recent understanding of the CTL pathways employed by donor T cells for GVL responses, but, the role and context of utilization of these pathways by donor NK and NKT cells after allogeneic HCT are not known.

DONOR LEUKOCYTE INFUSIONS

Until recently the evidence for an important GVL effect in clinical transplantation was strong but largely circumstantial. The use of donor leukocyte infusion (DLI) to treat relapses after allogeneic HCT has now provided direct evidence of the GVL effect.[399–401] Kolb et al. first reported three patients with relapsed CML who achieved complete cytogenetic remission after treatment with IFN-α and DLI from the original donors.[402] Subsequently these findings have been confirmed in several reports.[403–405] Two large retrospective studies of DLI have been reported from Europe and North America.[401,406] Although the treatment protocols varied slightly among institutions, the results have been remarkably consistent. When results from these trials are combined, the complete remission rate for patients treated for relapsed CML is consistently 60–80%.[399] In many patients with CML the response to DLI is not immediate. The average time to obtain a molecular remission is between 4 to 6 months but disease free survival after DLI depends on the stage of CML.[407,408] Complete cytogenetic and molecular responses are achieved in almost 80% of patients treated with either early relapse (cytogenetic or molecular) or hematologic relapse of chronic phase.[336] Patients with more advanced CML (accelerated phase or blast crisis) are less likely to respond. Two recent analyses suggest that the outcome after unrelated DLI is similar to matched sibling DLI in CML patients.[401,406]

DLI has also produced remissions in acute leukemias. Several retrospective studies have reported response rates in AML ranging from 20–65%.[336,406,409–411] A prospective study of 65 patients with advanced myeloid leukemia who received cytarabine and GCSF primed DLI showed that 47% of the patients achieved complete remission with an overall survival of 19% at two years.[412] A recent EBMT analysis of DLI in patients with relapsed AML showed a response rate of 41% that did not change if chemotherapy was used prior to DLI.[413] Generally, DLI produces lower response rates and higher relapse rates in patients with AML than with CML.[336,383,406,409–411] Extramedullary relapses at multiple regions that are usually not considered sanctuary sites for leukemia have been observed after DLI.[411]

Although GVL responses to ALL after allogeneic HCT have been noted, DLI for ALL has generally been ineffective.[414] Reports both from Europe and from America found little benefit for DLI in ALL patients.[383,406,409,410] Furthermore Ruggeri et al found that following TCD haploidentical HCT where the donors had antirecipient NK cells, the probability of relapse was 85% for ALL in contrast to 0% for AML.[367,415]

The experience with DLI for other hematologic malignancies such as NHL and multiple myeloma is much more limited. Case reports and small series demonstrate responses to DLI in patients with posttransplant relapses of low-grade lymphoma and CLL and also after low-intensity HCT.[416,417] In multiple myeloma, complete responses to DLI were observed in 25% of the patients in two small series.[383,418,419] DLI has also been shown to induce complete remission in a majority of patients with posttransplant lymphoproliferative disorders (PTLD) after allogeneic HCT.[403,420] Viral infections may be treatable with DLI, and adoptive immune therapy with T cells specific for EBV and CMV have been shown to both treat and prevent these complications.[421–425]

Complications of Donor Leukocyte Infusion

Adoptive immunotherapy with DLI causes significant morbidity. The major complications are myelosuppression and GVHD. Myelosuppression with anemia/ thrombocytopenia/leukopenia or pancytopenia occurs in 34% of the patients.[408] Marrow aplasia presumably results from the destruction of host leukemia cells before recovery of normal donor hematopoiesis. This idea is supported by the observation that patients treated with donor mononuclear cell infusions for cytogenetic or molecular relapse rarely experience pancytopenia.[401] Occasionally, marrow aplasia has been persistent,[403,404,426] although this toxicity has been successfully reversed with the infusion of additional donor stem cells in some patients.[403,404] If pancytopenia is associated with chronic GVHD then immunosuppression might be the most appropriate therapy.[427] Acute and chronic GVHD have been the major direct complications from DLI. In retrospective and prospective studies, acute or chronic GVHD has been reported in 40% to 60% of patients (see Fig. 107–1). In most studies, GVHD correlates with GVL activity and response.[401,406] In the North American analysis, over 90% of complete responders developed acute GVHD and 88% of responders developed chronic GVHD. Of 23 patients who did not experience GVHD, only 3 achieved a complete remission. In 92 patients who had no response, only 35% had acute GHVD and only 13% had chronic GVHD. In the EBMT analysis, 41% of DLI recipients developed grade II–IV acute GVHD.[401] It should be noted, however, that many patients who fail to respond to GVL induction will die shortly of progressive disease and may not survive long enough for GVHD to develop. This is particularly important for patients with acute leukemia. It is also important to emphasize that a number of complete responses were seen in patients without any sign of GVHD. The GVL effect in the absence of clinical GVHD provides important evidence for GVL activity separate from GVHD.

In general, GVHD that occurs after DLI has been mild to moderate and has been responsive to immunosuppressive therapy. This observation is important because the dose of T cells often administered with DLI may be 10- to 100-fold higher than the T-cell dose administered at the time of transplant, and DLI is given without additional immunosuppression. At the time of transplant, if immunosuppression is withheld or a similar dose of donor T cells are given as are used for DLI (to augment GVL), toxicity is unacceptable.[428,429] This may be because the effects of GVHD are more tolerable when separated from the acute transplant toxicity. GVHD can be stimulated and exacerbated by the "cytokine storm" that can accompany transplantation. Tissue damage from the intensive conditioning regimen, infections, and other physiological insults result in a cascade of events that ultimately augment the GVHD reaction.[235] When GVHD is induced independent of other transplant-related toxicity, it may be more manageable with appropriate immunosuppression. Nevertheless, in some cases DLI-induced GVHD may be quite severe; as shown in Table 107–1, 20% to 35% of DLI recipients can be anticipated to develop grade III–IV acute GVHD. Furthermore, acute GVHD has contributed to death in almost 10% of patients.[430] Chronic GVHD occurs in 30% to 60% of recipients of unmanipulated DLI.

It is notable that the clinical presentation of GVHD after DLI is somewhat different than after myeloablative allogeneic HCT. For instance, the onset of GVHD may be later after DLI. The median time to onset of acute GVHD is approximately 32 to 42 days[406,431] compared to a median time to onset of 16 to 20 days following myeloablative T-replete transplantation.[260,432] Therefore, not only can the severity of GVHD be influenced by the use of intensive conditioning, the tissue damage and inflammatory cytokine release may

influence the pace of GVHD development as well. This possibility is supported by the finding that time to onset of acute GVHD is also delayed following reduced-intensity transplantation.[433] The target organs of acute GVHD following DLI are the same as those seen following HCT, but the clinical manifestations may differ. A hepatitic variant of liver GVHD characterized by marked elevations of serum aminotransferase levels more than 10 times the upper limit of normal was observed in 11/73 (15%) patients who received DLI at Johns Hopkins University.[273] Characteristic skin, liver, and intestinal acute GVHD manifestations can be seen following DLI, but their frequency and severity has not been well described. In a study of 81 patients who received DLI for relapse, mixed chimerism, or prophylaxis following reduced-intensity HCT, skin, liver, and intestinal GVHD developed in 26%, 8%, and 14%, respectively.[434] Likewise, characteristic findings of chronic GVHD can be seen following DLI,[434] and on occasion both acute and chronic GVHD can develop simultaneously following DLI.[435]

In recent years, DLI has been utilized in the context of reduced-intensity allogeneic HCT. When conditioning is minimal and GVHD has not already occurred, DLI is often required to either reverse mixed chimerism or treat persistent disease.[434,436,437] GVHD after DLI following nonmyeloablative setting develops 19% to 45% of the time, whereas chronic GVHD develops 28% to 34% of the time. In two studies of a combined 134 subjects who received DLI after reduced-intensity transplantation, 37 (28%) patients developed acute GVHD, 15 (11%) developed grade 3–4 GVHD, and 8 (6%) died from GVHD.[434,436] There was no statistically significant relationship between DLI dose and GVHD in either study. The clinical features of GVHD after DLI following reduced-intensity HCT are similar to the GVHD that occurs after DLI is used to treat relapse following myeloablative HCT. The similarity between GVHD after DLI in either setting suggests that the reduction of tissue damage associated with either no chemotherapy (as in DLI for relapse following prior myeloablative HCT) or reduced-dose chemotherapy (as in DLI after reduced-intensity HCT) may be an important common theme.

It is likely that effector cells responsible for the GVL and GVHD effects of HCT will similarly be responsible for the GVL effect associated with DLI, although this assumption has not been formally proven. The administration of select subsets of donor mononuclear cell fractions is the ideal setting in which to dissect the cellular mechanisms responsible for GVL induction, and strategies that delay the infusion of these various cellular subsets will help define the mechanisms and enhance the efficacy of DLI.

SUMMARY

Complications of HCT, particularly GVHD, remain major barriers to the wider application of allogeneic HCT for a variety of diseases. Recent advances in the understanding of genetic polymorphisms, the chemocytokine networks, several novel cellular subsets including regulatory T cells and of the direct mediators of cellular cytotoxicity have led to improved understanding of this complex disease process. Animal studies show that modulation of several mediators of the complex GVHD cascade may reduce the undesirable inflammatory aspects of GVHD while preserving the benefits of GVL. However, most of the laboratory observations remain to be studied in well-controlled clinical trials. Multiple cellular effectors may be involved in GVL, although donor T-cell recognition of host antigens is an important element of this process. Cellular immunotherapy such as DLI offers a strategy for separating GVHD and the GVL effect. Both experimental and clinical data suggest that posttransplantation cellular immunotherapy can be performed relatively safely and effectively, and optimization of patient selection, cell dose, and timing of administration may all serve to limit toxicity and enhance the potential GVL effects.

CHAPTER 108

PRACTICAL ASPECTS OF STEM CELL COLLECTION

Scott D. Rowley and Michele L. Donato

Hematopoietic stem cell (HSC) products for autologous or allogeneic transplantation are available from bone marrow, peripheral blood, or umbilical cord blood (UCB) sources. Bone marrow was the original source of cells for transplantation because of the ease and reliability of collecting adequate numbers of cells for transplantation, and it remains the standard to which other sources of HSC are compared. Because of the relative immunologic naivete of the donor with the feasibility of multiple-antigen mismatched transplantation, UCB has found an important niche in the treatment of patients undergoing unrelated donor transplantation who lack an appropriate related or unrelated volunteer donor.[1] The primary limitations of UCB transplantation derive from the small cell dose collected, which can result in a longer time to hematologic recovery and a higher risk of primary engraftment failure. This same relative immunologic incompetence of the donor results in a greater risk of posttransplant opportunistic infections. Peripheral blood stem cells (PBSC) have virtually replaced bone marrow as the HSC component for autologous transplantation and are widely used for allogeneic transplantation. The rapid engraftment kinetics of PBSC compared to bone marrow are widely recognized. Median times to achieve an absolute neutrophil count greater than 500/μL and platelet transfusion independence after PBSC transplantation typically are approximately 11 to 14 days.[2–7] The improvement in engraftment kinetics reduces the cost of autologous transplantation (Table 108–1).[8–11] Although graft-versus-host disease (GVHD) prophylaxis with methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient is similar to that experienced by the autologous PBSC recipient.[12–18] A number of phase III studies involving either autologous or allogeneic HSC transplantation have confirmed the more rapid engraftment kinetics for recipients of PBSC (Table 108–2).[19–25] This effect is not limited to HSC collected from the peripheral blood because cytokine administration to the patient or donor before marrow harvesting will also increase the number of HSC collected and result in quicker hematologic recovery (Table 108–2).[26–30] The disadvantages to use of PBSC components compared to bone marrow or UCB for autologous or allogeneic transplantation include the usual need for multiple days of collection (especially for autologous transplantation), the inability to collect adequate components from all patients and donors, and a possibly higher risk for GVHD or the occurrence of GVHD that is more difficult to control.[31–33]

COLLECTION OF BONE MARROW FOR TRANSPLANTATION

Background

Most bone marrow products are collected from the posterior iliac crests using virtually the same techniques used to obtain diagnostic samples in the clinic as originally described by Thomas and Storb.[34] The primary differences between obtaining diagnostic specimens and cell quantities adequate for transplantation are the volume of blood and marrow removed, which requires attention to fluid replacement during the procedure and the need for appropriate anesthesia. Bone marrow harvesting from healthy donors presents little risk of serious morbidity, permitting the ethical recruitment of allogeneic donors including unrelated and pediatric bone marrow donors.[35,36]

Bone Marrow Collection Techniques

Bone marrow typically is harvested from the posterior iliac crests. Multiple aspirations are performed with collection of approximately 5 mL of marrow from each puncture site. If properly spaced, no more than two to three skin puncture sites per side usually are required. Other harvest sites, such as the anterior iliac crests or sternum, can be used, but at increased risk of complications from accidental laceration or perforation of contiguous anatomic structures. Extending the harvest to the anterior crests or sternum is unusual, used for less than 10% of patients undergoing autologous collections[37] and much less commonly for volunteer donors. For patients with a history of radiation or tumor involvement of one pelvic crest, adequate cells can be harvested from the anterior and posterior crests of the other side.

Marrow is collected in the day surgery suite using either general or regional anesthesia.[37] With proper fluid and blood replacement, overnight hospitalization should not be required. For the healthy donor, the risks of serious complications from either general or regional anesthesia are about the same. Spinal or epidural anesthesia avoid the nausea that may occur with general anesthesia, especially for young women, but hypotension from loss of vascular tone in the lower extremities often occurs as the volume of marrow is collected. General anesthesia is preferable for the donor with comorbid disorders such as cardiovascular or cerebral vascular disease because of the better control of donor airway and lower risk of hypotension during the harvest procedures. Local anesthesia is acceptable only if a very limited harvest is being performed, as large quantities of lidocaine are cardiotoxic and local anesthesia does not achieve anesthesia of the marrow space. The operating room is an intensive care unit, which is preferable to blood stem cell harvesting in an outpatient apheresis unit for the patient with serious comorbid illnesses.

Evaluation of Bone Marrow Donors

Anesthesia and blood loss present the greatest risks of serious complications, and patients and donors must undergo a thorough medical examination. Most marrow harvesting is performed under general anesthesia, which requires intubation for control of the airway for a surgical procedure performed on a prone patient. Regional (spinal or epidural) anesthesia may not be effectively established, so patients and donors who express a preference for this anesthesia must be counseled about the potential need for general anesthesia. The health assessment must include questioning about a history of joint disease of the cervical spine and mandible and examination of the mouth if general anesthesia requiring intubation is chosen. Patients and donors with comorbid conditions, such as aortic stenosis sensitive to changes in blood volume and blood pressure, may require anesthesia consultation and plans for invasive monitoring during the surgical procedure. A history of marrow fibrosis, pelvic irradiation, or pelvic tumor involvement may exclude a patient from marrow harvesting.

Table 108–1 Costs of Autologous Transplantation by Source of Hematopoietic Stem Cell

Study	No. of Patients	Days to Engraftment		Hospital Stay (Days)	Costs
		ANC >500/μL	*Platelet >20,000/μL*		
Hartmann et al.[8]	BM 65	12	36.5[a]	31	$28,429
	PBSC 64	8	17.5	24	$23,591

[a]Shown are number of patients enrolled in each arm of the study, quantity of CD34+ cells × 10^6/kg (CFU-GM × 10^4/kg for reports by Beyer and Hartman), days after transplantation to achieve a peripheral blood absolute neutrophil count >500/μL and platelet count >20,000/μL (25,000/μL for report by Blaise and 30,000/μL for report by Hartmann), and percentage of patients developing acute graft-versus-host disease.
ANC, absolute neutrophil count; BM, bone marrow, G-BM, granulocyte colony-stimulating factor–stimulated bone marrow, PBSC, peripheral blood stem cell.

Patients undergoing autologous bone marrow collection and transplantation are not at risk for transmitting disease to themselves, but the laboratory must be notified of the infectious disease status of the patient because some viruses can cross-contaminate other products stored in the liquid phase of nitrogen. All allogeneic bone marrow (and PBSC) donors must be evaluated using the criteria currently applied to blood donors, including a targeted history regarding behaviors exposing the donor to virus infection, recent and concurrent illnesses, and medication use.[38,39] Some groups advocate age-specific screening for all donors because of the higher risk of malignant diseases in older donors.[40,41] Numerous infectious diseases that would not exclude the donor from blood donation, such as cytomegalovirus, may be transmitted with the allograft.[42] However, donors who otherwise would be excluded for health reasons from donating blood for transfusion (e.g., individuals with a history of hepatitis) still may be selected to donate bone marrow if the needs of the recipient outweigh the risks and consequences of disease transmission. Guidelines regarding the management of patients and donors with hepatitis virus infection have been published.[43] Procedures involving donors with acute infectious illnesses should be delayed, if at all possible, because of the risk of disease transmission.[44] Hematopoietic disorders, such as hemoglobinopathies, will be transmitted to the recipient as a direct consequence of stem cell engraftment. Cancer can be transmitted, as illustrated by the transmission of donor leukemia not detected during initial evaluation of the donor.[45] The United States Food and Drug administration has not established donor health criteria for bone marrow donors, but criteria for PBSC donors can be applied to the marrow donor. Criteria for donor selection are established by the National Marrow Donor Program for evaluation and selection of unrelated donors and by volunteer accreditation programs such as the Foundation for Accreditation of Cellular Therapies and the American Association of Blood Banks. Use of a donor who does not meet eligibility criteria and poses a risk for transmission of disease requires appropriate informed consent both from the donor (to allow disclosure of this confidential health information and counseling of the recipient) and from the recipient (for use of the stem cell product).

Toxicity of Bone Marrow Collection

Anesthesia complications present the major health risk to the donor; marrow aspiration is generally well tolerated. Major complications occur in approximately 0.27% of healthy allogeneic donors[46] and up to 0.97% of autologous transplant patients.[47] Complications include hemorrhage and infections at skin puncture sites. Severe hematomas and neuralgias rarely occur, but attention to pelvic anatomy is required to decrease the risk of damage to vessels and nerves lying under or adjacent to the iliac crest harvest sites. Irritation of the sacral nerves may result from needle penetration through the pelvic bone or from blood tracking into the nerve roots and requires several months of convalescence. Localized pain is common, may last for several days, and may require a brief period of medication with opioid/acetaminophen combinations.[48] In a survey of almost 500 donors for unrelated marrow transplantation, the average time for recovery was 15.8 days, although 10% of donors required more than 30 days for self-reported complete recovery.[35] Most donors are able to return to routine activities 1 to 2 days after harvesting. In a study of related donors, an equivalent level of pain was reported by donors undergoing bone marrow harvesting and those receiving filgrastim for mobilization of PBSC.[49]

The usual volume harvested from healthy donors is approximately 10 to 15 mL of marrow per kilogram of recipient body weight to achieve the desired nucleated cell and $CD34^+$ cell doses. This results in an average blood loss of 800 to 1000 mL for donors providing for an adult recipient. The quantity of marrow harvested from autologous patients may be greater, reflecting previous chemotherapy given to these patients. Donors for pediatric recipients will lose proportionately less blood. Most patients and donors receive blood transfusions to alleviate symptoms of volume depletion. With proper preharvest autologous blood storage, use of homologous blood for healthy allogeneic donors should be extremely rare. For a blood loss of less than 10 mL/kg of donor weight, salt solutions are acceptable replacement. Colloid solutions, such as hydroxyethyl starch, also can be used to avoid homologous blood transfusion. Homologous blood transfusions must be irradiated to prevent transfusion-associated GVHD in the recipient. Donors undergoing second harvest shortly after the first harvest are more likely to require homologous blood.[50] Oral iron supplements should be considered for healthy donors.

Quantity of Bone Marrow Cells for Transplantation

Cell dose normally is used as a surrogate for the stem cell content of the marrow product because the definition of adequate HSC products predated the availability of flow cytometric analysis of HSC content, and nucleated cell counting is the only quality control measure easily performed during the collection procedure. For autologous transplantation, cell doses of 1×10^8 nucleated cells per kilogram are adequate. Based on early reports that smaller quantities increased the risk of engraftment failure, most centers target 3×10^8 nucleated cells per kilogram of recipient weight for allogeneic transplantation.[51] However, those early reports were of patients being treated for aplastic anemia, in which engraftment failure is a more common event. A study of 100 patients who received allogeneic transplantation for treatment of acute leukemia found that cell dose per kilogram of recipient body weight (range $0.5–13.0 \times 10^8$) did not predict the likelihood of successful engraftment.[52] A review of unrelated donor transplantation found that recipients of higher cell doses experienced faster neutrophil and platelet engraftment as well as better leukemia-free survival.[53] Pretreatment of the marrow donor with either sargramostim (granulocyte-macrophage colony-stimulating factor [GM-CSF]) or filgrastim (granulocyte-macrophage colony-stimulating factor [G-CSF]) may increase the number of myeloid progenitor cells harvested and decrease the period of post-transplant aplasia to that achievable by PBSC transplantation (see Table 108–2).[54] $CD34^+$ cell dose now is being correlated with transplant outcomes, with more rapid engraftment kinetics, possibly lower transplant-related mortality, and better overall survival, for example, in recipients of allogeneic products containing higher quantities of $CD34^+$ cells. This assay should be a routine component of bone marrow product quality control.[55–57]

COLLECTION OF UMBILICAL CORD BLOOD STEM CELLS FOR TRANSPLANTATION

Cord Blood Collection Techniques

UCB is collected from the placental vein after delivery of the infant and transection of the cord. UCB can be collected before delivery of the placenta by the obstetrician or by laboratory personnel after delivery of the placenta. Published reports conflict regarding the volume of UCB collected and the likelihood of obtaining a product inadequate for storage with either in utero or ex utero collection.[58–60] The timing of cord clamping after delivery of the infant is associated with the volume of cord blood collected. Greater volumes are collected with earlier clamping. UCB usually is collected by cannulation of the umbilical cord veins. Collection of cord blood into open containers has an unacceptable 12.5% rate of bacterial contamination,[61] and the collection techniques should be viewed as the first step in a manufacturing process with adequate quality control and improvement. However, successful "remote site" collection is feasible for parents intending to collect cells for family use.[62]

Many cord blood units are discarded because of small cell doses.[63] Investigators from the Madrid UCB Bank found that perfusion of the placenta with 50 mL of saline increased the numbers of nucleated cells collected from approximately 1×10^9 to 1.26×10^9, an increase of 15%.[64] A 36% increase was achieved by limiting the processing to UCB units of at least 0.8×10^9 nucleated cells, resulting in an average cell content of $1.46 \pm 0.52 \times 10^9$ nucleated cells. A pressure device applied to the placenta increased the yield of blood by an additional 14.3 ± 7.8 ml ($26.5\% \pm 15.1\%$).[65] Although an increase in nucleated cells was not observed, the later fractions contained increased proportions of $CD34^+$ cells, including $CD34^+CD38^-$ cells, which is considered a more immature phenotype. Whether perfusion of the placenta with cytokines or chemokines will affect the numbers or types of cells that can be collected for transplantation has not been reported.

Quantity of Cord Blood Cells for Transplantation

Cell dose is an important predictor of outcome after UCB transplantation. The importance of cell dose to transplant outcome is discussed in Chapter 106. Two studies of cell quantities in approximately 8000 and 1000 UCB units, respectively, found strong correlations between nucleated blood cells, colony-forming unit granulocyte-macrophage (CFU-GM), and $CD34^+$ cells contents.[66,67] Greater cell quantities were found for infants with greater birth weight, but no difference was found based on gender or gestational age. Ethnic background is important, with smaller quantities of cells collected from ethnic minorities compared to Caucasian ethnicity.[68] Many cord blood banks volume reduce the product by red cell and plasma depletion to minimize storage space for the many units to be stored and reduce possible infusion-related toxicities from mature blood cells contained in unfractioned cord blood units.[69] UCB will maintain viability for periods of at least 15 years if appropriately cryopreserved.[70]

COLLECTION OF PERIPHERAL BLOOD STEM CELLS FOR TRANSPLANTATION

Background

The presence of HSC in the peripheral circulation was suggested by animal studies as early as 1951.[71] Although the nature of the survival agent was not recognized at that time, parabiosis experiments dem-

onstrated that some factor in the blood of a healthy animal was able to rescue another animal from the effects of lethal irradiation. Subsequently, a number of animal models demonstrated the presence of HSC in the peripheral blood and the use of these cells to rescue animals from the marrow-lethal effects of radiation.[72,73] Experience in human PBSC transplantation began for patients with chronic myelogenous leukemia because of the high number of clonogenic cells circulating in the peripheral blood of those patients.[74] The concentration of HSC in the peripheral blood normally is very low. Thus, very large quantities of blood must be processed to collect a quantity of HSC equivalent to what could be collected in a bone marrow harvest. For this reason, PBSC transplantation initially was limited to a few centers that explored this source of HSC for patients who otherwise were ineligible for marrow harvesting. Some transplant centers used the transient increase in circulating HSC during recovery from marrow hypoplasia-producing chemotherapy.[75–77] Other centers collected cells from the patient or donor without any preceding perturbation of the host.[78–80] These early reports noted that engraftment could be faster after infusion of PBSC components compared to marrow cell transplantation. However, because of the occasionally limited quantity of HSC that was collected from the peripheral blood, the kinetics of engraftment for some patients was considerably slower (Table 108–3). Moreover, the desired quantity of cells could not be collected from a significant proportion of patients. The effective mobilization of HSC into the peripheral blood and the reliability of flow cytometric technique in assessing within hours the quality of the collection are the direct bases for the rapid and widespread adoption of PBSC as a source of HSC for transplantation.

Mobilization of Hematopoietic Stem Cells into Peripheral Blood

The discovery that administration of hematopoietic cytokines caused a transient increase (mobilization) of HSC in the peripheral blood enabled the collection of much greater numbers of PBSC for transplantation or to ensure quick recovery after repetitive cycles of nonmarrow-ablative chemotherapy.[2,81–83] No randomized studies comparing the engraftment of cytokine-mobilized HSC to those collected during steady state or after chemotherapy mobilization have been reported, although retrospective studies demonstrated much quicker engraftment of cytokine-mobilized HSC (see Table 108–3).[84] Cytokine-mobilized PBSC components contain much greater numbers of cells expressing the CD34 antigen ($CD34^+$ cells) that, along with myeloid progenitor cells grown in culture (CFU-GM), serve as surrogate markers for the engraftment capacity of the stem cell component. Whether it is merely the quantity of cells or some other characteristic imparted by chemotherapy or cytokine mobilization that accounts for the rapid engraftment cannot be stated with certainty. $CD34^+$ cells isolated from the peripheral blood have many characteristics different from those isolated from marrow,[85] and effective mobilization requires both an expansion in the number of cells as well as release of these cells from the marrow compartment. The mechanisms involved in mobilization of HSC into the peripheral blood with cytokine or chemokine administration are only now being elucidated.[86,87] Multiple adhesion molecules appear involved in the homing and tethering of HSC in the bone marrow. Disruption of stromal cell-derived factor-1 (SDF-1) and CXCR4 interaction appears to be a critical step in HSC mobilization by G-CSF (and new chemokine agents currently in development); proteinases released by neutrophils are one possible cause. The diversity of mobilizing agents, including chemotherapy, cytokines, and some chemokines, suggests a common mechanism of action despite the distinct targets of these agents.[88] However, the dose of $CD34^+$ cells infused predicts the kinetics of engraftment. Patient groups that receive higher quantities show a higher probability of quicker recovery of neutrophil and platelet counts.[89,90] Although most transplant centers probably will accept components containing at least 1×10^6 to 2×10^6 $CD34^+$ cells per kilogram of recipient weight, cell doses of 2.5×10^6 to 5×10^6 $CD34^+$ cells per kilogram are desirable, and quicker engraftment will be observed with even higher doses.[89,90] Administration of G-CSF after transplantation will further speed the recovery of granulocytes[91–93] but may have a detrimental affect on platelet engraftment in patients receiving components containing low numbers of $CD34^+$ cells.[89]

A variety of mobilization schemes have been developed for both patients and donors. Before the availability of hematopoietic cytokines, marrow hypoplasia-producing chemotherapy, such as that used as induction therapy for acute leukemia, was noted to result in a transient increase in the number of HSC circulating in the peripheral blood. A variety of transplant programs used this approach to obtain PBSC for patients with leukemia or other diagnoses. Juttner et al.[75] demonstrated rapid engraftment in patients receiving chemotherapy-mobilized PBSC (median 11 and 12 days to achieve an absolute neutrophil count ANC >500/μL and platelet count >50,000/μL) as long as the dose of CFU-GM exceeded 63.0×10^4/kg. The finding that the quantity of CFU-GM infused roughly correlated with the

speed or success of engraftment was also found by Fermand et al.[76] for chemotherapy-mobilized patients with multiple myeloma and by Brice et al.[77] for patients with non-Hodgkin lymphoma and Hodgkin lymphoma. However, Juttner et al.[75] also described a proportion of patients who received low doses of CFU-GM and experienced prolonged posttransplant aplasias or a secondary drop in blood counts 3 to 4 weeks after infusion. Moreover, some patients, mostly those with progressive disease, marrow infiltration, or extensive prior exposure to alkylating agents or radiation therapy, failed to exhibit this response to chemotherapy and had inadequate collections for transplantation.[77,94] The timing of apheresis was considered crucial, with maximal numbers of CFU-GM in the peripheral blood when leukocyte and platelet counts rose simultaneously during early recovery from chemotherapy.[95,96]

Administration of GM-CSF or G-CSF during recovery from chemotherapy subsequently was discovered to increase the numbers of circulating progenitor cells as much as 1000-fold higher than the level in the blood before treatment.[2,81–83] This finding started the exploration of efficacious mobilization regimens using hematopoietic cytokines, cytokine combinations, chemotherapy plus cytokines, or chemokines alone or in combination with cytokines.

Cytokine Mobilization

The ability of recombinant hematopoietic cytokines to increase the level of myeloid progenitor cells in the blood as well as mature blood cells was reported in 1988 by different groups for both G-CSF and GM-CSF.[82,83] Subsequently, a number of different investigators reported the collection of PBSC from patients after chemotherapy and GM-CSF or G-CSF mobilization.[4,81,97,98] Chemotherapy is not required to increase the numbers of HSC in the peripheral blood, and many patients and all donors are treated with hematopoietic cytokines alone. Various recombinant human hematopoietic cytokines, including fusion molecules, increase the quantity of $CD34^+$ cells in the peripheral blood (see Other Hematopoietic Cytokines below). few studies have directly compared cytokines with regard to their ability to mobilize $CD34^+$ cells. Furthermore, many of the single-arm cytokine studies were conducted in patient groups, and the effects of prior therapy on HSC mobilization is a confounding variable that hinders the comparison of these phase II studies.

Granulocyte Colony-Stimulating Factor

G-CSF is the cytokine most commonly used because of its efficacy compared to other cytokines and its relatively benign toxicity profile. Recombinant methionyl human G-CSF (filgrastim) and recombinant human G-CSF (lenograstim) are the two forms of this cytokine available for clinical use.[99] There is slight, if any, difference between these two cytokines in their ability to mobilize PBSC. Watts et al.[100] studied 20 healthy volunteers and found that peak levels of CFU-GM in the peripheral blood were 28% higher after treatment with the glycosylated molecule (lenograstim). Hogland et al.[101] found a similar comparative effect in 32 healthy male donors, with an average of 104 versus 82 $CD34^+$ cells per microliter of blood ($P < 0.0010$) on the fifth day of administration of either drug at a dose of 10 μg/kg/day. The glycosylated molecule has a higher specific activity that may account for this difference. De Arriba et al.[102] treated 30 women with breast cancer in a randomized study of these two drugs using dosages containing bioequivalent units of activity and found no difference in mobilization of $CD34^+$ cells. The two forms have otherwise similar biologic activity and are not further distinguished in this discussion.

Mobilization of Hematopoietic Stem Cells Using Granulocyte Colony-Stimulating Factor

G-CSF is the most potent cytokine currently available for mobilization of HSC. In a randomized study of healthy volunteers comparing G-CSF, GM-CSF, and the combination of both, Lane et al.[103] reported an average 0.99% $CD34^+$ cells in the peripheral blood of healthy donors treated with 10 μg/kg/day of G-CSF compared to 0.25% for donors treated with the same dose of GM-CSF. The quantity of $CD34^+$ cells in the peripheral blood before treatment averaged 1.6/μL. After GM-CSF treatment, the level increased to 3/μL, but with G-CSF, the level increased to 61/μL. Each group underwent one leukapheresis on the fifth day of treatment, and the collections from donors treated with G-CSF averaged 119×10^6 $CD34^+$ cells compared to 12.6×10^6 for the donors treated with GM-CSF.

The appearance of $CD34^+$ cells during administration of G-CSF follows a distinct time course, with the maximal level of $CD34^+$ cells occurring on day 5 after daily G-CSF administration.[104,105] Smaller numbers of $CD34^+$ are present on days 4 and 6, and the level falls rapidly on subsequent days despite a continual rise in white blood cell (WBC) count.

The number of $CD34^+$ cells collected after G-CSF treatment is proportional to the number of these cells in the peripheral blood before initiation of the cytokine.[17] Although doses as low as 5 μg/kg/day have been used for allogeneic PBSC transplantation,[106] there is a dose response to G-CSF, with higher average levels of $CD34^+$ cells achieved with 10 μg/kg/day compared to 5 μg/kg/day.[107] The average collection from one group of healthy donors treated with 10 μg/kg/day averaged 4×10^8 $CD34^+$ cells.[107] With this dose of G-CSF and appropriate apheresis technique, adequate numbers of $CD34^+$ cells can be collected in one procedure for transplantation of most patients. A similar dose response is observed in autologous patients and may extend to doses as high as 40 μg/kg/day.[108] Waller et al.[109] studied twice-daily administration of G-CSF to healthy donors and found greater yields of $CD34^+$ cells in the apheresis component. However, the total amount of G-CSF administered also was doubled, so whether the twice-daily administration or the higher dose is responsible for this finding is not clear. Anderlini et al.[110] compared administration of 6 μg/kg given twice daily to 12 μg/kg given once daily and found no differences in $CD34^+$ cells per liter of blood processed or the yield of $CD34^+$ cells per kilogram collected. In contrast, a second trial enrolling primarily pediatric subjects noted better results with the twice-daily schedule.[111] Patients, especially those previously treated with chemotherapy or radiotherapy, will generally have lower quantities of $CD34^+$ cells mobilized. However, previous treatment with chemotherapy does not preclude the use of G-CSF. De Luca et al.[112] noted a median 76-fold increase in CFU-GM in a population of 30 patients who previously had received extensive treatment for B-cell malignancies. Older donors have lower levels of $CD34^+$ cells mobilized into the peripheral blood after G-CSF administration.[113]

Lymphocytes are also increased in the peripheral blood.[114] Murine studies suggest that G-CSF priming changes the cytokine response of these cells,[115] may decrease the risk of acute GVHD,[116] and may increase the graft-versus-leukemia effect.[117] The potential influence of these changes in outcome of allogeneic (or autologous) transplantation is not clear.

Toxicity and Complications of Granulocyte Colony-Stimulating Factor

The toxicity of G-CSF has been most clearly defined in studies of allogeneic donors.[106,107,118,119] The autologous patient will experience a similar toxicity profile, but with the added complications of the underlying malignancy and its treatment.

Almost all recipients of G-CSF will develop somatic complaints, of which skeletal pain is most prominent (Table 108–4). The somatic complaints are generally tolerable, and few donors will require reduction in dose or discontinuation of the medicine. At present, there appear to be minimal, if any, long-term health risks for the donor. Few serious complications of the mobilization regimen and donation process have been reported.[120,121] Splenic rupture that occurred in a healthy donor appeared to be temporally related to the donation

Table 108–4 Incidence of Somatic Complaints for Normal Donors Treated with Granulocyte Colony-Stimulating Factor

process, and a small study of normal donors showed an average increase in spleen size of 1.1 cm.[122] Another donor with known coronary artery disease experienced a myocardial infarction after the first of two intended donations. A third donor died of a cerebrovascular accident several days after donation and discontinuation of the cytokine. Although filgrastim induces a hypercoagulable state, any relationship of these events to the donation process in these last two donors remains unclear because similar events have not been reported for autologous donors or others receiving these cytokines.[123,124] Patients with autoimmune disorders may experience a flare of their disease during administration of filgrastim.[125] A variety of case reports of ophthalmologic and other adverse events have been reported for healthy donors or patients treated with filgrastim.[126–129] Also of concern is the possibility that cytokine administration will increase the risk of marrow dysplasia or malignancy. Although this is a theoretical concern in that the cytokines used are known to stimulate growth of leukemia cells, no clinical evidence indicates that these agents will induce abnormalities in the hematopoietic cell. An increased risk of myelodysplasia or hematologic malignancies in either healthy donors or patients who have been treated with short courses of G-CSF has not been reported.

G-CSF administration results in a number of changes in blood counts and chemistries in addition to the coagulation factor changes.[107,118] Alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase levels increase, and the levels of blood urea nitrogen and bilirubin may decrease. The elevation in alkaline phosphatase level is primarily of bone origin; γ-glutamyl transferase levels remain normal. These abnormalities of serum chemistries resolve within 2 weeks after discontinuation of the medication. G-CSF administration also will result in a decrease in platelet count, especially if the cytokine is administered over 5–10 days.[107,119] WBC counts fall rapidly after discontinuation of G-CSF. In approximately 10% of donors, the WBC count may fall to abnormal levels (but generally will remain above 1000/μL), reaching a nadir 10 to 14 days after discontinuation of the cytokine before stabilizing at normal levels.

Granulocyte-Macrophage Colony-Stimulating Factor

Much of the early experience with the use of hematopoietic cytokines for mobilization of HSC involved GM-CSF and chemotherapy.[2,81,83] The increase in CFU-GM in the peripheral blood can increase by as much as 1000-fold in this setting.[2] For some patients, the combination of cyclophosphamide (CY) and GM-CSF is more effective than is mobilization with G-CSF alone.[130] GM-CSF is not as potent as G-CSF (see Granulocyte Colony-Stimulating Factor above). Haas et al.[131] treated 12 patients with 250 μg/m^2/day of GM-CSF and observed only an 8.5-fold increase in the number of CFU-GM in the peripheral blood (to median of 1347 CFU-GM/mL). As with G-CSF, there is a dose response in mobilization of PBSC with GM-CSF over a range from 0.3 to 20 μg/kg/day, without a plateau.[132] In this latter study, however, the average increase in CFU-GM in the blood at this highest dose level again was only 8.4-fold. In a randomized study comparing GM-CSF to G-CSF or both drugs used in sequence after chemotherapy administration, patients had faster recovery of counts, required less supportive care including transfusions, and achieved greater collections of CD34$^+$ cells if given one of the G-CSF–containing regimens.[133]

Administration of GM-CSF results in similar somatic complaints and hepatic function abnormalities reported after G-CSF administration.[134] In addition, 44% to 80% of patients experience fever, sometimes after each dose, and generalized or local skin reactions. Lieschke and Burgess[135] noted that doses greater than 20 μg/kg/day are poorly tolerated because of fluid retention, pleural and pericardial inflammation, and venous thrombosis. A "first-dose reaction" characterized by hypoxia and hypotension occurring within 3 hours of administration has been described for some recipients, especially after IV administration.[136]

Other Hematopoietic Cytokines

Recognition of the mobilization potential of G-CSF led many investigators to study other hematopoietic cytokines for their capacity to mobilize HSC into the peripheral blood. Used as single agents, these cytokines resulted in only an approximately 5- to 10-fold increase in circulating CFU-GM or CD34$^+$ cells. These cytokines are not currently used for HSC mobilization, and the mechanism(s) of HSC mobilization with these other cytokines is less well elucidated.

M-CSF: Few studies have investigated the efficacy of M-CSF in the mobilization of PBSC. In one study involving six patients with acute myelogenous leukemia (AML) treated with two cycles of consolidation therapy, no significant difference in the number of CFU-GM in the peripheral blood was observed after either cycle despite the addition of M-CSF at a dose of 8×10^6 U/day during the second.[137] Based on this experience, M-CSF likely does not have a major effect on the mobilization of HSC, but interpretation of this study is hindered by the facts that the study was not randomized, all patients received the cytokine only during the second consolidation cycle, and the chemotherapy regimens differed for the two consolidation cycles.

Erythropoietin: Recombinant human erythropoietin (Epo) has a mild mobilization effect. Pettengell et al.[138] treated 11 patients with malignant lymphoma with either 300 or 450 IU/kg thrice weekly for 2 weeks and found a 4.6-fold increase in CD34$^+$ cells. The peak level of these cells was found on days 5 to 8 of administration of this cytokine.

Interleukin-3: Interleukin (IL)-3 has been studied primarily as a component of sequential cytokine mobilization with either GM-CSF or G-CSF.[139–141] In the nonhuman primate treated with 33 μg/kg/day, IL-3 administration results in an approximately 12-fold increase in the number of circulating CFU-GM.[142] In contrast, Ganser et al.[139] treated patients who had advanced malignancies with 60 to 250 μg/m^2/day of IL-3 for 15 days and found minimal increase in circulating CFU-GM on day 8 and a decrease in some patients on day 15. Geissler et al.[141] reported similar findings.

PIXY 321: This fusion molecule of GM-CSF and IL-3 was studied by Bishop et al.[143] in 13 patients with malignant lymphoma in a phase I study involving doses ranging from 250 to 750 μg/m^2/day by continuous infusion. Peak levels of CFU-GM in the blood were found on days 4 to 6 of treatment. A mild increase in CFU-GM in the blood was observed, but no consistent increase in CD34$^+$ cells.

Stem Cell Factor: Most clinical studies of stem cell factor (SCF) report the use of this agent in combination with other cytokines (see Combinations of Cytokines below). Limited reports of use of SCF by itself are available. This cytokine appears to result in a dose-dependent 6- to 10-fold mobilization of CFU-GM.[144,145]

MOBILIZATION AND COLLECTION OF PBSC FOR AUTOLOGOUS TRANSPLANTATION

Four important considerations when prescribing a mobilization regimen for collection of PBSC for autologous transplantation are as follows. (a) A regimen of chemotherapy followed by G-CSF results in higher numbers of circulating $CD34^+$ cells than will be found with G-CSF alone. (b) The choice of chemotherapy (or cytokine alone mobilization) should be appropriate to the disease and stage of disease for the patient. (c) Each cycle of prior chemotherapy or previous treatment with radiotherapy will decrease the response to mobilization therapy. (d) Tumor infiltration of the marrow will increase the probability of circulating tumor cells and will decrease the response to mobilization therapy. With these considerations in mind, elective collection of PBSC either before extensive treatment or after a limited number of cycles of debulking chemotherapy should be considered. If tumor contamination is found, additional components can be collected after additional rounds of chemotherapy. The timing of apheresis after chemotherapy and G-CSF mobilization is best guided by measurement of the level of peripheral blood $CD34^+$ cells. Daily or every other day quantification of these cells can be initiated after the WBC count reaches 1000/μL. Patients with poor mobilization of $CD34^+$ cells should be considered for large-volume apheresis to reduce the costs associated with daily doses of G-CSF, laboratory testing, apheresis procedures, and cryopreservation. Patients who fail to mobilize often will have successful collections if given a 2-week drug holiday and then undergo mobilization with high-dose G-CSF without chemotherapy.

Considerable dose-dependent toxicity, including angioedema, urticaria, pruritus, and laryngospasm, presumably from degranulation of mast cells, has been observed.[146,147]

Combinations of Cytokines

The mechanisms by which any of these cytokines causes mobilization of PBSC is not known. Multiple mechanisms probably are involved, including both an effect on proliferation of HSC as well as release of these cells from the marrow. Therefore, it is conceivable that combining different cytokines could result in an additive or synergistic effect. Limited studies have been conducted to date, with considerable potential to explore different cytokines with variations in both dose and schedule.

G-CSF + GM-CSF: Addition of G-CSF to GM-CSF greatly increases the number of HSC mobilized. The converse is not true. Winters et al.[148] treated patients who had a variety of malignancies with regimens of GM-CSF or G-CSF (both at 5 μg/kg/day) to which the other cytokine was added at day 7 of treatment and both continued through day 12. A third group of patients received both cytokines (at 5 μg/kg/day) simultaneously throughout the treatment. Apheresis was conducted on days 5, 7, 11, and 13. Simultaneous use of both cytokines achieved much greater mobilization of CFU-GM on day 5 than either of cytokine used singly to that point. Addition of GM-CSF on day 7 resulted in greater numbers of CFU-GM collected in subsequent apheresis procedures than were collected on day 5, although the effect was not very great. In contrast, addition of G-CSF on day 7 to patients treated with GM-CSF resulted in a strong release of CFU-GM 4 days later. Ho et al similarly studied the administration of GM-CSF or G-CSF at doses of 10 μg/kg/day or of the two cytokines together at doses of 5 μg/kg/day each and found that G-CSF alone achieved greater mobilization than GM-CSF or both drugs given in combination at a lower dose.[149] Among healthy allogeneic donors, sequential combination of GM-CSF 10 μg/kg/day for 3 days followed by G-CSF 10 μg/kg/day for 2 to 3 days yielded superior $CD34^+$ cell collections compared to GM-CSF at the same dose or concurrent G-CSF and GM-CSF (both at 5 μg/kg/day).[150]

SCF + G-CSF: SCF by itself is a relatively weak mobilizing agent. Studies in dogs and baboons found that animals administered the combination of SCF and G-CSF had a 3.5- to 21.6-fold increase in progenitor cells in the blood.[151,152] The clinical effect has been much more modest. Moskowitz et al.[153] reported 38 patients with NHL randomized to SCF at 5 to 20 μg/kg/day plus G-CSF 10 μg/kg/day or to G-CSF alone. They found no difference between the cohorts with regard to mononuclear cells, $CD34^+$ cells, or CFU-GM contents of the components collected by apheresis. However, patients with extensive prior therapy had increased numbers of $CD34^+$ cells if given combination therapy, although the difference was not significant for this small number of patients. Begley et al.[154] conducted a similar phase I study of concurrent SCF and G-CSF in 62 women with early-stage breast cancer. In contrast, they found a significantly higher level of $CD34^+$ cells in the blood of recipients treated with G-CSF plus SCF at 10 or 15 μg/kg/day compared to G-CSF alone or in combination with SCF at 5 μg/kg dose. The duration of mobilization for patients given the combination therapy was much broader, with high levels of CFU-GM still released into the blood several days after discontinuation of the cytokines. Sequential therapy with SCF given 3 days before initiation of G-CSF was even more efficacious, but even for this cohort of patients the increase in $CD34^+$ cell levels averaged only twofold greater than for recipients of G-CSF alone. The combination of SCF and G-CSF also is effective after CY mobilization chemotherapy.[155] SCF plus G-CSF resulted in higher circulating CD34 counts on days 6 to 9 and a higher probability of collecting more than 2.5×10^6 CD34 per kilogram than G-CSF alone.[156] Side effects were mild flulike symptoms.

IL-3 + G-CSF: Geissler et al.[139] treated six patients with G-CSF at 5 μg/kg/day for 5 days, then a second course of IL-3 at a dose of 5 μg/kg/day for 7 days, followed by G-CSF again at a dose of 5 μg/kg/day for 5 days. They reported a 21-fold increase in CFU-GM in the peripheral blood after G-CSF alone, no increase after the course of IL-3, but a 56-fold increase after the combination. Peak levels of the progenitors in the blood were found on day 5 of G-CSF administration when given alone but on day 3 if the patient was first treated with IL-3.

IL-3 + GM-CSF: Brugger et al.[139] treated 32 patients with etoposide, ifosfamide or CY, and cisplatin. The chemotherapy was followed by GM-CSF for 15 days in one group, by IL-3 for 5 days and then GM-CSF for an additional 10 days in a second group, or with no cytokines for a third group. The dosages of the cytokines were not noted. The median peak numbers of $CD34^+$ cells per microliter in the blood were 46 for the patients who did not receive either cytokine. The median for patients treated with GM-CSF alone was 426 $CD34^+$ cells per microliter and for the group treated with both IL-3 and GM-CSF was 418 $CD34^+$ cells per microliter. The peak numbers of CFU-GM in the blood of the group receiving both cytokines was almost twofold greater than for the group treated with GM-CSF alone.

Epo + G-CSF: In a retrospective comparison, Olivieri et al.[157] studied the addition of Epo 50 U/kg/day to G-CSF 5 μg/kg/day after mobilization chemotherapy with CY, etoposide, or epirubicin. The experimental group consisted of 18 patients with a variety of malignancies. The control group included 16 patients who received G-CSF alone. The groups were matched for diagnosis, previous chemotherapy, disease status, and mobilization chemotherapy agent. Olivieri et al. found a 2.8-fold increase in the peak number of $CD34^+$ cells for the group that received both cytokines and a 1.7-fold increase in the number of $CD34^+$ cells collected during apheresis. A randomized study of 50 women with ovarian cancer treated with epirubicin, paclitaxel, and cisplatin with either G-CSF or G-CSF and Epo showed a reduced number of apheresis procedures and increased PBSC collection for patients treated with the combination.[158] In contrast, the combination of Epo plus G-CSF was not found to enhance $CD34^+$ cells in normal sibling donors and even may have been deleterious, with fewer total nucleated cells and CFU-GM collected compared to donors receiving G-CSF alone.[159]

Other Combinations: Compared to G-CSF alone, the combination of thrombopoietin and G-CSF yielded higher CD34+ cell doses (4.1 vs 0.8×10^6/kg) and thus fewer collections to meet the apheresis cell collection targets.[160] A limited pilot study of eight patients treated with chemotherapy followed by G-CSF with IL-11 demonstrated successful collection of CD34+ cells with a median of one apheresis procedure to collect the target dose of 5×10^6 CD34+ cells per kilogram.[161] The potential for chemokines in conjunction with cytokines is discussed below.

Chemotherapy Plus Cytokine Mobilization

The number of CFU-GM in the peripheral blood is greatly increased during the early hematologic recovery phase after marrow hypoplasia-producing chemotherapy.[6,75–77,94–96] A variety of chemotherapeutic regimens have been used for mobilization of PBSC, including DAT (daunorubicin, cytosine arabinoside, thioguanine),[6,75,96] high-dose CY,[94] low-dose CY,[162] (mitoguazone, ifosfamide, methotrexate, etoposide) MIME,[77] CAV (cyclophosphamide, adriamycin, vincristine),[76] DCEP (dexamethasone cyclophosphamide, etoposide, platinum),[163] and CY and etoposide.[164,165] To et al.[94] demonstrated a 14-fold increase of CFU-GM (compared to levels in healthy donors) in patients with non-Hodgkin lymphoma treated with a single dose of CY at 4 gm/m^2. However, only 69% of treatment courses achieve the desired mobilization of CFU-GM. As with any mobilization regimen, considerable variation between patients in their response to this treatment was observed.

Chemotherapy plus cytokine generally mobilizes greater numbers of PBSC than either agent alone.[166] Alegre et al.[130] compared the treatment of patients who had multiple myeloma with CY 4 g/m^2 followed by GM-CSF at 8 μg/k/day to a second group of patients treated with G-CSF alone at a dose of 10 μg/kg/day. Although G-CSF is the more potent mobilizing cytokine, the patients treated with chemotherapy plus GM-CSF achieved greater numbers of CD34+ cells per apheresis procedure, demonstrating the additive potential of chemotherapy mobilization. This finding was confirmed in a randomized study comparing CY followed by G-CSF versus G-CSF alone in which higher numbers of CD34 cells were found for the patients treated with the chemotherapy-based regimen.[167] However, no differences in the degree of tumor cell contamination of PBSC components, engraftment kinetics, or survival were found. In a randomized crossover design trial, Koc et al.[168] demonstrated that high-dose CY plus G-CSF resulted in mobilization of more progenitors than did GM-CSF plus G-CSF when tested in the same patient, regardless of sequence of administration. This trial suggests that patients who fail to mobilize with cytokine alone might be salvaged with chemotherapy-based mobilization but that the reverse might not be effective.

A wide variety of different chemotherapy regimens have been used successfully for mobilization of HSC into the blood. The primary consideration is that the choice of chemotherapy used must meet the treatment needs of the patient. However, evidence also indicates that the choice of chemotherapy regimens will affect the mobilization of HSC. Schwartzberg et al.[164] reported an average daily apheresis yield of 4.0×10^7 CD34+ cells in 395 apheresis components collected from 61 patients treated with CY and average yields of 8.3×10^7 CD34+ cells in 218 collections from 33 patients treated with both CY and etoposide. (Another group of 24 patients was treated with this latter chemotherapy regimen but also received 6 μg/kg/day of G-CSF. The average CD34+ cell contents for 122 collections from these patients were significantly higher at 38.8×10^7.) The average quantities of CFU-GM paralleled the numbers of CD34+ cells collected. Similarly, Demirer et al.[169] studied the effect of different chemotherapy regimens for mobilization of HSC for patients with breast cancer. Four regimens were used, all involving CY, but including etoposide with or without cisplatin, or paclitaxel. All patients also received G-CSF. The median quantity of CD34+ cells collected on the first day of apheresis after CY mobilization was 0.9×10^6 per kilogram of patient weight. The addition of etoposide and then of etoposide and cisplatin increased the yield to 8.1×10^6 and 3.5×10^6 CD34+ cells per kilogram, respectively. The median number of CD34+ cells harvested on the first day of apheresis after CY plus paclitaxel was 11.1×10^6/kg. More than 50% of the women mobilized with this last regimen achieved the target dose of CD34+ cells in one apheresis procedure. Of the 100 women studied, 94 achieved the target dose of greater than 5×10^6 CD34+ cells per kilogram. Only four patients failed to reach a lower but acceptable dose of 2.5×10^6 CD34+ cells per kilogram.

Chemokines

Chemokines (chemoattractant cytokines) are a family of approximately 40 related small proteins that influence leukocyte (and malignant cell) migration and function.[170,171] Chemokines with varying effects on different WBC populations have been identified, as have a number of chemokine receptors. The roles of chemokines and chemokine receptors in the trafficking of HSC into and from the bone marrow compartment are under active investigation.[172–178]

In a preclinical study, administration to both mice and rhesus monkeys of a modified CXC chemokine GRO-β after 4 days of G-CSF resulted in a fivefold increase in the number of circulating stem and progenitor cells compared to G-CSF alone, with a much shorter time course measured in hours.[179] Furthermore, more rapid recovery of hematopoietic function was observed for animals given similar quantities of cells collected after administration of the chemokine and cytokine combination.[179,180] IL-8, a related ligand for the CXCR2 receptor, mobilizes stem cells within 15 to 30 minutes of injection into mice,[181] which appears to involve increased matrix metalloproteinase-9 activity detectable immediately before the appearance of HSC in the peripheral circulation. Murine studies demonstrate a mobilizing effect of the chemokine SDF-1 and its receptor CXCR4 that can be blocked by neutralizing antibodies to either.[176] The bicyclam molecule AMD3100 disrupts SDF-1/CXCR4 binding and has been shown to result in mobilization of HSC in murine, canine, and nonhuman transplant models.[182–184]

Similar signaling pathways are used for mobilization and homing of normal and malignant hematopoietic cells. Although PBSC products collected after G-CSF mobilization generally contain fewer detectable tumor cells than does bone marrow harvested from the same patient, the effects of chemokine treatment on the degree of PBSC contamination and on disease relapse after autologous transplantation remain to be elucidated. Tavor et al.[185] demonstrated that acute myelogenous leukemia cells express CXCR4 in varying levels and that homing of primary human AML cells into NOD/SCID mice is CXCR4 dependent, similar to normal human stem cells. Similar studies of chemokine control on tumor cell growth, migration, and metastasis are being reported from a number of laboratories.

AMD3100

Clinical studies of HSC mobilization using AMD3100 with or without G-CSF priming are being reported in both healthy donors and patients undergoing autologous HSC transplantation. In a study involving normal volunteers, a single dose of AMD3100 was equal in mobilization to administration of a standard 5-day course of G-CSF.[186] However, a single dose of AMD3100 on day 5 of G-CSF administration resulted in a further 3.8-fold increase in circulating CD34+ cells (as well as B and T cells, which may be important in allogeneic transplantation). A nontransplant study of patients with either myeloma or non-Hodgkin lymphoma demonstrated a rapid increase in circulating WBC and CD34+ cells 4 and 6 hours after AMD3100 given at a dose of either 160 or 240 μg/kg.[187] CD34+ cells increased from a mean of 2.6 ± 0.7/μL to a mean of 16.2 ± 4.3/μL at 6 hours after injection. A subsequent crossover study compared collection from patients given a daily dose of G-CSF 10 μg/kg/day, with up to four apheresis procedures starting on day 4 of G-CSF

PHYSICIAN PRESCRIPTION FOR APHERESIS AND PBSC PROCESSING

The attending physician should be aware of apheresis and laboratory procedures in order to maximize the value of PBSC components. The choices of venous access, anticoagulant(s), blood volume processed, target dose of $CD34^+$ cells, and cryopreservation volumes can be individualized. Apheresis unit staff may ask for guidance regarding pain medications, concurrent medications, and blood transfusions (although it is advisable to avoid transfusion during the apheresis procedure because of citrate or other reactions and because changes in the hematocrit may affect the efficiency of the collection). Adequate numbers of $CD34^+$ cells can be collected for more than one cycle of chemotherapy. It is important to communicate with the cryopreservation facility if PBSC components will be used to support more than one cycle of chemotherapy or if DMSO toxicity is of concern. Current cytometric techniques for quantification of $CD34^+$ cells require at least 1 hour of processing, so it is generally not practical to prescribe the number of $CD34^+$ cells to be frozen in each bag. However, it is possible to divide the component into the number of bags equaling the number of anticipated infusions so that equal numbers of $CD34^+$ cells will be available for each.

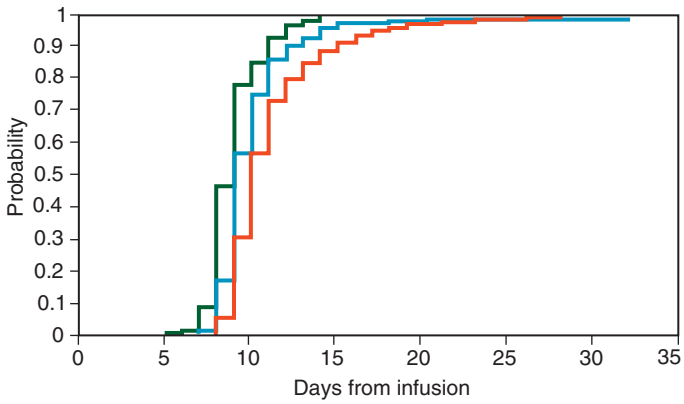

Figure 108–1 Kaplan-Meier probability of achieving $\geq 0.5 \times 10^9$ neutrophils/L for $< 5.0 \times 10^6$ (–), > 5.0 to 10.0×10^6 (..), and $> 10 \times 10^6$ (—) $CD34^+$ cells per kilogram ($P = 0.0001$). (From Weaver CH, Hazelton B, Birch R, et al: An analysis of engraftment kinetics as a function of the CD34 content of peripheral blood progenitor cell collections in 692 patients after the administration of myeloablative chemotherapy. Blood 86:3961, 1995.)

administration, followed, after a 2-week washout period, with a second attempt at PBSC collection after the same schedule and dose of G-CSF with AMD3100 160 to 240 μg/kg/day given on day 4 of cytokine administration and continuing daily until the target quantity of $CD34^+$ cells was met.[188] Of the 25 patients enrolled in the study, two with the highest quantities of $CD34^+$ cells mobilized by G-CSF showed nonsignificant (1.1-fold) increases in $CD34^+$ cells after treatment with the combination. Overall, however, the number of $CD34^+$ cells circulating in the blood increased a median of 2.9-fold. Fourteen of the 25 patients collected greater than 2.0×10^6 $CD34^+$ cells per kilogram on the first collection after the combination drug treatment compared to only five patients treated with the G-CSF mobilization cycle. A provocative finding of this study was the observation that nine patients who failed to reach the target goal of 2×10^6 $CD34^+$ cells per kilogram after four apheresis procedures using priming with G-CSF alone each met or exceeded this target after treatment with G-CSF in combination with AMD3100. This finding suggests that the combination decreases the interpatient variability seen with cytokine mobilization and may be a treatment option for patients treated with cytokines who fail to collect adequate quantities of PBSC for transplantation.

STRATEGIES FOR THE DIFFICULT TO MOBILIZE PATIENT

Most patients achieve the targeted dose of $CD34^+$ cells after processing of 20 to 30 L of blood in one to three apheresis procedures. However, approximately 5% to as many as 30% of patients in various series have inadequate collections because only small numbers of HSC are present in the peripheral blood despite the administration of hematopoietic cytokines. Different chemotherapy and cytokine regimens affect the mobilization of HSC (see Cytokine Mobilization). Patient-specific factors predictive of poor mobilization include older age, marrow disease, prior radiotherapy, and prior chemotherapy.[29,189–192] Specifically, previous administration of marrow-toxic drugs suppresses subsequent mobilization of HSC.[193–196] Approximately 50% of patients who fail to achieve the targeted dose of $CD34^+$ cells will achieve this goal on a second attempt.[197] High-dose (15 mg/kg bid) G-CSF after a 2- to 4-week drug holiday to allow marrow recovery is one strategy. Combination cytokine therapy is also of potential value in this situation, and the combination of SCF with G-CSF may be effective for patients who reside in countries where the former drug is available.[198,199] Initial experience with AMD3100 suggests that the agent may be effective when used in combination with G-CSF for collection of PBSC from patients who failed a prior mobilization attempt. Repetition of a chemotherapy plus cytokine regimen also will be effective but may be associated with increased toxicity.[192] Bone marrow can be harvested, but the poor mobilization of PBSC predicts for a poor marrow harvest,[200] although G-CSF administration before marrow harvesting may be effective in increasing the number of $CD34^+$ cells collected.[201,202] Consideration should be given to infusing a lower dose of $CD34^+$ cells (as low as 1×10^6 $CD34^+$ cells per kilogram) because, although the risk of delayed engraftment is incurred,[89,90] failure of engraftment has not been reported.[192,203]

Consideration should be given to collection of PBSC early in the course of treatment for patients who later may be candidates for autologous HSC transplantation but who are advised to receive multiple courses of therapy or therapy involving alkylating agents or radiation therapy. HSC can be collected and cryopreserved before extensive therapy while the patient has good marrow function and stored for years without obvious progressive loss of engraftment potential.[204]

DEFINITION OF ADEQUATE COMPONENT(S)

The quantity of $CD34^+$ cells in a PBSC component varies greatly and is dependent upon the number in the peripheral blood at the time of apheresis, the volume of blood processed, and the efficiency of the apheresis device. Therefore, any definition of an adequate component cannot include a set number of $CD34^+$ cells to be contained in any single apheresis component. Instead, one or more components will be collected to meet the appropriate dose of these cells for transplantation. The dose of $CD34^+$ cells required for infusion depends upon the intended treatment regimen. For marrow-ablative regimens, increasingly higher $CD34^+$ doses results in greater likelihood of rapid engraftment (Figs. 108–1 and 108–2).[89,90] Lower doses of $CD34^+$ cells appear satisfactory for nonablative regimens.[205–208] For example, Bokemeyer et al.[207] infused 1×10^6 $CD34^+$ cells per cycle for patients treated with high-dose ifosfamide and doxorubicin. Despite an overall doubling of the ifosfamide dose in this phase I study, the median times between cycles did not differ.

Many transplant programs have used quantification of hematopoietic progenitors by cell culture in an attempt to determine the adequacy of the bone marrow or PBSC collections for transplantation.[78,94,209] Based on delayed engraftment failure in some patients, Juttner et al [75] recommended a minimum CFU-GM dose of 6.3×10^5 per kilogram of recipient weight. Others have suggested lower doses of 2 to 5×10^5 CFU-GM per kilogram.[210] Patients who receive

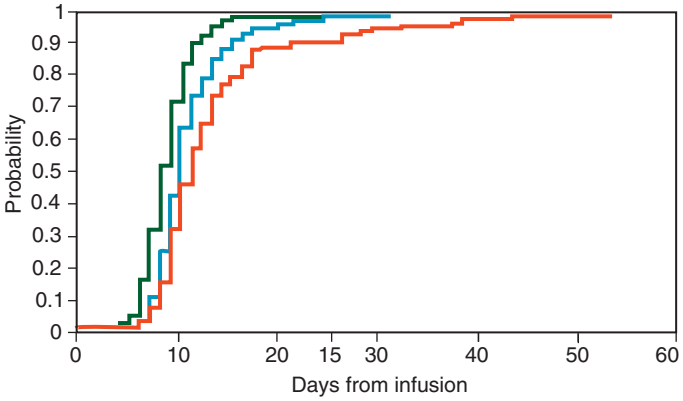

Figure 108–2 Kaplan-Meier probability of achieving ≥20.0 × 10^9 platelets/L for < 5.0 × 10^6 (–), > 5.0 to 10.0 × 10^6 (..), and > 10 × 10^6 (—) CD34⁺ cells per kilogram (P = 0.0001). (From Weaver CH, Hazelton B, Birch R, et al: An analysis of engraftment kinetics as a function of the CD34 content of peripheral blood progenitor cell collections in 692 patients after the administration of myeloablative chemotherapy. Blood 86:3961, 1995.)

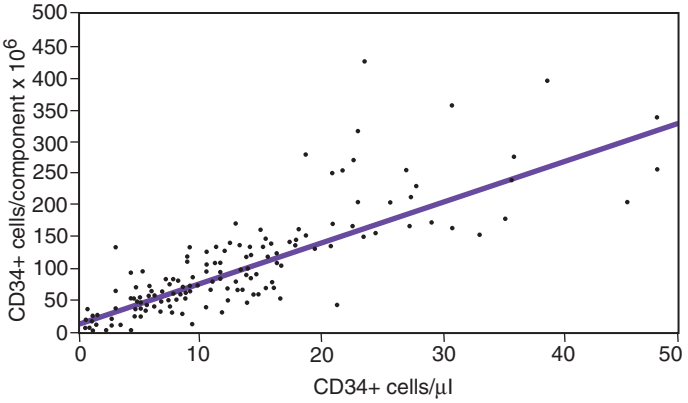

Figure 108–3 Relationship between quantity of CD34⁺ cells in the peripheral blood and number collected by apheresis using apheresis and flow cytometric techniques.[3,89,334] Data shown are limited to peripheral blood CD34⁺ cell numbers <50.0/μL (n = 157, r = 0.82, P < 0.001).

a dose of CD34⁺ cells (or CFU-GM) above a certain threshold will engraft. At lower doses of CD34⁺ cells there is considerable heterogeneity in engraftment speed, especially for platelet engraftment. Why this heterogeneity exists is not known, but it may reflect a weakness in the correlation between CD34⁺ cells and the cells responsible for engraftment or, more simply, a greater degree of error in the measurement of CD34⁺ cells at the lower cell concentrations. As the dose of CD34⁺ cells increases, the engraftment speed becomes more consistent for the population studied.[89,90] Several investigators showed more rapid granulocyte and platelet engraftment for recipients of products containing a quantity of CD34⁺ cells above a dose of approximately 2 to 3 × 10^6 per kilogram of recipient weight.[190,191,211] Investigators at the Fred Hutchinson Cancer Research Center found a threshold of 5 × 10^6 CD34⁺ cells per kilogram achieved reliably prompt platelet engraftment,[212] and studies that included large patient populations found that higher doses of CD34⁺ cells resulted in even higher proportions of patients achieving quick engraftment.[90] Investigators at the Hutchinson Center noted that the dose of CD34⁺ cells infused was more important than the type of mobilization therapy. In a study of allogeneic transplant recipients, Singhal et al.[213] reported higher transplant-related mortality for patients who received a CD34⁺ cell dose less than 2 × 10^6/kg, regardless of the source of HSC.

The incidence of acute GVHD does not appear to be proportionately greater after PBSC compared to bone marrow transplantation. However, one group reported, in retrospective analysis, greater risk of acute GVHD in recipients of cells from donors, with a greater response to PBSC mobilization.[214] Allogeneic transplant recipients may have a higher risk of chronic GVHD with higher CD34⁺ cell doses independent of the dose of T lymphocytes infused.[215]

TIMING OF APHERESIS

A major problem with chemotherapy-based mobilization regimens is the difficulty in determining the optimal time to commence HSC collection. Apheresis devices can collect only those CD34⁺ cells actually circulating in the peripheral blood. It is possible to estimate the quantity of CD34⁺ cells that will be collected during apheresis by multiplying the quantity of CD34⁺ cells in the blood by the total volume of blood processed during the apheresis procedure and by the efficiency of the apheresis device in collecting these cells. If the device has an efficiency of 50% and the patient undergoes a 10-L exchange, approximately 5 × 10^7 CD34⁺ cells will be collected for a peripheral blood level of 10 CD34⁺ cells per microliter and 5 × 10^8 CD34⁺ cells for a blood level of CD34⁺ cells that is 10-fold higher. Although many protocols call for initiation of apheresis after chemotherapy mobilization when the WBC count has recovered to greater than 1000/μL, there is a poor, if any, correlation between the peripheral blood white cell or mononuclear cell counts and the CD34⁺ cells in the peripheral blood. Characteristics that suggest a higher CD34⁺ cell level are rapidly rising WBC count, shift in differential to immature myeloid cells, circulating nucleated red cells, and platelet transfusion independence. These features may be more valuable in a homogeneous patient population receiving a uniform mobilization regimen.[216] However, it is much more cost effective to obtain an actual measurement of CD34⁺ cells in the blood and to time the apheresis collection when these cells are present in adequate numbers. The published experience from many transplant centers describes a correlation between CD34⁺ cells in the peripheral blood and in the harvested component.[190,211,217,218] Figure 108–3 shows such a relationship for patients with lower concentrations of CD34⁺ cells in the peripheral blood and illustrates the very poor collections obtained when the peripheral blood CD34⁺ count is less than 10/μL. Although there is considerable error in the enumeration of CD34⁺ cells at levels less than 5/μL, these finding is not clinically relevant because even doubling the CD34⁺ cells in this low range still results in a very poor apheresis yield.

The level of CD34⁺ cells in the peripheral blood at which to start apheresis is a clinical decision. Although levels in the range from 50–100/μL or greater will reduce the number of apheresis procedures necessary to achieve a target goal of CD34⁺ cells, each day's delay in initiating apheresis incurs the costs of additional cytokine administration and blood testing. In some patients who previously had undergone extensive treatment and who may show a slowly rising WBC count, multiple apheresis procedures may be necessary to achieve the target goal. No patient should undergo apheresis if the peripheral blood count is less than 5/μL (see Fig. 108–3). For patients with CD34⁺ cell counts in the range from 10/μL to 20/μL, it is possible to process more blood per day using large-volume leukapheresis (LVL) techniques and thereby reduce the numbers of days the patients is required to return to the apheresis unit. Most patients have a rising CD34⁺ cell count in the peripheral blood, so starting apheresis the day after the patient has achieved a desirable CD34⁺ level generally is feasible.[218]

The timing of apheresis after G-CSF mobilization differs from the timing after chemotherapy and cytokine mobilization. For both patients and healthy donors, the peak concentration of CD34⁺ cells occurs on day 5 of G-CSF administration (after four daily doses).[104,105] Lower levels are present on day 4, and the concentration continues to fall after day 6 even if cytokine administration is continued and despite a continued rise in WBC count. Thus, PBSC collection should be initiated on day 4 or 5 of G-CSF administration. The kinetics of CD34⁺ cells in the peripheral blood for patients and donors mobilized with G-CSF alone are so reliable that monitoring of peripheral blood levels is not necessary unless there is concern that

MANAGEMENT OF PATIENTS WHO FAIL INITIAL HSC COLLECTION

Patients donating cells for autologous use are much more likely than are healthy donors to fail collection because of marrow infiltration by tumor and the HSC-toxic effects of previous chemotherapy and radiotherapy. Patients who fail initial collection attempts frequently will fail subsequent attempts, and transplantation of these patients may require use of below optimal quantities of cells with resulting delayed or incomplete hematologic recovery. A healthy donor who does not meet the target goal of PBSC can undergo bone marrow harvesting. Patients who fail an initial attempt of PBSC collection using filgrastim can undergo another attempt, preferably after a brief 1- to 2-week holiday and, possibly, with use of cyclophosphamide- or ifosfamide-based mobilizing chemotherapy. Higher doses of filgrastim (>20 μg/kg/day) given in a twice-daily schedule may be more effective. If clinically available, combinations of filgrastim and SCF may be effective. Other cytokine combinations such as filgrastim and sargramostim do not appear more effective than filgrastim alone. The combination of filgrastim with a chemokine agent is promising in early trials, and these agents are expected to be clinically available in the near future. Bone marrow collection can be attempted for patients who fail PBSC collection, and treatment of patients with filgrastim may result in a higher $CD34^+$ cell content. Bone marrow collection of patients should be delayed until the platelet count has increased to greater 100,000/μL after prior chemotherapy.

the patient has failed to mobilize cells and it is practical to obtain the cell count rapidly enough to initiate apheresis on the same day.

Apheresis Technology

Apheresis technology is widely used for collection of platelets from healthy donors and is considered to be without major risk to the donor. The important safety considerations for PBSC collection are the same as for platelet collection and include the venous access to be used for the procedure, the extracorporeal volume of blood during the procedure, and the solutions administered to the donor. Of note, however, PBSC collection for autologous transplantation involves patients with underlying medical conditions who may require considerable nursing care during the procedure. In a retrospective review of more than 5000 plasmapheresis procedures in 627 patients for treatment of a variety of diseases, complications of apheresis were observed in 12% of procedures, and 40% of patients experienced at least patients one complication during a course of therapy.[219] Most of the complications were mild and transient, such as fever, chills, urticaria, hypotension, and reactions to citrate anticoagulants. In contrast, patients and donors undergoing PBSC collection do not require the replacement fluids used during plasmapheresis and will not experience the toxicities associated with plasma protein infusions. However, rare anaphylactic reactions may occur in pediatric patients who require blood priming of the extracorporeal circuit, in patients treated with angiotensin-converting enzyme inhibitors with use of albumin priming solutions,[220] or those allergic to ethylene oxide used to sterilize the apheresis disposable set.[221] Goldberg et al.[222] studied the complications occurring during 554 PBSC collections from 75 consecutive patients. Patient diagnoses and the mobilization treatment regimens were varied. All but one patient had subclavian or jugular venous system catheters placed for apheresis. A median of nine collections per patient was performed using a discontinuous flow apheresis device. The most common problems were related to the venous catheters; 50% of patients developed at least one occlusion. Hypocalcemia occurred in 14.6% of patients and hypotension in 13.3%. Sixteen percent of patients experienced infectious complications during the PBSC collection period.

Staffing of the apheresis unit should be appropriate for the medical condition of the patients undergoing apheresis. Staffing must include nurses familiar with the care of the oncologic patient who may be recovering from marrow hypoplasia complicated by neutropenic fever requiring multiple medications and with the care of a central line. Collection of PBSC by apheresis performed in the outpatient setting should never be assumed to be a safer alternative for the healthy donor or patient with a comorbid illness than marrow harvesting conducted in the intensive care setting of the operating room without careful review of the medical support requirements for the individual patient or donor.

Venous Access

Adequate venous access is required for optimal apheresis technique. Continuous-flow apheresis devices require two-lumen access with a stable blood flow capacity generally greater than 20 mL/min. Single-lumen access may be used with discontinuous-flow apheresis devices, although at a much slower rate of blood processing. The great majority (≈90%) of adult allogeneic PBSC donors have adequate arm veins for the procedure to be conducted "vein to vein." Some allogeneic donors, especially those with small veins and undergoing several daily procedures, may require placement of a temporary venous catheter. Venous access for the patient undergoing collection for autologous PBSC transplantation is much more heterogeneous. Vein-to-vein procedures can be performed, even on several consecutive days, with proper phlebotomy technique and postcollection care of the phlebotomy site. Most patients received previous chemotherapy or are proceeding directly to transplantation, conditions for which tunneled access is commonly placed. Ideally, this venous access should be appropriate both for the apheresis procedures and the subsequent transplant. Length, lumen size, and wall stiffness all affect the blood flow that can be achieved through a catheter. For this reason, the commonly used dual-lumen Hickman or Broviac catheters usually are unsuitable for apheresis as are all subcutaneously placed ports.[223] Most triple-lumen catheters are inadequate because of the small lumen size. If such access is already in place, consideration can be given to replacement with a shorter, stiffer tunneled catheter or to placement of a temporary percutaneous dialysis/apheresis catheter.[224,225] The catheters designed for dialysis and apheresis have adequate wall thickness to prevent collapse during aspiration of blood as well as a tip design that decreases local recirculation of blood and the resulting decrease in apheresis efficiency. Catheters of 10 F or larger size are appropriate for adult patients. Pediatric patients whose blood flow rates are considerably slower may use catheter sizes of 5 to 7 F.[226]

Problems directly related to venous access account for a considerable amount of the toxicity associated with PBSC collection. Mobilization with GM-CSF has been suggested to increase the incidence of catheter occlusion.[227] Haird et al.[228] suggested that catheters placed in the subclavian vein in particular were associated with a high incidence of thrombosis, a complication seen less frequently with translumbar inferior vena cava placement. Goldman et al.[222] reported this complication in 50% of patients. In contrast, Alegre et al. reported an only 1.8% incidence of thrombosis or clotting of catheters,[224] possibly because of differences in cytokine or catheter type and care. Catheter thromboses are easily managed with streptokinase, urokinase, or recombinant tissue plasminogen activator instillation by the apheresis unit staff. One randomized study reported that low doses of warfarin decreased the incidence of venous thrombosis associated with indwelling catheters, but this study did not address catheter patency, nor were the patients enrolled in this study treated with hematopoietic cytokines.[229] Consultation with apheresis unit staff about venous access for an individual patient is appropriate. For example, for patients with adequate peripheral veins, a needle can be placed in one arm of the patient for blood draw with simultaneous use of both lumens of a tunneled catheter for return of the blood, thereby avoiding the need for placement of another venous access device.

Apheresis Devices

A number of apheresis devices are available for separating HSC from the peripheral blood. The devices may be classified as continuous flow (e.g., Fenwal CS3000, COBE Spectra, Fresenius AS104) or discontinuous flow (e.g., Haemonetics family of equipment). Discontinuous-flow devices have the advantage of requiring only a single venous access. Continuous-flow devices require two access lines for aspiration and return of blood, but they process much larger volumes of blood in a shorter period of time. Devices now available enrich the HSC-containing mononuclear cell fraction, reducing the quantities of granulocytes and platelets collected that may interfere with cryopreservation or other laboratory processing.

All apheresis devices collect HSC. The choice of apheresis device used by the collection center depends primarily on the needs and experience of the center. The CS3000 achieves a greater enrichment of mononuclear cells than does the COBE Spectra,[230] reducing the number of granulocytes in the component, but without a difference in the collection efficiency for $CD34^+$ cells. In contrast, the Spectra allows a much higher blood-to-anticoagulant ratio because additional anticoagulant solution can be added to the collect bag at the initiation of the procedure, thereby avoiding much of the citrate toxicity that may occur with processing large volumes of blood during PBSC collection.[231] Continuous-flow devices are more efficient in the collection of PBSC and are preferred over discontinuous-flow devices. In a randomized study comparing the Haemonetics MCS-3P with the COBE Spectra, Morton et al.[232] found that the latter device processed significantly more blood in a shorter period of time and collected over twice as many $CD34^+$ cells and CFU-GM.

Anticoagulation

Anticoagulants are added to the blood during apheresis to prevent clotting of the extracorporeal circuit and clumping of cells in the component. Citrate anticoagulants have a proven record of safety in the apheresis of healthy platelet donors and are used extensively for collection of PBSC. The major drawback is the risk of a symptomatic decrease in the level of ionized calcium ("citrate toxicity"), especially during processing of large volumes of blood.[233,234] Citrate ions chelate calcium ions (and other divalent cations such as magnesium), making them unavailable for Ca^{2+}-dependent metabolic reactions. ACD-A contains 10.67 g of citrate per 500-mL volume in the form of trisodium citrate and citric acid. Citrate is diffused throughout the extravascular space, and this diffusion probably is the first defense against citrate toxicity. Metabolism by liver, kidney, and muscle also reduces the concentration of citrate. Metabolism of citrate becomes more important during prolonged apheresis procedures such as LVL. The initial signs of citrate toxicity include circumoral or acral paresthesias and may progress to nausea, vomiting, loss of consciousness, tetany, and seizures. Fatal cardiac dysrhythmias have been reported (rarely) for patients undergoing plasmapheresis.[235] Citrate infusions may depress myocardial function, and it has been suggested that this effect may be worsened by the use of calcium channel-blocking medications, although reports of such complications in patients or donors undergoing apheresis have not been published.[233] Because pediatric patients may not be able to relate the initial symptoms of the condition, citrate toxicity should be considered as the cause of any change of behavior, such as crying, during the apheresis procedure. Citrate toxicity is prevented by limiting the quantity of citrate infused either by decreasing the blood flow rate through the apheresis device or changing the blood to citrate ratio. For example, the COBE Spectra limits the blood flow rate so that the amount of citrate infused is a maximum of 1.1 ml/min/L of patient blood volume as calculated from the patient's gender and size. However, these machine parameters do not account for alterations in electrolytes, plasma protein levels, muscle mass, or renal or hepatic function that may occur in patients receiving chemotherapy. The processing of blood of patients experiencing the initial symptoms of citrate toxicity should be temporarily halted until the symptoms abate and then resumed at a slower rate. The benefit of oral calcium supplements for these patients is not certain. Heparin can be used as a replacement for some or all of the citrate, although additional citrate is added to the component bag to prevent clumping of platelets.[3,236] Some centers that use citrate anticoagulants also administer intermittent or continuous infusions of calcium gluconate during the procedure, especially if large volumes of blood are being processed.[237,208] However, excessive calcium replacement can induce cardiac dysfunction.[233] "Point of care" devices that measure the ionized calcium within minutes are available and greatly simplify obtaining this test.[238,239]

Large-Volume Leukapheresis

The apheresis device has a uniform and fairly reproducible efficiency of collection. Thus, for a consistent quantity of blood processed through the machine, the quantity of $CD34^+$ cells collected is directly related to the number present in the peripheral blood. Greater quantities of $CD34^+$ cells can be collected by increasing the number of these cells in the peripheral circulation or by increasing the volume of blood processed by the device. For patients with lower $CD34^+$ cell levels, multiple apheresis procedures will be required to achieve the target dose of $CD34^+$ cells needed for transplantation. An alternate approach is to process the same total quantity of blood but in fewer, longer procedures. LVL is not standardly defined but in general usage refers to processing of more than two or three times the patient's blood volume.[239–248] Typically, the quantity of blood processed is six or more times the patient's blood volume, often 25 to 36 L of blood. The advantage of LVL is that it reduces the number of days of cytokine administration and apheresis, with associated reduced costs of laboratory processing and testing. The apheresis techniques are the same as those used for processing of smaller volumes of blood, although blood flow rates may be increased to reduce the time required. The risks of LVL are the increased time required and the higher risk of citrate (or other anticoagulant) toxicity. Patients will also incur a proportional drop in platelet counts and may become profoundly thrombocytopenic.

Most reports of LVL describe the collection of more $CD34^+$ cells than are calculated to be present in the peripheral blood at the initiation of the apheresis procedure. Release of cells from the marrow replaces those cells removed by apheresis. Apheresis of $CD34^+$ cells is a three-compartment system consisting of the extracorporeal circuit of the apheresis device (including the collection bag), the peripheral blood, and the marrow. However, it is not obvious that the apheresis technique itself consistently "mobilizes" $CD34^+$ cells, as suggested by some reports. Initial investigation of LVL in dog and rhesus monkey models and in human patients and healthy donors not receiving cytokine mobilization demonstrated an increased number of CFU-GM collected such that a doubling of these cells in the circulation must have occurred during the apheresis procedure.[242,245,249,250] The experience with patients and donors treated with cytokines or chemotherapy plus cytokine is much more variable, with reports describing an increase,[241,242,244,245] no change,[239,247,248] or even an exhaustion of $CD34^+$ cells from the peripheral blood.[247,251] Animals receiving hematopoietic cytokine stimulation have a diminished apheresis-associated increase in circulating CFU-GM compared to animals collected without any mobilization treatment.[250] This increase also may not be evident in patients with subsequent poor marrow function because they previously had received extensive treatment with chemotherapy.[246]

Clinically most important is the possibility of exhaustion of HSC such that the processing of large blood volumes exposes the patient to the risks of anticoagulant toxicity and thrombocytopenia without achieving an increased collection of HSC. However, studies at the Fred Hutchinson Cancer Research Center demonstrated continuous release of $CD34^+$ cells from the marrow (and, presumably, return to the marrow space).[231] Patients having higher levels of $CD34^+$ cells in the peripheral blood appeared to have a greater number of these cells circulating between the marrow and peripheral blood compartments (Table 108–5). In this model the apheresis device merely serves as a

Table 108–5 Replenishment of CD34⁺ Cells During Large-Volume Leukapheresis

	CD34⁺ Cells				
UPN	*Blood (per μL)*	*Blood Total*	*Harvest Total*	*Released Total*	*Released (per min)*
10605	6.8	34.9	123.5	88.6	0.3
10698	15.6	603.3	1438.1	540.8	2.1
10849	30.7	109.7	211.1	62.6	0.3
10920	37.9	214.2	952.8	57.0	1.6
11128	66.1	280.6	1010.8	532.7	1.9

Shown are numbers of CD34⁺ cells in the peripheral blood or apheresis component for five patients with acute myelogenous leukemia or multiple myeloma undergoing large-volume leukapheresis after granulocyte colony-stimulating factor (G-CSF) or chemotherapy plus G-CSF mobilization treatment. Blood volumes processed were six times the calculated blood volume of the patient. Peripheral blood stem cell collection was performed on the COBE Spectra as previously described.[3] The total number of CD34⁺ cells in the blood (third column) was calculated from the level of CD34⁺ cells in the blood and the estimated blood volume of the patient. The total number of CD34⁺ cells released (fifth column) was calculated from the total number in the apheresis component and the number in the peripheral blood after collection minus the total number in the peripheral blood at the start of the collection procedure. All CD34⁺ cells quantities (except blood levels reported per μL) are $\times 10^6$.

Full data are given in Rowley et al.[231]

siphon, removing these cells from the blood as they are released from the marrow. If this description of CD34⁺ cell kinetics is accurate, it may be possible to deplete these cells from the blood and marrow by prolonged processing, but probably only if limited numbers of these cells are present in the marrow compartment. Also, the model suggests that higher blood flow rates used to shorten the apheresis procedure may be counterproductive for patients with low CD34⁺ cell levels in the blood because of the slower rate of release of CD34⁺ cells in these patients.

The explanation for the increase in CFU-GM circulating in the peripheral blood during the procedure reported by some investigators is obscure. Murea et al.[244] suggested that this phenomenon may be related to a decrease in divalent cations resulting from the citrate anticoagulant. Divalent cations are necessary for the function of some but not all cell adhesion molecules.[252] A progressive decrease in ionized calcium levels in some patients during the prolonged LVL procedure could result in an increase in circulating HSC. This may explain why some investigators using heparin-containing anticoagulation solutions or concomitant infusion of calcium solutions have not observed this phenonmenon.[247,248,251]

LVL is appropriate management for the patient or donor who needs to complete apheresis in a limited number of procedures. The quality of the component collected by LVL does not differ from that collected by the processing of smaller volumes of blood, and patients experience the same rapid kinetics of engraftment after infusion of these components.[244]

PEDIATRIC DONORS AND PATIENTS

PBSC can be collected from pediatric patients, including infants. The special challenges of the pediatric patient arise from the fixed extracorporeal blood volume of the apheresis device, the need for venous catheters for blood access, and the management of a patient who may be unwilling or unable to rest quietly for the period of apheresis. It is especially important in management of the pediatric patient that timing of apheresis be optimal to minimize the number of procedures required to achieve the desired quantity of PBSC. Given these considerations, a number of centers have reported successful collection of PBSC from pediatric patients and donors.[208,236,251,253–260]

Almost all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected, although older patients(>12 years) may tolerate vein-to-vein procedures. The whole blood flow rate for the pediatric patient is much reduced compared to adult patients, and catheters as small as 5 F may be adequate.[226] Some centers have used arterial catheters for blood access.[256]

Appropriate management of fluid balance during the apheresis procedure is critical for the smaller patient. The volume of red blood cells contained in the extracorporeal circuit of continuous flow apheresis device could represent 30% to 50% of the red cell mass of a pediatric donor. Although discontinuous-flow devices are appealing because of the feasibility of performing apheresis with a single-lumen venous access, they may result in even higher extracorporeal volumes and should be avoided in the smallest patients. The obvious solution to this problem is to prime the apheresis device with ABO-compatible, irradiated, red blood cells (leukocyte-depleted and cytomegalovirus-negative blood may also be desirable) when the blood in the extracorporeal circuit is expected to exceed 15% of the patient's blood volume. Packed red blood cell units can be diluted with saline or albumin to reduce the loss of this plasma protein that may occur. The red cells remaining in the extracorporeal circuit at the completion of the run need not be returned ("rinse-back"),[261–263] although if performed slowly with monitoring of vital signs, rinse-back may actually increase the hematocrit after the procedure and otherwise reduce the need for red cell transfusions for these patients. Körbling et al.[258] collected and stored the red cells remaining in the machine after the first day's apheresis for use in priming for the second day's procedure for allogeneic donors requiring 2 days of apheresis, thereby avoiding the use of homologous blood transfusion. For the intermediate-size pediatric patient (weight 25–50 kg), the apheresis device can be primed with a 5% albumin solution. This steep will reduce the albumin loss that otherwise would occur. However, clotting proteins and other proteins not contained in this solution may decrease with repetitive apheresis.

The pediatric patient may not exhibit or relate the prodromal symptoms associated with citrate toxicity. Continuous calcium gluconate infusion can be incorporated into the procedure, or heparin can be added to the citrate anticoagulant solution or used as the sole anticoagulant.[3,243,244,251] Some centers report the use of sedating medications, such as chloral hydrate, during the procedure.[254,208,258] Sedation of the pediatric patient is not necessary, however,[253,257,260] and hinders the ability to recognize the symptoms of citrate toxicity. (Some patients may require antihistamine premedication if the apheresis device is primed with red blood cells.) Centers routinely performing pediatric PBSC collection should design an environment conducive to the management of pediatric patients and develop support procedures that recognize the unique physical and cognitive features of pediatric patients.[264]

The range in blood volumes for pediatric donors of differing ages is greater than for adult donors. Therefore, most centers set a goal for volume processed based on the individual's blood volume instead of a set volume (e.g., two blood volumes vs 6 L of blood) for all patients. The pediatric patient may undergo LVL to achieve the target goal of HSC with fewer procedures.[251,259] Blood flow rates for pediatric patients are slower than for adults to minimize the risk of citrate reaction. As with adults, the timing of apheresis can be optimized by monitoring the quantity of CD34⁺ cells in the peripheral blood.[265]

ALLOGENEIC DONORS

Multiple centers have reported their experience with the use of PBSC for syngeneic or allogeneic HSC transplantation.[12–22,266] These reports consistently describe more rapid engraftment kinetics than observed with marrow transplantation (see Table 108–2). The incidence of acute GVHD appears to be equivalent to that after marrow transplantation despite the 10-fold higher number of T lymphocytes infused.[12,13] However, chronic GVHD may be more common after PBSC transplantation, or it may be more difficult to control.[31–33] The differing reports about acute and chronic GVHD may reflect the GVHD prophylactic regimens used in these clinical trials. The

reports of improved survival of patients who undergo PBSC transplantation similarly may be particular to transplant regimens or patient selection.[20] Peripheral blood mononuclear cell components collected from donors either with or without treatment with G-CSF also are effective in the immunotherapy of patients with progressive disease after allogeneic transplantation.[267–269]

The apheresis procedure is well tolerated by the allogeneic PBSC donor. In contrast to the collection of PBSC intended for autologous transplantation, the collection for allogeneic transplantation usually is performed on a healthy donor. Almost all allogeneic donors are treated with G-CSF for mobilization of PBSC, and the toxicities incurred with the use of this cytokine are discussed in the section above (cytokine mobilization). Adverse events associated, at least temporally, with the collection procedure include myocardial infarction, cerebral vascular accident, and rupture of the spleen.[121–129] Anderlini et al.[120] suggested that G-CSF specifically not be administered to patients with a history of inflammatory ocular disorders, venous thrombosis, autoimmune disorders, or malignancy treated with chemoradiotherapy. In an interim analysis of an ongoing study of healthy donors receiving one of two different doses of G-CSF, Beelen et al.[270] reported 478 acute adverse events for the first 150 donors enrolled. Most (80%) of these adverse events were transient bone pain or headache, and no persistent hematologic or nonhematologic events were recorded. The discomfort of PBSC donation measured using open-ended pain scales is rated as equivalent to that experienced by marrow donors enrolled in a randomized trial comparing marrow to PBSC transplantation, although the PBSC donor reports more rapid resolution of symptoms.[49] Similar findings regarding pain and comparable high levels of anxiety were reported for a subset of donors enrolled in a separate trial comparing marrow to PBSC donation.[271] However, Switzer et al.[272] conducted for the National Marrow Donor Program a retrospective analysis of donor experiences for donors who underwent PBSC donation after a prior bone marrow donation. They reported that donors found the marrow harvest procedure physically more difficult, time consuming, and inconvenient. The risks to the allogeneic PBSC donor conferred by apheresis should not differ greatly from the risks to the platelet donor if the apheresis techniques are similar, although the PBSC donor may undergo larger volume and repetitive exchanges with different anticoagulants compared to the platelet donor. The risk of larger-volume exchange is citrate toxicity if the donor is small or if the blood flow rate is increased to achieve this volume in a shorter period of time. Also, larger-volume and repetitive exchanges will result in platelet depletion, although the platelets can be separated from the component for infusion back to the donor.[107,118] The platelet count may reach its nadir several days after completion of the apheresis collections and discontinuation of G-CSF, and donors should be counseled in this regard.[107,119]

Most donations can be obtained using a vein-to-vein procedure. Some donors, especially pediatric donors, may require placement of a temporary central venous catheter. The risks of catheter placement are well known and are not discussed here.

Older donors will have more underlying medical conditions,[273] and the risks to the donor with underlying health problems must be fully considered before subjecting the donor to mobilization and apheresis. Published standards describe evaluation of the donor for the risk of the donation process as well as the risk of transmission of disease to the recipient.[274,275] Collection of PBSC is generally an outpatient procedure conducted in the clinic setting. In contrast, marrow harvesting has the luxury of the intensive support capability of the operating room. PBSC collection should never be viewed as a safer alternative to marrow harvesting for the donor with underlying health problems.

Management of Red Blood Cell Incompatibility

Management of red blood cell incompatibility between the PBSC donor and recipient is the same as for bone marrow transplantation.[276] Marrow processing to reduce the quantity of red cells and careful transfusion practices are used to prevent acute or delayed hemolytic transfusion reactions from infusion of incompatible red blood cells or immunocompetent B lymphocytes. Eventually, recipient red cells and isoagglutinins are replaced by donor type. Red cell incompatibility is classified into two categories: one in which the recipient has antibodies directed against donor red cells with the potential for acute hemolysis upon infusion of the component (major incompatibility), and one in which the donor has antibodies against the recipient. Although the latter rarely causes difficulty during infusion of incompatible plasma, B lymphocytes carried in the component can form isoagglutinins, resulting in a delayed transfusion reaction 7 to 12 days after transplantation. Apheresis devices are commonly used to remove red cells from marrow component for major red cell incompatibility.[277] Red blood cell quantities no more than 10 mL appear to be tolerable. Therefore, secondary processing of a PBSC component collected by the same technology used for depletion of red cells from marrow grafts and already containing low quantities of red cells is not required. Minor ABO incompatibility can result in delayed transfusion reactions that may be fatal if appropriate blood transfusion support (avoiding the infusion of donor-type red cells) is not initiated before transplant. Two case reports of severe red cell hemolysis after allogeneic PBSC transplantation have been reported. In the first, transfusion support before the event was not described.[278] The second patient received recipient-type red cells on day 7 after transplantation,[279] which is the point at which donor-derived isoagglutinins will be increasing in the recipient. Although both author groups discussed the much greater numbers of B cells in PBSC components as a possible factor in these events, it is not clear from these reports that delayed-type transfusion reactions will be more likely or of greater severity in PBSC recipients. The risk of delayed-type reaction may be reduced by the use of multi-agent posttransplant immunosuppressive medications. The Seattle transplant program found no delayed transfusion reactions in a large retrospective review of patients undergoing PBSC transplantation and who received cyclosporine and methotrexate.[280]

CELL COUNTING, PROCESSING, AND CRYOPRESERVATION

Tumor Cell Contamination

The probability that tumor cell contamination of the component could contribute to relapse was demonstrated by Brenner et al. and others in studies involving the transplantation of genetically marked marrow cells.[281–283] Sensitive immunocytostaining techniques, clonal assays, flow cytometric analysis, and polymerase chain reaction amplification of malignant genetic material detect tumor cells in the PBSC components of many patients with a variety of malignancies.[284–287] In general, the incidence of contamination (number of patients with positive components) and the level of contamination (number of tumor cells per number of normal cells) is much less for PBSC than for marrow components,[284] although this has not been a consistent finding in all studies.[285] Whether patients transplanted with PBSC have a lower relapse rate compared to patients receiving bone marrow is not well defined, and appropriate phase III studies of this question will be difficult to design and enroll with patients. In a retrospective study, Sharp et al.[288] demonstrated similar probabilities of relapse-free survival in recipients of PBSC or marrow components if the components were free of lymphoma cells. In that study, patients with marrow involvement by lymphoma were assigned to transplantation with PBSC. The authors concluded that PBSC transplantation is a sensible approach to the patient with overt marrow involvement. However, Brugger et al.[289] demonstrated that patients with breast cancer involvement of the marrow at the time of chemotherapy mobilization were likely to mobilize tumor cells into the blood. The most disturbing finding of this study is that the tumor cells were detected in the peripheral blood at the same time as $CD34^+$ cells. Similarly, Pecora et al.[290] found a relationship between the ability to

detect tumor in PBSC components and in bone marrow samples, but they also found a higher incidence of positive PBSC components for patients who required greater numbers of apheresis procedures to achieve the target dose of $CD34^+$ cells. Investigators at The Johns Hopkins Oncology Center found no difference in the incidence of tumor contamination of PBSC components between patients treated with chemotherapy and cytokines or cytokines alone.[291] The probability of tumor contamination of PBSC components decreases after induction chemotherapy.[292] Patients with marrow involvement may benefit from several cycles of debulking (in vivo purging) chemotherapy before collection of PBSC, with the caveat that extensive chemotherapy will decrease the subsequent yield of PBSC. Tumor cells in the HSC inoculum likely will not benefit the patient, but until further data are available, it is advisable that reports of tumor contamination in the collections for individual patients be interpreted with caution.

Purging of Hematopoietic Stem Cell Components for Autologous or Allogeneic Transplantation

PBSC components can be purged of tumor cells or T lymphocytes using the same techniques developed for marrow, although the larger cell quantities collected and the multiple days of collection will increase the cost of processing. Because of the commercial availability of devices that enrich $CD34^+$ cells, most purging studies involving PBSC components have focused on this technology. The CD34 glycoprotein is an approximately 115-kd molecule found on lymphohematopoietic stem and progenitor cells, including malignant cells derived from these, vascular endothelium, and possibly other tissues.[293] The presence of this marker on hematopoietic stem and progenitor cells enables the enrichment of these cells from peripheral blood, cord blood, or marrow. Enriched populations of $CD34^+$ cells then can be used for transplantation or further component manufacturing, such as gene therapy or cell expansion. Numerically, simple enrichment of $CD34^+$ cells from levels less than 1% to levels from 70% to 95% results in greater than 90% to 99% depletion of $CD34^-$ cells, leading many investigators to explore $CD34^+$ cell enrichment as a technique of T-cell depletion to prevent GVHD in allogeneic cell recipients[294–297] or tumor depletion to decrease the risk of relapse for autologous component recipients.[298–301] Engraftment does not appear to be affected by $CD34^+$ cell enrichment unless low quantities of $CD34^+$ cells are infused.[298]

Positive enrichment of HSC achieves nonspecific tumor-cell depletion as $CD34^+$ cells are separated from antigen-negative cells. Because this depletion is nonspecific, the degree of purging achieved will equal the depletion of other $CD34^-$ cells such as lymphocytes. Typically, depletion ranges from 99% to 99.99%. By itself, $CD34^+$ cell enrichment will reduce the number of tumor cells below the level of detection of some assay systems. For example, Shiller et al.[298] reported that five of eight components were negative for myeloma cells after processing, but Lemoli et al.[301] found the persistence of detectable disease in five of six patients tested. The median purity of $CD34^+$ cells actually was greater in the latter study (77% vs 89.5%). Phase III studies of CD34 enrichment for patients undergoing treatment of myeloma show the feasibility of $CD34^+$ cell enrichment of PBSC components, although these studies were not powered to demonstrate efficacy in control of disease.[302] $CD34^+$ cells can be successfully enriched after thawing using the same techniques used for prefreeze separations.[303–305] Cell recovery is lower compared to prefreeze processing, but the postthaw processed samples do not undergo the potentially damaging osmotic shock that occurs with the infusion of cells cryopreserved in dimethylsulfoxide (DMSO). Greater depletion of tumor cells can be achieved with combinations of $CD34^+$ cell enrichment followed by depletion of tumor cells. Few clinical trials of combination purging techniques currently were conducted, so the usefulness of this purging cannot be assessed at this time.

Microbial Contamination of Hematopoietic Stem Cell Components

The incidence of culture-positive PBSC components is considerably less than that for marrow.[306–308] In a prospective study conducted by Attarian et al.[306] of 1263 PBSC components from 376 sequential patients, bacteria were detected in only three. Most of these patients were treated with chemotherapy mobilization, and approximately 50% were still receiving antibiotics for treatment of neutropenic fevers at the time of apheresis. None of the components collected from the patients receiving antibiotics were culture positive. The collection of cells from febrile patients appears acceptable if they are clinically stable for apheresis, the timing of apheresis is appropriate as determined by enumeration of $CD34^+$ cells in the blood, and the patients are receiving appropriate anti-microbial therapy. The collecting facility should arrange for microbial culture of the component. Skin flora are the bacteria usually isolated, and contaminated components need not be destroyed. Infusion of these components is generally without clinical sequelae, although serious infections have occurred after infusion of components contaminated during processing.[306–311] Any decision regarding the disposition of culture-positive HSC must be made by the patient's transplant physician after considering the type of contamination, the anticipated risks from use of the component, and the ability to replace the culture-positive component(s) in a timely manner.

Quantitation of $CD34^+$ Cells

Quantification of CD34 antigen-positive cells by flow cytometry has become the standard of care for management of the PBSC donor because it provides a rapid and clinically relevant assessment of HSC content in the peripheral blood or the PBSC component. This antigen is found on HSCs and limited populations of other blood cells[293] and can be identified using a variety of commercially available antibodies. If antibodies directly conjugated with dyes are used, the technique requires only about 1 hour of preparation time. Cell viability using propidium iodide (PI) or 7-aminoactinomycin D (7-AAD) exclusion can simultaneously be determined if the cells are analyzed while still fresh,[312] or the cells can be fixed after staining for analysis at a later date. Other antibodies can be added for analysis of CD34 subsets if desired (and if the flow cytometer has proper detectors to detect the different emission wavelengths of the fluorochromes used).[81] Many centers are finding strong correlations between the numbers of $CD34^+$ cells and CFU-GM in the sample, but with ratios of 5:1 to 20:1.[217,313] Thus, CD34 analysis will provide data similar to that obtainable with cell cultures, except that the latter demonstrates the viability of the progenitor cells.

The major difficulty with analysis of $CD34^+$ cells is the low frequency of these cells. Clinical decisions to initiate apheresis are being made for $CD34^+$ cell levels as low as 10/μL. This may represent a cell frequency that is 0.01% or less of the nucleated cells in the specimen. This enumeration is possible because of multidimensional measurements obtained by flow cytometry. Most cytometers can measure at least five characteristics of each cell, including size, granularity, and the presence of up to three different fluorochromes. Thus, the cells of interest can be separated in five-dimensional space, achieving discrimination of cells as rare as 1:10,000. The difficulties arise from developing an adequate technique that makes optimal use of the cytometer to measure these rare cells. Sources of errors include (a) sampling of the component, (b) cell counting, (c) cytometer calibration and operation, (d) choice of antibody and fluorochrome, (e) lysis technique, and (f) gating strategy. Skilled operators will avoid many of these errors by selecting appropriate antibodies and properly operating the cytometer. However, cytometry provides a proportion of cells, which must be multiplied by the cell count to obtain an absolute number. The steps involved in preparing a specimen for cytometry may alter the proportion of cells in the sample, and this error will be translated into an error in the absolute number.[314] The direct relationship between the number of events ($CD34^+$ cells

counted) and the precision of this count dictates that large cell numbers be analyzed.[315] Serke et al.[315] found a coefficient of variation of 30% in counting of CFU-GM colonies and 10% in flow cytometric counting of $CD34^+$ cells. The coefficient of variation in $CD34^+$ cell enumeration could be as high as 65% for specimens containing few cells. This variation was decreased by analysis of larger cell samples. Clinically, this imprecision may explain some of the range in engraftment kinetics observed for patients receiving low doses of $CD34^+$ cells.

A variety of different cytometric techniques are used for measuring $CD34^+$ cells. They may involve only one antibody, although other techniques use two antibodies for better discrimination between $CD34^+$ and $CD34^-$ cells.[316–318] Gating on cells that are $CD45^+$ helps separate nucleated cells from red blood cells, platelets, and debris, a step that is otherwise performed using the light scatter characteristics of the cells.[318] Alternately, gating on $CD14^-$ cells allows the separation of $CD34^+$ cells from monocytes that nonspecifically bind the CD34 antibody. However, there is considerable variation in results even between laboratories using the same cytometric technique, and no cytometer-based technique has proven to have a lower interlaboratory variability.[317]

Subset analysis will provide additional information but does not appear to be clinically useful at this time. Pecora et al.[319] reported that the quantity of $CD34^+CD33^-$ cells infused was identified as an independent factor predictive of engraftment kinetics. Dercksen et al.[320] reported better correlation between the number of $CD34^+CD33^-$ cells and time to granulocyte engraftment and between the number of $CD34^+CD41^+$ cells and time to platelet engraftment than found with the overall number of $CD34^+$ cells. This group reported a similar finding for the number of $CD34^+$L-selectin$^+$ cells infused and platelet engraftment.[321] Given the limited range in recovery times when adequate numbers of $CD34^+$ cells are collected and infused, however, this additional information is of limited clinical value.

There is considerable disagreement about which flow cytometry technique is best for the measurement of $CD34^+$ cells. Any particular technique may have advantages over the others in specific settings, but no technique will be adequate if the cytometer is not calibrated and is not clean, if adequate events are not obtained for "rare event" analysis, and if a uniform gating strategy is not followed. These issues will become moot with the development of automated devices that provide quick and reproducible enumeration of $CD34^+$ cells, leaving the flow cytometer for research use. The ideal technique will provide an actual count of $CD34^+$ cells (instead of a percentage) and be sensitive to $CD34^+$ cell levels at least as low as 10/μL (levels below this are generally not clinically relevant). Single platform devices that provide an actual count of $CD34^+$ cells have been evaluated.[322,323] It may be possible to adopt some hematology analyzers to this purpose.[324]

Progenitor Cell Cultures

Hematopoietic progenitor cells committed to granulocytic (CFU-GM), erythroid (burst-forming unit-erythroid), or mixed granulocytic and erythroid (CFU-granulocyte, erythrocyte, megakaryocyte, macrophage; CFU-Mix) lineages can be identified using a variety of culture techniques. These techniques require expertise and equipment not available in many clinical laboratories, and they have other drawbacks that may limit their utility as routine quality control. Other than availability of equipment and expertise, the major limitation is that progenitor cell assays require 10 to 14 days of culture before the results are available. Thus, progenitor cell cultures cannot be used in the day-to-day management of the PBSC donor or the immediate quality control of bone marrow products. As with quantitation of $CD34^+$ cells, the lack of standard culture technique adopted by all laboratories complicates comparisons between laboratories of progenitor cell quantities harvested and infused. The clinical relevance of the culture technique to the transplant population must be determined if the data obtained are to be used in the management of individual patients.

Unlike other measures of component quality, progenitor cell cultures demonstrate the functional capacity of the cells. Progenitor cell cultures are the only currently available relevant assay of HSC viability other than actual engraftment of the recipient and should be available at the HSC processing facility for use in quality control or if questions about the viability of a particular component are raised.

Cryopreservation

HSC harvested from the peripheral blood, bone marrow, or UCB are frozen and stored using the same techniques. The general parameters include cryopreservation in DMSO and a source of plasma protein with or without hydroxyethyl starch, cooling at 1 to 3°C/min, and storage at −80°C or colder.[325] Variations on this technique include the concentration at which the cells are frozen, the amount and source of the plasma protein, and the cooling techniques used.[326,327] Most of these variations probably have little effect on the survival of HSC, as shown by the consistent engraftment of cryopreserved components. However, cryopreservation results in loss of an undefined but potentially substantial proportion of HSC, and delay in engraftment can occur if the component being frozen has borderline quantities of HSC.[328,329] A considerable incidence of generally minor toxicity associated with infusion of cryopreserved cells must be considered when developing cryopreservation techniques.[330]

PBSC differ from marrow components in their much larger cell quantity, frequently exceeding 4×10^{10} cells. Cryopreservation of these cells at a set cell concentration, especially if multiple days of collection are performed, may result in large volumes of cryopreserved material to be infused. DMSO itself has a variety of pharmacologic effects,[331] which may be compounded by the presence of lysed blood cells, foreign proteins from tumor-cell purging procedures, or contaminants from nonpharmaceutical grades of reagents used in the processing. The LD_{50} values (amount of DMSO required to kill 50% of test animals) reported for intravenous infusion of DMSO are 3.1 to 9.2 g/kg for mice and 2.5 g/kg for dogs.[332] The acute toxic dose of DMSO for humans has not been determined. A report cited two instances of encephalopathy after infusion of cryopreserved PBSC components.[333] The components for both patients were cryopreserved with a final DMSO concentration of 10%. The volumes infused were 2254 and 1198 mL, containing 249.7 and 132.7 g of DMSO, respectively. Patient weights were not provided in this report, but the dosage of DMSO probably neared or exceeded 2 g/kg of patient weight, at least for the first patient. For this reason, the volume of DMSO infused should be limited to 1 g/kg/day. Patients with larger volumes can receive the cells over more than 1 day.

Cryopreservation of these cells at the concentrations frequently used for bone marrow ($5–10 \times 10^7$ nucleated cells per milliliter) could result in component volumes greater than 400 mL for each collection. To minimize the volume infused, PBSC can be concentrated before cryopreservation. In one series, the average cell concentration of cryopreserved PBSC was 5.59×10^8 nucleated cells per milliliter.[334] High concentrations of red cells and platelets also were frozen. No detrimental effect of cryopreservation at these high cell concentrations on the recovery of nucleated cells, mononuclear cells, or $CD34^+$ cells was found. No clinical studies have addressed the effect of cell concentration on engraftment speed or toxicity of infusion. Of concern, however, is that several patients infused at that center developed alterations in mental status, including seizures, after infusion of PBSC concentrated before cryopreservation.[335] These events very likely were not related to the small volumes of DMSO infused but may be related to the concentration of cells frozen.

PBSC can be frozen in solutions using reduced concentrations of DMSO. A large (294 patients) randomized phase III study comparing engraftment after autologous transplantation of PBSC frozen using either 10% DMSO or 5% DMSO with 6% hydroxyethyl

starch showed faster granulocyte recovery in patients receiving cells frozen using the combination cryoprotectant solution.[336] No difference in platelet recovery speeds was found, suggesting a lineage-specific benefit. These investigators did not report on infusion-related toxicity, although others have suggested that infusion-related toxicities are proportional to the quantity of DMSO infused.[337]

Alternately, the cells can be washed after thawing, with removal of most of the DMSO.[338] The risk is that of cell loss, so a strategy ensuring that not all cells are at risk during a single processing should be adopted. An effect of postthaw washing on the speed or success of engraftment after infusion of marrow or PBSC components has not been published.

Nonfrozen Storage

Cryopreservation is not required for short-term storage of HSC. Nonfrozen storage is a less costly alternative, especially for immediate transportation of products and for transplantation of patients conditioned with brief courses of chemotherapeutic agents with short in vivo half-lives. Although most products are infused or processed within a few hours of collection, products collected for unrelated donor hematopoietic cell transplant may be shipped over long distances, sometimes requiring more than 24 hours of transit time. Similarly, products intended for autologous hematopoietic cell transplant may be transported to regional processing centers, requiring 24 to 48 hours of transit time before processing.[339,340] The major advantages of cryopreservation are the lack of progressive loss of HC over time and the greater flexibility in timing of hematopoietic cell transplant relative to collection of HSC, including the ability to modify or postpone a transplant conditioning regimen already started.

Progressive loss of HSC occurs during nonfrozen storage. One author reported a 61% loss of myeloid colony-forming progenitor cells (CFU-GM) from marrow after 72 hours of storage at 4°C.[341] However, another found only a 3% loss of CFU-GM from marrow stored for 96 hours, but a 95% loss if the source of the cells was peripheral blood.[342] Preti et al.[343] compared the survival of mature hematopoietic progenitor cells isolated from marrow during frozen or nonfrozen storage and reported an immediate loss of myeloid (CFU-GM) progenitors of 33% during cryopreservation and thawing. In contrast, cells stored at 4°C showed progressive, linear loss of total nucleated cells, cell viability, and HSC cloned in vitro. The quantity of erythroid colony-forming progenitor cells (burst-forming unit-erythroid BFU-E) in these nonfrozen samples became significantly less than cryopreserved samples after only 5 days of storage. The difference for myeloid progenitor cells (CFU-GM) was not yet significant even after 9 days of storage. These differing reports demonstrate that storage conditions such as concentration of cells, chemicals added, product volume, storage bag, and temperature of storage affect the survival of cells kept in nonfrozen storage.[344]

Most published reports of noncryopreserved storage describe storage at 4°C. This condition provides a stable temperature compared to storage at ambient temperatures, which can be quite variable (and which must be considered during the shipping of products). The optimal temperature is not known and probably depends on factors such as prestorage processing, quantity and concentration of mature blood cells, buffering capacity of the solution, and gas diffusion capacity of the storage container. Beaujean et al.[340] reported a much lower pH for PBSC products stored overnight at room temperature compared to storage at 4°C. Although they did not find a difference in recovery of progenitor cells in their experiments, this effect may be damaging to HSC under other circumstances. None of these studies entailed marrow reconstitution as the experimental endpoint. The conflicting reports about optimal storage temperatures are difficult to interpret. Storage conditions for nonfrozen storage have not been tested in an engraftment model, so proper storage conditions are not adequately defined. For laboratories intending to store stem cell products, particularly PBSC components, for prolonged periods without freezing, rigorous validation of the storage conditions must be pursued.

Regulatory Aspects of Stem Cell Collection and Processing

The United States Food and Drug Administration (FDA) developed a regulatory strategy that encompasses the wide range of cellular- and tissue-based products being developed without requiring an extensive number of focused regulations specific for each possible cell source or derived product. In 1997 the FDA proposed an approach for regulation of cellular- and tissue-based products using a continuum of regulation that is intended to enable the FDA to meet its task of protecting public health without being unfair to specific practitioners of this field of medicine or stifling the development of novel uses of these products.[345] The proposed rigor of control is proportional to the extent of risk involved, with the level of regulation dictated by five considerations: prevention of disease transmission, processing controls to prevent contamination and maintain product integrity and function, clinical safety and efficacy, labeling and promotion, and communication with and monitoring of the tissue industry. The regulatory approach taken by the FDA addresses facility registration, selection and evaluation of the tissue donor, and manufacturing of the product. The FDA views cell processing as a manufacturing activity. Therefore, the FDA expects that donor evaluation and the collection, processing, and distribution of HSC-derived components will comply, at least, to Current Good Tissue Practices (CGTP), with the much more detailed Current Good Manufacturing Practices (CGMP) required for extensively manipulated products. CGMP and CGTP differ in the level of control over the manufacturing pathway required to prevent contamination or loss of potency of the final product The FDA developed Part 1271 of Chapter 21 of the Code of Federal Regulations (CFR) for these regulations. Part 1271 does not replace CGMP regulations for drugs and medical devices found elsewhere in Chapter 21 of the CFR. Cell therapy products that combine cell products with devices or drugs must comply with Part 1271 *and* with the applicable CGMP regulations.

The CGTP regulations are designed to prevent the introduction, transmission, and spread of communicable diseases. For example, compliance with CGTP requires precautions such as cleaning facilities and equipment, storage procedures designed to prevent product mix-ups, and controls over processing to prevent product contamination and impairment to function or integrity. CGTP includes, at a minimum, requirements for the appropriate collection, processing, labeling, storage, and distribution of cellular products to ensure maintenance of the product's function and integrity but does not require the rigorous environmental and manufacturing controls inherent in CGMP.

In the final rule enacting establishment registration, the FDA defined products regulated solely under this section (lowest level of regulation) if they are (a) minimally manipulated, (b) intended for homologous use only (i.e., serves same basic function as cells being replaced), (c) not combined with a drug or a device, except for a sterilizing, preserving, or storage agent, and (d) either without a systemic effect[1] and not dependent upon the metabolic activity of living cells or has a systemic effect or is dependent upon the metabolic activity of living cells for its primary function but is for autologous use or for allogeneic use in a first-degree or second-degree blood relative.[346] This includes most HSC transplantation excluding transplantation of HSC from unrelated PBSC or cord blood donors (the FDA does not regulate bone marrow products). Products not meeting this description still are subject to the core requirements found in Part 1271 but also are subject to more stringent requirements, including the requirement for premarketing approval (gained through submission of data from preclinical and clinical studies demonstrating safety and efficacy for the use being requested) and CGMP manufacturing requirements, as described in the regulatory approach for somatic cell therapy products.[347]

[1]Systemic effect is not defined in the proposed regulations but is clearly distinct from tissues such as bone grafts used for local effect.

CHAPTER 109

GRAFT ENGINEERING AND CELL PROCESSING

Adrian P. Gee

The last decade has seen growth in the use of hematopoietic cell transplant, with or without high-dose chemotherapy or radiotherapy, for treatment of marrow failure syndromes, certain genetic disorders, and cancers that are refractory to conventional dose therapy. The collection and characterization of marrow or peripheral blood stem cell products used for such transplants is described in Chapter 108. In the majority of cases the marrow or peripheral blood stem cell graft is infused after characterization (see Chapter 108) with minimal manipulation. However, in some cases the product undergoes more extensive manipulation to deplete or positively select certain cell types. In addition the cell processing facility often supports more novel cell therapies used either in the adjuvant setting posttransplant or as investigational therapy in clinical trials. These products are subject to different regulations that influence the facility, processing methodology, and release testing.[1,2]

REGULATORY ISSUES WITH CELL PROCESSING

Over the past 15 years the United States Food and Drug Administration (FDA) has been developing a regulatory approach that could be applied to cellular therapy products and would include some products traditionally used in hematopoietic progenitor cell (HPC) transplantation. The evolution of these regulations provides insight into how the FDA formulates laws and develops its regulatory position; however, an extensive discussion is outside the scope of this chapter. In brief, manufacturers of cellular therapy products need to determine whether they fall under Investigational New Drug (IND) regulations, which require manufacturing of the product under Good Manufacturing Practices (GMP); whether they fall under Part 1271 of Title 21 of the Code of Federal Regulations (21CFR) "Human Cells, Tissues, and Cellular and Tissue-based Products (HCT/Ps)," which require manufacturing of the product under Good Tissue Practices (GTP); or whether the product is exempt from these regulations.[3]

Stratification of regulations is based upon the relative degree of risk that is posed to the donor, the recipient, and the product during ex vivo processing.[2] The newer GTP regulations, which came into effect in May 2005, were established nominally to prevent the introduction, transmission, and spread of communicable diseases by HCT/Ps. This was based on the presumption that the majority of posttransplant infections and admissions to the intensive care unit were attributable to the receipt of contaminated products. The basis of this statement is open to question, but the regulations provide a framework for screening, performing ex vivo processing, storing and distributing HCT/Ps, and providing the FDA with an overview of current activities by an annual registration of collection and processing facilities. The Part 1271 regulations effectively filled a gap in the law where few regulations could be applied to HCT/Ps that were minimally manipulated (e.g., were not cultured ex vivo, genetically modified, activated ex vivo), that were intended for homologous use, and/or were not combined with another article (e.g., a matrix or gel) for administration. In addition, the HCT/Ps should not exert a systemic effect and should not be dependent upon the metabolic activity of living cells for its function; or for autologous use, or for use in a first or second-degree blood relative, or for reproductive use. Cellular products that fall into this classification are referred to as Type 361 products. These regulations do not apply to vascularized organs for transplantation, whole blood or blood components, and, importantly for this discussion, minimally manipulated bone marrow for homologous use and not combined with another article.

With the exceptions noted, most other cellular therapy and HPC transplant products fall under IND regulations and are referred to as Type 351 products. These products have been cultured, ex vivo, transduced or transfected, or activated ex vivo and, therefore, are more than minimally manipulated. The facility processing these cells is required to operate under GMP,[4] which is a set of regulations originally developed for the pharmaceutical industry to ensure that drugs are manufactured under a controlled and auditable process that ensures their safety, purity, and potency. The FDA has indicated that the application of GMP follows a continuum, such that products that are prepared for a phase I/II clinical trial under IND are not expected to be prepared under full GMP. As the trial proceeds the expectation is that the application of GMP will become more rigorous, such that a phase III product would be well characterized and would be manufactured using a fully validated process.

Implementation of Part 1271 regulations has had an impact on the "routine" laboratory that prepares cells primarily for hematopoietic transplantation.[5] Laboratories that use cells other than bone marrow now must register annually with the FDA, ensure that donors meet eligibility requirements (or document why noneligible donors are used), and manufacture, store, and distribute the cells under GTP. If the laboratory has previous experience manufacturing products for IND studies under GMP conditions, it already will be familiar with most of the features of GTP. In general, these cover personnel, procedures, facilities, environmental control and monitoring, equipment, supplies and reagents, recovery, processing and process controls, process changes, process validation, labeling controls, storage receipt, predistribution shipment and distribution, records, tracking, and complaints. Implementation of the components of either GMP or GTP operations is a time-consuming process that requires the development, implementation, and maintenance of numerous components and generates a considerable volume of paperwork. Professional societies, such as the Foundation for the Accreditation of Cellular Therapy (FACT)[6] and the AABB (formerly the American Association of Blood Banks),[7] have developed an accreditation process that takes into account GTP regulations and provides a framework around which compliance can be built.

One of the most important components of both GMP and GTP regulations is the establishment and maintenance of a quality program. This should ensure that the appropriate regulations are being followed on an ongoing basis, that mechanisms are in place for monitoring, reviewing, and remediating errors and deviations from regulations, policies, and procedures, and that an audit program will be developed and implemented. Evidence of the work of the quality program should be documented, and the program should be staffed by individuals who are not involved in hands-on manufacturing of the products.

Each year facilities are required to register their establishment with the FDA and provide a listing of the types of products they prepare. Holders of INDs should provide the agency with an annual report on the protocol and include a listing of the products administered and those that have been prepared but not used. In addition, cell processing facilities should be prepared to assist in reporting to the

FDA information on products that have been associated with severe adverse reactions in the recipients. For Type 361 products, the facility is also required to report as Biological Product Deviations any contaminated products that have been administered to a patient.

PROFESSIONAL STANDARDS

Regulations issued by the FDA have the power of law. Standards are voluntary recommendations that are published by professional societies. They can be enforced through a voluntary inspection and accreditation process that usually involves an on-site inspection. The two major accrediting organizations for cellular therapies are FACT[6] and the AABB.[7] FACT offers accreditation of collection, processing, and clinical use of cellular therapy products, whereas the AABB focuses on collection and laboratory processing. Both organizations inspect based on standards that are published every 18 months to 3 years. In the case of FACT, the standards are published in collaboration with the Joint Committee on Accreditation in Europe (JACIE). FACT also publishes separate standards in collaboration with NetCord that cover cord blood banking.[8] Both organizations have worked to harmonize their standards with American, Canadian, and European regulatory agencies; therefore, accreditation by either organization is of great assistance on the pathway to regulatory compliance. A number of other professional organizations accredit particular aspects of operations within the cell processing facility. They include the College of American Pathologists (CAP), which inspects general laboratories, hematology, and flow cytometry; the American Society for Histocompatibility and Immunogenetics (ASHI); and the European Federation for Immunogenetics (EFI), which accredits histocompatibility testing laboratories. Some organizations, such as CAP, also provide proficiency testing services for laboratory staff.

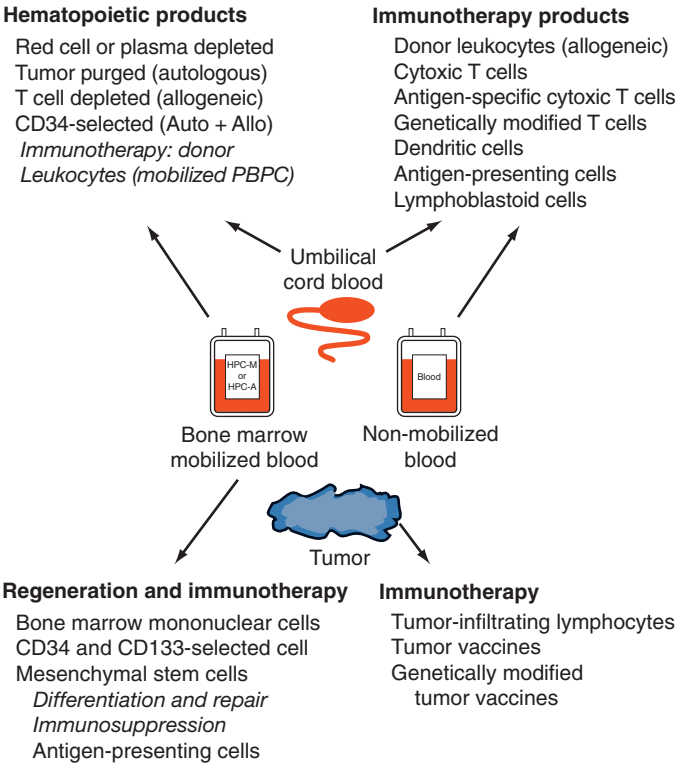

Figure 109–1 Processing methods for hematopoietic cell transplantation and immunotherapy products.

MANIPULATION OF HEMATOPOIETIC STEM CELL TRANSPLANTATION PRODUCTS

Manipulation of a product intended for hematopoietic stem cell rescue is intended to remove a component that is unwanted or may cause adverse effects, or to positively select a desired population such as CD34 cells (Fig. 109–1).

Routine Minimal Manipulation for Volume Reduction or ABO incompatibility

The most widely form of manipulation in the HPC processing facility probably is removal of erythrocytes or plasma to overcome ABO incompatibility between donor and recipient. This process is performed using techniques that were developed by the blood banking industry. Plasma depletion to remove donor antibodies that may react with recipient cells is achieved by centrifugation of the graft, usually in a transfer pack. The pack then is placed in a plasma expresser, which compresses the product so that plasma can be forced out and into a separate collection bag. Plasma depletion is also used to reduce the volume of ABO-compatible grafts when the donor is large and the recipient small.

Red cell depletion removes incompatible donor erythrocytes to prevent the donor from mounting a reaction to them upon administration. Most facilities establish a maximum volume of incompatible red cells that can be infused with HPC; exceeding this limit can result in hemolysis and a transfusion reaction. Depletion of erythrocytes can achieved most simply by centrifugation in which the product is centrifuged and the leukocyte-rich buffy coat is collected at the interface between the plasma layer and the red cells. Similar results can be achieved by sedimenting erythrocytes using hetastarch, which promotes rouleaux formation by red cells, resulting in more rapid sedimentation without centrifugation. The most rigorous erythrocyte depletion is achieved by centrifugation of the collection on a Ficoll-Hypaque density gradient. This process enriches mononuclear cells at the interface between the gradient and the layered collection following centrifugation. As a result of enrichment for mononuclear cells, the overall nucleated cell recovery is lower than with other techniques.

Purging of Autologous Grafts

Autologous HPC can be used for recipients lacking a human leukocyte antigen (HLA)-matched related or unrelated donor. Debate is ongoing as to whether occult tumor cells collected with the graft and returned to the patient is in a viable state, acting as the source for disease relapse.[9] Gene marking studies have suggested this possibility.[10–12] As a result, much effort has been exerted to develop methods for the detection and removal of tumors from autologous grafts. Methods have ranged from use of chemotherapeutic drugs such as 4-hydroperoxycyclophoshamide, photosensitizing agents, and antisense oligonucleotides to methods that use tumor-directed monoclonal antibodies to identify the cells and effect their removal.[13–15] Antibody-coated tumor cells can be eliminated by adding serum complement or by linking them to a solid phase, such as a column matrix, plastic sheet, or magnetic particles. These particles may be large (5-μm diameter) so that they can be collected, with the attached tumor cells, in a standard magnetic field, or they may be much smaller, such as nanoparticles or ferrofluids, which coat the cells that are collected on a metal matrix placed in a field generated by permanent magnets. Such systems are capable of depleting 4 to 6 logs of tumor cells from a graft. However, even at such high efficiencies and given the limits of our ability to detect residual tumor cells, the clinical value of purging autologous grafts is debated. Concomitant with the potential benefits of the graft-versus-tumor (GVT) effect detected in recipients of allogeneic grafts has been a declining interest in tumor techniques.

T-Cell Depletion of Allogeneic Products

T cells in HPC grafts have the potential to cause severe or lethal graft-versus-host disease (GVHD) or to exert a potentially beneficial GVT effect (discussed in Chapters 107 and 111).[16] Considerable work has been done to determine whether these opposing effects are produced by distinct subpopulations of T lymphocytes.[17] This would allow ex vivo manipulation of allogeneic grafts to remove GVHD-producing T cells while sparing those that produce GVT responses. Various subpopulations of T cells have been identified as candidate effector subpopulations; however, there is no widespread consensus as to which populations should be targeted.[18,19]

Methods are available for eliminating T cells from grafts using approached similar to those used for purging tumor cells.[20] Early approaches included use of soybean agglutinin to aggregate the majority of nonprogenitor cells and resetting of sheep erythrocytes with T cells to increase their density and facilitate their removal.[21] Although successful, these techniques are not "FDA friendly" and do not offer the specificity that likely is required to engineer T-cell subpopulations in allogeneic grafts. This is possible by use of monoclonal antibodies directed toward the antigens that currently are used to identify T-lymphocyte subpopulations. The target population then can be removed with high efficiency using immunomagnetic separation, as described previously for purging autologous graft of tumor cells. The challenge remains to identify the target population and to source clinical grade monoclonal antibodies for these procedures. A number of potential target antigens have been identified and separation techniques implemented. They range from pan–T-cell depletions using antibodies to CD3 and CD2, to depletions of helper and suppressor T cells using monoclonals against CD4 and CD8, to stimulation and removal of alloreactive populations by targeting activation antigens.[19,22–27]

Methods that eliminate or physically remove either T cells or tumor cells from grafts are referred to as *negative selection techniques*. They are affected by variables such as target antigen expression, detection technologies, and other technical hurdles. They may be difficult to manipulate to achieve the ideal composition of the graft. For many years the goal was to replace these techniques with one in which HPC populations could be specifically enriched by positive selection. This would effectively deplete T cells and tumor cells from allogeneic and autologous graft respectively. The problem was the lack of a method for identifying the target HPC until the CD34 antigen was identified on a small population of progenitor cells, including the pluripotent cells required for transplantation.[28,29] The subsequent availability of monoclonal antibodies directed against this antigen made possible the development of techniques for enrichment of cells. Immobilization of the antibodies on a matrix (e.g., plastic sheets) and cellulose and magnetic particles was used as the primary approach, and a number of devices were commercially developed. The two most widely used are marketed by Miltenyi: the Baxter Isolex 300i, which uses Dynal 5-μm magnetic beads as the separation modality and releases $CD34^+$ cells from the beads using a competitive binding peptide, and the CliniMACS system, which uses anti-CD34 nanoparticles to effect separation, with these biocompatible particles remaining on the HPC (Fig. 109–2). The Isolex is approved for use in the United States and Europe. The CliniMACS currently has only European regulatory approval.

One concern expressed about positive selection techniques is that they remove from the graft certain cells that are of potential benefit to the recipient. They include some stromal elements, GVT-mediating T cells, and other subpopulations that may facilitate engraftment. As our understanding of the identity of these populations improves, it may be possible to recover them from the nonpositively selected fraction and add them back to the $CD34^+$ cells.

Table 109–1 lists various methods of direct T-lymphocyte depletion and indirect depletion by hematopoietic cell enrichment.

EVALUATION OF MANIPULATED GRAFTS

Most allograft engineering has focused on T0lymphocyte depletion and has emphasized quantitative versus qualitative removal. The

Table 109–1 Methods for T-Cell Depletion

Destruction In Situ	Physical Separation
Monoclonal antibody-based	Monoclonal antibody-based
Antibody + complement	Immunomagnetic separation
Immunotoxins	Negative selection

majority of allografts are infused immediately on preparation rather than after cryopreservation and storage, and the implications of infusing large numbers of T lymphocytes can be severe or lethal. Therefore, it is important to have available methods that can rapidly enumerate the numbers of T lymphocytes within the graft. Although early methods used detection of E-rosette–forming cells or manual immunofluorescence following staining with pan–T-lymphocyte–directed monoclonal antibody, most laboratories currently rely on flow cytometry. This technology is widely used in routine clinical laboratories; however, some precautions must be taken when it is used for T-depleted allografts.

Flow Cytometry

Accurate enumeration of very small numbers of target cells by cytometry requires rare event analysis. In this technique, large numbers of events must be accumulated and carefully analyzed if reliable data are to be obtained. This approach has been widely adopted for counting $CD34^+$ cells but still is often neglected when enumerating T lymphocytes in depleted grafts. The choice of antibodies for detection of the T-lymphocyte population also is critical when a monoclonal antibody-mediated depletion technology is used. The same monoclonal antibody should not be used for depletion and analysis because cells that became coated with the antibody during the depletion phase but were not effectively removed will be blocked from detection. However, they can be detected by adding an antiimmunoglobulin antibody conjugated to a fluorochrome different from the one conjugated to the T-lymphocyte–directed monoclonal antibody. The most sensitive detection is achieved by using panels of non–cross-blocking anti–T-lymphocyte antibodies directed against a variety of epitopes.

It is important to include a viability stain in the analysis panel. Although this is less crucial when T-lymphocyte depletion is achieved by physical removal of target cells, it is extremely important when in situ elimination methods are used. Under these circumstances, the depleted allograft may contain dead or dying T lymphocytes that will be detected by flow but may not contribute to postinfusion events. Suitable viability stains include propidium iodide and 7-aminoactinomycin. Analysis of cell viability after ex vivo depletion is not straightforward. Cell death may not be expressed immediately but may develop in the hours or days after processing and infusion. It may be possible to obtain a more accurate estimate by incubating the cells for a period before analysis. This has been particularly true in the case of depletion by immunotoxins that require the cells to divide in order to exert their toxic effects.[30] Stimulation of cells with interleukin (IL)-2 and ex vivo culture also has been used to facilitate detection of the residual T lymphocytes by flow cytometry. In some cases, this process has provided a correlation between the numbers of T lymphocytes in the cultured sample and the development of clinical GVHD in the graft recipient.

Tetramer Analysis

Enumeration of T cells bearing receptors for specific antigens can be achieved using tetramer analysis (Fig. 109–3). In this procedure, soluble versions of heavy chain of major histocompatibility complex (MHC) molecules are synthesized and adopt the appropriate conformation when a synthetic peptide representing the epitope is recognized by the T-cell receptor (TCR) and β_2-microglobulin is added. The carboxyl-terminus of the MHC molecule is biotinylated, and four of these peptide/MHC–biotin complexes assemble into a tetramer when streptavidin is added. The streptavidin is tagged with a fluorochrome; therefore, T cells reactive with the chosen peptide–MHC complex become fluorescently stained and can be detected by flow cytometry,

Functional Assays

Flow cytometry detects residual cells by their ability to bind monoclonal antibodies. Routine flow does not provide information on the

functional capacity of these cells, which may be important when assessing the graft for it potential to mediate GVHD or GVT. For this purpose a number of assays have been developed. They include limiting dilution analysis, in which a range of dilutions of the graft are plated out and assessed for the ability of T cells to form colonies in response to the addition of stimulants, such as phytohemagglutinin and IL-2. Based on the proportion of colony-forming wells at the various dilutions, it is possible to determine by the Poisson distribution the number of T cells present in the original graft.

Another approach is use of an enzyme-linked immunosorbent spot (ELISpot) assay, in which cells are stimulated to produce an analyte that is characteristic of their normal function.[31] The cells are plated onto a surface that has been coated with an antibody directed against that analyte and incubated for a fixed period. The secreted analyte binds to this antibody, and the cells and any other unbound material are washed away. The surface is incubated with a biotinylated antibody directed against the analyte, and washed and incubated with alkaline phosphatase linked to streptavidin. After washing the plate is incubated with a substrate solution. A blue-black precipitate will appear at sites were the analyte was produced, with each spot representing an analyte-secreting cell. The spots can be enumerated manually or using an ELISpot reader.

CELLULAR THERAPY PRODUCTS

A number of cellular therapy products, including some that have been genetically modified, are being evaluated in the clinic. To date, clinical trials have examined the safety and efficacy of different cell populations, including, but not limited to, unmanipulated leukocyte infusions from bone marrow donors, cytokine-induced T cells, lymphokine activated killer cells, tumor-infiltrating lymphocytes (TILs), mesenchymal cells, natural killer (NK) cells, and antigen-specific T cells. Detailed accounts of the scientific basis for such studies as well as results of clinical trials are given in Chapters 110 and 111. This section focuses on processing and product evaluation issues.

Cells that have been more than minimally manipulated must be prepared under GMP conditions.[3] This requires that manufacturing be performed by trained staff following formal standard operating procedures. These procedures will have been submitted to the FDA as part of the IND application and will specify how the product is prepared, the reagents and materials that will be used, and the criteria for the release of the product for clinical use. Release criteria are test specifications that are designed to ensure that the product is sterile and pure, and they may include assays for functionality. The specific tests for sterility and purity that have been approved by the FDA are described in 21CFR and a number of guidances issued by the FDA. Some of these assays are dated, but it is important to obtain clearance from the FDA before substituting alternative tests. In the normal release mechanism for a cellular therapy product, the quality unit reviews the production records and issues a certificate of analysis. This document details the testing that was performed, who performed the tests, the specification required by the FDA, and the actual results obtained. Routine testing required for most cellular therapy products consists of aerobic, anaerobic, and fungal sterility, endotoxin levels, mycoplasma, identity/purity by flow cytometry (and in some cases HLA typing), and, for products in later stages of evaluation, functionality (e.g., cytotoxic activity toward target cells or secretion of specific bioactive products). In most cases, regulatory agencies also like to see some form of stability testing program that evaluates the stability of the cellular product over time in storage in the frozen state and when thawed for administration.

Phase I studies are designed to assess the safety of the product and should include assessment of reactions to infusion, risks for contamination during preparation, and delayed effects following administration. Clinical efficacy is evaluated during phase II/III. At this time, progress should be made toward the development of some in vitro assay for functionality that correlates with clinical efficacy. This can be problematic because most in vitro assays currently used are unreliable as predictors of the clinical value of the product, and some form of surrogate marker has been substituted.

Donor Leukocyte Infusions

The ability of donor leukocyte infusion (DLI) to effect antitumor responses initially was described in patients with chronic myeloid leukemia in hematologic relapse after allogeneic SCT,[16] but lymphomas and Hodgkin lymphoma also are sensitive to the effects of DLI.[32,33] DLI has been most successful in patients with chronic myeloid leukemia who relapse after transplant (70%–80% cytogenetic remission rate) or with Epstein-Barr virus (EBV)–associated lymphoproliferative disease (up to 90%).[16,34,35] In general response rates are higher in patients with Hodgkin lymphoma or low-grade lymphoma than in those with high-grade lymphoma.[36,37] Moderate success has been achieved with use of DLI after relapse in other malignancies such as acute myeloid leukemia (15%–40%), low-grade lymphomas (≈60%), and metastatic multiple myeloma (40%–60%). Less than 5% of patients with relapsed acute lymphoblastic leukemia respond to DLI alone. Although the etiology is unclear, the reason could be lack of antigenic expression, downregulation of T-cell recognition molecules, and/or overall tumor burden at the time of treatment.

The regulatory situation for DLI is complicated and probably is in transition. At present, they are classified as Type 361 products and fall under Part 1271 of 21CFR. It is possible that they will be reclassified as Type 351 products requiring an IND application. This is currently the case for DLI that have been manipulated ex vivo in any way (e.g., by targeting them to specific antigens). Donors of minimally manipulated DLI must be screened for eligibility, and the required infectious disease test sample must be obtained at the time of collection of the cells or up to 7 days before or after collection. Release criteria normally consists of evaluating the sterility of the final product. This provides results after the product has been infused. Formal procedures should be in place to inform the recipient's physician if a positive result is subsequently received. The contaminant should be speciated and antibiotic sensitivities obtained and communicated to the physician. Gram staining of the product prior to administration can be used, but this assay is notoriously insensitive, except in cases of gross contamination.

Natural Killer Cells

NK cells are effectors from the innate immune system that also mediate antiviral and antitumor immunity. Studies have shown that haploidentical NK cells infused after lymphodepleting chemotherapy can have antitumor effects.[38] Most facilities use a simple positive selection with clinical-scale immunomagnetic methods involving CD56 selection and/or CD3 depletion for such products.[39,40] These procedures should be done under an IND because of lack of commercially available devices or reagents for this indication. Although clinical-grade anti-CD3 is commercially available, magnetic beads and the Isolex device currently are not approved for this application. The Miltenyi device must be used under IND in the United States because it does not have regulatory approval for any indication at the present time.

When preparing an IND application for NK cell enrichment, care should be taken to ensure that the monoclonal reagents are of the highest quality available. Certificates of analysis for these reagents should be submitted with the IND application, and the agency probably will require detailed information on their manufacturing (i.e., to ensure that the process includes procedures for virus inactivation/removal). The same type of information may be required for any ancillary reagents (e.g., materials that are used to release NK cells from magnetic beads). Preclinical data demonstrating that the enrichment technique is effective should be provided and accompanied by data from clinical scale validation enrichments providing evidence that the NK cells can be enriched with an acceptable viability, purity,

and yield for the proposed study. The Chemistry Manufacturing and Controls (CMC) section of the IND application should include information on the methods used to store, label, and administer the cells.

Ex Vivo Expanded Cell Therapy Products

Autologous T-Cells Nonspecifically Activated Ex Vivo

T cells can be expanded ex vivo through polyclonal activation using phytohemagglutinin, OKT3 (anti-CD3 antibody), or a combination of OKT3 and anti-CD28 antibody. Several groups have evaluated whether such expanded T cells have antitumor activity. Over the past few years several studies have correlated faster recovery of lymphocyte counts with improved outcome after autologous transplant for both non-Hodgkin lymphoma and Hodgkin lymphoma.[41,42] This led to a phase I study evaluating infusion of autologous CD3/CD28 activated cells after a CD34-selected stem cell graft.[43] Preliminary results suggested that this approach is associated with rapid recovery of lymphocyte counts.[43] The investigators subsequently combined this approach with a seven-valent pneumococcal conjugate vaccine in a phase I/II study of patients undergoing autologous stem cell transplantation for myeloma.[44] Patients who received vaccine-primed T cells early after transplant had better antipneumococcal humoral response and better $CD4^+$ proliferative response to the vaccine carrier protein than did other treatment groups. Another strategy uses interferon-μ, IL-2, and OKT3 to generate large numbers of $CD3^+CD56^+$ cytokine-induced killer T cells, which are a unique population of cytotoxic T lymphocytes (CTLs) with a characteristic $CD3^+CD56^+$ phenotype. These cells can mediate non–MHC-restricted cytotoxicity thorough NKG2D. In a phase I trial of patients with relapsed lymphoma, no toxicity or transient response was observed in a minority of patients.[45]

Cells prepared for these types of studies generally are Type 351 products because they are cultured ex vivo and they may have undergone some form of activation. Manufacturing must be carried out under GMP, and the clinical studies must be performed under an IND. The IND application must describe the procedure for manufacturing the cells and the criteria that will be used to determine whether they can be released for clinical use. Many manufacturing procedures use reagents and materials that are not approved for human use, and the application should include information about these materials and what testing will be performed before they can used in manufacturing the clinical product.

The release criteria for autologous T-cell products are similar to those described for generic Type 351 products. They include tests for sterility, endotoxin, mycoplasma, and identity and purity (i.e., by flow cytometry); some test of functionality is recommended but not usually required for phase I studies. A draft certificate of analysis, which will be used for release, should be included in the IND submission

Tumor-Infiltrating Lymphocytes

TILs are cells harvested from tumor sites and are expanded ex vivo with IL-2.[46] As the cells are being expanded, increased tumor specificity is achieved by pulsing the cells with tumor-specific peptides or exposing the lymphocytes to a retrovirus encoding a tumor-specific TCR. Although a major limitation is that patients must have preexisting lymphocytes that can both respond to tumor and be expanded ex vivo, in one study transfer of these cells led to tumor regression in 50% of lymphodepleted patients with metastatic melanoma.

A number of methods have been developed for isolation of TIL from tumors. They include mechanical, enzymatic, and differential centrifugation approaches and positive immunomagnetic selection. The method of choice depends on the type of tissue from which the cells are to be extracted and the availability of reagents, such as monoclonal antibodies, targeting the T-cell population of interest. As with T-cell depletion of allogeneic grafts, the predominant effector TIL cell population is not fully characterized, and the availability of this information should facilitate the design of more effective separation techniques. A number of approved enzymes and centrifugation media can be used, and several companies have monoclonal antibodies that have been prepared under GMP conditions but have not been submitted for FDA approval.

The extracted cells are expanded ex vivo, usually starting in semiopen systems such as cluster plates. The initial populations may be tested in a cytotoxicity assay in an attempt to identify the effector population, which then is selected for expansion. The expansion phase usually progresses through a number of types of cultures as cell numbers increase. They may progress from plates to T flasks and gas-permeable bags to hollow fiber and culture bag bioreactors. The culture medium contains IL-2 as the primary cytokine, although other agents alone and in combination may be used to promote outgrowth of specific cell subpopulations. Some investigators have used irradiated tumor cells to restimulate TILs during culture; others have performed selective separations to enrich the effector cells during expansion. Highly characterized tissue culture media, such as the serum-free lymphocyte medium AIM V, have been used for expansion. The goal is to use the simplest medium with the fewest additives that will support cell growth. Where possible the media should be free of animal serum and proteins in order to simplify the regulatory issues. However, the FDA is aware that complex media and serum combinations may be required to support growth of some cell types and is willing to consider them, particularly if the cells can be washed into an approved carrier for administration.

Initiation of a phase I study using TIL or TIL subpopulations will not require complete characterization of the effector cell population, but some preliminary information should be available that allows quantification of the putative effectors for dosing. In most cases flow cytometric analysis will be used, and the target antigens may be pan–T-cell markers or specific combinations of T subset markers. In the case where other constituents of the product may adversely affect the activity of effector cells, it may be necessary set an upper limit for contamination by these cells in the clinical product. Most facilities perform some type of functional assay as a part of the release process, which in the case of TIL may be cytokine release or cytotoxic activity toward tumor cells of the appropriate histologic type.

Allodepleted Cells

The major drawback of DLI is the significant risk of GVHD, which is the most important source of treatment-related mortality. Given that the frequency of tumor or viral antigen-specific T cells in most cases is considerably lower than that of alloreactive T cells,[47] it is necessary to expand antigen-specific T cells ex vivo not only to enhance antitumor activity but also to separate GVHD from GVT effect. An alternative method for separating GVHD from GVT effect is to selectively deplete alloreactive donor T cells ex vivo. Selective allodepletion is performed by removing donor T cells that express activation markers following coculture with nonleukemic recipient cells. Activation markers investigated include CD25[48,49] and CD69,[50] and the increased sensitivity of activated T cells to photosensitizing dyes.[51] A number of phase I/II studies using immunotoxin directed against CD25 have demonstrated the feasibility of this approach, with accelerated reconstitution of virus-specific and total T-cell numbers and low rates of severe GVHD.[48,49,52] Relapse rates remained high in these studies, which likely reflects the high-risk nature of the patient population.

Potential recipients of allodepleted cells often receive a CD34-selected HPC graft. As a part of the CD34 selection process a negatively selected population of cells that includes T cells becomes available. However, this fraction usually is not used as the source of cells for allodepletion. These cells usually have been obtained from donors who received granulocyte-macrophage colony-stimulating

factor for mobilization of peripheral blood progenitor cells, and during processing for CD34 selection they were exposed to anti-CD34 monoclonal antibody. Therefore, it is preferable to obtain cells for allodepletion from a peripheral blood draw of the donor prior to administration of growth factor for mobilization. The T-cell fraction usually is obtained by centrifugation on a Ficoll-Hypaque density cushion. The cells are washed and coincubated with irradiated recipient mononuclear cells, which act as stimulators. A convenient source for stimulator cells is obtained by generation of a cell line from the donor by infection of his or her peripheral blood mononuclear cells with a laboratory strain of EBV. The coincubation step produces stimulation of alloreactive donor T cells with resulting expression of activation markers, which then can be targeted to remove the alloreactive population. Methods for elimination include cytotoxic drugs (such as methotrexate), anti-CD25 monoclonal antibody conjugated to the toxin ricin, and immunomagnetic selection. Allodepleted cells can be cryopreserved for storage until required for administration.

All of the regulatory issues associated with the manufacturing and release of Type 351 products apply to allodepleted T cell products. Release criteria include routine assays for sterility and purity. HLA typing may be included as a confirmation that the cells in the product are of donor origin. Functional assays may include demonstration that the allodepleted cells fail to proliferate when cultured in a primary mixed lymphocyte reaction (MLR).

Antigen-Specific Cytotoxic T Lymphocytes

Two major prerequisites for generating antigen-specific CTL are the identification of appropriate viral or tumor target antigens and the availability of suitable antigen-presenting cells (APCs).[53] Once identified, CTL lines can be generated by coculturing T cells with APC that express the target antigen. These lines are expanded by restimulation with the antigen of choice and the addition of cytokines such as IL-2 (Fig. 109–4).

Use of ex vivo expanded antigen-specific T cells was first reported in 1992 by Riddell et al., who showed that $CD8^+$ T-cell clones specific for cytomegalovirus administered prophylactically after allogeneic transplantation could reconstitute cytomegalovirus-specific CTLs in vivo.[54,55] Subsequent studies using EBV-specific CTLs confirmed that donor-derived CTLs could provide effective prophylaxis and therapy against posttransplant lymphoproliferative disease.[56,57] Since then many other groups have confirmed the activity of CTLs specific for these two viruses.[58–61] An approach has been developed in which multivirus-specific CTLs generated ex vivo provide protective immunity against adenovirus, cytomegalovirus, and EBV in recipients.[62]

To generate antigen-specific CTLs, it is necessary to have a good source of APCs and a source of antigen to present to T cells. A variety of APCs have been evaluated, including fibroblasts,[55] monocytes,[60] and dendritic cells (DCs),[63–65] with different types using different sources of antigen, including virus lysate[63] or lysate of antigen-positive cells, peptides,[64] or transduction of the APC with an immunodominant antigen.[65] Use of lysates as the antigen source can be problematic because they are likely to be variable and difficult to standardize, and many processing laboratories may not be experienced in handling virus and virus-infected cells.

Lymphoblastoid cell lines (LCL) prepared using laboratory strains of EBV (as described above) make excellent APCs for use in manufacturing EBV-specific T cells. They present EBV antigens efficiently, and they express high levels of costimulatory molecules. The normal procedure for generating the LCL is coincubation with EBV derived from the tamarin B95-8 cell line. This line has undergone extensive testing and is allowed for use as a source of "clinical" EBV. The resulting LCLs are cultured in media containing acyclovir to eliminate any residual EBV. The LCLs are used to repeatedly stimulate T cells (a mononuclear cell fraction of peripheral blood leukocytes), resulting in a population that is directed toward the immunodominant EBV antigens (see Fig. 109–2). These CTLs can be frozen while release testing is performed. They are delivered frozen to the bedside, where they are thawed and administered intravenously. Release testing consists of the routine tests described earlier. For allogeneic CTL, functionality usually is assessed by cytotoxicity assays, which must demonstrate less than 10% killing of autologous phytohemagglutinin (PHA) blasts.

One limitation of this approach is that expansion of virus-specific T cells to achieve adequate dose levels is extremely time consuming. All of these procedures requires several weeks to generate APCs. One means of overcoming this problem is to manufacture banked allogeneic EBV-specific CTLs so that an "off the shelf" product is available. Clinical responses have been described for some patients who received partially matched allogeneic CTL. However, immunosuppressive drug dosage was reduced and some patients also received other therapies, so how much the allogeneic CTLs contributed to the observed

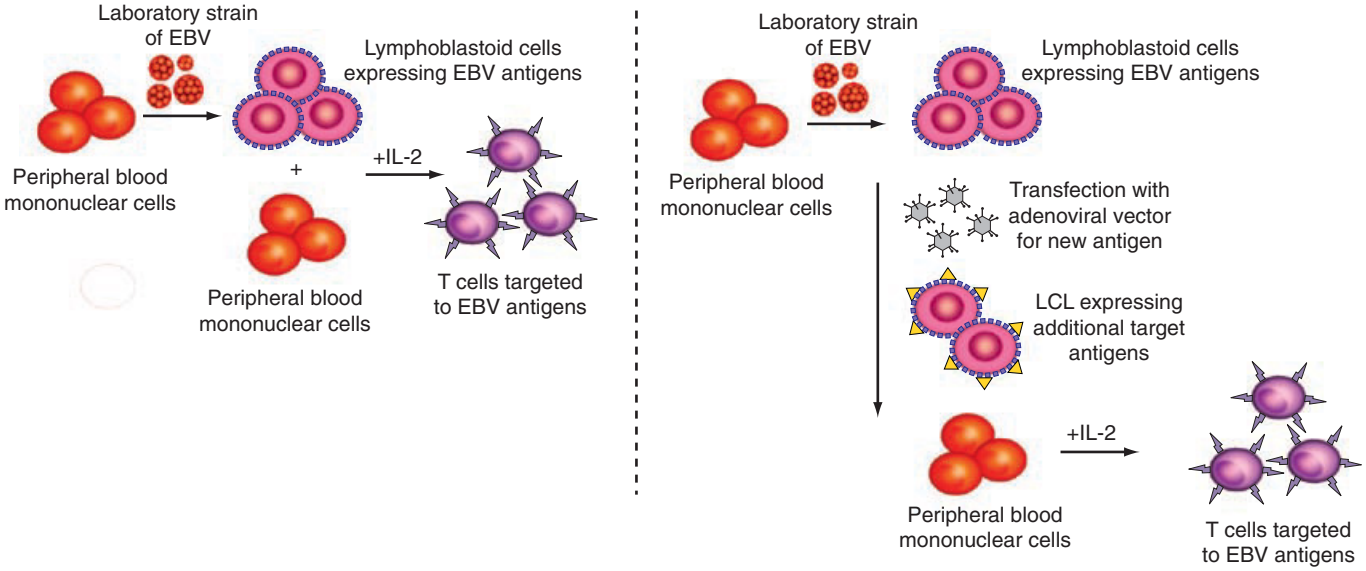

Figure 109–4 Generation of virus-specific T cells. **Left**, Use of lymphoblastoid cell line (LCL) to present Epstein-Barr virus antigens. **Right**, Use of transfected LCL to present additional antigens to T cells.

responses is unclear.[66–68] The generation of banks of CTL will require careful donor screening and HLA typing and generation of products from a sufficiently wide range of donors to allow at least partial matching with the intended recipient.

Another method for overcoming this limitation is use of rapid selection techniques such as tetramer selection and γ-interferon capture. A potential problem is the more restricted specificity of the product.

Processing and Testing Issues

Dendritic Cell Immunotherapy

DCs are powerful APCs that can be used in vitro or in vivo to elicit immune response to the antigen they are presenting.[69] A number of studies have evaluated tumor antigen-primed DCs for treatment of hematologic malignancies and solid tumors. Antigen-primed DCs are used to target T cells in vitro toward specific antigens. These cells then can be used therapeutically to eliminate viruses or tumor cells bearing that antigen. DC can be derived from bone marrow, cord blood, and mobilized and resting peripheral blood obtained from normal donors and patients.[70] The normal procedure consists of enriching monocytes from the source material, which has been accomplished by plastic adherence or CD14-based immunomagnetic selection (or by depletion of $CD19^+$ B cells and $CD2^+$ T cells). An alternative approach is use of elutriation to collect an enriched monocyte fraction from the donor. A purpose-built elutriation system for collection of monocytes is available. This method also has been used successfully to enrich monocytes from cryopreserved mobilized apheresis collections.[71]

The monocyte fraction can be cultured in polystyrene tissue culture flasks or gas-permeable bags in culture medium containing IL-4 and granulocyte-macrophage colony-stimulating factor to induce DC differentiation. This is followed by culture in medium containing proinflammatory mediators to accelerate maturation. A number of supplements have been used during this phase, including CD40 ligand or poly(I:C), interferon-γ, tumor necrosis factor-α, IL-6, IL-1β, and prostaglandin E_2. Some protocols add proinflammatory mediators at the initiation of the cultures rather than after induction of differentiation. One issue for facilities is finding clinical or GMP cytokines and growth factors. Some sources now are available, and many manufacturers will assist centers by providing information on test procedures and stability information. This information is submitted as part of the IND application, and the FDA will determine whether non-GMP reagents can be used for the specific application.

Attempts have been made to expand DC in serum-free medium, with varying degrees of success; improved growth and maturation have generally been obtained in the presence of human AB or autologous serum. Of note, minor changes in composition of the culture medium and even in the type of vessel used for culture have been reported to affect the yield, phenotype, and functional activity of the resulting DCs. Cultured DCs have been effectively transfected using native tumor DNA or lentiviral or adenoviral vectors. The cells can be cryopreserved for later administration or use.

Assessment of DC product usually involves immunophenotyping ($CD1a^+$, $CD80^+$, $CD83^-$) and some type of functional assay (ability to generate an allogeneic T-cell response or response to a recall antigen as measured by proliferation assay).

Mesenchymal Cells

Mesenchymal stem cells (MSCs) are cells with multilineage potential that have shown efficacy in promoting engraftment and suppressing GVHD.[72,73] In vitro MSCs are capable of differentiating into bone, cartilage, cardiac and skeletal muscle, neuronal cells, adipose and connective tissue, and tendons. The cells are not inherently immunogenic and do not appear to be recognized by allogeneic T cells or NK cells. They express very low levels of MHC class II and intermediate levels of class I antigens. They appear to be able to suppress in vitro T-cell proliferation and function of both memory T and naive T cells and to inhibit the development of monocyte-derived DCs in vitro.

A number of technical variables affect MSC culture and expansion ex vivo.[74] They include culture medium, passaging density, serum type and concentration, population selection, culture vessel, and use of growth factors. The following is a basic procedure. MSCs usually are isolated from bone marrow collected from the iliac crest. The cells are diluted, and the mononuclear fraction is isolated using a Ficoll-Hypaque density cushion. This fraction is plated into culture flasks to enrich for adherent cells. The nonadherent population is removed after approximately 7 days of incubation. The adherent cells are washed and detached by incubation with trypsin/ethylenediaminetetraacetic acid (EDTA) and then cultured and passaged at weekly intervals. In a study designed to optimize culture conditions, the best results were obtained when cells were cultured in low-glucose Dulbecco modified Eagle medium (DMEM)-based media containing 10% fetal bovine serum and GlutaMAX instead of L-glutamine. The cells also proliferated better when plated at low cell densities (5000–10,000 cells/cm^2) and grown in Falcon flasks. Use of basic fibroblast growth factor as a growth supplement was found to be effective; however, it caused HLA-DR induction and upregulated HLA class I expression. This did not affect the immunosuppressive capabilities of the cells. An increase in osteogenic and adipogenic potential was noted, whereas neurogenesis and CD34 engraft support were slightly suppressed. A number of media specifically designed for culture of MSC are commercially available. Various investigators have reported success growing MSCs in serum-free media, using platelet lysate, autologous serum, or human AB serum as alternatives to fetal bovine serum.

MSC can be characterized by their expression of CD105, CD73 and CD90 and their lack of expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR. They must be plastic adherent under standard culture conditions and must be capable of differentiating into osteoblasts, adipocytes, and chondroblasts in vitro. Differentiation assays involve growing MSCs under specific conditions that promote differentiation along the specific pathway. For neurogenic differentiation the medium contains linoleic acid, platelet-derived growth factor, and epidermal growth factor. Neural cells are identified by immunostaining with antibodies against tubulin BIII, synaptophysin, galactocerebroside, neurofilament M, and neuronal nuclei (NeuN). To assess adipogenic potential the medium contains dexamethasone, isobutylmethylxanthine, and indomethacin. The lipid droplets in the generated adipocytes are visualized by staining with Sudan Black IV. Osteogenic differentiation is measured by culturing the cells in medium containing dexamethasone, b-glycerol phosphate, and L-ascorbic acid 2-phosphate. Calcium accumulation and alkaline phosphatase activity in the resulting cells is visualized by alkaline phosphatase/Von Kossa staining, and the osteogenic differentiation is measured as the percentage of mineralized area in the total cultured area.

The ability of MSC to suppress an MLR is used as an indication of their immunosuppressive activity. A traditional MLR assay is used, however, in the test wells the MLR is performed on a layer of MSC seeded the day before. The response traditionally is measured by uptake of tritiated thymidine. Numerous animal assays for MSC are available but are predominantly used in preclinical studies and are not useful as release assays. Release criteria consist of the usual assays for sterility, endotoxin, and mycoplasma, with immunophenotyping for the MSC population. Depending on the intended use of the MSC, the release process likely includes an assay showing potential for differentiation into a specific lineage or ability to suppress an immune response such as an MLR assay.

Genetically Modified Cell Therapy Products

Many cell therapy approaches involve genetic modification of either APCs or effector cells. This therapy requires a source of vector that

has been manufactured to meet regulatory requirements. Vector specifications changed markedly after the death of a gene therapy patient in Philadelphia, and they continue to evolve. Manufacturers must maintain close contact with the FDA to ensure that their products meet current specifications. Manufacturing and testing of viral vectors are extremely expensive, and use of genetically modified products requires additional monitoring of recipients. Use of vectors to transduce or transfect cellular therapy products ex vivo usually requires additional testing of the product, which may include detection of replication competent virus and checking the functionality of the introduced vector (by detecting expression of the gene product).

Suicide Gene Transduced Lymphocytes

Although treatment with DLI has led to remission in patients with disease after hematopoietic stem cell transplantation, unmanipulated cells also contain alloreactive T cells and can induce GVHD. The incidence of GVHD ranges from 55% to 90% and is associated with a treatment-related mortality rate of 20%. Approaches that maintain the GVT effect while decreasing the incidence of GVHD have been evaluated and include transduction of donor T cells with a "suicide gene." Genes can be introduced into DLI to express the herpes simplex virus-1 thymidine kinase (HSV-tk). This can be activated, with resulting suicide of the donor leukocytes, by administration of ganciclovir to the recipient if GVHD develops.[75–77]

The drawbacks of this system include the reduced immune function of transduced cells,[78] the immunogenicity of HSV-tk,[79] and the occurrence of truncated HSV-tk due to cryptic splice donor and acceptor sites that render the cells resistant to ganciclovir.[80] Addition of CD28 costimulation to CD3 activation helps to preserve the immune competence of T cells.[81,82] Alternative suicide genes based on the dimerization of Fas[83] or caspase-9[84] in the apoptotic pathway have been developed to circumvent the problem of immunogenicity of HSV-tk.

T Cells Transduced with Antigen Receptors

T cells can be transduced with genes encoding a different antigen receptor: either physiologic αβ TCR heterodimers or artificial chimeric TCRs.[85,86] Several αβ TCR heterodimers specific for tumor antigens have been evaluated in the clinic, and responses have been seen in some cases.[87] Although some inefficiency from heterologous pairing between endogenous and transduced TCR chains is expected, primary T cells transduced with cloned α and β TCR chains do mediate antitumor activity in vitro.[88–90] The main drawback of cloned TCR is HLA restriction, which limits its use to a subset of patients with a particular HLA type. Chimeric TCRs recognize target antigens on tumor cell surface through an extracellular domain, which most commonly is derived from the variable domains of an immunoglobulin. The extracellular domain is linked via a spacer to the intracellular signaling domain, which triggers T-cell activation. The latter consists of either the ζ-chain of the TCR complex or the γ-chain from FcεRI.

These studies require considerable upfront work to develop the TCR construct and to evaluate the construct for satisfactory expression. The producer cell line then must be prepared using a Master Cell Bank (e.g., of PG13 cells) and the vector generated as a supernatant from the line, purified, and tested extensively prior to use for transduction. This is a labor-intensive and expensive process that usually is beyond the expertise of cell processing facilities. Preparation of the cell product can be complex, depending on the specific protocol. Some form of stimulation may be necessary to expand the T cells and achieve the doses required. This may involve addition of immobilized or fluid phase antibody or third party cells.

Tumor Vaccines

Tumor vaccines as an approach to inducing immunity have been evaluated. Various techniques have been evaluated, including use of DCs pulsed with a tumor-associated antigen preparation and use of the entire tumor cell as an immunogen, either unmodified and/or transduced with immunostimulatory genes, aimed at eliciting a broad-based, robust immune response. This method has been used in two patient populations. In the first study, the patient's autologous Chronic Lymphocyric Leukemia or acute leukemia cells were used as the immunogen after transduction with CD40 ligand and IL-2. The results demonstrated induction of immunity and some clinical responses.[91–93] In the second study, a transduced allogeneic tumor cell line was used as the immunogen.[94]

From the manufacturing perspective, the autologous product is much more of a challenge because a stable tumor cell line must be isolated from each patient. This can be extremely difficult process. Many isolated lines do not expand well in culture, or they change phenotype over time. In some patients the line cannot be generated; other patients progress clinically before the vaccine is available and are excluded from the study. As a result, the autologous approach has a relatively high "failure rate," making it difficult to accrue a sufficient number patients into study and adding to the cost of manufacturing. The allogeneic cell line approach is technically easier because a line is selected prior to the study and can be used as the generic immunogen. This line must be tested extensively for infectious agents and should pass the FDA testing criteria for Master and Working Cell Banks. Currently testing of this type costs $100,000–$200,000 for each line. Scientifically, the drawback is that the selected line may not adequately express the antigen or range of antigens located on each patient's tumor. In addition, the choice of immunostimulatory molecules that are expressed or enhanced by transduction of the cell line may not be those that would most effectively evoke an immune response. These products are relative expensive to produce, involving not only the costs of testing the tumor cell line but also the expense of manufacturing and testing the vectors used for transduction. However, these are one-time costs because the same vaccine is used for all patients in the study.

Release testing involves testing for sterility, endotoxin, and mycoplasma, with immunophenotyping of the cells and some form of test demonstrating that the line has been effectively transduced (e.g., flow cytometry for CD40 ligand and IL-2 production in the examples described earlier). Because the product will be stored cryopreserved over the course of the study and thawed for administration to each patient, the requirement for an ongoing stability study should be anticipated.

FUTURE DIRECTIONS

Immunotherapy is undergoing a resurgence in interest. Improvements in our understanding of immune responses, targeting, immunomodulation, T-lymphocyte biology, and antigen presentation all have contributed to the revival, as has the new area of regenerative medicine using pluripotent progenitors capable of differentiation along multiple pathways. These two fields will ensure the future of cell-based therapies. The development of a new regulatory framework that applies to both areas has added to the complexity of manufacturing cell therapy products for clinical trials. This emphasizes the need for close collaboration among basic scientists, manufacturing staff, clinical researchers, and regulatory agencies. These rapidly moving areas of medicine require a flexible approach that facilitates the generation of fundamental data while allowing prompt incorporation of new findings as they emerge. This is a challenge to all involved, and the only way to meet that challenge is to open and maintain lines of communication. From the manufacturing perspective we must ensure patient and donor safety and the highest quality of the products. We face the scientific hurdles of preparing cell products that frequently are poorly characterized with regard to effector cell content and for which almost no in vitro functional assays reflecting clinical efficacy

are available. Methods for separating, expanding, manipulating, and storing these products are at a relatively early stage of development, and the market opportunities for many products presently do not warrant interest from commercial entities. In spite of these hurdles, much remains to be learned from this field, and these lessons should benefit basic science, manufacturing technologists and clinicians, and hopefully many patients.

CHAPTER 110

GENE TRANSFER FOR HEMATOLOGIC DISORDERS

Katherine A. High and Malcolm K. Brenner

Gene transfer is a novel area of therapeutics in which the active agent is a nucleic acid sequence, rather than a protein or small molecule. Originally conceived as a method for treating genetic disease by supplying a normal copy of a missing or defective gene, the therapeutic possibilities have been extended to include enhancement of natural protective mechanisms (eg, tumor vaccines) and augmentation of response to conventional therapies (eg, gene transfer of thymidine kinase to render tumor tissue sensitive to ganciclovir). Clinical experience with gene transfer began in 1990 when two children with severe combined immunodeficiency disease due to adenosine deaminase (ADA) deficiency underwent gene modification of lymphocytes that were then reinfused into the peripheral circulation. Since that time, over 4000 patients have been enrolled in gene transfer studies,[1] with many clear successes and two fatalities directly attributable to the gene transfer event.[2–4] There are at this time, however, no licensed gene transfer products in the United States and the field remains a developmental one, with most ongoing studies in early phase testing.

All gene transfer strategies consist of three basic elements—a therapeutic gene to be transferred in, commonly referred to as the transgene; a method of delivering the gene, termed a vector; and a physiologically relevant target cell or tissue. The disease entity itself and its pathophysiology generally determine the target cell: for sickle cell disease, hematopoietic cells; for cystic fibrosis, respiratory epithelium, etc. In hematology, the detailed elucidation of the pathophysiology of disease at the molecular level has made it fertile ground for the pursuit of gene transfer approaches to disease, because in many cases the defective gene has been identified and the cloned cDNA is available. The major limitation to progress in gene transfer at this point lies with the vectors, which have a series of shortcomings that have limited successful application. A comprehensive discussion of vector technology is beyond the scope of this chapter, but the subject has been recently reviewed,[5,6] and some of the more troublesome limitations are listed in Tables 110–1 and 110–2.

Vectors are often divided into viral and nonviral classes. Nonviral vectors, although theoretically quite attractive, have generally been characterized by low efficiency, which has limited their application in clinical settings. The viral life cycle is well suited for gene transfer, and viruses have been extensively adapted for use as vectors. This generally involves removing some or all of the viral genome and replacing it with genes of therapeutic interest. Viral genes required for replication are then supplied in *trans* during vector manufacture, with only the therapeutic gene cassette being packaged into the viral capsid. Such vectors are capable of a single round of infection but not of additional rounds of replication in the host.

Most of the clinical experience with gene transfer has been with viral vectors. Both viral and nonviral vectors can be delivered either ex vivo, where the target cells are removed from the host, transduced in the laboratory, and then reinfused, or in vivo, where the vector is injected directly into the recipient. Ex vivo transduction has been extensively explored using hematopoietic cells, either $CD34^+$ cells or their later progeny, as target cells, and much of the progress in gene transfer over the last decade has involved methods for achieving more efficient transduction of hematopoietic cells.

In an ideal setting, the donated gene persists for the duration needed (which may range from days to a lifetime), whereas the gene delivery vehicle is present only transiently. Toxicities associated with gene transfer can arise from the vector itself or from the transgene product; the distinction is worth making, because it informs future work with both components. Clinical studies in the last decade have been key to defining the safety and toxicity profiles of the available classes of vectors. Toxicities arising from the transgene product are gene-specific and defy generalizations except that there is a growing recognition that certain classes of genes, including those encoding growth factors, their receptors, signal transduction molecules, and transcription factors, may represent a higher level of risk than those encoding proteins with more narrowly circumscribed functions, such as globins or coagulation factors. The field has been more successful at identifying toxicities arising from vectors; these include problems related to the immune response, to complications arising from integration of the donated gene sequence into the target cell DNA, and to the risk of germline transmission of the donated gene sequences, if the vector transduces unintended target cells (oocytes or spermatocytes). Toxicity arising from an immune response to a viral vector is illustrated by the response to systemic infusion of adenoviral vectors, which routinely leads to fevers, myalgias, nausea, and occasional vomiting.[7] Evidence suggests that this is primarily an innate immune response to the viral capsid, because a similar toxicity profile is seen in animals even with infusion of UV-irradiated adenoviral vector.[8,9] The potential consequences of a vector-directed immune response include immune-mediated destruction of transduced cells, promotion of an adaptive immune response to the transgene product, and systemic inflammatory response syndrome, which can be fatal. Viral vectors differ widely in their propensity for triggering harmful immune responses; this is an area of ongoing investigation. The risks arising from integration of the vector into the target cell DNA are clearly illustrated by the development of an acute lymphoblastic leukemia (ALL)-like complication in five children who had been treated for X-linked severe combined immunodeficiency (SCID) by retroviral transduction of $CD34^+$ cells.[10] In these cases, the proliferative clone of cells was characterized by a proviral integration event occurring near a gene encoding a component of a hematopoietic transcription factor complex (vide infra). Vectors differ widely in terms of integrating capacity; however, even in the case of those that are classified as nonintegrating, it should be noted that foreign DNA that enters a cell always carries the potential to integrate. Investigation of integration sites, mechanisms, and consequences is also an area of active research in the field.[11–13] The inclusion of flanking insulator elements that can block promoter activity from an integrated vector sequence may reduce the risk associated with this feature of integrating vectors.[14]

The risk of germline transmission from systemic infusion of a vector at this point remains theoretical, although there have been cases where DNA extracted from semen of recipients has been transiently positive by polymerase chain reaction (PCR) for vector sequences.[15–17] Expression of the donated gene in a fetus, or altered expression of an endogenous gene at a site of integration, could theoretically disrupt the normal program of development and lead to fetal malformation or death and also raises ethical concerns arising from lack of consent. The risk of germline transmission depends on the route of administration of the vector and whether the vector efficiently transduces germ cells. Obviously, ex vivo transduction of target cells reduces this risk considerably.

Table 110–1 Limitations of Current Vector Technology

Low transduction efficiencies
Limiting tissue tropisms
Size of insert that can be accommodated
Difficulty in achieving regulated expression
Risk of insertional mutagenesis
Toxicity related to the vector capsid or viral proteins

Other limitations of current vector technology need to be addressed. These include vector-specific tissue tropisms that limit the cell types that can be transduced, and limitations on the size of the insert that can be accommodated (Tables 110–1 and 110–2). The development of promoters that can be precisely regulated by orally administered small molecules is underway, and will be an important prerequisite for safe delivery of some transgenes.

To those outside the field, the pace of development of clinical gene transfer has appeared slow. For novel classes of therapeutics, however, early clinical studies are perforce time-consuming, as key safety issues are uncovered and addressed. The fruit of the first decade of clinical studies in gene transfer was the identification of most of the critical safety issues. None of these are yet judged to be insuperable obstacles, and the potential benefits of gene transfer, which are considerable, still appear to outweigh the problems. Strides in vector manufacturing and standardization have resolved the issue of whether a biologic product as complex as a multicomponent viral vector can be reliably and reproducibly produced. What remains an issue is whether the human immune response, particularly to viral vectors, can be managed so as to achieve optimal responses in human subjects. Work over the next decade is likely to provide the answer.

GENE TRANSFER FOR GENETIC DISEASE

Hematologists have played a leading role in the field of gene transfer. In principle, any inherited genetic disorder that can benefit from transplantation of normal hemopoietic stem cells (see Chapter 100) could benefit from genetic correction of autologous stem cells as well. When Moloney-derived vectors were all that were available for clinical protocols, concerns about inefficient gene transfer and poor expression, the lack of selective advantage for transduced cells, and risks of oncogenesis all served to limit clinical investigation even of promising preclinical studies. With the successful development of lentiviral derived vectors (see also gene transfer for hemoglobinopathies and thalassemia) and the realization that submyeloablative treatment of patients can permit engraftment of gene-modified cells, there are now several efforts underway to treat a broader range of inherited metabolic disorders using gene-modified hematologic progenitor cells. Other hematologic disorders, such as hemophilia or porphyrias, will likely require the use of different target cells, eg, liver. This section will review the progress and problems over the last several years in three classes of genetic disease, hereditary immunodeficiency states, hemoglobinopathies and thalassemias, and hemophilia. These have been chosen because there is a considerable body of data available and because they illustrate well the problems presented by gene transfer and the strategies that have been used to overcome them. It should be noted that other disorders, such as Fanconi anemia, have been approached by gene transfer techniques; for overviews of these, the reader is referred to the literature.[18]

Gene Transfer Using Hematopoietic Cells as Targets—Immunodeficiency Diseases

X-Linked Severe Combined Immunodeficiency

The first example of therapeutic gene transfer in a clinical setting was reported in 2000, when Alain Fischer and colleagues reported reconstitution of T, NK, and B cell function in children with X-linked severe combined immunodeficiency disease following retroviral transduction of $CD34^+$ cells from affected infants.[19] X-linked SCID is a rare disorder affecting less than 1 in 100,000 births and is due to a mutation in the gene encoding the γc subunit of the cytokine receptor for IL-2, -4, -7, -9, -15, and -21. In the absence of the receptor, differentiation of hematopoietic stem cells to mature T and NK cells does not occur; B-cell immunity is thus also affected. The disease is lethal without treatment but is cured by bone marrow transplant from an HLA-identical donor. For those who lack an HLA-matched donor, a haploidentical transplant (eg, from a parent) results in a 78% survival rate (at the most experienced centers[20]), but survival is generally complicated by poor B-cell function, requiring monthly infusions of intravenous immunoglobulin (IVIg). In the study by Fischer and colleagues, marrow $CD34^+$ cells from infants and young children without an HLA-identical donor were transduced daily for 3 days with a retroviral vector expressing the γc subunit. T-lymphocyte counts began to rise approximately 30 days after infusion of the transduced cells and had reached normal levels within a few months. Detailed studies of T-cell function and response to primary vaccination documented reconstitution of immune function.[19,21] In all, the group treated 11 boys with X-linked SCID, and in follow-up in early 2002, 9 of 11 had had an excellent response,[22] and were well on no treatment. One teenager and one infant who had disseminated bacilli Calmette–Guerin infection at the time of gene transfer failed to reconstitute T-cell function and, in the case of the infant, went to bone marrow transplant. Failure of the procedure in the 16-year-old patient likely reflected poor thymic function, because efficient transduction of his $CD34^+$ T cells was documented.[23] Similar success was attained in a gene transfer trial in London, with 10 of 10 treated subjects well up to 59 months after initial treatment.[13] The key features contributing to the success of this work included the disease itself, where there is a strong in vivo proliferative advantage for transduced cells compared with nontransduced cells,[24] and the series of incremental advances in retroviral transduction of human hematopoietic stem cells (HSCs) that occurred in the 1990s, including improved techniques for isolating $CD34^+$ cells, identification of combinations of early-acting cytokines that could induce cell proliferation without loss of repopulating capacity and recognition of the utility of colocalizing vector particles and HSCs using fibronectin fragments.[25]

Compared with a haploidentical bone marrow transplant, gene transfer appeared to provide a better outcome, because there were no fatalities and those with a positive response had complete reconstitution of immune function (vs continued requirement for IVIg infusions in bone marrow transplantation [BMT]). In addition, reconstitution appeared to occur more quickly with gene transfer, sometimes a critical issue in children gravely ill with infections. However, the analysis of risk–benefit changed approximately 3 years after the first subjects were treated, when one of these developed a T cell-proliferative syndrome characterized by lymphocytosis (WBC 300,000) and splenomegaly. Molecular analysis of these cells revealed a monoclonal population of αβ T cells characterized by a single integration event on chromosome 11, in which the retroviral-encoded sequence was positioned in reverse orientation within the first intron of the *LMO-2* gene, which encodes a protein involved in transcription factor complex assembly.[3,26] This integration event was associated with increased expression of LMO-2 in the circulating T-cell population (LMO-2 is normally expressed only in earlier progenitors), a finding that has been reported previously in acute lymphoblastic leukemia, usually in association with a t(11:14) translocation.[27] Within months a second patient presented with similar findings,

Numbers of Clinical Trials Worldwide	293	8	322	46	0	43	1	0	0	99	230	0
Main Advantages	Persistent gene transfer in dividing cells	Persistent gene transfer in transduced tissues	Highly effective in transducing various tissues	Elicits few inflammatory responses, non-pathogenic	Persistent gene expression in both dividing and non-dividing cells	Large packaging capacity with persistent gene transfer	Wide host cell range; lack of immunogencity	Limited immune responses against the vector	Transfects many cell types with long term gene expression	Transfects many cell types. Large holding capacity to enable a high number of base pairs	Efficient in gene transfer, limited immunogenecity	Specific integration site
Main Disadvantages	Theoretical risk of insertional mutagenesis (occurred in 2 cases)	Might induce oncogenesis in some cases	Viral capsid elicits strong immune responses	Limited packaging capacity	In need of a stable packaging system	Residual cytotoxicity with neuron specificity	Limited packaging capacity	Transduced gene expression is transient	Early Stage in development	Expensive to produce	Transient and low level expression	Early stage in development

including a clonal population of cells showing proviral integration adjacent to the *LMO-2* locus, and since that time an additional three subjects have also developed a leukemia-like syndrome.[3,10] A puzzling aspect of this serious complication of therapy is that a similar X-linked SCID trial carried out in London had initially reported no instances of leukemia or lymphoproliferative disorders in any of their 10 successfully treated subjects; recently, however, one of these subjects also developed a leukemia-like syndrome. A comprehensive study of retroviral integration sites in these subjects[12,13] has demonstrated that the retroviral insertion sites in the transduced $CD34^+$ progenitor cells differ from those detected in engrafted $CD3^+$ cells. This suggests that vector integration sites may influence cell survival, engraftment, or proliferation.

Clinical gene transfer experiments started in 1990, and hundreds of patients have received cells transduced with retroviral vectors. The question thus arises as to why the subjects in the X-linked SCID trial developed this complication whereas so many others did not. Several factors may have contributed. The cytokine receptor is required for T and NK cell maturation; there is thus a powerful and stringent in vivo selection for and expansion of the transduced cells, a situation that does not occur in most other hematologic diseases for which hematopoietic stem cell gene transfer has been attempted. Second, in this case, the transgene product is essentially a growth factor receptor; genes encoding growth factors, their receptors, signal transduction molecules, and transcription factors, may represent a higher level of risk (in terms of altering cell growth) than genes with more narrowly defined functions.[28] Finally, two of the patients who developed this complication were among the youngest treated, and received a higher dose of cells per kg body weight than other subjects, reflecting the fact that their $CD34^+$ cells expanded rapidly in culture. Whether cells from young infants are in some way different from those of older children (eg, related to differences in cord blood $CD34^+$ vs adult $CD34^+$ cells) in terms of abundance and identity of open chromatin remains to be explored. At the time of writing, the federal regulatory agencies in the United States have advised against the use of retroviral transduction of $CD34^+$ cells in the setting of X-linked SCID, although exceptions may be made for those without other treatment options. Continued follow-up of children who have already received gene-modified cells for this disease will define the frequency of deleterious consequences of retroviral integration in this setting.

Adenosine Deaminase–Severe Combined Immunodeficiency

Severe combined immunodeficiency due to ADA deficiency is of special interest, since the first clinical gene transfer trials were conducted in children with this disorder. The absence of functioning ADA results in accumulation of large amounts of deoxyadenosine, an ADA substrate, which is converted to a toxic metabolite in T cells, with resulting loss of function. The disease is cured by HLA-matched bone marrow transplantation. Those who lack an HLA-matched donor can be treated, generally less successfully, with a haploidentical transplant and/or with polyethylene glycol-conjugated bovine ADA. It had been postulated that gene-corrected cells have a survival advantage, and a report of reconstitution of the immune system in a patient with ADA deficiency after a spontaneous gene reversion event[29] supports this hypothesis. Moreover, the observation that immunologic reconstitution occurred in patients who achieved only donor T-cell engraftment after BMT suggested that transduction of T cells alone would be adequate for clinical improvement. Finally, because most patients experience some increase in circulating numbers of T cells after PEG-ADA therapy, it is possible to test the efficacy of T-cell transduction by harvesting and transducing these cells.

The first clinical gene transfer trial took place in 1990 in two children with ADA-SCID; both children lacked an HLA-matched donor and failed to achieve full immune reconstitution on PEG-ADA administered for at least 9 months. T cells were harvested from peripheral blood and transduced with a retroviral vector encoding ADA. Cells were expanded in culture and infused after 9 to 12 days, with no selection to enrich for transduced cells and no myeloablation prior to cell infusion. Each patient received a total of approximately 10^{11} cells, although the number of *transduced* cells was approximately 10-fold higher in the first patient compared to the second. Both patients were continued on PEG-ADA therapy at doses in the range of 10–14 U/kg/week. The first full-length report of results[30] documented increased T-cell count and ADA enzyme activity in the first patient; the second patient showed an improvement in T-cell count but no measurable ADA activity above baseline. A follow-up report[31] documented that 10 years after gene transfer, 20% of the circulating T cells in the first patient were still positive for the donated gene by real-time PCR, with multiple integration sites documented on Southern, whereas only 0.1% were positive in the second patient. This report is important in that it provides evidence supporting the long-term safety of retroviral transduction of T cells. It also documents their long lifespan in the periphery, and the fact that the Moloney retroviral promoter is resistant to silencing in vivo. However, interpretation of efficacy in this setting has been complicated by the continuation of PEG-ADA infusion therapy, so that it is not clear what contribution gene transfer made to the patients' clinical courses.

Kohn and colleagues[32] assessed this issue in a trial in which PEG-ADA therapy was reduced and then stopped in one patient. In their study, cord blood $CD34^+$ cells from three infants with ADA-SCID were transduced with a retroviral vector expressing ADA and reinfused. Children were also treated with PEG-ADA at doses ranging from 30 to 60 U/kg/week. In subject 1, who had the highest levels of gene marking (1%–3% PBMCs, 10%–30% of T cells) and of T-lymphocyte numbers, PEG-ADA was gradually reduced starting at 30 months post gene transfer, and stopped altogether at 48 months. Over the ensuing 2 months, there was a more than 100-fold decline in plasma ADA level, a 100-fold increase in levels of erythrocyte deoxyadenosine nucleotides, and large decreases in numbers of B and NK cells. The proliferative response to tetanus toxoid, previously demonstrated to be present, was lost entirely, although absolute numbers of $CD4^+$ and $CD8^+$ T cells remained constant. Two months after stopping PEG-ADA, the child presented with an upper respiratory tract infection, sinusitis documented on X-ray, and oral monilia. PEG-ADA was restarted, with resolution of infection and return of immunologic parameters to baseline. Although these data are from a single patient, they strongly suggest that the levels of gene transfer and expression achieved in this instance were not adequate to support immune function.

More recently, Alessandro Aiuti, Maria Grazia Roncarolo, and colleagues have reported clinical success in the setting of ADA-SCID after two key changes to the protocol.[33] First, the five subjects received nonmyeloablative conditioning with busulfan 2 mg/kg/day × 2 days prior to infusion of the gene-modified cells, to facilitate engraftment of the gene-modified cells. Second, the subjects were not treated with PEG-ADA at any point after gene transfer, conferring a survival advantage on the transduced cells. With these modifications, all subjects showed marked improvement in levels of circulating peripheral blood lymphocytes, with 70% to 100% of circulating T cells shown to contain vector.[11] All subjects have shown reconstitution of immune function, and were able to return home on no treatment, with documented gains in growth. Either or both of the modifications to the protocol may have been critical to success; studies in which one but not both of these maneuvers (myelosuppression, withdrawal of PEG-ADA) are carried out may help to answer this question.

In terms of safety, at a median follow-up of 3.1 years, there have been no adverse events related to gene transfer in the ADA-SCID trial.[11–13] In a recent study of retroviral integration sites in these patients, the investigators confirmed a bias toward gene-dense regions, with a preference for the region around transcriptional start sites and highly expressed genes, in both preinfusion transduced $CD34^+$ cells and in lymphoid and myeloid progeny from blood and bone marrow at a series of time points after transduction. The investigators identified insertion sites proximal to protooncogenes and genes controlling cell growth, including *LMO-2*, but there was no associated clonal

selection or expansion noted.[11] One can speculate that the difference in outcome for ADA-SCID versus X-linked SCID reflects some contribution from the transgene itself in the case of X-linked SCID, but definitive proof is lacking. Clearly, the results in the ADA-SCID trial are at this writing the best example of safe and effective gene transfer for genetic disease. It will be important to confirm that these findings can be safely extended to larger numbers of patients.

OTHER IMMUNODEFICIENCIES

Inherited disorders in which there is no selective advantage to cells expressing the corrective gene represent more of a challenge to gene therapy, given the inefficiency of most gene transfer vectors. Nonetheless, recent data from patients treated for chronic granulomatous disease (CGD) have shown success even in the absence of selection.[34] CGD is a disorder of the innate immune system, in which there is a deficiency of the oxidative microbial activity due to mutations in the X-linked gene encoding $gp91^{phox}$, a component of the oxidase complex. Affected individuals suffer persistent infection with organisms such as staphylococci that are normally killed after phagocytic ingestion. In an initial report on 2 patients (a third was treated subsequently), Ott et al[34] showed that administration of myeloreductive chemotherapy provided sufficient "space" for engraftment of gene-modified stem cells. Newly emergent gene-modified neutrophils were able to substantially improve the patients' infections, even to the extent of healing a persisting lung abscess. Though extremely encouraging for efforts to broaden the application of stem cell gene therapy, two subsequent observations have led to caution. First, analysis of the proviral integration site showed that there was progressive selection of clones with integrants close to a restricted number of genes (MDSI-EVI1, PRDM16 and SETBPI), which became activated. Given the experience in X-SCID, this is clearly concerning. It implied that a selective growth advantage had developed because of disruption of normal growth-regulating mechanisms and raised the specter of progression to monoclonality and then malignancy. Indeed, 3 years after treatment 2 patients developed myelodysplasia, one of whom has received a stem all transplant (Grez, personal communication). Another concern is that one of the treated patients subsequently died of infection, implying that correction may have been incomplete. Clearly, cautious treatment of additional patients will be needed to obtain a true risk–benefit assessment.

Gene Transfer for Hemoglobinopathies and Thalassemias

Sickle cell disease and thalassemia have attracted considerable interest as disease targets for gene transfer approaches: current treatment for both entities is unsatisfactory, the globin genes are available, the diseases are well-characterized at the molecular level, and the target levels of expression required for improvement of disease phenotype are relatively modest—around 20% of normal levels of expression of the β-globin genes. Despite these advantages as a model, gene transfer for these diseases has proven to be a complex undertaking, with progress stalled until more efficient (lentiviral) vectors were developed. The current state of the field is cautious optimism, the optimism based on long-term improvement in mouse models of the diseases,[35,36] the caution based on the results in the X-linked SCID trial (vide supra). Clinical trials of gene transfer for these diseases have been initiated, but results have not yet been reported.

Early studies documented that murine retroviral vectors expressing the β-globin genes could transduce murine and human hematopoietic stem cells, but levels of expression were low.[37–39] Concurrent studies revealed that the regulation of the β-globin locus depended on a 25-kb sequence located approximately 60 kb upstream of the adult β-globin gene; this locus control region (LCR) was required for high-level expression in transgenic mice.[40] Molecular analysis of the LCR identified smaller regions that were sufficient for high-level expression, but retroviral vectors composed of these LCR fragments and globin gene sequences failed to achieved integration of unrearranged copies of the transgene in target cells at high frequency.[41] A decade of research uncovered factors responsible for this, including cryptic splice sites that resulted in internal deletions in the LCR/globin minigene[42,43]; the quiescence of hematopoietic stem cells, an obstacle given the requirement of retroviruses for nuclear mitosis to gain access to nuclear chromatin; in *human* HSCs, the low level of receptor protein needed for retroviral entry into the cell,[44–46] position-dependent levels of expression following integration[43,47,48]; and silencing of gene expression over time. Solutions to several of these problems have been demonstrated (Table 110–3), but a substantial breakthrough awaited the development of a vector with improved transduction characteristics. In 2000, Michel Sadelain and colleagues designed and produced a lentiviral vector that achieved long-term "cure" in a mouse model of thalassemia.[36] Success in this case depended on several unique features of their vector. Lentiviral vectors have a higher packaging capacity than retroviral vectors, and Sadelain et al used this to incorporate larger fragments of the LCR, which helped to overcome position effects. The HIV rev protein acts to suppress splicing of the viral RNA genome; its inclusion prevented LCR/globin splicing. The lentiviral vector was pseudotyped with an alternative envelope protein (vesicular stomatitis virus-G, VSV-G), allowing higher transduction rates into murine HSCs. For reasons that are not entirely clear, silencing of expression occurs less frequently with lentiviral vectors than with retroviral vectors. In Sadelain's experiment, lethally irradiated recipient mice were transplanted with lentiviral-transduced cells from syngeneic mice.[36] Expression of human β-globin was high-level and persistent, so that at 24 weeks, tetramers composed of mouse α-globin and human β-globin constituted 13% of total hemoglobin. The same experiment in β^0-thalassemic heterozygote mice resulted in long-term clinical improvement, including increased hemoglobin and hematocrit and

Table 110–3 HIV Gene Therapy

Cells Given	Proposed Benefit	Type of Study	Outcome
Autologous T cells expressing nonfunctional Rev M10 or wild-type M10[97]	Cells should resist HIV infection if nonfunctional Rev M10 present	Phase I	Safe. Improved short-term survival of cells with nonfunctional M10
Autologous T cells expressing Rev M10 or nonfunctional M10[98]	As above	Phase I	Safe. Cells combining mutant Rev M10 survived up to 140 days. No change in viral load
HIV-specific CD4 and $CD8^+$ T cells transduce to express chimeric CD4-zeta T-cell receptors[99]	Modified T cells inhibit viral replication and kill virus-infected cells in vitro	Phase II	Gene-modified cells persistent and produced reduction in two of four viral reservoirs and tend toward fewer recurrent viremias
T cells from identical twin discordant for HIV infection expressing chimeric CD4/CD3-zeta chimeric receptor[100]	Cells have lytic activity against virus-infected cells	Phase I	Safe. Prolonged persistence when CD4 and $CD8^+$ cells infused together

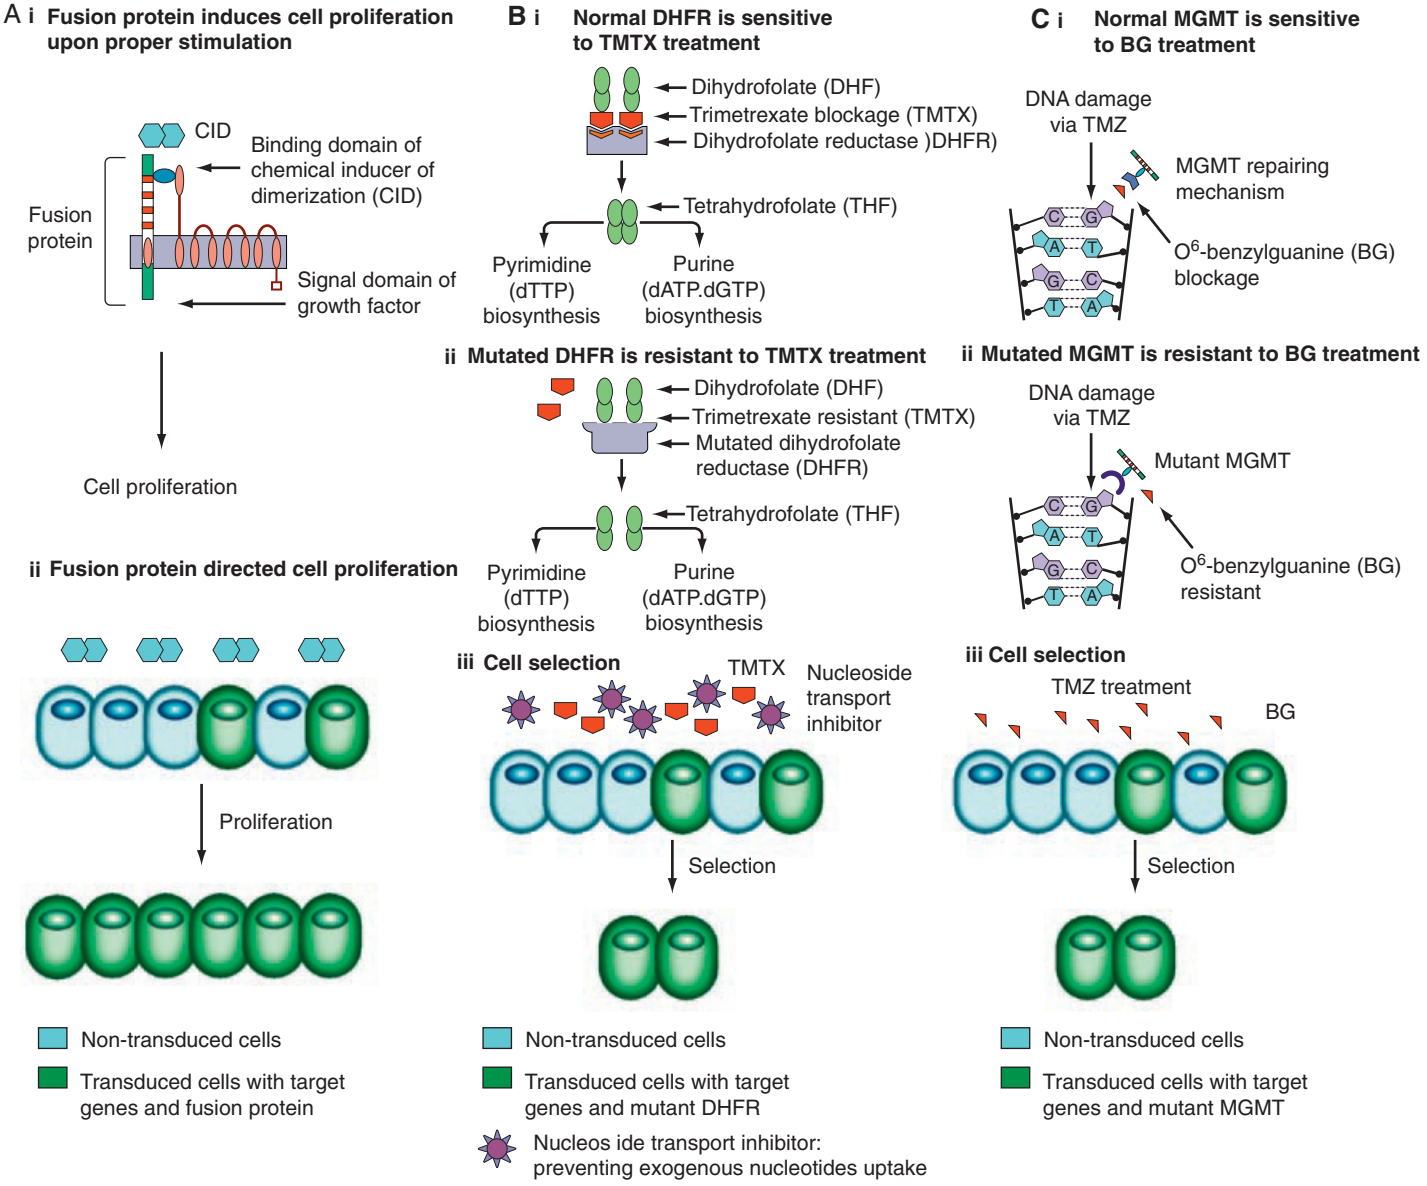

Figure 110–1 Experimental strategies for providing survival or proliferative advantages to transduced cells. **A**, Cells are transduced with sequences encoding a transmembrane fusion protein with an intracellular domain that signals cell growth, and extracellular domains that, when induced to dimerize by a small molecule (orally delivered) drug, result in growth of the transduced cell. **B**, Cells are transduced with a vector expressing a mutant dihydrofolate reductase, which is resistant to methotrexate, an inhibitor that blocks the endogenous nucleotide synthesis pathway. When cells are treated with TMTX along with a nucleoside transport inhibitor, the transduced cells enjoy a survival advantage over nontransduced cells. **C**, Cells are transduced with a vector expressing a mutant MGMT, which is resistant to BG, an inhibitor that blocks the DNA-repairing ability of MGMT. When cells are treated with TMZ, which induces DNA damage, in the presence of BG, the transduced cells enjoy a survival advantage over nontransduced cells.

a drop in the reticulocyte count. This group has now extended their findings to a novel mouse model of β^0-thalassemia major, with similar impressive results.[49] The robustness of the findings is attested to by the fact that success using a similar vector was achieved by another group in a different disease model. Leboulch and colleagues transplanted lethally irradiated mice with murine HSCs transduced with a lentiviral vector expressing an antisickling β-globin variant. Transduction and transplantation of cells from normal mice resulted in 16% of circulating hemoglobin comprised of tetramers containing the variant β chain, whereas in two different murine models of sickle cell disease they constituted 10% or 48% of total hemoglobin, with accompanying improvement in all hematologic parameters.[35]

These recent results are encouraging in a field where progress had seemed slow over the last decade. Translation of these findings to the clinic will require a few additional components that are not yet in hand. For example, complete myeloablation, as occurs when mice are lethally irradiated, is not an acceptable risk in most patients with sickle cell disease or thalassemia. Several strategies that confer a survival advantage (such as occurs naturally in immunodeficiency diseases) on transduced cells are under development (Fig. 110–1[50–52]); one that shows safety and efficacy in large animal models and humans would facilitate gene transfer for hemoglobinopathies and thalassemias. Lentiviral vectors have been extensively engineered to reduce the risk of recombination events that can lead to replication-competent virus, and transcriptional regulatory sequences have been deleted from the 3' LTR, so that the integrated proviral genome lacks viral regulatory sequences that can interfere with transgene expression or promote expression of adjacent genes. The question has been raised

about whether the adverse events in the X-linked SCID trial should halt development of gene transfer into hematopoietic cells; it seems likely in that case that a number of disease- or protocol-specific factors (vide supra) may have contributed to the outcome. Whether or not additional adverse events are observed in those who have undergone retroviral transduction of HSCs, it may be prudent to incorporate insulator elements,[14] which can block effects of distal enhancers, into new vectors. Clinical studies addressing the safety of lentiviral vectors in humans are now underway in patients with HIV (see below) or with adrenoleukodystrophy.

Gene Transfer for Hereditary Disease Using Nonhematologic Target Cells—Hemophilia as a Model

Hemophilia differs from the other hematologic disorders discussed here in that the target cell is generally not one of hematopoietic origin; rather, target cells have included liver, skeletal muscle, and fibroblasts (in the clinic), and the GI tract, endothelial cells, and other cell types (in preclinical studies). Hemophilia has been an attractive model for studying gene transfer for several reasons; there is latitude in the choice of target tissue, because biologically active clotting factors can be made in many different cell types, and improvement of circulating levels of F.VIII or F.IX by even a modest amount is likely to improve the phenotype of the disease. Moreover, the existence of genetically engineered mice and of naturally occurring dog models of the disease, coupled with the availability of the murine and canine F.VIII and F.IX genes, offers the possibility of evaluating gene transfer strategies for safety and efficacy before moving to the clinic. Finally, the biologically relevant endpoint for most hemophilia gene transfer strategies is the circulating plasma level of Factor VIII or Factor IX; this endpoint is easily measured in most hospital coagulation laboratories and is known to correlate well with disease symptoms. Patients with levels lower than 1% normal have severe disease with frequent spontaneous hemorrhage; those with levels of 1% to 5% are more moderately affected; and those with levels 5% or higher are only mildly affected.

The attractiveness of hemophilia as a model and the relatively large numbers of affected patients initially resulted in active interest and the initiation in the United States of five clinical studies using five different gene transfer strategies. In the first of these, a plasmid carrying a selectable marker and a truncated form of the *F8* gene, with a deletion of the B domain, was introduced by ex vivo electroporation into autologous fibroblasts cultured from skin biopsies of affected patients. Clones expressing high levels of F.VIII were selected and expanded, then reimplanted onto the omentum of patients in a laparoscopic procedure. Results in the first six subjects showed evidence for a clinical response in terms of reduced frequency of spontaneous bleeds, reduced number of factor infusions, and levels of F. VIII activity above baseline (but not >2% in most cases) in 3 of 6 subjects.[53] These markers of gene expression were detected for a period of months but eventually returned to baseline in all subjects. Possible explanations for the decline in circulating levels include fibrosis surrounding the site of cell implantation, senescence or immune-mediated destruction of the genetically modified cells, or loss of promoter activity. A preliminary report detailed results from six additional subjects with severe hemophilia A who underwent this procedure; these did not differ substantially from those reported in full-length form. This is a potentially useful approach, particularly if the F.VIII levels could be increased, either through implantation of more cells or higher F.VIII expression per transfected cell, but it is also labor-intensive and will likely require repeat administration. This approach is not currently being actively pursued.

Retroviral vectors have also been evaluated as an approach to gene transfer for hemophilia. A major obstacle for in vivo gene transfer with retroviral vectors in the setting of hemophilia is the requirement for a dividing target cell. Kay and coworkers initially explored this approach for Factor IX deficiency in the hemophilia B dog model.[54] To induce replication in the target cells (hepatocytes), they first carried out a two-thirds partial hepatectomy in recipient animals, followed by portal vein infusion of vector. This resulted in long-term expression of canine F.IX in these animals, but at levels too low to improve disease phenotype (<1%). Vanden Driessche et al subsequently showed that one could achieve therapeutic levels of Factor VIII in mice by injecting a retroviral vector (4×10^9 cfu/kg) during the neonatal period when the rate of hepatocyte replication is still high,[55] and Ponder and colleagues have recently extended these findings to the large animal model of hemophilia B, showing that intravenous infusion of retroviral vector doses of approximately 1×10^{10} transducing units (TU)/kg into newborn hemophilic puppies results in long-term expression of Factor IX at levels higher than 10% normal.[56] Several groups have shown that pretreatment of adult mice with hepatocyte growth factor results in increased transduction of hepatocytes,[56–59] but this finding has not yet been extended to large animals. A clinical study of intravenous infusion of a retroviral vector expressing B-domain deleted F.VIII in 13 adults with severe hemophilia A documented safety of the infusion at doses up to 8×10^8 TU/kg,[60] but there was no evidence of long-term expression at levels greater than 1%; the animal studies suggest that higher doses combined with some method to induce hepatocyte replication would be required for efficacy in adults. On the basis of animal studies one would predict that infusion of vector into newborns would be more likely to demonstrate efficacy, but such an approach would require much more extensive safety studies, in animals and in adult humans, before it is undertaken.

The use of adeno-associated viral vectors has also been explored in gene transfer for hemophilia, using both skeletal muscle and liver as target tissues. AAV vectors can accommodate only a relatively small insert, so clinical studies for hemophilia have thus far been confined to hemophilia B. However, multiple preclinical studies have demonstrated that the F8 gene can be delivered by an AAV vector, either by using two distinct vectors that subsequently concatemerize as DNA in the nucleus[61] or that encode separate protein subunits that assemble in the cell,[62] or by using a very short promoter in a single vector.[63] The first AAV-mediated clinical gene transfer study for hemophilia B used skeletal muscle as the target.[64,65] As shown in Table 110–2, AAV has tropism for liver, muscle and brain, and preclinical studies in mice and hemophilic dogs had demonstrated efficacy when an AAV-Factor IX vector was administered either to skeletal muscle by IM injection[66,67] or to liver via portal vein injection.[68–70] However, at the time that the first study was undertaken, there was no previous experience with parenteral administration of AAV in humans, and it was thus decided to begin with peripheral (intramuscular) rather than systemic (intravascular) administration. Also in favor of a muscle-directed approach is the high prevalence of hepatitis C infection in the adult hemophilia population, making the liver a less attractive target organ for initial studies. Preclinical studies in mice[67] and hemophilic dogs[66] showed that doses in the range of approximately 1×10^{13} vg/kg were required to achieve therapeutic levels in animals when vector was delivered to muscle. In the clinical study, AAV-F.IX was administered at intramuscular sites in the legs and arms in a dose escalation design, but the highest doses administered (2×10^{12} vg/kg) fell short of those required for efficacy in animal studies. The practical obstacle to dose escalation was the number of injections required; the low efficiency of the required posttranslational modifications in skeletal muscle,[71] and the propensity for inhibitory antibody formation as the dose/site was raised[72] meant that dose escalation required injection of progressively larger numbers of intramuscular sites, rather than higher doses/site. An advantage of muscle as a target tissue is that it is easily sampled, and muscle biopsy at sites of injection showed gene transfer (on Southern blot) and expression of Factor IX (on immunofluorescent staining) in all eight subjects injected with AAV-F.IX, at time points as late as 3.5 years after vector injection.[73] Circulating levels were generally not higher than 1%, however. Improved delivery techniques that allow transduction of more extensive areas of skeletal muscle by introducing vector into muscle by a vascular route have been developed and tested

in large animals, and will be required for further development of a muscle-based approach for hemophilia.

Infusion of AAV into the portal vein results in high-level expression of F.IX in mice and in hemophilic dogs.[68–70,72] Using a liver-specific promoter, circulating F.IX levels in the range of 5% to 10% are observed after a vector dose of approximately 1×10^{12} vg/kg.[72] Thus, compared to muscle, there is a decided dose advantage (>10-fold) in favor of liver, probably because of the hepatocyte's efficient secretion of F.IX into the circulation. In addition, more recent data in mice[74] and data in hemophilia B dog models suggest that AAV-mediated expression of F.IX in hepatocytes can promote tolerance to F.IX by inducing regulatory $CD4^+$ T cells that can suppress anti-F.IX antibody formation after adoptive T-cell transfer. These considerations and the safety data from the original muscle trial supported the safety of a proposed AAV-mediated, liver-directed gene transfer trial for hemophilia B. An early problem encountered in the clinical study was the observation of vector sequences (detected by a sensitive PCR assay) in semen samples of all treated subjects.[16,75] Additional animal studies suggested that AAV does not readily transduce spermatocytes, and that vector sequences are cleared from the semen over time, suggesting that this is a phenomenon of vector shedding rather than transduction of precursor cells,[76] with the attendant risk of germline transmission. In fact, all seven human subjects who underwent vector infusion have shown complete clearing of the semen over time. Results from this study[75] showed that the third dose cohort tested (2×10^{12} vg/kg) resulted in circulating levels of F.IX in the range of 10% for 4 to 5 weeks after infusion, but this was followed by a gradual reduction in levels to the pretreatment baseline (<1%). Accompanying the fall in F.IX levels was a transient asymptomatic transaminitis that resolved fully several weeks after it began. Subsequent study of another subject revealed that vector infusion triggered expansion of a pool of circulating capsid-specific $CD8^+$ T cells,[77] followed by contraction of these as the transaminitis resolved. The fact that such cells are not detected in the circulation of experimental animals after infusion of the same dose of vector suggests that humans, the only natural hosts for AAV infection, may harbor a population of memory $CD8^+$ T cells to AAV capsid. Because memory T cells are more readily activated than naïve T cells, this may account for the difference in observed outcomes (short-term vs long-term expression) in humans versus other species. Upcoming trials will test the hypotheses that this $CD8^+$ T-cell response to capsid can be managed by a short course of immunosuppression or avoided by use of an AAV vector engineered from a serotype that does not normally infect humans.[78]

Adenoviral Vectors

Certain features of adenoviral vectors make them attractive as potential gene delivery vehicles, for hemophilia A in particular. The vector is relatively straightforward to manufacture in high titer, and it can accommodate large inserts. Kay et al[54] and Connelly et al[79–81] exploited these characteristics early on to demonstrate high-level expression of canine clotting factors in the hemophilia dog models. However, expression was short-lived, and work by a number of other groups established that the immune response to the vector, characterized by a cytotoxic T-lymphocyte response against cells harboring the vector, prevents long-term expression from early-generation adenoviral vectors.[82,83] Moreover, systemic administration of early-generation adenoviral vectors in dogs and humans has been associated with substantial toxicity, including an early thrombocytopenia, a biphasic hepatotoxicity, and an acute systemic inflammatory response syndrome as noted above.[2] The subsequent development of fully deleted adenoviral vectors[84] raised the possibility of using these later-generation vectors as an approach for hemophilia A, since Morral et al[85] demonstrated that fully deleted adenoviral vectors could direct expression of α_1-antitrypsin for as long as 1 year in baboons (compared to only weeks for earlier-generation adenoviral vector) and that the hepatotoxicity (although not the thrombocytopenia) was greatly reduced by the use of these fully deleted vectors.[86,87] Their work also demonstrated though that over the course of 12 months there was an inexorable decline in circulating levels of α_1-antitrypsin in the baboons[86]; this highlights what may be a limiting feature of this vector, even under optimal circumstances, for genetic diseases where long-term expression is required.

The use of helper-dependent or "gutted" adenoviral vectors to treat hemophilia A was explored by Zhang and colleagues.[88] They first demonstrated that a fully deleted adenoviral vector expressing the full-length human FVIII cDNA under the control of a 12.5-kb albumin promoter could correct the phenotype of mice with hemophilia A. Injection of a dose of 8×10^{12} vp/kg resulted in circulating levels of 100 to 800 ng/mL FVIII (normal levels are 100–200 ng/mL) in 3 of 8 mice; the other mice rapidly developed antibodies to the human transgene product, and FVIII levels could no longer be measured. Vector administration in mice was not associated with any hepatotoxicity. Subsequent experiments in nonhuman primates yielded circulating levels of 3% to 8% with doses of 4.2×10^{12} vp/kg (although it should be noted that interpretation of these experiments was complicated by the use of the human transgene in the nonhuman primates, with subsequent development of antibodies to the foreign protein making it difficult to reliably measure factor levels). This dose also resulted in transient transaminitis and thrombocytopenia in nonhuman primates, although a dose of 1.4×10^{12} vp/kg did not. A phase I dose escalation study of a fully deleted adenoviral vector for hemophilia A enrolled a single subject at a dose of 4.3×10^{10} vp/kg in 2001; but in contrast to the cynomolgus primates, the subject experienced transient thrombocytopenia and transaminitis even at this low dose. A critical issue in analysis of results with fully deleted adenoviral vectors is the presence of contaminating helper adenovirus, which supplies gene products required for assembly of the fully deleted adenoviral vector. Contamination of vector preparations with helper virus can alter the toxicity profile of the vector. Differences in duration of expression and in toxicity have been observed using different preparations of fully deleted adenoviral vector. Additional studies will be required to analyze whether fully deleted adenoviral vectors will be of use for treatment of genetic disease.

GENE THERAPY FOR MALIGNANT DISEASES

To date, the widest use of gene transfer has been in patients with cancer, including those with hematologic malignancies. More than a thousand cancer gene therapy protocols exist, and most fit into one of three major approaches:

1. Modifying the tumor cell itself either by "repairing" one or more of the genetic defects associated with the malignant process or by delivering a prodrug-metabolizing enzyme that will render the tumor sensitive to the corresponding cytotoxic agent. This approach has an attractive elegance but is handicapped by the inefficiency of current vectors and their lack of targeting.
2. Modifying normal host tissues, delivering cytotoxic drug-resistance genes, thereby increasing the therapeutic index of chemotherapy. This approach also is hampered by the inefficiency of the gene transfer technology, which makes it difficult to protect sufficient cells in all organ systems that are damaged by conventional cytotoxic drugs.
3. Modifying the immune response to the tumor, by altering the specificity or effector function of immune system cells, or by transducing a small proportion of the tumor cells with immunostimulatory genes, thereby generating an immune response to tumor-associated or tumor-specific antigens. This last approach makes use of the efficiency of the immune system and its capacity to target specific cell types to compensate for the limitations of current vectors.

In addition, gene-marking studies have been used to track normal or malignant cells in vivo to monitor the effects of treatment, and conditionally replication-competent viruses that have been genetically modified to be able to replicate in and destroy malignant but

not normal cells have been used for tumor oncolysis. Neither approach is described here, but both are reviewed elsewhere.[89,90]

TUMOR MODIFICATION

Tumor Correction

There is an attractive elegance to the strategy of introducing genetic material into a malignancy to correct the specific genetic defects contributing to the neoplastic phenotype. Multiple mutant oncogenes and fusion transcripts have been identified that are certainly specific to the malignant clone and frequently form a critical component of the malignant process. Unfortunately, this approach is technologically demanding, because all malignancies result from a multiplicity of genetic abnormalities. Unless correction of a single defect is subsequently lethal to the malignant cell, transfer of an individual corrective gene to a patient with 10^{11} to 10^{12} tumor blasts will leave a multiplicity of premalignant cells, with a high risk of later transformation. Present methods of gene transfer also are inefficient. Even if it were possible to transfer genes to 90% or more of malignant cells in vivo—a feat currently beyond the capability of any available vector—it would be insufficient to produce more than transient clinical benefit. Moreover, many relevant gene defects result in molecules with transdominant effects that will continue to produce a malignant phenotype, even if a wild-type gene is introduced. Under these circumstances, it would be necessary to neutralize the genes by destroying their function using ribozymes, antisense RNA, or with use of RNA interference.[91–93]

These limitations notwithstanding, several tumor correction protocols have been proposed. For example, efforts are being made to neutralize fusion transcripts such as *BCR-ABL* in patients with chronic myeloid leukemia *or* activated oncogenes such as *MYB*, using ribozymes, antisense RNA, or wild-type genes.[94] More extensive experience has been obtained with efforts to replace nonfunctioning tumor suppressors such as p53 in patients with localized solid tumors. In patients with head and neck cancers and those with bronchial carcinoma, striking tumor responses have been obtained using adenoviral vector-mediated wild-type p53 gene transfer. These benefits have been seen with even low levels of gene transfer, and there is increasing evidence for "bystander" activities that may include effects on tumor vasculature, the immune system, and intercellular signaling. A p53 adenoviral vector has received a product license in China[95] and it is estimated that well over 10,000 patients have been treated. The outcomes analyses are eagerly awaited. Meanwhile, in the United States, a long-delayed Biologics License Application is still awaited in 2008 for Ad-p53 treatment of recurrent/resistant squamous cell carcinoma of the head and neck. Approvability will be based in large part on the agent's ability to prolong survival.[96]

Interest also is increasing in targeting the gene pathways involved in regulating apoptosis, because even minor perturbations in these pathways can greatly modify the sensitivity of cancer cells to chemotherapy.[97] Because of problems with targeting, these approaches that directly correct the tumor cell itself will likely continue to be used primarily for treating localized solid tumors, rather than for hematologic malignancies, which are almost invariably widely distributed.

Increasing Tumor Sensitivity to Cytotoxic Drugs

Prodrug-metabolizing enzyme (PDME) genes encode enzymes able to convert harmless prodrugs into lethal cytotoxins.[98] More than a dozen have been described, of which the thymidine kinase (TK) gene has been the most widely used. TK itself phosphorylates the prodrugs acyclovir, valacyclovir, and ganciclovir to toxic nucleoside, and as for other PDME approaches, tumor selectivity requires either the vector or the prodrug product to be targeted to the malignant cell. Initial therapeutic study of *TK* gene transfer was made in patients with primary or secondary brain tumors; in this context, there is a particularly clear distinction between tumor cells (which divide and are destined to be killed following DNA incorporation of the phosphorylated nucleoside) and normal neurons (which do not divide and should escape unharmed). Retroviral vectors offer additional tumor specificity in this system because they function only in dividing cells and therefore do not transduce normal neurons. Later studies have used less selective vectors, such as adenoviruses, and have relied on preferential transduction of malignant targets and increased proliferation of malignant versus normal tissues to provide the desired therapeutic index.

Even when only a small percentage of tumor cells are transduced, administration of ganciclovir can produce large-scale destruction of the tumor cell population. This bystander effect is most evident in tumor cells that have gap junctions, so it probably represents the transfer of a toxic metabolite or an apoptotic signal. An immunologic bystander effect might also occur in vivo: once the tumor cell is killed by the toxic metabolite and is processed and presented by antigen-presenting cells, the host may be immunized against tumor development.

A significant added attraction of the Tk system is that the enzyme allows transduced cells to sequester radiolabeled nucleoside analogues (such as ^{131}I-labeled 2'-fluoro-2'-deoxy-1-β-D-arabinofuranosyl-5-iodouracil [FIAU]), which can then be detected by PET imaging.[99,100] The ability to assess gene transfer and expression noninvasively and in real time (rather than by analysis of biopsies) provides a much more convenient way of assessing the effectiveness of different gene transfer approaches. Insertion of the TK gene is conditionally replication competent. PDME gene transfer with the *TK* gene is now being used for the treatment of localized or recurrent prostate, bladder, breast, and colon cancer and for retinoblastoma. Although hematologic applications are more limited because of the problems of targeting widely distributed tumor cells in vivo, successful ex vivo retroviral transduction of Tk into donor T lymphocytes has provided a contingent "suicide" gene to increase the safety of these cells following adoptive immunotherapy after allogeneic hemopoietic stem cell transplantation.[101–103] The potential benefits of these T cells (reduced infection and relapse after stem cell transplant) can be preserved, with the option of destroying them should they produce unwanted graft-versus-host disease. Following promising single center data, this approach has extended to a large Phase III multicenter trial.[102]

INCREASING HOST RESISTANCE TO CYTOTOXIC DRUGS

Instead of attempting to modify the malignant cells by gene transfer, it is possible to target normal tissues by transferring genes that protect normal host tissues from the toxicity of chemotherapy. Although many different systems have been developed and studied preclinically, it is the multidrug resistance gene mutidrug resistance 1 (*MDR1*) that has been the most widely studied in humans. Its product, P-glycoprotein, functions as a drug efflux pump and confers resistance to many chemotherapeutic agents. The feasibility of using *MDR1* to protect hematopoietic cells has been demonstrated by in vitro and in vivo murine experiments, and it is likely that other drug resistance genes could function analogously.[104]

The clinical application of drug resistance gene transfer has several potential pitfalls. The low efficiency of stem cell transduction and poor gene expression observed in the earliest clinical protocols resulted in no selection of gene-modified cells and hence no in vivo protection. Although improved transduction technology is beginning to result in measurable in vivo protection in humans (albeit not yet to clinically useful levels), many problems remain.[105] There is a risk of transferring the genes to neoplastic cells to produce drug-resistant relapse, and toxicity to unprotected organs, including gut, heart, and lungs, may rapidly supervene when marrow resistance allows intensification of cytotoxic drug dosages. Moreover, expression of drug resistance genes such as *MDR1* or dihydrofolate reductase in primitive normal cells has proved leukemogenic in mice and primates, an effect of particular concern.[106,107] Hence, the approach will come to full fruition only when it becomes possible to target all sensitive normal tissues in vivo, to transduce them with high efficiency, and

to prove after extensive animal testing that the approach is safe. Because of these concerns, more recent attention has shifted to alternative drug resistance genes such as O^6-methylguanine-DNA-methyltransferase (*MGMT*). This enzyme protects against toxicity to nitrosourea compounds, (such as temozolomide) that may be used for treatment of brain tumors, and occasionally for hematologic malignancies such as Hodgkin disease. Clinical trials using this approach have begun.

MODIFYING THE IMMUNE RESPONSE TO THE TUMOR

Most human cancers kill because of metastatic disease, not because of uncontrolled growth of the primary tumor. The lack of targeting of current vectors and their inefficiency mean that gene therapy aimed directly at modifying the tumor will work best on local, not systemic, disease, with limited value for hematologic malignancy. Accordingly, there has been great interest in combining gene transfer techniques with the inherent efficiency and targeting capacity of the immune system. Human tumors express tumor-associated or tumor-specific antigens that even if originally intracellular, may be processed and presented in association with major histocompatibility complex (MHC) antigens on the cell surface, where they can be targets for immune attack. There also is ample evidence, albeit primarily in studies of hematologic malignancy and melanoma, that immune intervention can eradicate even extensive malignant disease.[108–111]

Gene transfer may be used in several ways to augment the anti-tumor activity of the immune system.

Tumor Vaccines

To enhance immune recognition of poorly immunogenic tumors, investigators have evaluated the effect of genetically modifying tumor cells directly, or antigen-presenting cells modified to express tumor-derived antigens. Genetic modifications are aimed at enhancing recruitment of an effective (usually cellular) immune response, and include expression of cytokines such as GM-CSF and IL2, lymphotactic chemokines, allogeneic MHC molecules, or costimulatory molecules such as B7.1 or CD40 ligand. More recent efforts have focused on modifying the functionality of antigen-presenting cells by incorporating genes that counteract the normal inhibitory processes that limit the duration and degree of stimulation the cells produce. In murine model systems, the transfection of tumor cell lines with these molecules has shown that injection of neoplastic cells in doses that would normally establish a tumor instead recruits immune system effector cells, which eradicate the injected tumor cells. Often, the animal is then resistant to challenges by further local injections of nontransduced parental tumor. The transduced tumor has therefore acted like a vaccine. In some models, established, nontransduced, parental malignant cells also are eradicated.

Tumor vaccines are being evaluated in more than 300 different clinical trials. Despite gloomy prognostications,[112] positive results are being obtained in lymphoma and chronic lymphocytic leukemia as well as in solid tumors such as prostate cancer, melanoma, renal cell carcinoma, and neuroblastoma. Immunized patients may develop peripheral blood eosinophilia, a rise in natural killer (NK) and activated killer (AK) cell number and activity, and an increase in tumor-specific cytotoxic T-lymphocyte precursor frequency.[113–116] Substantial and sustained clinical responses in tumor sites/circulating malignant cells have been reported, sometimes in association with autoimmune phenomenon, which have so far been mild. Of note, an antigen-presenting cell vaccine expressing transgenic GM-CSF for the treatment of locally recurrent prostate cancer was recommended for approval by an FDA Advisory Committee, on the bass of benefits to overall survival in a phase II randomized trial. The FDA, however, has required additional clinical data. If finally successful, this application will be the first approved cell/gene therapeutic. Ultimately vaccines may have their greatest value as adjuvants to prevent relapse in patients with presumed minimal residual disease, although studies to validate this approach will need to be both large and lengthy.

Bypassing Immune Evasion Strategies

Tumor cells may fail to generate a specific immune response because they lack expression of HLA molecules, or express tumor-associated antigens that are only weakly stimulatory to the immune system and/or because they possess active defenses that thwart the immune system. Gene transfer may be used to combat both obstacles. For example, the malignant cells of Epstein–Barr virus (EBV)-associated Hodgkin disease expresses EBV-associated antigens that either are poorly processed (eg, Epstein-Barr virus nuclear antigen-1 [EBNA-1]) for presentation to CD8+ cytotoxic effector cells or are only weakly stimulatory to the immune system (such as latent membrane proteins LMP-1 and LMP-2). These malignant cells also have several active immune evasion strategies directed toward inhibition of antigen presentation, induction of an inhibitory T-cell response, and inhibition of any cytotoxic response that arises. As a consequence, adoptively transferred EBV-specific cytotoxic T cells that are highly effective against EBV-infected B lymphocytes of immunoblastic lymphoma are much less active against EBV-associated Hodgkin disease.[117] Similar active and passive immune evasion strategies are used by other hematologic and solid organ malignancies, probably contributing to the frequent failure of immunotherapy.

One way in which gene transfer can enhance the response to a weak tumor-associated antigen is exemplified by the tumor vaccine studies described in the preceding section. An alternative is to transduce professional antigen-presenting cells, such as dendritic cells or their precursors, with a vector encoding the weak tumor antigen.[118] This approach ensures that a high level of a weak antigen is expressed in an environment that favors an immune response. Alternatively, inhibitory signals for DC activation such as SOCSI may be knocked down.[118a] Gene transfer can also overcome active immune evasion strategies. For example, many tumor cells (including those of Hodgkin disease) secrete TGF-β, which inhibits cytotoxic T-cell proliferation and function. Cytotoxic T cells specific for tumor-associated antigens can be transduced with a dominant negative mutant of the TGF-receptor that renders them entirely resistant to inhibition mediated by the cytokine.[119,120]

As we learn more about the molecular basis of tumor immune evasion, it should prove possible to design effective countermeasures, and ultimately to generate immune T lymphocytes specific to even weak tumor antigens that are resistant to active tumor evasion.

Chimeric T Cells

Tumor-specific T lymphocytes can also be produced by genetically modifying human T cells to express tumor antigen-specific chimeric immune receptors that are based on antibody molecules (T-bodies) or on transgenic alpha and beta chains of the T-cell receptor.[121–123] Chimeric antibody receptors can be generated by joining the heavy- and light-chain variable regions of a monoclonal antibody, expressed as a single-chain Fv (scFv) molecule, to the T-cell receptor-ζ (TCR-ζ) (see Fig. 110–1), or Fc immune receptor domain. Antigen stimulation of the extracellular component of the chimeric receptor results in tyrosine phosphorylation of immune-receptor activation motifs present in the cytoplasmic domain, initiating T-cell signaling to the nucleus. Human T lymphocytes genetically engineered to express the recombinant receptor genes lyse tumor cells expressing the relevant target antigens, and adoptively transferred chimeric receptor-transduced cells are protective in murine tumor models.

T cells transduced to express chimeric antibody receptors have numerous potential advantages over immunotherapies based on monoclonal antibodies or T lymphocytes alone. They can be directed toward any native tumor- or virus-associated antigen for which a monoclonal antibody exists, making this strategy applicable to a wide variety of malignancies and viral diseases. Because chimeric T-cell

receptors provide T-cell activation in an MHC-unrestricted manner, they permit the immune system to recognize tumors that have downregulated HLA class I molecules or that have defects in antigen processing. Chimeric receptors have been developed for a variety of antigens associated with solid tumors of breast, colon, and kidney, including Neu/HER2, folate-binding protein (FBP), carcinoembryonic antigen (CEA), TAG-72, and renal tumor-associated antigen, as well as for antigens associated with hematologic malignancy (CD30 and CD33), and the pediatric tumors neuroblastoma and Ewing sarcoma. Unfortunately, these cells have proved clinically disappointing, because they are short-lived or are rapidly inactivated in the circulation.[124–126] Clearance of modified T effector cells by immune effector mechanisms may be delayed by humanization of currently available hybridoma antibodies, or by the generation of fully human single-chain antibodies by phage display technology. Enhanced and sustained function may require chimeric receptor molecules that are coupled to the intracellular signaling mechanisms of costimulator molecules such as CD28, and clinical trials adopting this approach have begun in B-CLL.[123]

Artificial receptors based on the αβ chains of the T-cell receptor have also been exploited. Until recently, technical limitations associated with cross-pairing of transgenic and endogenous TCR, as well as competition for the limiting numbers of "chaperone" molecules that enable TCR transport and expression, has limited the functionality of this approach. Recent advances that have served to increase receptor affinity and favor appropriate rather than cross αβ-chain linkage have enabled a clinical trial in patients with melanoma using receptors specific for the melanoma-associated antigen MART-1. Four of 33 patients had tumor responses, including two complete remissions.[109]

ULTIMATE VALUE OF GENE THERAPY FOR CANCER

With recent results from the study of dendritic cell vaccines in prostate cancer, gene therapy for cancer has finally been able to show prolonged patient survival in a randomized phase III clinical trials. All the approaches we have described are now clearly feasible and are producing numbers of responses that are clearly greater than anecdotal, albeit still below the consistency and robustness desired. One of the most important characteristics of gene therapy for cancer is that it represents a series of treatment approaches that are generally not cross-resistant with other treatment modalities. Hence, the real value of the approach will become evident when it is combined with preexisting treatments. Clinical data already suggest that radiation and gene therapy approaches for recurrent prostate cancer may be superior to either alone, and combinations of low-dose chemotherapy agents and tumor vaccines may increase the response rate in patients with otherwise resistant disease. If these results are confirmed, the challenge over the next few years will be to design—and fund—studies to optimize these combination approaches.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

The treatment of HIV infection in the developed world changed dramatically with the advent of highly active antiretroviral therapy (HAART), with monitoring of viral load. Successful treatment means undetectable viral loads, increased $CD4^+$ counts, and few opportunistic infections or other complications of AIDS. The increasing effectiveness and simplicity of HAART has substantially reduced the impetus to develop gene therapies for the disease, because the quality and duration of life are now so much better for patients in whom treatment has been successful. Nonetheless HAART remains expensive and induces many adverse effects. It is not curative, and resistant strains of HIV may emerge. These and other reasons have ensured continuation of efforts to develop and clinically test gene therapy for the disease.[127]

Cellular Targets

For successful gene therapy of HIV infection, both T cells and macrophages should be permanently protected against infection, which currently requires an integrating murine retroviral or lentiviral vector. Peripheral mature T cells can be transduced, expanded ex vivo to large numbers (10^{10} to 10^{11}), and then reinfused into patients, as in reported clinical trials.[128] This strategy has several limitations:

- It is technically challenging.
- Less than 1% of the circulating T cells are typically transduced.
- Transgene expression can be lost.
- The average half-life of the T cells is unknown.

An alternative target is the HSC, which would serve as a T-cell, monocyte/dendritic cell, and microglial progenitor. Submyeloablative therapy will likely be sufficient for adequate repopulation. Because thymic architecture is progressively destroyed during HIV infection, however, it is unknown whether T-cell functionality will be completely restored.

Most clinical protocols to date have used modified lentiviral vectors based on HIV itself as the means of gene transfer, and these clinical safety and efficacy data are helping to broaden the applications in which such lentiviral vectors can be used.

POTENTIAL TARGETS FOR GENE THERAPY

Viral Receptors

HIV requires both CD4 and a coreceptor on the cell surface for productive infection. More than a dozen chemokine receptors function as HIV coreceptors in vitro, but the two most critical for the replication of T-cell-tropic and macrophage-tropic isolates in vivo are CXCR4 and CCR5, respectively. The latter is an attractive target because persons who are homozygous null (the so-called D32 mutation) are phenotypically normal but relatively resistant to HIV infection.[129] Downregulation of the CCR-5 coreceptor on the cell surface of $CD4^+$ cells was accomplished by transgenic expression of intrakines. These are modified chemokines (including MIP-1a and RANTES) that bind the endoplasmic reticulum (known as intrakines) and sequester intracellularly the newly synthesized CCR-5, preventing its transport to the cell surface. Alternatively, CCR5 knockdown can be obtained by stably expressing transgenic ribozymes or small interfering RNAs that act on CCR5 mRNA. Such genetically modified T lymphocytes are resistant to HIV-1 infection.[130]

Viral Transcription

HIV encodes a transcriptional transactivator (Tat) that acts at the level of RNA elongation in conjunction with cellular factors. A stem-loop RNA element, TAR, is recognized by Tat as well as by cyclin T1. This complex recruits the cyclin-dependent kinase CDK9 to hyperphosphorylate the carboxyl-terminal (C-terminal) domain of RNA polymerase II and increase enzyme activity. Anti-Tat single-chain variable-fragment antibodies (intrabodies) interfere with Tat function intracellularly; anti-TAR ribozymes cleave TAR, and polymeric TAR decoys compete with TAR for Tat binding.[131] Transdominant mutants of Tat also have been developed[132] that sequester cellular cofactors, including cyclin T1 and CDK9, but in general these mutants produce only limited inhibition of HIV replication and remain to be evaluated in clinical trials.

Viral RNA Transport

The HIV gene *rev* directs the export of intron-containing viral messenger RNAs from the nucleus to the cytoplasm and interacts with the Rev response element (RRE), an RNA stem-loop structure found

within the *tat-rev* intron. In the presence of both Rev and the RRE, competition between the host's splicing apparatus and Rev allows export of intron-containing viral mRNAs. Anti-Rev intrabodies, similar to those against Tat, have been tested, as have RRE decoys.[133] Dominant negative Rev mutants such as Rev M10 bind to the RRE, thereby interfering with wild-type Rev RNA export. Escape mutants have rarely, if ever, been observed. Although rev M10 has now been introduced into clinical trials, effects to date have been limited.

Combination Therapy

Single gene transfer approaches to treat HIV, like single antiviral small molecules, rapidly select for resistant strains of the virus. Newer gene transfer strategies therefore target two or more anti-HIV genes at once, choosing those that are implicated at different phases of viral replication. For example, multimeric TAR decoys bearing a trans-dominant or antisense GAG sequence synergistically inhibited HIV replication, although combination of an anti-Rev intrabody with an RRE ribozyme blocked HIV replication in established T cells for prolonged periods of time. With improved technology, a single lentiviral vector can now transfer an anti-CCR5 ribozyme, an siRNA for Tat/Rev, and a TAR RNA decoy.[134] Although untested in vivo, these types of strategy are among the most promising.

Clinical Trials of Human Immunodeficiency Virus Gene Therapy and Their Ultimate Value

It is uncertain whether gene therapy will ever be used successfully against HIV infection. A multiplicity of small-molecule antiretroviral agents are currently approved by the Food and Drug Administration (FDA), and many more probably will be approved in the coming years. Many technologic barriers remain before gene therapy can contribute. These include the identification of genes that will protect against HIV at high levels of virus and the development of integrating vectors able to safely and efficiently transduce potential target cells. Ultimately, as with cancer, gene therapy may supplement rather than supplant vaccines and conventional small molecule therapeutics.

CHAPTER 111

EXPERIMENTAL CELL THERAPY

Jeffrey S. Miller and Robert S. Negrin

INTRODUCTION

Cell-based therapies are attractive alternatives to conventional treatment modalities. The exquisite functional specificity of cellular populations, identification of precursor and stem cell populations as well as advances in our basic understanding of cell and molecular biology have generated enthusiasm for future treatment concepts. Technical progress in cytokine biology, cellular manipulation, cell separation, expansion, and purification have made the idea of isolating a specific cell type, expanding relatively pure populations of cells that are active and functional, a reality. Several such concepts have been extended to the clinic and are in routine clinical use whereas others are under active exploration, with encouraging results. This chapter focuses on the cellular populations and immunological mechanisms underlying successful transfer of immune functions for the treatment of infectious diseases and malignancies focused on patients with hematologic diseases. The clinical settings in which cell therapy has been applied in hematologic practice are outlined in Table 111–1. The general concepts discussed here have broad clinical implications, with the potential to treat a wide variety of other clinical disorders such as autoimmune diseases, degenerative disorders, neurologic diseases, vascular diseases, and possibly traumatic injuries.

HISTORICAL CONSIDERATIONS

Hematopoietic Cell Transplantation

The concept of cellular therapy in hematologic practice is not new. The best example in clinical medicine is the field of hematopoietic cell transplantation (HCT). HCT developed from seminal studies in murine and canine models, which established the role of the bone marrow in protecting animals from the lethal effects of radiation.[1] These early studies also demonstrated the unexpected potential adverse effects of donor-derived cells, namely that of graft-versus-host disease (GVHD). Further investigation demonstrated that long-term surviving animals not only had a fully intact hematopoietic system but were also tolerant to tissue grafts from the donor animals.[2] These studies, and many others, ushered in the modern era of HCT. Initially, the beneficial effects of allogeneic HCT were thought to result from the high-dose chemotherapy and radiation therapy used prior to the transplant. Subsequent studies have demonstrated that HCT is more complex, with much of the benefit being derived from the transfer of immunoreactive cells capable of exerting a graft-versus-tumor (GVT) effect. The existence of a GVT phenomenon was initially based on the observation that relapse rates were lower in those patients who developed some degree of GVHD, especially chronic GVHD.[3,4] Further documentation of the GVT effect came from clinical situations where it is absent, such as following an identical twin or syngeneic transplantation[5,6] or following rigorous T-cell depletion.[7,8] Direct demonstration of the GVT effect following the transfer of donor-derived lymphocytes has been an important advance in HCT and further demonstration of the powerful therapeutic benefits of cellular therapy.[9] These studies have led to the development of nonmyeloablative allogeneic transplantation, which has allowed for the treatment of older or medically infirm patients with diseases who would otherwise benefit from this form of therapy.[10,11] Coincident with these developments has been the exploration of a number of different cellular populations with different therapeutic potential.

Donor Leukocyte Infusions for Treatment and Prevention of Disease Relapse

A clear example of the potential effectiveness of cellular therapy is in the application of donor leukocyte infusions (DLIs). The use of DLI to treat patients who have suffered a relapse following allogeneic HCT has been a well-established use of cellular therapy, which further documents the importance of GVT reactions. Two large retrospective analyses of DLI for post-HCT relapse have been reported from Europe and North America. The results of the European Group for Blood and Marrow Transplantation have further documented the beneficial effects of DLI.[12] In a series involving 27 transplant centers, 84 relapsed HCT patients had CML and of these 54 (73%) were induced into complete remission (CR) with DLI. Many of these patients who entered a hematologic CR also achieved molecular remissions assessed by polymerase chain reaction analysis of *bcr/abl* transcripts. However, DLI has been much less effective for patients with other diseases, where only five (29%) of the AML patients developed a CR, and none of the 22 patients with ALL had a CR. A major limitation with the use of DLI is the risk of GVHD, and 52 patients (41%) developed clinically significant GVHD following DLI. Seventeen patients (12.6%) died of causes other than their underlying leukemic disorder.

A similar review of 25 North American bone marrow transplant programs evaluated 140 HCT recipients with relapsed disease who underwent DLI.[13] Again CML patients responded most favorably, with a CR rate of 60% following DLI. Responses were better for those patients with cytogenetic and chronic-phase relapses only as compared to those patients with accelerated or blastic disease. Responses were durable as actuarial probability of remaining in CR at 2 years was 89.6% for those patients who achieved a CR. Longer-term results have confirmed that patients who achieve a molecular remission following the administration of DLI have remarkably durable responses, with the majority of patients continuing to have molecular remissions with long-term follow-up.[14] Results were not as favorable for HCT patients with relapsed AML (15.4% CR) or ALL (18.2% CR). Complications included GVHD (60%) and pancytopenia (18.6%).

Overall, these results indicate that DLI has substantial efficacy in the control of relapse following allogeneic HCT. This is especially true in patients with CML detected while in either cytogenetic or early hematologic relapse.[15] Upon progression to accelerated or blastic phase of the disease, DLI has clearly much less efficacy. With the resurgence of allogeneic transplantation for patients with multiple myeloma, DLI has also been used successfully for patients with progressive disease following allogeneic HCT for this disease.[16] DLI has been less effective for the treatment of patients with leukemia and lymphoid malignancies who suffer a relapse although responses have been noted.[17,18] In patients with acute leukemia the poorer results may be due to the more rapid proliferative capacity of the leukemic cells. Chemotherapy is often used to gain control of the disease before

administering DLI. The mechanism(s) through which DLI controls malignancies is not clear. Cytotoxic T lymphocytes (CTL) directed against minor histocompatibility antigens have been found in some patients, and their presence can be correlated with disease response.[19] B-cell maturation antigen has been identified as a potential target antigen in some of the responses in myeloma patients.[20] DLI has also been utilized to treat patients who develop Epstein–Barr virus-induced lymphoproliferative disease (EBV-LPD) which occurs in a minority of patients following allogeneic HCT, especially in those patients who have undergone T-cell depletion.[21]

Despite the durable clinical responses noted in many patients, the use of DLI has been limited by the risk of GVHD following infusion. One strategy has been to utilize dose escalation of T cells for infusion. In one study, a dose of 1×10^7 T cells/kg resulted in a low incidence of GVHD despite an obvious antitumor cell response. Using escalating numbers of T cells for those patients who do not have a complete antitumor response may decrease the risk of GVHD assuming the disease is sufficiently indolent.[22] However, the concept of T cell dose-limited GVHD risk has been challenged.[23] Other groups have attempted to deplete $CD8^+$ cells in an effort to reduce the incidence of GVHD while retaining GVL activity.[24,25] These studies are difficult to interpret because of patient and disease heterogeneity.

The "suicide gene strategy" is an elegant approach to reduce the risk of clinically significant GVHD, which involves genetically modifying the donor lymphocytes so that they can be eradicated with otherwise well-tolerated drugs in the event that the patient develops GVHD. For example, donor lymphocytes have been transfected with the herpes simplex virus tyrosine kinase (HSV-TK) gene by retroviral-mediated gene transfer, and those transfected donor lymphocytes have been infused into patients who have relapsed or developed an EBV-induced lymphoma. In one study of eight patients, the transferred lymphocytes survived for up to 12 months and resulted in antitumor activity in five of the patients. Three patients developed GVHD, which could be controlled by treating the patients with gancyclovir.[26] These exciting data pave the way for engineering cell types with specific functions whose activities can be controlled with certain drug treatments. A limitation of this approach has been the immunogenicity of HSV-TK, and other suicide gene strategies are under active investigation.

The other major complication associated with DLI has been myelosuppression and in some instances severe pancytopenia, requiring retransplantation. The more severe cases have been observed in patients who have no evidence of donor-derived hematopoiesis at the time of DLI.[27] Because of these limitations, improvements in DLI are needed. Because DLI contain dendritic cells, T and natural killer (NK) cells, one possibility is to gain a better understanding of the individual components comprising the DLI product, as discussed below.

IMMUNOLOGIC EFFECTOR CELLS

The evaluation of immune-reactive cells capable of recognizing and lysing virally infected cells and tumor cell targets has been the subject of intense investigation. Effective cellular populations can be mechanistically divided into two broad categories termed innate (NK cells and antigen-presenting cells) and adaptive (T-cell and B-cell) immunity. Cell populations capable of innate immunity are genetically poised to perform their biological functions, whereas cells of the adaptive immune response generally require activation, expansion, and education. These two general categories of immune-reactive cells interact, however, to expand and enhance an antigen-specific immune response.

THE ROLE OF NATURAL KILLER CELLS IN INNATE IMMUNITY

Basic Biology

Unlike T cells, NK cells are innate immune effectors capable of direct lysis of targets and cytokine production. NK-cell functions are regulated by a complex balance of activating and inhibitory signals transferred via several classes of receptors, including killer immunoglobulin-like receptors (KIRs).[28] Several inhibitory KIRs recognize ligands that are MHC class I molecules, where ligation protects a target from being killed. This may explain why NK cells with established lytic function do not damage normal tissues recognized as "self." The loss of KIR-ligand expression by an infected or malignant target renders it susceptible to NK-cell lysis. NK cells can kill tumors without requiring prior sensitization, can be easily isolated from donor lymphapheresis products, and do not cause GVHD when infused. These characteristics make NK cells an attractive cell population to exploit for antitumor immunotherapy. Several clinical strategies have been developed using alloreactive NK cells for therapeutic benefit.

NK cells are large granular lymphocytes that were first described in 1975 by their ability to lyse virally infected and tumor targets without MHC restriction or prior sensitization.[29,30] They were further characterized for their ability to mediate the rejection of allogeneic or parental-strain hematopoietic grafts in lethally irradiated mice,[31] a function that was first noted in 1971 when the phenomenon of "hybrid resistance" was defined.[32,33] Although they have no known capacity for sensitization or memory, NK cells express a diverse array of inhibitory and activating receptors that mediate recognition and lysis of a variety of infected and transformed cells. Human NK cells are found in the marrow, spleen, lymph nodes, and peripheral blood, where they comprise approximately 10% to 15% of the lymphocyte pool. NK cells are defined phenotypically by their expression of CD56 and by their lack of T-cell markers (CD3, CD4, and T-cell receptors) and are distinct from $CD3^+CD56^+$ lymphocytes. Peripheral blood NK cells are further categorized by their level of CD56 expression, which correlates with their effector functions. Approximately 10% of NK cells are CD56(bright), a subset that is more proliferative and produces more cytokines (especially interferon gamma [IFN-γ]), whereas the CD56(dim) subset is more cytotoxic and bears Fc receptors to mediate antibody-dependent cellular cytotoxicity.[34] Cytokine-activated cells, sometimes referred to as lymphokine-activated killer cells, show more proliferation, increased cytokine production, and higher cytotoxicity to kill targets than do resting NK cells.[35] NK cells respond to IL-2, IL-15, and IL-21, all of which signal via the IL-2 receptor γ chain,[36–38] as well as the combination of IL-12 and IL-18, which is an especially strong stimulant to increase IFN-γ production.[39]

NK cells are major producers of several cytokines such as granulocyte colony stimulatory factor, granulocyte–monocyte colony stimulatory factor, IL-5, TNF, IFN-γ, and transforming growth factor-beta. These, in turn, can stimulate or inhibit hematopoiesis

and the effects of other immune cells. These cytokines and cell–cell interactions may stimulate dendritic cells (DC) to activate both NK cells and T cells, providing a link between the innate and adaptive immune system.[40,41] The interaction between DC and NK cells leads to mutual coactivation of each cell type.

NK cells have demonstrated in vivo antitumor cytotoxicity against both hematologic malignancies and a wide variety of solid tumors, including breast, ovarian, hepatocellular, and colon cancer,[42–45] as well as against virally infected cells. Most NK cells kill directly using perforin and granzyme, but they can also use Fas ligand (FasL) and tumor necrosis factor-related apoptosis-inducing ligand pathways.[46] In addition, NK cells mediate antibody-dependent cellular cytotoxicity via CD16 (FcRγIII), the Fc receptor that recognizes Ig-coated targets.[47] The recognition and response to a wide array of foreign damaged, malignant, and virally infected cells are regulated through a complex network of cell–cell interactions. NK cells express β2 integrins and CD2, which bind to target adhesion molecules such as ICAM-1 and LFA-3. In addition, NK cells express several classes of activating and inhibitory receptors that are both MHC class I-specific and nonspecific. The net balance of signals, dependent on both the target phenotype and the NK cell receptor repertoire, determines whether or not a target is lysed.

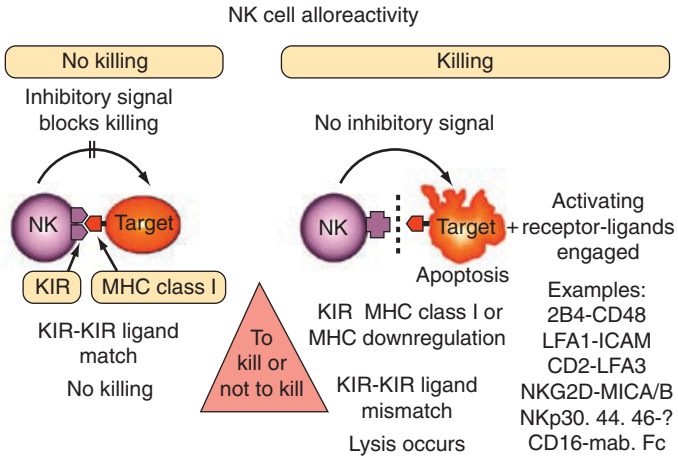

Figure 111–1 Natural killer (NK) cell alloreactivity is determined by a balance between activating and inhibitory signals. NK cells recognize targets when appropriate activating receptors are engaged by their corresponding ligands. For killing to occur (right side of figure), the activating signals must not be inhibited by recognition of "self" which can occur when MHC is downregulated by viral infection or malignant transformation or when KIR are mismatched with their respective cognate ligands. Normal tissues are protected from lysis by the lack of activating ligands or the recognition of "self" inhibitory ligands (left side of figure).

Natural Killer Cell Receptors

Human NK cells express KIRs, type I transmembrane molecules belonging to the Ig superfamily that are all are encoded on chromosome 19. KIRs are named by the number of extracellular immunoglobulin domains (2D or 3D) and the length of the intracellular tail, which determines whether they are stimulatory (Short) or inhibitory (Long). A nomenclature committee has assigned a cluster of designation (CD) number of CD158 for the KIR genes with individual loci designated by a small letter ± a number (eg, KIR3DL1 = CD158e1).[48] All individuals contain the framework genes KIR3DL3, KIR2DL4, and KIR3DL2. In addition, a variable number of activating and inhibitory genes are inherited and population studies show diverse evolutionary patterns.[49] Individuals with only one activating receptor are referred to as having an A KIR haplotype. Individuals with more than one activating receptor are referred to as having a B KIR haplotype. These genes are highly polymorphic and new alleles continue to be reported. Some of these polymorphisms are functionally important. For example, KIR3DL1*004 is not expressed on the surface, so it cannot function to recognize its respective Bw4 ligand.[50] Murine NK cells do not express KIR, but do express Ly49 receptors of the same class.[51] Although the ligands for many KIRs are unknown, the inhibitory receptors KIR2DL1, KIR2DL2/KIR2DL3, and KIR3DL1 bind HLA class I C2, C1, and Bw4 alleles, respectively. The KIR repertoire is determined primarily by KIR genotype and at steady state is only minimally affected by class I HLA (KIR-ligand) genes, which segregate independently (chromosome 6). The recognition of self-class I HLA by the higher-affinity inhibitory receptors suppresses NK-cell effector responses, including cell-mediated lysis and cytokine release.[52] Both human and murine NK cells express CD94, which heterodimerizes with the NKG2 family of C-type lectin receptors. They are either inhibitory (NKG2A) or activating (NKG2C/E) receptors that recognize nonclassical HLA-E.[53] NKG2D is unique in that it does not heterodimerize with CD94 and it recognizes stress-induced molecules such as MHC class I polypeptide-related sequence A/B (MICA and MICB) and the class I-like CMV-homologous ULBP proteins that are often upregulated on tumor or virally infected cells.[54–56] NK cells also express Ig-like transcript (ILT) receptors, some of which bind HLA-G expressed in the placenta and on fetal tissue. Several other receptors have been identified that regulate killing of MHC class I-negative targets, including but not limited to the natural cytotoxicity receptors NKp30, NKp46, and NKp44, 2B4 (which binds CD48), and DNAM-1 (CD226) (which recognizes PVR [CD155] and Nectin-2 [CD112] as their ligands).[57]

In 1985 Ljunggren and Karre described the phenomenon of "missing self," by which the loss of MHC class I expression renders autologous targets more sensitive to NK-mediated killing, providing a mechanism by which these innate killer cells can recognize tumor or virally infected cells.[58] The discovery of class I-specific inhibitory KIR and the observation that cloned NK cells all express self-inhibitory receptors[59] led to the belief that mature peripheral blood NK cells must express "at least one" inhibitory NK receptor for self-MHC class I to prevent autoreactivity.[60] Although recent reports of murine[61] and human[62,63] NK cells lacking self-inhibitory receptors challenge this model of autoreactivity, the concept remains important for clinical applications involving alloreactive NK cell clones that may be generated by using donor NK cells expressing inhibitory KIR for which the recipient lacks the appropriate ligand (Fig. 111–1).

The stepwise evolution of the innate and adaptive immune systems in response to viral pathogens is illustrated by the example of murine cytomegalovirus (MCMV). Although the downregulation of MHC class I expression in infected cells allows them to evade recognition by T cells, it makes them good NK-cell targets. MCMV also upregulates the expression of the m144 gene, a mimic of MHC class I, which is recognized by NK cell inhibitory receptors, protecting the cell. In response, murine NK cells express Ly49H, an activating receptor that recognizes the MCMV glycoprotein m157.[64,65] This case in point provides proof of principle that activating receptors may recognize viral proteins. A similar role for human activating receptors is supported by studies of patients with HIV showing an association between AIDS progression and the activating receptor KIR3DS1.[66] However, precise mechanisms for this association remain complex because KIR3DS1 does not directly recognize Bw4 as its cognate ligand. Although antigen peptide bound to MHC is not required for recognition by KIR, it remains possible that some peptides modulate KIR interactions. Infectious natural ligands for activating KIR will likely be discovered, and it may be that activating KIR are analogous to the role of conserved pathogen-associated microbial proteins (PAMPs) and Toll-like receptors[67] expressed on other cells of the innate immune system.

Human NK cells are derived from $CD34^+$ hematopoietic progenitors found in many tissues, including bone marrow, thymus, and umbilical cord blood, and can be derived from human embryonic stem cells.[68–70] Their maturation is induced by IL-15, fms-like tyrosine kinase 3 (flt3) ligand, c-kit ligand or stem cell factor (SCF), IL-7, and IL-3.[71–73] Discrete stages of NK-cell development in lymphoid

tissues are defined by the acquisition of IL-15-responsiveness[74] and a number of developmental intermediates.[75] The CD56(bright) subset, which is more proliferative, may be more primitive than CD56(dim) NK cells. The CD56(dim) subset expresses a high frequency of KIR, the variegated expression of which is controlled by transcriptional regulation of several homologous promoters under epigenetic control,[76,77] but other mechanisms may also be active.[78,79] In healthy subjects the KIR repertoire is predicted mainly by the KIR genotype, although it is influenced by HLA class I KIR ligand status.[80] The wide allelic variation in KIR genes includes several common alleles exhibiting poor or no surface expression.[50,81–83] Interestingly, KIR expression is decreased on NK cells reconstituting in patients after allogeneic HCT in whom dysregulated KIR expression correlates with clinical outcomes.[84,85]

Development of Natural Killer Cell Self-Tolerance

The developmental mechanism by which NK cells acquire self-tolerance has been referred to as NK-cell education. This has been one of the most widely debated topics in NK-cell biology over the past several years. Several models have been proposed to explain the integration of inhibitory receptor expression with the acquisition of effector functions. These concepts differ in their implied mechanisms and whether the process is one of activation or loss of function. *Disarming* refers to the suppression of effector function in maturing NK cells that receive stimulatory signals unopposed by inhibitory signals via self-MHC receptors, analogous to the development of T-cell anergy.[86,87] Licensing describes a terminal differentiation step by which NK cells acquire mature function only when they receive an appropriate signal via an inhibitory receptor ligating with self-MHC.[88,89] What is agreed on between these and other models is that human NK cells lacking inhibitory receptors are hyporesponsive.[62,63] Therefore, rather than being autoreactive, they are self-tolerant. Although the exact mechanism remains unknown, self-tolerance may be the result of a coordinated genetic developmental sequence during which mature NK function is synchronized with the acquisition of adequate expression of self-inhibitory molecules.

Autologous Natural Killer Cell Strategies

The first therapeutic trials using adoptive immunotherapy were performed in the 1980s when several groups tested autologous lymphokine-activated killer cells to treat a variety of malignancies. Peripheral blood mononuclear cells were stimulated ex vivo with IL-2 and then reinfused with high-dose IL-2 to treat immune-sensitive malignancies, including melanoma, lymphoma, and renal cell cancer. Although it was shown that the cytotoxicity was mainly mediated by NK cells, limited clinical benefit was seen.[90] The significant toxicity of the capillary leak syndrome induced by high-dose IL-2 led to trials using low-dose subcutaneous IL-2, either alone or in combination with activated NK cells. These strategies failed to show efficacy in patients with lymphoma and breast cancer.[91]

Subsequent discoveries may explain the failure of autologous lymphokine-activated killer- and NK-cell-based therapies. Such failures may occur because host lymphocytes compete with infused cells for access to cytokines[92] or possibly because infused autologous NK cells are suppressed by regulatory T cells.[93] A favorable milieu for adoptive transfer may optimally require adequate lymphodepletion or "clearing of space."[94] Rosenberg's group at the NIH developed a successful therapy for melanoma using cyclophosphamide (60 mg/kg/day × 2) followed by fludarabine (25 mg/m^2/day × 5 days) to induce T-cell lymphopenia prior to the infusion of cytotoxic T cells.[95] Although the induction of lymphopenia prior to the adoptive transfer of NK cells may enhance their expansion, autologous NK-cell strategies were abandoned after the discovery of inhibitory KIRs and their role in preventing NK-cell killing of "self" MHC-expressing tumor cells. The inherent self-tolerance of autologous NK cells was a good explanation to previous failures, leading to studies exploring the use of allogeneic donor sources. The hypothesis is that allogeneic donors will have a high frequency of alloreactive cells capable of killing tumors.

Allogeneic Natural Killer Cell Strategies

The current generation of therapeutic trials is based on a better understanding of the biologic concepts that regulate the antitumor activity of NK cells. Tumors that express ligands for activating NK receptors are more responsive to NK-cell killing, and although an attractive strategy, it is difficult to alter tumor phenotype in vivo. Therefore, more interest has been focused on ways to manipulate the interactions between inhibitory KIR and their ligands. The selection of NK-cell or stem-cell donors on the basis of their KIR ligand (HLA) status in relation to the patient has led to finding higher numbers of alloreactive NK cells in donors who express a KIR ligand lacking in the recipient.[96]

The two main strategies to harness the therapeutic power of alloreactive NK cells are (a) stem cell transplantation and (b) adoptive transfer of NK cells. Each approach has its own advantages and disadvantages. Advantages to adoptive transfer include minimal toxicity because NK cells are not believed to induce GVHD. However, the efficacy of adoptive transfer protocols is limited by the transient nature of the NK antitumor effect. Alternatively, the beneficial effects of alloreactive NK cells can be incorporated into HCT protocols by selecting donors based on one of several KIR mismatch algorithms. Although these strategies assume the risks of HCT (higher treatment-related mortality, GVHD, etc) they provide a permanently engrafted potentially alloreactive NK-cell pool that can provide ongoing antitumor activity, presuming the alloreactive cells do not become tolerant after infusion. Although NK cells are the first lymphocyte population to reconstitute after HCT, the use of exogenous IL-2 to boost their activity posttransplant is potentially dangerous as it may exacerbate GVHD. A third option may be to incorporate advantages of both strategies while lessening the cumulative toxicity associated with two separate procedures.

Regardless of the treatment strategy, the first step is to select a suitable allogeneic donor. The subtleties among the various methods by which KIR alloreactivity between donor and recipient has been defined have caused confusion (Table 111–2). The Perugia group used the KIR-ligand mismatch or KIR-ligand incompatibility model, which predicts that donor-derived NK cells will be alloreactive in the GvH direction when recipients lack C2, C1 or Bw4 alleles that are present in the donor. In this model, no alloreactivity is predicted for the approximately one-third of recipients who express all three KIR ligands. A KIR ligand match calculator based on this model, which requires knowledge of both the donor and recipient HLA types, is available on the Immuno Polymorphism Database (IPD) www.ebi.ac.uk/ipd/kir/ligand.html.[97] Alternatively, the KIR-ligand absence model categorizes recipients based on their C2, C1, and Bw4 allele status with no regard to the donor status. As most human populations have high frequencies of inhibitory KIR specific for C2, C1 and Bw4 alleles, it is assumed that most donor-derived NK cells will express inhibitory KIR and that alloreactive potential is based on the number of KIR ligands a recipient lacks. The receptor-ligand model accounts for inhibitory KIR and recipient KIR ligand status. As KIR genes have multiple alleles with variable function and expression levels, this model may be more precise if based not just on donor KIR genotype but on functional measures of KIR phenotype. This model allows for NK alloreactivity in HLA-identical transplants where recipients lack KIR ligands for inhibitory KIR expressed on self-tolerant clones in donors who may be alloreactive in the posttransplant setting.

Many groups are testing the clinical efficacy of selecting donors for HCT on the basis of their predicted alloreactivity against the host using one of the models discussed above. Potential benefits include (a) decreased rates of GVHD as host dendritic cells are killed by donor NK cells,[98,99] (b) decreased rates of graft rejection mediated by NK-cell lysis of host T cells, (c) decreased relapse via direct cytotoxcity,[46] (d) improved engraftment mediated by NK-cell release of hema-

Table 111–2 Models to Predict KIR Alloreactivity

Name	Information Needed	Model	Assumptions and Implications
KIR Ligand Mismatch *or* KIR ligand incompatibility	Donor class I HLA typing Recipient class I HLA typing (recipient KIR ligand status)	NK cells derived from donors who possess KIR ligands that are absent in the recipient (C2, C1 or Bw4) will be alloreactive in the GvH direction	Assume that NK cells will express inhibitory KIRs for all of their class I KIR ligands (C2, C1, and Bw4) Assume that donor class I HLA type predicts donor KIR expression No potential for NK alloreactivity for recipients who express C2, C1, and Bw4 (approximately one-third of patients)
KIR ligand absence	Recipient class I HLA typing (recipient KIR ligand status)	As the gene frequency for inhibitory KIRs that recognize C2, C1, and Bw4 is high in most populations, most donors will express those KIRs and alloreactivity can be estimated by recipient ligand status alone	Assume the respective inhibitory KIR genes are present in the donor Assume the donor KIR allele is expressed and functional
Receptor ligand	Donor KIR genotype (for inhibitory KIR) Recipient class I HLA typing (recipient KIR ligand status)	Both the donor KIR profile and recipient KIR ligand status are needed to accurately predict alloreactivity	Allows for NK alloreactivity in HLA-identical transplants if self-tolerant donor clones expressing KIR for which they lack the ligand become alloreactive in the posttransplant setting

KIR, killer immunoglobulin-like receptor; NK, natural killer.

topoietic cytokines,[100,101] and (e) enhanced immune reconstitution and decreased infectious complications mediated by NK-cell antiviral activity. The Perugia group demonstrated that alloreactive NK-cell clones were detected in patients after stem cell engraftment in KIR-mismatched patients and correlated KIR mismatch with improved engraftment, less relapse, and less GVHD.[96] In a recently published update, however, the only significant effect of KIR mismatch was a reduction in the relapse rates and prolonged survival in patients transplanted while in CR.[102] Results were not as good in patients who were transplanted in relapse. Additional clinical trials have supported the finding that KIR ligand mismatch is associated with these favorable clinical outcomes in myeloid malignancies, especially when T cells are depleted in vivo with antithymocyte globulin.[103] However, other studies looking at outcomes after KIR ligand-mismatched T cell-replete transplants did not achieve the same effect,[104,105] perhaps because T cells in the graft interfere with NK-cell development and KIR reconstitution after unrelated donor transplant.[85] Even in the T cell-depleted setting, some investigators have found worse outcomes in the KIR-mismatched transplants.[106] Analyses based on KIR ligand absence have also shown conflicting results. Improved survival has been reported for patients with myeloid malignancies undergoing HLA-matched sibling HCT[107] and for patients with myeloid and lymphoid malignancies after HLA-mismatched unrelated HCT.[108] Another study of unrelated HCT found that KIR ligand absence was associated with decreased relapse in early myeloid leukemias, but that patients with early CML had more GVHD.[109] Taken together, these results suggest that NK cells play a role in allogeneic transplant but the complexities of the KIR system and the heterogeneity of AML and other transplanted diseases result in some confusion. Clinical trials incorporating extensive KIR genetic analysis of donor–recipient pairs may result in better donor selection to improve transplant outcome.

Another way to promote antitumor activity with alloreactive NK cells is through adoptive transfer. This can be achieved using several strategies. One approach is based on ex vivo NK cell expansion but there are several potential limitations. Most importantly, NK cells stimulated by supraphysiologic concentrations of cytokines may undergo apoptosis when removed from ongoing stimulation and may not persist or expand in vivo. In addition, marked size changes occur with activation, which may alter homing characteristics in vivo. Consequently, developing strategies for in vivo NK-cell expansion may be optimal. The safety and success of this approach was established in a trial using in vivo expanded haploidentical, related-donor NK-cell infusions to treat 43 patients with metastasic melanoma, renal cell carcinoma, refractory Hodgkin disease, and refractory AML.[110] The trial, which tested three preparative chemotherapy regimens of differing intensity confirmed that successful NK cell expansion was only seen in the AML cohort who received the fully lymphodepleting cyclophosphamide and fludarabine regimen used by Rosenberg. Patients received NK cell infusions on day 0 following 1 or 2 doses of intravenous cyclophosphamide (60 mg/kg) days −4 and −5 and daily intravenous fludarabine (25 mg/m^2) days −5 to −1, followed by 10 million units of subcutaneous IL-2 administered over 2 weeks. Successful expansion was only seen after the high-dose cyclophosphamide-containing regimen (Hi-Cy/Flu), which was the only regimen to induce pancytopenia. In addition, it was the only one to induce a surge of endogenous IL-15 after chemotherapy. A significant inverse correlation was seen between the IL-15 levels and the absolute lymphocyte count, and high levels correlated with successful NK-cell expansion, supporting the importance of IL-15 for NK-cell homeostasis.[111]

In vivo expansion of NK cells was assessed using a PCR-based chimerism assay, with successful expansion defined by the presence of measurable donor NK cells at 2 weeks, following the IL-2 therapy. Eight of 15 evaluable patients had successful in vivo NK-cell expansion, and the circulating donor-derived NK cells were functional in standard cytotoxicity assays. Clinical efficacy correlated with in vivo NK expansion and KIR ligand mismatch. Of the 19 patients with poor prognosis AML, five achieved CRs. The remission patients had significantly higher proportions of circulating NK cells that were significantly more cytotoxic against K562 targets, suggesting that the observed clinical efficacy was mediated in part by the in vivo-expanded allogeneic donor NK cells. In this small cohort, 4 of the 19 NK donors were predicted to exhibit alloreactivity on the basis of KIR ligand mismatch in the GvH direction. CR was achieved in three of the four (75%) KIR ligand mismatch and only 2 of 15 (13%) KIR ligand match recipients, supporting a role for KIR ligand mismatching in the treatment of AML.

Adoptive transfer of allogeneic NK cells is being studied in several other disease settings on the basis of their ability to lyse targets in vitro including breast cancer,[112] non-Hodgkin lymphoma (NHL), multiple myeloma, hepatocellular carcinoma, melanoma, and renal

cell carcinoma.[113–115] Another approach to achieve the benefits of NK alloreactivity has been to incorporate adoptive transfer of allogeneic NK cells into standard HCT protocols. NK-cell products are infused either prior to or during the early recovery phase. Other variables include cell source, and studies are in progress using haploidentical umbilical cord blood based on the high frequency of lymphoid precursors found in umbilical cord blood. Other groups are using NK-cell DLIs after haploidentical HCT to consolidate engraftment in adults with AML[116] or children with leukemia and solid tumors.[117] Conclusions from these studies await well-designed clinical trials with definitive clinical and biologic endpoints to understand the role of NK cells in this process.

Natural Killer Cell Therapeutic Limitations and Future Directions

There are several limitations to the therapeutic potential of adoptively transferred allogeneic NK cells. The NK-cell yield from lymphapheresis collections is limited. Although NK cells can be successfully expanded in vivo, the success is unpredictable and the expanded cell population is transient. In addition, the homing signals needed to direct NK cells to tumor sites are not fully understood. Furthermore, the alloreactivity of in vivo expanded NK-cell populations may be heterogeneous because of variable KIR repertoire expression or to differences in NK cell or accessory cell subsets. The use of monoclonal antibodies that block NK-cell inhibitory receptors may increase antitumor killing,[118] and more sophisticated techniques for subset selection of NK-cell products may affect the interaction between the innate and adaptive immune responses. For example, removing regulatory T cells that can suppress NK-cell proliferation and killing may improve the immune effector functions of the expanding NK cells.[93] NK-cell expansion may be improved by refining the use of lymphodepleting chemotherapy or the use of concurrent exogenous cytokine therapy. Irradiated cell lines such as NK92 and KHYG-1 may provide an inexhaustible supply of highly cytotoxic NK cells, but their in vivo survival is not well known.[119,120] Ex vivo expanded cells from any source can be genetically modified to express tumor-specific receptors. For example the NK92 cell line has been transfected with a chimeric antigen receptor for HER2/neu, which conferred superior cytotoxicity against HER2/neu positive targets.[120] Lastly, the antitumor activity of NK cells depends not only on the KIR ligand mismatch status, but also on tumor expression of appropriate activating ligands. For example, the lack of efficacy of KIR-mismatched transplants in lymphoid leukemias may be due to their low expression of LFA-1 or NKG2D-ligands. Additional strategies to enhance activating ligand expression on tumor cells are needed to increase tumor susceptibility to NK cell-mediated lysis. Other avenues of research for NK-cell immunotherapy include engineering NK cells with transferred genes, incorporating NK cells into dendritic cell vaccine therapies, and combination therapy with immunomodulatory drugs such as thalidomide, Toll-like receptor agonists, and monoclonal antibodies to target antibody-dependent cellular cytotoxicity.

DENDRITIC CELLS

The dendritic cell (DC) population initiates immune responses through the presentation of appropriate peptides in the context of major histocompatibility complexes (MHC) along with the expression of costimulatory molecules. There has been much interest in the adoptive transfer of DC populations that are primed with specific antigens in vitro. A number of different strategies have been explored for the isolation, expansion, activation, and priming of DC populations. To date there is no unanimity on what is the best population for clinical application, nor on the optimal priming approach. Some strategies include the use of tumor antigens, peptides, whole tumor lysates, or RNA for DC priming.

Dendritic cells are capable of presenting endogenous peptides on HLA class I proteins, or peptides derived from extracellular material or pathogens on HLA class II proteins. These peptides, typically 8 to 11 amino acids long, must have the appropriate structure to fit precisely into the peptide binding groove on HLA class I and II molecules. Using known peptide binding rules, it is possible to deduce possible peptides that might bind to an appropriate HLA molecule by defined algorithms and then search for possible responses in the blood or tissues of patients.

Dendritic cells have been isolated directly from peripheral blood or lymphoid organs or expanded in culture. Dendritic cells can be mobilized into the peripheral blood following cytokine treatment.[121] Clinical grade products have been prepared using centrifugation techniques.[122] Alternatively, DCs can be expanded from monocyte and hematopoietic progenitor precursors by the timed addition of different cytokines such as IL-4, granulocyte–monocyte colony stimulatory factor, TNF-α, and others.[123,124] Dendritic cells can be pulsed with peptides, protein, tumor lysates, RNA, or DNA in an effort to introduce and present peptide antigens of interest. Determining the optimal methodology for DC preparation, expansion and presentation of peptide antigens continues to be an area of much research activity, and no definitive approach has been developed. Alternatively, tumor cells themselves of hematopoietic origin can be activated and expanded from precursor populations, which in turn may present specific tumor-associated peptides.[125]

Dendritic cell-based treatment strategies have been extended to the clinic. One approach has been to utilize idiotype proteins in an effort to generate an immune response directed at B-cell malignancies such as NHL or multiple myeloma. Id-pulsed DCs were first used to treat patients with follicular lymphoma. In these initial studies, human DCs were harvested from peripheral blood by differential centrifugation and pulsed with patient-specific idiotype antigen.[126] The Id-pulsed DCs were then infused into patients with low-grade NHL. Impressive responses have been observed, with improvement in outcome for those patients who appeared to respond.[127] A randomized trial of newly diagnosed patients with low-grade NHL comparing chemotherapy plus idiotype vaccination to chemotherapy alone has completed accrual. A limitation of this approach has been the need to isolate patient-specific idiotype, which can be challenging and labor intensive although the fact that it could be developed for a randomized clinical trial is encouraging. Secreted idiotype can also be utilized, for example, in patients with multiple myeloma (MM). In this disease, secreted paraprotein can be readily isolated and used for DC pulsing. Initial clinical trials using this approach, for example, following autologous HCT have been performed, demonstrating feasibility and safety.[128] Unfortunately, tumor-specific responses have only been noted in a minority of patients and it is yet unclear what clinical impact these immunological responses may have.[128,129] This may be due to the often relatively large amounts of paraprotein that persist in these patients even after treatment. Alternatively, patients may be tolerant of their idiotype protein. An alternative approach is to perform idiotype-based DC vaccinations utilizing DCs isolated from the healthy HLA-matched donors or vaccinate donors with idiotype proteins followed by allogeneic HCT. Such approaches are currently being tested in early-phase clinical trials.[130,131] DC-pulsed vaccination approaches have also been applied in a number of other clinical settings of solid tumors; these are not reviewed here.

Once DCs are generated and loaded with antigen, the route of administration may be an important variable. Traditional routes of administration have included intravenous and subcutaneous injections. Relatively little is known about the trafficking of injected DCs to nodal sites or about their survival in vivo. Intradermal administration of DCs has also been explored in a dose-escalation format using between 10^6 and 10^9 tumor lysate pulsed DCs. No grade III or IV toxicities or autoimmune reactions were observed.[132] Other studies have demonstrated links between innate and adaptive immunity. The lysis of tumor cell targets by NK cells may enhance presentation of tumor-specific antigens by DCs.[133,134] Therefore, an alternative strategy may be to use a combined cellular approach of both NK cells

Use of Donor Leukocyte Infusions

Donor leukocyte infusion (DLI) is an effective treatment for patients who suffer a relapse following allogeneic HCT, yet is associated with GVHD and graft failure. Chimerism should first be checked to ensure that adequate donor hematopoiesis persists, because the presence of donor cells decreases the risk of graft failure following DLI. Lower doses of DLI can be effective for relapse of indolent diseases and avoid the risk of GVHD. Higher DLI doses may be required for effective treatment of more aggressive disease. Therefore, patients with CML, CLL, low-grade NHL and MM who relapse following allogeneic HCT can be treated initially with DLI containing a calculated T-cell dose of 1×10^7 $CD3^+$ T cells/kg. If no response is noted within 4 to 6 weeks, a second infusion of 5×10^7 $CD3^+$ T cells/kg followed by a third dose of 1×10^8 $CD3^+$ T cells/kg may be indicated. Patients with more aggressive diseases such as acute leukemias should be treated with higher-dose DLI (1×10^8 $CD3^+$ T cells/kg or higher). Induction chemotherapy should also be considered for patients with more aggressive leukemias because DLI alone is rarely effective.

and DCs. This combined approach is in the early phases of investigation. As with all of the approaches discussed, technical feasibility and practical and regulatory issues can be daunting.

ADAPTIVE IMMUNITY

Basic Biology

The adaptive immune response is characterized by selection of specific populations of B and T cells with appropriate activity, priming of clonal populations of cells, expansion and stimulation of effector function through the production of antibodies, or direct cytotoxic attack through DC populations, which initiate an adaptive immune response.[135]

Cytotoxic T cells are particularly attractive for clinical use owing to their exquisite specificity and direct lytic capabilities. The mechanistic aspects of CTLs have been characterized in great detail. CTLs recognize their targets through engagement of the T-cell receptor (TCR), which specifically binds to HLA class I (CD8 T cells) and II (CD4 T cells) molecules expressing an appropriate peptide.[136] In order for a productive interaction to occur, accessory and costimulatory molecules are also necessary.[137] In the absence of costimulatory molecules, anergy results, however, if the TCR is engaged along with costimulatory molecules, a productive interaction results in the synthesis of cytokines such as IL-2 and clonal expansion.[138] The best characterized system of costimulatory molecules are the CD28-B7 system, of which at least two members, B7.1 and B7.2, have been cloned and extensively studied.[137] Other costimulatory molecules, including CD2/LFA-3, are also important.

In addition to these protein molecules, adhesion molecules such as LFA-1 and its counterreceptor ICAM-1 play important roles in CTL function.[139] Binding of the TCR results in an increased affinity of LFA-1 toward ICAM-1 for a finite period of time, which allows for a stable interaction with the target cell.[140] Cytotoxic granule contents are then recruited along the cytoskeleton and released into the space between the two cells, resulting in pore formation by perforin and induction of apoptosis by granzymes.[141,142] For perforin to function properly, Ca^{2+} is required. In addition to granzyme/perforin-mediated lysis, a Ca^{2+}-independent pathway mediated through fasL–fas interactions also play important roles in CTL-mediated cytotoxicity.[143,144] Many tumor cell targets express fas, and fasL has been found to be upregulated on activated NK cells and T cells, which may be an important mechanism of tumor evasion (see Mechanisms of Tumor Cell Escape). CTL-based immunotherapy has been applied in a number of clinical settings for the treatment of hematologic malignancies and infectious complications that develop following allogeneic transplantation. These studies vary from the use of relatively diverse cellular populations to highly purified clonal populations of cells, which will be discussed below.

Activated T Cells

T cells can be activated and expanded in the laboratory prior to infusion. The use of anti-CD3 plus IL-2 activated lymphocytes has been extended to clinical trials. Limited toxicity has been observed following infusion.[145,146] A randomized clinical trial has been performed in the setting of patients with hepatoma following surgical resection where patients were randomized to receive several courses of activated lymphocytes or no further therapy. Those patients who received the T-cell immunotherapy had a reduced risk of disease relapse and improved progression-free survival.[147]

Another protocol utilizes interferon pretreatment followed by anti-CD3 and IL-2 exposure in extended culture for 14 to 21 days. The expanded cells have been termed cytokine-induced killer (CIK) cells. In these cultures, the cells with the greatest cytolytic activity have the phenotype $CD3^+D16^-D56^+$.[148] CIK cells are lytic to a broad range of tumor cells, including autologous tumors, and recognize target cells through an NKG2D-mediated mechanism.[149,150] The effector cells contain granzymes and perforin, which are released in the presence of tumor cell targets or by crosslinking of CD3.[151] The in vivo activity of CIK cells has been tested in a variety of animal models of human disease in mice with severe combined immunodeficiency, as well as syngeneic and allogeneic murine models.[148,152–155] Interestingly, allogeneic CIK cells have a markedly reduced capacity for GVHD induction, at least in part due to the production of high levels of interferon-γ.[154] Using a bioluminescent imaging system, luciferase-labeled CIK cells could be visualized tracking to the tumor within 3 days of injection and persisting at the site for at least 8 to 10 days.[156] An attractive approach has been to infect the CIK cells with oncolytic viruses, which are then delivered to the tumor site and released, triggering lysis and upregulation of NKG2D ligands.[157] CIK cells have been shown to be expandable from patients with a variety of hematologic malignancies and to lyse autologous and allogeneic acute myeloid leukemia cells.[158,159] Preliminary clinical trials have been performed with CIK cells, demonstrating the feasibility and tolerability of this approach.[145,146] The potential advantages of this form of immunotherapy are that the cells are readily expandable, have rapid in vivo activity without the requirement for exogenous IL-2 administration, and appear to have a reduced propensity for GVHD induction. Clinical trials in both the autologous and allogeneic transplant settings are underway in an effort to reduce the risk of tumor relapse.

Another approach of T-cell activation includes the use of anti-CD3 and anti-CD28 costimulation. The induction of CD4 T cells with capacity for T-cell help as well as the production of cytokines that may enhance the generation and survival of tumor or viral-reactive CTLs underlies the principles of potential therapy. The simultaneous activation of CD3 and costimulation through CD28 has been achieved with beads displaying these two MAbs.[160] Clinical trials using this novel strategy are currently ongoing in a number of clinical settings.[161] A particularly promising approach has been to utilize the adoptive transfer of costimulated T cells early after transplantation in a setting of lymphodepletion (Fig. 111–2). Vaccination demonstrated that earlier time points were optimal to generating an effective immune response, which could be applied to tumor-based vaccinations in the future.[162]

Cytotoxic T Lymphocytes

The specificity of CTLs has made their clinical application an attractive goal. A number of groups have attempted to identify and expand

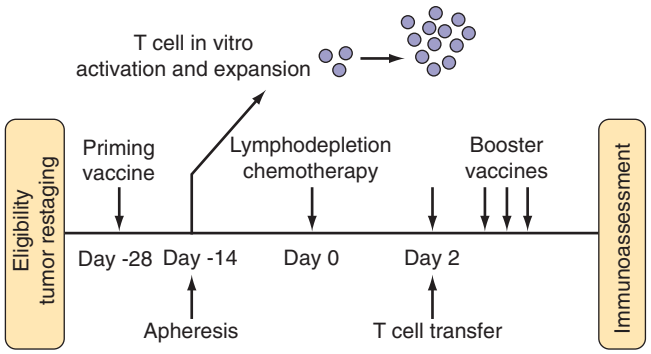

Figure 111–2 Schema for adoptive transfer of autologous, vaccine-primed, in vitro expanded T cells. As shown here, eligible patients are primed with vaccine on day −28, followed by lymphocyte harvest on day −14. The autologous T cells undergo polyclonal in vitro activation and expansion, and are reinfused on day 2 after lymphodepleting chemotherapy. Antigen-specific immune function is measured after the administration of booster vaccines. (Adapted from Cooley S, June CH, Schoenberger SP, *Miller JS*: Adaptive Therapy with T Cells/NK Cells. Biol. Blood and Marrow Transpl. 13:33–42, 2007.)

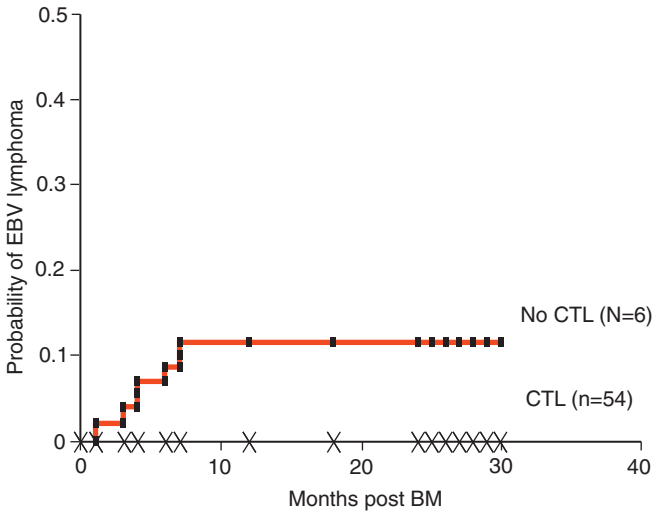

Figure 111–3 Reduced risk of Epstein–Barr virus-associated lymphoproliferative disorders in patients receiving cytotoxic T lymphocytes as compared to historical experience (H. Heslop, unpublished observations).

CTL populations capable of lysing target cells. CTL-based immunotherapy has been applied clinically for the recognition of virally infected cells and tumor cell targets. Developing viral-specific CTLs is theoretically a simpler proposition owing to the exogenous nature of the viral infection and the ability to replicate such interactions in vitro. The clinical settings that have been explored for CTL therapy most extensively are EBV and CMV infection.

Human EBV-specific CTLs have been selected from PBL isolated from seropositive donors and expanded ex vivo. These CTLs exhibit strong EBV-specific and HLA-restricted activity in vitro and in animal models. Clinical application has been explored both in the setting of treatment of patients with EBV-associated lymphoproliferative disorders or in the prophylaxis of high-risk patient populations. Clinical responses have been noted in the former setting with trafficking of marked CTLs to the tumor sites.[163,164] Prophylaxis has been very effective in reducing the risk of EBV-associated LPD (Fig. 111–3).[165] Because a significant percentage of patients with Hodgkin disease harbor latent EBV viral sequences and often express viral gene products, this strategy has been extended to the treatment of relapsed HD or for the prevention of relapse following autologous transplantation.[166] In this initial report, 14 patients with recurrent EBV^+ HD were treated with EBV CTL lines. Using gene marking studies, it was determined that these CTLs were well tolerated, expand in vivo, and functioned. An extension of this work has been to introduce the CD30 chimeric antigen receptor (CAR) into the CTLs because most malignant Reed–Sternberg cells express CD30. In a murine xenograft model, the CD30 CAR^+ CTLs induced antitumor effects against EBV^-CD30^+ tumors.[167] These elegant studies clearly demonstrate the potential of specific CTLs in the clinic.

Cytotoxic T-cell clones have also been generated against CMV-infected cells. These $CD8^+$ CTLs were isolated from the blood of the patient's donor. In the first study using this concept, CTLs were infused into recipients beginning at 30 to 40 days after allogeneic bone marrow transplantation. In these patients, cellular immunity against CMV was monitored before, during, and after the infusions of the CTLs.[168] The infusion of the CTLs did not result in significant toxicity and the transferred cells persisted for up to 12 weeks. None of these patients developed clinical CMV disease.[168] A similar study of eight patients refractory to antivirals showed clinical responses in seven patients with a reduction in CMV viremia.[169] A problem with the use of $CD8^+$ CTL clones has been the relatively short persistence of these cells following injection. Different strategies such as infusion of IL-2 or coinfusing $CD4^+$ helper T cells have been considered. In addition, this approach is technically challenging for routine use. More rapid expansion techniques are under development.[170] Other potential targets for T cell-based therapies such as aspergillosis,[171,172] papilloma viruses, adenovirus,[173] and HIV, to name a few, are actively being pursued. A clever approach has been to generate genetic modification of antigen-presenting cells to generate CTLs against multiple pathogens simultaneously.[174] More rapid selection techniques have made these approaches more feasible and clinically applicable.

The positive results of CTL-mediated immunotherapy demonstrate not only feasibility but also that these effects can be persistent and have clear biological activity. Despite these successes, there are considerable obstacles that need to be overcome to make CTL-based therapies feasible options for the routine treatment of patients. The isolation and expansion of CTLs is laborious and costly. Another major drawback in the application of CTL-based immunotherapy of cancer has been the lack of tumor-specific antigens that can be recognized by T cells. Significant advances have been made in this field, and there are a number of putative human tumor antigens expressed on solid tumors and hematologic malignancies that are recognized by T cells.[175–177] A variety of novel techniques to identify new tumor antigens are being actively pursued.[178]

A number of groups have attempted to generate CTLs against leukemic cells. In one study, two such CTL lines were cloned by limiting dilution and were found to be HLA class I and II restricted.[179] These studies demonstrate the feasibility of generating CTLs against these types of malignancies, but underscore the general difficulty in obtaining such clones and expanding them to a sufficient number of cells for clinical use. An alternative approach has been to use CTLs that are reactive against minor histocompatibility antigens and determine whether these cells will also recognize clonogenic leukemic cells. Faber and colleagues have performed such studies and demonstrated that the $CD8^+$ CTL clones were able to recognize minor histocompatibility antigen HA-1 and HA-2.[180] However, these minor histocompatibility antigens are also expressed on immature hematopoietic progenitor cells.

Another approach has been to extract tumor tissue from the patient and culture infiltrating lymphocytes (TIL cells). The cells with the majority of activity in these cultures are typical CTLs with the phenotype of $CD3^+D8^+D56^-$ and are MHC restricted.[181,182] TILs have been reported to be more potent than lymphokine-activated killer cells; however, the generation of sufficient numbers of TIL cells with significant antitumor activity is difficult. Nonetheless, this approach was used to treat a series of patients with metastatic melanoma following treatment with chemotherapy similar to that used in the nonmyeloablative transplant setting. Significant proliferation of the TILs was associated with clinical responses and in some instances the development of vitiligo.[183] This study underscored the concept

of using cytoreductive chemotherapy to induce lymphopenia in an effort to stimulate in vivo expansion of the infused lymphocytes through homeostatic mechanisms.

A number of reports have suggested that tumor cells may lack the appropriate costimulatory molecules necessary for a productive interaction between the tumor cell and the CTLs. In an attempt to overcome this, follicular lymphoma cells were preactivated with CD40, which is known to upregulate expression of costimulatory molecules including the B7 proteins. Using this approach, autologous TILs could be generated by the addition of IL-2 and further expanded in the presence of IL-4, IL-7, and interferon.[184] These activated T cells showed cytotoxicity against follicular lymphomas in four of five patients tested. These studies suggest that CTLs may be present but are not stimulated owing to the lack of expression of the appropriate costimulatory molecules that may be upregulated ex vivo to enhance the generation of CTLs. In fact, many tumor cells do not express the costimulatory molecules B7–1 and B7–2.[185,186] To overcome this, several groups have attempted to introduce these costimulatory molecules into the tumor cells by transfection. This has been performed successfully and results in enhanced recognition or rejection of transfected tumor cells using in vivo model systems.[187] These observations have been extended to hematopoietic tumors such as murine AML cells that have been found not to express B7–1. When B7–1 was transfected into the tumor cells with a B7–1-containing retrovirus, the resulting transduced AML cells were used in murine models that induced immunity against the wild-type AML cells.[188] It should be pointed out, however, that these studies were performed in animals that had not previously been exposed to the leukemic cells. It remains to be seen whether the injection of B7-expressing tumor cells into diseased hosts or patients will be able to overcome the potential of T-cell anergy.

An alternative strategy has been to introduce receptors into T cells in an effort to redirect cytolytic responses to shared antigens expressed by tumor cells.[189] For example, T cells capable of recognizing and lysing CD19-expressing acute lymphocytic leukemia cells or CD20-expressing lymphoma cells could be used to treat patients with these disorders.[190] A variety of other potential receptors could be introduced in this fashion.[191] A potential problem may be the long lifespan of the T cells reactive toward normal cells also expressing these antigens. Nonetheless, these approaches are being explored in the clinic for the treatment of a variety of malignancies.

Immunoregulatory T Cells

Control of immune reactions has been an area of intense investigation. The best-characterized population of T cells capable of immune regulation are $CD4^+$ T cells that coexpress the IL2R (CD25). These $CD4^+D25^+$ regulatory T cells (T_{reg}) express a specific transcription factor FoxP3 and are capable of suppressing the mixed lymphocyte reaction in vitro and a variety of immune reactions in vivo. Most relevant to this discussion is the ability of T_{reg} to suppress GVHD in animal models from a number of different laboratories.[192–194] Coadministration of T_{reg} and defined numbers of conventional $CD4^+$ and $CD8^+$ T cells has resulted in the control of GVHD with maintenance of GVT responses.[195] The ability of T_{reg} to separate GVHD from GVT appears to be due at least in part to the ability of T_{reg} to suppress the proliferation of alloreactive T cells required for GVHD. T_{reg} are rare populations of cells, typically approximately 10% of $CD4^+$ T cells or 1% of peripheral blood lymphocytes; therefore, the isolation of sufficient numbers of cells for clinical application is difficult.[196] T_{reg} can be expanded using similar techniques to those described for the expansion of T cells, such as CD3 plus CD28 and IL-2.[197] The addition of rapamycin may help reduce the expansion of conventional T cells that also expand under these culture conditions.[198] The adoptive transfer of T_{reg} is an exciting area of clinical research that several groups are pursuing.

Another population of immunoregulatory lymphocytes that share phenotypic expansion and functional attributes of both of NK and T cells has been described. These cells, termed NK-T cells, have demonstrated immunoregulatory and cytotoxic capabilities.[199,200] NK-T cells have been separated into two broad categories based on the TCR expression profile. Some NK-T cells express an invariant TCR (Vα14Jα281 in murine systems and Vα24Vβ11 in humans). These cells express CD3 and the NK markers NK1.1 in murine cells and CD154 in humans.[200–202] The population of NK-T cells expressing the invariant TCRs interacts with the nonpolymorphic HLA molecule CD1. CD1-expressing cells in turn present nonprotein lipopolysaccharides. On activation, this population of NK-T cells play important immunoregulatory functions in large part related to cytokine production, in particular, IL-4. These NK-T cells typically either express CD4 or are $CD4^-CD8^-$.[203] Although the adoptive transfer of NK-T cells has not been pursued as aggressively as with T_{reg}, certain preparatory regimens, for example using total lymphoid irradiation and antithymocyte globulin, may alter the ratio of conventional to NK-T cells, with an apparent reduction in acute GVHD risk.[204]

A second population of NK-T cells that express a broad array of TCRs has also been described.[205] These NK-T cells are not regulated by CD-1 and do not produce IL-4 on activation. Instead, these cells appear to have primarily cytolytic functions. This population of cells is readily expandable unlike NK cells.

Mechanisms of Tumor Cell Escape

These more basic biological and mechanistic studies not only suggest strategies for therapeutic intervention but also demonstrate the complexity of the cells and cellular interactions. They also highlight mechanisms by which tumor cells may escape immune recognition (Table 111–3). With respect to NK cell-mediated killing, tumor cells may merely inactivate the effector cells through the appropriate expression of MHC molecules. The fact that many investigators have demonstrated autologous cytolysis of tumor cell targets suggests that this inhibition can be overcome. Other mechanisms of escape include the production of inactivating cytokines such as TGF-β[206] and others, as well as molecules that may inactivate perforin and granzymes. More recently, some tumor types have been found to produce and secrete ligands for NKG2D that may inactivate and help evade recognition and lysis by NK cells.[207] In regard to CTL recognition of tumor cell targets, there are a number of possible mechanisms of escape. First, there may be a lack of tumor-specific antigens expressed by a particular tumor cell that can be recognized by CTLs. There has been an intensive search for tumor-specific Ags that have been identified for a minority of malignant cells.[176] Second, if tumor cells do not express costimulatory molecules, anergy results. In fact, this mechanism has been shown to be operative in a number of tumor cell types, suggesting that the tumor itself can downregulate response directed toward it.[186] Third, tumor cells may be relatively resistant to apoptotic signals. Finally, evidence has indicated that certain tumor cell types express fasL. FasL expression that was initially demonstrated on melanoma cells, however, has subsequently been found on a variety of other tumor cell types, including those of hematopoietic malignan-

Table 111–3 Possible Mechanisms of Tumor Cell Evasion of the Immune System

Inhibition of NK cell function through the appropriate expression of HLA molecules
Lack of expression of tumor-specific antigen or peptide
Lack of costimulatory and/or adhesion molecule expression by the malignant cells
Resistance to apoptosis
Expression of fas-ligand on the tumor cell, thereby inactivating fas-expressing effector cells
Release of inhibiting cytokines or receptor ligands

Use of Allogeneic Natural Killer Cells in Patients With Advanced Myeloid Malignancies

Chemotherapy refractory leukemia remains a clinical challenge. Hematopoietic cell transplantation (HCT) studies suggest a role for the endogenous antileukemia activity of alloreactive natural killer (NK) cells. This activity is predicted by donor–recipient killer immunoglobulin-like receptor (KIR)–ligand mismatch or incompatibility. In this setting, donor NK cells expressing inhibitory KIR will result in better tumor kill if they are not inhibited by MHC class I ligands on residual recipient tumor cells. Progress has been made in adoptive transfer of allogeneic NK followed by in vivo expansion and activation as an alternative to HCT. This strategy is dependent on a high-dose chemotherapy regimen consisting of cyclophosphamide and fludarabine chemotherapy along with IL-2 administration. This lymphodepleting chemotherapy alters the milieu in vivo resulting in a surge of endogenous IL-15 and IL-7, which probably contributes to in vivo expansion of donor NK. Although promising, treatment of patients with advanced malignancy using allogeneic NK cells and IL-2 is still experimental and should be performed only in a clinical trial setting. Exploiting NK cell therapy alone or in combination with HCT is being actively pursued. Other strategies to maximize this effect, such as KIR genotyping for better donor selection, are also being explored.

cies.[208,209] Therefore, tumor cells expressing fasL could inactivate CTLs or NK cells by inducing apoptosis of the effector cell through engagement of fas. The significance of these various mechanisms of tumor cell escape and the development of strategies designed to overcome them is an area of intense basic and clinical investigation.[177]

NONHEMATOPOIETIC IMMUNOREGULATORY CELLS

Mesenchymal Stromal Cells

Nonhematopoietic stem cells (embryonic and adult tissue derived), capable of giving rise to a variety of somatic tissues, have been of great interest in regenerative medicine. Among the first adult derived cells described from bone marrow and other tissues are mesenchymal stromal cells (MSCs), which are fibroblast-like plastic adherent cells of nonhematopoietic cell origin.[210] Although they are termed mesenchymal stem cells by several investigators, the International Society for Cellular Therapy position paper encouraged a name change to mesenchymal stromal cells to accurately reflect the fact that many reports do not qualify these cells as stem cells and because not all MSCs are alike.[211] Comparing MSC populations characterized in different laboratories is difficult because of differences in culture techniques and the lack of distinct surface antigens that accurately distinguish developmental maturity or differentiating capacity. The major interest in MSCs in HCT is their potential immunomodulatory effects.

Mesenchymal stromal cells produce a number of cytokines[212] that suppress allogeneic T-cell stimuli in mixed lymphocyte reaction assays or by other nonspecific stimuli.[213] More detailed in vitro studies show that MSCs can alter the cytokine secretion profile of DCs, T cells, and NK cells to induce a tolerant phenotype.[214] Specifically, MSC can mature type 1 DC to decrease TNF-α secretion, mature type 2 DC to increase the suppressive factor IL-10, and can cause an increase in regulatory T cells. These changes lead to a shift from TH1 to TH2 responses in T cells and a decrease in interferon-γ production by NK cells. Taken together, these reports as well as studies transplanting human cells into immunodeficient mice[215,216] suggest that MSCs may play a role in facilitating engraftment and modulating GVHD much like the Treg discussed above. One concern about these reports is whether all the in vitro findings will be important in vivo. This concern is highlighted by a study evaluating the effects of mouse MSC. Although these mouse MSCs have potent suppressive effects on T cells in vitro, they had no clinical benefit on the incidence or severity in a bone marrow transplant model. Clinical trials using human MSC are under study in several centers.

The first report of clinical use of human MSC was by Koc et al, in which autologous MSCs were infused in women with breast cancer.[217] Conclusions from this study were MSC infusions were safe and hematopoietic recovery was rapid but this phase I–II study could not definitively compare effects on engraftment. In 2004, LeBlanc and colleagues first reported clinical benefit in treating grade IV GVHD of the gut and liver after 2 infusions of 1 to 2×10^6 haploidentical MSCs.[218] A follow-up study by this group in eight patients showed six responses demonstrating the potential promise of this therapy.[219] MSCs have been safely coinfused with HCT after sibling transplant[220] and other trials are in progress. In summary, MSCs remain a promising cellular therapy to enhance the safety of or to treat complications of HCT.

CONCLUSIONS

The use of cellular therapy for the treatment of a variety of conditions is an area of intense laboratory and clinical investigation. Some forms of cellular therapy are part of routine clinical care whereas others are just being developed. The rapid expansion in basic biological understanding of the types of effector cells, role of accessory cells and molecules, as well as the cytokines that expand and activate these cells has resulted in renewed optimism. Clinical successes have been evident in controlling infectious and malignant disease using adoptive therapy approaches. Ongoing and future clinical studies will determine where and how this novel therapeutic approach will be best applied in clinical medicine.

CHAPTER 112

STEM CELLS FOR TISSUE REPAIR

Felipe Prosper and Catherine M. Verfaillie

BACKGROUND

Stem cells have become a major area of discussion in the scientific, public, and clinical arena.[1] The characterization of human embryonic stem cells[2] and the demonstration of their pluripotentiality as well as the isolation of stem cells derived from adult somatic and germinal tissues have expanded our perspective of how cell therapy may be useful for patients with a variety of diseases. The past decade has seen enormous progress in our understanding of the specific requirements of stem cells and of their potential plasticity in the context of multiple tissues including the bone marrow, the central nervous system, the cardiovascular system, and almost any other tissue. Mechanisms regulating self-renewal and differentiation of stem cells have been described. Growth factors and substrates have been discovered that guide differentiation and proliferation of stem cells into specified lineages in vitro. However, the behavior of stem cells in tissue culture does not reflect fully how these cells will act when grafted into the living host, where multiple factors both intrinsic (intracellular) and extrinsic (environmental) govern the interaction of cells and the extracellular matrix, instructing them to adopt specific cellular fates. In this chapter we focus on defining the characteristics that define a cell as stem cell, the different types of stem cells and their potential. We also discuss the current applications of stem cells for tissue repair and finally address the concept of stem cell plasticity and transdifferentiation.

CHARACTERISTICS AND DEFINITION OF STEM CELLS

Stem cells are defined functionally as clonogenic cells that can undergo self-renewal as well as differentiation to committed progenitors and eventually to differentiated, functional tissues. We will explore three aspects of the stem cell: (a) self-renewal capacity: stem cells can proliferate and give rise to cells identical to each other. Although most somatic cells can be cultured in vitro for a limited number of duplications (60 duplications) it is reasonable to say that a cell that can undergo over 100 duplications without oncogenic transformation or senescence has an extensive proliferative capacity. This proliferative potential does not mean that a cell is "immortal." (b) A second parameter to define stem cells refers to the concept of clonality, which means that a single stem cell has the potential to create new stem cells. We also refer to clonality when a population of cells with different or even the same characteristics are all derived from a single unique cell (stem cell in this case). (c) Stem cells have the potential to provide a variety of differentiated cell types. According to their potential, stem cells have been clarified as totipotent (capable of giving rise to both embryonic and extraembryonic tissues), pluripotent (may differentiate into tissues derived from any of the three germ layers) or multipotent (limited differentiating capacity to cells of a given tissue only). Finally, stem cells should differentiate not only in vitro but also in vivo, contributing robustly to the reconstitution of a given tissue after transplantation.

ORIGIN OF STEM CELLS

Stem cells can be subdivided according to their tissue of origin. Embryonic stem cells are derived from the embryo, germ stem cells from germinal tissue, and tissue-specific stem cells from differentiated tissue such as cardiac, neural, or hematopoietic sites.

Embryonic Stem Cells

Embryonic stem cells (ESCs) are derived directly from the inner cell mass of preimplantation embryos at the blastocyst stage and were first isolated from mice in 1981.[3,4] Embryonic stem cells are pluripotent; they have the capacity to contribute to all somatic lineages and to produce germ line chimeras in mice. The extensive proliferative capacity as well as the pluripotentiality of ESCs have made them particularly attractive as a source of cells for tissue repair. The derivation of the first human ESC lines in 1998 and the new cell lines derived more recently[5] has raised the possibility that ESCs will provide the basis for new cell therapies useful in the treatment of many diseases.[6]

Embryonic stem cells have been extensively tested in vitro and in different animal models with very promising results; however, a number of obstacles currently prevent the widespread application of ESC therapy. It is not yet known whether it will be possible to obtain efficient differentiation of ESCs to yield pure cultures of the desired type of cells and not a mixed population. The presence of undifferentiated cells in the graft has been invariably associated with the development of teratomas,[7] as would be expected from a pluripotent stem cell. The use of promoters for specific genes expressed in the differentiated tissues of interest with a selectable cassette (fluorochrome, cell surface antigen, or antibiotic resistance gene) has allowed the effective selection of the desired cells.[8] However, it remains to be seen whether this system will be readily applicable to the clinic. The other major limitation for clinical application of ESCs is the problem of immune rejection due to donor-recipient HLA differences. Although there are some suggestions that ESCs are immune-privileged, once ESCs differentiate to mature tissues they are subjected to the same process of immune rejection.[9] Establishing ESC lines from blastocysts derived by nuclear transfer has been advocated as a way of tailoring grafts to individual patients, thus eliminating the problem of graft rejection. While nuclear transfer is a reality in several small mammals, it is not yet known whether nuclear transfer can be applied efficiently and safely to human cells. The development of enough cell lines covering the majority of the human HLA repertoire has also been advocated as a means to prevent graft rejection.

At the blastocyst stage of early embryonic development, a population of primordial germ cells (PGCs) can be identified near the epiblast. Primordial germ cells migrate to the genital ridges where they produce mature germ cells. Pluripotent stem cells have also been isolated from the genital ridges giving rise to embryonic germ cells that share many of the characteristics of ESCs with respect to their differentiation capacity and their contribution to the germ line of chimeric animals.[10,11] Although embryonic germ cells are pluripotent, recent studies indicate that primordial germ cells have already initiated epigenetic reprogramming so that erasure of imprinting starts at the early stage after conception (before 10.5 dpc in mice).[12,13] Embryonic germ cells can be obtained from PGC before extensive epigenetic reprogramming of the genome occurs and that is followed by progressive downregulation of some pluripotency-specific genes.[14] Embryonic germ cells have the same limitations of ESCs with regard to

teratoma formation and immune rejection, as embryonic germ cells are derived from PGC that have already repressed part of the somatic differentiation program. This may have an impact on their differentiation potential despite expression of the right pluripotent genes Nanog, Sox2, or Oct-4.[14]

Adult Somatic Stem Cells

The existence of stem cells in adult tissues has been recognized for more than 50 years with the first proof of concept that bone marrow contains cells that can rescue animals or humans from marrow failure.[15,16] However, complete identification and characterization of hematopoietic stem cells (HSCs) is yet to be achieved in humans despite the significant advances in the isolation of HSCs in mice.[17] Current evidence demonstrates that a single murine HSC can reconstitute all blood cell types following transplantation into a lethally irradiated animal and that the progeny of such cells can reconstitute secondary recipients, thus fulfilling all the characteristics of a stem cell derived from an adult tissue.[18]

More recently, several other tissue-specific cells have been identified, including neural,[19] epidermal,[20] gastrointestinal,[21] skeletal muscle,[22] cardiac,[23] liver,[24] pancreas,[25] or lung stem cells[26] among others. In some cases, such as neural stem cells, prospective isolation has been possible; however, this has not yet been achieved for all stem cells. Tissue-specific stem cells are multipotent, that is, they have the potential to differentiate into cells present in the tissue of origin but not other cells types. However, this concept has been challenged by a large number of studies suggesting that cells originating from one germ layer (eg, mesoderm) can generate cell types derived from a second germ layer (eg, ectoderm or endoderm).[27,28] Moreover, different studies have suggested that some adult tissues may harbor pluripotent stem cells capable of giving rise to tissues derived from all three germ layers.[29–34] The great enthusiasm generated from these studies has been paralleled by a healthy skepticism surrounding the concept of adult stem cell plasticity and pluripotency.[35–37] It is not our goal to discuss all studies and the different arguments against or in favor of stem cell plasticity but rather to provide a general view of the possible explanations of these observations.

Mesenchymal Stem Cells

Beside HSCs, BM also contains stem cells that have been termed mesenchymal stem cells (MSC or marrow stromal cells).[38] In 1976, Friedenstein et al described that fibroblastic colonies could be obtained from BM cells selected by their adherence to plastic in the presence of fetal calf serum.[39,40] Further work indicated that these cells could differentiate into bone, cartilage, and adipocytes in vitro and were transplantable.[41–43] Plastic adherent cells are a very heterogeneous population, and about 30% of these cells can be considered MSCs.[38] More recent studies by Caplan and colleagues have identified a set of surface markers that are expressed by MSCs, including SH2, SH3, CD29, CD44, CD71, CD90, and CD106. A number of hematopoietic markers are not present on MSC (CD34, CD45 or CD14).[44,45] In vitro, human, and mouse MSCs can differentiate into functional mesodermal-derived tissues. MSCs differentiate into osteoblasts, chondroblasts, adipocytes, and skeletal myoblasts.[44,46] Ring cloning[44] as well as single cell sorting strategies[47] have been used to demonstrate that single MSCs give rise to all these different lineages. A recent study also suggested that MSCs differentiate in cardiac myoblasts: injection of MSCs into an infarcted pig heart resulted in differentiation to cells staining positive for certain cardiac muscle markers and improvement of cardiac function.[48,49]

When human MSCs were transplanted by intraperitoneal injection into preimmune and immune fetal sheep, contribution to different tissues was detected by PCR for human-specific β2 microglobulin[50] and by immunohistochemical staining for chondrocytes, adipocytes, myocytes, cardiomyocytes, stromal marrow cells, and thymic stroma combined with in situ hybridization for human-specific DNA. The potential of MSCs to differentiate into mesenchymal lineages has been exploited clinically in patients with osteogenesis imperfecta undergoing allogeneic hematopoietic cell transplant. Similar to what was shown for murine BM cells[51] transplantation of whole BM was associated with osteoblast engraftment between 1% and 2% and improvement in symptoms associated with the underlying disease.[52]

Several studies have suggested that MSCs may also differentiate into neuroectoderm-derived tissues.[53–55] In vitro, both rat and human MSCs can be induced to express neuronal markers such as enolase, NeuN, neurofilament, and tau.[54] However, these studies did not demonstrate that cells with neuroectodermal staining profile also acquired functional characteristics of neurons or glial cells. When MSCs were injected into the ventricle of neonatal mice, cells migrate throughout the forebrain and cerebellum without disrupting the brain architecture, and may acquire markers of astrocytes and possibly neurons,[53,54] although again no functional data are available. In one study, MSCs were transplanted in a mouse model of Parkinson's disease. Survival of cells and acquisition of tyrosine hydroxylase expression were demonstrated. Furthermore, animals transplanted with MSCs intrastriatally had improved functional recovery compared with saline-injected animals.[55] Despite their mesodermal multipotentiality and possible neuroectodermal differentiation ability, MSCs do not differentiate into endoderm-derived tissues and thus cannot be consider pluripotent. MSCs may be a useful resource for clinical application in a number of diseases, both for regenerative therapy as well as a gene therapy vehicle.[45]

Adipose-Derived Stem Cells

Adipose tissue is a mesoderm-derived organ that has demonstrated an unexpected plasticity and potential for tissue regeneration based on the existence of a remarkable population of adipose-derived stem cells (ADSCs). Like marrow-derived mesenchymal stem cells (also frequently referred to as marrow stromal cells), adipose tissue contains a stromal population comprised of microvascular endothelial cells, smooth muscle cells, and stem cells. These cells have many properties that suggest considerable potential utility in cellular therapy for a variety of disorders. These cells can be enzymatically digested out of adipose tissue (commonly from lipoaspirate) and separated from the abundant adipocytes by centrifugation given a more homogeneous population termed ADSC. Adipose tissue-derived stem cells share many of the characteristics of their counterpart in marrow, including extensive proliferative potential and the ability to undergo multilineage differentiation.[56]

Adipose tissue-derived stem cells have been characterized by their phenotype and their potential to differentiate into mesoderm-derived tissues. The cell surface phenotype of human ADSCs is quite similar to bone marrow-derived MSCs.[45,57] It is worth noting some of the key similarities and differences between these cells. For instance, CD105, STRO-1, and CD166 (ALCAM) are three common markers used to identify cells with multilineage differentiation potential and are consistently expressed on ADSCs and MSCs. Adipose tissue-derived stem cells and MSC express adhesion molecules such as CD29 (β1 integrin), CD44 (hyaluronate receptor, which is crucial in the development of neo-extracellular matrix and plays a role in numerous pathologic and physiologic events) and CD49e (alpha-5 integrin, important for cell adhesion to fibronectin). Adipose tissue-derived stem cells also express high levels of CD54 (ICAM-1), a member of the immunoglobulin supergene family that can be upregulated in response to numerous inflammatory mediators and cytokines. Adipose tissue-derived stem cells lack the expression of known hematopoietic and endothelial markers such as CD3, CD4, CD11c, CD14, CD15, CD16, CD19, CD31, CD33, CD38, CD56, CD62p, CD104, and CD144. Less than 1% of ADSCs express the HLA-DR protein, and the majority express MHC Class I molecules.[58] The differentiation potential of ADSCs is remarkable. Besides differentiation along classical mesenchymal lineages, adipogenesis, chondrogenesis, osteogenesis, and myogenesis,[57,59] differentiation into other

mesoderm-derived tissues like endothelial and cardiac cells and non-mesenchymal stem cells such as neural progenitors has been described.[60–62] These attributes make ADSCs a very promising population of stem cells for tissue repair.

PLASTICITY, CELL FUSION, AND ADULT STEM CELLS

Although there is yet no "official" definition of stem cell plasticity, it could be defined as the capacity of a given cell to acquire phenotypic and functional characteristics of cells in a tissue different from the one from which the cell is originally derived. True stem cell plasticity should include the following criteria: a single tissue-specific adult stem cell, for instance an HSC, thought to be committed to a given cell lineage can under certain microenvironmental conditions acquire the ability to differentiate to cells of a different tissue. The differentiated cell types should be functional in vitro and in vivo. Engraftment should be robust and persistent in the presence (and absence) of tissue damage. Most reports of adult stem cell plasticity have not fulfilled all of these criteria.

The idea of "stem cell plasticity" originated over 100 years ago when it was recognized that epithelial changes, for instance from squamous to columnar epithelium, occur in response to different stresses. Such changes occur in the esophagus in response to gastric reflux. Furthermore numerous examples of lineage switch exist in lower species like Drosophila in which the imaginal discs can give rise to different organs depending on the position where the discs are placed.[63] What are then the mechanisms that may explain the capacity of stem cells to transdifferentiate (stem cell plasticity)?

One possibility is that pluripotent stem cells persist after birth in the BM or even in multiple organs. These embryonic remnants may under certain in vitro culture conditions acquire proliferative potential and when stimulated either in vitro or in response to local cues in vivo, differentiate into the tissues in which they engraft. It is not unreasonable to think that only under very special circumstances in vivo they would undergo proliferation-differentiation. This would not really be transdifferentiation but rather true pluripotency. However, there is currently very little evidence that such stem cells remain in adult tissues either in animals or humans. Two recent studies have described the isolation of a population of stem cells with such pluripotent characteristics.[29,64] Very small embryonic-like cells (VSELs) have been defined as a population of $CXCR4^{+}C133^{+}D34^{+}$ in $D45^{-}$ mononuclear cells derived from umbilical cord blood and are a counterpart of a similar pluripotent stem cell population found in mice. VSEL cells express embryonic transcription factors such as Oct-4 and Nanog and differentiate into tissues derived from all germ layers. A similar population named pre-MSC has been isolated from mice BM based on the expression of SSEA-1 that also express markers and behaves as pluripotent stem cells.[29] Although other cells with phenotypic and functional characteristics of pluripotent stem cells have been isolated from cord blood (USSC),[65] bone marrow,[31,33] mouse testis,[34] or amniotic fluid,[66] all these cell populations are obtained after in vitro culture. Whether they represent a true stem cell population existing in the adult tissues or are induced after culture remains to be demonstrated.

A second possibility is that a tissue-specific stem cell may undergo genetic reprogramming in culture. This is similar to what occurs in the cloning process induced by specific culture conditions. In other words, organ-specific stem cells overcome their intrinsic restrictions when exposed to a novel microenvironment.[67,68]

It has been demonstrated that apparent plasticity can be the result of cell fusion.[69–71] Some of the original descriptions of stem cell plasticity[72] are the result of cell fusion between stem/progenitor cells and local resident differentiated cells. Fusion has been demonstrated in vitro and in vivo, particularly in studies of liver regeneration but also in other organs such as the heart and the brain (Purkinje cell).[70,73] Although the phenomenon of cell fusion has long been known and exploited (formation of hybridomas for antibody production), the extent of cell fusion's role in plasticity and the potential to use cell fusion therapeutically are not known.

Finally, it is possible that some examples of plasticity can be attributed to presence of multiple stem cells in BM, or other organs. The cell population responsible for giving rise to different tissues may, in fact, be composed of multiple stem cells with different potential (muscle stem cells, neural stem cells, liver stem cells).[74,75] Strictly speaking, this phenomenon cannot be considered "stem cell plasticity"; however, such cell populations might still have therapeutic potential.

We do not yet understand which of these mechanisms (probably several of them) underlie the phenomena of stem cell plasticity. However, stem and progenitor cell populations other than HSCs have already been used to treat a variety of diseases and comprise a very active area of research for tissue repair and cell therapy. Embryonic stem cells eventually may be used therapeutically; however, only adult stem cells have been used for tissue repair or as vehicles for gene therapy to date. We will limit our discussion to therapy with stem and progenitor cell progenitors derived from adult humans.

THERAPY WITH STEM CELLS

Multipotent adult stem cells obtained from human BM have been used therapeutically for at least 50 years, and analyses of allogeneic BM, peripheral blood, and umbilical cord blood transplants have definitively demonstrated that HSCs contribute to long-term and complete hematopoiesis after myeloablation.[76,77] The use of stem and progenitor cell populations other than HSCs to repair their tissue of origin as well as other tissues is now entering an intense phase of investigation.

Stem Cells for Cardiac Repair

The idea of repairing the diseased heart using different types of stem cells has gained widespread attention recently, leading not only to a number of preclinical studies but also to early phase I–II and even randomized clinical trials.[78,79] Efforts have been made to restore function of the damaged heart by transplanting nonresident stem cells like fetal cardiomyocytes,[80] ESCs,[8] skeletal muscle cells,[81] bone marrow-derived MSCs,[82] or ADSCs.[83] These efforts have met with variable success.

Initial studies demonstrated that fetal cardiomyocytes grafted in noninfarcted hearts can integrate into the cardiac muscle and establish gap junctions, which allows electrical conductance between the host cells and the donor cells. Both murine and human ESCs can differentiate into functional cardiomyocytes,[84] and a number of studies have shown that like fetal cardiomyocytes, ESC-derived cells can integrate into the heart muscle of both normal hearts and infarcted areas.[8,85] However, grafting of ESC-derived cardiomyocytes in ischemic areas of the heart leads to very poor survival of cells.

Other cells used to treat heart disease in preclinical models include skeletal muscle cells, a number of BM-derived or adipose-derived cells as well as putative cardiac stem cells.[78] In contrast to ESCs, there is no convincing evidence that cells from postnatal tissues other than the heart can generate functional cardiomyocytes in vivo. Nevertheless, a number of cell populations, including BM mononuclear cells, enriched hematopoietic stem and progenitor cells,[86] EPCs,[87] BM MSC[88] and adipose MSC,[83] and skeletal myoblasts have been grafted in models of chronic as well as acute myocardial infarction.[79] Improved function has been seen in a number of studies without evidence that the cells contributed to a large degree to cardiac muscle itself. As a consequence of these preclinical studies, a large number of clinical trials in patients with chronic as well as acute MI using mostly bone marrow cells[89] (freshly isolated total BM, mononuclear cells, cultured cells to increase putative endothelial progenitor cells, CD34, or AC133 selected cells) but also skeletal myoblasts[90] have been developed. These clinical trials are predominantly phase I/II.[91,92] More recently, a phase III randomized trial has been initiated.[93] The largest experience has been gained in patients with acute MI using BM-derived cells. Although some trials suggest a benefit from cell

transplant in patients with acute MI, other studies do not find any effect due to cell therapy.[93–96] The differences have been attributed to the heterogeneity of the type of cells used in each trial, the type of patients, or even the endpoints.

Most clinical investigators have postulated that delivery of the appropriate cells would repair a damaged heart via active myocardial regeneration resulting from transdifferentiation of the administered cells; however, alternative mechanisms may be at play: (a) exogenous cells may stimulate proliferation of endogenous cardiac precursors or stem cells through neovascularization or paracrine signaling actions facilitating the ability of the heart to heal itself[97]; (b) exogenous cells may lead to cardiac repair via fusion of donor cells with host cardiomyocytes as has been demonstrated in animal models[98]; and (c) the effect of therapeutic cells could also be mediated by altering the mechanical properties of the scar, thereby preventing deterioration in cardiac function.[99]

Recent work from several laboratories indicates that the adult heart contains a resident population of progenitor cells with cardiomyogenic potential.[100–102] Beltrami et al isolated clusters of multipotent cardiac stem cells (CSCs) expressing the cell surface antigen Sca-1, KIT, and/or multidrug resistance transporter gene 1 (MDR1) localized throughout the myocardium and, more particularly, at the atria and lower region of the left ventricle of the heart, termed apex.[100] Cardiac stem cells possess the ability to self-renew and differentiate into myocytes, smooth muscle cells, and endothelial cells. These are the main cell components of the myocardium contributing to the maintenance of heart homeostasis, and repair of myocardial tissue after injury in animal models of infarction.[100,103] A second population of cardiac progenitor cells was isolated on the basis of the expression of Sca-1 antigen.[104] When these cells were injected into mouse 6 hours after infarction, they engrafted and differentiated into cells expressing the cardiac markers sarcomeric actin and troponin I. Using a Cre-Lox model, it could be demonstrated that half of the donor-derived cells had fused with the host cardiomyocytes while the other half had differentiated directly without fusion. A third population of cardiac stem cells was described on the basis of the isolation and differentiation potential of side population (SP) cells expressing the stem cell marker ABCG2.[105] Less information is available in terms of functional cardiac potential of this population of cardiac progenitor cells. Recently, a candidate progenitor population has been described both from human and mouse heart as cells expressing the transcription factor islet-1.[102,106,107] During development, Isl1$^+$ cells contribute to a second wave of cardiomyocyte formation. These cells are also present at birth and, to a lesser extent, during adulthood. Isl1$^+$ cells can be isolated and expanded in vitro and differentiated into all three lineages—cardiomyocytes, endothelial cells, and smooth muscle cells—required for the development of the heart.[106] There is currently little evidence, however, that these cardiac progenitor populations have a major in vivo role as robust progenitors capable of regenerating the damaged heart.

Stem Cells for Muscle Repair

Skeletal muscle has the capacity for complete regeneration and restoration of the cellular architecture in response to repeated injuries. This regenerative capacity is attributed to muscle stem cells, also known as satellite cells.[108] This ability to withstand multiple injuries implies that the satellite cell pool is replenished during the regenerative process and suggests the presence of a cycling pool of satellite cells. This pool may be analagous to the transit amplifying cell (TAC) population described in other lineages (ie, skin and gut)[109,110] and maintained by a residual pool with self-renewal capacity.[111,112]

Although recent studies establish that the majority of the satellite cells are derived from the somite (Pax3$^+$/Pax7$^+$ cells located in the central region of the myotome),[113,114] other stem cell/progenitor cell populations that contribute to the satellite cell pool and muscle regeneration have been described. These stem cell populations either reside in skeletal muscle or may be recruited from nonmuscle pools in response to signals or cues associated with injury and regeneration and include muscle-derived stem cells (MDSCs),[32] side population cells,[115] bone marrow cells (hematopoietic stem cells),[116] mesenchymal stem cells,[117] multipotent adult progenitors cells,[118] or mesangioblasts.[119]

The satellite cells have a specialized niche in adult skeletal muscle between the basal lamina and the sarcolemma and are characterized by size (ie, small), high nuclear-to-cytoplasm ratio, relative absence of cytoplasmic organelles, and increased nuclear heterochromatin representing a quiescent state of the cell. At the molecular level, satellite cells lack expression of the myogenic regulatory factors, including members of the MyoD family.[120] Recently, investigators have utilized an array of transgenic and gene disruption strategies to identify and further characterize the satellite cell population. Factors that have a restricted expression pattern and serve as markers for the satellite cells in adult skeletal muscle include cell surface receptors (c-met),[121] adhesion proteins (M-cadherin and NCAM),[122] and transcription factors such as Pax3 and Pax7.[123] These cells are usually in a quiescent state, and when muscle regeneration is required they enter an active state of proliferation in which muscle-specific transcription factors are upregulated in an orchestrated fashion, eventually leading to the formation of myofibers and restoration of the normal architecture of the muscle. It is likely that a stem cell/progenitor cell hierarchy comparable to the hematopoietic system exists for the satellite cell pool (ie, stem cells vs transit amplifying progenitors vs progenitors).[124] The definition of this satellite cell hierarchy will serve as a platform for cell-based therapies.

The myogenic potential of other cell populations has recently been established. Investigators have demonstrated the presence of a population of stem cells with myogenic potential in the skeletal muscle characterized by the expression of the CD45$^+$ Sca-1$^+$ that rapidly expands following injury to the muscle. The myogenic potential of this population is dependent on the activation of the Wnt signaling.[125]

In an interesting report, Qu-Petersen et al. isolated different populations of muscle-derived stem cells from mice based on the adhesion and proliferation characteristics of the cells.[32] One of these populations named muscle-derived stem cell (MDSC) was characterized by expression of muscle markers (MyoD) and hematopoietic markers (Sca-1 and CD34) as well as lack of expression of MHC class I. MDSCs could be maintained for more 60 population doublings without evidence of genomic abnormalities and when transfected with LacZ and transplanted into the muscle of mdx mice, contributed to generation of muscle progenitors from MDSC, indicating their self-renewal capacity. MDSCs could differentiate in vitro but also in vivo to endothelium, muscle, and neural lineages.[32]

Side population (SP) cells constitute a stem cell/progenitor cell population that resides in adult tissues including bone marrow[126] and skeletal muscle[127] and that can be identified based on their ability to efflux the Hoechst 33342 dye because of the presence of the multidrug resistance protein ABCG2.[105] Recent studies performed in chick and mouse reveal that the majority of limb muscle satellite cells arise from cells expressing Pax3. At least a subpopulation of skeletal muscle SP cells is derived from Pax3$^+$ hypaxial somitic cells,[128] establishing a relation between muscle SP cells and satellite cells. Although cultures of purified muscle SP cells fail to differentiate into muscle cells,[115] transplantation studies have demonstrated that the muscle SP population contains cells that are capable of differentiating into regenerated fibers.[129] This cell population can give rise to satellite cells in regenerating muscle following transplantation, suggesting that myogenic differentiation only develops in response to the muscle environment. Interestingly, myogenic specification of muscle SP cells was observed in vitro following coculture with primary myoblasts, indicating the inability of muscle SP cells to undergo myogenic specification unless induced by myogenic specific signals.[115]

The bone marrow is a source of stem cell populations that have myogenic potential. Genetically labeled marrow-derived mouse cells have been recruited to injured muscle and generate fully differentiated myofibers.[130] Bone marrow-derived multipotent adult progenitors cells (MAPCs) are capable of forming differentiated myotubes in vitro and in vivo following delivery into murine muscle[33,118] while

studies published recently have demonstrated that GFP-labeled bone marrow-derived cells become satellite cells that are capable of myogenesis and formation of labeled myofibers.[116]

Mesoangioblasts comprise another population of multipotent progenitors of mesodermal tissue with myogenic potential.[131,132] Mesoangioblasts are vessel-associated progenitors isolated from the embryonic dorsal aorta and defined by the expression of the key marker VEGFR-2 (Flk-1). Recent evidence suggests that this type of progenitor cell can also be isolated from the bone marrow.[119] Using a dog model of Duchenne muscular dystrophy, it has been reported that intraarterial delivery of wild-type canine mesoangioblasts (vessel-associated stem cells) results in an extensive recovery of dystrophin expression, normal muscle morphology, and function (confirmed by measurement of contraction force on single fibers) with a remarkable amelioration of clinical abnormalities and preservation of active motility. These data indicate that mesoangioblasts are future candidates for stem cell therapy of patients with Duchenne's muscular dystrophy.[133]

Stem Cells for Skin Diseases

The skin epidermis is composed of pilo-sebaceous units containing a hair follicle, sebaceous gland, and interfollicular epidermis.[109] The interfollicular epidermis is a stratified squamous epithelium with a basement membrane that contains resident basal stem cells responsible for maintaining homeostasis of the interfollicular epidermis by continually replenishing the suprabasal terminally differentiating cells. The hair follicle is formed during embryogenesis as an appendage of the epidermis. Postnatally, the base of the follicle forms the hair bulge that contains multipotent stem cells responsible for differentiation into all epithelial cell lineages residing in the tissue.[134] In skin, they not only serve as a reservoir of cells for regeneration during the normal cyclic periods of hair growth but also in conditions of hyperproliferation of sebaceous glands[135] and in the repair of the interfollicular epidermis following wounding.[136]

Cell-based therapy with keratinocytes has been practiced successfully for many years. Reconstitution of a functional epidermal barrier with regeneration of the papillary dermis has been accomplished with autologous epidermal layers in patients with skin burns as well as other skin diseases. Since the first description of cultivation of human keratinocytes in 1975,[137] it took Green and his coworkers over 8 years before the first transplant of cultured autologous keratinocytes was performed.[138] The technology has been successfully used to treat hundreds of patients with extensive burns.

A combination of cell therapy using keratinocyte stem cells (known as holoclones) with gene therapy has recently been used to treat a patient with a mutation in the gene encoding the basement membrane component laminin 5 that causes junctional epidermolysis bullosa.[139] Epidermal stem cells from this patient were transduced with a retroviral vector expressing LAMB3 cDNA (encoding LAM5-b3) and used to prepare genetically corrected cultured epidermal grafts. Transplantation of epidermal grafts induced the formation of normal epidermis for up to a year after treatment as well as the synthesis of normal levels of functional LAM5. This may provide a new therapeutic approach for patients with epidermolysis bullosa.

Orthopedic Applications of Stem Cells

The initial description of the existence of a population of stem cells in the bone marrow termed mesenchymal stem cells (MSCs) (also marrow stromal cells)[38] was made by Friedenstein et al. in 1976.[39,40] Subsequently, a large body of evidence has demonstrated that these cells can differentiate into bone, cartilage, and adipocytes in vitro and are transplantable.[44] These findings constitute the bases for the application of MSC therapy in orthopedic diseases.[140] In the case of orthopedic applications of stem cells for regenerative therapy, it has been clearer that the reconstruction of any tissue requires not only a population of repair cells (ie, MSCs) but also adequate scaffolds where the implanted MSCs can proliferate and interact with specific growth factors and cytokines.

On the basis of in vitro observations, it has become apparent that MSCs can differentiate into osteocytes and chondrocytes. Marrow-derived MSCs have been seeded on extracellular matrices such as hydroxyapatite and then implanted in vivo into NOD/SCID mice or in animals with segmental bone defects, demonstrating the formation of new bone.[141] Marrow-derived MSCs have been transplanted into mice with osteogenesis imperfecta, a genetic disorder of mesenchymal tissues and also in children with osteogenesis imperfecta undergoing bone marrow transplant, demonstrating not only engraftment without side effect but also an increase in the number of osteoblasts and the formation of new lamellar bone and the total body mineral content, reducing the frequency of fractures and contributing to enhanced body growth rate.[52]

Particularly promising for orthopedic applications, especially for bone formation, is the use of natural or synthetic biomaterials as carriers for MSC delivery.[142] Newer materials such as biodegradable polymers poly-L-lactide (PLA) and poly-L-lactide-*co*-glycolide (PLGA) facilitate adhesion, proliferation, and differentiation of cells.[143] These observations have resulted in the development of clinical studies in which scaffolds loaded with in vitro expanded autologous bone marrow-derived MSCs were successfully implanted in patients with large bone defects.[144] More recently, an extended mandible discontinuity was successfully repaired through a heterotopic bone induction with biomaterials and patient's marrow cells and growth factors.[145]

The use of chondrocytes to treat cartilage lesions was reported for the first time in 1994.[146] The potential of MSCs to differentiate into chondrocytes and the possibility of obtaining large numbers of cells has led to the use of MSCs to repair joint cartilage defects in animal models using various carrier matrices.[147] Injection of mesenchymal stem cells in combination with hyaluronic acid in goats after meniscectomy has resulted in regeneration of the meniscus, a decrease in bone resorption, subchondral bone remodelling, osteophyte formation and cartilage destruction, as well as a better preservation of the joint. In other cases, repair of full-thickness defects of joint cartilage was observed after transplantation of autologous MSCs using a gel of type I collagen as carrier[148] or sponges of calcium phosphate and hyaluronic acid loaded with autologous marrow-derived MSCs.[149]

Synthetic polymers, particularly PLA and PLGA, have been developed that offer the possibility of using tridimensional scaffolds in combination with MSCs and growth factors to reconstruct joint cartilage defects.[150] Recently, autologous marrow-derived MSCs have been applied in patients with cartilage lesions.[151] Mesenchymal stem cells were injected on the medial femoral condyle and covered with autologous periosteum. The results in 12 cases were compared to control patients treated with the same procedure but without receiving MSCs. Patients treated with MSCs had better arthroscopic and histological grading scores, although the clinical improvement was not significantly different between the two groups.[151] However, this study shows the feasibility, safety, and potential efficacy of MSC therapy for cartilage repair.

Vision Restoration with Stem Cells

Stem cell transplantation has gained significant support across the medical and scientific communities as a new therapy to restore visual function. The eye is derived from three types of embryonic tissue: the neural tube (neuroectoderm), from which arise the neurosensory retina and the retinal pigment epithelium; the mesoderm, from which the corneoscleral and uveal tunics develop; and the surface ectoderm, which gives rise to the lens. Understanding cellular and molecular mechanisms that drive differentiation of early progenitors into adult competent cells in this complex environment is essential to develop approaches for stem cell therapies to treat ocular diseases. There is now well-documented evidence that the adult human eye harbors various sources of stem cells, although characteristic markers

to identify individual cell types have not been clearly established. Adult stem cells that contribute to major structural ocular tissue have so far been identified in the limbal region,[152] the pars plana and pars plicata of the retinal ciliary margin,[152] and the neural retina.[153] The potential for stem cell-based therapies to treat a variety of ocular diseases is well acknowledged, particularly the successful use of limbal stem cells to treat corneal diseases. Limbocorneal epithelial stem cells (LSCs) are located in the basal layer of the limbus between the cornea and the conjunctiva and have a high capacity for self-renewal. However, no specific markers for LSCs have been clearly identified and although the expression of p63 and the transporter ABCG2 has been associated with stem cells, these markers can also be expressed by committed cells.

Transplantation of LSCs has been recognized as a therapeutic option for patients with diseases characterized by limbal stem cell insufficiency such as Stevens–Johnson syndrome, chemical or thermal injury, chronic limbitis, limbal surgery, and contact lens keratopathy.[154,155] Pioneering studies from the group of Tseng demonstrated that transplants of cultured autologous limbal epithelium in patients with unilateral limbal stem cell deficiency can restore normal corneal function.[156] Given our understanding that the stem cell niche environment is important for LSC survival and function, the amniotic membrane has been used as a "surrogate" niche for the ex vivo expansion of LSCs.[157] Transplantation of LSCs to restore visual function caused by corneal defects is at present the only recognized stem cell-based therapy in the ophthalmic field that has been clinically validated and the only one with immediate prospects for widespread use.

Fish and amphibians can regenerate the neural retina throughout life, and the existence of neural retinal stem cells in humans during fetal development and in the adult eye in both the ciliary body and the neural retina has recently been demonstrated.[158] Retinal stem cell lineage analysis studies in small vertebrates indicate that retinal neurons share a common progenitor that is multipotent and present during all stages of retinal histogenesis. This suggests that there is not a restricted lineage giving rise to specific retinal cells and that if neural retinal progenitors could be isolated and expanded from adult human tissue, they might be used for cell replacement therapy to regenerate all types of retinal neurons as has been indicated by recent studies.[159] In that sense, stem cell-based therapies offer for the restoration of sight in individuals whose visual function has been irreversibly damaged in diseases that are associated with the loss of retinal neurons, such as macular degeneration. One recent study indicates that transplantation of committed photoreceptor progenitors may be useful for retina repair, at least in a mouse model.[159] Although isolation and cultivation of adult retinal stem cells may prove feasible, at present lack of knowledge on the conditions that promote their survival and axonal integration within the neural circuit remain obstacles to grafting and constitute a major subject of intensive research.

Stem Cells for Diabetes

Replacement of insulin-producing cells in patients with diabetes has become a major goal in regenerative therapy. Promising strategies have included therapy with cells that have the potential to generate insulin-producing β cells by expansion of existing β cells, differentiation of embryonic stem (ES) cells to β cells, and conversion of either pancreatic or nonpancreatic adult stem/progenitor cells to β cells. Alternatively, investigators have tested pharmacological agents that regenerate β cells in the pancreas, either by replication of existing β cells or by the generation of β cells from other cell types.

In vitro, β-cells with the capacity to secrete insulin have been successfully derived using different types of cells, including pluripotent stem cells (ESCs), pancreatic-derived progenitors, or nonpancreatic progenitor cells such as bone marrow or peripheral blood-derived cells.[160,161] Recent studies have demonstrated that insulin-producing β cells capable of sensing glucose levels can be derived from human ESCs.[162] However, it is yet to be established whether these cells could restore normal pancreatic function in vivo.

Other studies have focused on the potential of pancreatic progenitors to proliferate and regenerate islets and insulin-producing cells. Although some authors have favored the concept that pancreatic ductal epithelial cells have the potential to regress to a less differentiated progenitor cell capable of producing new islets and acini,[163] others have supported the potential of acinar cells to transdifferentiate to islets.[164] Alternatively, beta cells may dedifferentiate to a mesenchymal-like cell type that can be extensively expanded and then redifferentiated.[165] However, lineage-tracing studies in mouse have shown that mesenchymal cells growing in such cultures are not of endodermal origin.[166] Yet others have suggested that like in the liver, beta cells can undergo cell divisions and may be responsible for regeneration.[167] Additional studies will be needed to identify which stem and progenitor cell populations may exist in the pancreas and will be available to repair endocrine pancreatic tissue.

The possibility that adult stem cells from sources other than the pancreas may be used to treat diabetes has also been studied. Some studies have suggested that marrow cells can become glucose-responsive, insulin-secreting cells in islets in vivo.[168] Others have not been able to replicate these results. Alternatively, marrow cells may contribute to the endothelium of damaged pancreas, leading to the production of cytokines and growth factors that stimulate β-cell neogenesis, β-cell proliferation, or increased survival of the residual β cells.[169,170] Another approach to the generation of β cells is transdifferentiation of differentiated cells of endodermal origin, such as liver or intestinal cells,[171,172] as those cells are derived from the same germ layer as pancreatic cells. This may be accomplished by introducing one or more transcription factors implicated in pancreatic and endocrine pancreatic commitment such as Pdx1 and/or Ngn3.[173]

The in vitro evidence for stem–progenitor cell differentiation into insulin-producing cells is clear. However, it is not yet clear that these cells closely resemble normal β cells, which are very well characterized with regard to their gene expression, metabolism, growth potential, and secretory function. Furthermore, insulin-producing cells destined for therapeutic replacement must match the extraordinary performance of normal β cells, with their ability to store large quantities of insulin and secrete it precisely to meet the complex demands of meals, exercise, and fasting.

CNS Disorders

Diseases of the CNS, although a very attractive target for cell therapy, represent a significant challenge for cell-based strategies of repair owing to the complexity of the interactions between different types of cells and the required need for integration in the different CNS structures. During prenatal development in the mammalian CNS, the neural stem cells (NSCs) and their progenitors expand and produce functional neurons and glial cells that constitute the growing brain.[174] Unlike the more classical view sustaining the lack of regenerative capacity of the CNS, a number of studies during the last 15 years have clearly demonstrated that in the adult CNS of mammals, a small number of NSCs are also able to self-renew and generate different neural cell lineages including neurons, astrocytes, and oligodendrocytes under specific microenvironmental stimuli.[175] The subventricular zone of the lateral ventricles and the subgranular zone of the hippocampal dentate gyrus in the adult contain stem cell-like precursors capable of driving neurogenesis and gliogenesis.[176] These regions have been defined as highly specialized CNS germinal niches which contain slowly-proliferating putative CNS stem cells immunoreactive for glial fibrillary acidic protein (GFAP).[176]

The regulation of proliferation, maturation, and/or migration of adult NSCs is mediated by a large array of growth factors that include EGF, bFGF, SHH, Wnt/b-catenin, Notch 1 ligand jagged 1, platelet-derived growth factors (PDGFs), ciliary neutrophic factor, NGF, neuregulins, and BMPs, among others.[176–178] This knowledge has been used to develop several novel methods for in vitro expansion and differentiation of embryonic and adult NSCs. This information also constitutes the basis for new therapeutic strategies aimed to stimulate adult neurogenesis in vivo by supplying growth factors

involved in neural development or in cell proliferation such as EGF, bFGF, or BDNF. This strategy may be used to restore the impaired functions in numerous damaged brain areas after ischemia, seizures, and traumas or in degenerative disorders.[179,180] For instance, it has been recently reported in a rat model of ischemic brain injury that the intraventricular infusion of recombinant bFGF and EGF recruited novel endogenous neuronal progenitors that contributed to a massive regeneration of hippocampal pyramidal neurons.[181] Observations such as these have led to speculation that delivery of NSCs or their progenitors in brain regions could represent an effective strategy for the treatment of neurologic diseases such as stroke and spinal cord injuries as well as neurodegenerative disorders, including Huntington disease, Parkinson disease, and Alzheimer disease.

Besides NSCs, other types of stem cells are endowed with the potential to differentiate into neurons and glia. One example is ESCs.[182–185] Transplantation of both ESCs and ESC-derived neural (neuronal or glial) progenitors[186] promotes CNS regeneration in preclinical models of stroke,[187] myelin deficiency,[188] acute spinal cord injury,[189] and Parkinson disease.[190] Terminal neural differentiation can also be seen with non-CNS-derived multipotent somatic stem cells, such as marrow stem cells,[191] mesenchymal stem cells,[192] placental cord blood stem cells,[65] skin stem cells,[193] and adipose tissue stem cells.[194] Most of these studies are based on the potential of nonneural stem cells to acquire certain "neural" markers in vitro after treatment with certain cytokines or factors that induced neural differentiation.[54] However, recent studies have started to address whether putative neural progeny from MSCs or other stem cells have functional characteristics consistent with neurons.[195] The evidence for in vivo differentiation and functional integration is even less conclusive as none of the published studies have demonstrated beyond reasonable doubt that nonneural cells contribute to neural regeneration.[196] For instance, MSCs themselves, and even more so when engineered to express neurotrophic factors, promote functional recovery and decrease the infarct size following middle artery occlusion.[197] Potential mechanisms responsible for the functional benefit have been described such as induced angiogenesis in models of stroke,[198,199] paracrine production of cytokines, or recruitment of endogenous stem cells.[200,201]

Parkinson Disease

The motor dysfunction that is associated with Parkinson disease results from the progressive loss of dopaminergic neurons in the substantia nigra pars compacta, a region of brain that controls muscle movement. Cell replacement therapy that delivers new dopaminergic neurons represents a promising strategy for the treatment of this neurodegenerative disease.[202] Clinical studies have focused on implanting fetal midbrain cells, which include those destined to become dopaminergic neurons, into the neostriatum. Yet despite promising studies in experimental models, such fetal cell grafts into adult patients with Parkinson disease have yielded poor results characterized by limited clinical efficacy and significant morbidity, the latter manifested as refractory, medication-independent dyskinesias.[203] Despite the lack of success with this approach, other sources of stem cells have been used at least in preclinical models of Parkinson disease. Mouse and human ESCs can be differentiated into functional midbrain dopaminergic neurons in vitro,[204] and when implanted in animal models of Parkinson disease (mice and primates) there is a functional and histological recovery of the nigrostriatal pathway.[185,205] However, the development of tumors as well as the immune suppression required in these transplants remains significant hurdles for clinical application in humans.

Spinal Cord Injuries

Spinal cord injuries have also been an attractive target for cell-based therapies. Because the major cause of neurologic disability in spinal cord injuries is oligodendrocyte death, leading to demyelization and axonal degeneration, rescuing the oligodendrocytes and preserving myelin should result in a significant improvement in the functional outcome after such injuries. Again the use of growth factors involved in proliferation and differentiation of oligodendrocytes, such as sonic hedgehog (Shh), bFGF, and PDGF, might result in the differentiation of endogenous NSCs into oligodendrocyte progenitor cells (OPCs) in vitro and/or in vivo. However, because spinal cord injury is associated with the loss of both neurons and glia, cell-based strategies for reconstituting the injured spinal cord must accommodate the need to replace multiple cell types.

The use of neural stem cell implants into the injured spinal cord is based on the possibility that regionally appropriate phenotypes can be generated in response to local cues. Unfortunately, this approach has provided limited success.[206] Recently, investigators have demonstrated some functional benefit from NSC transplant in animal models of spinal cord injury, likely associated with local neurogenesis and suggesting a trophic effect more than true regeneration.[207] Because the sensory tracts of the posterior columns are frequently affected in spinal cord injuries, transplantation of glial progenitors has been an especially appealing strategy for treating spinal cord injury.[208] Other sources of adult stem cells have been used in preclinical models, namely mesenchymal stem cells from the marrow[209,210] and glial cells from the olfactory bulb,[211] with promising results.

There is evidence that NSC can survive after transplantation, migrate, and maintain their multipotency; however, there are very limited data to support the concept that these cells give rise to terminally differentiated neural cells able to sustain a program of CNS repair through significant cell replacement and tissue integration.[212] Furthermore, recovery obtained by stem cell transplant does not correlate with absolute numbers of transplant-derived, newly generated, terminally differentiated neuronal cells. Several mechanisms other than classical engraftment and differentiation of the stem cell may contribute to whatever efficacy has been observed. These include the release of growth factors and neurotrophins that can stimulate endogenous stem cells or prevent further loss of neurons and glia by releasing survival factors, increasing angiogenesis, or reducing the inflammation that ensues after the acute insult.[213]

CONCLUSIONS

Intrinsic mitogenic signaling cascades that are activated in mammalian embryonic, fetal, and adult stem cells during the normal process of self-renewal and differentiation have been identified. These cellular events may also be implicated in the regenerating process after tissue injuries. These observations hold great promise that stem and progenitor cells will be feasible and useful for the therapy of diverse degenerative disorders. Further in vitro and in vivo investigations with embryonic, fetal, umbilical cord blood, and adult stem cells and their more differentiated progenitors are required to determine their physical characteristics, interactions with the microenvironment, and respective therapeutic roles in the repair and restoration of tissue and organ function.

CHAPTER 113

COMPLICATIONS AFTER HEMATOPOIETIC CELL TRANSPLANTATION

Navneet Majhail and Daniel Weisdorf

The high-dose therapy used in hematopoietic cell transplantation (HCT) results in toxicities induced directly by the treatment and secondarily by the prolonged immunodeficiency and extended recovery process. Recognition of risk factors for particular complications allows the design of risk-specific supportive care regimens that reduce the rates of morbidity and mortality accompanying transplantation. HCT-related complications can be broadly classified into infections, early noninfectious complications (within 3 months of HCT), late noninfectious complications (after 3 months of HCT), and graft-versus-host disease (GVHD) (Table 113–1).

INFECTIONS

Infections are among the foremost causes of nonrelapse mortality in HCT recipients and can cause significant morbidity, both in the early and late transplant periods (Table 113–2). Immune defects occurring in the posttransplant period can be divided into predictable phases based on time from engraftment (sustained absolute neutrophil count >500/μL), with characteristic infections in each phase (Fig. 113–1). Antimicrobial prophylaxis regimens tailored to address the risk of specific infections during these time periods are effective in decreasing the incidence of posttransplant opportunistic infections (Table 113–3).

Engraftment generally occurs within 7 to 14 days in autologous HCT recipients and 14 to 28 days in allogeneic HCT recipients. Unrelated donor transplant recipients tend to engraft later compared to sibling donors, and 5% to 10% of unrelated donor transplant recipients may fail to engraft, leading to prolonged neutropenia. The main risk factors for infection during the preengraftment phase are disruption of mucocutaneous barriers and indwelling venous catheters. Bacterial infections can occur in up to 30% of transplant recipients during the initial period and usually arise from normal flora of the skin (coagulase-negative *Staphylococcus*), oropharynx and gastrointestinal tract (*Streptococcus viridans*, *Enterococcus* spp. and enteric gram-negative bacilli).[1] Colonizing yeasts invade because of neutropenia and disruption of normal host flora and can lead to systemic mycotic infections in 10% to 15% of patients.[2] Reactivation of herpes viruses can occur in the absence of prophylaxis. Patients with prolonged neutropenia are at risk for developing infections due to *Aspergillus* spp. The Centers for Disease Control, the Infectious Disease Society of, America and the American Society of Blood and Marrow Transplantation have published a joint guideline for preventing infections in HCT recipients.[3]

The predominant defects seen in the early to late postengraftment period are impairments of cellular and humoral immune systems.[4] This state of underlying severe immune dysfunction is enhanced and prolonged by acute and chronic GVHD and by corticosteroids and immunosuppressants used for GVHD treatment.[5,6] The incidence of late opportunistic infections is much lower in autologous HCT recipients because of quicker immune reconstitution. Immune reconstitution can take up to 2 years to recover in allogeneic HCT recipients. Patients needing long-term immunosuppression for ongoing chronic GVHD are particularly at risk and are susceptible to infections by encapsulated bacteria (*Streptococcus pneumoniae*, *Neisseria meningitides*, and *Haemophilus influenzae*), fungi (*Aspergillus* spp., *Candida* spp., and *Pneumocystis jiroveci*), and viruses (cytomegalovirus [CMV] and varicella-zoster virus).[7] Additional factors that can prolong these immune deficiencies include donor–recipient human leukocyte antigen (HLA) disparity, graft manipulation with depletion of T cells, and use of unrelated donors and possibly umbilical cord blood as a graft source.[5,8,9] Antimicrobial prophylaxis should continue beyond the initial posttransplant period, typically at least 3 to 6 months after cessation of all immunosuppression, especially in patients being treated for chronic GVHD. Some centers use total T-cell ($CD3^+$) or CD4 cell levels as surrogate markers of T-cell immunity and to guide decisions regarding antimicrobial prophylaxis. Supplemental immunoglobulin administered intravenously has been considered for patients with persistent hypogammaglobulinemia (immunoglobulin [Ig]G levels <400 mg/dL), but its prophylactic use is costly, does not prevent late infections, and may impair humoral immune reconstitution.[10] Patients with GVHD and those with indwelling venous access undergoing dental procedures should receive antibiotics for endocarditis prophylaxis.[11] Published guidelines are available for immunization of HCT survivors.[3] Vaccinations should begin 12 months posttransplant, or later if the patient is receiving chronic immunosuppression (Table 113–4).

Following HCT using nonmyeloablative or reduced-intensity preparative regimens, early experience suggests a decreased incidence of bacterial infections, most likely due to shorter duration of posttransplant neutropenia.[12] However, risks of invasive aspergillosis[13,14] and CMV reactivation remain unchanged.[15] The incidence and pattern of infections seen after unrelated umbilical cord blood transplantation are similar to those seen with adult unrelated marrow or blood graft sources.[16,17]

The approach to managing posttransplant infections is generally similar to that for infections in patients with cancer, especially leukemia (see Chapter 91). However, certain infections, particularly those due to viruses and fungi, are unique to the HCT population and are discussed in further detail here.

Febrile Neutropenia

A large proportion of patients develop fever in the early posttransplantation period, although an infectious pathogen is identified in only 50% of patients. Fever also may be due to tissue inflammation (oropharyngeal or enteric mucositis), transfusions, amphotericin, or other drug fever. Bacterial infections due to aerobic bacteria, such as coagulase-negative staphylococci, *Viridans* streptococci, and enteric gram-negative bacilli, are the primary concern during this neutropenic phase, although risk of infections with yeasts is ongoing. Prophylactic strategies can include suppressive antimicrobials against both bacteria and yeasts. Although antibiotics for bacterial prophylaxis reduce rates of bacteremia, they have not reduced infection-related mortality.[18–20] Antifungal agents, including fluconazole, have been very effective in preventing systemic candidiasis, although resistant species (*Candida krusei* or *Candida tropicalis*) have emerged as secondary pathogens.[21,22] Newer antifungal agents with activity against molds (mold-specific azoles [voriconazole, posaconazole] and echinocandins [caspofungin, micafungin, anidulafungin]) are being investigated for antifungal prophylaxis. In addition to antimicrobial prophylaxis, a few centers keep patients in a pathogen-free environment using laminar flow isolation, gut sterilization, and special diets

Table 113–1 Major Complications of Hematopoietic Cell Transplantation

	Complication	Incidence
Infections	Bacterial infections	
	Gram-positive bacteremia	20%–30%
	Gram-negative bacteremia	5%–10%
	Viral infections	
	Cytomegalovirus	5%–40% in high risk patients[a]
	Herpes simplex virus	5%–10% in seropositive patients
	Varicella-zoster virus	10%–50% in seropositive patients
	Respiratory viruses	10%–20%
	Fungal infections	
	Candida	5%–10%
	Aspergillus and other molds	5%–15%
	Pneumocystis jiroveci	<1%
	Other infections	
	Toxoplasma gondii	2%–7% in seropositive patients
Early noninfectious complications (0–3 months)	Regimen-related toxicity	
	Mucositis	60%–75%
	Hemorrhagic cystitis	5%–10%
	Venoocclusive disease	5%–40%
	Pneumonitis	10%–20%
	Alveolar hemorrhage	5%–10%
	Graft failure	2%–10%
	Adverse drug reactions	Common
Late noninfectious complications (>3 months)	Organ-specific late effects	
	Cataracts	25%–40%
	Hypothyroidism	30%–50%
	Sterility/hypogonadism	50%–90%
	Growth disturbances	30%–50% in prepubertal children
	Osteoporosis/avascular necrosis	5%–20%
	Malignant relapse	Variable
	Second cancers	2%–12%
Graft-versus-host disease	Acute	20%–50% with related, 40%–90% with unrelated donors
	Chronic	20%–40% with related, 40%–70% with unrelated donors

[a]Cytomegalovirus (CMV)-seropositive hematopoietic cell transplantation recipients or CMV-seronegative recipients with a CMV-seropositive donor.

to reduce the risk of infections. These intensive isolation measures are both cumbersome and expensive and have not proven to be helpful in preventing early posttransplant mortality.

Empiric therapy with broad-spectrum antibiotics usually is started at fever onset along with appropriate clinical and microbiologic evaluation. Choice of antibiotics depends on prior and current antibiotic usage modified by local resistance patterns and can be based on recommendations available for treatment of febrile neutropenia in general cancer patients.[23] Invasive fungal infections are a common cause of persistent febrile neutropenia, that is, fever without an identified focus that continues despite 3 to 5 days of therapy with appropriate broad-spectrum antibiotics.[24] Initiating empiric antifungal therapy with amphotericin or more commonly a mold active agent such as voriconazole or caspofungin is generally recommended at this stage.[23] Repeated vigorous investigation to identify sources of infection, even for fever recurring after initial defervescence, is essential. Although administration of myeloid growth factors (granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]) reduces the duration of neutropenia and accelerates engraftment, they have not been demonstrated to reduce mortality from early posttransplant infections.[25]

Cytomegalovirus Infection

Epidemiology and Risk Factors

Despite the introduction of effective antiviral therapies, CMV infection continues to be a major cause of infection-related morbidity and mortality in HCT recipients. The risk of CMV reactivation spans both the early and late transplant periods, especially in patients with GVHD on prolonged immunosuppression. Although the incidence of early CMV disease has declined to 3% to 6% with use of antiviral drug therapy, late-onset CMV infection still is seen in up to 20% to 40% of patients.[26–29]

Seropositivity of the recipient is the most important risk factor for CMV infection in HCT recipients, and reactivation of latent virus is the most important mechanism resulting in CMV disease.[29–31] Nearly all CMV infections (<5%) in seronegative recipients are the result of exogenous exposure (primary CMV infection), either from a seropositive stem cell donor or from cellular blood products from CMV seropositive donors. Early CMV reactivation also may be observed in recipients with false-negative serology. CMV infection and especially end-organ disease are more frequent following allogeneic HCT, with CMV infections occurring in less than 5% of autograft recipients.[32,33] Among patients undergoing allogeneic transplantation, the risk may be greater with unrelated donors compared to related donors.[34] Although the prevalence of donor seropositivity is nearly zero in umbilical cord blood grafts, the risk of posttransplant CMV infection may be similar because recipient CMV status still is the predominant risk factor for infection[35] and CMV-naive umbilical cord blood graft confers no latent protective immunity against CMV. Other factors that delay immune reconstitution may increase the risk for CMV infection, including older recipient age, increasing donor–recipient HLA mismatch, acute or chronic GVHD, and need for prolonged immunosuppression, especially with high-dose corticosteroids.[26,32,36–38]

Table 113–2 Common Infections in Hematopoietic Cell Transplantation Recipients

Pathogen	Risk Period After HCT	Risk Factors	Common Clinical Syndromes	Treatment
Gram-positive cocci	1–4 weeks	Neutropenia Mucositis Central venous catheters Skin breakdown	Bacteremia	Antibiotics based on susceptibility testing
Enterobacteriaceae spp.	1–4 weeks	Neutropenia Skin breakdown GI mucosal breakdown	Bacteremia	Antibiotics based on susceptibility testing
Clostridium difficile	1–8 weeks	Antibiotics	Colitis	Metronidazole Oral vancomycin
Encapsulated bacteria[a]	>12 weeks	Chronic GVHD Chronic immunosuppression	Sinusitis Pneumonia	Antibiotics based on susceptibility testing
Candida spp.	1–4 weeks	Neutropenia Skin breakdown GI mucosal breakdown	Candidemia Mucocutaneous Hepatosplenic	Azoles Echinocandins Amphotericin
Aspergillus spp.	1–4 weeks >8 weeks	HLA disparity CMV infection Acute or chronic GVHD Chronic immunosuppression High-dose corticosteroids	Sinusitis Pulmonary nodules or infiltrates	Mold-specific azoles Echinocandins Amphotericin
Pneumocystis jiroveci	>4 weeks	Chronic GVHD Chronic immunosuppression	Pneumonia	Trimethoprim-sulfamethoxazole Dapsone Pentamidine
CMV	>4 weeks	Recipient or donor seropositivity HLA disparity Acute or chronic GVHD Chronic immunosuppression	Viremia Enteritis Interstitial pneumonitis	Ganciclovir Foscarnet Valganciclovir
Herpes simplex virus	1–4 weeks	Recipient seropositivity	Oropharyngeal Esophagitis	Acyclovir Valacyclovir Foscarnet
Varicella-zoster virus	>4 weeks	Recipient seropositivity History of chicken pox HLA disparity Acute or chronic GVHD Chronic immunosuppression	Cutaneous Interstitial pneumonitis Hepatitis	Acyclovir Valacyclovir Foscarnet
Epstein-Barr virus	>4 weeks	HLA disparity T-cell depletion	Viremia Posttransplant lymphoproliferative disorder	Rituximab Reduce immunosuppression Cytotoxic chemotherapy

Clinical Presentation and Diagnosis

The most common manifestation of CMV infection is asymptomatic reactivation noted by screening antigenemia or DNA polymerase chain reaction (PCR) testing. CMV organ infection and disease are most often pneumonia and enteritis. CMV is the most common cause of interstitial pneumonitis and is responsible for up to 50% of cases.[39] Infection at other sites, such as retinitis, hepatitis, and central nervous system disease, are less common and usually are seen in late-onset CMV infection.[26] Indirect effects of CMV infection include increased risks of graft rejection and bacterial and fungal superinfection.[26,29] The presence of posttransplant CMV viremia is a strong predictor of subsequent clinical disease.[38,40,41] CMV pneumonia develops in 60% of patients with untreated asymptomatic viremia, and treatment of viremia can reduce the incidence of CMV pneumonia to less than 5%.[40,42–44] Although autologous HCT recipients have a lower risk of developing CMV infection, the severity of infection (e.g., pneumonia), if it develops, is similar to that observed in recipients of allogeneic transplantation.

The diagnosis of CMV can be made either by demonstration of characteristic cytopathic effects in tissue culture or by use of more sensitive molecular methods that detect viral protein or DNA. Commonly used molecular assays include CMV DNA detection methods and the pp65 antigenemia assay. Detection of the CMV pp65 antigen in leukocytes has been a commonly used method for CMV surveillance after HCT but is ineffective during early post-HCT leukopenia. However, direct detection of CMV DNA by either PCR or DNA hybrid capture assay is the most sensitive method for detecting CMV.[45–48] Plasma CMV DNA PCR, although not as sensitive as whole-blood PCR, can be a valuable tool for monitoring CMV during periods of neutropenia when CMV antigenemia testing is unreliable. Viral cultures of urine, saliva, blood, or bronchoalveolar lavage (BAL), using either rapid shell-vial or routine culture techniques, have limited clinical utility because they are less sensitive than antigen or DNA detection techniques and take much longer to report. Shell-vial cultures of CMV from BAL fluid are less specific for CMV pneumonia and can be positive in asymptomatic seropositive patients without pneumonia who are shedding CMV in oral or

respiratory secretions.[49] Despite this lack of specificity, even in asymptomatic people, finding CMV in BAL fluid is a strong predictor for the development of subsequent CMV pneumonia, and such patients should be treated.

Prevention and Treatment

For seronegative recipients, use of seronegative donors and blood products is the mainstay of prevention of CMV disease (see box on Approach to Prevention and Treatment of Cytomegalovirus Infection). Probably as effective as use of seronegative products, removal of white blood cells from transfused unscreened blood products by filtration is an alternative in the prevention of primary CMV infections.[50–52] For high-risk patients (seropositive recipients or seropositive donors of seronegative recipients), two general strategies can be used, both of which have been effective in reducing early CMV infection rates to less than 10%.[26,43,44,53–55] The first is the "preemptive" approach, which involves prompt treatment of early CMV viremia with ganciclovir or foscarnet before the infection leads to clinical

Table 113–4 Recommended Vaccinations for Hematopoietic Cell Transplantation Recipients

Vaccine or Toxoid	Time After Transplant[a]
Tetanus diphtheria acellular pertussis	12, 14, and 24 months
Haemophilus influenzae type b conjugate	12, 14, and 24 months
23-valent pneumococcal polysaccharide	12 and 24 months
Inactivated polio	12, 14, and 24 months
Hepatitis B[b]	12, 14, and 24 months
Influenza[c]	Lifelong, seasonal administration
Measles, mumps, and rubella[d]	24 months

[a]Vaccinations are deferred in patients with chronic graft-versus-host disease until discontinuation of immunosuppression,
[b]Recommended for all susceptible persons aged ≤18 years and for adults at high-risk for hepatitis B infection.
[c]Vaccination of household contacts may be valuable.
[d]Live attenuated vaccine not to be administered to patients with graft-versus-host disease or patients taking pharmacologic immune suppression.

disease. The second is the "general prophylaxis" approach, in which all at-risk patients are treated with ganciclovir irrespective of CMV viremia status. The former approach requires availability of reliable and rapid early diagnostic tests. The latter approach can reduce the rate of early CMV infection but does not reduce the incidence of mortality or the risk for late CMV infection and is associated with a higher incidence of ganciclovir-induced myelosuppression and secondary infections.[44,53,56] Both approaches require aggressive surveillance to allow prompt detection of infection. High-dose acyclovir or valacyclovir, although not as effective as ganciclovir, also reduces the incidence of CMV viremia, but continued surveillance for CMV still is required, with prompt initiation of preemptive therapy with ganciclovir or foscarnet in case viremia develops.[57–59] Unlike ganciclovir, which must be administered intravenously, its prodrug valganciclovir has excellent oral bioavailability and is being investigated for prophylaxis and preemptive therapy of CMV infection.[60–63] An additional role for preventing exogenous exposure in high-risk CMV seropositive patients through choosing seronegative donors or blood products is not proven. Because autologous HCT recipients have a lower risk of CMV disease, the preemptive approach to preventing CMV infection usually is sufficient. Surveillance for CMV is continued weekly until at least day 100 posttransplant for high-risk patients and longer for patients with chronic GVHD on high-dose immunosuppression.

CMV disease, especially pneumonia, must be diagnosed and treated promptly. If patients already are ventilator dependent when therapy for CMV pneumonia is instituted, the therapy almost always is ineffective, and mortality rate is nearly 100%.[32] The combined use of ganciclovir and immunoglobulin has been the most successful treatment of CMV pneumonia, with resolution in 50% to 75% of nonventilator-dependent patients.[32,64,65] Prolonged therapy (>2 months) with the combination of ganciclovir and immunoglobulin is indicated because shorter treatment regimens have been associated with recurrence of CMV pneumonia. Foscarnet can be effective in clinical settings where ganciclovir fails or is associated with excess toxicity, usually myelosuppression.[66] Although treatment is generally similar, with ganciclovir or foscarnet plus immunoglobulin, CMV enteritis, hepatitis, and retinitis are variably responsive.[26,67] The efficacy of valganciclovir for treatment of CMV organ disease is being investigated. Adoptive cellular therapy also is being explored as a treatment strategy.[68–70]

Approach to Prevention and Treatment of Cytomegalovirus Infection

Prevention

1. Seronegative Recipient with Seronegative Donor (Allogeneic and Autologous): Transfuse only cytomegalovirus (CMV)-safe blood products. Leukocyte depletion by filtration and blood from CMV-seronegative donors are clinically equivalent alternatives.
2. Seronegative Recipient with Seropositive Donor (Allogeneic): Deliver only CMV-safe blood products (seronegative or leukocyte depleted), but administer chemoprophylaxis as well to prevent reactivation of donor-derived endogenous virus.
3. Seropositive Recipient: Prophylaxis with acyclovir appears to be somewhat useful. Use of immunoglobulin may be beneficial. No proven role for seronegative blood products. Ganciclovir is highly effective when given prophylactically but is myelosuppressive. Patients who must interrupt the course of ganciclovir because of leukopenia are at risk for development of CMV pneumonia. Ganciclovir is the current best prophylaxis in high-risk patients but is not indicated for autologous recipients.
4. All patients require periodic (weekly) monitoring for CMV antigenemia or CMV DNA for 8 to 12 weeks posttransplantation. Longer-duration (beyond 12 weeks) surveillance is appropriate for allograft recipients, especially those with graft-versus-host disease.

Treatment

1. Asymptomatic Infections (Allogeneic and Autologous): Ganciclovir treatment of asymptomatic infection detected in blood or bronchioalveolar lavage (BAL), by either molecular detection or antigenic methods, is recommended to prevent development of CMV pneumonia. Intensive induction treatment (2 weeks) followed by a maintenance phase of 5–7 days/week therapy for an additional 4 to 8 weeks is necessary.
2. CMV Pneumonia: Ganciclovir in combination with immunoglobulin is recommended and should be instituted promptly. Once the disease has progressed to cause respiratory failure and ventilator dependence, survival is limited.

No Treatment

1. Empiric CMV therapy for interstitial pneumonitis is not indicated in seronegative recipients with seronegative graft and blood donors. Diagnostic evidence of CMV infection should be obtained.
2. Empiric CMV therapy for interstitial pneumonitis also is not indicated in patients whose BAL is negative for CMV by direct staining and molecular testing. However, BAL CMV studies have a small (<5%) false-negative rate, and close followup and monitoring are required.
3. Asymptomatic CMV viruria does not require therapy but does need close followup and serial blood viral testing for surveillance of systemic disease.

Fungal Infections

Invasive fungal infections are among the leading causes of mortality in HCT recipients. The vast majority of fungal infections in this setting are caused by yeasts (*Candida* spp.) or molds (*Aspergillus* spp.).

Candida infections

Candida albicans has been the leading cause of yeast infections in HCT recipients, but the current widespread use of azole prophylaxis in the early transplant period has led to the emergence of a variety of non-*albicans* species, such as *Candida tropicalis*, *Candida krusei*, and *Candida glabrata*, as important pathogens.[71] These yeasts are normal inhabitants of the skin and the oral and gastrointestinal mucosa. Breakdown of these mucosal surfaces due to radiation and chemotherapy, compounded by neutropenia in the preengraftment period, can greatly increase the risk of invasion and systemic infections. Presence of indwelling central venous catheters and alteration of normal surface flora due to antibiotics are additional risk factors for *Candida* infections.[2,72]

Clinical manifestations can range from localized mucocutaneous to disseminated deep-tissue infection. A high index of suspicion is needed for the diagnosis of *Candida* infections, especially in patients with persistent febrile neutropenia, because blood cultures usually are not very sensitive for isolation and identification of *Candida* spp. Oral and esophageal candidiasis frequently occur in the early posttransplant period and should be treated aggressively because they can serve as portals for subsequent systemic infection. Venous catheter infections can be difficult to eradicate with antifungal agents alone and require removal of the central line. Patients with candidemia are at risk for endovascular infections such as endocarditis and thrombophlebitis. Hepatosplenic candidiasis is the most common manifestation of disseminated candidiasis but is increasingly rare with widespread use of effective anticandida azoles and echinocandins. Specific signs or symptoms related to organ involvement may be absent, and the diagnosis frequently must be made by abdominal imaging using computed tomographic scan.

Prophylaxis with an azole, particularly fluconazole, is recommended in the preengraftment and early postengraftment periods and has been shown to be effective in reducing the incidence of invasive infections due to sensitive *Candida* spp from 30% to less than 10%.[21,22,73] Micafungin, itraconazole, voriconazole and posaconazole are other agents that have been shown to be effective for yeast prophylaxis in HCT recipients; they also have antimold activity.[74–77] Mucocutaneous infection can be treated with fluconazole. *Candida krusei* and *C. glabrata* are intrinsically resistant to fluconazole, and nonazole agents should be considered for their management. Patients with invasive disease should be treated with an echinocandin such as caspofungin or an amphotericin formulation, especially when infection occurs in the setting of ongoing fluconazole prophylaxis. The preferential hierarchy of the newer azoles and echinocandins for prophylaxis and therapy for yeast infections is not known and is under study.

Aspergillus Infections

Most mold infections in HCT recipients are due to *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger*, which gain entry through breakdown of skin or mucosal surfaces or through the nasal passages and respiratory tract. *Aspergillus* infections can occur early after HCT (during the neutropenic phase) or later, especially complicating the immunosuppression associated with acute or chronic GVHD.[78,79] Risk factors for *Aspergillus* infections include allogeneic (more than autologous) HCT, prolonged neutropenia, and GVHD.[13,78–80] Transplantation for certain diseases, such as chronic granulomatous disease, aplastic anemia, and myelodysplastic syndrome, is associated with a higher than usual risk of aspergillosis. History of *Aspergillus* infection has been observed to be a risk factor for reactivation after HCT.[81]

Aspergillus occurring in the posttransplant setting can be difficult to diagnose premortem. Hence, a high index of suspicion and an aggressive approach are required to establish its diagnosis and initiate therapy. Because nasal passages and the tracheobronchial tree are the most common portals of entry for *Aspergillus* spp., these two sites are also the most common sites of infection. Sinusitis frequently is symptomatic, and more advanced disease can be associated with erosion and necrosis of surrounding structures. Pulmonary manifestations typically include nodular infiltrates, usually distributed along the lung periphery, with pleuritic pain or cough as an initial symptom. Frank consolidation or cavitary lesions can be seen in more advanced stages of pulmonary involvement. *Aspergillus* has angioinvasive properties and can present with hemoptysis or with intravascular dissemination of the skin or brain.

Blood cultures have very low sensitivity in detecting *Aspergillus*. Diagnosis must rely on demonstration of typical fungal morphology on culture or histopathology or on tests to detect fungal components or nucleic acids. Nasal and bronchial washings for *Aspergillus* may not be sensitive, and lung biopsy may be required to obtain a definitive diagnosis.[82] The galactomannan assay is an enzyme-linked immunosorbent assay that detects the *Aspergillus* cell wall glycoprotein. It has a high specificity but low sensitivity for diagnosing invasive aspergillosis and has not been validated in well-designed trials.[83–85] Molecular methods for diagnosis, including PCR for *Aspergillus* DNA, are undergoing development.[86]

Use of high-efficiency air filters has reduced the nosocomial acquisition of *Aspergillus*.[71] Pharmacologic measures for preventing aspergillosis include prophylactic low-dose amphotericin, inhaled amphotericin, and early empiric use of amphotericin, itraconazole, or voriconazole; however, the relative effectiveness of these approaches is not yet defined.[87–89] Newer antifungal agents, including micafungin and posaconazole, have demonstrated activity as mold prophylaxis, but this role requires confirmation in more clinical trials.[74,77] Agents with significant mold activity, including voriconazole and caspofungin, are available. These drugs have a more favorable side-effect profile compared to amphotericin formulations, and many experts consider voriconazole to be the drug of choice for treatment of *Aspergillus* infection in HCT recipients. Patients with disease that progresses with a single antimold drug might require combination therapy with two antimold agents. The role of adjunctive measures such as cytokine growth factors, immunoglobulin infusion, or granulocyte transfusion remains undefined.

EARLY NONINFECTIOUS COMPLICATIONS

High-dose chemotherapy and radiation regimens are used before transplantation for their antineoplastic and immunosuppressive effects. However, these treatments can damage host tissue, resulting in significant morbidity.[90] Early HCT-associated complications frequently can simulate infections or be compounded by concurrent infections. In addition, because epithelial tissue repair may be delayed by ongoing neutropenia and local microinvasive infection, delay in hematopoietic engraftment can exaggerate and prolong these toxicities.

Graft Failure

Failure to establish hematologic engraftment (primary graft failure) and loss of an established graft (late graft failure) are serious complications of both autologous and allogeneic HCT. Delayed or poor graft function can exaggerate and prolong the risks of infection and increase the risk of peritransplant mortality. Failure to engraft can occur if an insufficient number of hematopoietic progenitors is infused. Approximately 2×10^4 colony-forming cells from marrow per kilogram recipient weight are needed to establish autologous engraftment. This is accomplished by infusing approximately 1×10^8 autologous marrow mononuclear cells/kg. Most investigators recommend infusion of a minimum of at least 2×10^8 mononuclear cells/kg to ensure establishment of an allogeneic graft. Umbilical cord blood-derived hematopoietic grafts can engraft with a lower number of cells.[91] Stem cells and progenitors can be damaged by cryopreservation or by ex vivo purging, and additional cells are required if intensive purging, especially with alkylators, is performed.

Use of hematopoietic stem cells and progenitors harvested from the blood by apheresis rather than from the bone marrow has

become widely prevalent for both autologous and allogeneic HCT. Autologous blood hematopoietic cell grafts are collected after mobilization of marrow-derived progenitors into the blood by cytokine (G-CSF or GM-CSF) therapy or during recovery from myelosuppressive chemotherapy, often in combination with growth factors.[92–95] Allogeneic grafts are mobilized from healthy donors using growth factors alone, nearly exclusively G-CSF. Progenitor content of blood or marrow grafts is assayed by quantitation of mononuclear cells expressing the hematopoietic progenitor-associated surface marker CD34.

Graft failure is uncommon if 2×10^6 $CD34^+$ cells/kg or more are collected, cryopreserved, and later infused as an autologous graft.[93,94] The minimum CD34 content for an allogeneic graft is less well defined, but more than 5×10^6 $CD34^+$ cells/kg is frequently cited as a target collection for a sibling donor allograft.[96–98] Mobilized peripheral blood-derived stem cells yield satisfactory and more rapid trilineage hematopoietic recovery than do grafts from marrow-derived cells.[98–101] Similar to marrow grafting, late graft failure is possible but unlikely (<5%) after transplantation using peripheral blood derived stem cells. Infusion of a sufficient graft cell dose (nucleated or $CD34^+$ cells) may be the most important controllable factor limiting the risk of graft failure.

Recipient myelofibrosis or splenomegaly can interfere with engraftment. Splenomegaly can delay hematologic recovery, presumably because both progenitors and mature blood cells are sequestered in the spleen.[102] The presence of moderate or severe myelofibrosis also delays engraftment, perhaps because of faulty homing of stem cells in the marrow microenvironment.[103,104]

Posttransplantation therapy can jeopardize engraftment. Graft failure or poor graft function with continuing pancytopenia has been associated with use of methotrexate, antithymocyte globulin (ATG), acyclovir, ganciclovir, trimethoprim-sulfamethoxazole (TMP-SMX), and mycophenolate mofetil (MMF). Posttransplant complications, such as CMV, human herpes virus-6 or fungal infections, acute and chronic GVHD, and, rarely, Epstein-Barr virus-associated posttransplant lymphoproliferative disorder, can compromise successful engraftment.

Allogeneic HCT, especially using unrelated or mismatched donors, poses unique engraftment problems. Transplants between siblings completely matched at HLA-A, HLA-B, and HLA-DR loci are rarely (1%–3%) associated with graft failure. However, the probability of graft failure in the related donor transplantation setting increases to almost 10% with greater degrees of donor-recipient HLA incompatibility.[105–108] The problem is frequent (5%–15%) in the unrelated donor setting, where primary or secondary graft failure may occur even after transplantation from donors well matched at the HLA-A, HLA-B, and HLA-DR loci.[107–110] In some cases, failure of unrelated donor stem cells to engraft may result from reactivity against other important histocompatibility determinants, including HLA-C.[111] Early failure of an allogeneic graft can be accompanied by emergence of cytotoxic T lymphocytes of host origin, presumably representing immune-mediated graft rejection.[112,113] T-lymphocyte depletion of donor marrow performed as GVHD prophylaxis can adversely affect engraftment, even from matched sibling donors.[106,114] Ex vivo marrow manipulation can deplete stem cells. T-cell depletion can render the graft immunoincompetent and functionally less capable of preventing graft rejection.

Compared to related or unrelated allografts, time to neutrophil recovery is significantly delayed in patients receiving umbilical cord blood grafts. Additionally, the overall incidence of graft failure is somewhat greater.[115–118] The most critical determinant of engraftment following umbilical cord blood transplantation is cell dose, and units with a total nucleated cell dose of at least 2×10^7 cells/kg have a greater probability of successful engraftment.[117–119] Because each umbilical cord blood unit has a limited number of hematopoietic progenitor cells, methods for overcoming this limitation of cell dose are being investigated. They include transplantation using multiple umbilical cord blood units, ex vivo expansion to increase the number of progenitor cells, and intra-bone marrow injection of the graft. Increasing overall cell dose with transplantation of two umbilical cord blood units has been shown to be feasible and lead to successful engraftment.[120,121]

Use of recombinant G-CSF or GM-CSF, which stimulate myelopoiesis, has improved the treatment of graft failure.[122] Improvement in myelopoiesis can be seen in 50% to 60% patients with poor graft function within 14 to 21 days after initiation of growth factor therapy. Myeloid growth factor therapy can increase peripheral blood leukocyte recovery but has no effect on platelet reconstitution. Recombinant human thrombopoietin has been tested in conjunction with myelosuppressive nontransplant chemotherapy and for stimulation of platelet recovery after HCT, but it is not available for clinical trials to confirm its efficacy.[123–125] Limited experience suggests the value of recombinant erythropoietin in reducing red blood cell transfusion needs.[126]

A second stem cell infusion can be useful if graft failure occurs. In the case of a failed autograft, infusion of previously harvested and frozen marrow or blood cells frequently reestablishes a graft. Procurement and storage of "backup" stem cells should be considered for autograft protocols in which a high rate of graft failure is anticipated. In the case of graft failure after related-donor transplantation, a second infusion of donor marrow or cytokine-stimulated peripheral blood stem cells may allow successful engraftment.[127] In some cases, reconditioning with reduced doses of cytotoxic agents or further immunosuppression with ATG, corticosteroids or cyclosporine is used to prepare the recipient for a second infusion.

Treatment of graft failure after unrelated donor transplantation poses special problems. Unrelated donors may not be available for a second marrow harvest or blood stem cell apheresis. In experimental settings where graft failure risks are high, storing autologous stem cells from patients undergoing unrelated donor transplantation is a prudent practice but is rarely done. The original donor is unavailable in recipients of unrelated umbilical cord blood grafts, and the only treatment option for graft failure in this setting is a second transplant using umbilical cord blood cells from a different donor or other unrelated donor allograft, or reinfusion of autologous backup cells.

Hepatic Venoocclusive Disease

Hepatic venoocclusive disease (VOD), also known as *sinusoidal obstruction syndrome*, is a serious liver disorder characterized by jaundice, ascites, fluid retention, and hepatomegaly. It complicates up to 5% to 50% of HCTs, with different incidences based on the stringency of definition of the clinical diagnosis.[128–131] The primary initiating event is thought to be portal hypertension due to obstruction of hepatic sinusoids and venules, which secondarily leads to damage to surrounding centrilobular hepatocytes.[132–134] Chemotherapy and total body irradiation (TBI) used in pretransplant conditioning regimens lead to sinusoidal endothelial injury, and subsequent deposition of fibronectin and factor VIII/von Willebrand factor at the site of damaged endothelium can lead to activation of the coagulation system and subsequent sinusoidal obstruction.[135] Such changes are often associated with depressed plasma protein C levels and other signs of procoagulant activity, including lower antithrombin III levels and elevated factor VIII and fibrinogen levels.[136–140] Cytokines such as tumor necrosis factor (TNF)-α and alterations in the levels of nitric oxide and matrix metalloproteinases may also have a role in its pathogenesis.[141–144]

Risk factors associated with the development of VOD include history of pretransplant hepatitis or liver injury, intensive preparative regimens, increased TBI dose and dose rate, and increased busulfan dose.[128–131,134,145–148] VOD may be more frequent after mismatched related or unrelated donor transplantation.[129–131] Prior therapy with gemtuzumab ozogamicin increases the risk of posttransplant VOD.[149]

Signs of VOD usually occur within 1 month after hematopoietic graft infusion but may be recognized much sooner, even during administration of the preparative regimen. Clinical evidence of VOD includes hyperbilirubinemia, hepatomegaly, ascites, and

weight gain.[128,130,134] More advanced stages can be associated with encephalopathy and renal, pulmonary, and multiorgan failure. Establishing a definite diagnosis of VOD is difficult because the diagnosis is primarily based on clinical criteria. Most investigators require the presence of jaundice, with either hepatomegaly, weight gain, and/or ascites within 2 to 3 weeks of stem cell infusion.[128,150] However, other causes of hyperbilirubinemia and weight gain early after transplantation (e.g., drugs, hepatitis, capillary leak, cardiac failure, and salt and colloid overloading) can complicate the differential diagnosis. Percutaneous or transabdominal needle biopsy of the liver is hazardous in severely thrombocytopenic transplant recipients and should be avoided. Transvenous biopsies may provide sufficient histologic material for diagnosis and may allow determination of hepatic wedge pressure product (>10 mm is associated with VOD) but may be associated with hemorrhagic complications.[151] Ultrasonographic Doppler flow studies demonstrating reversal of portal flow or a higher portal vein resistive index have been suggested as a noninvasive means of confirming the diagnosis, but their validity has been questioned.[152–154] VOD can be graded from mild to severe depending on the degree of hyperbilirubinemia and weight gain. Severe VOD is almost universally fatal within several weeks of onset.[130,155]

Effective methods for prevention and treatment of VOD have not been defined. Limited understanding of the cellular and microvascular pathophysiology of VOD has confounded development of more rational approaches to its prevention and treatment. Possible approaches include preventive therapy with low-dose heparin,[156–158] prostaglandin E,[159] pentoxifylline (a TNF-α blocking agent),[160,161] or ursodiol,[162,163] although none has proved effective in carefully performed prospective trials. Recombinant tissue plasminogen factor has been used successfully to treat established VOD; however, thrombolytics are associated with substantially increased risk of hemorrhage.[164–167] Transjugular portosystemic shunts have been used with some success.[168,169] Early experience with defibrotide, a single-stranded polyribonucleotide with fibrinolytic, antithrombotic, and antiischemic properties, has been favorable; 30% to 40% of patients with severe VOD have achieved complete resolution and improvement in survival.[170–173] Its efficacy in the prophylaxis and management of severe VOD is being investigated in larger clinical trials.

Interstitial Pneumonitis

Interstitial pneumonitis is a common and frequently fatal complication, affecting up to 35% of allogeneic transplant recipients, although advances in supportive care have led to substantial reductions in this risk.[174,175] Interstitial pneumonitis is notably less common after autografting.[176] It is characterized by diffuse, nonbacterial interstitial inflammation accompanied by hypoxemia, dyspnea, and nonproductive cough, sometimes with fever. Risk factors associated with development of interstitial pneumonitis include use of methotrexate for GVHD prophylaxis, older age at transplant, severe GVHD, interval from diagnosis of hematologic disease to HCT of 6 months or greater, poor pretransplant performance status, and use of higher TBI dose rate (>4 cGy/min).[174,175] Remarkably, one study reported the risk of interstitial pneumonitis was 8% when none of these risk factors was present, compared to 94% when all six factors were present.[174] It has been hypothesized that unrelated donor transplantation is more immunosuppressive and thus associated with more severe opportunistic infections and greater risk of interstitial pneumonitis, but this has not been rigorously investigated.

The course of interstitial pneumonitis often is catastrophic, manifesting as rapidly progressive tachypnea, hypoxemia, and hemodynamic compromise. Therefore, therapeutic intervention most frequently occurs before the return of definitive results of diagnostic tests and must be initiated based on the assessment of clinical risk factors and the underlying clinical setting (see box on Approach to Interstitial Pneumonitis).

Infectious Causes of Interstitial Pneumonitis

Infections are the most common cause of interstitial pneumonitis in HCT recipients. CMV and *Aspergillus* are the most common infections associated with interstitial pneumonitis (see CMV Infections, Fungal Infections). Other important but relatively uncommon infections to consider are *Pneumocystis jiroveci*, respiratory syncytial virus (RSV), and similar respiratory viruses.

Pneumonitis caused by *Pneumocystis* has a typical bilateral distribution, with a "butterfly" pattern on chest radiograph and prominent hypoxemia.[177] The previously reported 5% to 15% risk of *Pneumocystis* pneumonia has been largely eliminated by routine use of prophylaxis with TMP-SMX (first choice), dapsone, or inhaled pentamidine.[178,179] Prophylaxis with TMP-SMX virtually eliminates *Pneumocystis* pneumonia from the differential diagnosis, but only if patient compliance with therapy is certain. Diagnosis requires cytologic evaluation of silver-stained preparations of BAL cells or sputum, although transbronchial lung biopsy may slightly increase the diagnostic yield of a bronchoscopic examination. *Pneumocystis* pneumonia is effectively treated with TMP-SMX or parenteral pentamidine. Prophylaxis against *Pneumocystis* pneumonia should be continued through the period of immunosuppression (6 months to 1 year posttransplantation) and for the duration of any therapy for chronic GVHD.

RSV is a potentially fatal cause of interstitial pneumonitis and typically occurs in the fall and winter months.[180] RSV should be suspected if the patient presents a history of rhinorrhea and if RSV has been frequently recognized in the community or in the hospital. Diagnosis can be made by rapid antigen testing on nasal washings or BAL specimens. Because of the possibility of horizontal transmission, patients with RSV should be isolated. Inhaled ribavirin is used for treatment of RSV-associated pneumonia.[181] Other community-acquired viruses, such as parainfluenza or influenza, also can cause interstitial pneumonitis in the transplant recipient. Their presentation is clinically indistinguishable from RSV, although parainfluenza pneumonitis is not seasonal and is seen year round. Yearly influenza vaccination for HCT recipients and especially their household contacts may be effective in reducing risks of this infection.

Noninfectious Causes of Interstitial Pneumonitis

Idiopathic Interstitial Pneumonitis

Idiopathic interstitial pneumonitis is a diagnosis of exclusion based on typical findings and by ruling out infectious causes. Its timing is somewhat earlier than other causes of interstitial pneumonitis, typically occurring within the first 2 to 7 weeks after HCT.[39,182] Recognized risk factors for idiopathic interstitial pneumonitis include older age at transplant, extensive pretransplant chemotherapy, high-dose cyclophosphamide, TBI (higher total dose and dose rate), blood transfusions, administration of methotrexate, and GVHD.[183–186]

The observation that idiopathic interstitial pneumonitis is as frequent among syngeneic as among allogeneic recipients and has an equally high incidence in T-cell–depleted grafts suggests that immunosuppression is less of a risk factor for idiopathic interstitial pneumonitis than it is for infectious interstitial pneumonitis.[187,188] Clinical observations support a toxic cause for idiopathic interstitial pneumonitis. Radiation-induced lung damage appears to be the major contributor, especially use of high-dose TBI.[189,190] Effective therapy has not been established, although high-dose corticosteroids are often administered. Inflammatory cytokines, including interleukin (IL)-1 and TNF-α, have been implicated in lung injury.[191,192] The TNF-α binding protein etanercept has been reported to improve lung function in patients with idiopathic interstitial pneumonitis and is undergoing evaluation in clinical trials.[193]

Approach to Interstitial Pneumonitis

The presentation of interstitial pneumonitis after hematopoietic cell transplantation (HCT) should be considered an urgent medical situation. Empiric broad-spectrum therapy must be initiated early. The choice of therapy is influenced by the following factors:

1. Timing: Within the first 3 weeks after HCT, interstitial pneumonitis is more likely to be idiopathic (including diffuse alveolar hemorrhage) or fungal than due to cytomegalovirus (CMV) infection. Beyond 6 weeks, idiopathic pneumonitis is unusual, and the cause more likely is infectious. *Pneumocystis jiroveci* pneumonia is rare beyond 1 year after transplantation, except in patients with ongoing chronic graft-versus-host disease. Respiratory syncytial virus (RSV) infections are seasonal (fall and winter), and community outbreaks can be prevalent. Influenza also is seasonal, whereas parainfluenza can occur year round.
2. CMV Serology and Prophylaxis: If a seronegative recipient has received a seronegative graft and noninfective (seronegative or leukocyte-depleted) blood, CMV pneumonia is unusual. Seropositive recipients are at higher risk, although the risk is markedly reduced with ganciclovir prophylaxis. Other prophylactic regimens for CMV, such as acyclovir or intravenous immunoglobulin, still are associated with significant risk for serious CMV infection in the seropositive recipient. Serial negative testing for CMV antigenemia or DNA polymerase chain reaction (PCR) makes CMV pneumonitis less likely.
3. Prolonged Neutropenia: This factor is associated with infectious causes, particularly with fungal pneumonias.
4. Type of Transplant: Diffuse alveolar hemorrhage is seen less frequently in patients undergoing autologous HCT. CMV pneumonia is unusual (2%–3%) in autologous recipients but has a high case fatality rate. All infectious causes are more common after allogeneic hematopoietic cell transplantation. More intensive conditioning regimens (e.g., higher total body irradiation, carmustine) are associated with more frequent pneumonitis.
5. Compliance and Prophylaxis: A thorough assessment of what prophylaxis the patient has actually been receiving (e.g., trimethoprim-sulfamethoxazole, penicillin, CMV prophylaxis, transfusions outside the transplant center) is critical for risk assessment.
6. Chest Radiograph: The pattern and distribution of the infiltrate may narrow the differential diagnosis. Cardiac enlargement or pleural effusions may suggest pulmonary edema. A chest computed tomographic scan is useful, especially if nodularity, pleural involvement, or cavitary lesions (possibly fungal) are suspected.
7. Epidemiology: Identification of the causes of other recent cases can be most helpful with infections that are horizontally transmitted (e.g., RSV) or have common environmental risk factors (e.g., *Aspergillus* infection associated with construction).
8. Bronchoalveolar Lavage: This can be extremely useful to establish a specific diagnosis or to exclude others. CMV rarely causes pneumonia without positive bronchoalveolar lavage (BAL) findings (either direct staining of CMV-associated antigens in BAL cells or DNA PCR). BAL also usually detects RSV, *Pneumocystis jiroveci*, and other respiratory viruses, although not as rapidly, but is required to identify alveolar bleeding. It is less sensitive for diagnosis of fungal pneumonias.
9. Lung Biopsy: This is the gold standard for definitive diagnosis of most possible causes of interstitial pneumonitis, but it often can be avoided by use of the clinical diagnostic measures listed. It may be necessary for definitive diagnosis of fungal pneumonias, pulmonary changes associated with chronic graft-versus-host disease (bronchiolitis obliterans), or idiopathic interstitial pneumonitis.
10. Ventilator Therapy: Progressive respiratory failure after HCT rarely is reversible, especially in adults. Although aggressive diagnostic and therapeutic measures are essential, some centers offer patients and their families the option of foregoing mechanical ventilatory support, if survival is not expected. Preliminary discussion of this possible complication in pretransplant patient counseling can facilitate decision making if respiratory failure does occur.

Diffuse Alveolar Hemorrhage

Alveolar hemorrhage is a clinical syndrome of acute onset of pulmonary infiltrates and hypoxemia with a progressively bloodier BAL on bronchoscopy.[194] Alveolar hemorrhage due to noninfectious causes has been called *diffuse alveolar hemorrhage* but often is difficult to distinguish from infection-associated pulmonary hemorrhage, especially in the early posttransplant period.[195] The reported incidence of diffuse alveolar hemorrhage ranges from 2% to 5% in autologous and 5% to 10% in allogeneic HCT recipients.[194–198] Its pathogenesis is not known but it most likely develops as result of a complex interaction of a variety of factors, including alveolar injury from radiation and chemotherapy, inflammatory damage due to neutrophils and cytokines, and underlying infections. Older age at transplant, use of allogeneic donor source, and GVHD are risk factors for the syndrome.[195,197] The risk is similar with nonmyeloablative and myeloablative conditioning regimens.[196] Onset typically occurs within the first 3 months of transplantation with dyspnea, hypoxia and cough, although late-onset alveolar hemorrhage is not uncommon. Hemoptysis usually is absent, and bronchoscopy with BAL is required to confirm the diagnosis and to exclude infectious etiologies. The syndrome is very serious, and the majority of patients develop severe respiratory failure with mortality rates of more than 70%.[195,198] Hemorrhage occurring in the periengraftment period is associated with a better outcome compared to later-onset hemorrhage. Treatment includes correction of any coagulopathy and aggressive ventilatory support. High-dose corticosteroids have been used for its management, but their efficacy has not been clearly proven.[194,195,198] Small case series have reported successful use of recombinant factor VIIa and aminocaproic acid, but their efficacy requires confirmation in clinical trials.[199–201] Cytokine antagonists (e.g., anti–TNF-α) might have a therapeutic role, but this has not yet been investigated.

LATE NONINFECTIOUS COMPLICATIONS

Improvements in transplantation techniques and supportive care have led to an increasing number of long-term HCT survivors. These survivors remain at risk for late transplant-associated complications, which include organ specific dysfunction, second cancers, infections due to ongoing immunodeficiency, and functional impairments and changes in quality of life (Table 113–5).[202–207] Guidelines for screening and prevention of late effects in HCT survivors have been published.[11] In addition, following general population guidelines for screening and prevention of cancers and chronic diseases and promoting a generally healthy lifestyle are recommended for all HCT survivors.

Organ-Specific Late Effects

A variety of exposures, both before and during transplantation, can lead to organ-specific late toxicity. In general, transplant-related risk

Table 113–5. Selected Late Complications of Hematopoietic Cell Transplantation

Complication	Risk Factors	Monitoring and Prevention
Endocrine		
Hypothyroidism Hypogonadism Growth retardation	TBI/radiation Chronic GVHD Chemotherapy	Periodic assessment of thyroid and gonadal function
Ocular		
Cataracts Keratoconjunctivitis sicca	TBI/radiation Corticosteroids Chronic GVHD	Periodic ophthalmic examination
Oral		
Dental caries Dry mouth	TBI/radiation Chronic GVHD	Periodic dental assessment
Cardiovascular		
Coronary artery disease Cerebrovascular disease	TBI/radiation Chemotherapy	Periodic clinical evaluation Modification of risk factors
Respiratory		
Bronchiolitis obliterans Interstitial pneumonitis	TBI/radiation Chronic GVHD Infections	Periodic clinical evaluation Smoking cessation
Hepatic		
Cirrhosis Iron overload	Hepatitis B or C Transfusions	Periodic hepatic function tests Serum ferritin level
Renal		
Nephropathy	TBI/radiation Chemotherapy Cyclosporine	Periodic serum creatinine and urinalysis Control hypertension
Skeletal		
Osteoporosis Avascular necrosis	TBI/radiation Corticosteroids	Periodic bone densitometry
Second cancers	TBI/radiation Chemotherapy Chronic GVHD	Periodic cancer screening

GVHD, graft-versus-host disease; TBI, total body irradiation.

factors for delayed complications include use of TBI in conditioning, GVHD, and protracted use of corticosteroids or calcineurin inhibitors.[205,208] Although any organ system can be involved, certain organs have a greater predilection for late-onset problems post-HCT. Cataracts develop in more than one third of patients by 5 years posttransplantation and often require surgical therapy.[209] Hypothyroidism can be seen in up to 50% and hypogonadism in up to 90% of HCT survivors.[210–212] The majority of HCT survivors become permanently sterile, although HCT without TBI can spare fertility in nearly one third of men and women.[211,213] Prepubertal children may retain fertility, although secondary sexual development may be delayed. Up to 50% of children undergoing HCT develop growth retardation.[214] Musculoskeletal complications including osteoporosis and avascular necrosis can be particularly debilitating. An increased incidence of cardiovascular events and diabetes has been reported.[206,215] The risk for most organ-specific late complications continues to increase with time, and continued surveillance for these problems is indicated in all HCT survivors. Education of both patients and their primary care providers may be most effective in establishing this surveillance.

Second Cancers

Compared to the general population, HCT survivors have a fourfold to 13-fold higher risk for developing secondary leukemias, lymphoproliferative disorders, and solid tumors.[207,216–229] Secondary leukemias and myelodysplastic syndrome are limited to recipients of autologous HCT, typically have a short latent period, and occur relatively early, with a peak incidence between 2 to 5 years posttransplant. Older age at HCT, exposure to alkylating agents or topoisomerase II inhibitors pretransplant, and use of TBI in conditioning have been associated with increased risk for this complication.[216,228,230–235] Posttransplant lymphoproliferative disorder and secondary lymphomas tend to develop in the early posttransplant period, with a peak incidence in the first 1 to 2 years. Specific risk factors for posttransplant lymphoproliferative disorder include use of HLA-mismatched donor, chronic GVHD, and T-cell depletion, either in vitro or in vivo with ATG.[218,222,236] In contrast to secondary leukemias and posttransplant lymphoproliferative disorder, solid cancers have a longer latency period, and their incidence continues to increase over time post-HCT. Factors that increase the risk for secondary solid tumors are young age at HCT, use of TBI in conditioning, and chronic GVHD.[217,222,223,225,229]

Quality of Life After Transplantation

Despite the early morbidity associated with HCT, the majority of transplant survivors attain high levels of physical and psychological quality of life and return to full-time employment by 3 to 5 years posttransplant.[205,237–244] However, up to 20% of long-term survivors continue to have functional impairments years after HCT. The major risk factors for poor quality of life are older age and advanced disease at transplantation, chronic GVHD, and presence of medical late effects.[238,239,241,245] Although chronic GVHD is a strong predictor of poor quality of life, the patient's overall health and functional status improves with resolution of GVHD and eventually reaches a level comparable to that seen in patients with no history of chronic GVHD.[245,246] Gender-specific differences in quality of life have been observed, with females more likely to report impairments in psychological and sexual domains.[238,247] Cognitive deficits, particularly involving executive function, memory, and motor skills, have been reported in 30% to 60% of HCT survivors.[248–252] The risk of developing these neuropsychological sequelae is increased in patients receiving transplantation at an older age, use of TBI-based conditioning regimens, and cyclosporine.

GRAFT-VERSUS-HOST DISEASE

GVHD is a clinicopathologic syndrome of T-cell–mediated alloreactivity that commonly occurs as a complication of allogeneic HCT and leads to significant morbidity and mortality. It usually is classified as *acute* GVHD (within 3 months of HCT) or *chronic* GVHD (after 3 months of HCT), but considerable overlap can exist between acute and chronic GVHD. There has been increasing emphasis on use of clinical manifestations to distinguish acute and chronic GVHD.[253]

Current understanding of the pathogenesis of GVHD suggests that alloreactive donor T lymphocytes recognize histocompatibility antigens on host cells and initiate secondary inflammatory injury, leading to the clinical symptoms of GVHD.[254,255] The alloreactive response can be initiated or accelerated by conditioning regimen-induced tissue injury with release of proinflammatory cytokines, primarily IL-1 and TNF-α.[256–259] GVHD is more frequent and more severe in recipients of partially matched or histoincompatible transplants, suggesting that major histocompatibility complex encoded molecules are the prime antigenic targets initiating the alloreactive T-cell response.[108,110,260] Minor histocompatibility antigens also play an important role in its pathogenesis, especially in HLA-identical sibling donor grafts.[261] Activated donor-derived T cells produce IL-2 and interferon-γ, expand and differentiate into effector cells, and

recruit mononuclear phagocytes and neutrophils, ultimately leading to host tissue destruction.[254,255,258,262–264] T-cell depletion of the graft reduces the risk of acute and chronic GVHD, albeit at the cost of increasing risks of disease relapse due to blunting of the graft-versus-tumor response.[265,266] Alternative mechanisms possibly involved in the pathogenesis of chronic GVHD include autoreactivity, loss of self-tolerance, and B-cell dysregulation.[254,267,268]

Acute Graft-Versus-Host Disease

Risk Factors and Clinical Features

Up to 50% of patients receiving HLA-identical sibling donor HCT and up to 90% of patients receiving unrelated donor HCT develop acute GVHD.[108,110,260,269] Donor–recipient HLA disparity is the most important risk factor for acute GVHD.[108,270] Additional risk factors include increasing recipient and donor age,[260,269,271,272] use of alloimmunized donors such as parous women,[271,272] and HCT from unrelated instead of sibling donors.[108,271] Use of peripheral blood stem cells instead of bone marrow as the graft source may be a particular risk for chronic GHVD.[273,274] Skin, liver, and gastrointestinal tract are the most common sites of GVHD. Acute GVHD of the skin is characterized by a maculopapular rash that, when severe, can lead to bullae or even resemble toxic epidermal necrolysis. Hepatic involvement manifests as cholestatic hepatitis with marked elevation of serum bilirubin and alkaline phosphatase but usually only mild transaminase alterations. Hepatocellular function (e.g., protein synthesis and coagulation factor production) is not impaired. In the intestine, upper gastrointestinal tract GVHD can produce nausea, vomiting, and anorexia, whereas small bowel and colon GVHD produces large-volume secretory diarrhea. The diagnosis is established by the clinical symptomatology but frequently requires histologic confirmation to distinguish it from other frequent toxicities in the early posttransplantation period (e.g., hypersensitivity drug rash, drug-induced cholestasis, infectious enteritis). The histologic hallmark of acute GVHD is apoptosis of the proliferative and regenerative cell layer of the epidermis or intestinal or biliary epithelium. This manifests as basal epidermal cell vacuolization with dyskeratosis, exocytosis, and, when more advanced, dermal–epidermal clefting with bullae formation. Similarly, the basal cells of the intestinal glands or the colonic crypts show single epithelial cell degeneration, satellite cell necrosis, and sometime crypt abscesses progressing to mucosal sloughing. In hepatic portal tracts, single cells of the bile ducts are affected first, with eventual disruption or disappearance of the bile ducts.

Acute GVHD is graded according to organs involved (skin, liver, gastrointestinal tract) and the extent of each organ involvement.[275,276] Mild to moderate (grade I or II) GVHD is characterized by limited organ involvement and carries an excellent prognosis. Severe (grade III or IV) GVHD has extensive multiorgan involvement with significant morbidity and poor survival, commonly progresses to chronic GVHD, and is associated with an increased risk of secondary opportunistic infections.[277,278]

Prophylaxis of Graft-Versus-Host Disease

The most effective techniques for GVHD prevention have involved ex vivo depletion of donor T lymphocytes, most often coupling immunologic recognition (monoclonal anti–T-cell antibodies) with depletion techniques (immunomagnetic beads, complement cytotoxicity, or toxin immunoconjugates). Although vigorous T-cell depletion prevents acute GVHD, it also increases the risk of graft failure and neoplastic relapse after transplantation.[265]

Pharmacologic immunosuppression administered in the first several months after transplantation can prevent or blunt the initiating T-cell recognition and proliferative response that triggers GVHD and can allow development of immune system tolerance and complete lymphohematopoietic chimerism. Methotrexate, corticosteroids, ATG, cyclosporine, tacrolimus, MMF, and sirolimus have been used for prophylaxis of GVHD and have successfully reduced both the frequency and severity of clinical GVHD.[269,277,279–286] Despite the potential role of inflammatory cytokines in the initiation and amplification of GVHD, clinical blockade of IL-1, IL-2, or TNF-α has not been effective in GVHD prophylaxis.[287–289]

Treatment of Acute Graft-Versus-Host Disease

Therapy for acute GVHD requires immunosuppression to blunt T-cell–induced tissue injury and appropriate supportive care. Therapy should be intensified to achieve a complete response to GVHD therapy because effective treatment of acute GVHD can both protect against chronic GVHD and improve survival. Corticosteroids are the mainstay of initial therapy for acute GVHD.[277,290,291] GVHD involving limited areas of the skin can be treated with topical corticosteroids alone. Oral beclomethasone can be used to treat early-stage GVHD of the gastrointestinal tract.[292] Regimens using a tapering schedule of corticosteroids starting with methylprednisolone 1 to 2 mg/kg/day are used for more advanced GVHD with systemic or multiorgan involvement. Approximately 30% to 50% of patients will achieve a response to therapy with corticosteroids.[293–295] Patients with lesser severity and single-organ involvement tend to be more responsive to therapy, although some reports suggest that GVHD following unrelated donor HCT is more resistant to therapy.[277,290,296] Alternative treatment regimens include cyclosporine or ATG alone or in combination with corticosteroids; however, no regimens have shown a consistent increase in response rates or improvement in survival compared to corticosteroids alone.[293,297,298] Newer immunosuppressive agents under clinical investigation as initial therapy in addition to corticosteroids include MMF, pentostatin, the TNF-α receptor blocker etanercept, and the IL-2 receptor inhibitor denileukin diftitox.[280,299]

Prognosis is serious for patients with steroid-resistant disease, which is GVHD that does not respond to initial therapy with corticosteroids. From 10% to 40% of patients will respond to salvage therapy with ATG or other drugs such as sirolimus, tacrolimus, MMF, pentostatin, or cyclosporine, either as a single agent or in combination.[300–303] Monoclonal antibodies and immunotoxins directed against T cells or inflammatory cytokines have been investigated, although their effectiveness has not been demonstrated outside of small case series. Specific agents with reported activity in steroid-refractory acute GVHD include pentostatin,[304] etanercept and infliximab (TNF-α receptor blockers),[305–307] daclizumab and denileukin diftitox (IL-2 receptor inhibitors),[308–310] and visilizumab (anti-CD3 antibody).[311] Extracorporeal photochemotherapy has been reported to have some efficacy in cutaneous and hepatic steroid-refractory acute GVHD.[312]

In addition to effective immunosuppression, successful management of acute GVHD involves attention to supportive care. Infections are a leading cause of death in patients with GVHD. Infection surveillance and prophylaxis directed against fungi, encapsulated bacteria, CMV, and PCP are essential components of GVHD therapy. Hyperalimentation is frequently needed for patients with advanced GVHD, especially in those with involvement of the gastrointestinal tract.

Chronic Graft-Versus-Host Disease

Risk Factors and Clinical Features

Chronic GVHD is a complex syndrome in recipients of allogeneic HCT. It typically occurs between 3 to 7 months posttransplant, but it can begin after 2 years. Its incidence ranges from 30% to 50% in HLA-matched sibling donor transplants to 50% to 70% in HLA-matched unrelated donor transplants. It is the leading cause of nonrelapse late mortality in allogeneic HCT survivors.[204,313–317] Chronic GVHD occurs most frequently in patients with preceding acute GVHD, but it can manifest de novo without any preceding acute

Table 113–6. Clinical Manifestations of Chronic Graft-Versus-Host Disease

Organ System	Clinical Manifestations
Cutaneous	Poikiloderma, lichen planus, dermal sclerosis, morphea-like features, hypopigmentation or hyperpigmentation, ichthyosis, nail dystrophy, onycholysis
Ocular	Keratoconjunctivitis sicca, conjunctivitis, corneal ulcerations
Oral	Lichen planus, hyperkeratotic plaques, xerostomia, mucosal atrophy, ulcers, restriction of mouth opening from sclerosis
Pulmonary	Bronchiolitis obliterans, bronchiolitis obliterans-organizing pneumonia
Gastrointestinal	Esophageal web and strictures, malabsorption syndrome, exocrine pancreatic insufficiency
Hepatic	Cholestasis
Genitourinary	Vaginal stenosis or scarring, lichen planus
Musculoskeletal	Fasciitis, joint contractures from sclerosis, myositis or polymyositis, arthritis
Hematopoietic	Thrombocytopenia, eosinophilia, lymphopenia, hemolytic anemia, hypogammaglobulinemia

GVHD. The distinction between acute and chronic GVHD has been based on the time of onset of GVHD (within or after 100 days of transplantation). More recent guidelines for the diagnosis of chronic GVHD emphasize the presence of typical clinical signs and symptoms instead of time of onset. Acute GVHD can occur later in patients receiving reduced-intensity preparative regimens or after donor lymphocyte infusions).[253] Acute and chronic GVHD can coexist simultaneously.

Acute GVHD is the most important risk factor for development of subsequent chronic GVHD.[316,318] Use of mismatched or unrelated donors and transplantation using peripheral blood derived hematopoietic stem cells instead of bone marrow increases risk.[273,317,319,320] Other reported risk factors for chronic GVHD include older recipient age, use of female donor, CMV seropositivity, high graft $CD34^+$ cell count, treatment with donor lymphocyte infusions, and underlying diagnosis of chronic myeloid leukemia or aplastic anemia.[314–318] Similar to acute GVHD, in vitro or in vivo T-cell depletion of the graft can reduce the incidence of chronic GVHD.[281,321–323] Lower rates of chronic GVHD have been observed following umbilical cord blood grafts.[91,118]

Chronic GVHD can affect any organ system; however, certain pathognomonic clinical signs and symptoms must be present to establish its diagnosis (Table 113–6).[253] Other clinical manifestations, although not diagnostic of chronic GVHD, can be characteristic, but they may resemble acute GVHD as well. Additional investigations, including biopsies, might be needed to verify the diagnosis and to rule out other etiologies, such as infections, drug effects, and malignancies.[324] The skin, mouth, eyes, and liver are the most commonly involved sites of chronic GHVD. Cutaneous manifestations resemble autoimmune disease and can include poikiloderma, lichen planus-like eruptions, or scleroderma (sclerosis). Inflammatory dermatitis can progress to severe dermal and periarticular fibrosis with loss of skin appendages (hair and sweat glands) as well as significant skin tightness, fasciitis, and loss of joint flexibility. Additional manifestations include dry eyes and dry mouth, which can resemble Sjögren syndrome clinically and histologically; enteritis with anorexia, early satiety, malabsorption, weight loss, and failure to thrive; and cholestatic jaundice. Pulmonary involvement in the form of bronchiolitis obliterans is an uncommon manifestation but can be particularly debilitating. The profound immune dysfunction associated with chronic GVHD due to hypogammaglobulinemia, impaired cellular immunity, and functional asplenia, greatly increases the risk of secondary infections from bacteria, viruses, and fungi. After onset of chronic GVHD, 25% to 40% of patients die within 2 years, often of secondary infections.[313,314,316]

Chronic GVHD can be classified as mild, moderate, or severe, depending on the number of organs involved and the degree of individual organ involvement.[253] In general, factors associated with an adverse prognosis include thrombocytopenia, progressive onset from acute GVHD, poor performance status, lack of response to initial therapy, and extensive skin or lung involvement.[313,314,325]

Treatment of Chronic Graft-Versus-Host Disease

Although acute GVHD is one of the strongest predictors for chronic GVHD, strategies to limit acute GVHD, such as prolonging or intensifying initial immunosuppression, have not been consistently effective in preventing subsequent chronic GVHD.[326,327] Experience with T-cell depletion, both mechanical and pharmacologic, shows decreased rates of both acute and chronic GVHD but increased risks of relapse due to blunting of the graft-versus-tumor effect; thus, T-cell depletion has not improved survival.[265]

As with acute GVHD, the specific immunosuppressive therapy for chronic GVHD most often is corticosteroids, usually in combination with cyclosporine.[328,329] The ongoing and long-lasting nature of the syndrome demands use of reduced doses and, if possible, alternate-day steroid therapy to minimize chronic complications of prolonged corticosteroid therapy. Typical corticosteroid regimens start with daily prednisone 1 mg/kg/day. In patients who respond, the dosage is tapered down to 0.5 to 1 mg/kg every other day and this dosage continued for 6 to 9 months beyond any active GVHD symptoms, followed by a slow withdrawal of immunosuppression. Longer therapy may be required for some patients, and early withdrawal of therapy frequently has been accompanied by flares of chronic GVHD. Salvage therapies, including high-dose corticosteroids, sirolimus, tacrolimus, MMF, rapamycin, thalidomide, azathioprine, and hydroxychloroquine, have been attempted, with limited response rates.[315]

Newer approaches being investigated as potential therapies for chronic GVHD include modulation of T-cell function, B-cell depletion, induction of immune tolerance, and cytokine blockade.[326] Small uncontrolled studies have reported the use of pentostatin, alemtuzumab, and ATG to inhibit T-cell function and rituximab to eliminate B cells, with response rates of 30% to 50%.[321,323,330,331] T-cell immunomodulation using extracorporeal photopheresis has been shown to have some activity, especially in sclerotic cutaneous chronic GVHD.[332,333] Preliminary studies using daclizumab, etanercept, and infliximab for blockade of the cytokine-mediated inflammatory response have shown short-term responses.[305,334]

Treatment of chronic GVHD, even more than acute GVHD, demands particular attention to prophylaxis and aggressive therapy for secondary opportunistic infections. Consequently, ongoing antibacterial, antifungal, and antiviral prophylaxis should be continued. Intravenous immunoglobulin support should be considered, but only for patients with recurring infections and persistent hypogammaglobulinemia. Most successful strategies for treating chronic GVHD incorporate long-term reduced-dose immunosuppressive therapy, aggressive antimicrobial prophylaxis, and nutritional support.

FUTURE DIRECTIONS

Complications of HCT are one of the major barriers to the wider application of transplantation for a variety of diseases. The impact of newer transplantation modalities, including the use of nonmyeloablative or reduced-intensity conditioning regimens, alternative donor transplantation with umbilical cord blood, and incorporation of immune-based therapies within transplantation regimens, on early and late complications are areas of vigorous current investigation.

Better tools for predicting the risk of post-HCT complications and nonrelapse mortality are needed.[335,336] Genomic and proteomic approaches for monitoring and predicting HCT complications are being investigated.[337,338] Although they are some years from use in clinical practice, these approaches potentially could have many applications in transplantation, including prediction of risk for complications and GVHD, refining donor selection, and utilization of pharmacogenomic data to individualize conditioning regimens and immunosuppression, all to improve the safety and effectiveness of HCT.

CHAPTER 114

MEGAKARYOCYTE AND PLATELET STRUCTURE

Joseph E. Italiano, Jr. and John H. Hartwig

Platelets are small anucleate fragments that are formed from the cytoplasm of megakaryocytes and have a characteristic discoid shape. To assemble and release platelets, megakaryocytes become polyploid by endomitosis and follow a maturation program that results in the conversion of the bulk of their cytoplasm into multiple long processes called *proplatelets*. To produce its quota of 1000 to 2000 platelets, a megakaryocyte may protrude as many as 10 to 20 proplatelets, each of which begins as a blunt protrusion that over time thins and branches repeatedly. Platelets form selectively at the ends of proplatelets. As platelets develop, their content of granules and organelles is delivered to them in a stream of individual particles moving from the megakaryocyte cell body to the nascent platelet buds at the proplatelet tips. Once the nascent platelet is filled with its components and a single microtubule (≈100 μm in length) is rolled into a peripheral coil, it releases into the circulation. Platelet formation can be arbitrarily divided into two phases. The first phase takes days to complete and requires megakaryocyte-specific growth factors. Massive nuclear proliferation to 16 to 32 × N and enlargement of the megakaryocyte cytoplasm occur as the platelet is filled with cytoskeletal proteins, platelet-specific granules, and sufficient membrane to complete the platelet assembly process. The second phase is relatively rapid and can be completed in hours. During this phase, proplatelets are extended and mature discoid platelets are released.

MEGAKARYOCYTE DEVELOPMENT

Endomitosis

Hematopoietic stem cells, which are endowed with the genetic capacity to differentiate into multiple lineages, are induced down the pathway to become megakaryocytes by their exposure to certain growth factors.[1] Megakaryocytes become polyploid (i.e., 4N, 16N, 32N, 64N) through repeated cycles of DNA replication without cell division.[2–5] Normally ploidy ranges from four to 64 times the haploid DNA complement, but the majority of cells fall within three ploidy classes (8N, 16N, and 32N), with 16N being dominant.[6,7] Ploidy number appears to be a predetermined event, possibly signifying genetic diversity among megakaryocyte populations. Megakaryocyte polyploidization results in a functional gene amplification whose likely function is an increase in protein synthesis.[8] This process, called *endomitosis*, is a shortened mitosis caused by a block in anaphase.[9,10] Megakaryocytes proceed from prophase to anaphase A, but they do not enter anaphase B or telophase or undergo cytokinesis. During polyploidization of megakaryocytes, the nuclear envelope breaks down, and an abnormal spherical mitotic spindle forms. The spindle has attached chromosomes that align from a position equidistant from the spindle poles. Sister chromatids segregate and move toward their respective poles (anaphase A). However, the spindle poles fail to move apart and do not undergo the microtubule-driven separation typically observed during anaphase B. Individual chromatids are not moved to the poles, and subsequently a single nuclear envelope encapsulates the entire set of sister chromatids.[9,10] In most cell types, checkpoints and feedback controls ensure that DNA replication and cell division are tightly coupled. Megakaryocytes appear to be an exception to this rule, indicating they have managed to deregulate this process. Proposed mechanisms for regulating endomitosis include a reduction in mitosis-promoting factor[11,12] or decreased expression of cyclin B.[12–15] Cyclins appear to play a critical role in directing endomitosis. Cyclin D3 is overexpressed in the G_1 phase of maturing megakaryocytes,[16] but a triple knockout of cyclins D1, D2, and D3 in mice does not appear to affect megakaryocyte development.[17] Cyclin E-deficient mice exhibit a profound defect in megakaryocyte development.[18] The molecular programming involved in endomitosis is characterized by the mislocalization or absence of at least two critical regulators of mitosis: the chromosomal passenger proteins Aurora-B/AIM-1 and survivin. AIM-1, a serine/threonine kinase in the Aurora family that is implicated in mitosis, is downregulated as megakaryocyte polyploidization occurs, suggesting its loss may lead to the abortive mitosis and polyploidization.[19,20] One explanation for endomitosis could be inhibition of microtubule-based forces in anaphase B. Spindle pole separation during anaphase B is believed to be powered by the sliding of antiparallel interdigitating microtubules past each other[21] by the mitotic kinesin-like protein 1 that localizes at regions of overlapping microtubules during anaphase B and has been shown to slide microtubules past one another in vitro.[22] Therefore, lack of spindle pole separation during endomitosis may result from failure of megakaryocytes to undergo normal spindle orientation and/or the absence of signals that localize or activate a kinesin motor molecule that provides force for sliding.

Cytoplasmic Maturation

Megakaryocytes, the largest of the hematopoietic cells, undergo a pronounced cytoplasmic maturation to attain their large volumes (15,000 fL). Cytoplasmic maturation begins during endomitosis and increases considerably after all DNA amplification has ended (Fig. 114–1). Megakaryocytes enlarge dramatically as they mature, reaching sizes of 100 to 150 μm in diameter in culture and in bone marrow. During this process, the megakaryocytic cytoplasm rapidly fills with platelet-specific proteins, organelles, and membrane systems that ultimately are subdivided and packaged into platelets (Fig. 114–2). Their cytoplasmic space expands and, except for the most cortical regions, becomes densely filled with internal membranes that subsequently serve as the repository for the plasma membrane to be regurgitated for coating proplatelets as they extend.[23] This internal membrane system is one of the most striking features of a mature megakaryocyte and has been referred to as the demarcation membrane system (DMS). The DMS, first described by Yamada[24] in 1957, consists of an extensive, tortuous, branching network of membrane channels composed of flattened cisternae and tubules. Initially, the DMS was proposed to play an essential role in platelet formation by defining preformed "platelet territories" or "platelet fields" within the megakaryocyte cytoplasm.[25,26] Release of individual platelets was postulated to occur by massive fragmentation of the megakaryocyte cytoplasm along DMS fracture lines between these fields. However, studies demonstrating that platelets are primarily assembled and released from proplatelet ends (see Platelet formation section) are inconsistent with this notion and indicate instead that the DMS functions predominantly as a membrane reserve for proplatelet formation.[23,27] Direct visualization of mature DMS containing phosphatidylinositol 4,5-bisphosphate suggests that it is the source of proplatelet membranes.[28] Maturing megakaryocytes, like other gran-

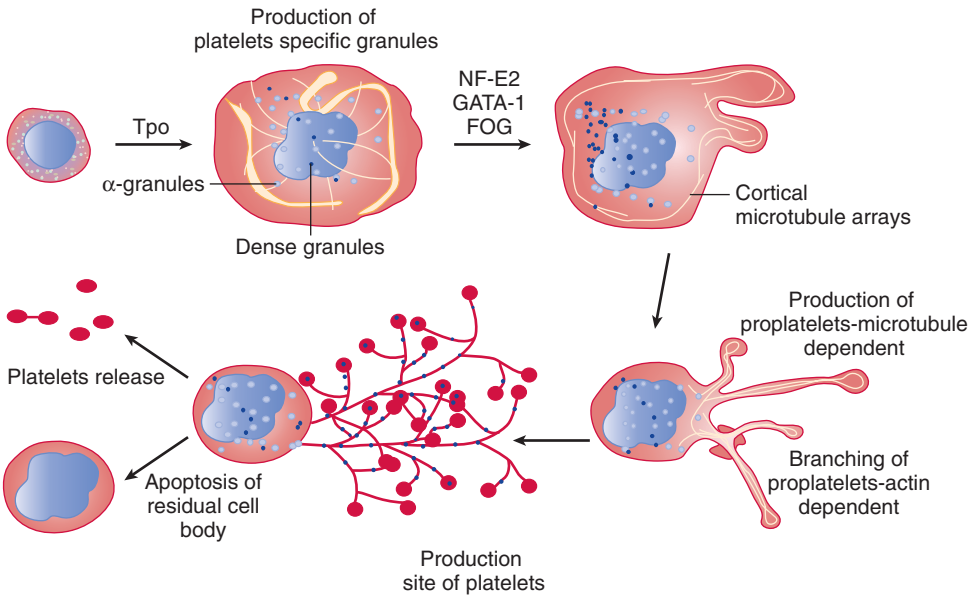

Figure 114–1 Summary of the major events that lead to platelet formation and release from megakaryocytes. Hematopoietic stem cells are converted into megakaryocytes by exposure to the specific growth factor thrombopoietin (TPO). TPO initiates a maturation program that amplifies the megakaryocyte DNA and leads to synthesis of platelet-specific proteins. In particular, cytoskeletal elements, membrane systems, and receptor proteins are made in bulk, and the megakaryocyte becomes filled with platelet-specific granules. Platelet production begins when microtubules aggregate in the cell cortex, and one pole of the megakaryocyte spontaneously elaborates pseudopodia. These begin as large blunt pseudopodia, which subsequently thin and branch into proplatelets. The branching reaction is dependent on a localized assembly of actin and is inhibited by drugs that disrupt actin filaments. Platelets are assembled primarily at the ends of the proplatelets. Intracellular organelles are delivered to the platelet buds along microtubule tracks in the shafts. Platelets are released from the ends of proplatelets.

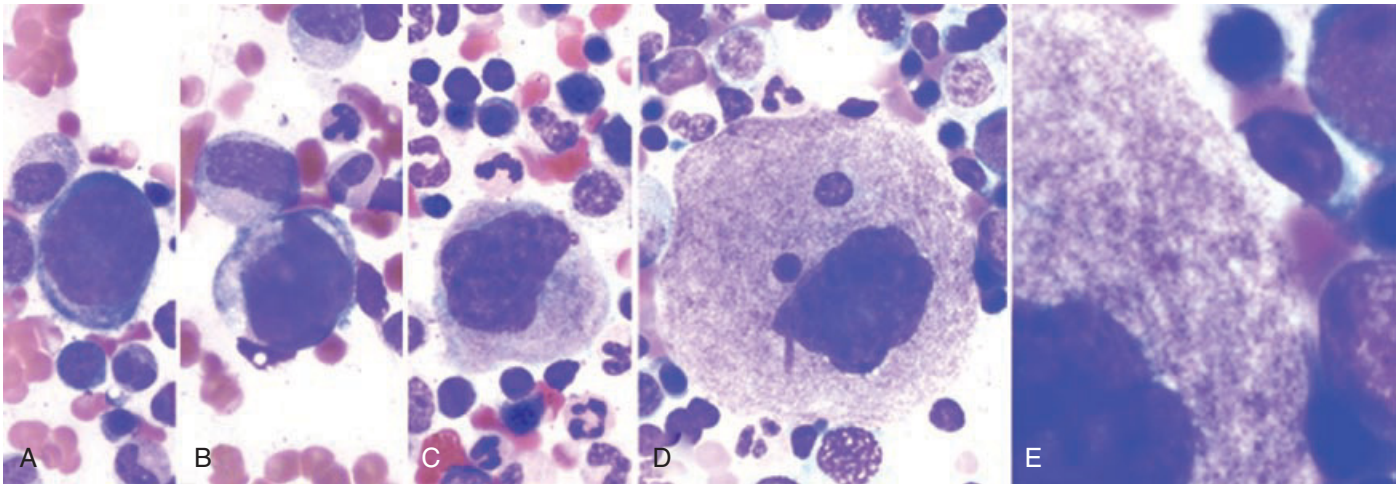

Figure 114–2 Platelet production in the megakaryocyte: **A**, Immature polyploid megakaryoblast with little differentiation. **B**, Megakaryocyte with early Golgi zone. **C**, Early platelet production in cytoplasm. **D**, Late-stage megakaryocyte with abundant internal membranes, organelles, and platelet-specific proteins. **E**, Early formation of demarcation membranes.

ulated cells, contain an abundance of ribosomes and rough endoplasmic reticulum, where protein synthesis occurs. During this phase of megakaryocyte development, the cytoplasm fills with cytoskeletal proteins, platelet-specific receptors and secretory granules, and normal cellular organelles such as mitochondria and lysosomes.

One of the hallmark features of the mature megakaryocyte is its abundance of platelet-specific secretory granules. The two specific granules destined for platelets are α granules and dense granules. α-Granules are the more abundant and larger of the two (200–500 nm in diameter). They contain proteins that enhance the adhesion of platelets, promote cell–cell interactions, regulate angiogenesis, and stimulate vascular repair. α Granules store matrix proteins and contain glycoprotein receptors in their membranes (see Fig. 114–5, *A*). The bulk of cellular P-selectin and a portion of $\alpha_{IIb}\beta_3$ and the glycoprotein Ib/IX/V complex (GPIb-IX-V; a receptor for von Willebrand factor [vWF]) are expressed in the membranes of α granules. Adhesion molecules within the granules include vWF, fibrinogen, fibronectin, vitronectin, and thrombospondin. α-Granule proteins can derive from different origins. Some proteins, such as β-thromboglobulin and vWF, are synthesized by megakaryocytes.[29] However, fibrinogen, also a major component of α granules, is not synthesized by megakaryocytes and is taken up from plasma by an endocytic mechanism requiring fibrinogen binding by $\alpha_{IIb}\beta_3$.[30–32] Although little is known about the intracellular trafficking of proteins in megakaryocytes, experiments using cryosectioning and immunoelectron microscopy suggest that multivesicular bodies are an essential intermediate stage in the formation of platelet α granules.[33] During megakaryocyte development, large (≈0.5 μm) multivesicular bodies

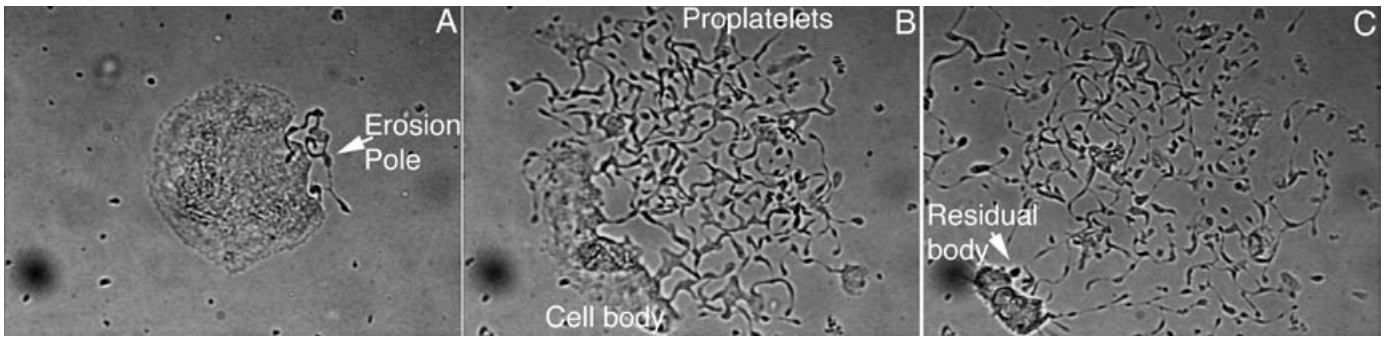

Figure 114–3 Formation of proplatelets by a mouse megakaryocyte. Time-lapse sequence of a maturing megakaryocyte showing the events that lead to elaboration of proplatelets in vitro. **A**, Platelet production begins when the megakaryocyte cytoplasm starts to erode at one pole (arrow). **B**, The bulk of the megakaryocyte cytoplasm has been converted into multiple proplatelet processes that continue to lengthen and form swellings along their length. These processes are highly dynamic and undergo bending and branching. **C**, Once the bulk of the megakaryocyte cytoplasm has been converted into proplatelets, the entire process ends in a rapid retraction that separates the released proplatelets from the residual cell body.

undergo a gradual transition from granules containing 30- to 70-nm internal vesicles to granules containing secretion concentrates. The second and smaller type of platelet granule is the dense granule. Platelets contain a small number of dense granules, which are approximately 150 nm in diameter. Dense granules have electron opaque cores and function primarily to recruit additional platelets to sites of vascular injury. Dense granules contain the soluble activating agents serotonin and ADP as well as divalent cations. When the megakaryocyte reaches a certain point of maturation, proplatelet production begins, and dense granules are sent into the proplatelets destined for platelets.

REGULATION OF MEGAKARYOCYTE DEVELOPMENT

The development of megakaryocytes and the process of platelet biogenesis occur within a complex bone marrow environment where both cytokines and adhesive interactions play an essential role. Megakaryocytes are imprisoned within the subendothelial layer of the bone marrow sinuses where development and platelet biogenesis are regulated at multiple levels by several cytokines. Thrombopoietin (Tpo), which is synthesized in bone marrow and liver, is the principal regulator of thrombopoiesis.[34] Tpo also plays a central role in hematopoietic stem cell survival and proliferation. Circulating levels of Tpo induce proliferation and maturation of megakaryocyte progenitors by binding to the c-Mpl receptor and signaling induction. Tpo regulates all stages of megakaryocyte development, from the hematopoietic stem cell stage through cytoplasmic maturation.[35] Tpo increases platelet production by increasing both the number and size of individual megakaryocytes. c-Mpl activation is regulated by a complex array of signaling molecules that turn on specific transcription factors (see Transcriptional Regulation of Platelet Formation section) to drive megakaryocyte proliferation and maturation. Although Tpo appears to function as the main regulator of megakaryocyte development, it is not exclusive in this action. The cytokine stem cell factor, granulocyte-macrophage colony-stimulating factor, FLT ligand, interleukin (IL)-3, IL-6, IL-11, and erythropoietin also can regulate megakaryocyte development but appear to function mainly in concert with Tpo.[36–40] Mice that lack Tpo or its receptor c-Mpl have approximately 15% of the normal platelet count.[41,42] The discovery of Tpo in 1994 and the development of primary megakaryocyte or mouse embryonic stem cell cultures that can be induced to faithfully reconstitute platelet formation have provided systems for studying megakaryocytes in the act of making platelets in vitro.[43–45] Megakaryocytes isolated from mouse fetal liver and incubated with Tpo for 4 to 5 days mature into huge polyploid cells that are capable of generating and releasing large numbers of platelets.[46] In similar fashion, mouse embryonic stem cells can be induced to mature into large polyploid megakaryocytes in the presence of stromal cells and Tpo, IL-6, and IL-11.[44] This process requires 10 to 12 days, during which the conversion of embryonic stem cells into hematopoietic stem cells very likely occurs in the first half of the period and the maturation of hematopoietic stem cells into proplatelet-producing megakaryocytes in the second half. Human embryonic stem cells can be coaxed to differentiate into mature megakaryocytes, although the process takes several more days in culture.[47]

PLATELET FORMATION

Proplatelets and the Cytoskeletal Mechanics of Platelet Formation

The discovery of Tpo and the development of megakaryocyte cultures that reconstitute platelet formation in vitro have allowed visualization of megakaryocytes in the act of forming platelets. The actual mechanical process of platelet production begins when mature megakaryocytes begin to elaborate proplatelets (Figs. 114–1 and 114–3).[48–52] This process is distinguished by the erosion of one pole of the megakaryocyte cytoplasm (Fig. 114–3).[27] Multiple thick pseudopodia are extended and subsequently elongate to yield thin tubules. As these slender tubules grow, they branch repeatedly and develop periodic densities along their length that impart a beaded appearance. The first insight into the cytoskeletal mechanics of platelet formation dates from the work of Tablin et al.,[53] who showed that proplatelet formation is dependent on microtubules, that is, proplatelet elaboration is inhibited by microtubule poisons. Microtubule poisons are effective because the extension of proplatelets from the megakaryocyte is mediated by the assembly of microtubules and their reorganization into cortical bundles. Cortical bundles align in the shafts of proplatelets, and proplatelet elongation is driven by sliding movements between microtubules composing these bundles. The microtubule bundles form loops at the end of each proplatelet, and ultimately a single microtubule is rolled into a coil at the proplatelet end to define the platelet territory. Cytoplasmic tubulin in solution is an $\alpha\beta$ dimer that reversibly polymerizes into microtubules, which are long hollow cylinders with an outer diameter of 25 nm. Several studies reveal an essential role in platelet biogenesis for β_1 tubulin, a divergent and lineage-specific β tubulin, which is a major component of the megakaryocyte proplatelet cytoskeleton and marginal microtubule coil of the platelet.[54] β_1 Tubulin is expressed exclusively in platelets and megakaryocytes during late stages of megakaryocyte development and is essential for the production of normal platelet numbers as well as the discoid shape of the platelet as judged by a number of criteria. First, mRNA subtraction between wild type and NF-E2-deficient megakaryocytes demonstrates that β_1 tubulin is a downstream effector of the megakaryocyte transcription factor NF-E2 and is absent from NF-E2-deficient megakaryocytes.[46] Second, genetic elimination of the β_1-tubulin gene in mice results in

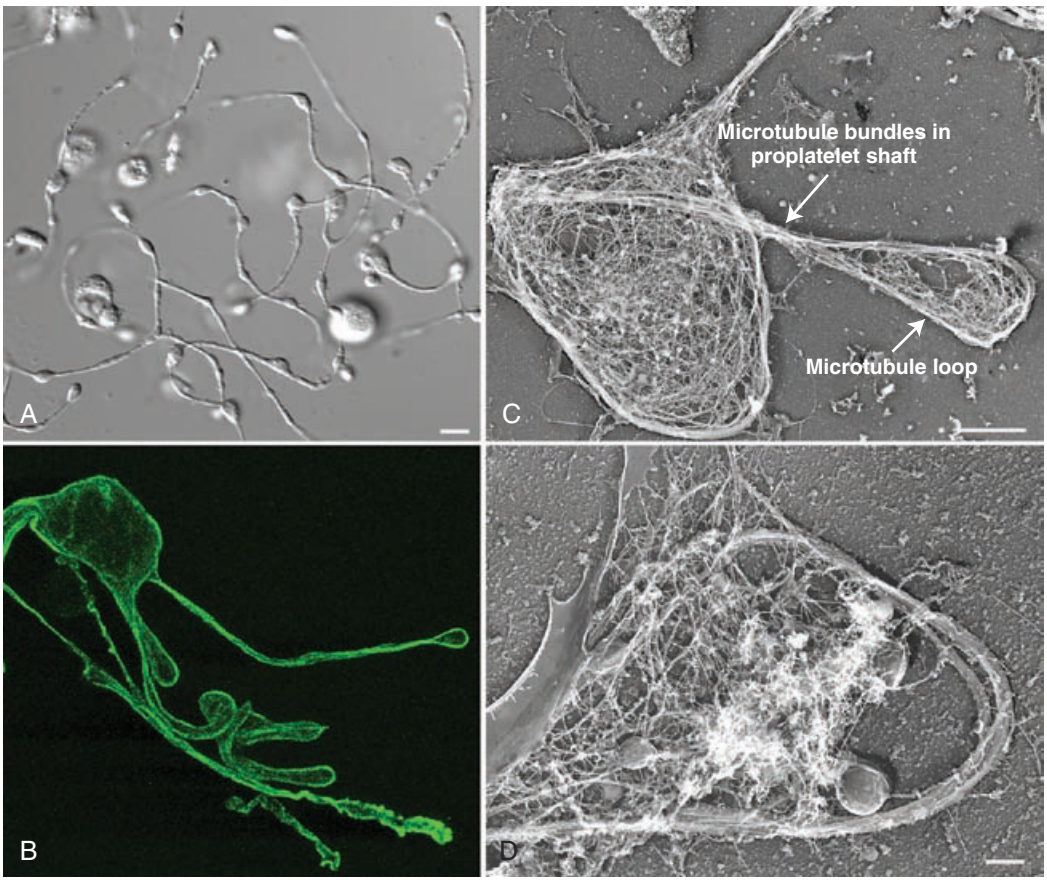

Figure 114–4 Structure of proplatelets. **A**, Differential interference contrast image of proplatelets elaborated by mouse megakaryocytes in culture. (Bar = 5 μm.) **B**, Staining of proplatelets with Alexa 488 antitubulin IgG reveals that the microtubules line the shaft of the proplatelet and form loops at the proplatelet tips. thrombocytopenia.[55] Third, megakaryocytes isolated from β_1-tubulin knockout mice fail to form proplatelets *in vitro* and instead extend only a small number of blunt protrusions.

The first event that signals proplatelet production is the consolidation of microtubules into large bundles at the megakaryocyte cortex that subsequently are reorganized into parallel bundles in the shafts of the proplatelets (Fig. 114–4). Microtubule bundles are thick near the body of the megakaryocyte as they enter the proplatelet shaft but thin progressively throughout the shaft, such that only five to 10 microtubules remain at the end of the proplatelet. Importantly, the microtubule bundles that run down the proplatelet shaft make characteristic U turns in the tips and reenter the shaft, forming teardrop-shaped structures (Fig. 114–4). This observation demonstrates a bipolar orientation of bundles in the vicinity of the proplatelet tip, a geometry required to explain the observation of bidirectional granule and organelle traffic in proplatelets.[56] The looped arrangement of microtubules in proplatelet tips also places constraints on the elongation mechanism used to grow proplatelets and indicates that assembly of microtubules at the end of the process does not elongate proplatelets because of an insufficient number of free microtubule ends to nucleate this reaction.

Direct visualization of microtubule dynamics in living megakaryocytes using green fluorescent protein (GFP) technology has provided insights into how microtubules orient to power proplatelet elongation (Fig. 114–5, *A* and *B*).[57] End-binding protein 3 (EB3), a microtubule plus end-binding protein associated only with growing microtubules, fused to GFP was retrovirally expressed in murine megakaryocytes and used as a marker to locate microtubule plus ends and follow plus end dynamics. Immature megakaryocytes without proplatelets use a centrosomal-coupled microtubule nucleation/assembly reaction, which appears as a prominent starburst pattern when visualized with EB3-GFP. Microtubules assemble only from the centrosome and grow outward into the cell cortex, where they turn and run in parallel with the cell edges. However, just before proplatelet production begins, centrosomal assembly ends and microtubules release and consolidate into the cortex as bundles. Fluorescence time-lapse microscopy of living, proplatelet-producing megakaryocytes expressing EB3-GFP reveals that as proplatelets elongate, microtubules assemble continuously throughout the entire proplatelet. EB3-GFP studies also reveal that microtubules polymerize in both directions in proplatelets, that is, toward both the tips and cell body, demonstrating that microtubules composing the bundles have a mixed polarity.

Even though microtubules are continuously assembling at their plus ends in proplatelets, polymerization per se does not provide the force for proplatelet elongation. First, the rates of microtubule polymerization (average 10.2 μm/min) are approximately 10-fold faster than the proplatelet elongation rate. Second, proplatelets continue to elongate even when microtubule polymerization is blocked by drugs that inhibit net assembly, suggesting an alternative mechanism for proplatelet elongation. Third, proplatelets possess an inherent microtubule sliding mechanism. Dynein, a minus end microtubule molecular motor protein, localizes along the microtubules of the proplatelet and appears to directly contribute to microtubule sliding, as inhibition of dynein through disassembly of the dynactin complex prevents proplatelet formation. Microtubule sliding can be reactivated in detergent-permeabilized proplatelets. Adenosine triphosphate, known to support the enzymatic activity of microtubule-based molecular motors, activates elongation in permeabilized proplatelets that contain dynein and its regulatory complex dynactin. Thus, dynein-facilitated

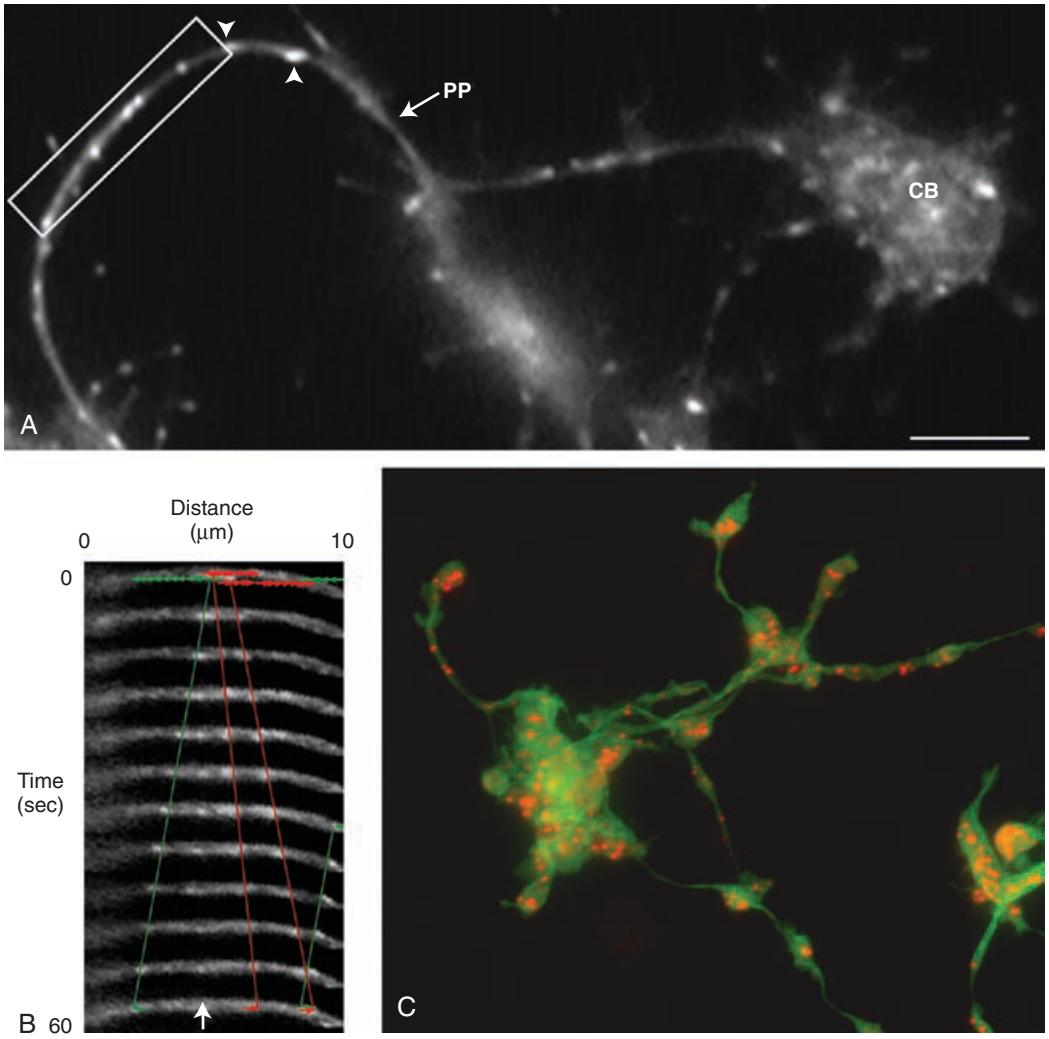

Figure 114–5 Microtubule dynamics during proplatelet formation. **A**, Visualization of plus end microtubule assembly in living megakaryocytes expressing end-binding protein 3 (EB3)-green fluorescent protein (GFP). First frame from the time-lapse sequence (shown in B) of a living megakaryocyte that was retrovirally directed to express EB3-GFP. The cell body (CB) is at the right of the micrograph and proplatelets (PP) extend to the left. EB3-GFP labels growing microtubule plus ends in a characteristic "comet" staining pattern that has a bright front and a dim tail. **B**, The kymograph shows movement over time. Images are every 5 seconds. EB3-GFP comets undergo bidirectional movements in proplatelets, demonstrating that microtubules are organized as bipolar arrays. Some EB3-GFP comets move toward the tip and are highlighted in green; others that move toward the cell body are highlighted in red. **C**, Distribution of α granules in megakaryocytes and proplatelet projections visualized by fluorescence microscopy. α Granules are stained with Alexa 568 (red)-labeled anti–von Willebrand factor antibodies. The proplatelets have been costained with Alexa 488 (green) antitubulin antibodies to highlight the microtubules.

microtubule sliding appears to be the key event in driving proplatelet elongation.

Nascent platelets form only at the bulbous ends of proplatelets as defined by the rolling of a single microtubule into a coil having the same diameter as the coil found in the mature platelet.[27] Given that maturation of the platelet is limited to these sites, efficient platelet production requires a large number of proplatelet ends. Megakaryocytes use a unique mechanical process to repeatedly bifurcate the shafts of the proplatelet and hence amplify the number of ends. To accomplish this task, the shaft of elongating proplatelets is bent upon itself and a new proplatelet grows out of the bend, a process that results in bifurcation of the shaft. Whereas proplatelet elongation is mediated by microtubules, the bending and branching of proplatelet shafts are mediated by actin. Actin filament assemblies decorate branch points, and agents that disrupt actin assembly, such as the cytochalasins, abolish proplatelet branching.[27] One possibility is that proplatelet bending and branching are powered by the actin-based molecular motor myosin. Myosin II is an ATPase motor that makes up 2% to 5% of the total platelet protein.[58,59] Myosin II binds to actin filaments and generates force for contraction. Each myosin has two heads and a long, rod-like tail whose function is to permit the molecules to assemble into bipolar filaments. Interestingly, a mutation in the tail domain of the nonmuscle myosin heavy chain A gene in humans results in several diseases, including May-Hegglin anomaly, Sebastian syndrome, and Fechtner syndrome. These rare autosomal platelet disorders are characterized by thrombocytopenia with giant platelets.[60–62] Because bipolar filament assembly is crucial for the function of myosin II, the hematologic phenotype of May-Hegglin may be due to a block in the polymerization of myosin II into filaments during megakaryocyte development and platelet formation.

In addition to playing an essential role in proplatelet elongation, the microtubules lining the shafts of proplatelets serve a secondary function: transport of membrane, organelles, and granules into proplatelets and assembling platelets at proplatelet ends (see Fig. 114–5, *C*).[56] Individual organelles are sent individually from the cell body into the proplatelets, where they move bidirectionally until they are captured at proplatelet tips. Immunofluorescence and electron microscopic studies indicate that organelles are intimately associated with

microtubules, and actin poisons do not diminish organelle motion. Thus, movement appears to involve microtubule-based forces. Bidirectional organelle movement is conveyed in part by the bipolar arrangement of microtubules within the proplatelet, as kinesin-coated latex beads move in both directions over the microtubule arrays of permeabilized proplatelets. Of the two major microtubule motors, kinesin and dynein, only the plus end-directed kinesin is localized in a pattern similar to organelles and granules and likely is responsible for transporting these elements along microtubules. It appears that a twofold mechanism of organelle and granule movement occurs in platelet assembly: first, organelles and granules travel along microtubules; and second, the microtubules themselves slide bidirectionally in relation to other motile filaments, indirectly moving organelles along proplatelets in a piggyback manner.

Platelet Maturation at the Proplatelet Tip

Platelet maturation at proplatelet tips finalizes when a single microtubule detaches from the microtubule bundle and is rolled into a coil.[27] To complete its construction of mature platelets, once the fundamental cytoskeletal components have been delivered to and assembled in the platelet buds, the buds must fill with their organelle and granule content.

Granules are sent to nascent platelets on the microtubule tracks of the proplatelets. The concentration of this cargo in the platelet occurs by an end-trapping mechanism as granules and organelles, which enter the nascent platelet, continue to move in the tip but do not return to the proplatelet shaft.

Release of Mature Platelets

Details of how mature platelets release from the proplatelet tips are lacking. In vitro, maturation of proplatelets ends in a rapid retraction that separates a variable portion of the proplatelets from the residual cell body, leaving behind a naked, denuded nucleus (see Fig. 114–3, *C*). [27] Activation of apoptotic pathways in the cell body has been shown to be coincident with this event.[63–69] In vivo, the finished platelet may be shed into blood as a mature disc or released in a "preplatelet form," perhaps having a long cytoplasmic projection directly related to its previous attachment to the proplatelet process. This cytoplasmic bridge would either be subsequently shed or be absorbed into the platelet body. Because platelet buds appear discoid and contain microtubule coils, it is likely that discoid shape is established prior to shedding, and unlikely that elongated shapes are generated that have an uncoiled microtubule, although it is possible that platelets release with a portion of their microtubule uncoiled.[45] It also is likely that the microtubule motors that drive proplatelet extension are involved in aspects of platelet release as well as in the process of microtubule coiling. Sliding of an uncoiled portion of the microtubule relative to the rigid microtubule bundle in the proplatelet tip would provide a simple mechanism to effect platelet release and would explain the variable morphology of a small but reproducible percentage (<5%) of dumbbell-shaped platelets that are present in blood.

Location of Platelet Release

Although studies on megakaryocytes in culture have provided insight into the mechanics of platelet production, whether proplatelet elaboration follows the same rules in situ remains unclear. Megakaryocytes are produced in the bone marrow and certainly some undergo fragmentation into platelets at this location. The function of proplatelets has been suggested to provide a mechanism for extension into the bone marrow sinusoids, allowing release of platelets directly into circulation. Megakaryocytes have been identified in intravascular sites within the lung, leading to a theory that some platelets are formed from their parent cell in the pulmonary circulation.

Transcriptional Regulation of Platelet Formation

Megakaryocyte development and platelet formation are controlled by the coordinated action of transcription factors that specifically turn on the genes of megakaryocyte precursors or suppress gene expression that supports other cell types. Genetic approaches involving gene targeting in mice have revealed several genes that are crucial for megakaryocyte development and platelet formation. Leading the list of transcription factors that play an essential role in megakaryocyte maturation and platelet biogenesis is the basic leucine zipper heterodimer NF-E2.[70] NF-E2 is a protein composed of a ubiquitously expressed 18- to 20-kd small-Maf subunit and a p45 subunit restricted to the erythroid and megakaryocytic lineages. NF-E2 originally was thought to be a transcription factor that specifically drove the expression of genes essential for erythropoiesis, but mice lacking p45 NF-E2 do not exhibit defects in erythropoiesis. Instead, mice deficient in the p45 subunit or two of the small-Maf subunits die of hemorrhage shortly after birth due to a complete lack of circulating platelets.[71,72] These megakaryocytes undergo normal endomitosis and proliferate in response to Tpo. Mice that are deficient in p45 NF-E2 produce increased numbers of megakaryocytes that are larger than normal, contain fewer granules, exhibit a highly disorganized DMS, and fail to generate proplatelets in vitro, a phenotype indicative of a late block in megakaryocyte maturation.[46] NF-E2 appears to control the transcription of a limited number of genes involved in cytoplasmic maturation and platelet formation. Shivdasani et al.[55] generated a subtracted cDNA library that is enriched in transcripts downregulated in NF-E2 knockout megakaryocytes, and this approach has started to define the downstream targets of NF-E2 and allowed analysis of their precise role in the terminal stages of megakaryocyte differentiation. Putative transcriptional targets of NF-E2 include β_1 tubulin,[55] thromboxane synthase,[73] and proteins that regulate inside-out signaling via $\alpha_{IIb}\beta_3$ integrin.[74] The zinc finger protein GATA1 is also a transcription factor that plays a critical role in driving the expression of genes essential for megakaryocyte maturation. However, unlike NF-E2, which appears to drive the later stage of megakaryocyte development, GATA1 functions at multiple stages of development. GATA proteins initially were thought to regulate red blood cell maturation because genetic disruption of the GATA1 gene in mice results in embryonic lethality due to a block in erythropoiesis.[75] However, several observations also implicate GATA1 as an important regulator of megakaryocyte differentiation. First, forced expression of GATA1 in the early myeloid cell line 416b induced megakaryocyte differentiation of these cells.[76] Second, Shivdasani et al.[77] used targeted mutagenesis of regulatory elements within the GATA1 locus to generate mice with a selective loss of GATA1 in the megakaryocyte lineage. These knockdown mice expressed sufficient levels of GATA1 in erythroid cells to circumvent the embryonic lethality caused by anemia. GATA1 deficiency in megakaryocytes leads to severe thrombocytopenia. Platelet counts are reduced to approximately 15% of normal, and the small number of circulating platelets typically are round and significantly larger than usual. These mice have an increased number of small megakaryocytes that exhibit an increased rate of proliferation. The small cytoplasmic volume of GATA1-deficient megakaryocytes typically contains an excess of rough endoplasmic reticulum, very few platelet-specific granules, and an underdeveloped or disorganized DMS, suggesting that maturation of megakaryocytes is arrested in GATA1-deficient megakaryocytes.[78]

A family with X-linked dyserythropoietic anemia and thrombocytopenia due to a mutation in GATA1 has been described.[79] A single nucleotide substitution in the amino-terminal zinc finger of GATA1 inhibits the interaction of GATA1 with its essential cofactor, friend of GATA1 (FOG). Although the megakaryocytes in affected family members are abundant, they are unusually small and exhibit several abnormal features, including an abundance of smooth endoplasmic reticulum, an underdeveloped DMS, and a lack of granules. These observations suggest an essential role for FOG1–GATA1 interaction in thrombopoiesis. Genetic elimination of FOG in mice unexpectedly resulted in specific ablation of the megakaryocyte lineage, suggesting a GATA1-independent role for FOG in the early stages of

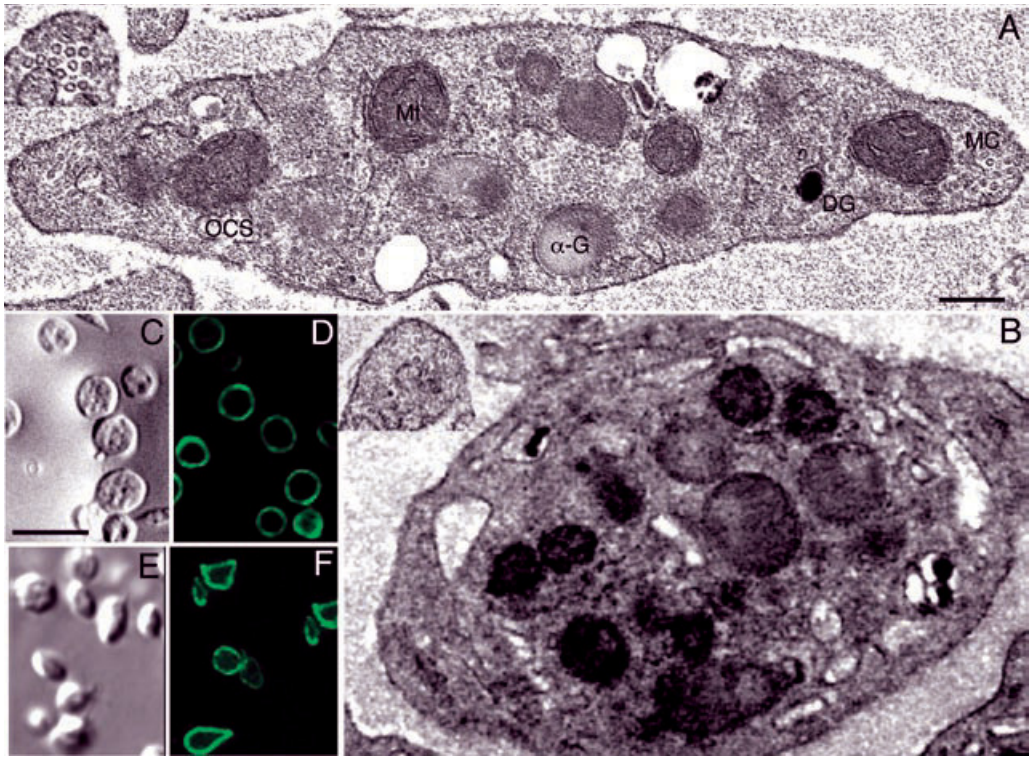

Figure 114–6 Structure of normal mouse platelets (**A**, **C**, **D**) compared to platelets lacking β_1 tubulin (**B**, **E**, **F**). **A**, Electron micrograph of a resting mouse platelet. This platelet was sectioned through its thin axis. The cut plane reveals the microtubule coil (MC) at the cell periphery. The inset shows a high-magnification cross-section through the microtubule coil of the resting platelet. The microtubule is wound 11 times in this platelet, forming the coil. The cytoplasmic space embeds mitochondria (MT), α granules (α-G), and dense granules (DG). The spaces created by the open canalicular system (OCS) are apparent. **B**, Electron micrograph of a thin section through a platelet isolated from a mouse lacking β_1 tubulin.[55] (Bar = 0.2 μm.) Platelets from these animals are spherical (E) and have only a rudimentary microtubule coil (inset). In this platelet the microtubule is twisted twice. **C**, Differential interference contrast image of resting platelets shows them to be flat discs. **D**, Microtubule coil of the resting mouse platelet. Staining of fixed mouse platelets with Alexa 488 antitubulin IgG reveals the microtubule coil. This coil resides at the periphery of the platelet. **E**, Differential interference contrast image of platelets lacking β_1 tubulin. **F**, Staining of fixed mouse β_1-tubulin–deficient platelets with Alexa 488 antitubulin IgG reveals the coil is defective and bent in a number of places throughout the platelets. (C–F are the same magnification; bar = 5 μm.)

megakaryocyte development.[80] GATA1 and FOG are required to generate megakaryocytes from a common bipotential progenitor.[80,81]

Several knockout mice also indicate a role for additional transcription factors in megakaryocyte development. Mice carrying a null mutation in Fli-1, a member of the ETS family of winged helix-turn-helix transcription factors that bind purine-rich sequences in gene promotors, exhibit defects in megakaryocyte development. Megakaryocytes cultured from mice lacking Fli-1 contain reduced numbers of α granules, disorganization of the demarcation membranes, and a reduction in size.[82,83] Mice lacking the hematopoietic zinc finger (Hzf) protein, a transcription factor that is predominantly expressed in megakaryocytes, have reduced numbers of α granules in megakaryocytes and platelets.[84] Therefore, Hzf may regulate the transcription of genes involved in the synthesis of α-granule components and/or their packaging into α granules. SCL, a basic helix-loop-helix transcription factor initially identified in a subset of human T-cell leukemia with multilineage characteristics, also appears to be critical for megakaryopoiesis. Deletion of SCL in mice indicates this transcription factor is required for proper erythroid and megakaryocyte development.[85,86]

PLATELETS

Structure of the Resting Platelet

Megakaryocyte development culminates with the release of mature discoid platelets having dimensions of approximately 3.0 × 0.5 μm and a cytoplasmic volume of 7 fL. The evolutionary explanation for the discoid shape of the platelet is unknown. Discoid shape may permit more efficient flow or dispersion of clot-promoting elements or may simply reflect the microtubule-based mechanism by which platelets are produced. In humans, platelets, once released from the ends of proplatelets, normally circulate for 7 to 10 days. Given that nearly one trillion platelets circulate in an adult human, each day an adult produces approximately 100 billion platelets.

The precise morphology of newly released platelets is unknown. However, once released into the circulation or maintained in culture, platelets have a very reproducible structure, although they are heterogeneous in size as a population in blood presumably due to changes in size as they age. Platelets have discoid shapes with flat, featureless surfaces (Figs. 114–6, *A* and 114–7, *A*) that are interrupted only by pit-like openings into the open canalicular system (OCS). The OCS is an extensive system of internal membrane conduits that serves as a passageway to the outside world into which granular contents release. It also is a reservoir of plasma membrane, membrane receptors, and proteins. For example, approximately 30% of the thrombin receptors are localized in the OCS of the resting cell, awaiting movement to the surface of the activated cells. Although contiguous with the plasma membrane, not all proteins on the cell surface can enter the OCS. Factors controlling movement into the OCS remain to be defined but likely depend on the actin cytoskeleton. Entry restriction, however, occurs at the necks of OCS infoldings. The third function of the OCS is to serve as a source of redundant plasma membrane for cell spreading. OCS membrane initially is disgorged to the surface following cell activation. When cells are activated in solution, much of this membrane subsequently is reabsorbed into the remnants of the OCS.

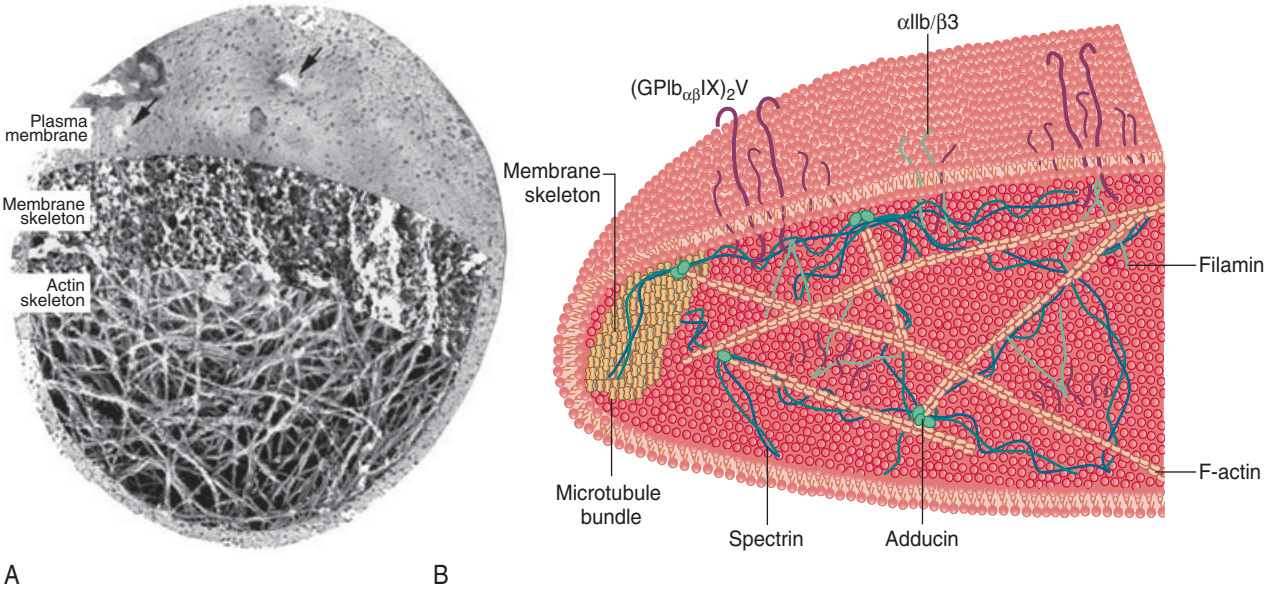

Figure 114–7 Structure of the resting human blood platelet and its actin-based cytoskeleton. **A**, Composite illustrating the major actin cytoskeletal layers of the resting platelet. Plasma Membrane: The plasma membrane of the resting cell is flat and featureless, except for periodic invaginations that lead into the open canalicular system (OCS) (arrows). Membrane Skeleton: The plasma membrane of the platelet is supported by a submembranous spectrin-based skeleton. This network is composed primarily of spectrin molecules, which are tetramers with actin binding sites at the ends. Actin filament ends dock on spectrin to complete the network. The association between spectrin and F actin is promoted by adducin. Actin Cytoskeleton: As discussed above, the spectrin network is both directly and indirectly attached to the underlying actin filaments. Filament ends interconnect spectrin molecules, while the filamin links run from the filament sides to the plasma membrane receptor $(GPIb_{\alpha\beta}IX)_2V$. The cytoplasmic space has a dense filling of actin filaments. Actin filaments from the cell center radiate outward. As the filaments approach the plasma membrane, they turn and run in parallel with it. The actin filaments have been decorated using myosin subfragment 1 (S1), which gives them a twisted cable-like appearance in frozen samples. Myosin S1 labeling reveals the polarity of the actin filament. "Pointed" and "barbed " ends are definable. The ends of actin filaments are bound by the ends of spectrin molecules on the edges of the membrane network (arrowhead). A microtubule coil composed of a single long microtubule resides just beneath the plasma membrane at the periphery of the thin axis of the platelet (not shown). (Bar = 0.5 μm.) **B**, Schematic showing the structural features of the resting blood platelet cytoskeleton. Resting cells have discoid shapes. Structural elements that support this shape are (1) a marginal microtubule coil, (2) a spectrin-based membrane skeleton, and (3) a rigid network of cross-linked cytoplasmic actin filaments (only a small number of the actin filaments have been added to this illustration so that they will not obscure the rest of the structures in the cell). Platelets have a specialized membrane skeleton composed of spectrin, actin, and many associated proteins. Spectrin tetramers (200 nm long and 5 nm wide) have actin filament binding sites at each molecular end. The membrane skeleton is held in compression between the plasma membrane and the cytoplasmic actin by filamin connections from the sides of actin filaments to the cytoplasmic tails of $GPIb_{\alpha}$ subunit of the membrane glycoprotein complex that binds to von Willebrand factor $(GPIb_{\alpha\beta}IX)_2V$ complex. Greater than 98% of the barbed ends of actin filaments are capped by adducin and capZ in the resting platelet.

A small thin zone of cytoplasm separates the plasma membrane of the resting platelet from a marginal microtubule coil and the general intracellular space, which contains all inclusion bodies and the internal cytoskeleton of the cell. This zone is filled with the spectrin-based membrane skeleton (see Fig. 114–7, *A*). Beneath this zone sits a microtubule coil. Then follows the cytoplasmic space, which is filled with filaments of actin that embed granules, organelles, the OCS, and other specialized membrane systems such as smooth endoplasmic reticulum.

Platelets actively recruit other bloodborne cells to areas of vascular damage by releasing mediators packaged in intracellular granules (described earlier in Cytoplasmic Maturation) that initiate secondary homeostatic interactions and that express a "sticky" apical surface after the platelets adhere. In the resting platelet, granules are juxtaposed together and are in intimate association with the membranes of the OCS. The release reaction of platelet granules differs from that of other cells. Granules rarely fuse with the plasma membrane; instead they exocytose into the OCS. Platelets also contain lysosomes and a few mitochondria, which are easily identified under the electron microscope by their internal system of membrane cristae.

Cytoskeleton of the Resting Platelet

Although both microtubule- and actin-based forces have been considered in the elaboration and branching of proplatelets, respectively, it is the integration of the microtubule and actin cytoskeletal elements that uniquely defines the shape of the mature platelet.

One of the most distinguishing features of the resting platelet is its marginal microtubule coil (see Fig. 114–6).[87] αβ–Tubulin dimers assemble into microtubule polymers under physiologic conditions. In resting platelets, tubulin is equally divided between dimer and polymer fractions. In many cell types, αβ-tubulin subunits are in a dynamic equilibrium with microtubules such that reversible cycles of assembly–disassembly of microtubules are observed. Microtubules are long hollow polymers (24 nm in diameter) that are responsible for many types of cellular movements, such as segregation of chromosomes during mitosis and transport of organelles across the cell. The microtubule ring of the resting platelet, initially characterized in the late 1960s by White and Krivit,[88] has been described as a single microtubule approximately 100 μm long and is coiled eight to 12 times inside the periphery of the platelet.[89] The primary function of the microtubule coil is to maintain the discoid shape of the resting platelet. Disassembly of platelet microtubules with drugs such as vincristine, colchicine, or nocodazole causes platelets to round and lose their discoid shape.[88] Cooling the platelets also causes disassembly of the microtubule coil and loss of the discoid shape.[87] Mice lacking the major hematopoietic β-tubulin isoform (β_1 tubulin) produce platelets that lack their characteristic discoid shapes and have defective marginal bands.[90] Genetic elimination of β_1 tubulin in mice results in thrombocytopenia with circulating platelet counts below 50% of normal. β_1-Tubulin–deficient platelets are spherical in shape,

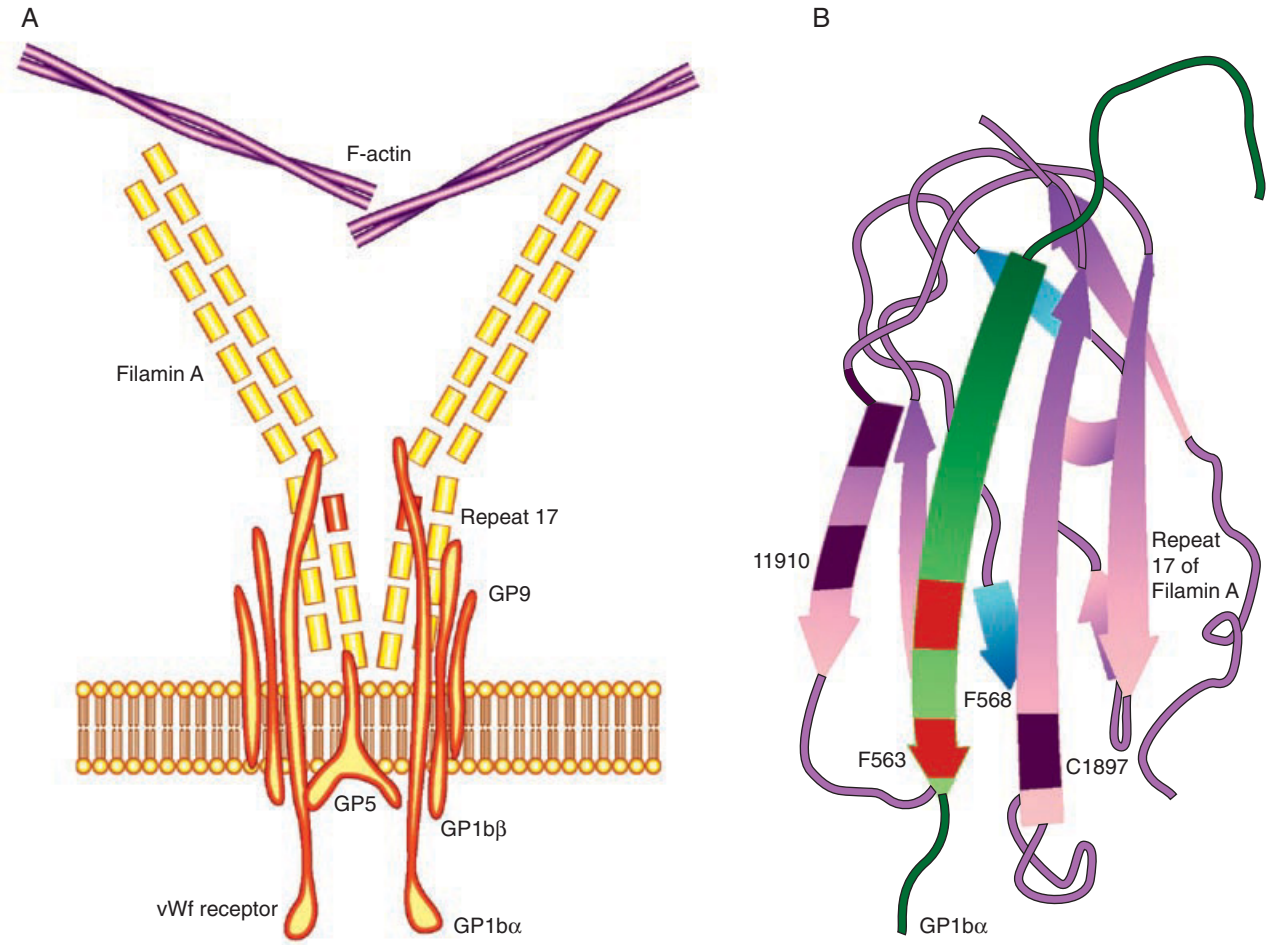

Figure 114–8 Interaction of filamin A with the von Willebrand factor receptor (vWFR). **A**, Model showing the orientation of filamin A when interacting with the GPIbα chain of the vWFR and cytoplasmic actin filaments. For tight binding of filamin A to vWFR, both GPIbα chains of the receptor must be engaged by a single filamin A molecule. **B**, Ribbon diagram showing the interface between filamin A repeat 17 and the filamin A binding region of the GPIbα tail (residues 556–577). Critical residues that provide the lock-and-key interaction between the two domains are indicated.

apparently due to shortened marginal bands with fewer coilings. Whereas normal platelets possess a marginal band that consists of eight to 12 coils, β_1-tubulin knockout platelets contain only two to three coils.[91] A human β_1-tubulin functional substitution (AG→CC) inducing both structural and functional platelet alterations has been described.[92] Interestingly, the Q43P β_1-tubulin variant was found in 10.6% of the general population and in 24.2% of 33 unrelated patients with undefined congenital macrothrombocytopenia. Electron microscopy revealed enlarged spherocytic platelets with a disrupted marginal band and structural alterations. Interestingly, platelets with the Q43P β_1-tubulin variant showed mild platelet dysfunction, with reduced ATP secretion, thrombin receptor-activating peptide (TRAP)-induced aggregation, and impaired adhesion to collagen under flow conditions. A more than doubled prevalence of the β_1-tubulin variant was observed in healthy subjects not undergoing ischemic events, suggesting it could confer an evolutionary advantage and a protective cardiovascular role.

Actin is the most abundant of all the platelet proteins, with two million molecules expressed per platelet.[59] Of these molecules, 800,000 assemble to form the 2000 to 5000 linear actin polymers that exist in the resting cell (see Fig. 114–7, *A*).[93] The rest of the actin is maintained in storage as a 1:1 complex with β_4 thymosin,[94] which can be converted to filaments during platelet activation to drive cell spreading. All evidence indicates that the filaments of the resting platelet are interconnected at various points into a rigid cytoplasmic network, as platelets express high concentrations of actin cross-linking proteins, including filamin[95,96] and α actinin.[97] Both filamin and α actinin are homodimers in solution. Three filamin genes are located on chromosomes 3, 7, and X. Filamin A (X)[98] and filamin B (3)[99] are expressed in platelets. Filamin A is expressed greater than 10-fold more than filamin B. Filamin subunits are elongated strands composed primarily of 24 repeats, each approximately 100 amino acids in length that are folded into IgG-like β barrels.[100,101] Each strand has an amino-terminus actin binding site that shares homology with other actin-binding proteins, two rod domains that are end-to-end assemblies of the repeat units, interrupted by two hinge domains between repeats 15 and 16, and 23 and 24, and a C-terminal self-association site (Fig. 114–8, *B*). Subunits assemble to form V-shaped bipolar molecules, that is, the self-association site is the vertex of the V, and the actin binding sites are on the free ends. Inclusion of the first hinge in filamin depends on alternative RNA splicing. Filamin now is recognized to be a prototype "scaffolding molecule" that collects binding partners and localizes them adjacent to the plasma membrane.[102] Partners bound by filamin members include the small GTPases RalA, Rac, Rho, and Cdc42, with RalA binding in a GTP-dependent manner[103]; the exchange factors Trio and Toll; kinases such as PAK1; phosphatases; and transmembrane proteins. Most partner proteins are bound within the carboxyl-terminal portion of filamin.[102]

Central to the structural organization of the resting platelet is an interaction between filamin and the cytoplasmic tail of the GPIbα subunit of the GPIb-IX-V complex. The second rod domain (repeat 17) of filamin has a binding site for the cytoplasmic tail of GPIbα.[104] The interaction between filamin A and GPIbα occurs at the atomic level.[105] Repeat 17 of filamin A has a groove between certain β-sheet strands that forms a pocket for the GPIbα tail (see Fig. 114–8).

Binding between filamin A and GPIbα is driven by entropic forces, and the alignment and specificity are provided by large residues that create a lock-and-key fit between the two molecules. Whereas the interaction between one filamin A subunit and GPIbα has affinity of approximately 10 μM, high-affinity binding (10 nM) results when each filamin A subunit in a molecule and both GPIbα chains in a vWF receptor are engaged. Biochemical experiments have shown that the bulk of platelet filamin (>90%) is in complex with GPIbα.[106] This interaction has three consequences. First, it posits filamin's self-association domain and associated partner proteins at the plasma membrane while dangling filamin's actin binding sites into the cytoplasm. Second, because a large fraction of filamin is bound to actin, it aligns the GPIb-IX-V complexes on the surface of the platelet over the underlying filaments (see Fig. 114–7, *B*). Third, because the filamin linkages between actin filaments and the GPIb-IX-V complex pass through the pores of the spectrin lattice, it restrains the molecular movement of the spectrin strands in this lattice and holds the lattice in compression. The filamin–GPIbα connection is essential for the formation and release of discoid platelets by megakaryocytes; platelets lacking this connection are large and fragile and are produced in low numbers. However, the role of the filamin–vWF receptor connection in platelet construction is unknown. Because a low number of Bernard-Soulier platelets form and release from megakaryocytes, it can be argued that this connection is a late event in the maturation process and is not required for platelet shedding. Both filamin and GPIbα are synthesized early, but linkage between the two may not occur until later, perhaps as late as the final stages of platelet shedding.

The platelet is the only cell besides the erythrocyte whose membrane skeleton has been visualized at high resolution. Like the erythrocyte, the platelet membrane skeleton is a self-assembly of elongated spectrin strands (see Fig. 114–7) that interconnect through binding to actin filaments. Platelets express approximately 2000 spectrin molecules.[93,107,108] Although considerably less is known about how the spectrin–actin network forms and is connected to the plasma membrane in the platelet relative to the erythrocyte, certain differences between the two membrane skeletons have been defined. First, the spectrin strands composing the platelet membrane skeleton interconnect using the ends of long actin filaments instead of short actin oligomers.[93] These ends arrive at the plasma membrane originating from filaments in the cytoplasm. Hence, the spectrin lattice is assembled into a continuous network by its association with actin filaments. Second, tropomodulins are not expressed at sufficiently high levels, if at all, to have a major role in capping the pointed ends of the platelet actin filaments. Instead, biochemical experiments have revealed that a substantial number (≈2000) of these ends are free in the resting platelet. Third, although little tropomodulin protein is expressed, α and γ adducin are abundantly expressed and appear to cap many of the barbed ends of the filaments composing the resting actin cytoskeleton.[109] Adducin is a key component of the membrane skeleton, forming a triad complex with spectrin and actin. Capping of barbed filament ends by adducin also serves the function of targeting them to the spectrin-based membrane skeleton, as the affinity of spectrin for adducin–actin complexes is greater than for either actin or adducin alone.[110–112] Platelet glycoproteins involved in attaching spectrin to the membrane remain to be defined.

Relationship Between Structure of the Circulating Platelet and That of Nascent Platelets Released by Megakaryocytes

Because the final phase of platelet birth has not been visualized, the size and shape of platelets released are unknown. Given that young platelets in animals made thrombocytopenic are larger than the normal platelet population, platelets likely are born large and shrink as they circulate in the blood. Whether platelets release as discs, as essentially discoid shapes but with residual cytoplasmic protrusion, or as small proplatelet chains of two or more platelets that can undergo further fragmentation into individual platelets remains to be clarified. Behnke and Forer[113,114] have hypothesized that the formation of individual platelets occurs exclusively in the blood, based on the observation that proplatelet-like structures circulate in blood and can make up 5% to 20% of the platelets in plasma. Dumbbell-shaped particles are found in abundance in the media of megakaryocyte cultures, which suggests that they are a preferred release form.

CHAPTER 115

THE MOLECULAR BASIS OF PLATELET FUNCTION

Charles S. Abrams and Edward F. Plow

Platelets ordinarily circulate in blood vessels as individual cells that do not interact with other platelets or other cell types. A transition from this nonadhesive to an adhesive state can be rapidly initiated if platelets are exposed to a stimulatory agonist. Platelet adhesive reactions that may be initiated in response to an injury to a blood vessel wall, as exemplified by rupture of an atherosclerotic plaque, are shown in Fig. 115–1. Disruption of the endothelial cell lining of the vessel exposes constituents within the subendothelial matrix, including a variety of adhesive proteins that can support initial platelet attachment. After attachment, platelets may undergo a spreading reaction that permits formation of multiple and tight contacts between the cell surface and the matrix. These additional contacts may be critical in stabilizing the association of the platelets with the matrix in flowing blood. In conjunction with these adhesive reactions, the cells encounter agonists in the microenvironment that can trigger platelet secretion. The platelet secretory response results in the release of contents of intracellular storage granules. Granule constituents include substances, such as adenosine diphosphate (ADP), which can stimulate circulating platelets and cause them to acquire new adhesive properties. These stimulated platelets interact with one another, during platelet aggregation, to form an effective plug that seals the injured vessel wall and prevents excessive blood loss. This series of platelet responses (attachment, spreading, secretion, and aggregation) is essential for the hemostatic function of platelets. Nevertheless, these same events, occurring on an injured endothelial cell or on an atherosclerotic plaque, may result in the formation of a platelet-rich thrombus, which can compromise the patency of the blood vessel and lead to thrombosis. At the other extreme, abnormalities in platelet adhesive reactions of either a genetic (e.g., Glanzmann thrombasthenia or Bernard-Soulier syndrome; see Chapter 141) or an acquired origin (e.g., drug-induced thrombocytopenia; see Chapter 140) can result in bleeding. Thus, platelet adhesive reactions and secretion are central events in health and disease processes. Bleeding, hemostasis, and thrombosis are in delicate balance and are regulated by these platelet functions.

This chapter addresses the molecular basis of platelet adhesive reactions and secretory responses. Great strides have been made in defining the mechanisms that govern these functional responses. At the heart of these platelet responses are ligand–receptor interactions. The platelet has often served as a model cell type for studying ligand–receptor interactions and establishing basic mechanisms of cell adhesion and secretion.

MOLECULAR BASIS OF PLATELET ADHESION

Studies in vitro, particularly under flow conditions (i.e., in closed chambers permitting whole blood or isolated components to flow across a selected matrix at selected shears), and in vivo experiments using transgenic mouse models in which specific molecules have been deleted, mutated, or overexpressed have demonstrated the complexity of the reactions leading to thrombus formation, growth, and stability. For simplicity, we dissect these events; however, in reality these events occur very rapidly and often in overlapping fashion.

Substrates for Platelet Attachment and Spreading

Some of the major subendothelial matrix proteins that support platelet attachment or spreading reactions are listed in Table 115–1. From the extent of this list, it is clear that the platelet can adhere to a variety of substrates once the endothelium has been disrupted. The endothelium must also create an effective barrier to prevent circulating platelets from reaching the matrix and initiating thrombus formation. In addition to serving as a physical barrier, endothelial cells synthesize and elaborate components, notably prostaglandin I_2, nitric oxide, and an enzyme termed CD39 that degrades ADP, which prevent platelet activation and impart a nonthrombogenic character to the normal endothelium (see Chapters 116 and 117).

Studies of mice deficient in individual matrix proteins have documented the involvement of multiple adhesive proteins in the formation, growth, and stability of platelet-rich thrombi.[1–4] Several considerations affect the role of individual matrix constituents in mediating platelet adhesion:

1. Not all of the adhesive proteins listed in Table 115–1 support the same spectrum of platelet adhesive responses. For example, under some conditions, platelets attach to, but do not spread on, laminin,[1] whereas von Willebrand factor (vWF) and fibronectin support cell attachment and spreading.[5–7] Collagen not only supports the attachment and spreading of platelets but can provoke a secretory response.[8] Of the multiple forms of collagen, types I, III, and VI are regarded as particularly important in supporting platelet adhesion.
2. A wealth of evidence indicates that the phenotypic properties of endothelial cells from different blood vessels vary, as does the composition of the subendothelial matrix. The characteristics of the endothelial cells may differ even within the same vessel. Areas of turbulent flow, which occur at bifurcations of vessels, are prone to development of atherosclerotic lesions, and shear-responsive elements in the promoters of certain genes can lead to changes in the expression of endothelial proteins[9,10] and alterations in their adhesive properties.[11,12] Thus, certain proteins may play a dominant role in supporting platelet adhesion in certain blood vessels.
3. Shear rate developed by flowing blood varies with vessel caliber and greatly influences platelet adhesion. Shear is particularly important in defining the contribution of vWF to platelet adhesion. Patients with von Willebrand disease (see Chapter 129) have a major bleeding diathesis, attesting to the importance of vWF in supporting platelet function. However, in vitro experiments show a role for vWF in platelet adhesion at high but not at low shear rates.[6,13] In contrast, a role for fibronectin in supporting platelet adhesion can be demonstrated at both high and low shear.[14,15] Both proteins have been implicated in thrombus formation.[2,4]
4. A variety of adhesive proteins interact with one another. For example, vWF, fibronectin, and thrombospondin all bind to collagen[16–18] (although they exhibit differential reactivity with different collagen types). These interactions may bridge the platelet to a matrix protein or may modulate the adhesive properties of a matrix protein.
5. Several adhesive proteins are present in platelet secretory granules, plasma, or both, as well as being matrix constituents. vWF and

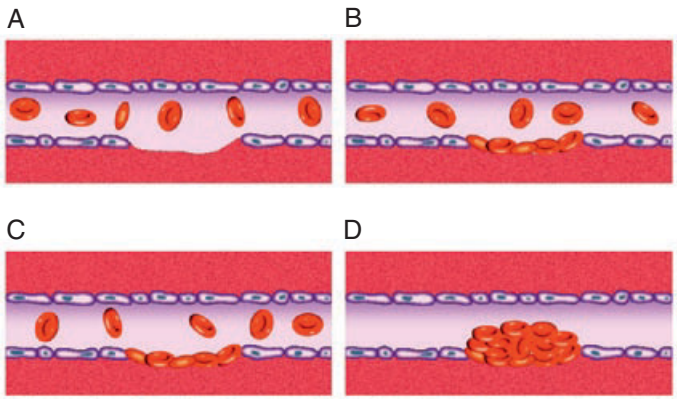

Figure 115–1 Hemostatic response of platelets to injury. **A**, Disruption of the endothelial cell lining of the blood vessel exposes constituents of the subendothelial matrix. **B**, Platelets attach to, and spread on, the matrix constituents. **C**, Platelet secretion may be initiated. **D**, Released platelet constituents can activate additional platelets, which aggregate and form a thrombus.

Table 115–1 Some Major Subendothelial Matrix Constituents That Support Platelet Adhesion

Matrix Constituent	Comment
Collagens	Large family of proteins with certain members supporting platelet adhesion, aggregation, and secretion
von Willebrand factor	Large multimeric protein critical for hemostatic function of platelets
Fibronectin	Dimeric or multimeric protein that supports attachment and spreading of platelets
Thrombospondin-1	Trimeric protein exhibiting both adhesive and antiadhesive properties
Laminins	Proteins supporting platelet attachment
Microfibrils	Fibular bundle of protein constituents found in certain matrices

fibronectin are present in all three locations, and thrombospondin is a major platelet granule constituent.[19,20] Proteins from all three sources (matrix, platelet, and plasma) contribute to platelet adhesion. The adhesive proteins derived from these different sources may be functionally distinct because they are not structurally identical. For example, the degree of vWF and fibronectin multimerization differs for molecules derived from plasma and the matrix. With fibronectin, the splice forms of the molecules derived from plasma and platelets differ.[21]

6. Matrix proteins are subject to degradation by a variety of proteolytic enzymes. Such proteolysis can modulate the adhesive properties of the matrix proteins. In some cases, cryptic adhesive sequences can be exposed that interact with additional sets of platelet adhesion receptors.[22,23]

Overall, the subendothelial matrix should be viewed as a dynamic and mutable interface that provides multiple substrates that support platelet adhesion.

Platelet Adhesion Receptors

The individual adhesive proteins come in contact with the platelet by serving as ligands for specific cell surface receptors (Table 115–2). Because several nomenclature systems have been used to identify the membrane proteins of the platelet, the same receptor may have multiple designations. One of the most widely used nomenclatures is based on electrophoretic mobility of the membrane proteins on polyacrylamide gel systems, in which the higher-molecular-weight proteins move more slowly. This separation gave rise to glycoprotein (GP) I, II, III, and so on, with GPI having the highest molecular weight. As the gel systems used became more discriminating, several proteins were discerned in the GPI position, hence GPIa, GPIb, and GPIc, and so forth.[24] Further refinement still is required; for example, there are at least three distinct polypeptides in the GPIc position. Several of the membrane proteins exist on the platelet surface as noncovalent complexes; thus, GPIb-V-IX-V, GPIc-IIa, and GPIIb-IIIa can be regarded as single-membrane proteins. Several of these membrane proteins are members of the integrin family of adhesion receptors (see Integrin Family of Adhesion Receptors), and the integrin nomenclature now tends to prevail in designating these particular membrane proteins (e.g., GPIc-IIa now is most commonly referred to as $\alpha_5\beta_1$ and GPIIb-IIIa as $\alpha_{IIb}\beta_3$). Other nomenclature systems have arisen from the fact that several platelet membrane proteins are present and have been assigned different names on other cell types. This is the basis for the VLA (very late antigen) designations for some of the platelet membrane proteins. Similarly, certain proteins also have extracellular matrix (ECM) and leukocyte differentiation antigens (CD) designations. Some receptors have been named based on their function (e.g., vitronectin, fibrinogen, and fibronectin receptors). Although functional designations seem highly appropriate from a descriptive standpoint, at least two membrane proteins on platelets can serve as receptors for vitronectin, fibrinogen, and fibronectin (see Table 115–2), and several platelet constituents have been referred to as collagen receptors (see Collagen Receptors). With the exception of the CD identifications, the latter nomenclature systems now are rarely used compared to the GP and integrin nomenclature but still may be encountered in reference to particular membrane proteins in the older platelet literature. Beyond creating a nomenclature complexity, the redundancy of the platelet receptors enables the cell to establish multiple contacts with a single matrix constituent; thus, a single ligand may initiate several distinct functional responses by engaging different receptors.

Table 115–2 Platelet Receptors for Adhesive Proteins

Ligand	Receptor(s)	Other Common Designations
Collagen	GPIa-IIa, $\alpha_2\beta_1$ GPIIb-IIIa, $\alpha_{IIb}\beta_3$ GPIV GPVI	VLA-2 GPIIIb CD36
Fibrinogen	GPIIb-IIIa, $\alpha_{IIb}\beta_3$ Vitronectin receptor, $\alpha_V\beta_3$	
Fibronectin	GPIc-IIa, $\alpha_5\beta_1$ GPIIb-IIIa, $\alpha_{IIb}\beta_3$	VLA-5
Thrombospondin	Vitronectin receptor, $\alpha_V\beta_3$ GPIV Integrin-associated protein	GPIIIb CD36 IAP
Vitronectin	Vitronectin receptor, $\alpha_V\beta_3$ GPIIb-IIIa, $\alpha_{IIb}\beta_3$	
von Willebrand factor	GPIb-V-IX GPIIb-IIIa, $\alpha_{IIb}\beta_3$	
Laminin	GPIc-IIa region, $\alpha_6\beta_1$	VLA-6

GP, glycoprotein; VLA, very late antigen.

Integrin Family of Adhesion Receptors

Many of the adhesive protein receptors on platelets are members of the integrin family. The integrins are a broadly distributed family of

Table 115–3 Platelet integrins

Integrin	Major Ligands
$\alpha_2\beta_1$ (GPIa-IIa, VLA-2)	Collagen
$\alpha_5\beta_1$ (GPIc-IIa, VLA-5)	Fibronectin
$\alpha_{IIb}\beta_3$ (GPIIb-IIIa)	Fibrinogen, fibronectin, vitronectin, von Willebrand factor, CD40L
$\alpha_v\beta_3$ (Vitronectin receptor)	Fibrinogen, fibronectin, vitronectin, von Willebrand factor, thrombospondin, osteopontin
$\alpha_6\beta1$ (GPIc-IIa region)	Laminin

GP, glycoprotein; VLA, very late antigen.

heterodimeric (two subunits) cell surface molecules that share certain structural, immunochemical, and functional properties.[25–33] The β subunits, of which eight are known, are highly homologous to one another, exhibiting at least 35% to 45% identity at the primary amino acid sequence level and a common structural organization. The α subunits, of which 14 are known, also are similar to one another but exhibit less extensive sequence identity.[34,35]

The α subunits fall into two categories: those with and those without I (also called A) domains. Integrin I domains are inserted domains of approximately 200 amino acids that frequently are involved in ligand binding of the integrins containing them.[36] Only one of the major integrins on platelets, $\alpha_2\beta_1$, a collagen receptor, contains an I domain in its α subunit. The α subunits are synthesized as single-chain polypeptides; some, such as α_{IIb}, are proteolytically processed to a two-chain form.[37–40] Each β subunit combines in a noncovalent complex with an α subunit to form a functional adhesive protein receptor. A single β subunit can combine with several α subunits.

Platelets express two major β subunits, β_1 and β_3 (β_2 has been reported to be present at low levels but this requires confirmation),[41] and five α subunits (Table 115–3). Of the integrins expressed on blood cells, $\alpha_{IIb}\beta_3$ is the most narrowly distributed and is restricted predominantly to platelets/megakaryocytes. $\alpha_{IIb}\beta_3$ plays a prominent role in platelet aggregation and many other platelet responses, including the association of platelets with tumor cells, an interaction important to the metastatic dissemination of neoplastic cells.[42–44]

Role of GPIb-V-IX in Platelet Adhesion

GPIb-V-IX is a notable example of a cell surface molecule involved in platelet adhesion that is not a member of the integrin family.[45] Platelets from patients with Bernard-Soulier syndrome lack GPIb-V-IX, and patients with this syndrome have a marked bleeding diathesis (see Chapter 141).[46–48] A major role of GPIb-V-IX in hemostasis can be traced directly to its function as a receptor for vWF. vWF is composed of multiple functional domains, including the 24-kd A1 domain that binds to the amino-terminus of GPIbα and interacts, along with the A3 domain, with matrix constituents such as collagen and microfibrils (see Chapter 128).[16,49–55] Thus, by associating with matrix proteins, vWF directly mediates rapid and reversible platelet adhesion that promotes the rolling of these cells along the surface of vascular injury.[56] This rolling may transiently bridge the cells to subendothelial matrix components until a more stable adhesive bond forms. Integrins are the most likely receptors responsible for the stable platelet-adhesive bond that permanently halts the rolling of the platelet. In vitro, vWF does not interact directly with GPIb on platelets. An interaction can be measured in the presence of ristocetin, an antibiotic, or botrocetin, a snake venom peptide. Altered forms of vWF, such as asialo-vWF (protein treated to remove sialic acid residues from its carbohydrate moieties) and bovine vWF, can interact directly with platelets.[57–59] High shear appears to serve as the physiologic counterpart of ristocetin or botrocetin in humans. High shear alters the conformation of vWF, permitting their high-affinity interaction.[60,61] Such high shear stress can be attained in the microcirculation or in narrowed arteries.

Several laboratories have reported the structures of the vWF A1 domain as well as A1 domain mutants interacting with the GPIbα complex.[62–64] The globular vWF A1 domain interacts with the amino-terminus of GPIbα. This vWF-binding region of GPIβα is composed of two β loops flanking a backbone composed of eight leucine-rich repeats. This entire interaction depends on the displacement of the termini of the vWF A1 domains, an event that likely occurs under shear conditions present at the sites of vascular injury.

The role of GPIb in hemostasis is not restricted to its vWF binding function. GPIb also can serve as a binding site for thrombin,[65,66] and this activity plays an important role in the generation of platelet microparticles and procoagulant activity.[67–70] GPIb also is a target for certain drug-induced platelet antibodies[71] and is a counter-receptor for $\alpha_M\beta_2$ (CD11b/CD18 [Mac-1]) leukocyte integrin, an interaction that helps to mediate platelet-leukocyte conjugates.[72] The full primary structures of GPIb,[73,74] GPIX,[75] and GPV[76] were determined from cDNA cloning approaches in the 1980s. GPIb is composed of a heavy chain (α) and a light chain (β), both of which span the platelet membrane. GPIbα associates with the cytoskeleton within the platelet.[46,77–79] This chain is highly susceptible to proteolysis, and a large proteolytic fragment, glycocalicin, can be detected in the plasma of some patients with thrombocytopenic disorders.[80] GPIX is a small, single-chain polypeptide with a molecular weight of 20,000 Da. The contribution of GPIX to the function of GPIb-V-IX is uncertain. GPV also is deficient in Bernard-Soulier platelets and forms a loose association with GPIb-V-IX.[48,67,68] Platelets from mice deficient in GPV show enhanced sensitivity to thrombin, which may reflect a role of GPV in controlling the thrombin-binding function of GPIb.[81] An important consequence of occupancy of GPIb-V-IX by vWF is the induction of intracellular signaling events that ultimately lead to activation of $\alpha_{IIb}\beta_3$ and then platelet aggregation (see Aggregation response of platelets).[46,82] Such communication between adhesion receptors is a repeating theme for platelets as well as other cells. Key events in this communication between platelet receptors may include changes in the phosphorylation of the cytoplasmic tails of GPIb-V-IX and their association with the signaling molecule 14.3.3.[83,84]

Collagen Receptors

Subendothelial collagen has been long recognized as an important initiator of platelet responses, serving both as a substrate for platelet adhesion and as a potent platelet agonist. Three different receptors have been implicated in platelet responses to collagen.[85] The first receptor is the GPIb-V-IX complex. The second receptor, $\alpha_2\beta_1$ (also known as VLA-2, platelet GPIa-IIa), is a member of the integrin family of adhesion receptors and primarily serves as an anchor for platelets to attach to collagen exposed after disruptions in the vascular endothelial layer.[86] A patient with an acquired deficiency of this integrin exhibited a mild bleeding diathesis.[87,88] In addition to binding collagen with high affinity, $\alpha_2\beta_1$ binds laminins, E-cadherins, matrix metalloproteins, C1q, echovirus, and rotavirus. The identification of a patient with a mild bleeding diathesis who had normal amounts of $\alpha_2\beta_1$ but marked reduced amounts of platelet GPVI suggested that GPVI also served as an important collagen receptor.[89] It also can serve as a collagen adhesion receptor (at least under low shear conditions). Mice that lack GPVI on the surface of their platelets have a complete loss of collagen-induced platelet activation and a profound defect in collagen adhesion.[90] The deficiency of GPVI on platelets can be generated by inactivating either GPVI or Fc receptor γ-chain (FcRγ) genes. The latter forms a complex with GPVI and is required for surface expression of GPVI.[88] In contrast, $\alpha_2\beta_1$ serves primarily as an auxiliary receptor for platelet adhesion to collagen and functions as an agonist receptor only under unusual circumstances.[86]

Experiments using receptor-blocking antibodies, heterologously expressed receptors, and genetically altered mice have elucidated the

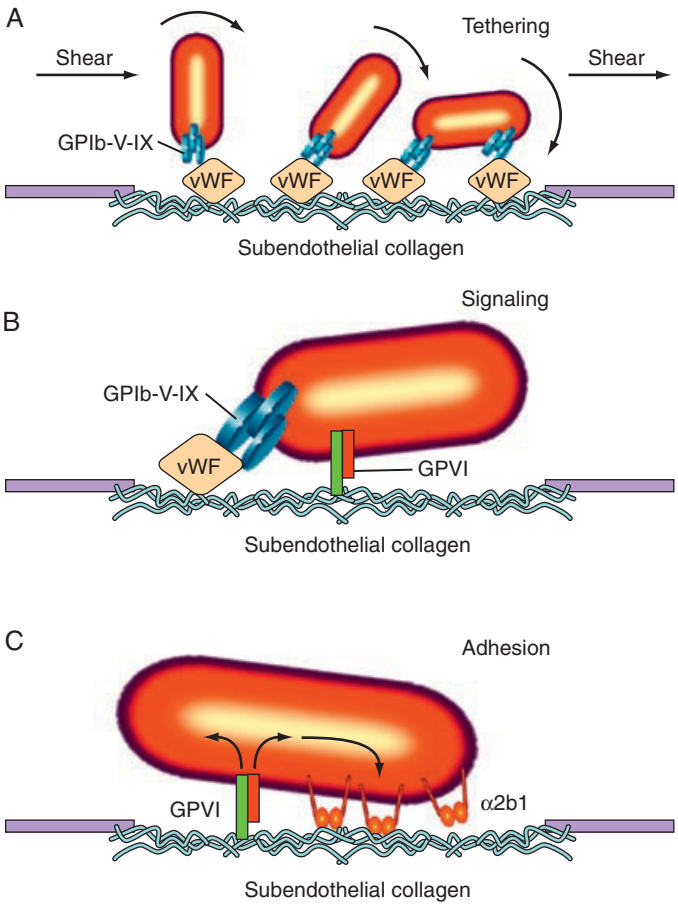

Figure 115–2 Adhesion to collagen is a multistep process. **A**, Once exposed to an injured vascular wall, von Willebrand factor adheres to subendothelial collagen and undergoes a conformational change that allows it to bind to the platelet receptor glycoprotein Ib/V/IX (GPIb-V-IX). This rapidly formed bond is quickly broken and reestablished, causing the platelet to roll along the injured vascular wall. **B**, The rolling process slows down the platelet and allows the platelet signaling receptor GPVI to bind collagen. **C**, This process induces a cascade of signaling events that ultimately activate the integrin $\alpha_2\beta_1$. This final association between the platelet and collagen is stable and allows the platelet to firmly adhere to the vessel wall.

relative roles of each of these proteins.[86,90–93] Platelet adhesion to collagen is a multistep process (Fig. 115–2). Initially platelets adhere to collagen-immobilized vWF via platelet GPIb-V-IX. This is a rapidly formed but short-lived interaction that only transiently tethers the platelet. The interaction repeatedly forms and breaks, thereby causing the platelet to slowly roll along the surface of vWF immobilized upon exposed collagen. Ultimately, GPVI directly interacts with collagen. GPVI is a low affinity receptor, but is capable of stimulatory intracellular signaling pathways. As a result of this signaling cascade, $\alpha_2\beta_1$ is induced to bind collagen with high affinity. This latter interaction promotes the stable association of platelets with collagen. The interaction between platelets and collagen is complex, and whether pharmacologic inhibition of either platelet collagen receptor has a therapeutic benefit is not known.

Reorganization of the Actin Cytoskeleton

One of the more dramatic events during platelet activation is the metamorphosis that occurs when platelets adhere and spread on exposed collagen fibrils or become activated in the circulation by soluble factors such as thrombin or ADP. In either case, platelets lose their distinct discoid shape and acquire an irregular morphology with multiple filopodial projections.[94] This transformation is associated with, and largely due to, cytoskeletal rearrangements within the platelet.[95] The proteins are arranged in three major structures: a cytoplasmic actin network, a rim of membrane-associated cytoskeleton, and a marginal band consisting of a microtubule coil.[96] Together, these structures lend support to the platelet plasma membrane and give shape to both resting and activated platelets.

The cytoplasmic actin network is composed of actin filaments and associated proteins. Actin is a 42-kd protein that accounts for as much as 20% of total platelet protein.[96] In resting platelets, 40% to 50% of the actin is present as filamentous F-actin; the remainder is present as globular monomeric G-actin.[97,98] The shift to increase the proportion of F-actin to 70% to 80% during platelet activation involves a coordinated sequence of events in which the actin filaments present in resting platelets are severed and the resultant smaller fragments are used as the nidus for new, longer actin filaments. This process is thought to be regulated in part by the increase in levels of a phosphatidylinositol-4,5-bisphosphate (PIP_2) that accompanies platelet activation.[99,100] At the same time, myosin is phosphorylated by myosin light chain kinase and becomes associated with F-actin, forming filaments that are anchored to the platelet plasma membrane by attachment (via actin-binding protein) to the glycoprotein Ib/V/IX complex.[101,102]

The cytoskeletal rim is composed of actin, filamin, P235 (talin), vinculin, spectrin, α actinin, and several membrane glycoproteins. Filamin is an elongated 280-kd protein that is present in platelets and functions as an actin-binding protein.[103] In resting platelets, filamin is part of a semirigid array that helps maintain the platelet's discoid shape and limits the lateral movement of GPIb.[77,104,105] This role is analogous to that performed by spectrin in erythrocytes.[78] When platelets are activated, actin filaments form and attach to actin-binding protein. Later the rising cytosolic Ca^{2+} concentration activates calpain, which cleaves actin-binding protein, severing the link to GPIb.[104,106,107]

The third major structural element in platelets is the marginal microtubule band.[96] This microtubule coil is a tightly wound polymer of tubulin that encircles the platelet perimeter and helps maintain its discoid shape.[108] During platelet activation, the microtubule coil contracts. That contraction of the marginal band is required for stable adhesion of platelets under arterial shear pressures has been proposed; however, this theory remains controversial.[109,110]

PLATELET SECRETION

The foregoing discussion has emphasized the adhesive functions of platelets in mediating the physical closure of breaks in blood vessels. Another important function of platelets is the release of a variety of substances that stimulate or inhibit platelets or other blood and vascular cells, which can covalently modify the thrombus and affect its mechanical properties, as well as regulate coagulation, contribute to cell adhesive events, and modulate the growth of cells of the vessel wall. Thus, the platelet is not simply the stop plug of the vasculature; it also has the capacity to signal its presence in a thrombus and modify the hemostatic response in a variety of ways. In addition, although platelets do not contain a nucleus, they do contain mRNA and may synthesize some proteins.[111,112] Although such synthesis had long been regarded as a vestigial activity of megakaryocytes, data indicate that a restricted repertoire of proteins, which are related to apoptosis and inflammation, are produced,[113] and a functional importance to the platelet "transcriptome" has been suggested.[112] Most of these substances that are actively and selectively secreted from platelets are packaged in preformed storage granules, or are synthesized de novo from membrane phospholipids. Platelets contain three types of granules: (a) dense granules containing platelet agonists that serve to amplify platelet activation, (b) α granules containing proteins that enhance the adhesive process, and (c) lysosomal granules containing glycosidases and proteases that have an unclear function in platelet biology.[114] In addition, factors in the platelet cytoplasm released as a

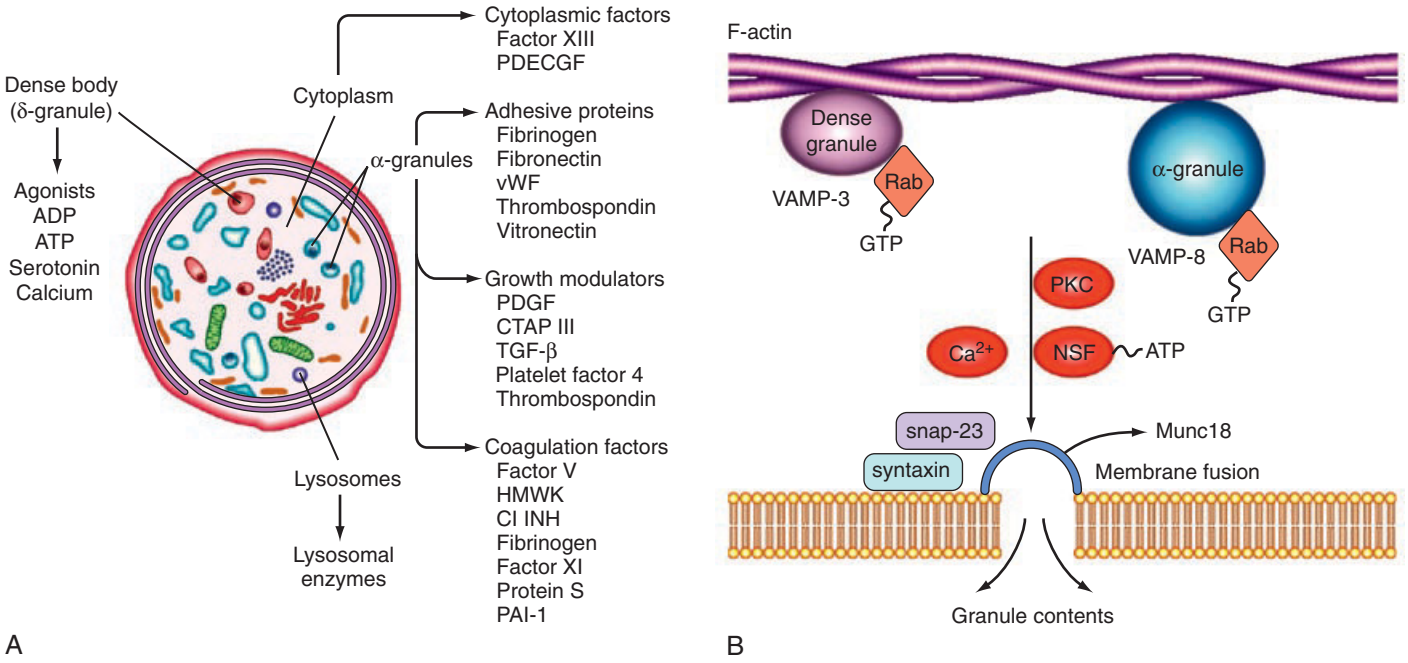

Figure 115–3 **A**, Substances released by platelets and their intraplatelet sources. Illustrated are some of the bioactive substances released from dense bodies, α granules, lysosomes, cytoplasm, and platelet membrane. **B**, In resting platelets, the actin cytoskeleton must be disassembled prior to platelet secretion. Secretion of α and dense granules occurs through a complex signaling pathway dependent on small GTPases, protein kinases, and members of the SNARE/SNAP family. These signaling pathways are highly homologous to those used during neuronal cell exocytosis. C1 INH, C1 inhibitor; CTAP, connective tissue-activating peptide; HETEs, hydroxyeicosatetraenoic acids; HMWK, high-molecular-weight kininogen; PAF, platelet-activating factor; PAI-1, plasminogen activator inhibitor 1; PDECGF, platelet-derived endothelial cell growth factor; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-β; vWF, von Willebrand factor.

result of minor degrees of platelet lysis during hemostasis can have effects on thrombus structure or vascular cell growth. Some of these factors and their intraplatelet sources are shown in Fig. 115–3, *A*.

Dense Granules

The dense bodies and platelet membranes are a source of rapidly secreted mediators. These mediators either are quickly inactivated or are promptly diffused away from the site of the thrombus; thus, they function for only a brief period of time. Their rapid effects on surrounding cells serve to modulate the behavior of platelets as well as the behavior of vessel wall cells (particularly with regard to vascular tone.)

Platelets contain approximately three to eight dense granules that are the most rapidly secreted of platelet organelles.[115] The granules contain ADP (which is a potent agonist to recruit other platelets); upon activation the granules release ADP as well as adenosine triphosphate (which is an agonist for other cells of the blood).[116,117] In addition, they release biogenic amines such as serotonin, which can influence vascular tone, and divalent cations. The physiologic role of released dense body calcium is not clear; however, one could speculate it serves to ensure adequate calcium for some of the calcium-dependent enzymes involved in coagulation or cross-linking of the thrombus.

α Granules

A large number of plasma proteins involved in cell adhesion and coagulation are present in platelet α granules. Some of the proteins found within α granules are synthesized only in megakaryocytes (e.g., β thromboglobulin and platelet factor 4); other molecules are less specific for platelets and megakaryocytes. Platelets contain approximately 80 α granules that contain adhesive plasma proteins including vWF, fibrinogen, fibronectin, and vitronectin as well as the platelet and cellular adhesive protein thrombospondin-1.[20,118] Platelet vWF is concentrated in the platelets, megakaryocytes synthesize it,[119] and the platelet form is enriched in the larger, presumably more hemostatically effective multimers.[120] Megakaryocytes clearly take up fibrinogen, but its biosynthesis by megakaryocytes remains controversial.[121] Platelet fibronectin appears to be enriched in alternatively spliced forms that are relatively lacking in plasma,[21] suggesting a possible role for platelet fibronectin in events such as matrix assembly. Vitronectin is present in platelets[122]; however, its concentration suggests that it probably is passively taken up from the plasma. Nevertheless, studies have suggested a role for platelet and plasma vitronectin in thrombus formation.[123,124] Plasminogen activator inhibitor type 1 (PAI-1) binds vitronectin,[125] and these two proteins are released as a complex.[126] Consistent with this observation, mice lacking vitronectin, PAI-1, or both have a similar deficiency in thrombosis formation.[127] A wide variety of procoagulant and anticoagulant enzymes and cofactors have been reported in platelet granules. Although controversial,[128] it appears that megakaryocytes can synthesize at least some factor V,[129–131] and more factor V is present in platelet α granules[132] than can be accounted for by nonspecific uptake from plasma. Moreover, platelet factor V appears to be distinct from plasma factor V[133] and plays a clear role in assembling the platelet prothrombinase,[134] which is involved in the final step of blood coagulation (i.e., generation of thrombin). Platelets also contain the cofactors protein S[135] and PAI-1.[136] Protein S is a cofactor for action of activated protein C (see Chapter 120), and PAI-1 is an inhibitor of urokinase and tissue plasminogen activators (see Chapter 119). Thus, the concentrations of these proteins in platelets suggest that platelets may be a favored site for the anticoagulant action of protein C, a tempting idea considering the local concentration of factor V, a protein C substrate, on the platelet surface. Similarly, local release of PAI-1 from platelets may play a role in modulating fibrinolytic events in the vicinity of thrombi.[137,138]

P-selectin[139–142] (GMP-140, GPIIa, PADGEM, CD62) is an α-granule membrane protein that is absent from the surface of resting platelets. It is structurally similar to E- and L-selectins,[143] a family of

carbohydrate-binding proteins involved in adhesive interactions of circulating leukocytes. Platelet P-selectin plays a central role in mediating interactions of monocytes and neutrophils with platelets.[143] These interactions are important in "cross-talk" between these cell types[144] and in the recruitment of leukocytes to thrombi.[145] Some of the speculated pathologic roles of platelet P-selectin are promotion of thrombogenesis,[145] platelet–tumor cell interactions,[146] and monocyte recruitment. It may play a physiologic role in the leukocyte phagocytosis of platelets. In addition, P-selectin plays an important role in leukocyte–vessel wall interactions[142,147] and hemostasis.[148] Platelet–leukocyte conjugates are indicative cardiovascular events.[149,150] However, P-selectin and its counterreceptor PSGL on leukocytes[151] are not the only ligand–receptor pair that mediates these interactions.[152]

The most abundant component of α granules is platelet-activating factor[153] (alkyl-2-acetyl-*sn*-glycero-3-phosphocholine), which originally was described as platelet activator released from stimulated mast cells. Platelet-activating factor is a member of the chemokine family. Its biologic effects are much more widespread than on platelet activation,[154–156] although its effects on platelets clearly play a role in some of the platelet sequestration that occurs during allergic injury. It is produced by a variety of cells in addition to platelets. It is possible that this important mediator, produced locally, contributes either to recruitment of other platelets or to some of the vascular phenomena associated with hemostasis.

Platelet α granules contain growth-arrest specific gene 6 (Gas-6).[157,158] Gas-6 is similar to protein S, but it is a ligand for certain growth factor receptors, such as Axl.[159] Because platelets express the Axl receptor, it is speculated that secreted Gas6 functions to accelerate platelet recruitment and activation. Consistent with this hypothesis, mice lacking Gas6 have a platelet defect.[133,157]

Platelets are the major peripheral blood source of β-amyloid precursor protein (APP).[160] APP is a membrane protein, thought to be localized to α granules,[161] that serves as the precursor of the approximately 40 residue peptides found in amyloid deposits in the brains of patients with Alzheimer disease. APP is a protease inhibitor and is processed by proteolytic cleavage. Its inhibition of factors Xa, XIa, and IXa[162,163] suggests a possible role as a natural anticoagulant. The effects of platelet APP on the spectrum of coagulation and fibrinolytic proteases are of interest, as is its potential role in deposits of amyloid in the brain.

Platelets contain a wide variety of peptides and proteins, primarily in α granules, that can modulate the growth and patterns of gene expression of cells of the vessel wall. The first of these to be described was platelet-derived growth factor[164] (PDGF), which has three isoforms and two distinct receptors on smooth muscle cells and fibroblasts.[165] PDGF probably plays an important role in the smooth muscle cell proliferation that may occur consequent to platelet interaction with the vessel wall. Platelet-secreted PDGF may play a critical role in angiogenesis.[166] PDGF receptors are transmembrane tyrosine kinase-type receptors, and signal transduction from this receptor[167] is similar to that from other tyrosine kinase receptors such as insulin and epidermal growth factor receptors. Another α-granule growth factor is connective tissue-activating peptide (CTAP) III, which stimulates fibroblast proliferation. CTAP III is a probable precursor of β thromboglobulin,[168] and its structure is related to another α-granule protein, platelet factor 4. Both platelet factor 4 and CTAP III are members of a large protein family involved in growth control and inflammation.[169] Interleukin-1 is expressed on the surface of activated platelets,[170] but the mechanism explaining its presence there is unclear.

Transforming growth factor (TGF)-β was first isolated from platelets.[171] Platelets are a rich source of this peptide mediator, which is a potent stimulus for the biosynthesis of matrix molecules and their receptors. TGF-β has complex effects on cell proliferation, stimulating cellular proliferation in some cell systems but inhibiting cellular proliferation in other systems. In addition, thrombospondin-1 is present in and secreted from platelet α granules. Released thrombospondin-1 is believed to play a role in stabilizing platelet aggregates via its interaction with platelet cell surface receptors and fibrinogen bound to integrin $\alpha_{IIb}\beta_3$.[172] Another additional important role of thrombospondin-1 is its function as an activator of TGF-β[173] and as a potent antiangiogenic factor.[174] This latter function may contribute to regulation of angiogenesis by platelets, a process that has received wide attention.[175]

Thrombospondin-1 also is produced by endothelial and smooth muscle cells, and its mRNA is inducible by growth factors such as PDGF.[176,177] Thrombospondin-1 appears to play a role in regulating the proliferation of smooth muscle cells and in angiogenesis.[178–180] Platelets also contain and can secrete vascular endothelial cell growth factor.[181] Many clinical studies have assessed the prognostic/diagnostic value of various markers, including vascular endothelial cell growth factor, in various diseases. The possibility that elevated levels of these markers reflect platelet activation in the disease must always be considered.

Multimerin is a novel platelet granule and endothelial protein that exists as massive disulfide-linked multimers of a 155-kd subunit.[182,183] Multimerin has a repeating structure, and its sequence contains the adhesive motif Arg-Gly-Asp-Ser, central coiled-coil sequences, several epidermal growth factor-like motifs, and a globular domain that is similar to a protein-binding domain found in complement C1q and in collagens type VIII and X.[184] Multimerin binds the coagulation protein factor V and its activated form factor Va. In platelets, but not in plasma, all of the biologically active factor V is complexed with multimerin.[185] Multimerin also may have functions as an extracellular matrix or adhesive protein. Members of two Canadian families with autosomal dominant bleeding disorders are deficient in platelet multimerin.[185] This large granule protein may have important roles in platelet procoagulant activity and platelet adhesion.

Lysosomal Granules and Platelet Cytosol

Platelets contain a few primary and secondary lysosomes[31,114] whose enzymes are released. However, compared with neutrophils, platelets probably are a minor source of lysosomal hydrolases in the blood. Platelet-associated heparatinase,[186] which probably is a lysosomal enzyme, can cleave vascular endothelial cell surface glycosaminoglycans, producing an antiproliferative fragment.

Factor XIII is a major transglutaminase contained in the platelet cytosol.[187] It catalyzes the formation of isopeptide bonds between the γ-glutaminyl residues and the E amino groups of lysines, forming stable covalent cross-links between proteins. Factor XIII functions in the cross-linking of fibrin as well as the cross-linking of other components of a thrombus, such as fibronectin[188] and α_2 antiplasmin,[189] to fibrin (see Chapter 118). Moreover, platelet factor XIII has been suggested to play a role in cross-linking and stabilizing cytoskeletal elements.[190,191] It is likely that small quantities of platelet factor XIIIα are released into thrombi, where it may affect their stability. Transglutaminases also have been implicated in the signaling events associated with occupancy of G protein-coupled receptors,[192,193] and many of the agonist receptors, which activate platelets, are members of this family of receptors.

Secretion

Secretion of platelet granules occurs through mechanisms analogous to those required for exocytosis of granules from neurons and mast cells. Platelet secretion is triggered by a variety of strong agonists, such as thrombin. Induction of secretion by weak agonists (e.g., ADP) occurs when the cells are brought into close contact, as occurs during aggregation.[114,194,195] The latter secretory mechanism is clearly dependent on thromboxane A_2 (TXA_2) generated as a consequence of arachidonic acid release.

Granule Exocytosis

α Granules and dense bodies, the two morphologically prominent platelet storage granules, contain a variety of substances important in platelet function. Because these granules have a limiting membrane,

the final secretory event likely involves exocytosis[196] (i.e., fusion of the secretory granule membrane with the plasma membrane). This process has been observed in dense body secretion.[197,198]

Building upon lessons learned about the role of the soluble *N*-ethylmaleimide soluble factor attachment receptor (SNARE) complex in neuronal cell exocytosis, there has been a substantial increase in our understanding of platelet secretion. Platelets have the three basic components of the SNARE machinery: t-SNAREs (target receptors), v-SNAREs (vesicle-associated membrane receptors), and soluble components (including NSF and NSF-attachment proteins).[114,195] Through a pathway involving Rab-GTPase, protein kinase C, and intracellular calcium, the SNARE machinery regulates the association and subsequent fusion of vesicles with membranes (see Fig. 115–3, *B*). Mice deficient in one of these SNAREs, VAMP-8, show defects in platelet secretion,[199,200] and certain single nucleotide polymorphisms in VAMP-8 are associated with increased susceptibility to acute myocardial infection.[201]

Platelet microparticles are vesicles that are shed from the membrane of stimulated platelets. In addition to membrane lipids, they are enriched in certain platelet membrane proteins.[202] This property allows their detection by flow cytometry.[203] They are highly procoagulant and may contribute to clinical thrombosis in diseases such as heparin-induced thrombocytopenia (see Chapter 140),[204] and their presence in blood has been correlated with coronary artery disease.[205–207]

In addition to the outward movement of granules toward the cell surface is substantial inward membrane traffic in platelets.[208–211] This inward traffic can serve to clear adhesive and procoagulant proteins from the cell surface and hence limit prothrombotic events.[212]

Eicosanoids and Arachidonate

In addition to exocytosis of platelet granules, passive release of TXA_2 from platelets is another mechanism for amplifying platelet activation. Eicosanoids are formed from the arachidonate released from membrane phospholipids by phospholipase A_2 during platelet activation.[213–215] Because the availability of arachidonate is the rate-limiting step in this process, phospholipase A_2 is tightly controlled. Platelet phospholipase A_2 is stimulated by the rise in cytosolic Ca^{2+} that accompanies platelet activation.

Once released from membrane phospholipids, arachidonate can be metabolized to TXA_2 by cyclooxygenase 1 (COX-1).[216] Aspirin acetylates COX-1, causing it to be irreversibly inactivated.[217] Because platelets lack the ability to synthesize significant amounts of protein, inactivation of COX-1 by aspirin blocks TXA_2 synthesis until new platelets are formed. Hence, aspirin is the drug most commonly used for antithrombotic therapy. A subset of patients may be "aspirin resistant," but the molecular basis of this disorder, and a universally accepted definition for this term, is uncertain.[218,219] Aspirin resistance can lead to undermedication of patients and, therefore, an increased risk for recurrent thrombotic events. Nonsteroidal antiinflammatory drugs also inactivate COX-1 but without covalently modifying the enzyme.[220]

Once formed, TXA_2 can diffuse across the plasma membrane and activate other platelets through signaling pathways. This process leads to platelet shape change, aggregation, secretion, phosphoinositide hydrolysis, protein phosphorylation, and an increase in cytosolic Ca^{2+}, with little effect on cyclic AMP formation (see Chapter 116).[221] Like ADP, TXA_2 amplifies the initial stimulus for platelet activation and helps recruit additional platelets. This process is effective locally but is limited by the short half-life of TXA_2 in solution, which helps confine the spread of platelet activation to the original area of injury.

MOLECULAR BASIS OF PLATELET AGGREGATION

Aggregation Response of Platelets

Platelets in blood, in plasma, or as an isolated cell population do not interact with one another. If an appropriate agonist is added, rapid aggregation of the platelets can ensue. Some agonists that can initiate this response are listed in Table 115–4. Of particular physiologic relevance are the platelet-derived agonists ADP, serotonin, platelet-activating factor, and arachidonate metabolites, which provide a means for stimulated platelets to recruit additional cells; collagen, which supports platelet adhesion and secretion as well as aggregation; thrombin, which links platelets and the blood coagulation system in thrombus formation; epinephrine, which permits hormonal regulation of platelet function; and vWF upon its binding to GPIb-V-IX. These agonists activate platelets by interacting with specific receptors, many of which are members of the G protein-coupled receptor class. Receptor occupancy triggers a complex series of intracellular reactions (see Chapter 116) that ultimately converge to a set of common steps that permit the cells to aggregate. Platelet aggregation is energy dependent and can be distinguished on this basis from platelet agglutination induced by ristocetin or certain platelet antibodies.

Table 115–4 Common Platelet Aggregating Agonists

Agonist	Comment
Adenosine diphosphate (ADP)	Released from platelet α-granule; acts synergistically with many other agonists
Thrombin	Formed by activation of the coagulation system
Collagen	In subendothelial matrix
Epinephrine	May allow for hormonal regulation of hemostasis
Calcium ionophore	Not naturally occurring; mobilizes calcium in platelets
Arachidonate + metabolites	Active metabolites are formed and released from stimulated platelets
Serotonin	Released from platelets, may primarily sensitize platelets to other agonists
Platelet-activating factor	Lipid mediator produced by other cells that can activate a variety of cells, including platelets

At normal blood concentrations of 1 to 3×10^8/mL, platelet suspensions are opalescent. Upon addition of an agonist, a stirred suspension of normal platelets aggregates, and a visible decrease in turbidity can be observed. Platelet aggregometers are dedicated instruments that measure the changes in light transmission through platelet suspensions and are used extensively in clinical laboratories to evaluate platelet function (see Chapter 122). Certain instruments also provide simultaneous measurements of other platelet functions, such as secretion.[194] Although the information gained from aggregometry can be extremely useful, aggregation in vitro does not necessarily reflect platelet function in vivo. In particular, clinical bleeding and the aggregation response of platelets do not necessarily coincide. This disparity reflects the importance of platelet adhesion in thrombus formation, a reaction that is not detected by aggregometry. For this reason, several instruments, which consider platelet adhesion under shear or are more quantitative for more efficient monitoring of antiplatelet therapy,[222–224] are used, but aggregometry remains a mainstay of the clinical coagulation laboratory.

A typical aggregometer tracing obtained with a suspension of isolated human platelets is shown in Fig. 115–4, *A*. From this pattern, the three essential components required for this functional response can be identified. The first component is the *platelet agonist*. The agonist used in the setup shown in Fig. 115–4 is ADP. This agonist induces platelet shape change, from a discoid to a more spherical form, a transition that can be detected in the aggregometer as a decrease in light transmission. This transformation is not a prerequisite for platelet aggregation. Epinephrine aggregates platelets but does not induce a shape change that is recordable in most conventional

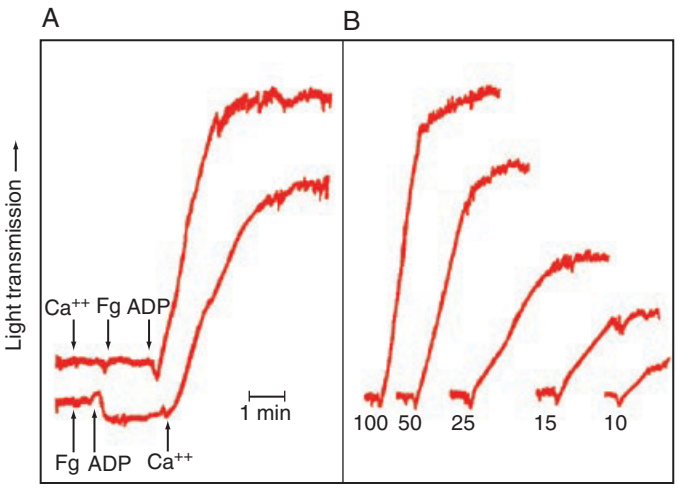

Figure 115–4 Aggregation response of human platelets. **A**, To aggregate, isolated human platelets require divalent ions (Ca^{2+}), an agonist (adenosine diphosphate [ADP], and an adhesive protein (fibrinogen [Fg]). Shape change is observed as a slight decrease in light transmission induced by ADP and is followed by an increase in transmission as the platelets aggregate. **B**, Both the rate and extent of platelet aggregation depend on the concentration of fibrinogen. The concentration of fibrinogen (in μg/mL) is indicated below each tracing.

aggregometers. At the molecular level, shape change reflects a reorganization of the platelet's actin cytoskeleton. The second component is *divalent cations*. Calcium and magnesium, as well as some other but not all divalent cations, support platelet aggregation.[225–227] The third component is *fibrinogen*. Fibrinogen not only is a major plasma protein; it also is present in and secreted from platelets (see Chapter 118).[228,229] By virtue of its capacity to form fibrin and support platelet aggregation, fibrinogen plays a dual role in thrombus formation. These activities, as well as the contribution of fibrinogen to blood viscosity, are believed to account for the increased risk of cardiovascular disease associated with elevated levels of fibrinogen.[230–232] Certain single nucleotide polymorphisms in fibrinogen have been associated with enhanced risk of myocardial infarction in some, but not all, studies.[233–235] The dependence of platelet aggregation on fibrinogen concentration is evident from the tracings shown in Fig. 115–4, *B*.

Although not evident in conventional aggregometers, vWF plays a central role in platelet aggregation and in the more complex process of thrombus formation, which entails platelet adhesion as well as aggregation. The role of vWF in platelet aggregation becomes apparent in certain pathologic circumstances such as platelet-type von Willebrand disease and type IIB von Willebrand disease (see Chapters 128 and 129).[236–240] In the setting of vascular injury in vivo, it is clear that both fibrinogen and vWF,[1–3] as well as other identified and as yet unidentified plasma and platelet molecules,[4,241] contribute to thrombus formation and stability.

Molecular Mechanisms Involved in Platelet Aggregation

The basis for the requisite roles of the agonist, calcium, and fibrinogen/vWF in platelet aggregation is well understood at the molecular level. Fibrinogen and vWF are ligands for integrin $\alpha_{IIb}\beta_3$. The absence of this integrin or its ligand binding function from the surface of platelets leads to the bleeding syndrome Glanzmann thrombasthenia, and platelet aggregation cannot be demonstrated. Further evidence for the critical role of $\alpha_{IIb}\beta_3$ in platelet aggregation and thrombus formation comes from genetically modified mice that are unable to express this receptor. These mice are unable to form a thrombus,[242] whereas mice that lack ligands for this receptor still can form a thrombus[1,2,3,4] (although excessive bleeding still occurs in these mice). Agonist is necessary to convert $\alpha_{IIb}\beta_3$ from the resting state on circulating platelets in which the integrin is unable to bind its plasma protein ligands to an activated state in which the ligands bind rapidly. All the platelet agonists listed in Table 115–4 can initiate platelet aggregation through this pathway. Calcium is needed for fibrinogen and vWF to bind to activated$\alpha_{IIb}\beta_3$. Activation of $\alpha_{IIb}\beta_3$ by agonists is very rapid. The platelet can become fully competent to bind fibrinogen/vWF via the receptor within seconds after its initial encounter with an appropriate agonist. More than 40,000 fibrinogen molecules can be bound to the platelet surface via engagement of $\alpha_{IIb}\beta_3$.[225,243–245] Fibrinogen is a dimer and vWF is a multimer. By virtue of their repeating and large structures, these ligands can bind to $\alpha_{IIb}\beta_3$ on adjacent platelets and bridge the cells together, leading to the formation of a platelet aggregate.[227,246–249]

$\alpha_{IIb}\beta_3$: Structure–Function Relationships

The resting platelet has 40,000 to 80,000 copies of $\alpha_{IIb}\beta_3$ on its surface.[250] Platelet activation can increase this number by up to 100% as a result of expression of internal pools of the receptor.[251] Each $\alpha_{IIb}\beta_3$ is capable of binding one fibrinogen molecule. $\alpha_{IIb}\beta_3$ is a typical integrin, composed of an α subunit and a β subunit, which combine to form a heterodimer.[32,34] The α subunit, α_{IIb} (GPIIb), is expressed primarily by cells of the platelet/megakaryocyte lineage, although its expression by various solid tumors and mast cells has been reported.[252–254] The β_3 subunit, GPIIIa, forms a complex not only with α_{IIb} but also with the α_V subunit to form $\alpha_v\beta_3$.[255] $\alpha_v\beta_3$ is expressed by a variety of cell types, including platelets, megakaryocytes, and endothelial cells.[256–258] These two sister receptors bind many of the same ligands and antagonists, but their specificities are not identical.[259] Complete amino acid sequences of both α_{IIb} and β_3 subunits were deduced from their cDNAs sequences.[35,38] The carbohydrate side chains and disulfide linkages also were located.[260–263] α_{IIb} is synthesized as a single chain in megakaryocytes, but it becomes proteolytically processed to the two-chain form during its transit to the cell surface.[264]

Structural biologic studies have provided significant insights into the molecular basis of the functions of $\alpha_{IIb}\beta_3$ and $a_V\beta_3$. The crystal structure of the extracellular domain of $\alpha_V\beta_3$ was solved with and without a bound peptide ligand.[265,266] A schematic model illustrating the domain organization of derived from these crystal structures is shown in Fig. 115–5. The extracellular domain of each subunit is composed of several domains, and at least one domain from each subunit directly contacts bound ligand. The primary ligand contact domain in the α subunit is the β-*propeller domain*, which is composed of seven "blades." Homologous structures are found in G proteins. In the β subunit, an A domain, also called an I domain, contacts ligand. When the β-propeller domain and the A domain come into close proximity, they form a globular head that is apparent on electron micrographs of isolated $\alpha_{IIb}\beta_3$.[267] Within the A domain of the β_3 subunit are three divalent cation-binding sites. One of these sites, termed the MIDAS, is intimately involved in ligand binding. One of the coordination sites for the cation bound within the MIDAS can be provided by an aspartic acid within the ligand. Thus, occupancy of the MIDAS cation establishes the role of divalent ions in ligand binding and platelet aggregation (Fig. 115–5). Located within the α_{IIb} and β_3 stalks, which extend out from the globular head, is a "genu," which allows bending such that the head domain can approach the cell membrane. It was this bent structure that was observed in the $\alpha_V\beta_3$ crystal structures. Subsequently, several crystal structures of portions of the extracellular domain of $\alpha_{IIb}\beta_3$ were solved.[268] They included several crystals with antagonists bound to the receptor, thus providing a clear picture as to how low-molecular-weight ligands can bind to $\alpha_{IIb}\beta_3$.

Structures for the transmembrane domains and the cytoplasmic tails have been observed or modeled.[269–273] The transmembrane segment of each subunit is composed of an α helix,[273] and evidence is clear that these transmembrane helices can interact with one

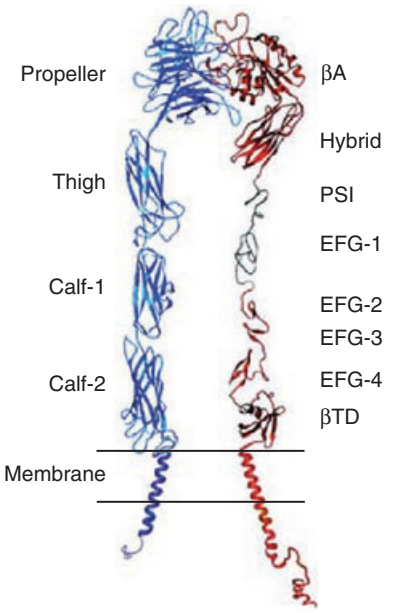

Figure 115–5 Model showing the structural organization of a β_3 integrin. The model is based on the crystal structure of the extracellular domain of $\alpha_V\beta_3$ and the cytoplasmic tails on the nuclear magnetic resonance structure of $\alpha_{IIb}\beta_3$. (Adapted from Xiong JP, Stehle T, Goodman SL, Arnaout MA: Integrins, cations and ligands: Making the connection. J Thromb Haemost 1:1642, 2003,[361] and Qin J, Vinogradova O, Plow EF: Integrin bidirectional signaling: A molecular view. PLoS Biol 2:e169, 2004.[362])

another.[274] The helices extend beyond the membrane boundary into the cytoplasm, and they also interact with one another through multiple hydrophobic and electrostatic contacts.[270]

Activation of $\alpha_{IIb}\beta_3$

$\alpha_{IIb}\beta_3$ activation is initiated by a platelet agonist and involves transmission of a signal induced by engagement of the agonist receptor to the cytoplasmic tail of the integrins. The signal is transmitted from the cytoplasmic tails through the transmembrane helices and ultimately induces a change in the extracellular domain, rendering the integrin functional. The signaling process responsible for this transformation is referred to as "inside-out" signaling.[275–277] A model for the structural basis of inside-out signaling is emerging. An integrin activator binds to the cytoplasmic tail of $\alpha_{IIb}\beta_3$ and disrupts the complex between the subunits.[270,278,279] The dissociation triggers a conformational change that is transmitted into or across the transmembrane segments and disturbs their interaction.[274] These events are transmitted to the extracellular region, allowing for acquisition of ligand competence. Within the transmembrane region, disassembly of the intramolecular interactions between helices can initiate homo-oligomerization between like subunits.[273,274,280] Consequently, the integrin heterodimers become clustered. Such clustering in itself can lead to and/or enhance activation by enhancing the avidity of the clustered extracellular domains for ligand and/or by altering the conformation of the extracellular domain.[281–283]

The crystal structures of the extracellular domain of $\alpha_V\beta_3$ are bent, with the head domain in proximity to the cell membrane.[265] This configuration was unanticipated because most electron micrographs suggested that the head domain resided at the end of long straight stalks.[267] These seemingly disparate results were reconciled in a "switchblade hypothesis," which suggested flexibility such that the integrin could exist between a bent and an extended conformation. Detailed micrographic studies supported the notion that the integrin could transit from these extreme states and could also exist in intermediate states between the fully bent and the fully extended conformation. It was further suggested that the extended conformation coincided with the activated integrin and that, in the bent state, the integrin was resting. This model provided an attractive mechanism accounting for activation of $\alpha_{IIb}\beta_3$ and integrins in general.[283] However, in a subsequent crystal structure, a macromolecular ligand, a fragment of fibronectin, was observed bound to the $\alpha_V\beta_3$ in a bent conformation.[284,285] Thus, the transition of $\alpha_{IIb}\beta_3$ from a bent to an extended conformation may occur and contribute to, but may not essential for, activation. From crystal structures of $\alpha_{IIb}\beta_3$, with or without bound ligands, differences are noted in the positioning of helices, in divalent ions in the β_3 A domain, and in movements of domains adjacent to the β_3 A domain. Such movements of structural elements relative to one another may provide local regulation of ligand binding.

Talin, a large protein intracellular protein, has been strongly implicated as a trigger of integrin activation.[286,287] Talin binds to two sites in the cytoplasmic tail of the β_3 subunit: the NPLY sequence in the midsegment of the cytoplasmic tail and a sequence in the membrane proximal region.[288–290] Its interaction with the two sites may be sequential. Its binding to the membrane proximal segment may be "unclasping," triggering separation of β_3 from the α_{IIb} cytoplasmic tail and resulting in activation.[289,290] Mice containing point mutations in the talin-binding regions of β_3 exhibit a bleeding phenotype.[291] Several other proteins bind to the NPLY sequence, and whether these function as coactivators or suppressors remains to be resolved.[292–294] Molecules that bind to the C-terminal region of β_3 or to the α_{IIb} cytoplasmic tail may regulate activation.[292] Talin itself must undergo activation in order for $\alpha_{IIb}\beta_3$ activation to be regulated, and multiple pathways involving talin activation have been identified. Thus, at this juncture, the mechanism by which inside-out signaling triggers activation of $\alpha_{IIb}\beta_3$ appears to be complex.[104,287,295–297]

Several mechanisms can be envisioned to explain how fibrinogen binding to $\alpha_{IIb}\beta_3$ results in platelet aggregation. The simplest possibility is that a single fibrinogen molecule, by virtue of its dimeric structure, bridges two $\alpha_{IIb}\beta_3$ molecules symmetrically on adjacent platelets. Evidence supporting this possibility is available.[298–300] Because multiple sites within each fibrinogen molecule can be recognized by $\alpha_{IIb}\beta_3$ (see Recognition Specificity and Antagonism of $\alpha_{IIb}\beta_3$), asymmetric variations of direct bridging can be envisioned. Still another possibility is that changes subsequent to fibrinogen binding are required for platelet aggregation. Irreversible fibrinogen binding,[227] conformational changes in bound fibrinogen[203,301] and in occupied $\alpha_{IIb}\beta_3$,[302] clustering of fibrinogen/$\alpha_{IIb}\beta_3$,[303] and additional interactions of the receptor with the cytoskeleton of the cells[304–306] occur after initial binding of fibrinogen to the cells. Moreover, a series of intracellular signaling events, including tyrosine and serine/threonine kinase and phosphatase activation, are initiated and propagated as a consequence of receptor occupancy and platelet aggregation.[275,276] These events are referred to as "outside-in" signaling. Whether such postreceptor occupancy events play a direct role in platelet aggregation is unknown, However, circumstances in which fibrinogen is bound to $\alpha_{IIb}\beta_3$ without induction of platelet aggregation have been described,[275] and mice in which the tyrosine phosphorylation sites in the β_3 subunit have been mutated showed decreased thrombus stability,[307] which implies a role for outside-in signals in platelet aggregation.

Recognition Specificity and Antagonism of $\alpha_{IIb}\beta_3$

Linear amino acid sequences define the recognition specificity of $\alpha_{IIb}\beta_3$ (Table 115–5). One peptide corresponds to the extreme COOH-terminus of the γ chain,[298,308] one of the three constituent chains of fibrinogen. The recognized amino acid sequence may be as small as the extreme six amino acid residues.[309] The second peptide is as small as four amino acids and contains the following three amino acids in sequence: arginyl-glycyl-aspartic acid (RGD).[310–313] RGD sequences occur in two sites within the Aα chain of fibrinogen.[314] RGD sequences are also found in a variety of other proteins, including several that bind to $\alpha_{IIb}\beta_3$. In addition, several other integrin receptors recognize RGD sequences within their ligands.[32,315–319]

Table 115–5 Recognition Peptides of $\alpha_{IIb}\beta_3$[a]

Peptide Designation	Structure[b]
Fibrinogen γ-chain	-XXKQAGDV
RGD	RGDX

[a]The naturally occurring sequences in human fibrinogen; S (serine) or F (phenylalanine) at the COOH-terminus of the two RGD sequences within the α chain; and H (histidine)—H-L (leucine)—G-G-A at the NH_2-terminus of the γ-chain peptide.

[b]Amino acids: K, lysine; Q, glutamine; A, alanine; G, glycine; D, aspartic acid; V, valine; X, one of several amino acids.

Thus, the RGD amino acid sequence is a broadly used recognition code in cellular adhesive reactions. RGD with specific flanking residues can react selectively with individual integrins, and it was one such peptide that was crystallized in complex with $\alpha_V\beta_3$.[266] In contrast, the γ-chain sequence appears to be unique to fibrinogen. Synthetic peptides containing either the γ-chain peptide sequence or the RGD sequence interact directly with $\alpha_{IIb}\beta_3$ and bind to the same or mutually exclusive sites within the receptor.[320,321] Crystal structures of $\alpha_{IIb}\beta_3$ with mimetics of these two peptide sequences suggest a similar binding mechanism,[268] but allosteric effects for additional binding sites for each cannot be excluded,[322] and allosteric inhibitors of ligand binding to integrins have been identified.[323] The preponderance of evidence indicates that the COOH-terminus of the γ chain is critical for fibrinogen binding to $\alpha_{IIb}\beta_3$.[324–326] Nevertheless, in the design of $\alpha_{IIb}\beta_3$ antagonists, the RGD sequence has often served as the starting compound because of its smaller size.[327] The characterization of these two sequences does not exclude that other sequences are involved in fibrinogen binding to $\alpha_{IIb}\beta_3$. Evidence indicates that additional sequences are involved in the recognition of fibrinogen by $\alpha_{IIb}\beta_3$.[328]

Fibrinogen is not the only ligand that binds to $\alpha_{IIb}\beta_3$. Several other adhesive proteins that can serve as ligands are listed in Table 115–2. All of these adhesive proteins contain at least one RGD sequence. RGD peptides interfere with binding of fibronectin[310,313] and bind of vitronectin[329] to platelets. Because plasma fibrinogen concentrations are 10-fold higher than its dissociation constant for $\alpha_{IIb}\beta_3$, under physiologic conditions, the receptor is nearly saturated with fibrinogen. Thus, fibrinogen is the dominant ligand for $\alpha_{IIb}\beta_3$ in this environment. However, all of these ligands, except fibrinogen, are present in subendothelial cell matrices, and these other interactions may dominate in this microenvironment. Because vWF is bound to platelets via GPIb-V-IX, it resides in close proximity to $\alpha_{IIb}\beta_3$ on the platelet surface, and this proximity may favor its engagement by $\alpha_{IIb}\beta_3$. In addition to its role in platelet aggregation, $\alpha_{IIb}\beta_3$ may be involved in platelet adhesion, particularly in stabilizing cell–matrix interactions.[330] It may be in this latter function that these other $\alpha_{IIb}\beta_3$ ligands play a key role. Thrombospondin-1 associates with the surface of resting and stimulated platelets.[331–333] On the surface, it plays an auxiliary role in platelet aggregation by stabilizing platelet aggregates.[334] This activity may arise from its capacity to bind to fibrinogen.[172,335] Several candidate receptors for thrombospondin have been proposed,[305,336–339] and the interaction may be mediated by a complex of several of these candidate receptors, including CD36, integrin-associated protein, and $\alpha_{IIb}\beta_3$.[340] Complexation of $\alpha_{IIb}\beta_3$ with other platelet membrane proteins (e.g., CD9,[341–343] CD40L,[241] Gas6[157]) also may play a role in controlling its activation, ligand-binding functions, and platelet responses in general. Increasing evidence indicates that a number of these and other membrane proteins in platelets can influence the adhesive responses of platelets in vitro and in vivo.[344]

Throughout the 1980s, a number of compounds that bound to $\alpha_{IIb}\beta_3$ and inhibited platelet aggregation were described. Furthermore, bleeding in patients with Glanzmann thrombasthenia was noted to be relatively mild. These observations led to the notion that blockade of $\alpha_{IIb}\beta_3$ might represent a new antithrombotic strategy. This realization spawned development programs throughout the pharmaceutical industry.[345,346] Antagonists of ligand binding to $\alpha_{IIb}\beta_3$ that were identified included monoclonal antibodies, small peptide ligands, and nonpeptidic ligand mimetics. Representatives of these classes of antagonists were evaluated in various animal models of thrombosis and in large clinical trials.[347–354] Three such agents, all intravenous drugs, ultimately were approved by the U.S. Food and Drug Administration for use in patients. Abciximab is a Fab fragment of a humanized monoclonal antibody; eptifibatide is a cyclic peptide based on the sequence of a snake venom peptide; and tirofiban is a nonpeptide that was designed with RGD as a starting structure. In 2007, all three $\alpha_{IIb}\beta_3$ antagonists continued to be used in patients, primarily in the setting of coronary interventions to prevent periprocedural thrombosis.[355,356] The broader use of these agents in acute coronary syndromes has been supplanted by clopidogrel and anticoagulants.[357,358] There was great optimism that orally active $\alpha_{IIb}\beta_3$ antagonists would be of great benefit for chronic antithrombotic therapy. A number of drugs with excellent pharmokinetic properties were developed. However, several drugs tested in clinical trials proved to be ineffective or even detrimental.[359] The reason for the failure of these oral antagonists was not fully understood. One explanation that received broad acceptance is that patients were underdosed to avoid safety issues, but this in itself would not explain detrimental effects. Another suggestion was that these drugs leave $\alpha_{IIb}\beta_3$ in an activated state as they dissociate from the receptor.[360] Regardless of the explanation, the initial clinical trials dampened the entire effort throughout the pharmaceutical industry to develop orally active $\alpha_{IIb}\beta_3$ antagonists, and all such programs were abandoned. It does appear that the intravenous $\alpha_{IIb}\beta_3$ antagonists are effective in preventing acute thrombosis in the context of coronary interventions. With approximately 800,000 such procedures performed annually, use of the approved $\alpha_{IIb}\beta_3$ antagonists remains significant.

CHAPTER 116

THE MOLECULAR BASIS OF PLATELET ACTIVATION

Lawrence F. Brass

Platelets have evolved as a means to respond to holes in a high-pressure, high-flow circulatory system. Many of the most pertinent properties of platelets, including their shape, the contents of their secretory granules, their high density of regulated adhesion receptors, and their ability to promote thrombin generation, are optimized to form a stable hemostatic plug under high-flow conditions. To be maximally useful, circulating platelets must be able to sustain repeated contact with the normal vessel wall without premature activation, recognize the unique features of a damaged wall, cease their forward motion upon recognition of damage, adhere despite the forces produced by continued arterial blood flow, and aggregate to each other, forming a stable plug of the correct size that can remain in place until it is no longer needed.

This chapter discusses how platelet activation begins and how platelets help to produce a stable hemostatic plug. The contribution of platelets to hemostasis is different in arteries and veins. In the venous system, low flow rates and stasis permit the accumulation of activated coagulation factors and the local generation of thrombin largely without the benefit of platelets. Although venous thrombi contain platelets, the dominant cellular components are trapped red cells. In the arterial circulation, higher flow rates limit fibrin formation by washing out soluble clotting factors. Hemostasis in the arterial circulation requires platelets to form a physical barrier, to accelerate thrombin formation, and to provide a base upon which fibrin can accumulate. Platelets work best under high shear conditions. As a result, thrombi formed in the arterial circulation are enriched in platelets as well as fibrin.

THREE STAGES IN PLATELET PLUG FORMATION

Platelet activation can be divided into three overlapping stages: initiation, extension, and perpetuation (Fig. 116–1). *Initiation* can occur in more than one way. In the setting of trauma to the vessel wall, it may occur because circulating platelets are captured and then activated by exposed collagen decorated with von Willebrand factor (VWF) multimers, thereby forming a monolayer that supports thrombin generation and the subsequent piling on of additional platelets. A key to these events is the presence of receptors on the platelet surface that can support the VWF-dependent capture of tumbling platelets (glycoprotein Ib/IX/V [GPIb-IX-V] and, to a lesser extent, $\alpha_{IIb}\beta_3$) and the subsequent intracellular signaling (via GPVI and $\alpha_2\beta_1$) that causes captured platelets to spread on the vessel wall and provide a nidus for subsequent platelet–platelet interactions. Imagine a flexible patch in which the surface in contact with the vessel wall optimizes its ability to stick to collagen, while the luminal surface acquires the ability to stick to other platelets, forming a plug. Platelet activation, particularly in thrombotic or inflammatory disorders, can also be initiated by thrombin, which activates platelets via G protein-coupled receptors (GPCRs) in the protease-activated receptor (PAR) family. *Extension* occurs when additional platelets are recruited and activated, sticking to each other and accumulating on top of the initial monolayer. Thrombin can play an important role at this point, as can secreted adenosine diphosphate (ADP) and released thromboxane A_2 (TxA_2). Each of these agonists is able to activate phospholipase C (PLC), causing an increase in the cytosolic Ca^{2+} concentration within platelets. The receptors that mediate this response are also members of the GPCR superfamily. The signals that they engender support the activation of integrin $\alpha_{IIb}\beta_3$, making possible the cohesive interactions between platelets that are critical to the formation of the hemostatic plug. ADP receptors have proved a fruitful target for antiplatelet agents, just as inhibition of TxA_2 generation has been a clinically useful target for aspirin. *Perpetuation* refers to the late events of platelet plug formation, when the intense, but often time-limited, signals arising from GPCRs may have faded. These late events help to stabilize the platelet plug and prevent premature disaggregation. Such events typically occur after aggregation has begun and are facilitated by close contacts between platelets. Examples include outside-in signaling through integrins and other cell adhesion molecules, and signaling through receptors whose ligands are located on the surface of adjacent platelets.

The platelet surface is crowded with receptors that are critical for hemostasis. Those that are directly involved in binding to collagen, VWF, or fibrinogen are expressed in the greatest numbers. Approximately 80,000 copies of integrin $\alpha_{IIb}\beta_3$ and 15,000 to 25,000 copies of GPIb-IX-V are present on the surface of human platelets. In contrast, receptors for thrombin, ADP, and TxA_2 range from a few hundred to a few thousand per platelet (Table 116–1). Many of these receptors float within the lipid bilayer; others are anchored via interactions with the membrane skeleton. Receptor distribution rarely is uniform. Some receptors tend to accumulate in cholesterol-enriched microdomains.[1–5] This position may increase the efficiency with which platelets are activated. Lateral mobility also may allow adhesion and cohesion receptors to accumulate at sites of contact.

Stage I: Initiation Platelet Activation

Although many molecules have been shown to cause platelet activation in vitro, platelet activation in vivo typically is initiated by collagen and thrombin. This may take place at a site of acute vascular injury where platelet plug formation serves to stop bleeding, but the same platelet responses can be invoked in pathologic states in which thrombin or other platelet-activating molecules are formed or exposed. Thrombin is generated at sites of vascular injury after exposure of tissue factor that is sequestered within the vessel wall, upregulated on the surface of activated monocytes and endothelial cells, or carried in the circulation on microvesicles. In pathologic states, tissue factor expression can be upregulated on the surface of endothelial cells or monocytes. Tissue factor may also be present on circulating, monocyte-derived microvesicles that bind to activated platelets at sites of injury.[6–8]

Under static conditions, collagen is able to capture and activate platelets without the assistance of cofactors, but under the flow conditions that exist in the arterial circulation VWF plays an essential role in supporting platelet adhesion and activation. Platelets can adhere to monomeric collagen but require the more complex structure found in fibrillar collagen for optimal activation. Four receptors for collagen have been identified on the surface of human and mouse platelets. Two bind directly to collagen ($\alpha_2\beta_1$ and GPVI). The other two bind to collagen via VWF ($\alpha_{IIb}\beta_3$ and GPIb-IX-V; Fig. 116–2). Of these four receptors, GPVI is the most potent in terms of initiating signal generation. The structure of GPVI places it in the immunoglobulin domain superfamily.[9] The ability of GPVI to generate signals rests

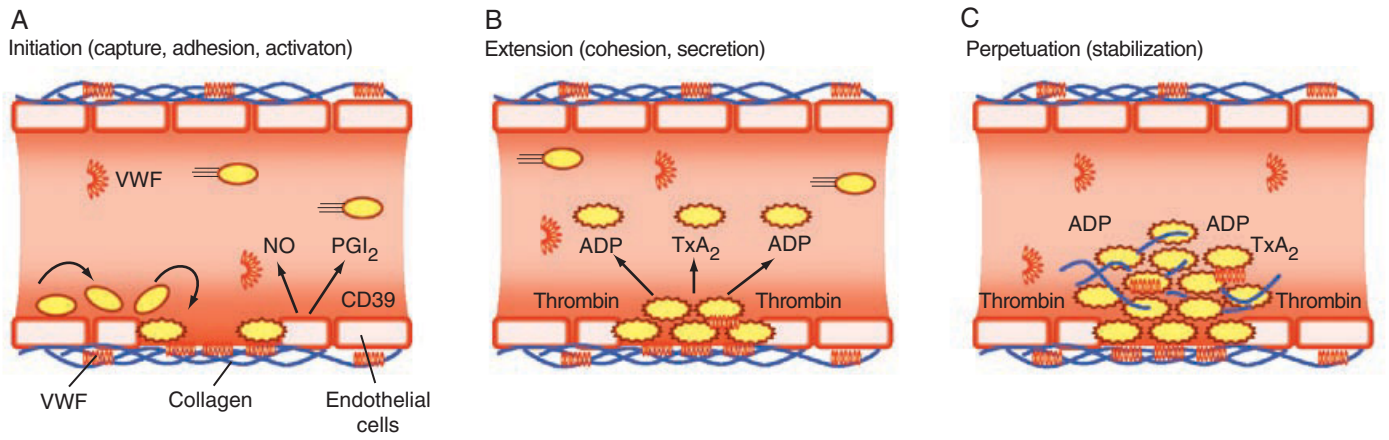

Figure 116–1 Stages in platelet plug formation. Prior to vascular injury, platelet activation is suppressed by endothelial cell-derived inhibitory factors. They include prostaglandin I_2 (PGI_2 [prostacyclin]), nitric oxide (NO), and CD39, an ADPase on the surface of endothelial cells that can hydrolyze trace amounts of ADP that otherwise might cause inappropriate platelet activation. **A,** Initiation. Development of the platelet plug is initiated by thrombin and by the collagen–von Willebrand factor (VWF) complex, which captures and activates moving platelets. Platelets adhere and spread, forming a monolayer. **B,** Extension. The platelet plug is extended as additional platelets are activated via the release or secretion of thromboxane A_2 (TxA_2), ADP, and other platelet agonists, most of which are ligands for G protein-coupled receptors on the platelet surface. Activated platelets stick to each other via bridges formed by the binding of fibrinogen, fibrin, or VWF to activated $\alpha_{IIb}\beta_3$. **C,** Perpetuation. Close contacts between platelets in the growing hemostatic plug, along with a fibrin meshwork (shown in red), help to perpetuate and stabilize the platelet plug.

Table 116–1 G Protein-Coupled Receptors Expressed on Human Platelets

Agonist	Receptor	G protein Families	Approximate Number of Copies Per Platelet
Thrombin	PAR1	G_q, G_i, G_{12}[a]	2000
	PAR4	G_q, G_{12}[a]	?
ADP	$P2Y_1$	G_q, G_{12}	150
	$P2Y_{12}$	G_i (particularly G_{i2})	600
TxA_2	TPα/β	G_q, G_{12}	1000
Epinephrine	α_{2A}-adrenergic	G_i (particularly G_z)	300
PGI_2	IP	G_s	?

[a]The assignment of G_q and G_{12} but not G_i family members to PAR4 is by inference. Selective PAR4 agonists cause platelet aggregation and shape change but do not appear to inhibit adenylyl cyclase. In contrast, PAR1 has been shown to couple to G_i in platelet membrane preparation but appears to do so less well in intact platelets.

ADP, adenosine diphosphate; PAR, protease-activated receptor; PGI_2, prostaglandin I_2; TxA_2, thromboxane A_2.

on its constitutive association with the Fc receptor γ chain. Platelets that lack either GPVI or the γ chain have impaired responses to collagen, as do platelets in which GPVI has been depleted or blocked.[10–13] The $\alpha_2\beta_1$ integrin also appears to be necessary for optimal interaction with collagen. Human platelets with reduced expression of $\alpha_2\beta_1$ have impaired collagen responses,[14,15] as do mouse platelets that lack β_1 integrins when the ability of these platelets to bind to collagen is tested at high shear.[13,16]

According to current models, collagen causes clustering of GPVI. This leads to phosphorylation of FcRγ by tyrosine kinases in the Src family, creating a tandem phosphotyrosine motif recognized by the Src homology 2 (SH2) domains of Syk. Association of Syk with the GPVI/γ-chain complex activates Syk and leads to phosphorylation and activation of PLCγ2. Much of the initial response of platelets to agonists consists of activating PLC. PLCγ2, like other PLC isoforms, hydrolyzes phosphatidylinositol-4,5-bisphonate (PIP_2) to form 1,4,5-inositol triphosphate (IP_3) and diacylglycerol. IP_3 opens Ca^{2+} channels in the platelet-dense tubular system, raising the cytosolic Ca^{2+} concentration and triggering Ca^{2+} influx across the platelet plasma membrane. The changes in cytosolic Ca^{2+} concentration that occur when platelets adhere to collagen under flow can be visualized in real time.[17,18] Diacylglycerol activates the conventional and novel protein kinase C (PKC) isoforms that are expressed in platelets, allowing regulatory serine/threonine phosphorylation events.

Collectively, collagen receptors support the capture of fast-moving platelets at sites of injury, cause activation of captured platelets, and stimulate cytoskeletal reorganization that allows the previously discoid platelets to flatten out and adhere more closely to the exposed vessel wall. VWF supports this process by increasing the density of potential binding sites for collagen per platelet, especially under the conditions of flow, which stretches out VWF multimers and exposes the platelet binding sites on each monomer. This increases the likelihood that platelets will encounter an available binding site and, once bound, will be able to increase the number of contacts with collagen by bringing additional receptors into play. It appears likely that only GPVI and GPIb-IX-V are able to bind collagen and VWF, respectively, without prior platelet activation, However, once activation begins, $\alpha_2\beta_1$and $\alpha_{IIb}\beta_3$ are able to bind their respective ligands as well. Some integrin-activating signaling occurs downstream of GPVI, but growing evidence indicates that the GPIb-IX-V complex also can signal, as can $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ once they are engaged. Given these findings, it is perhaps not surprising that impairment of platelet receptors for collagen or loss of functional VWF produces defects in hemostasis that range from modest to profound, depending on the degree of impairment or the extent of VWF deficiency.

Stage II: Extension of the Platelet Plug

The formation of a platelet monolayer following exposure of collagen and VWF is sufficient to initiate platelet plug formation but is not sufficient to prevent bleeding. The next step is extension of the platelet plug by having one platelet stick to another, a process that technically is termed *cohesion* but commonly is referred to as *platelet aggregation* when it is studied ex vivo with the platelets in suspension. Recruitment of additional platelets beyond those in the collagen-bound monolayer is made possible by local accumulation of agonists that are secreted or released from platelets, such as ADP and TxA_2, and by local generation of thrombin (Fig. 116–1, *B).* Contacts between platelets are maintained by a variety of cohesive interactions, of which the most essential is the binding of fibrinogen or VWF to activated $\alpha_{IIb}\beta_3$. Circulating or locally secreted catecholamines can

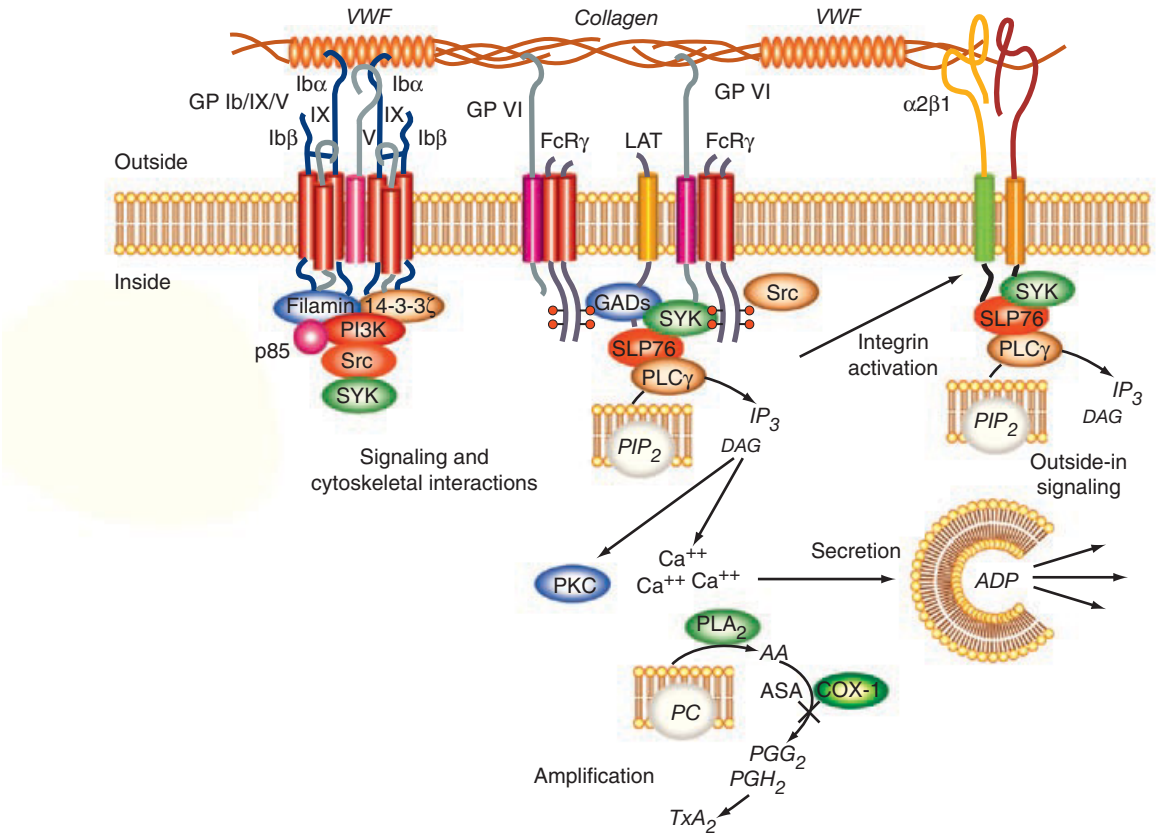

Figure 116–2 Platelet activation by collagen. Platelets use several different molecular complexes to support platelet activation by collagen. They include von Willebrand factor (VWF)-mediated binding of collagen to the glycoprotein Ib/IX/V (GPIb-IX-V) complex and integrin $\alpha_{IIb}\beta_3$, a direct interaction between collagen and both the integrin $\alpha_2\beta_1$, and the GPVI/γ-chain complex. Clustering of GPVI results in phosphorylation of tyrosine residues in the γ chain, followed by binding and activation of the tyrosine kinase Syk. One consequence of Syk activation is phosphorylation and activation of phospholipase Cγ, leading to phosphoinositide hydrolysis, secretion of ADP, and production and release of thromboxane A_2 (TxA_2). AA, arachidonic acid; ADP, adenosine diphosphate; ASA, aspirin; COX-1, cyclooxygenase 1; DAG, diacylglycerol; GP, glycoprotein; IP_3, inositol triphosphate; PC, phosphatidylcholine; PG, prostaglandin; PI3K, phosphatidylinositol 3-kinase; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLA_2, phospholipase A_2; PLCγ, phospholipase Cγ; VWF, von Willebrand factor.

cause vasoconstriction but also can promote platelet activation by potentiating the effects of other platelet agonists. Inherited or acquired defects in cohesion can produce significant risk of bleeding. Two examples are Glanzmann thrombasthenia, in which affected patients lack functional $\alpha_{IIb}\beta_3$ and therefore cannot bind fibrinogen or other cognate ligands, and administration of $\alpha_{IIb}\beta_3$ antagonists, which work as antiplatelet agents by blocking ligand binding.

Most of the agonists that extend the platelet plug do so via GPCRs. The properties of these receptors make them particularly well suited for this task. First, most GPCRs bind their ligands with high affinity. Second, they typically are composed of a single subunit, although receptor dimerization can affect the ligand preferences of the receptor. Third, they are constitutively associated with G proteins, reducing the time that otherwise would be required to recruit them into signaling complexes.[19] Fourth, because they act as guanine nucleotide exchange factors, each occupied receptor theoretically can activate multiple G proteins and, in some cases, more than one class of G proteins. This allows amplification of a signal that might begin with a relatively small number of receptors. It also potentially allows each receptor to signal via more than one effector pathway. Finally, because several mechanisms exist that can limit the activation of GPCRs, platelet activation can be regulated, a property that may be useful when platelet activation is inappropriate and must be controlled.

GPCRs are composed of a single polypeptide chain with seven transmembrane domains, an extracellular N-terminus, and an intracellular C-terminus.[20] Binding sites for agonists may involve the N-terminus, the extracellular loops, or a pocket formed by the transmembrane domains. The G proteins that act as mediators for these receptors are αβγ heterotrimers. The β subunit forms a propeller-like structure that is tightly associated with the smaller γ subunit. The α subunit contains a guanine nucleotide binding site that normally is occupied by guanosine 5′-diphosphate (GDP). Receptor activation causes the replacement (exchange) of the GDP by guanosine 5′-triphosphate (GTP), altering the conformation of the α subunit and exposing sites on both G_α and $G_{\beta\gamma}$ for interactions with downstream effectors. Hydrolysis of GTP by the intrinsic GTPase activity of the α subunit restores the resting conformation of the heterotrimer, preparing it to undergo another round of activation and signaling. Regulator of G-protein signaling (RGS) proteins accelerate the hydrolysis of GTP by α subunits, shortening signaling duration.[21]

Human platelets express at least 10 forms of G_α that fall into the $G_{s\alpha}$, $G_{i\alpha}$, $G_{q\alpha}$, and $G_{12\alpha}$ families. This includes at least one $G_{s\alpha}$ family member, four $G_{i\alpha}$ family members ($G_{i1\alpha}$, $G_{i2\alpha}$, $G_{i3\alpha}$, and $G_{z\alpha}$), three $G_{q\alpha}$ family members ($G_{q\alpha}$, $G_{11\alpha}$, and $G_{16\alpha}$), and two $G_{12\alpha}$ family members ($G_{12\alpha}$ and $G_{13\alpha}$). Much has been learned about the critical role of G protein α subunits in platelets. Much less is known about the $G_{\beta\gamma}$ isoforms that are expressed in platelets and the selectivity of their contributions to platelet activation.[22]

G Protein-Mediated Signaling In Platelets

The signaling events that underlie platelet activation have not been fully identified. Large gaps remain in signaling maps that attempt to

connect receptors on the platelet surface with the most characteristic platelet responses: shape change, aggregation, and secretion. In general terms, the events that have been described to date can be divided into three broad categories. The first begins with activation of PLC, which by hydrolyzing membrane PIP_2 produces the second messengers needed to raise the cytosolic Ca^{2+} concentration. Which isoform of PLC is activated varies with the agonist. Collagen activates PLCγ2 using a mechanism that depends on adaptor molecules and protein tyrosine kinases. Thrombin, ADP, and TxA_2 activate PLCβ isoforms using G_q and (less efficiently) the G_i family as intermediaries. Regardless of which isoform is activated, the subsequent rise in Ca^{2+} concentration triggers downstream events, which include integrin activation and generation of TxA_2.

The second broad category of necessary events involves monomeric G proteins in the cdc42/Rac/Rho family, whose activation triggers reorganization of actin cytoskeleton and allows the formation of filopodia and lamellipodia. Along with changes in the platelet's circumferential microtubular ring, this step is the essence of shape change. Most platelet agonists can trigger shape change, with the notable exception of epinephrine. The soluble agonists (thrombin, ADP, and TxA_2) that trigger shape change typically act through receptors that are coupled to members of the G_q and G_{12} families.

A third category of required events for platelet is mediated by G_i family members and includes suppression of cyclic adenosine monophosphate (cAMP) formation and activation of phosphatidylinositol 3-kinase (PI3K). Suppression of cAMP synthesis relieves a block on platelet signaling that otherwise limits inopportune platelet activation, particularly in the presence of endothelial cell-derived prostaglandin (PG) I_2 and nitric oxide. The agonists that inhibit cAMP formation in platelets (ADP and epinephrine) do so by binding to receptors coupled to the G_i family members. Suppression of adenylyl cyclase is critical when cAMP levels are elevated, but whether it is necessary under basal cAMP conditions is less clear.

Platelet Activation In vivo

Slicing the events of platelet activation into individual pathways that are activated or suppressed by individual agonists is a didactic convenience. In vivo, however, platelet activation typically results from contact with more than one agonist. The initial injury may expose collagen, but it also will produce thrombin. Similarly, tissue and red cell damage will release ADP, as will activated platelets, which will also synthesize and release TxA_2. Remember that different agonists couple to different pathways with differing efficiencies, and it is the combined effect of multiple agonists that produces the most robust platelet activation. Even thrombin, one of the most potent platelet agonists, relies on its ability to induce ADP and TxA_2 release to yield maximal platelet activation when used at lower concentrations in vitro. This is particularly important because endogenous antagonists of platelet activation, including PGI_2, antithrombin III, the *ecto*-ADPase CD39, and the diluting effects of continued blood flow, work against the accumulation of platelet agonists and limit the ability of platelets to respond.

G_q and Activation of Phospholipase Cβ

Agonists whose receptors are coupled to G_q can provide a strong stimulus for platelet activation by activating PLCβ. PLCβ hydrolyzes membrane PI-4,5-P_2 to produce 1,4,5-IP_3 and diacylglycerol (Fig. 116–3). IP_3 formation triggers an increase in cytosolic Ca^{2+}. Diacylglycerol activates PKC. In resting platelets, the cytosolic Ca^{2+} concentration is maintained at approximately 100 nM by limiting Ca^{2+} influx and by pumping Ca^{2+} out of the cytosol across the plasma membrane or into the dense tubular system. The latter is a closed membrane compartment within platelets thought to be derived from megakaryocyte smooth endoplasmic reticulum. In activated platelets, the cytosolic free concentration can exceed 1 μM (a 10-fold increase over baseline) with potent agonists such as thrombin. Activation of PLC also releases membrane-associated proteins that bind to PI-4,5-P_2 via their pleckstrin homology (PH) domains. PLCβ-activating α subunits typically are derived from G_q in platelets, but PLC also can be activated by $G_{\beta\gamma}$ derived from G_i family members.

The rising Ca^{2+} concentration in activated platelets is a trigger for numerous events, but one that has received recent attention is Ca^{2+}-dependent activation of the Ras family member Rap1B via the guanine nucleotide exchange protein Cal-DAG GEF.[23] Rap1B has been shown to be an important contributor to signaling pathways that converge on activation of $\alpha_{IIb}\beta_3$ in platelets.[24–26] PKC isoforms are serine/threonine kinases. PKC has been identified as the cellular receptor for the lipid second messenger diacylglycerol; therefore, it is a key enzyme in the signaling events that follow activation of receptors coupled to PLC. PKC isoforms phosphorylate multiple cellular proteins on serine and threonine residues.

G_q, G_{13}, and Actin Cytoskeleton

At least two effector pathways are involved in the reorganization of actin cytoskeleton that accompanies platelet activation: Ca^{2+}-dependent activation of myosin light chain kinase downstream of G_q family members and activation of low-molecular-weight GTP-binding proteins in the Rho family, which occurs downstream of G_{12} family members (Figs. 116–3 and 116–4).[27,28] Several proteins having both G_α-interacting domains and guanine nucleotide exchange factor (GEF) domains can link G_{12} family members to Rho family members. One example is p115RhoGEF, but others exist as well.[29] With the exception of ADP, shape change persists in platelets from mice that lack $G_{q\alpha}$[30] but is lost when $G_{13\alpha}$ expression is suppressed, alone or in combination with $G_{12\alpha}$.[31,32] Put somewhat differently, loss of $G_{q\alpha}$ expression prevents shape change when mouse platelets are activated by ADP. Loss of $G_{13\alpha}$ expression (but not loss of $G_{12\alpha}$ expression alone) suppresses shape change in response to thrombin and TxA_2.

These results indicate that for most platelet agonists, G_{13} signaling is essential for shape change and that the events underlying shape change are invoked by a combination of G_{13}- and G_q-dependent signals. A combination of inhibitor and genetic approaches suggests that G_{13}-dependent Rho activation leads to shape change via pathways that include the Rho-activated kinase p160ROCK and LIM kinase.[27,33,34] These kinases phosphorylate myosin light chain kinase and cofilin, helping to regulate both actin filament formation and myosin (see Fig. 16–4). ADP, on the other hand, depends more heavily on G_q-dependent activation of PLC to produce shape change and is able to activate G_{13} only as a consequence of TxA_2 generation, hence the loss of ADP-induced shape change when G_q signaling is suppressed.

G_i Family Members and Their Effectors

Rising cAMP levels turn off signaling in platelets, and an increase in cAMP synthesis is one of the mechanisms by which endothelial cells prevent inappropriate platelet activation. Regulatory molecules released from endothelial cells cause $G_{s\alpha}$-mediated increases in adenylyl cyclase activity (PGI_2) and inhibit hydrolysis of cAMP by phosphodiesterases (nitric oxide). When added to platelets in vitro, PGI_2 can cause a 10-fold or greater increase in the platelet cAMP concentration, but even relatively small increases in cAMP levels (twofold or less) can impair thrombin responses.[35] Many platelet agonists inhibit PGI_2-stimulated cAMP synthesis by binding to receptors that are coupled to one or more G_i family members (Fig. 116–5). Human platelets express four members of the G_i family: G_{i1}, G_{i2}, G_{i3}, and G_z. Deletion of the genes encoding $G_{i2\alpha}$ or $G_{z\alpha}$ increases the basal cAMP concentration in mouse platelets. Conversely, loss of PGI_2 receptor (IP) expression causes a decrease in basal cAMP levels, enhances responses to agonists, and predisposes mice to thrombosis in arterial injury models.[36,37]

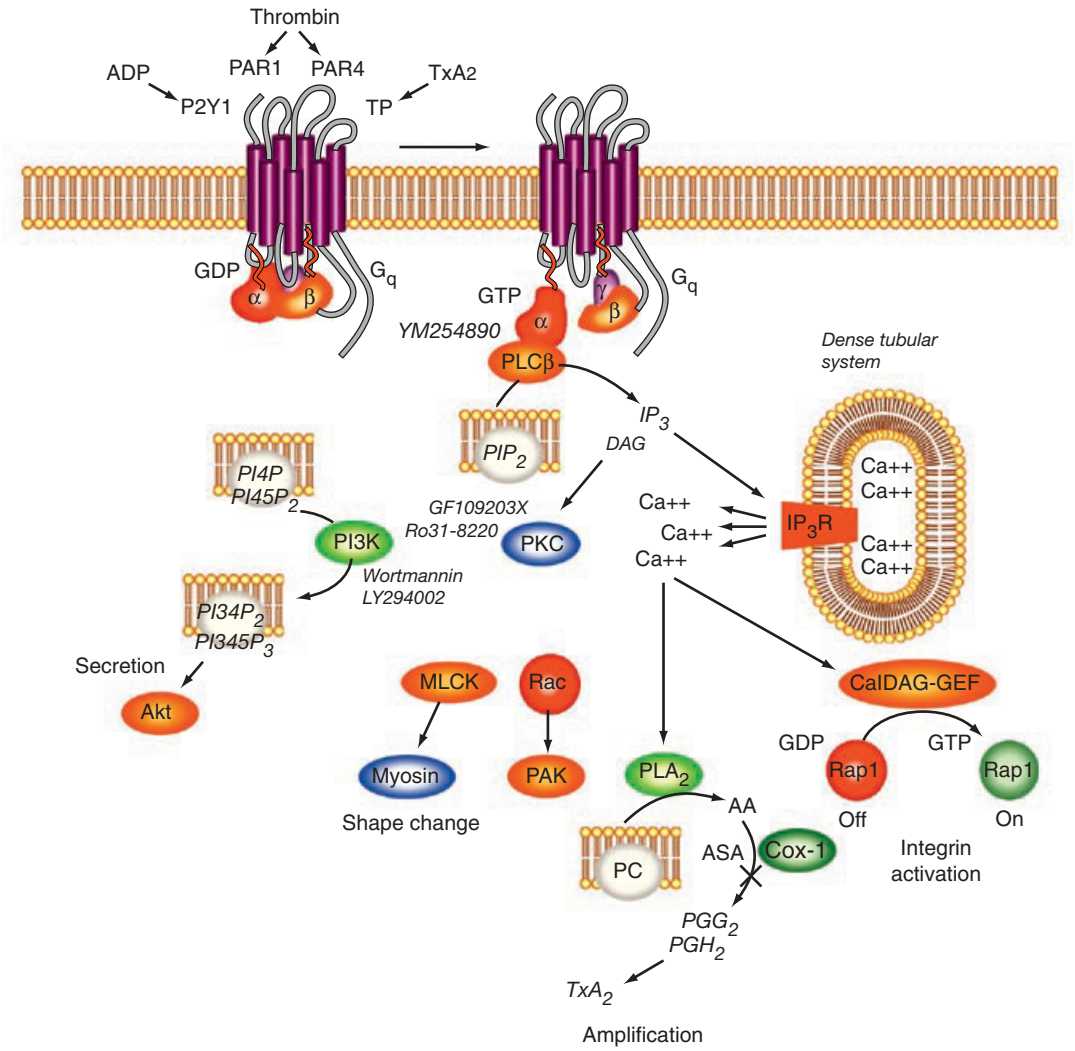

Figure 116–3 G_q signaling in platelets. Agonists whose receptors are coupled to G_q are able to activate phospholipase Cβ (PLCβ) via $G_{q\alpha}$. The potency with which activation occurs varies depending on the agonist, with thrombin and thromboxane A_2 (TxA_2) providing a stronger stimulus for PLCβ-mediated phosphoinositide hydrolysis than adenosine diphosphate (ADP). Thrombin activates two G_q-coupled receptors on human platelets, protease-activated receptor 1 (PAR1) and protease-activated receptor 4 (PAR4), which differ somewhat in the kinetics of PLC activation. YM254890 inhibits PLC activation by G_q.[140,141] GF109203X and Ro31–8220 are protein kinase C (PKC) inhibitors.[142] Wortmannin and LY294002 are phosphatidylinositol 3-kinase (PI3K) inhibitors. AA, arachidonic acid; ASA, aspirin; COX-1, cyclooxygenase 1; DAG, diacylglycerol; GDP, guanosine 5′-triphosphate; GTP, guanosine 5′-triphosphate; IP_3R, receptor for 1,4,5-inositol triphosphate; MLCK, myosin light chain kinase; PAK, p21-activated kinase; PG, prostaglandin; PI3K, phosphatidylinositol 3-kinase; PIP_2, phosphatidylinositol-4,5-bisphosphate; PLA_2, phospholipase A_2; PLCβ, phospholipase Cβ.

Although the G_i family members in platelets are most commonly associated with suppression of cAMP formation, this is not their only role. The defect of platelet function seen in mice that are missing $G_{i\alpha}$ family members cannot be reversed by adenylyl cyclase inhibitors.[36] In addition to providing $G_{\beta\gamma}$ heterodimers that can activate PLCβ, the downstream effectors for G_i family members in platelets include PI3K, Src family members, and Rap1B (see Fig. 116–5).[26,38–40] PI3Ks phosphorylate PI-4-P and PI-4,5-P_2 to produce PI-3,4-P_2 and PI-3,4,5-P_3. Human platelets express the α, β, γ, and δ isoforms of PI3K. PI3Kγ is activated by $G_{\beta\gamma}$.

Much of what is known about the role of PI3K in platelets comes from studies with inhibitors such as wortmannin and LY294002 or from studies of gene-deleted mouse platelets.[41] Those studies established that PI3K activation can occur downstream of both G_q and G_i family members and that effectors for PI3K in platelets include the serine/threonine kinase Akt[38] and Rap1B.[42] Loss of the PI3Kγ isoform causes impaired platelet aggregation.[43] Loss of PI3Kβ impairs Rap1B activation and thrombus formation in vivo, as do PI3Kβ-selective inhibitors.[42] Deletion of the gene encoding Akt2 results in impaired thrombus formation and stability and inhibits secretion.[38] Loss of Akt1 has been reported to inhibit platelet aggregation, suggesting that these are not redundant molecules.[44] Although it seems clear that PI3K activation leads to activation of Akt in platelets, what happens next is less clear. There are many established and predicted substrates for Akt, but, with the exception of GSK3β, the Akt substrates in platelets have not been identified, and much remains to be learned.

ADP: Two Receptors with Distinguishable Functions

ADP is stored in platelet dense granules and released upon platelet activation. ADP also is released by erythrocytes and damaged tissues at sites of vascular injury. When added to platelets in vitro, ADP causes TxA_2 formation, protein phosphorylation, increased cytosolic Ca^{2+} concentration, shape change, aggregation, and secretion. It also inhibits cAMP formation. These responses are half-maximal at approximately 1 μM ADP. However, even at high concentrations, ADP is a comparatively weak activator of PLC. Instead, its usefulness as a platelet agonist rests more upon its ability to activate other path-

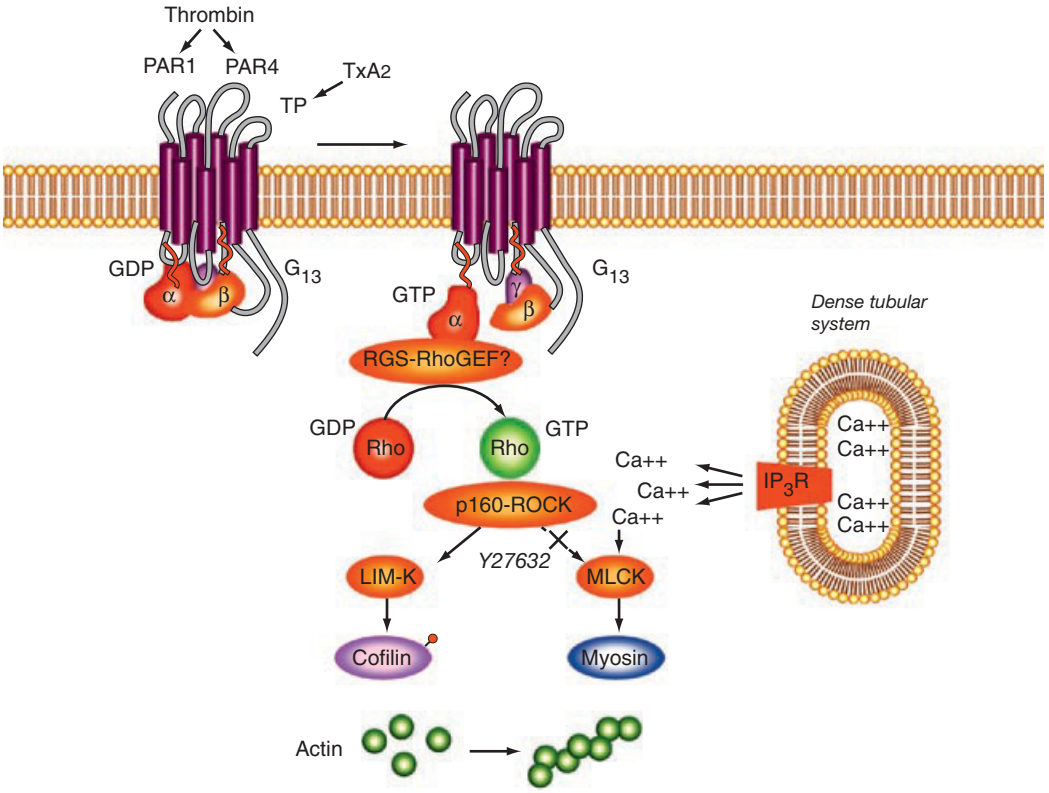

Figure 116–4 $G_{12/13}$ signaling in platelets. Agonists whose receptors are coupled to the G_{12} family members expressed in platelets are able to trigger shape change, in part by Rho-dependent activation of kinases that include the Rho-activated kinase p160 ROCK and the downstream kinases myosin light chain kinase (MLCK) and LIM kinase. Although G_{12} and G_{13} both are expressed, based on knockout studies, G_{13} is the dominant G_{12} family member in mouse platelets. Y27632 inhibits p160 ROCK.[143] GDP, guanosine 5′-triphosphate; GTP, guanosine 5′-triphosphate; IP_3R, receptor for 1,4,5-inositol triphosphate; PAR, protease-activated receptor; TxA_2, thromboxane A_2.

ways.[45,46] Human and mouse platelets express two ADP receptors: $P2Y_1$ and $P2Y_{12}$. Both receptors are members of the purinergic class of GPCRs (Table 116–1 and Fig. 116–6).[47–51] $P2Y_1$ receptors couple to G_q. $P2Y_{12}$ receptors couple to G_{i2} (see Figs. 116–3 and 116–5). Optimal responses to ADP require both. The third purinergic receptor on platelets, $P2X_1$, is an ATP-gated Ca^{2+} channel.[52–55] Platelet dense granules contain ATP as well as ADP, and studies suggest that $P2X_1$ activity is essential for platelet activation under certain conditions.[56–58]

When $P2Y_1$ is blocked or deleted, ADP still can inhibit cAMP formation, but its ability to cause an increase in cytosolic Ca^{2+} concentration, shape change, and aggregation is greatly impaired. $P2Y_1^{-/-}$ mice have a minimal increase in bleeding time and show some resistance to thromboembolic mortality after injection of ADP. Primary responses to platelet agonists other than ADP are unaffected. ADP, when combined with serotonin, which is a weak stimulus for PLC in platelets, still can cause aggregation of $P2Y_1^{-/-}$ platelets. Taken together, these results show that platelet $P2Y_1$ receptors are coupled to $G_{q\alpha}$ and are responsible for activation of PLC. $P2Y_1$ receptors also can activate Rac and the Rac effector p21-activated kinase (PAK),[59] but they do not appear to be coupled to G_i family members.

$P2Y_{12}$ receptors were characterized functionally before they actually were identified.[50,51] As predicted by the phenotype of a patient lacking functional $P2Y_{12}$,[60] platelets from $P2Y_{12}^{-/-}$ mice do not aggregate normally in response to ADP.[61] $P2Y_{12}^{-/-}$ platelets retain $P2Y_1$-associated responses, including shape change and PLC activation, but they lack the ability to inhibit cAMP formation in response to ADP. The G_i family member associated with $P2Y_{12}$ appears to be primarily G_{i2}, as platelets from $G_{i2\alpha}^{-/-}$ mice have an impaired response to ADP, whereas those lacking $G_{i3\alpha}$ or $G_{z\alpha}$ do not (Table 116–2).[36,62,63]

Identification of the receptors that mediate platelet responses to ADP, the development of antagonists that target each of the known receptors, and the successful knockouts of the genes encoding $P2Y_1$, $P2Y_{12}$, $G_{q\alpha}$, and $G_{i2\alpha}$ have brought an increased appreciation of the contribution of ADP to platelet plug formation in vivo. Absence of $P2Y_{12}$ produces a hemorrhagic phenotype in humans, albeit a relatively mild one.[50,60,64] Because the receptors for thrombin and TxA_2 can cause robust activation of PLC, the contribution of ADP when thrombin or TxA_2 is present appears to be largely due to the its ability to activate G_{i2}. Two antiplatelet agents, ticlopidine and clopidogrel, are irreversible antagonists of $P2Y_{12}$.

Thrombin: Two Receptors with Overlapping Functions

Thrombin is able to activate platelets at concentrations as low as 0.1 nM. Although other platelet agonists also can cause phosphoinositide hydrolysis, none appears to do so as efficiently as thrombin. Within seconds of the addition of thrombin, the cytosolic Ca^{2+} concentration increases 10-fold, triggering downstream Ca^{2+}-dependent events, including activation of phospholipase A_2. All of these responses, but not shape change, are abolished in platelets from mice lacking $G_{q\alpha}$.[65] Thrombin also activates Rho in platelets, leading to rearrangement of the actin cytoskeleton and shape change, responses that are greatly reduced or absent in mouse platelets that lack $G_{13\alpha}$.[31] Finally, thrombin is able to inhibit adenylyl cyclase activity in human platelets, either directly (via a G_i family member) or indirectly (via released ADP).[66–68]

Platelet responses to thrombin are mediated by members of the PAR family of GPCRs. The PAR family consists of four members. Three (PAR1, PAR3, and PAR4) can be activated by thrombin. PAR1 and PAR4 are expressed on human platelets; mouse platelets express PAR3 and PAR4 (see Table 116–1). Receptor activation occurs when thrombin cleaves the extended N-terminus of each of

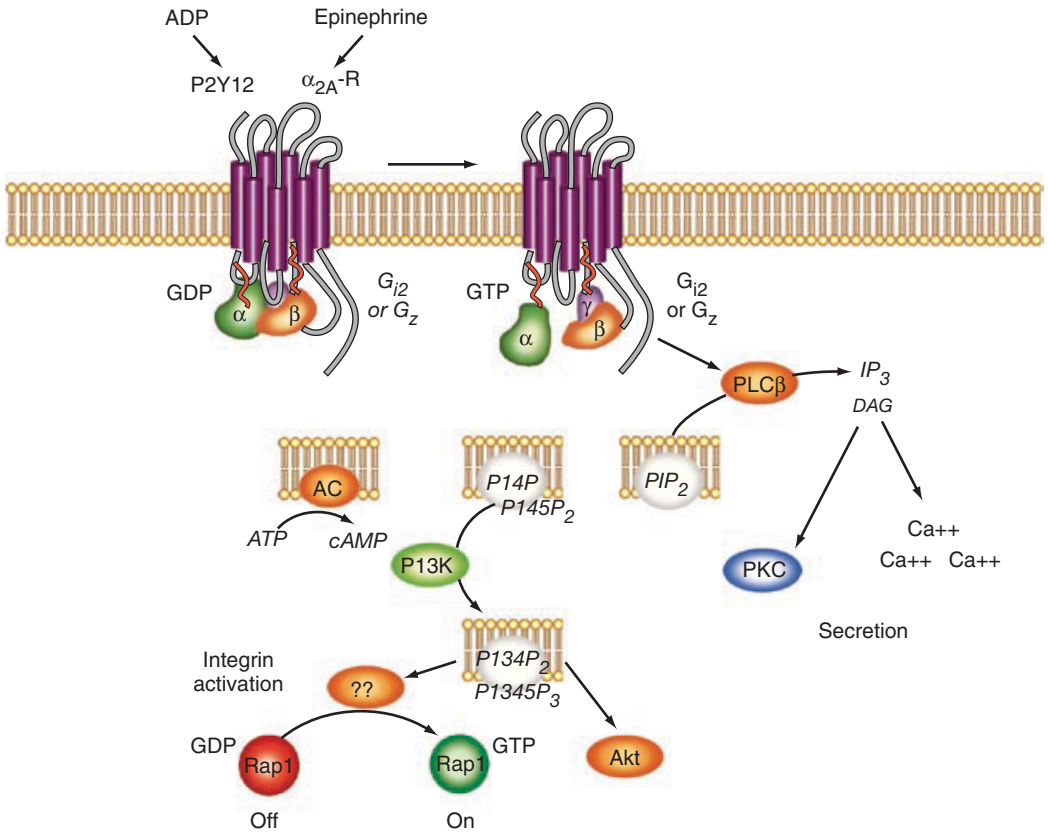

Figure 116–5 G_i signaling in platelets. G_{i2} is the predominant G_i family member expressed in human platelets. In addition to inhibiting adenylyl cyclase (alleviating the repressive effects of cyclic adenosine monophosphate [cAMP]), G_{i2} couples $P2Y_{12}$ ADP receptors to phosphatidylinositol 3-kinase (PI3K), Akt phosphorylation, and Rap1B activation. Other effectors may exist as well. The role of G_z in platelets appears to be limited to interactions with α_{2A}-adrenergic receptors and responses to epinephrine. Epinephrine appears to be primarily a potentiator of the effects of other platelet agonists, inhibiting cAMP formation and promoting activation of Rap1B and PI3K. AC, adenylyl cyclase; ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; GDP, guanosine 5′-triphosphate; GTP, guanosine 5′-triphosphate; IP_3, inositol triphosphate; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLCβ, phospholipase Cβ.

Table 116–2 Platelet Phenotypes of G_α Knockout Mice

Family	G_α	Platelet Phenotype
$G_{i\alpha}$	$G_{i2\alpha}$	Reduced aggregation and inhibition of cAMP formation with ADP. Normal shape change.
	$G_{i3\alpha}$	No apparent effect.
	$G_{z\alpha}$	Impaired aggregation and suppression of cAMP formation by epinephrine. Resistance to disseminated thrombosis initiated with collagen plus epinephrine but not with collagen plus ADP. Normal shape change. Increased bleeding time in one of two studies.
$G_{q\alpha}$	$G_{q\alpha}$	Predisposed to bleed. Absent aggregation with all agonists tested but normal shape change. Resistance to disseminated thrombosis initiated with collagen plus epinephrine.
	$G_{11\alpha}$	No apparent effect on platelet function.[a]
	$G_{15\alpha}$	No apparent effect on platelet function.[a]
$G_{12\alpha}$	$G_{12\alpha}$	No apparent effect on platelet function.[a]
	$G_{13\alpha}$	Embryonic lethal due to vascular defects but decreased platelet shape change and aggregation when limited to hematopoietic cells.

[a]Our unpublished observations.
ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate.

these receptors, exposing a new N-terminus that serves as a tethered ligand.[69] Synthetic peptides based on the sequence of the tethered ligand domain of PAR1 and PAR4 are able to activate the receptors, mimicking at least some of the actions of thrombin. Approximately half of $PAR1^{-/-}$ mice die in utero, but this appears to be due to loss of receptor expression in the vasculature rather than in platelets.[70] Human PAR3 can signal in response to thrombin, whereas mouse PAR3 appears to primarily serve to facilitate cleavage of PAR4.[71] Activation of PAR4 requires higher concentrations of thrombin than PAR1, apparently because it lacks the hirudin-like sequences that can interact with thrombin's anion-binding exosite and facilitate receptor cleavage.[71–74] Kinetic studies in human platelets suggest that thrombin signals first through PAR1 and subsequently through PAR4.[75,76]

Peptide agonists for either PAR1 or PAR4 cause platelet aggregation and secretion. Conversely, simultaneous inhibition of human PAR1 and PAR4 abolishes responses to thrombin,[77] as does deletion of the gene encoding PAR4 in mice.[78] Thus, PAR family members are necessary. The picture has emerged that thrombin responses in human platelets require PAR1 and PAR4 (Fig. 116–7), whereas those in mice are mediated by PAR3-facilitated cleavage of PAR4. Abundant evidence, including studies in knockout mice, shows that PAR1 and PAR4 are coupled to G_q and G_{13}. However, a requirement for PAR family members does not preclude the involvement of other participants. One long-standing candidate is GPIb. GPIb is a heterodimer composed of disulfide-linked α and β subunits that exist in a complex with GPIX and GPV. Together they provide a binding site for VWF and an anchor for the platelet cytoskeleton. GPIbα has a high-affinity thrombin binding site located within residues 268–

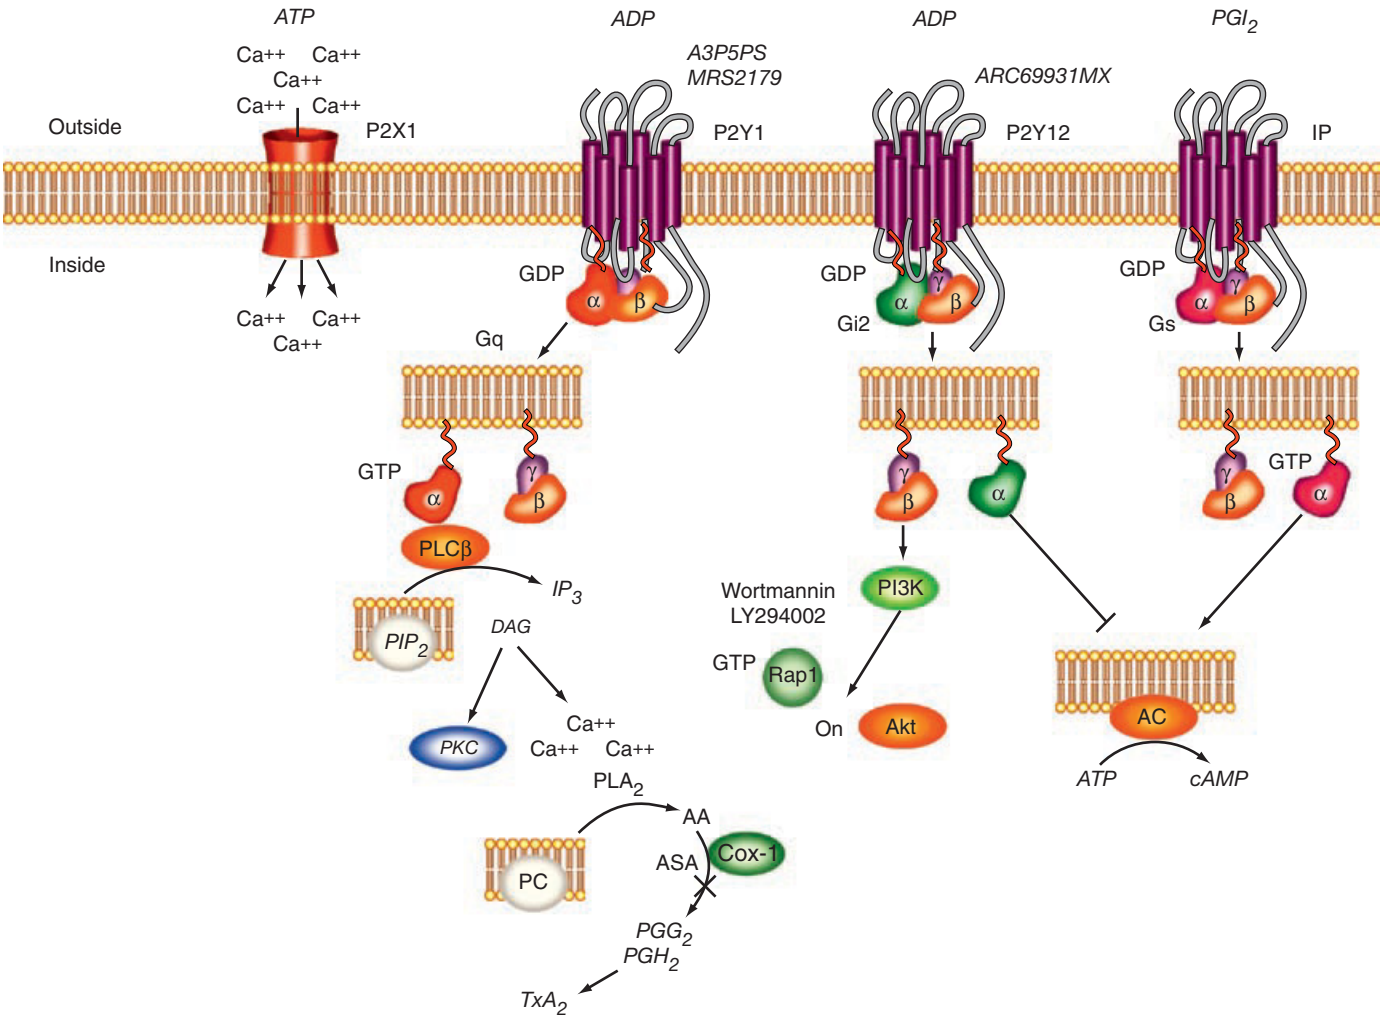

Figure 116–6 Adenosine diphosphate (ADP) receptors. Three receptors that can be activated by adenine nucleotides have been identified in platelets: $P2Y_1$ and $P2Y_{12}$ are ADP-activated, G protein-coupled receptors coupled to G_q and G_{i2}. $P2X_1$ is an adenosine triphosphate (ATP)-gated cation channel that can allow Ca^{2+} influx. A3P5PS and MRS2179 are $P2Y_1$-selective antagonists. ARC69931MX is a $P2Y_{12}$-selective antagonist. AA, arachidonic acid; AC, adenylyl cyclase; ASA, aspirin; cAMP, cyclic adenosine monophosphate; COX-1, cyclooxygenase 1; DAG, diacylglycerol; GDP, guanosine 5′-triphosphate; GTP, guanosine 5′-triphosphate; IP_3, inositol triphosphate; PG, prostaglandin; PI3K, phosphatidylinositol 3-kinase; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLCβ, phospholipase Cβ; TxA_2, thromboxane A_2.

287.[79] Deletion or blockade of this site reduces platelet responses to thrombin, particularly at low thrombin concentrations, and has been shown to impair PAR1 cleavage on human platelets.[80–84] VWF binding to GPIb leads to intracellular signaling that supports platelet activation. This also may occur when thrombin binds.

Epinephrine: Potentiator of Other Agonists

Compared to thrombin, epinephrine is a weak activator of human platelets when added on its own. Nonetheless, human families in which members have a mild bleeding disorder associated with impaired epinephrine-induced aggregation and reduced numbers of catecholamine receptors have been reported.[85,86] Platelet responses to epinephrine are mediated by α_{2A}-adrenergic receptors (see Table 116–1). In both mice and humans, epinephrine is able to potentiate the effects of other agonists so that the combination is a stronger stimulus for platelet activation than either agonist alone. Potentiation usually is attributed to the ability of epinephrine to inhibit cAMP formation; however, as discussed previously, other effects clearly are mediated by G_i family members as well. In contrast to other platelet agonists, epinephrine has no detectable direct effect on PLC and does not cause shape change, although it can trigger phosphoinositide hydrolysis indirectly by stimulating TxA_2 formation.[87]

The inability to stimulate phosphoinositide hydrolysis and shape change suggests that platelet α_{2A}-adrenergic receptors are coupled to G_i but not to G_q or G_{12} family members (see Fig. 116–5). Gene deletion studies have confirmed and extended this conclusion. Human and mouse platelets express four members of the G_i family. Of the four, the sequence of $G_{z\alpha}$ is the most distinct. $G_{z\alpha}$ also has the slowest rate of intrinsic GTP hydrolysis and is the only $G_{i\alpha}$ family member that is not a pertussis toxin substrate. Platelet responses to epinephrine were abolished when the gene encoding $G_{z\alpha}$ was removed. Loss of $G_{i2\alpha}$ or $G_{i3\alpha}$ had no effect.[36,62] Therefore, it appears that, in mouse platelets, α_{2A}-adrenergic receptors couple to G_z but not to G_{i2} or G_{i3}. G_z also appears to be responsible for the ability of epinephrine to activate Rap1B.[26,36]

Thromboxane A_2: Twin Receptors Coupled to G_q and $G_{12/13}$

TxA_2 is produced from arachidonate in platelets by the aspirin-sensitive cyclooxygenase 1 pathway. When added to platelets in vitro, thromboxane analogues such as U46619 cause shape change, aggregation, secretion, phosphoinositide hydrolysis, protein phosphorylation, and an increased cytosolic Ca^{2+} concentration while having

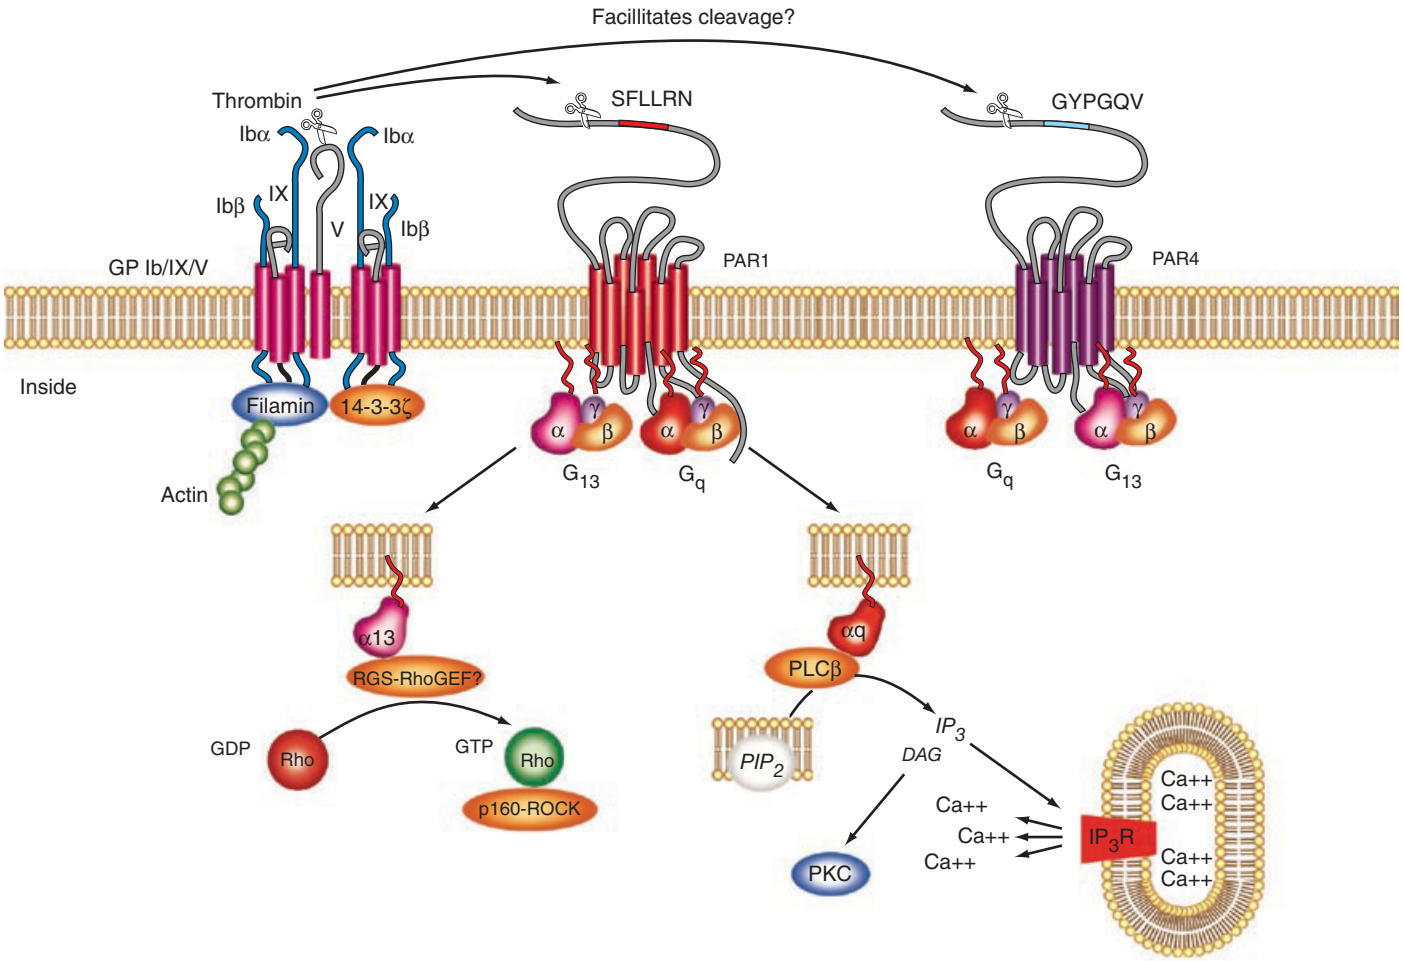

Figure 116–7 Thrombin receptors. Platelet responses to thrombin are mediated largely by members of the protease-activated receptor (PAR) family. Human platelets express PAR1 and PAR4, which collectively are coupled to G_q- and G_{13}-mediated effector pathways. Secretion of adenosine diphosphate (ADP) acts as a further activator of G_i-mediated pathways via the receptor $P2Y_{12}$. Cleavage of PAR1 by thrombin appears to be facilitated by binding of thrombin to glycoprotein Ibα (GPIbα) in the GPIb-IX-V complex. DAG, diacylglycerol; GDP, guanosine 5′-triphosphate; GTP, guanosine 5′-triphosphate; IP_3, inositol triphosphate; IP_3R, inositol triphosphate receptor; PIP_2, phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLCβ, phospholipase Cβ.

little, if any direct, effect on cAMP formation. Once formed, TxA_2 can diffuse outward and activate other platelets, amplifying the initial stimulus for platelet activation (see Fig. 116–1, *B*). This process is effective locally but is limited by the short half-life of TxA_2, which helps confine the spread of platelet activation to the original area of injury.

Only one gene encodes TxA_2 receptors, but two splice variants (TPα and TPβ) that differ in their cytoplasmic tails are produced (see Table 116–1). Human platelets express both.[88] TxA_2 receptors appear to be mapped to G_q and G_{13} but not to G_i (see Table 116–2). Biochemical studies have shown that platelet TxA_2 receptors are physically associated with $G_{q\alpha}$ and $G_{13\alpha}$ and are able to activate G_{12} family members.[89–91] Loss of $G_{q\alpha}$ abolishes U46619-induced IP_3 formation but not shape change.[65] Loss of $G_{13\alpha}$ abolishes TxA_2-induced shape change.[31] Although thromboxane receptors in cells other than platelets have been shown to couple to pertussis toxin-sensitive G_i family members,[92] in platelets the inhibitory effects of U46619 on cAMP formation appear to be mediated by secreted ADP.

Loss of TxA_2 signaling impairs platelet function. $TP^{-/-}$ mice have a prolonged bleeding time. Their platelets are unable to aggregate in response to TxA_2 agonists (Table 116–3) and show delayed aggregation with collagen, presumably reflecting the role of TxA_2 in platelet responses to collagen.[93] A group of Japanese patients with impaired platelet responses to TxA_2 analogues have proved to be either homozygous or heterozygous for an R60L mutation in the first cytoplasmic loop of TP.[94] However, the most compelling case for the contribution of TxA_2 signaling in human platelets comes from the successful use of aspirin as an antiplatelet agent. When added to platelets in vitro, aspirin abolishes TxA_2 generation and impairs, but does not abolish, responses to thrombin and ADP.

Stage III: Perpetuation (Stabilization) of the Platelet Plug

Signaling from collagen receptors and GPCRs is responsible for initiation and extension of the platelet plug, but additional signaling and adhesive events affect the continued growth and stability of the platelet mass once it begins to form (see Fig. 116–1, *C*). These events are facilitated and, in some cases, made possible by the close contacts between platelets that can occur only once platelet aggregation begins. Electron micrographs show the close proximity of the plasma membranes of adjacent platelets within an aggregate but do not show the adherens and tight junctions that are typical of contacts between endothelial cells. Estimates of the gap between adjacent platelets range from as little as zero to as much as 50 nm, making it possible for molecules on the surface of one platelet to bind to those on an adjacent platelet. This interaction can be direct, as when one cell adhesion molecule binds to another in *trans*. The interaction also can

Table 116–3 Platelet Phenotypes of GPCR Knockout Mice

Agonist	Receptor	Phenotype
Thrombin	PAR1	None (not expressed on mouse platelets).
	PAR3	Higher concentrations of thrombin required to elicit responses, presumably because of loss of normal contribution of PAR3 to PAR4 activation.
	PAR4	Complete loss of thrombin responsiveness.
ADP	$P2Y_1$	Impaired response to ADP. Absent increase in cytosolic Ca^{2+} and shape change in response to ADP. Normal inhibition of cAMP formation by ADP.
	$P2Y_{12}$	Greatly diminished aggregation in response to ADP. Absent inhibition of adenylyl cyclase by ADP. Increased bleeding time.
TxA_2	TPα/β	Prolonged bleeding time, absent aggregation in response to TxA_2 agonists, and delayed aggregation with collagen.
Epinephrine	α_{2A}-adrenergic	Mice have been developed but platelet function not reported.
PGI_2	IP	Increased aggregation in response to ADP. Increased rate of thrombosis following vascular injury.

ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; GPCR, G protein-coupled receptor; PAR, protease-activated receptor; PGI_2, prostaglandin I_2; TxA_2, thromboxane A_2.

be indirect, as occurs when multivalent adhesive proteins link activated $\alpha_{IIb}\beta_3$ on adjacent platelets. In either case, these interactions theoretically can provide both an additional adhesive force and a secondary source of intracellular signaling. The narrowness of the gap between platelets can restrict the inward diffusion of molecules such as plasmin and the outward diffusion of platelet activators, allowing higher local concentrations to be reached and maintained.[95]

Clot retraction is a platelet-dependent event in which a fibrin clot gradually pulls in upon itself, shrinking to a smaller volume after platelet activation and fibrin deposition are well underway. Clot retraction depends on the interaction between actin–myosin complexes and the cytoplasmic domain of $\alpha_{IIb}\beta_3$, as well as the binding of fibrinogen or VWF to the extracellular domain of the integrin. The absence of clot retraction is one of the hallmarks of platelets from patients with Glanzmann thrombasthenia, a condition in which platelets lack $\alpha_{IIb}\beta_3$. In the context of platelet–platelet interactions, clot retraction can be viewed as a mechanism for narrowing the gaps between platelets and increasing the local concentration of soluble ligands for platelet receptors.[96]

Integrins, Adhesion, and Outside-In Signaling

Activated $\alpha_{IIb}\beta_3$ bound to fibrinogen, fibrin, or VWF provides the dominant cohesive strength that holds platelet aggregates together. Outside-in signaling refers to the intracellular signaling events that occur downstream of activated integrins once ligand binding has occurred.[97] Integrin signaling depends in large part on the formation of protein complexes that link to the integrin cytoplasmic domain. Some of the protein–protein interactions that involve the cytoplasmic domains of $\alpha_{IIb}\beta_3$ help regulate integrin activation; others participate in outside-in signaling and clot retraction. Proteins that are capable of binding directly to the cytoplasmic domains of $\alpha_{IIb}\beta_3$ include β_3 endonexin,[98] CIB1,[99] talin,[100] myosin,[101] Shc,[102] and the tyrosine kinases Src[103] and Syk.[104,105] Talin binding is thought to be one of the final events in the allosteric regulation of integrin activation.[100,106–108] Some interactions require the phosphorylation of tyrosine residues Y773 and Y785 (Y747 and Y759 in mice) in the β_3 cytoplasmic domain by Src family members. Mutation of Y747 and Y759 to phenylalanine produces mice whose platelets tend to disaggregate and which show impaired clot retraction and a tendency to rebleed from tail bleeding time sites.[109] Fibrinogen binding to the extracellular domain of activated $\alpha_{IIb}\beta_3$ stimulates a rapid increase in the activity of Src family members and Syk. Studies of platelets from mice lacking these kinases suggest that these events are required for the initiation of outside-in signaling and for full platelet spreading, irreversible aggregation, and clot retraction.[110–113]

Other Adhesion Molecules

Integrins are not the only adhesion and signaling molecules found at the interface between platelets. Some of these molecules have been known for some time, but they have newly assigned functions in platelets that appear to counter original ideas about their roles. A better way to view them is as platelet surface molecules that can accumulate at sites of contact between platelets and enter into homophilic or heterophilic interactions in *trans* that modulate the growth and stability of platelet plugs. A good example is platelet endothelial cell adhesion molecule 1 (PECAM-1; CD31). PECAM is perhaps best known for its high level of expression on endothelial cells, where it accumulates at the junctions between cells. However, as its name suggests, PECAM-1 is also expressed on the surface of resting and activated platelets. PECAM-1 is a type 1 transmembrane protein with six extracellular immunoglobulin (Ig) domains.[114] The most membrane-distal Ig domain is able to support homotypic interactions in *trans*. The C-terminus contains phosphorylatable tyrosine residues capable of binding the tyrosine phosphatase SHP-2. Loss of PECAM-1 expression causes increased responsiveness to collagen in vitro and increased thrombus formation in vivo. The data are consistent with a model in which tyrosine phosphorylation of PECAM-1 brings the phosphatase near its substrates, including the GPVI signaling complex.[115–117] This finding suggests that, despite being named as an adhesion molecule, PECAM-1 can provide a braking effect on collagen-induced signaling and thereby help prevent either unwarranted platelet activation or the overly exuberant growth of platelet thrombi that otherwise might occlude the vessel lumen and cause ischemia.

Junctional adhesion molecules (JAMs) are members of the CTX family of Ig domain-containing cell adhesion molecules. Three have been identified: JAM-A (JAM-1; F11R), JAM-B (JAM-2; VE-JAM), and JAM-C (JAM-3).[118,119] Platelets express JAM-A and JAM-C. JAMs have an extracellular domain with two Ig domains, a single transmembrane region, and a short cytoplasmic tail that terminates in a PDZ domain binding site. JAM-A localizes to tight junctions of endothelial and epithelial cells. It also is found on monocytes, neutrophils, and lymphocytes. JAM-C has been found on endothelial cells, lymphatic vessels, dendritic cells, and natural killer cells. JAM-A contributes to cell–cell adhesion by forming *trans* interactions involving the N-terminal Ig domain. However, JAMs also support heterotypic interactions, including binding to integrins via their membrane proximal Ig domain.[120,121] Other CTX family members that have been identified on platelets include ESAM and CD226.[122–124] Their functional significance has yet to be determined.

Signaling lymphocytic activation molecule (SLAM; CD150) and CD84 are members of the CD2 family of homophilic adhesion molecules that have been studied extensively in lymphocytes; however, now they have been shown to be expressed in platelets as well.[125–127] The members of the family are type 1 membrane glycoproteins in the Ig superfamily. Among them are notable differences in the cytoplasmic domain, which supports binding interactions with a variety of adaptor/partner proteins. SLAM and CD84 become tyrosine phos-

phorylated during platelet activation, but only if aggregation is allowed to occur.[125] Mice that lack SLAM have a defect in platelet aggregation in response to collagen or a PAR4-activating peptide but have a normal response to ADP and a normal bleeding time. In a mesenteric vascular injury model, female (but not male) SLAM$^{-/-}$ mice showed a marked decrease in platelet accumulation.

Receptor–Ligand Interactions at the Platelet–Platelet Interface

Direct contacts between platelets can promote signaling by more than one mechanism. In addition to signaling events that occur downstream from cell adhesion molecules, there are receptors that interact in *trans* with cell surface ligands. One example is the family of Eph receptor tyrosine kinases and their ligands, known as *ephrins.* Ephrins are cell surface proteins with either a glycophosphatidylinositol anchor (the ephrin A family) or a transmembrane domain (the ephrin B family). The cytoplasmic domains of the ephrin B family members include phosphorylatable tyrosine residues and a PDZ target domain. Contact between an ephrin-expressing cell and an Eph-expressing cell causes bidirectional signaling. Human platelets express EphA4, EphB1, and ephrinB1. Clustering of ephrinB1 promotes platelet aggregation. Blockade of Eph–ephrin interactions leads to reversible platelet aggregation at low agonist concentrations and limits the growth of platelet thrombi on collagen-coated surfaces under arterial flow conditions. It also impairs β_3 phosphorylation, which inhibits clot retraction.[128] EphA4 colocalizes with $\alpha_{IIb}\beta_3$ at sites of contact between aggregated platelets. Collectively, these observations suggest a model in which the onset of aggregation brings platelets into close proximity and allows ephrinB1 to bind to EphA4 and EphB1. Signaling downstream of both the receptors and the kinases then promotes further integrin activation and integrin signaling.[128–130] A second example of ligand–receptor interactions made possible by close contacts between platelets is the binding of the ligand semaphorin 4D (sema4D) to its receptors CD72 and plexin B1. sema4D is an integral membrane protein in the semaphorin family. Signaling downstream of CD72 and plexin B1 promotes platelet activation by collagen. Loss of sema4D expression in mice inhibits platelet function in vitro and thrombus formation in vivo.[131]

A somewhat different paradigm of a ligand–receptor interaction that is facilitated by platelet–platelet contacts is binding of growth arrest-specific gene 6 (Gas-6) to its receptors. Gas-6 is a vitamin K-dependent protein related to protein S. In rodent platelets, Gas-6 is found in α granules.[132–134] Secreted Gas-6 is a ligand for the receptor tyrosine kinases Tyro3, Axl, and Mer,[135,136] all of which are expressed on platelets.[133] Because Tyro3 family members have been shown to stimulate PI3K and PLCγ, a reasonable hypothesis is that secreted Gas-6 can bind to its receptors on the platelet surface and cause signaling that promotes platelet plug formation and stability. Consistent with this hypothesis, platelets from Gas-6$^{-/-}$ mice were found to have an aberrant response to agonists in which aggregation terminates prematurely.[133] Platelets from receptor-deleted mice also failed to aggregate normally in response to agonists.[137–139] Secretion of Gas-6 into the spaces between platelets in a growing thrombus would be expected to allow it to achieve higher local concentrations and provide protection from being washed away.

CONCLUSION

The intracellular signaling that underlies platelet activation is a dynamic process in which different receptor and effector pathways are dominant at different phases in the initiation, extension, and perpetuation of platelet plugs. The main objective throughout normal hemostasis is to activate integrin $\alpha_{IIb}\beta_3$ so that it can bind adhesive proteins and then maintain it in an active (bound) state so that a platelet plug of the appropriate size will remain in place long enough for healing to occur. In general, this requires the activation of PLC- and PI3K-dependent pathways. It also involves the suppression of inhibitory mechanisms that normally are designed to prevent platelet activation, including the formation of cAMP by adenylyl cyclase. If the initial stimulus for platelet activation is the exposure of collagen, then $\alpha_{IIb}\beta_3$ activation is accomplished by a process that involves activation of PLCγ. If the initial stimulus is the generation of thrombin, then a G protein-dependent mechanism results in a more rapid and robust activation of PLCβ. Once $\alpha_{IIb}\beta_3$ has been activated and platelet aggregation has occurred, then a third wave of signaling is facilitated by the close contacts that form between platelets within a hemostatic plug or thrombus.

CHAPTER 117

THE BLOOD VESSEL WALL

Aly Karsan and John M. Harlan

The vasculature plays a major role in conveying and distributing hematopoietic cells, nutrients, gases, metabolites, and various chemical mediators.[1] The interior of the vessel wall is lined by the endothelium, comprising more than 10^{12} endothelial cells, covering a surface of approximately 500 m^2 and weighing approximately 1 kg in total.[2,3] The endothelium forms a continuous monolayer at the interface between blood and tissue. Thus it contributes significantly to sensing and transducing of signals between blood and tissue, trafficking of hematopoietic cells, and maintenance of a nonthrombogenic surface permitting flow of blood. Normally quiescent, with cell turnover measured on the order of years, endothelial cells have a remarkable capacity to proliferate and vascularize tissues in physiologic (menstrual cycle) and pathologic (tumorigenesis, diabetic retinopathy) situations.[4] The endothelium is critical for initiating and potentiating the inflammatory response. The pathogenesis of several disorders, such as atherosclerosis, hypertension, diabetic angiopathy, and microangiopathic hemolytic anemias, involves dysfunction of the endothelial lining. The complexity and the vast array of its functional responses have led to the description of the endothelium as a distributed organ.[5] This chapter provides a conceptual framework of the structure and development of the vessel wall and the physiologic functions of the endothelium as it relates to the hematopoietic system.

STRUCTURE OF THE VESSEL WALL

The circulatory system has traditionally been divided into the macrovasculature (vessels >100 μm in diameter) and the microvasculature.[6] The arterial system transports blood to tissues, resists changes in blood pressure proximally, and regulates blood flow distally. Veins return blood to the heart and act as capacitance vessels, as they contain approximately 70% of the total blood volume. Venules with luminal diameters less than 50 μm are structurally similar to capillaries.[6] Capillaries, and microvessels in general, are particularly important in the exchange of gases, macromolecules, and cells between blood and tissue. Although large vessels play an important role in maintaining vascular tone, a significant proportion of peripheral resistance arises from the capillaries.[7] Capillary endothelial cells also have a metabolic role, as in the conversion of angiotensin and hydrolysis of lipoproteins. Finally, sprouting of new vessels is initiated in the microvasculature.

Macrovasculature

Large vessels are composed of three layers: intima, media, and adventitia.[6,8] The intima comprises the endothelium and the subendothelium. The endothelial cells of large vessels contain a distinct rod-shaped organelle, measuring approximately 3 μm × 0.1 μm, called the *Weibel-Palade body.*[9] Ultrastructural studies indicate the presence of a single membrane around the Weibel-Palade body with tubular structures within. This organelle contains von Willebrand factor (vWF), and P-selectin has been reported to be present on the surrounding membrane.[10–12] The abluminal face of the endothelium rests on a basement membrane, which supports the endothelial cell and can act as a secondary barrier against the extravasation of blood.[2] The subendothelial matrix contains occasional smooth muscle cells and scattered macrophages. Both smooth muscle cells and endothelial cells contribute to the extracellular matrix (ECM) of the intima.[13,14] In large vessels the media is separated from the intima by a layer of elastin, the internal elastic lamina. The medial layer is composed primarily of concentric layers of smooth muscle cells and their secreted matrix, which is a complex mix of glycoproteins and proteoglycans. This layer is responsible for the structural integrity of the wall and for maintaining vascular tone. Mutations of the fibrillin-1 gene, a microfilament protein in elastic fibers, result in disruption of the media in Marfan syndrome.[12] Defects of type III collagen can cause aortic rupture in patients with Ehlers-Danlos syndrome type IV.[14] An attenuated band of elastic fibers, the external elastic lamina, separates the adventitia from the media. The adventitia is composed of loose connective tissue, and the outer portion of the media contains small nerves and nutritive blood vessels, the vasa vasorum. The external limit of the adventitial layer is loosely defined and becomes continuous with the surrounding connective tissue of the organ.[6,8]

Microvasculature

Capillaries and postcapillary venules are composed of two cell types: endothelial cells and pericytes.[15] Pericytes and endothelial cells are invested with a basement membrane and, depending upon the vascular bed, variable amounts of matrix separate the two cell types. Both cell types contribute to secretion of basement membrane proteins. Long pericyte processes extend over the abluminal surface of the endothelial cell, and reciprocal extensions of the endothelial cell make contact with the pericyte. Pericytes and endothelial cells communicate via gap junctions.[16] A variety of functions has been ascribed to the pericyte, including[15,17,18] (a) a contractile function, which regulates blood flow; (b) multipotential capabilities resulting in differentiation to adipocytes, osteoblasts, phagocytes, and smooth muscle cells; and (c) regulation of capillary growth. The best evidence probably exists for the last function. In animal models[19,20] and human disease (diabetic microangiopathy, hemangiomata),[21] a lack of pericytes is associated with microaneurysms and disordered microvasculature. In addition, there is a temporal correlation between pericyte contact and cessation of vessel growth in wound healing,[22] and pericyte contact suppresses endothelial cell migration and proliferation in vitro.[15]

Endothelial Structure and Function

In contrast to circulating blood cells and vascular smooth muscle cells but similar to epithelial cells, the endothelium exhibits polarity manifested by the asymmetric distribution of cell surface glycoproteins and by the unidirectional secretion of some ECM proteins and chemical mediators.[23,24] Although in cultured endothelial cells, an apical–basal polarity is established prior to confluence, intercellular junctions may have a role in maintaining the asymmetry in vivo.[23,25]

Four types of intercellular junctions between adjacent endothelial cells have been described[25,26]: tight junctions, gap junctions, adherens junctions, and syndesmos. Their distribution varies along the vascular tree, with tight junctions occurring more frequently in the larger

arteries and brain vasculature, correlating with a more stringent requirement for permeability control. The molecular structure of endothelial *tight junctions* is similar to that of epithelial cells, consisting of a network of fibrils, with the integral membrane components composed of occludin, claudin-5, and junctional adhesion molecules (JAMs), which associate with various structural and signaling proteins on the cytoplasmic face.[27] The distribution of *gap junctions* tends to follow that of tight junctions. Connexin37, connexin40, and connexin43 are gap junction proteins that have been detected in endothelial cells. Gap junctions mediate communication between adjacent endothelial cells and between endothelial cells and pericytes or smooth muscle cells; they also may contribute to the endothelial barrier. *Adherens junctions* are formed by transmembrane glycoproteins called *cadherins,* which make the link between cell-to-cell contacts and the cytoskeleton. Several different types of cadherins are expressed in endothelial cells. The endothelial-specific cadherin *vascular endothelial cadherin* (VE-cadherin [cadherin-5]) is expressed on virtually all types of endothelium.[26] Similar to other cadherins, VE-cadherin forms homotypic contacts with VE-cadherin on adjacent cells. Within the cell VE-cadherin complexes with catenins, which, through other proteins, contact the actin cytoskeleton. Homotypic engagement of VE-cadherin results in density-dependent inhibition of endothelial proliferation, which appears to be mediated by association of vascular endothelial growth factor receptor 2 (VEGFR-2) with VE-cadherin, thereby sequestering VEGFR-2 at the membrane and preventing its internalization into signaling compartments.[28] The structure of the fourth type of junction, the *syndesmos*, is not well elucidated.

Other membrane proteins that are located at interendothelial junctions include platelet endothelial cell adhesion molecule 1 (PECAM-1), which may be important in directing the formation of junctions, and the integrins (particularly $\alpha_2\beta_1$ and $\alpha_5\beta_1$).[29] In addition to the functions listed previously, intercellular contacts are important in maintaining cell survival.[30]

On the luminal side, endothelium is exposed to blood elements and, under pathologic conditions, to circulating molecules such as cytokines and bacterial products. Engagement of endothelial receptors by these humoral factors activates a well-described series of responses. including the recruitment and transmigration of leukocytes and changes in endothelial cell coagulant activity (see The Endothelium as a Nonthrombogenic Surface). Biomechanical forces resulting from pulsatile blood flow have been shown to mediate striking changes in endothelial morphology and metabolism. Vessels must withstand three types of physical forces: radial distension (tension), longitudinal stretch, and tangential shear stress. In response to flow (shear stress), endothelial cells reorganize their cytoskeletal architecture, rearrange focal contacts at the *basal* surface, and align in the direction of flow.[31–33] Some endothelial cell responses following exposure to physical forces occur within seconds, such as activation of potassium channels and increased release of nitric oxide (NO), resulting in vasodilation. Other endothelial cell responses to flow are related to changes in gene expression and occur after a delay of a few hours. Elements in the promoters of various adhesion molecule and growth factor genes have been shown to contain sequences that respond to shear stress (in a positive or negative fashion) and have been referred to as the *shear stress response element*.[31–33]

Endothelial cells vectorially secrete certain ECM proteins to the abluminal face. The matrix molecules that are secreted by endothelium include several types of collagen, elastin, fibronectin, laminins, and proteoglycans (e.g., heparan sulfate, dermatan sulfate). The exact composition of the subendothelium varies with location in the vascular tree, age, and disease states.[2,14,34] Endothelial cells bind to the ECM via heterodimeric cell surface glycoproteins—the integrins—which link and integrate matrix proteins to the cytoskeleton, at sites referred to as focal contacts.[35] The integrins detected in resting endothelium include $\alpha_6\beta_1$, $\alpha_5\beta_1$, $\alpha_2\beta_1$, and $\alpha_v\beta_3$.[36] Interestingly, endothelial cells express integrins on luminal as well as abluminal surfaces.[36] The ECM serves several important functions: (a) it serves as a barrier to macromolecules in the event of disruption of the endothelium; (b) it sequesters growth factors and mediates their high-affinity binding to endothelial cells (e.g., heparan sulfate binds to fibroblast growth factor [FGF]); (c) it acts as a counterstructure for the binding of endothelial cell integrins.[14,34,37] This binding of endothelial cells to the ECM serves at least four purposes: (i) Certain matrix molecules provide a physical scaffold, whereas others act as haptotactic agents, inducing endothelial cells to migrate.[14] (ii) Clustering of integrins at focal adhesion contacts by certain matrix molecules can transduce survival or differentiation signals by causing phosphorylation of various proteins and lipids.[37] Fibronectin and vitronectin provide survival signals, whereas laminins appear to signal differentiation.[38–40] (iii) By maintaining cell shape, integrin-mediated cell spreading provides an antiapoptotic signal independent of direct integrin-initiated signal transduction.[41] (iv) By anchoring the cell, the matrix provides a mechanism whereby blood flow at the luminal surface of the endothelium creates shear stress, which also transmits signals to cells.[31]

Endothelial Heterogeneity

Despite their common features, quiescent endothelial cells in vivo represent a widely heterogeneous population, with their phenotype depending on vessel caliber and location. Exposure to different physical forces (e.g., arteries vs veins) and the different functions served by vessels of different caliber are reflected in different endothelial phenotypes.[42] However, study of the molecular basis of the heterogeneity of these different populations is just beginning. Experiments using serial analysis of gene expression and in vivo delivery of phage display peptide libraries have revealed organ- and tumor vasculature-specific molecules that will help to elucidate the molecular basis of endothelial heterogeneity.[43–45] Within the microvasculature is a structural heterogeneity of capillaries, depending on the organ supplied. Even within a single organ endothelial cells exhibit different phenotypes, depending on their functional role. When microvessels from different organs are harvested and cultured in vitro, they lose some of their distinctive characteristics with progressive passaging. Some specialization of the different endothelial cells can be retained if they are cocultured with cells or matrix from the organ from which they are derived. Thus, matrix proteins, soluble factors from the organ, or heterotypic contacts with parenchymal cells or pericyte/smooth muscle cells are believed to be important factors in specifying endothelial cell phenotype.[46] Conversely, emerging evidence indicates that endothelial cells in turn provide instructive morphogenic cues during organogenesis and in the adult.[47] Specific examples of microvessels found in hematopoietic tissues are discussed in the following sections.

High Endothelial Venules

Lymphocyte migration into secondary lymphoid sites, such as lymph nodes, Peyer patches, and chronically inflamed nonlymphoid tissues, occurs at specialized postcapillary venules.[48] The endothelial cells of these venules exhibit a plump/cuboidal morphology (hence the name *high endothelial venule*), display intense biosynthetic activity, and are encircled by a continuous basal lamina. They secrete a thick glycocalyx of which a proportion is glycosylation-dependent cell adhesion molecule 1, a ligand for L-selectin.[49] CD34 is another high endothelial venule "addressin" on peripheral lymph node endothelial cells. Endothelium of mesenteric lymph nodes and Peyer patches express mucosal addressin cellular adhesion molecule 1 (MAdCAM-1) as a ligand for L-selectin and $\alpha_4\beta_7$ integrin. Expression of these different addressins may recruit specific subpopulations of lymphocytes to different lymphoid tissues (i.e., they facilitate the "homing" of lymphocytes). Several other proteins, including the chemokine receptor DARC (Duffy antigen receptor for chemokines) and the antiadhesive matrix protein Hevin, have been identified as being preferentially expressed by the high endothelial venule.[50] Tight junctions are present at intermittent spots, and extensive overlap between the membranes of adjacent cells prevents macromolecules from interendothelial transit. However, when lymphoid cells transit to the high endothelial

venule, there is a temporary breach in the barrier.[49] Evidence suggests that the high endothelial venule not only plays a critical role in homing and recruitment of immune cells but also can influence the outcome of the immune response.[51]

Bone Marrow Sinuses

Much less is known about the marrow sinuses than about the high endothelial venule. The marrow sinus endothelial cell is flat, in contrast to that of the high endothelial venule, and the basal lamina is discontinuous. It has been suggested that hematopoietic cells traverse pores present at attenuated areas of the endothelium rather than moving by an interendothelial route.[52] Clearly, the marrow sinus endothelial cell is specialized given the regulated egress of cells from the marrow. For example, if a red cell that still is nucleated begins to enter the circulation, the body of the cell is allowed to cross and is released as a reticulocyte, while the nucleus is retained extravascularly. The adventitial reticular cell (similar to a pericyte) is also thought to play an important role in controlling hematopoietic cell egress.[53] Stromal cell-derived factor 1 (SDF-1, also called CXCL12) and chemokine receptor CXCR4 interactions are essential for stem cell homing, mobilization, and transendothelial migration into the bone marrow.[54,55] SDF-1 activates the integrins lymphocyte function-associated antigen 1 (LFA-1 [$\alpha_L\beta_2$]), very late antigen 4 (VLA-4 [$\alpha_4\beta_1$], and very late antigen 5 (VLA-5 [$\alpha_5\beta_1$]). Vascular cell adhesion molecule 1 (VCAM-1), which is expressed on marrow endothelial cells (and spleen endothelial cells in the mouse), appears to be the major bone marrow addressin for hematopoietic progenitor cells expressing VLA-4, whereas intercellular adhesion molecule 1 (ICAM-1) binds LFA-1.[55,56] Endothelial selectins also have been implicated in promoting hematopoietic progenitor homing to the bone marrow.[57] Factors such as CD44, cytoskeletal rearrangement, and matrix metalloproteases are other key players in the homing process related to the endothelium.[55] The marrow endothelium also is involved in regulating hematopoiesis (see Relationship between Vascular Development and Hematopoiese).

VASCULAR DEVELOPMENT AND DIFFERENTIATION

The human embryo develops a vascular system by the third week, when its nutritional needs are no longer met by diffusion.[58] Vascular development proceeds in several ways. *Vasculogenesis* is the process whereby blood vessels form de novo from the differentiation of mesodermal precursors. *Angiogenesis* is the outgrowth of new capillaries from preexisting vessels and is thought to be the major mode of new vessel development in the adult. *Arteriogenesis*, or collateral development, is the rapid enlargement of preexisting collateral arterioles after occlusion of a supply artery. *Lymphangiogenesis* is the development of lymphatic vessels, which are required for transportation of extravasated lymph and lymphoid cells. Finally, in some neoplasms, tumor cells rather than endothelial cells form vascular channels or a portion of some vessels, a process termed *vasculogenic mimicry.*[59] A similar nonendothelial cell lining of vascular channels can be created by placental cytotrophoblasts forming hybrid fetal–maternal vessels in the endometrium.[59]

Vasculogenesis

Vasculogenesis in the yolk sac proceeds initially by the differentiation of mesodermal cells into angioblasts.[60] Angioblasts are vascular cells that express some, but not all, endothelial markers. These cells arise from mesodermal cells resting on the endoderm (splanchnopleuric mesoderm) but not from the mesoderm adjacent to the ectoderm (somatopleuric mesoderm). Thus, it is believed that the endoderm positively regulates vascular development, whereas the ectoderm negatively regulates vasculogenesis. Organs that are primarily of ectodermal origin (e.g., brain and kidney) are vascularized by angiogenesis and not by vasculogenesis. The mesodermal cells migrating outward from the endoderm form primitive structures termed *blood islands.* The cells at the center of the blood island are hematopoietic precursors, whereas those arranged peripherally are angioblastic precursors. Vasculogenesis within the embryo begins shortly after that in the yolk sac, again in close association with endoderm.[61] However, except for a region on the ventral aspect of the embryonic aorta, intraembryonic vascular development occurs in solitary angioblasts rather than blood islands. Angioblasts differentiate in situ and form primary capillary plexuses with lumens, or they migrate and fuse with other angioblasts or capillaries. Fusion of angioblasts or blood islands results in the formation of a capillary plexus that undergoes extensive remodeling over the developmental period.[60]

Vasculogenesis in the Adult

Although initially said to occur primarily in the embryo, vasculogenesis may also play a role in promoting vascular development in the adult. The identification of circulating bone marrow-derived vascular precursors and the demonstration that these precursors can integrate into the vasculature at sites of angiogenesis describe an adult form of de novo vessel development.[62] Two distinct marrow-derived precursors with the ability to differentiate into vascular cells have been identified: (a) accumulating evidence points to a single precursor, the hemangioblast, which can differentiate into either hematopoietic or endothelial cells[63]; and (b) a multipotent nonhematopoietic adult progenitor cell, which is thought to represent a bone marrow mesenchymal stem cell. When injected intravenously into adult mice, these mesenchymal stem cells differentiated into vascular cells, hematopoietic cells, as well as several epithelial cell types.[64,65] Both types of multipotential precursor populations express CD133, a cell surface marker that is lost upon further maturation.[66] However, only the hemangioblast expresses CD34. Whether mesenchymal stem cells are able to circulate and thus contribute to neovascularization outside the marrow remains to be shown. Various stresses, including neoplasia, sepsis, burns, and trauma, have been suggested to induce mobilization of marrow-derived endothelial precursors, which express CD133, CD34, and VEGFR-2.[66] Cytokines that reportedly induce mobilization of marrow-derived endothelial precursors include VEGF-A and granulocyte-macrophage colony-stimulating factor.[66] The contribution of bone marrow-derived vascular precursors to angiogenic vessels in tumors is highly variable, depending on the study, the model used, and the tumor cell type used.[67] The degree of endothelial precursor incorporation into the angiogenic vasculature is highly controversial; several groups suggest negligible if any involvement by distant precursors.[67] The problem arises in part from the poor definition of a circulating endothelial precursor cell. Many, if not all, of the markers used to define this rare cell population are shared with hematopoietic stem or progenitor cells, and the distinction between the endothelial and hematopoietic precursor has not been rigorously addressed in the majority of studies. More recent work has suggested that marrow-derived, perivascular $CD11b^+$ hematopoietic cells secreting angiogenic cytokines have been misidentified as endothelial precursor cells.[68,69]

Angiogenesis

In the normal adult, angiogenesis occurs primarily in the female reproductive system. However, angiogenesis is a process that has a major impact in several pathologic situations. Probably the best-known and studied example of pathologic neovascularization occurs during tumor progression. Angiogenesis also is important in chronic inflammation, ischemia, and wound healing.

Capillary sprouts from the existing microvasculature form secondary to an inciting stimulus that results in increased vascular permeability, accumulation of extravascular fibrin, and local proteolytic degradation of the basement membrane.[70–72] Endothelial cells overlying the disrupted region become "activated," change shape, and

extend elongated processes into the surrounding tissue. Filopodia extending from the specialized endothelial cells at the tip of the vascular sprout guide the migration of the nascent vessel.[73] Directed migration toward the angiogenic stimulation results in the formation of a column of endothelial cells. Just proximal to the migrating tip of the column is a region of proliferating endothelial cells. These proliferating cells cause an increase in the length of the sprout. In the region of proliferation, up to 20% of endothelial cells may enter the cell cycle. This is in marked contrast to quiescent endothelium, of which less than 0.01% of cells are cycling. Proximal to the proliferative zone, the endothelial cells undergo another shape change, adhere tightly to each other, and begin to form a lumen. Evidence suggests that endothelial lumina arise through the formation and fusion of intracellular vacuoles.[74] Secondary sprouting from the migrating tip results in a capillary plexus, and fusion of individual sprouts at their tips closes the loop and circulates blood into the vascularized area. Activated macrophages and platelets, by secreting growth factors, cytokines, proteases, and protease inhibitors, can influence all phases of the angiogenic process.[75]

The morphologic features described are characteristic of sprouting angiogenesis. *Intussusceptive microvascular growth* refers to vascular network formation by insertion of interstitial tissue columns, called *tissue pillars* or *posts,* into the vascular lumen and subsequent growth of these columns, resulting in partitioning of the vessel lumen. The mechanisms of intussusceptive angiogenesis are less well described, but hemodynamic factors appear to be involved.[76]

Recruitment of Periendothelial Cells

Whether formed by vasculogenesis or angiogenesis, maturation of new vessels requires recruitment of smooth muscle cells or pericytes to reestablish vessel integrity. Periendothelial cells provide structural support, assist in production of the ECM, provide contractile function so as to modulate vessel caliber, and maintain the cells in a quiescent state. Genetically altered mice that fail to invest their vessels with pericytes develop microaneurysms.[19] In the embryo, periendothelial cells are thought to be derived from locally available mesenchymal cells as endothelial cells invade organ rudiments. Local derivation of periendothelial cells may be one mechanism that allows for tissue-specific phenotype of the vasculature.[15] Evidence suggests that embryonic endothelial cells may transdifferentiate into vascular smooth muscle cells.[77] Evidence also indicates that some periendothelial cells are derived from the neural crest during embryogenesis and from marrow-derived precursors in the adult.[78–81] Although some studies have shown pericytes to be potential antivascular targets for tumor therapy,[80,82] other work has suggested that pericytes act to limit tumor metastasis.[83]

Extracellular Matrix

It is thought that interstitial collagens (e.g., collagen I) and provisional plasma-derived fibronectin/fibrin matrices stimulate endothelial tubular morphogenic events, whereas laminin-rich matrices lead to endothelial differentiation and stabilization events.[75] Mice deficient in fibronectin die during embryogenesis and show vascular defects. Type I collagen-deficient mice die of circulatory failure just before birth. Although most tumor vessels are covered by basement membrane, this layer has multiple structural abnormalities consistent with ongoing vascular activation in tumors.[84] ECM proteins and/or their proteolytic fragments have been shown to inhibit angiogenesis.

Dissolution of the underlying matrix by matrix metalloproteases and heparanases allows endothelial cells to migrate at the initiation of angiogenesis.[85,86] Matrix-bound growth factors are also released as a consequence of ECM degradation. The balance between positive and negative regulators is the basis of tight control in this process. Tissue plasminogen activator (tPA) and urokinase plasminogen activator, by generating plasmin, can activate collagenases and other matrix metalloproteinases. Plasminogen activator inhibitors may block angiogenesis at this step. Action of the matrix metalloproteinases is required for angiogenesis, and the tissue inhibitors of metalloproteinases regulate their function.[87]

Cell Adhesion Molecules

Of the various classes of cell adhesion molecules involved in angiogenesis, the integrins have been the most studied.[14,88,89] Although it is universally accepted that integrins and integrin ligands function in angiogenesis, their exact actions remain unclear. In particular, substantial controversy surrounds the role of $\alpha_v\beta_3$ integrin.[14,88,90] Immunohistochemical studies localize this integrin to the tips of sprouting vessels. Neutralizing antibodies abrogate angiogenesis and induce vascular cell apoptosis in vivo. However, mice lacking α_v show extensive angiogenesis, and mice and humans (Glanzmann thrombasthenia) lacking β_3 integrin also show normal angiogenesis. Notwithstanding the discrepancies outlined, preclinical studies have validated $\alpha_v\beta_3$ and potentially other integrins ($\alpha_v\beta_5$, $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_4$) as therapeutic antiangiogenic targets, and clinical trials with combination therapy are currently in progress.[91] One of the integrin receptors for fibronectin, $\alpha_5\beta_1$, has been shown to be necessary for vascular development, whereas $\alpha_2\beta_1$ seems important for the formation of tubes by endothelial cells in vitro. However, there likely is a dynamic regulation of β_1 integrins during angiogenesis because constitutive activation of this integrin inhibits endothelial sprouting in vitro and angiogenesis in vivo.[92] The junctional proteins VE-cadherin and PECAM-1, and possibly JAM-1, are expressed early in development and have a role in assembling the vasculature.[28,93,94]

Guidance Molecules

Similar to the nervous system, the vascular system forms a highly ordered, branching network. The ordering of this patterned network is dependent on multiple attractive and repulsive cues, many of which are common to both the nervous and vascular systems.[95,96] $VEGF_{165}$ acts as an attractive cue to the tip cell of the endothelial sprout, whereas Netrin1 signals to UNC5b on the vasculature act as a repulsive cue. Other guidance pathways implicated in vascular patterning and angiogenesis are ephrinB2-EphB4, plexinD1-semaphorin, and Slit-Robo interactions, as well as the neuropilins. Patterning and specification of small arteries along peripheral nerves in the skin of the embryonic limb involves nerve-derived VEGF; in other situations, neuronal patterning is dependent on the vasculature.[97,98] Thus, the congruent patterning of the neural and vascular systems likely is due to use of common signals and may require cross-talk between the two systems.

Remodeling, Regression, and Apoptosis

Even though the vasculature is laid down before circulation begins, hemodynamic forces are important for maintenance and remodeling. Most of the vessels laid down during vasculogenesis regress or are remodeled. Following neovascularization (e.g., during wound healing), the vessels regress when no longer needed. A chronic decrease in blood flow results in narrowing of the vessel lumen. This change in vessel caliber is dependent on an intact and functional endothelium.[99] Remodeling, which involves loss of some vessels as well as changes in lumen diameter and wall thickness, requires both cell death and proliferation (as well as remodeling of the ECM). In addition to survival signals transmitted by integrins, shear stress is important for endothelial survival and vessel healing following injury.[100–102] Oxygen tension is important in vascular maintenance. Hypoxia increases levels of VEGF, which provides signals for vessel maintenance and neovascularization.[103] Hyperoxia, on the other hand, inhibits VEGF expression, which leads to regression and death of retinal vessels.[104] In some models, regression of vessels occurs by

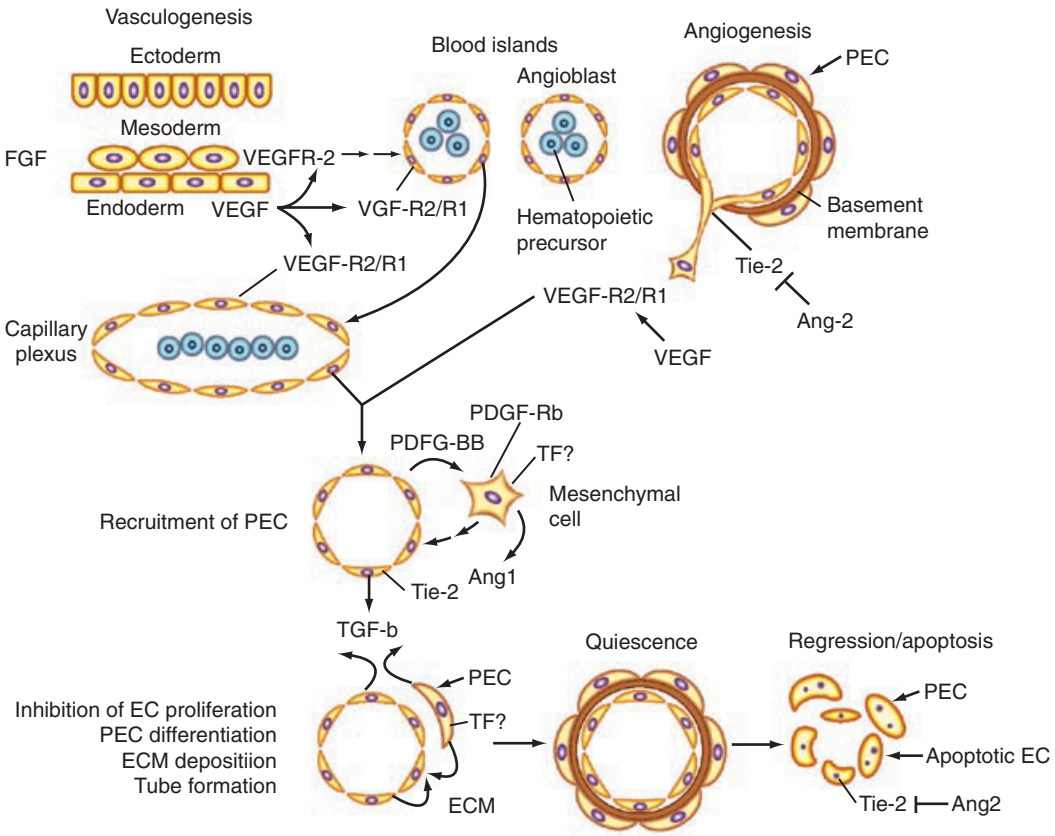

Figure 117–1 Model for vascular development. The role of secreted proteins and membrane receptors in vascular development is highlighted, but other factors such as cell adhesion molecules and extracellular matrix components also contribute significantly. Ang, angiopoietin; ECM, extracellular matrix; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; PEC, periendothelial cell (smooth muscle cell, pericyte); TF, tissue factor; TGF-β, transforming growth factor β, VEGF, vascular endothelial cell growth factor; VEGF-R, vascular endothelial cell growth factor receptor.

apoptosis of vascular cells.[105,106] Endothelial cells express several anti-apoptotic molecules in order to maintain viability when quiescent and when stressed.[107,108] Most likely, an intricate balance between cell death and proliferation is maintained by activators and inhibitors of both processes.

Role of Ligand–Receptor Interactions

Numerous factors regulate vascular development and differentiation in a positive or negative fashion. Some of the key molecules and their receptors are discussed here. A model for vascular development is shown in Fig. 117–1.

Inducers of Angiogenesis

Fibroblast Growth Factors

The role of FGFs in vascular development remains murky.[109–111] Because of possible functional redundancy in the numerous family members, assigning specific roles to the various members of the FGF family has been difficult. Evidence suggests that FGF receptors signal an inductive pathway by upregulating VEGFR-2 in differentiating mesoderm prior to vascular morphogenesis.[111–113] FGF2 may induce neovascularization in adults indirectly through activation of the VEGF–VEGFR pathway.[114]

Vascular Endothelial Growth Factors

Six members of the VEGF family have been identified[70,109,111,115–119]: VEGF-A (also called vascular permeability factor), VEGF-B, VEGF-C, VEGF-D, VEGF-E (a viral ortholog), and placental growth factor. Three members of the receptor tyrosine kinase family[109,118,119]—VEGFR-1 (flt-1), VEGFR-2 (flk-1/KDR), and VEGFR-3 (flt-4)—respond differentially to individual members of the VEGF family. In addition, the coreceptors for VEGF, neuropilin 1 and neuropilin 2, have been identified on arterial and venous endothelial cells, respectively. Neuropilin 1 is a coreceptor for VEGFR-2 that enhances binding of the VEGF-A isoform $VEGF_{165}$ to VEGFR-2.[118] VEGF-A functions as a homodimer. However, it also heterodimerizes with VEGF-B and placental growth factor, and it has a crucial dose-dependent effect on vasculogenesis[70,109,111,118,119] VEGF-A binds VEGFR-1 and VEGFR-2, whereas VEGF-C binds VEGFR-2 and VEGFR-3. Placental growth factor specifically activates VEGFR-1, whereas VEGF-E binds only VEGFR-2.[111,118,119] Lack of VEGFR-2 prevents the development of endothelial cells and a hematopoietic system because cells lacking VEGFR-2 do not reach the correct location to form blood islands.[120] Mice that have been rendered deficient for VEGFR-1 have normal hematopoietic progenitors and abundant endothelial cells, but they do not form capillary tubes or functional vessels.[121] Both VEGFR-2– and VEGFR-1–deficient mice die at an early embryonic stage, as do neuropilin 1– and neuropilin 2–deficient mice. In von Hippel Lindau disease, development of hemangioblastomas may be due to stabilization of VEGF mRNA.[122] VEGF is also believed to play a key role in propagating tumor angiogenesis. Tip cell migration has been shown to be dependent on a gradient of VEGF-A, whereas endothelial proliferation in the lengthening vascular stalk is dependent on the absolute concentration of VEGF-A, although both processes require VEGFR-2[73] Finally, injection of VEGF is capable of relieving limb ischemia by the generation of collateral vessels.[72] VEGF appears to collaborate with the angiopoietins to stimulate vascular development, whereas VE-cadherin acts to temper the VEGF response.[28]

Angiopoietins

The angiopoietin (Ang) family of secreted glycoproteins comprises four members: Ang1 to Ang4. All four bind to Tie2, a receptor tyrosine kinase.[123–126] Ang1 and Ang4 act as agonists of Tie2, whereas Ang2 and Ang3 function as antagonists of Tie2.[126] However, the action of Ang2 is context dependent, and in some environments it may behave as an agonist.[126] Binding of Ang1 to Tie2 results in tyrosine phosphorylation of Tie2 and promotes endothelial cell survival but not proliferation.[123,126] Early in development, Ang1 is found mainly in the myocardium surrounding the endocardium, but it also becomes expressed in the mesenchyme surrounding developing vessels.[123] Disruption of either Ang1 or its receptor Tie2 in the mouse results in embryonic lethality due to similar defects.[124,127] These mice die at a slightly later stage than do VEGFR-deficient mice. Although endothelial cells are present, there is a lack of vascular complexity and a scarcity of periendothelial cells. Reciprocal interactions between the endothelial cells and surrounding matrix and mesenchyme appear to be disrupted. An activating Tie2 mutation in humans causes vascular malformations that show a disproportionate number of endothelial cells compared to smooth muscle cells, resulting in dilated, tortuous vascular channels in certain tissues.[128] Mice engineered to overexpress Ang2 specifically in their vasculature show embryonic lethality and vascular defects that are reminiscent of those seen in Ang1- or Tie2-null embryos.[125] In one proposed model, Ang1–Tie2 coupling mediates vascular maturation by sustaining endothelial cell–periendothelial cell–matrix interactions and may be involved in maintaining endothelial cell quiescence. Because Ang2 is found only at sites of vascular remodeling, Ang2 loosen matrix contacts, thus allowing access and responsiveness to angiogenic factors such as VEGF.[125,126] In the absence of growth factors, disruption of the vessel architecture by Ang2 may result in vascular cell apoptosis and vessel regression. However, Ang2-deficient mice are born alive, and the major defect appears to be lymphatic development.[126] Thus, despite major advances the data are conflicting. The response of endothelial cells to angiopoietins likely is context dependent and endothelial cell type specific.[126]

Tie1 is a receptor tyrosine kinase that exhibits structural similarities to Tie2. A ligand for Tie1 has not yet been identified.[109,129] Disruption of the Tie1 gene in mice results in lethality at a much later point in development; Tie1-null mice may survive up to birth.[127,130] $Tie1^{-/-}$ mice die of hemorrhage and edema, implicating Tie1 in signaling the control of fluid exchange across capillaries and in maintenance of vessel integrity under hemodynamic stress. Chimeric mice that express $Tie1^{-/-}$ and $Tie1^{+/-}$ endothelial cells show underrepresentation of $Tie1^{-/-}$ cells in vessels primarily derived by angiogenesis but not in embryonic vessels derived by vasculogenesis, suggesting a differential function for Tie1 in angiogenesis.[131] Evidence also implicates a role for Tie1 in combination with Ang1 in establishing vascular polarity.[132]

Platelet-Derived Growth Factors

The platelet-derived growth factor (PDGF) family is composed of four chains. PDGF-A and PDGF-B can associate in a homodimeric or heterodimeric fashion.[133] Similarly, the receptors α and β are receptor tyrosine kinases that can form homodimers or heterodimers. PDGF-BB can bind the receptors PDGFR-ββ or PDGFR-αβ, but PDGFR-ββ binds only PDGF-BB and not PDGF-AA or PDGF-AB.[109] Mice null for PDGF-B die perinatally of renal, hematologic, and cardiovascular abnormalities.[134] The large vessels and heart of these mice are dilated, and microvessels exhibit microaneurysms due to lack of pericytes.[19,134] PDGFR-β knockout mice do not show an overtly abnormal cardiovascular phenotype, but generation of chimeric mice demonstrates that $PDGFR\text{-}\beta^{-/-}$ cells are underrepresented in all muscle lineages (smooth, cardiac, and skeletal).[135,136] Thus, it appears that PDGF-BB elaborated by the endothelial cell provides a signal to recruit mesenchymal periendothelial cells as part of the maturation process of vascular morphogenesis. Two novel PDGF chains, PDGF-C and PDGF-D, have been identified.[137] PDGF-CC can bind PDGFR-ββ or PDGFR-αβ, exhibits greater mitogenicity of mesenchymal cells than does PDGF-AA, and promotes wound repair. PDGF-DD activates PDGFR-ββ and possibly PDGFR-αβ. PDGF-DD expression has been found to be elevated in the serum of patients with various types of tumors and has been shown to have transforming and angiogenic activity.[137]

Transforming Growth Factors β

Members of the transforming growth factor β (TGF-β) family are multifunctional homodimeric peptides with diverse effects on cell proliferation, migration, differentiation, adhesion, and expression of cell adhesion molecules and ECM.[109,138,139] They are secreted as inactive precursors. Once activated, they transmit signals to cells by binding heteromeric complexes of type I and type II serine/threonine kinase receptors. In most cell types the type I receptor engaged by TGF-β is activin receptor-like kinase 5 (ALK5). However, in endothelial cells TGF-β can bind and signal through ALK5 and ALK1.[140] Contact between endothelial cells and periendothelial cells is required for production of active TGF-β.[15] Mice lacking TGF-β or TGF-β receptor type II exhibit similar defects in vasculogenesis and hematopoiesis.[138,139] Endothelial proliferation is not affected, but poor contacts between endothelial cell and mesothelial layers in embryos of $TGF\text{-}\beta^{-/-}$ mice result in a disorganized and reduced vascular network lacking capillary tubes. Mutations in two TGF-β receptors, ALK1 and the accessory TGF-β receptor endoglin, have been linked to the vascular disorder hereditary hemorrhagic telangiectasia.[140] Disruption of TGF-β signaling likely plays a role in the telangiectasia seen in this disorder.

Notch

The Notch family comprises four receptors (Notch1 through Notch4) and five ligands (Jagged1 and Jagged2, and Delta-like 1 [Dll1], Dll3, and Dll4). Ligand engagement results in a series of proteolytic clips that release the Notch intracellular domain, which then translocates to the nucleus where it effects transcriptional activation via the DNA-binding protein CSL (also called RBP-Jκ or CBF1).[141] Gene targeting studies have revealed a critical role for Notch1, Dll1, Dll4, and Jagged1 in vascular development and remodeling.[141] Dll4–Notch1 signaling between endothelial cells within the angiogenic sprout serves to restrict tip cell formation in response to VEGF.[142–144] Consequently, inhibition of Dll4 in adult mice results in increased endothelial proliferation, sprouting, and branching and increased tumor vascularity.[145,146] However, the vasculature is disorganized and poorly perfused; thus Dll4 blockade inhibits tumor growth in several models.[145,146]

Coagulation Factors

Tissue factor (TF) is a member of the cytokine receptor superfamily. In addition to its role in initiating coagulation as a cofactor for factor VII, TF may be involved in intracellular signaling. TF knockout mice have abnormalities of their large vessels and microvasculature secondary to defects in mesenchymal cell/periendothelial cell accumulation and function.[20] Elevated TF expression in various tumors and the associated angiogenic endothelium has been reported.[147] Expression of mutant oncogenes (K-*ras,* EGFR) or tumor suppressor genes (PTEN, p53) leads to increased TF expression and activity, and this may link tumor angiogenesis and the hypercoagulable states manifested in cancer.[147] Abnormal development of the vasculature also affects 50% of mice that are deficient in factor V. The affected mice die in utero, and the 50% embryonic lethality is similar to that observed in thrombin receptor-deficient mice that die without obvious coagulation defects.[148] Factor V-dependent generation of thrombin may be important for early vascular development by signaling through the thrombin receptor.[149] Thrombin can promote angiogenesis through a mechanism that is independent of fibrin formation.[149,150] Studies have suggested that thrombin can stimulate release of angiogenic factors (e.g., VEGF-A) from tumor cells and platelets as well induce VEGFR-2 on endothelial cells.[150]

Clinical trials have revealed that treatment with low-molecular-weight heparins improves the survival time of cancer patients receiving chemotherapy, an effect that appears to be independent of the anticoagulant properties of the low-molecular-weight heparins.[151,152] Although antiangiogenic effects of specific heparinase-generated fragments of unfractionated heparins have been demonstrated in vitro, the mechanism of the antitumor effect remains to be defined.

The potential involvement of fibrinolytic factors in angiogenesis has been mentioned. Interestingly, fragments 1 and 2 of prothrombin have been reported to inhibit angiogenesis, and various other fragments of coagulation and fibrinolytic proteins also may inhibit angiogenesis.[153]

Other Factors

Various other families of ligand–receptor pairs play a role in angiogenesis. They include Ephrin-Eph, Wnt-Frizzled, and Sonic Hedgehog-Smoothened. Various chemokines have been shown to modulate angiogenesis in either a positive or negative fashion.

Inhibitors of Angiogenesis

As with the angiogenesis inducers, multiple factors have been reported to negatively regulate vascular morphogenesis.[72,153] Of interest is a class of endogenous angiogenesis inhibitors that are fragments of larger proteins that have little or no angiogenesis-related activity in their intact form. They include fragments of ECM proteins such as fibronectin, collagen type IV α_3 chain (tumstatin), and collagen type XIII (endostatin), as well as coagulation protein fragments such as plasminogen (angiostatin) and antithrombin.[153] The mechanism of action of these protein fragments depends on the particular polypeptide, but the functional effect usually is inhibition of endothelial proliferation and/or induction of apoptosis.[153–155] Other endogenous inhibitors include interferons, chemokines, and interleukin-12 (IL-12).

More than 100 compounds are in clinical trials attempting to cause regression of tumors by inhibiting angiogenesis.[156] These compounds can be broadly divided into those that act directly by targeting the angiogenic endothelial cell and those that act indirectly by targeting activators of angiogenesis. The latter category includes targeting of oncogenes (e.g., mutant EGFR or Her2), as many aberrantly activated oncogenes have been shown to induce expression of angiogenic factors. The first clear-cut evidence of efficacy in clinical trials of an angiogenic inhibitor for tumor therapy came from regimens directed against the VEGF pathway (e.g., bevacizumab).[157,158] Because of the short improvement in overall and progression-free survival with the addition of VEGF inhibitors over standard chemotherapy, it is likely that heterogeneity and inherent instability of tumor cell populations result in the selection of malignant cells that feed their vasculature through factors other than VEGF. In this regard, use of indirect angiogenic inhibitors still suffers from the likelihood of tumors becoming resistant to the therapy.

Whether the mechanism of action of these inhibitors is truly due to the abrogation of a functional vascular supply is an open question. VEGF inhibitors "normalize" the aberrant, leaky tumor vasculature. Other than in renal cancer, VEGF inhibitors have shown effect only when used in combination chemotherapy regimens, which has led to the proposal that VEGF pathway inhibition improves vessel functionality and perfusion, thus facilitating delivery of chemotherapeutic agents.[157,158] VEGF–VEGFR signaling also acts in autocrine fashion within some tumor cell populations, raising the possibility that positive outcomes may have as much to do with direct tumor kill as with an antiangiogenic effect. Finally, as with organogenesis, the vasculature may provide a juxtacrine or paracrine role in supporting tumor viability and proliferation, independent of the provision of a circulatory system for delivery of nutrients and oxygen.[47]

Some of the more common side effects observed with use of VEGF-A inhibitors were not predicted a priori but may be understandable in retrospect. For instance, hypertension and arterial thrombosis are common side effects. Two possible reasons may explain the hypertensive side effect. One is that VEGF directly activates endothelial nitric oxide synthase (eNOS) and thus may be responsible in part for basal production of NO.[159] Another potential explanation is that podocyte-derived VEGF is required for proper glomerular function throughout life.[47] Heterozygous loss of podocyte VEGF results in hypertension and proteinuria in adult mice.[47] Given that proteinuria is also commonly seen in patients treated with VEGF inhibitors, the latter explanation would tie two of the side effects seen. The reasons for arterial thrombosis are less obvious. Because arterial circulation is more dependent on VEGF, it is possible that arterial endothelial apoptosis serves as a nidus for localized activation of coagulation and platelet aggregation. Apoptotic endothelial cells have been shown to increase thrombin-generating capacity and bind to unactivated platelets and leukocytes.[160–162]

More recently the use of PDGF inhibitors to target pericytes has been shown to be a potentially effective antiangiogenic strategy, particularly in combination with antiendothelial (anti-VEGF) molecules.[80,82] "Metronomic" or low-dose, frequent scheduling of traditional cytotoxic agents also is reported to have an antiangiogenic effect and has proven efficacious in animal studies.[163] Antivasculogenic therapy directed against recruitment of bone marrow-derived vascular precursors may have a role in future cancer therapeutic regimens, but thus far the evidence is weak at best.[66]

Arteriogenesis

Arteriogenesis is a term coined to distinguish the development of collateral vessels in the adult from the process of angiogenesis.[164,165] Remodeling of a preexisting collateral arteriole is thought to be due to flow-induced changes secondary to occlusion of a supply artery. The consequent increase in shear stress through the collateral arteriole activates endothelial cells, resulting in monocyte recruitment and infiltration into the media. Elaboration of various cytokines, growth factors, and proteases from monocytes and endothelial cells causes matrix degradation, smooth muscle cell proliferation, and rapid enlargement of the preexisting arteriole. Factors thought to promote arteriogenesis include FGF-2, placental growth factor, PDGF-BB, TGF-β1, monocyte chemoattractant protein 1, and granulocyte-macrophage colony-stimulating factor.[165,166]

Lymphangiogenesis

The lymphatics comprise a low-flow, low-pressure system that collects extravasated fluid from the tissues and transfer it back to the venous system via the thoracic duct. Lymphatic vessels also serve an immune function by transporting lymphoid and antigen-presenting cells to lymphoid organs.[167] Lymphatic vessels share features with blood vessels, but they also exhibit differences. Lymphatic vessels develop shortly after blood vessels and may arise de novo from precursor mesenchymal cells (lymphangioblasts) in a process akin to vasculogenesis.[168] Alternatively, other studies suggest that specific venous endothelial cells differentiate to lymphatic endothelium in response to signals that have yet to be determined.[169] VEGF-C and VEGF-D, by activating VEGFR-3 and Ang2 potentially through Tie2 activation, are growth factors necessary for lymphatic vessels.[170] The $\alpha_9\beta_1$ integrin also is necessary for proper lymphatic development, and the homeobox transcription factor Prox1 appears to induce transdifferentiation of venous to lymphatic endothelial cells.[169–171] Lymphedema can be caused by congenital defects, parasitic (filariasis) or neoplastic obstruction, or surgical resection. Congenital lymphedema (Milroy disease) is linked to inactivating mutations of VEGFR-3.[167] Whether lymphatic vessel density in human tumors correlates with disease progression is not clear, but in animal models induction of lymphangiogenesis by VEGF-C or VEGF-D promotes lymph node metastasis.[167]

Relationship Between Vascular Development and Hematopoiesis

Hematopoietic cells and endothelial cells are intertwined in several ways. First, there is the likely existence of a common precursor (see Vasculogenesis above). Second, the endothelium is intimately involved in hematopoiesis, having a supportive role structurally and nutritionally. Finally, the endothelium organizes the controlled egress and ingress of hematopoietic cells in hematopoietic and other tissues. The last issue is covered in Interaction of Blood Cells with the Vessel Wall section.

Bone marrow stromal cells secrete cytokines, produce ECM, and are in direct cellular contact with hematopoietic cells, thereby providing a microenvironment suitable for hematopoietic proliferation, differentiation, and self-renewal.[172] Many studies demonstrate the supportive role of endothelium in hematopoiesis.[173–175] The physical proximity of endothelium and hematopoietic precursors within the marrow and the requirement of blood cells to transit marrow endothelium to reach the circulation is presumptive evidence of an important role for endothelium. Marrow endothelial cells constitutively express high levels of IL-6, stem cell factor, granulocyte colony-stimulating factor, and granulocyte-macrophage colony-stimulating factor.[173] Both yolk sac and marrow endothelial cells support long-term proliferation and differentiation of hematopoietic cells in vitro.[173] However, endothelial cells also have been reported to inhibit hematopoiesis.[176]

Significant evidence now indicates that hematopoietic stem and progenitor cells are not randomly distributed in the marrow but rather are spatially and possibly physically associated with the endosteum and the blood vessels.[175] Functional differences between the osteoblastic and vascular niches have been described. It has been suggested that the osteoblastic niche maintains quiescence of hematopoietic stem cells, whereas stem/progenitor cells that are activated for differentiation and mobilization reside at the vascular niche.[174] Translocation of megakaryocyte progenitors to the vicinity of the marrow sinuses is sufficient to induce megakaryocyte maturation and platelet production.[175] However, a study has identified CXCL12 (SDF-1)-abundant reticular cells that are located in close proximity to the sinusoidal endothelium as well as the endosteum.[177] The authors confirmed that the CXCL12–CXCR4 signaling axis is required for maintenance of hematopoietic stem cells in the marrow, and these findings raise the possibility that the vascular and osteoblastic niches may not be that different.[177] In all likelihood, endothelial cells and osteoblasts, in concert with other stromal cells, provide a finely tuned system to modulate hematopoiesis in the marrow such that differentiation, proliferation, and self-renewal occur in a regulated fashion.

Human endothelial cells have been reported to express receptors for IL-3, stem cell factor, erythropoietin, and thrombopoietin and show functional responses to IL-3 and erythropoietin.[178–180] The shared responses to growth factors, combined with the importance of macrophages in angiogenesis and the production of cytokines by monocytes/macrophages, suggest that hematopoietic cells play a reciprocal role in maintaining the endothelium.

PHYSIOLOGIC FUNCTIONS OF THE ENDOTHELIUM

The Endothelium as a Barrier

The microvessels (capillaries and postcapillary venules) act as the exchange vessels of the circulation. However, as with other endothelial functions, vessel permeability is dependent on the type of vessel and its location. Movement of lipophilic and low-molecular-weight hydrophilic substances between blood and tissue is virtually unimpeded, but the vessels are selectively permeable to macromolecules. This semiselective barrier is necessary to maintain the fluid balance between intravascular and extravascular compartments, yet antibodies, hormones, cytokines, and other molecules must have access to the interstitial space for the initiation and potentiation of various processes, including inflammation, immune response, and wound repair.

Movement of macromolecules across the vessel wall is governed by (a) hydrostatic and oncotic pressure gradients; (b) physicochemical properties of the molecule, such as size, shape, and charge; and (c) properties of the barrier. The barrier of the vessel wall is formed by the cellular components, endothelial cells, and pericytes, as well as by the charge and compactness of the matrix components, glycocalyx, and basement membrane. Macromolecules can pass either directly through the endothelial cell (transcellular path) or between adjacent endothelial cells (paracellular path). Surprisingly, the mechanisms of macromolecular movement remain controversial, and data generated by physiologists, morphologists, and cell biologists have not been consolidated in a model that satisfies the findings of the different groups.[181]

To explain cellular transport in endothelium, physiologists have proposed the existence of two sets of "pores" based on experiments measuring the movement of dextran and other macromolecules: a small pore of radius 3 to 5 nm for transport of water and small hydrophilic molecules, and a large pore of radius 25 to 60 nm for macromolecular transport.[181–183] Although water mainly moves across the continuous endothelium via the paracellular route, a significant proportion (up to 40%) can traverse the endothelium via the transcellular route by water-transporting membrane channels, the aquaporins.[184] Macromolecular transport into cells can proceed by receptor-mediated systems, such as clathrin-coated pits, in which the molecules usually are targeted to the lysosome, but may be transported through the cell. Alternatively, molecules can be moved across the cell by plasmalemmal vesicles or caveolae, which are abundant in capillary endothelial cells. Caveolae are 50- to 100-nm membrane invaginations that can participate in transcytosis as well as in the translocation of glycosylphosphatidylinositol-linked proteins into the cytoplasm and in transmembrane signaling.[185] Because of the known leakiness of tumor microvasculature, investigators have studied these microvessels and identified a structure designated the vesiculovacuolar organelle.[186] These organelles are grape-like clusters of interconnecting uncoated vesicles and vacuoles that span the entire thickness of vascular endothelium, thereby providing a potential transendothelial connection between the vascular lumen and the extravascular space.[186] Interestingly, their function is enhanced by injection into normal skin of VEGF, which is known to increase the permeability of vessels.[186] Localization of caveolin to vesiculovacuolar organelles suggests that this structure is a fusion of caveolae.[186]

During inflammation, binding of neutrophils to the endothelium results in the generation of oxidants that can mediate endothelial cell injury and increase permeability.[187] Upon adhesion of neutrophils to the endothelium, leukocyte CD18 (β_2 integrin)-mediated signals trigger the release of the neutrophil cationic protein called heparin-binding protein/CAP37/azurocidin, which in turn induces formation of gaps between endothelial cells and macromolecular efflux.[188] Thrombin, an inflammatory mediator, can increase endothelial permeability by several mechanisms resulting from activation of its receptor on endothelial cells.[189–191] First is an increase in transcellular vesicular permeability. Second is increased paracellular permeability that results from phosphorylation of endothelial cell nonmyosin light chains and contractile activity generated by movement of actin and myosin filaments past each other. The contraction and retraction of endothelial cells are accompanied by "loosening" of intercellular junctions and focal integrin contacts with the ECM. Finally, thrombin may alter the repulsive effect of the negatively charged glycocalyx. An increase in paracellular permeability may result from alteration of cell–cell contacts present at tight junctions and adherens junctions, secondary to posttranslational modification of components of these junctions such as claudins and VE-cadherin.[181] Pericyte contractility also has been hypothesized as a mechanism for increasing permeability in inflammatory states.[191]

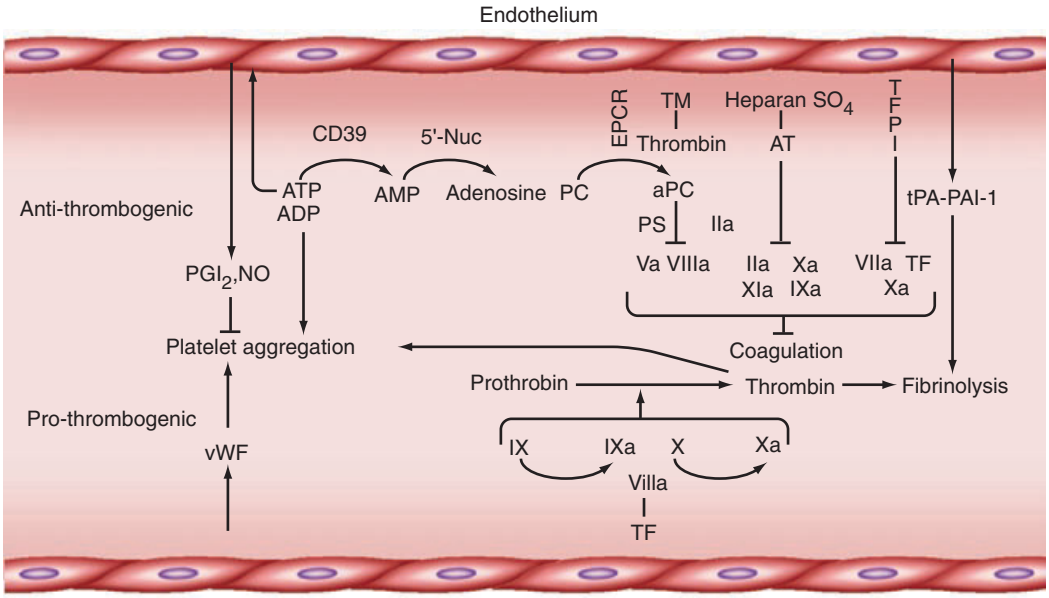

Figure 117–2 Overview of endothelial function in coagulation. ADP, adenosine diphosphate; AMP, adenosine monophosphate; AT, antithrmbin; ATP, adenosine triphosphate; EPCR, endothelial protein C receptor; NO, nitric oxide; 5′-Nuc, ecto-5′-nucleotidase; PAI-1, plasminogen activator inhibitor 1; PC, protein C; PGI_2, prostaglandin I_2 (prostacyclin); PS, protein S; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; tPA, tissue plasminogen activator; vWF, von Willebrand factor.

The Endothelium as a Nonthrombogenic Surface

The molecular mechanisms of hemostasis and thrombosis are addressed in Chapters 115 and 116 and 118 through 120. This section places the endothelium in the appropriate context in these processes. An overview of endothelial cell contributions to the anticoagulant and procoagulant states is shown in Fig. 117–2. Normal unperturbed endothelium presents a nonthrombogenic surface to the circulation by inhibiting platelet aggregation, preventing the activation and propagation of coagulation and enhancing fibrinolysis.[192–196] These activities are accomplished by both passive and active processes. Conversely, when injured or under inflammatory conditions, the endothelium may become procoagulant.

When in close proximity to endothelial cells, platelets become unresponsive to agonists. This inhibition of platelet aggregation is accomplished by secretion of prostacyclin (prostaglandin I_2 [PGI_2]) and NO and by surface expression of an ecto-adenosine phosphatase (ADPase)/CD39/nucleoside triphosphate diphosphohydrolase (NTPDase-1).[195,197] Prostacyclin is synthesized mainly by vascular endothelial and smooth muscle cells as a product of arachidonic acid metabolism. It inhibits platelet activation, secretion, and aggregation, and monocyte interactions with endothelial cells. It also causes vascular smooth muscle cell relaxation. NO similarly has a wide range of functions, including inhibition of platelet adhesion, activation, and aggregation. Most of the NO released from endothelial cells is elaborated abluminally, where it acts on the smooth muscle cell to cause vasodilation. However, some NO may enter the lumen and thereby diffuse into platelets. Prostacyclin and NO can act synergistically to reverse platelet aggregation.[195] The released platelet agonist, ADP, can be inactivated by endothelial membrane-associated CD39.[197] Metabolism of ATP and ADP to AMP by CD39 eliminates platelet recruitment and returns platelets to their resting state. Adenosine, which is generated by hydrolysis of AMP by ecto-5′-nucleotidase, acts to inhibit platelet aggregation and cause vasodilation. ATP/ADP can stimulate purinoreceptors on endothelial cells, resulting in synthesis and release of PGI_2 and NO.[198]

Endothelial cells use three main pathways to inhibit thrombin generation and limit coagulation: the antithrombin system, the protein C system, and tissue factor pathway inhibitor (TFPI).[192,194,199,200] (a) *Antithrombin system.* Heparan sulfate proteoglycans are secreted onto the luminal surface of endothelial cells and into the subendothelium. Heparan sulfates are capable of binding and activating antithrombin III, thereby accelerating inactivation of several procoagulant serine proteases, including thrombin, factor Xa, and factor IXa. (b) *Protein C.*[201] Thrombomodulin on the surface of endothelial cells binds thrombin. This coupling inhibits the coagulant properties of thrombin and increases its affinity for protein C, which it cleaves and activates. Activation of protein C by the thrombin–thrombomodulin complex is augmented by its binding to the endothelial cell protein C receptor. Protein S, which is thought to be synthesized primarily by the endothelial cell, acts as a cofactor for protein C but itself also has anticoagulant properties. Independent of the presence of activated protein C, free protein S is able to inhibit the prothrombinase and intrinsic tenase complexes and interact directly with factors Va and VIIIa. (c) *TFPI.*[202] TFPI is a Kunitz-type serine protease inhibitor that modulates TF-initiated coagulation. TFPI binds to and directly inhibits the tissue factor/factor VIIa/factor Xa complex. It is mainly produced by and bound to endothelial cells, likely to surface glycosaminoglycans. There is also a plasma pool bound to low-density lipoprotein.

If coagulation occurs despite the many anticoagulant mechanisms, endothelial cells also provide proteins to promote fibrinolysis.[194] Endothelium is a major source of tPA.[203,204] Approximately 40% of tPA is bound to its inhibitor, plasminogen activator inhibitor 1, which is also secreted by endothelial cells. Stresses such as exercise, acidosis, hypoxia, shear forces, increased venous pressure, and thrombin will cause release of tPA[203,204] and presumably activate plasminogen. Receptors for plasminogen and tPA are present on the endothelial cell surface, allowing for effective localized production of fibrinolytic activity.

Although intact endothelium is necessary to maintain blood in a fluid state and inhibit coagulation under normal conditions, injured endothelium can rapidly downregulate its anticoagulant functions and become procoagulant, even without overt vascular damage as occurs with trauma or surgery. Further tissue injury or vascular pathology also leads to exposure of the underlying matrix, which is procoagulant by virtue of its binding to and activation of platelets. Endothelial cells that have been induced to undergo apoptosis in vitro become procoagulant. Apoptotic endothelial cells expose phosphatidylserine on their surface and downregulate their anticoagulant properties. Apoptotic endothelial cells and vascular smooth muscle cells also increase thrombin formation in recalcified citrated plasma, and

apoptotic endothelial cells show increased adhesion to unactivated platelets.[160,161,205] Thrombosis resulting from procoagulant changes induced by endothelial apoptosis could contribute to the pathogenesis of diverse diseases.[206]

Even without endothelial death, perturbation of the vascular lining by inflammatory mediators could tip the balance such that the endothelium converts from a nonthrombogenic to a procoagulant surface due to downregulation of anticoagulant properties as well as induction of procoagulant properties. For example, the setting of acute inflammation is associated with increased release of vWF, platelet-activating factor, and fibronectin, all of which may potentiate thrombus formation. Tumor necrosis factor, IL-1, and lipopolysaccharide can increase the expression of plasminogen activator inhibitor 1 in endothelial cells with downregulation or no change in tPA levels, thereby impairing fibrinolysis. Tumor necrosis factor, IL-1, and lipopolysaccharide also have been shown to downregulate thrombomodulin as well as to induce expression of TF on cultured endothelial cells. However, whether endothelial cells express TF on their luminal surface in vivo is controversial.[207] More recently, circulating microparticles generated by leukocytes and vascular cells have been shown to be a source of blood-borne TF and to contribute to coagulation.[208] Although most microparticles probably are derived from platelets and monocytes, endothelial-derived microparticles may be an important source of circulating TF under conditions of drastic activation.[208,209]

Control of Vascular Tone

Control of vascular tone is orchestrated primarily by a balance between endothelium-derived vasodilators [NO, PGI_2, and endothelium-derived hyperpolarizing factor [EDHF]) and vasoconstrictors (endothelin 1 [ET-1] and superoxide). In addition to inhibiting platelet aggregation, NO and PGI_2 act as vasodilators.[210,211] NO is produced by conversion of l-arginine to l-citrulline by NO synthase (NOS). Three forms of NOS exist: a constitutive NOS in neuronal tissue; an inducible enzyme found in macrophages and other cells that plays a role in NO-induced cytotoxicity; and a constitutively active endothelial form, NOSIII (eNOS).[212] The inducible form of NOS also is present in endothelial cells and may be responsible for the uncontrolled vasodilation seen in septic shock.[212] Injection into the forearm of L-arginine analogues that inhibit NOS causes substantial vasoconstriction. Conversely, eNOS-deficient mice are hypertensive, suggesting that NO release is crucial for maintaining basal vasodilation.[210,211] The major physiologic stimulus for continuous production of NO in vivo is shear stress. The action of NO on platelets (antiaggregatory), endothelial cells, and smooth muscle cells (relaxation) is due to activation of guanyl cyclase and formation of cyclic guanosine 3′,5′-cyclic monophosphate. Whereas NO is quite unstable, the formation of *S*-nitrosothiols in the presence of oxygen and thiols provides a stable reservoir of NO.[213] Hemoglobin is an avid scavenger of NO, which may account for the vasoconstriction observed with administration of cell-free, hemoglobin-based red cell substitute.[214] Physiologically, however, *S*-nitrosohemoglobin acts as a regulator of blood flow. Deoxygenation is accompanied by an allosteric change in *S*-nitrosohemoglobin that releases the NO group, relaxing blood vessels to bring blood flow in line with local oxygen requirements.[215]

Prostacyclin (PGI_2), on the other hand, does not appear to have as global a role in vasodilation as does NO. PGI_2 is synthesized mainly by endothelial cells and acts locally at sites of injury. It may counterbalance the vasoconstriction induced by the platelet-produced arachidonic acid metabolite thromboxane A_2 (TXA_2). Most PGI_2 is released luminally, where it has an antiplatelet effect. Prostacyclin transduces a cellular signal by increasing the levels of cyclic AMP, whereas TXA_2 signals via the phosphoinositol pathway and lowering of cyclic AMP levels. Synthesis of prostaglandins begins by the action of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. Aspirin inhibits cyclooxygenase irreversibly in both platelets and endothelial cells. However, the clinical effect is seen primarily in platelets for two reasons.[211,212] One reason is that platelets, being nonnucleated, cannot synthesize new cyclooxygenase, whereas endothelial cells can. Therefore, TXA_2 synthesis recovers only when new platelets enter the circulation, whereas cyclooxygenase production by endothelial cells restores PGI_2 levels within a few hours. The second reason is that platelets encounter orally administered aspirin before it is deacetylated by the liver and diluted by the venous circulation.

Early experimental evidence suggested that endothelial cells release other relaxing factors (i.e., EDHF), which act by increasing the membrane potential of smooth muscle cells. Hyperpolarization of isolated coronary arteries occurs in the presence of an arginine analogue, a NOS inhibitor, and indomethacin, a cyclooxygenase inhibitor, suggesting that EDHF, NO, and prostanoids contribute differentially to relaxation in human coronary arteries.[216] The nature of EDHF is unclear, but it encompasses different biologic mechanisms. These mechanisms involve an increase in intracellular calcium concentration, the opening of calcium-activated potassium channels, and the hyperpolarization of endothelial cells, resulting in an endothelium-dependent hyperpolarization of smooth muscle cells.[217] Smooth muscle cell hyperpolarization may occur through direct myoendothelial electrical coupling and/or through accumulation of potassium ions in the intercellular space. Findings suggest that EDHF represents cytochrome P450-linked arachidonate metabolites in some blood vessels, but also lipoxygenase derivatives and hydrogen peroxide.[217]

ET-1 is a 21-amino-acid peptide, released preferentially at the abluminal surface of endothelial cells, that exhibits potent vasoconstrictor activity.[218,219] Of the three known endothelins, only ET-1 is produced by endothelial cells. At least two receptors (ET-A and ET-B) bind to all three endothelins. ET-A is abundantly expressed on smooth muscle cells, whereas ET-B is predominantly expressed on endothelial cells. The vasoconstrictor activity of ET-1 is preferentially mediated by ET-A receptors on smooth muscle cells. Engagement of ET-B on endothelial cells by ET-3 may paradoxically cause a transient vasodilation. Little evidence indicates that ET-1 plays a role in essential hypertension, but it might contribute to pregnancy-induced hypertension and may play a role in reperfusion injury following ischemia.[219] ET-1 does appear to play a role in pulmonary arterial hypertension, and the dual endothelin receptor antagonist bosentan has been approved for treatment of this disease.[220]

Another seemingly important regulator of vascular tone is the superoxide anion.[210,221] The source of this free radical may be the endothelium itself or inflammatory cells that have been recruited to sites of injury or inflammation. Interaction of superoxide radicals and NO produces peroxynitrite and reduces the concentration of NO. Peroxynitrite can oxidize low-density lipoprotein and deleteriously modify other proteins, thereby causing endothelial dysfunction. Increased production of superoxide inhibits synthesis of PGI_2 but not that of TXA_2.[221]

The endothelium expresses angiotensin-converting enzyme at its surface; this enzyme converts angiotensin I to angiotensin II, a potent vasoconstrictor. The interaction among endothelin, angiotensin II, and α-adrenergic agonists in the pathogenesis of hypertension is complex.[222] An altered balance of the vasoactive substances described in this section has been proposed to cause endothelial dysfunction and the attendant vascular pathology observed in atherosclerosis, hypertension, and diabetes mellitus. Alteration of vascular function in these diseases then may perpetuate endothelial dysfunction and, consequently, worsen disease.

Interaction of Blood Cells with the Vessel Wall

Leukocytes

In the absence of any inflammatory stimulus, neutrophils circulate freely and do not interact significantly with the endothelium. This contrasts with continuous, low-level physiologic traffic of monocytes and lymphocytes across the vessel wall. Monocytes emigrate from the bloodstream to develop into tissue macrophages that may exhibit

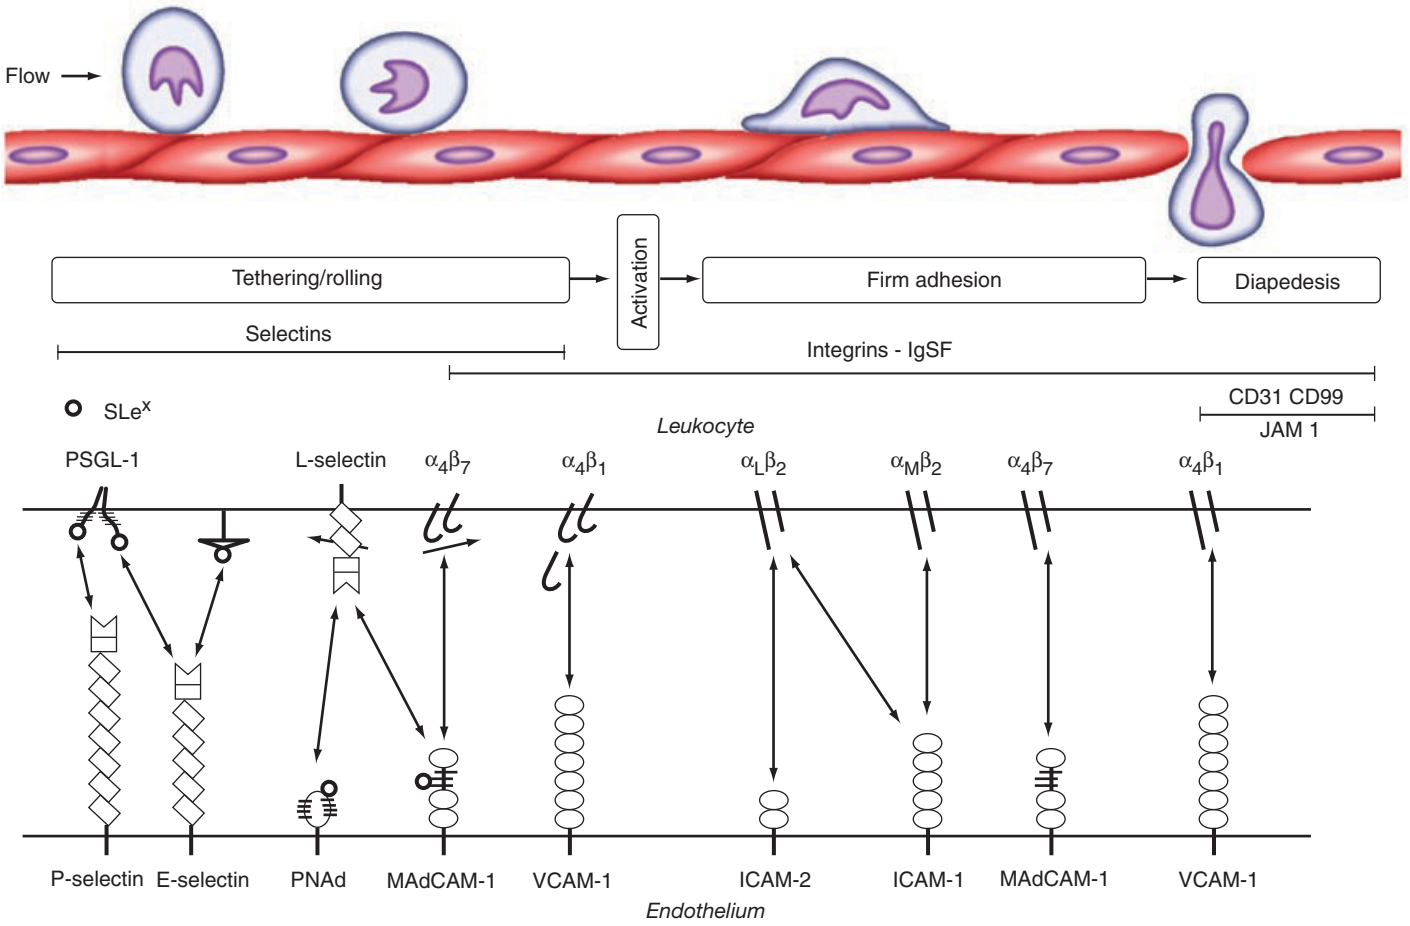

Figure 117–3 Adhesion cascade. Under conditions of flow, leukocytes first tether to endothelial ligands and then roll along the vessel wall. Tethering is mediated predominantly by interaction of P-selectin and L-selectin with their cognate glycoconjugate ligands. P-selectin binds to sialyl Lewis X (SLe^x) and sulfate residues expressed on P-selectin glycoprotein ligand 1 (PSGL-1). L-selectin binds to an uncharacterized ligand(s) on inflamed endothelium and to sulfated SLe^x-like moieties on peripheral node addressin (PNAd) and mucosal addressin cell adhesion molecule 1 (MAdCAM-1) on high endothelial venules. E-selectin, $\alpha_4\beta_1$ (very late antigen 4 [VLA-4]), and $\alpha_4\beta_7$ stabilize rolling initiated by P-selectin and L-selectin. E-selectin recognizes SLe^x on PSGL-1 and other glycoproteins or glycolipids. Following tethering and rolling, leukocyte integrin receptors are activated, most often by chemoattractants (e.g., chemokines) via G protein-coupled receptors. After activation, integrin receptors engage endothelial immunoglobulin gene superfamily ligands to promote firm adhesion. Leukocyte $\alpha_L\beta_2$ (leukocyte function antigen 1 [LFA-1]) binds to intercellular adhesion molecules ICAM-1 and ICAM-2, $\alpha_M\beta_2$ (macrophage 1 [Mac-1]) to ICAM-1, $\alpha_4\beta_1$ (VLA-4) to vascular cell adhesion molecule 1 (VCAM-1), and $\alpha_4\beta_7$ to MAdCAM-1. The adherent leukocyte then migrates across endothelium to interendothelial junctions, where it diapedeses between endothelial cells via leukocyte integrin receptors and their endothelial immunoglobulin gene superfamily ligands as well as endothelial junctional proteins such as CD31, CD99, and junctional adhesion molecule 1 (JAM-1).

tissue- or organ-specific functions. To maintain immune surveillance of tissue, lymphocytes recirculate between blood and lymphatics, gaining entrance to the latter at the high endothelial venule of postcapillary venules in lymphoid tissue.

Intravital microscopic studies have established a sequence of events involved in leukocyte emigration at extravascular sites of inflammation. Under conditions of flow, leukocytes first tether to and then roll along the endothelium of postcapillary venules adjacent to the site of inflammation. Some of the rolling leukocytes are activated and adhere firmly. The adherent leukocytes migrate along the endothelial surface and diapedese between endothelial junctions to enter the extravascular tissue. These steps in emigration tethering, rolling, activation, firm adhesion, and diapedesis also are involved in lymphocyte emigration at high endothelial venules. They result from the interaction of distinct leukocyte and endothelial receptors in an adhesion cascade (Fig. 117–3; see Chapter 16).[223,224] Rolling is observed only under flow conditions and is the consequence of shear forces acting on the leukocyte and adhesive interactions between selectin receptors and their glycoconjugate counterstructures.[225] It is initiated primarily by activation of the endothelium by extravascular stimuli such as bacterial-derived products or by endogenous mediators produced by the endothelium or cells in tissue. Early on, rolling is mediated by endothelial P-selectin, which is rapidly translocated from Weibel-Palade bodies to the luminal surface, and L-selectin on leukocyte microvilli. E-selectin is involved only at later time points, as it is not constitutively expressed by endothelium but rather is induced over hours by de novo synthesis.

In order for leukocytes to circulate freely, their integrin receptors must be minimally adhesive, but they also must be able to increase binding rapidly at sites of inflammation. Once tethered to endothelium by selectin interactions, leukocyte integrin receptors are activated by endothelial membrane-expressed platelet-activating factor, endothelial membrane-bound chemokines, or locally secreted chemoattractants. Activation of leukocyte integrins involves changes in receptor affinity or affinity-independent receptor clustering,[226] which promotes firm adhesion to endothelial ligands, which are members of the immunoglobulin gene superfamily (IgSF). These IgSF ligands are constitutively expressed (ICAM-1, ICAM-2), further upregulated (ICAM-1), or induced (VCAM-1) by inflammatory mediators (Table 117–1). Although these activation-dependent increases in leukocyte integrin binding to endothelial IgSF ligands are necessary for shear-resistant firm adhesion, subsequent leukocyte migration over the endothelium requires reversible adhesion due to cyclic modulation of receptor avidity.[227]

Table 117–1 Endothelial Cell Activation[a]

Agonist	Response
Thrombin	Secretion of vWF, P-selectin, TFPI, and PDGF Synthesis of PAF, IL-8, IL-6, and E-selectin
IL-1β, TNF-α, LPS	Synthesis of adhesion molecules (ICAM-1, VCAM-1, E-selectin), chemokines (IL-8, MCP-1), cytokines (IL-6, CD40), procoagulant proteins (TF, PAI-1, tPA, uPA), and cytoprotective molecules (A1, IAP) Downregulation of anticoagulant proteins (TM)
Reduced/disturbed shear stress	Increased expression of proinflammatory genes (e.g., VCAM-1, ICAM-1, MCP-1)
Vascular endothelial growth factor	Decreased eNOS activity Increased expression of cytoprotective genes (A1, MnSOD), angiopoietin 2, COX-2

[a]Selected agonists and responses. Many other stimuli (e.g., lipoproteins, hypoxia, ,microbes and microbial products) have been reported to upregulate or downregulate various endothelial responses.

A1, Bcl-2 homologue; COX-2, cyclooxygenase 2; eNOS, endothelial nitric oxide synthase; IAP, inhibitor of apoptosis protein; ICAM, intercellular adhesion molecule; IL, interleukin; LPS, lipopolysaccharide; MCP, monocyte chemoattractant protein; MnSOD, manganese superoxide dismutase; PAF, platelet-activating factor; PAI, plasminogen activator inhibitor; PDGF, platelet-derived growth factor; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; TNF, tumor necrosis factor; tPA, tissue plasminogen activator; uPA, urokinase plasminogen activator; VCAM, vascular cell adhesion molecule; vWF, von Willebrand factor.

There are several caveats regarding the current multistep model of initial selectin-mediated rolling and subsequent integrin-mediated firm adhesion.[228] First, selectin-mediated rolling is not a prerequisite for emigration under conditions of reduced flow, as might occur at sites of inflammation.[229] Second, the model was developed from observations in the systemic microcirculation, where leukocyte emigration occurs in postcapillary venules under relatively low shear forces. However, selectins do not appear to play a major role in neutrophil emigration in the pulmonary microcirculation, where emigration occurs predominantly in capillaries,[230] or in the liver microvasculature, where leukocytes emigrate primarily in sinusoids.[231] Third, under some conditions leukocytes are able to tether and roll via receptors other than selectins and α_4 integrins (e.g., CD44[232] or VAP-1[233]). Finally, several other adhesion pathways have been implicated in leukocyte adhesion to endothelium in vitro, and their roles in the adhesion cascade in vivo remain to be defined.[228]

Once adherent, leukocytes migrate upon the endothelial luminal surface. Upon encountering an intercellular junction, some leukocytes diapedese between endothelial cells, enter extravascular tissue, and then migrate to the site of inflammatory or immune reaction.[234,235] This process of transendothelial migration uses leukocyte integrin interactions with endothelial IgSF ligands[236] and several junctional proteins, including PECAM-1 (CD31)[237] JAM-1,[238] and CD99.[239] Diapedesis involves signaling by the leukocyte to the endothelial cell that triggers opening of endothelial cell junctions.[240] Although leukocyte migration is primarily paracellular (i.e., through endothelial cell–cell junctions), under certain circumstances leukocytes may emigrate by a transcellular pathway.[241]

Leukocyte recruitment is terminated by several mechanisms. E-selectin and P-selectin are removed from the endothelial cell surface by endocytosis,[242] whereas L-selectin is cleaved from leukocytes by a membrane protease.[243] Decay of cytokine, chemokine, or chemoattractant generation leads to gradual resolution of endothelial adhesion molecule expression and integrin activation. Locally expressed mediators, such as NO,[244] TGF-β,[245] and Fas ligand,[246] also inhibit further leukocyte adhesion to endothelium.

The adhesion molecules involved in leukocyte trafficking from bloodstream to tissue have emerged as important therapeutic targets. Extensive preclinical studies showed that blockade of leukocyte or endothelial adhesion molecules was efficacious in diverse disease models,[247] prompting the development of adhesion antagonists for clinical trials in a variety of diseases. However, results were disappointing overall, with many unsuccessful clinical trials of various adhesion antagonists in multiple disease indications.[248,249] Moreover, the report of progressive multifocal leukoencephalopathy, a rare viral infection of the central nervous system, in several patients treated with the α_4-integrin antagonist natalizumab[250] highlights the risks of targeting molecules that are pivotal in host defense and repair as well as in disease. Nevertheless, the potential of antiadhesion therapy is demonstrated by the approval of two integrin antagonists: efalizumab for treatment of psoriasis[251] and natalizumab for treatment of multiple sclerosis.[252]

Platelets

Like neutrophils, unactivated platelets do not interact with unperturbed endothelium. Following a vascular injury that produces endothelial denudation or retraction, platelets rapidly adhere to the exposed subendothelium. As discussed in greater detail in Chapters 115 and 116, at high shear rates this initial adhesion does not require platelet activation and involves platelet glycoprotein Ib/V/IX (GPIb-V-IX) binding to vWF in the subendothelial matrix and platelet GPVI binding to collagen in the injured arterial wall. Platelet activation occurs following adhesion, leading to platelet spreading mediated by integrin receptors binding to matrix components and aggregation mediated by fibrinogen binding to GPIIb/IIIa ($\alpha_{IIb}\beta_3$).

Evidence indicates that platelets can bind directly to activated endothelium in vivo via endothelial P-selectin[253] and PECAM-1[254] and to roll on venular endothelium via interaction of platelet GPIbα and endothelial P-selectin.[255] Platelets have been shown to bind to high endothelial venules in vivo via platelet P-selectin.[256] In vitro platelets can adhere to intact endothelium via a platelet GPIIb/IIIa-dependent bridging mechanism involving platelet-bound adhesive proteins and the endothelial cell receptors ICAM-1, $\alpha_V\beta_3$ integrin, and GPIbα.[257] Platelet adhesion to intact endothelium via these various pathways may contribute to thrombus formation in the circulation and may provide a link between thrombosis and inflammation in diseases such as atherosclerosis.[258] Platelet–endothelial interactions also may contribute to the pathogenesis of thrombotic thrombocytopenic purpura. Normally, ultralarge vWF remains attached to endothelium via P-selectin until it is cleaved by the plasma metalloproteinase ADAMTS-13. Failure of this mechanism in thrombotic thrombocytopenic purpura due to deficiency of ADAMTS-13 may lead to spontaneous platelet adhesion to endothelium and microvascular thrombosis.[259]

Red Blood Cells

Plasmodium falciparum-infected and sickled red blood cells interact significantly with endothelium, and these adhesive interactions are thought to play an important role in the pathogenesis of human diseases.

Among the human malarial parasites, only *Plasmodium falciparum* modifies the surface of the parasitized red blood cells so that asexual parasites and gametocytes are able to adhere to the vascular endothelium.[260,261] Binding of trophozoite- and schizont-infected red blood cells to endothelium not only allows the parasite to escape destruction in the spleen, but it also may contribute to the pathogenesis of cerebral malaria.[261,262] Multiple endothelial adhesion receptors have been implicated in mediating cytoadherence of infected red blood cells, including P-selectin, ICAM-1, VCAM-1, and CD36.[263]

Binding of young sickled red blood cells to postcapillary endothelium with secondary trapping of poorly deformable, often irreversibly sickled cells is thought to be an important pathogenic factor in vasoocclusive events.[264] Several interactions between sickle red cell receptors and endothelial ligands have been described, including $\alpha_4\beta_1$/VCAM-1[265]; $\alpha_4\beta_1$/Lutheran blood group (basal cell adhesion molecule)[266]; and ICAM-4/$\alpha_V\beta_3$.[267] The adhesive proteins thrombospondin and vWF promote adhesion by serving as bridging factors between various sickle red cell and endothelial adhesion molecules. In addition to direct adhesion to endothelium, sickle red cell binding to adherent leukocytes has been proposed as a mechanism for sickle cell vascular occlusion.[268] As with leukocyte adhesion to endothelium in inflammatory and immune disease, drugs targeting sickle red cell adhesive interactions with endothelial cells or leukocytes may prove useful in preventing or treating vasoocclusive crises.

Endothelial Cell Activation and Dysfunction

Although once viewed as a passive barrier between blood and tissue, the endothelium now is evident to be a dynamic and heterogeneous organ that responds to diverse stimuli, ranging from coagulation proteins and cytokines to hemodynamic forces and growth factors. Activation of endothelial cells induces a complex proinflammatory and prothrombotic phenotype as well as expression of certain cytoprotective genes (see Table 117–1).[269,270] Multiple transcription factors, particularly nuclear factor-κB[271] and early growth response 1,[272] regulate these responses.[269] Endothelial activation undoubtedly is an important event in host defense and repair, but it also may contribute to the pathogenesis of diverse diseases, ranging from sepsis[273] to atherosclerosis.[274]

Endothelial dysfunction is characterized by a reduction in the bioavailability of vasodilators, particularly NO, leading to impairment of endothelium-dependent vasodilation, or by an increase in endothelium-derived contracting factors.[275] Endothelial dysfunction is prominent in atherosclerosis but also has been described in diabetes, preeclampsia, hypertension, uremia, and other diseases. In a broader sense, endothelial dysfunction encompasses proinflammatory and procoagulant changes as well as apoptotic cell death.[206,276,277]

A number of noninvasive approaches for assessing endothelial function in vascular diseases have been developed. Endothelial vasodilatory responses can be evaluated by high-resolution ultrasound measurement of flow-mediated vasodilation or by plethysmography of changes in forearm blood flow during reactive hyperemia.[278] Endothelial activation can be assessed in plasma by circulating markers such as soluble endothelial adhesion molecules (e.g., sVCAM-1, sICAM-1, sE-selectin) and endothelial coagulation proteins (e.g., vWF and thrombomodulin)[279] or endothelial microparticles.[280] Circulating endothelial cells reflect significant vascular damage or cell death.[281]

CHAPTER 118

MOLECULAR BASIS OF BLOOD COAGULATION

Bruce Furie and Barbara C. Furie

Blood coagulation is a host defense system that maintains the integrity of the high-pressure closed circulatory system. After tissue injury, alterations in the capillary bed and laceration of venules and arterioles lead to extravasation of blood into soft tissues or external bleeding. To prevent excessive blood loss, the hemostatic system, which includes platelets, endothelial cells, and plasma coagulation proteins, is called into play. Immediately after tissue injury, a platelet plug is formed through the processes of platelet adhesion and aggregation. Concurrently, blood coagulation stabilizes the platelet plug with a fibrin clot.[1] A series of interdependent enzyme-mediated reactions translates the molecular signals that initiate blood coagulation into a major biologic event, the formation of the fibrin clot. Models of the initiation of blood coagulation by tissue factor emphasize that clotting is a nonlinear process, with a critical threshold of tissue factor activity necessary to generate thrombin.[2,3]

In vitro the generation of thrombin and the formation of a fibrin clot propagate through two separate pathways, the intrinsic pathway and the extrinsic pathway.[4,5] To generate a clot via the intrinsic pathway in a test tube, components intrinsic to whole blood are required. The contact system is activated by surface contact to generate a clot via the intrinsic pathway (Table 118–1). The intrinsic pathway of blood coagulation includes protein cofactors and enzymes (Fig.118–1). This pathway is initiated by activation of factor XII by kallikrein on negatively charged surfaces, including glass in vitro. High-molecular-weight kininogen facilitates this activation. The enzyme form of factor XII, factor XIIa, catalyzes the conversion of factor XI, a proenzyme, to its active enzyme form, factor XIa. In the presence of Ca^{2+}, factor XIa activates the proenzyme factor IX to its enzyme form, factor IXa. Factor IXa binds to the cofactor factor VIIIa bound on membrane surfaces in the presence of calcium ions to generate a complex with enzymatic activity known as "tenase," a nickname for the enzymatic activity that acts on factor X. This tenase complex converts the proenzyme factor X to its enzyme form, factor Xa. In a parallel series of interactions, factor Xa binds to the cofactor factor Va bound on membrane surfaces in the presence of calcium ions to generate a complex with enzymatic activity known as *prothrombinase*. This complex converts the proenzyme prothrombin to its enzyme form, thrombin. Thrombin acts on fibrinogen to generate the fibrin monomer, which rapidly polymerizes to form the fibrin clot. During clinical laboratory analysis of blood clotting, the intrinsic pathway of blood coagulation is evaluated by using the activated partial thromboplastin time. Clotting of plasma is initiated by the addition of negatively charged particles such as kaolin.

The extrinsic pathway of blood coagulation also includes protein cofactors and enzymes (see Fig. 118–1). This pathway is initiated by the formation of a complex between tissue factor on cell surfaces or microparticles and factor VIIa. Although the mechanism by which a small amount of factor VII is converted to factor VIIa in the absence of ongoing blood clotting is unknown, plasma contains factor VIIa at levels of 0.5 to 8.4 ng/mL.[6] When tissue factor is in contact with plasma following vascular injury, this factor VIIa complexes with tissue factor to form an enzyme complex that activates factor X to factor Xa. In turn, factor Xa can feed back to convert more factor VII to factor VIIa,[7] thus accelerating the rate of activation of the extrinsic pathway. Factor VIIa/tissue factor complex, like the tenase complex, converts factor X to its active form, factor Xa, which binds to the cofactor factor V bound on membrane surfaces in the presence of calcium ions to generate the prothrombinase complex. This complex converts prothrombin to thrombin, which converts fibrinogen to fibrin to generate the fibrin clot. During laboratory analysis of blood clotting, the extrinsic pathway of blood coagulation is evaluated using the prothrombin time. Clotting of plasma is initiated by the addition of exogenous tissue factor.

This scheme of blood clotting (see Fig. 118–1) remains invaluable for understanding clot formation in vitro and specifically for laboratory monitoring of anticoagulation therapy for, and diagnosis of, coagulation disorders. Yet the physiologic pathways relevant to blood coagulation in vivo are clearly different. A scheme of blood coagulation in vivo must consider the following salient features. First, because patients with hereditary factor XII, prekallikrein, or high-molecular-weight kininogen deficiency have a markedly prolonged partial thromboplastin time but no bleeding phenotype, these proteins are not required to maintain hemostasis in vivo and should not be included in an in vivo model of blood clotting.[8–10] Second, there is a P-selectin–dependent pathway of blood coagulation.[11] Tissue factor, a normal constituent of the surface of nonvascular cells and of stimulated monocytes and endothelial cells, is present in circulating blood, and bloodborne tissue factor is present in the developing thrombus.[12] Circulating microparticles carrying tissue factor and P-selectin glycoprotein ligand 1 (PSGL-1) accumulate in the region of vessel wall injury due to interaction of microparticle PSGL-1 and platelet P-selectin.[13,14] This tissue factor then initiates fibrin formation. Third, the tissue factor/factor VIIa complex activates not only factor X but factor IX as well, suggesting a central role for factors VIII and IX in coagulation initiated by the tissue factor pathway.[15] Fourth, factor XI deficiency is not invariably associated with a significant bleeding phenotype; as such, the position and prominence of factor IX in the blood coagulation cascade remain uncertain. Fifth, although deficiency of factor XII is not associated with a hemostatic defect, it appears to be protective from thrombosis.[16] Figure 118–2 shows a model of blood coagulation and the pathway of sequential reactions that might lead to clot formation in vivo.[17] The key to initiation of blood coagulation and thrombin generation is tissue factor. Exposure of cell surfaces expressing active tissue factor to the plasma proteins in blood leads to binding of factor VIIa to tissue factor. Tissue factor on some membrane surfaces, including microparticles and certain cells, may be inactive (encrypted). Thiol isomerases may be important for regulating the activity of tissue factor by formation of a disulfide bond on the surface of the protein.[18] Tissue factor complexed to the activated form of factor VII, factor VIIa, activates factors IX and X.[19] The protease responsible for initial activation of factor VII is unknown, but once clotting is activated, several proteases farther down the pathway can activate factor VII. Factors Xa and VIIa both catalyze activation of factor VII, so a potential mechanism for acceleration of factor VII activation exists.[20] Furthermore, both thrombin and factor XIa in the presence of negatively charged surfaces catalyze activation of factor XI.[21] Once factor XIa is generated, an additional mechanism augments activation of factor IX. Factor IXa in complex with factor VIIIa on membrane surfaces activates factor X. Factor Xa in complex with factor Va on membrane surfaces activates prothrombin. Thrombin cleaves fibrinogen, yielding monomeric fibrin, which then polymerizes to form the fibrin clot.

The blood coagulation cascade proceeds on membrane surfaces, although the source of these membranes remains uncertain. Only

Table 118–1 Properties of the Genes, mRNAs, and Gene Products of the Components of the Blood Coagulation Cascade

	Molecular Weight	Gene (kb)	Chromosome	mRNA	Exons (kb)	Plasma Concentration (μg/mL)	Function
Prothrombin	72,000	21	11p11–q12	2.1	14	100	Protease zymogen
Factor X	56,000	22	13q34	1.5	8	10	Protease zymogen

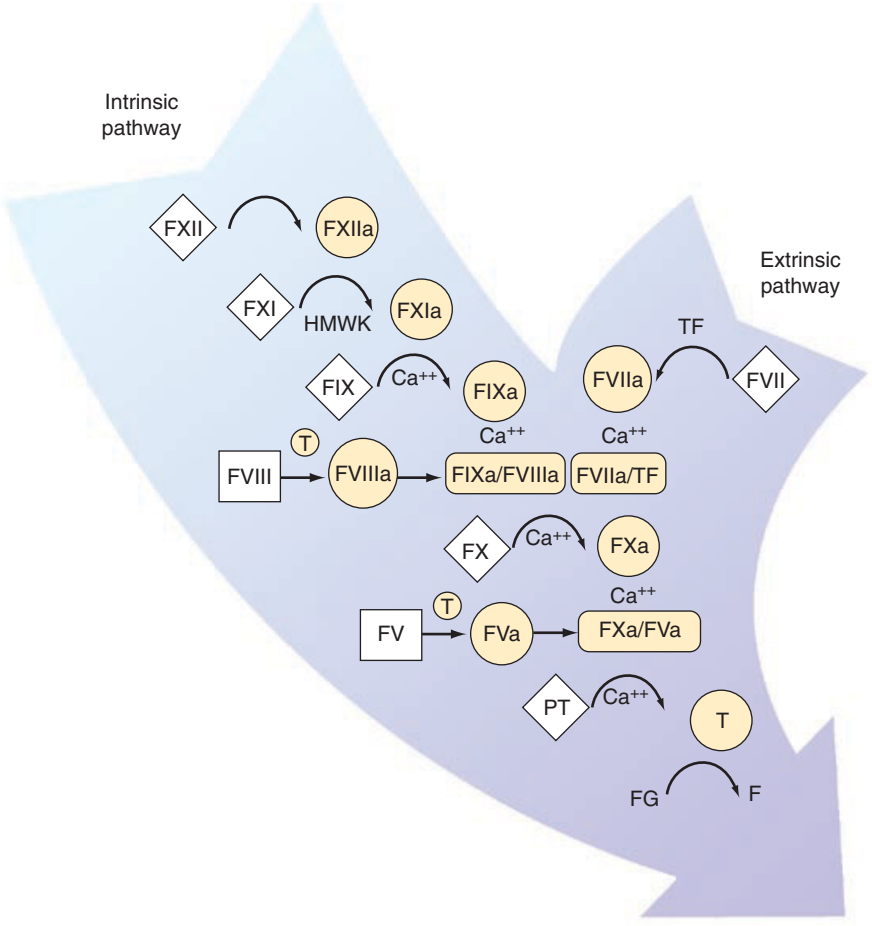

Figure 118–1 Blood coagulation cascade. Glycoprotein components of the intrinsic pathway include factors XII, XI, IX, VIII, X, and V, prothrombin, and fibrinogen. Glycoprotein components of the extrinsic pathway, initiated by the action of tissue factor located on cell surfaces, include factors VII, X, and V, prothrombin, and fibrinogen. Cascade reactions culminate in the conversion of fibrinogen to fibrin and the formation of a fibrin clot. Certain reactions, including activation of factor X and prothrombin, take place on membrane surfaces. Diamonds represent proenzymes; squares represent procofactors; circles represent enzymes and cofactors; shaded rectangles represent macromolecular complexes on membrane surfaces. F, fibrin; FG, fibrinogen; HMWK, high-molecular-weight kininogen; PT, prothrombin; T, thrombin; TF, tissue factor. *(Modified from Furie and Furie.[307])*

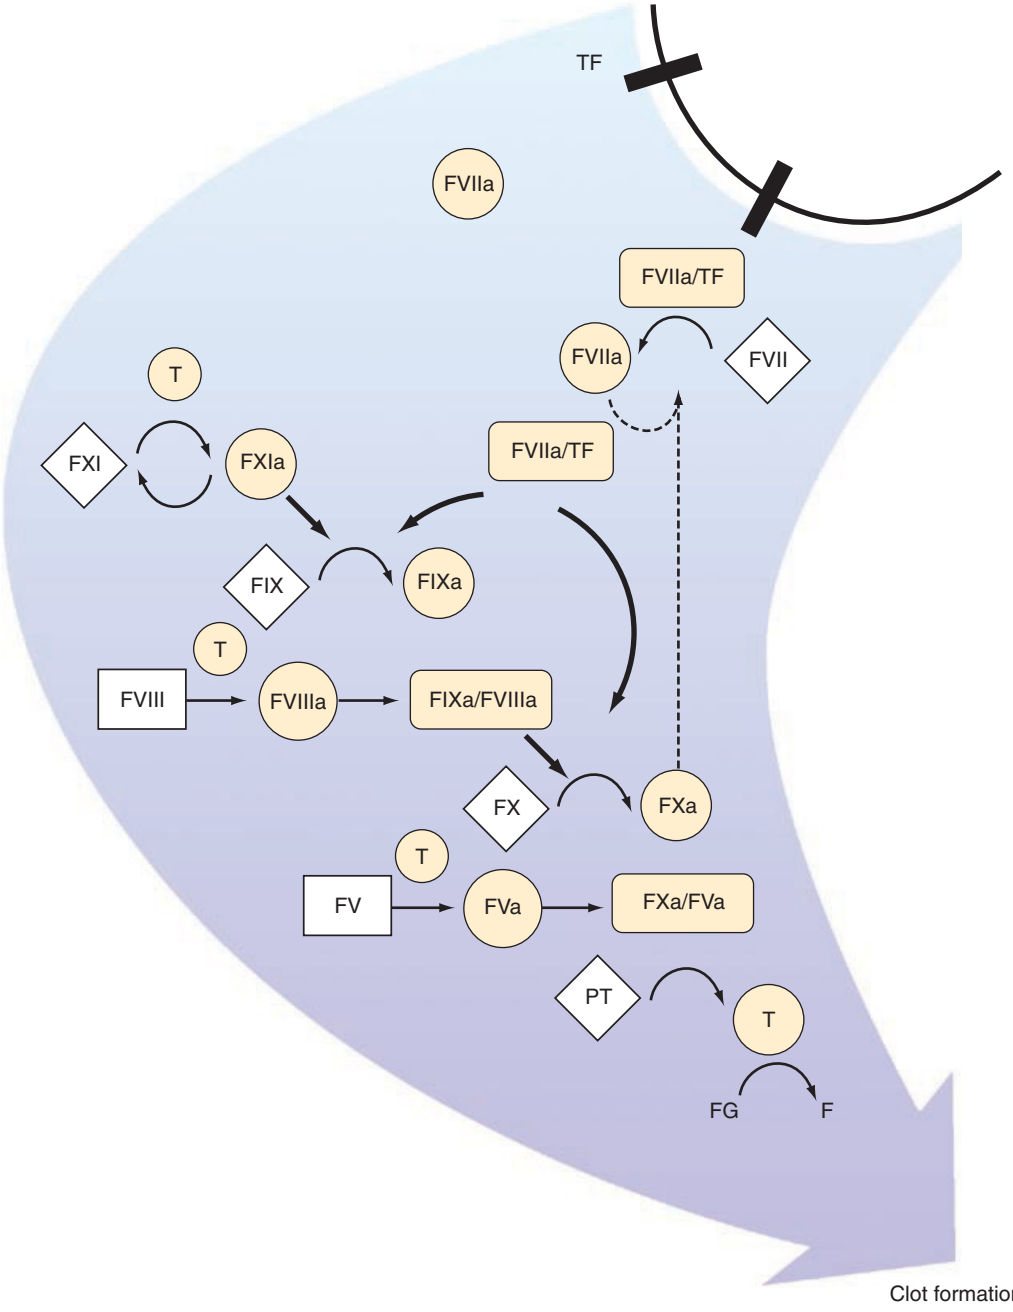

Figure 118–2 Physiologic pathways of blood coagulation. Blood coagulation is initiated by tissue factor (TF) expressed on cell surfaces. When plasma comes in contact with tissue factor, factor VIIa in plasma binds to this receptor. The factor VIIa/tissue factor complex activates both factor IX and factor X. The proteolytic activation of factor VII to VIIa, factor XI to XIa, factor VIII to VIIIa, and factor V to Va through feedback mechanisms (e.g., thrombin [T] or factor XIa [FXIa]) greatly accelerates the rate of blood clotting. The process culminates in the generation of fibrin and its polymerization to form a fibrin clot. *(From Furie B, Furie BC: The molecular basis of blood coagulation. Cell 53:505, 1988.)*

the membrane surfaces of stimulated cells can support the reactions involved in blood clotting. Phosphatidylserine, a critical component of the cell membrane that is required for assembly of blood clotting proteins on membrane surfaces, is exposed on the external membrane surface following cell activation. Phosphatidylserine is asymmetrically distributed on the phospholipid bilayer of the plasma member. An enzyme known as phospholipid scramblase catalyzes the calcium-dependent redistribution and phosphatidylserine exposure to the outer leaflet.[22–24] Tissue factor is an integral membrane protein constitutively expressed on the surface of nonvascular cells,[25–27] on the surface of monocytes and endothelial cells following cell stimulation with certain agonists, and present on leukocyte-derived microparticles circulating in the blood.[13,14,28] This protein binds to factors VII and VIIa, generating the tissue factor/factor VIIa complex on membrane surfaces that activates factor X.[29] In another example of enzyme assembly on membrane surfaces, factors IXa and VIIIa both bind to anionic phospholipid membranes.[30,31] It is envisioned that these two proteins skate about on the membrane, collide, and form the tenase complex, factor IXa/factor VIIIa. This complex has the enzymatic activity to convert factor X, also bound to the cell membrane, to factor Xa. Similarly, factors Xa and Va bind to anionic phospholipid membranes.[32] These two proteins also skate about on the membrane, collide, and form the "prothrombinase" complex, factor Xa/factor Va.[33] This complex has the enzymatic activity to convert prothrombin, also bound to the cell membrane, to thrombin, which is released from the cell surface. Although it has been suggested that individual phospholipids might be allosteric effectors of protein assembly on membrane surfaces,[34,35] a two-dimensional membrane bilayer surface with multisite features of participating phospholipid head groups appears critical.[36] In vivo, platelet membranes, endothelial membranes, or microparticle membranes may contribute to the critical surface for blood clotting. Activated (but not resting) platelets express a factor VIIIa-binding site.[37] During platelet activation in vitro, microparticles are released from the plate-

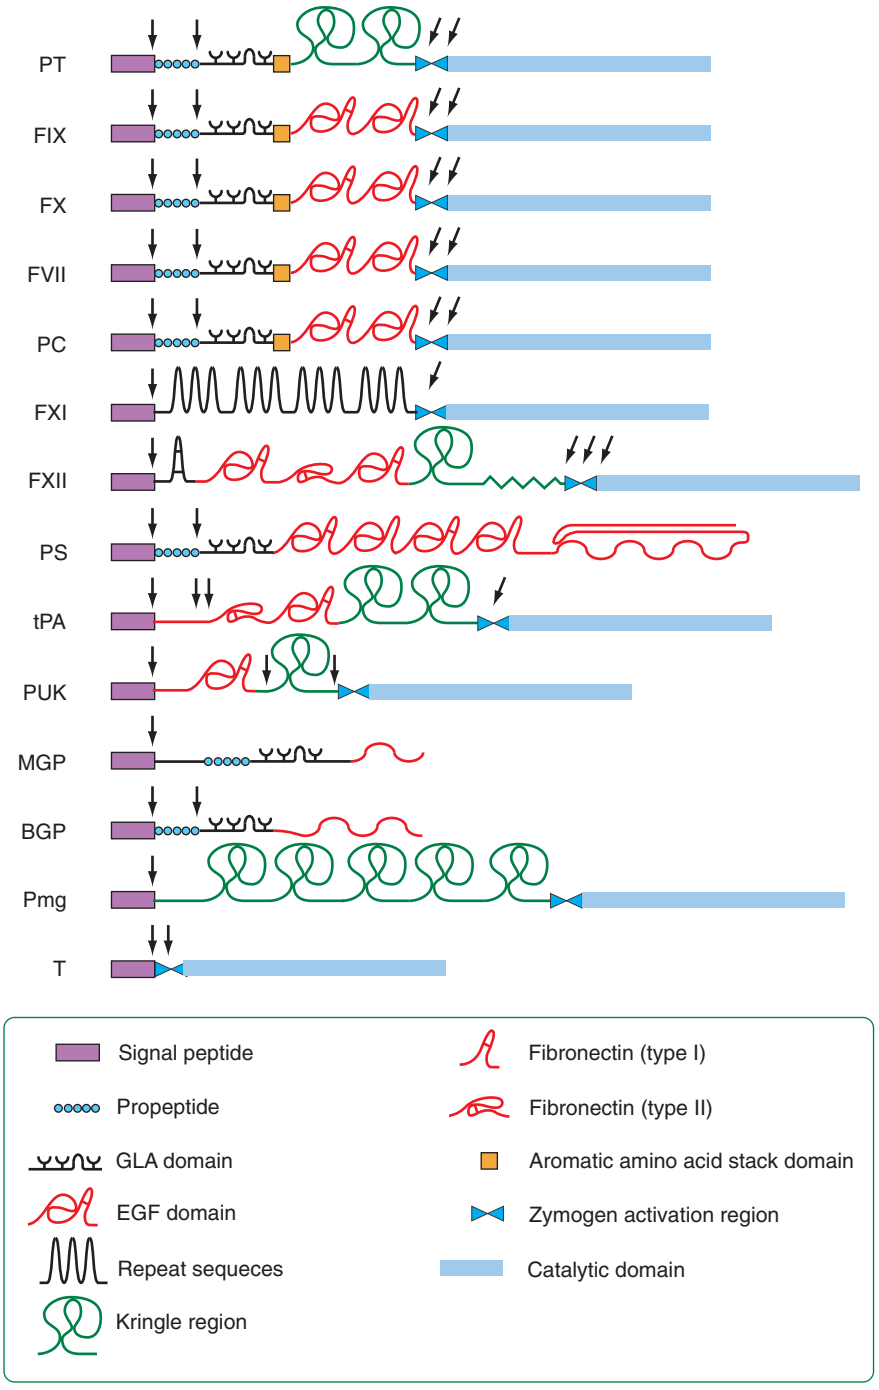

Figure 118–3 Structural domains of the proteins involved in hemostasis and related proteins. Domains, identified in the key, include signal peptide, propeptide, Gla domain, epidermal growth factor (EGF) domain, repeat sequences, kringle region, fibronectin (types I and II) domains, aromatic amino acid stack, zymogen activation region, and catalytic domain. Sites of proteolytic cleavage associated with synthesis of mature protein are indicated by thin arrows and those associated with zymogen activation by thick arrows. BGP, bone Gla protein; FIX, factor IX; FVII, factor VII; FX, factor X; FXI, factor XI; FXII, factor XII; MGP, matrix Gla protein; PC, protein C; Pmg, plasminogen; PS, protein S; PT, prothrombin; PUK, prourokinase; T, trypsin; tPA, tissue plasminogen activator. *(Modified from Furie B, Furie BC: The molecular basis of blood coagulation. Cell 53:505, 1988.)*

let membrane that are especially rich in receptors for factors VIIIa and Va.[38]

STRUCTURE OF THE BLOOD COAGULATION PROTEINS

Domain Structure

Each of the blood coagulation proteins contains multiple functional units, derived from common ancestral genes (Fig. 118–3). As a rule these functional units, or domains, are encoded by individual exons. Although the domains are not structurally identical, they have sufficient homology in structure to suggest homology of function as well. These domains are responsible for directing protein trafficking and posttranslational processing during biosynthesis and for membrane-binding properties, protein complex formation, and enzyme function of the mature protein. In factor IX, for example, these domains are independently folded but give evidence of significant interdomain interaction.[39]

Signal Peptide

The nascent chains of secreted proteins contain a short domain that permits translocation of the growing polypeptide chain into the endoplasmic reticulum. This domain is dominated by hydrophobic amino acids and usually is approximately 15 to 30 residues in length. The blood coagulation proteins found in the plasma initially are

synthesized with a signal peptide, which is cleaved within the endoplasmic reticulum by the signal peptidase.

Propeptide/γ-Carboxyglutamic Acid-Rich Domain

The vitamin K–dependent proteins contain a propeptide domain between the signal peptide and the γ-carboxyglutamic acid-rich N-terminal region. This propeptide, 18 residues long in factor IX,[40,41] contains a γ-carboxylation recognition site that directs γ-carboxylation of the vitamin K–dependent proteins after synthesis[42] and is sufficient to carboxylate glutamic acid residues regardless of their sequence context.[43] Adjacent to the carboxylation recognition site is the γ-carboxyglutamic acid-rich region of these proteins. Glutamic acid residues within this region serve as substrates for the vitamin K–dependent γ-carboxylase. After carboxylation, the propeptide is cleaved from the mature protein in a late posttranslational processing step. A single exon in the vitamin K–dependent proteins encodes the propeptide (including the γ-carboxylation recognition site) and the γ-carboxyglutamic acid-rich region of approximately 40 residues. The γ-carboxyglutamic acid (Gla) domain of the vitamin K–dependent proteins contains 10 to 12 γ-carboxyglutamic acid residues and is critical to the Ca^{2+}-binding properties of these proteins. This domain is responsible for promoting the calcium-dependent interaction of these proteins with membrane surfaces, a characteristic essential for the function of these proteins.

The three-dimensional structure of the γ-carboxyglutamic acid-rich region in bovine prothrombin fragment 1 is disordered in the absence of Ca^{2+}.[44] In the presence of Ca^{2+} the Gla domain assumes a unique structure.[45] Of the 10 γ-carboxyglutamic acid residues, four residues on one side and two residues on the other define a carboxylate surface that chelates five Ca^{2+} organized in a linear cluster that extends from one side of the molecule to the other (Fig. 118–4).

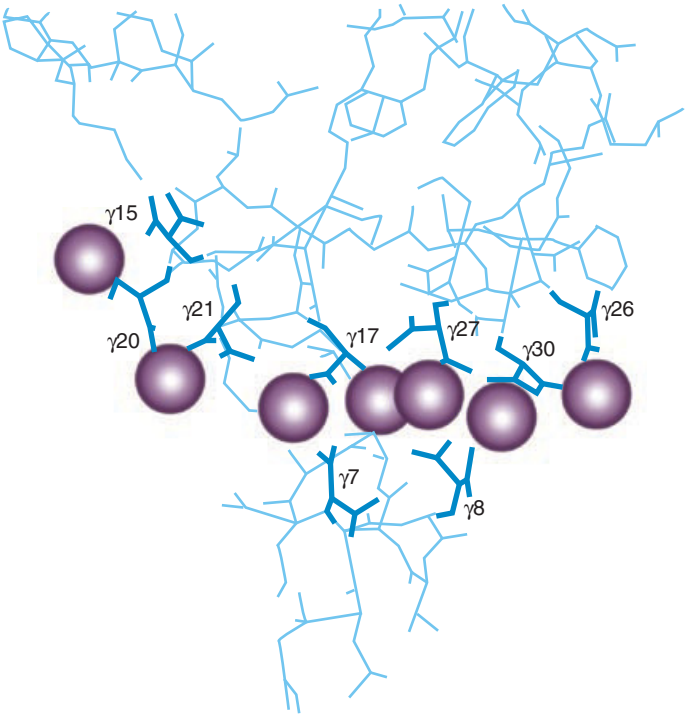

Figure 118–4 Three-dimensional structure of the γ-carboxyglutamic acid-rich region of prothrombin. This region is responsible for metal binding and membrane-protein interaction. *(Modified from Soriano-Garcia M, Padmanabhan K, de Vos AM, Tulinsky A: The Ca^{2+} ion and membrane binding structure of the Gla domain of Ca-prothrombin fragment 1. Biochemistry 31:2554, 1992.)*

The NH_2-terminal alanine loops back to form an ion pair with Gla17, Gla21, and Gla27. With the exception of Gla6, all the γ-carboxyglutamic acid residues are critical for prothrombin function.[46] The mechanism by which this region promotes interaction of the protein with membrane surfaces involves the formation of this unique fold and the expression of a membrane-binding site. The Gla domains of factors VII, X, and IX show marked three-dimensional structural homology in their calcium-stabilized conformer compared to the Gla domain of prothrombin.[47–51]

Epidermal Growth Factor Domain

The epidermal growth factor (EGF)-like domain is a common motif found in many proteins, including some of the proteins involved in blood coagulation. In the blood clotting proteins it is highly homologous with the EGF precursor. This domain, approximately 43 to 50 amino acid residues in length, contains three disulfide bonds arranged in a characteristic covalent structure. Although the EGF domain in some proteins mediates their interaction with an EGF or EGF-like receptor on cell surfaces, the EGF domains on the blood clotting proteins participate in protein complex formation. A calcium-binding site, present in some of the EGF domains of the vitamin K–dependent proteins, is defined by carboxylate groups on aspartic acid.[52] The structures of the EGF domains of factors IX and X, determined by nuclear magnetic resonance spectroscopy, demonstrate marked homology with the three-dimensional structure of EGF.[53,54] Factors IX, X, and VII contain two adjacent EGF domains (as does protein C, whereas protein S has four EGF domains). Factor XII contains two nonadjacent EGF domains, whereas tissue plasminogen activator (tPA) and prourokinase each has a single EGF domain. This domain appears to be critical for protein complex formation.[55]

Kringle Domain

Another common motif in proteins is the kringle domain. This region, with a characteristic covalent structure defined by a pattern of three disulfide bonds, is approximately 100 amino acid residues in length. The three-dimensional structure of the prothrombin kringle reveals an oblate ellipsoid, with folding defined by close contacts between the sulfur atoms of two of the disulfide bridges.[44] Internal structures are well conserved among kringles from various proteins, but molecular surface differences relate to differences in function. The kringle domains play a role in protein complex formation. In prothrombin, the second kringle domain interacts with factor Va in the prothrombinase complex.[56] Among the proteins involved in hemostasis, kringles are found in prothrombin,[57] factor XII,[58] plasminogen,[59] prourokinase,[60] and tPA.[61]

Catalytic Domain

A catalytic domain that is highly homologous with the structure of trypsin and chymotrypsin is common to all blood clotting enzymes. This protease domain includes a site for conversion of an inactive proenzyme to an active enzyme via cleavage of peptide bonds, a regulatory process known as *zymogen activation by limited proteolysis.* Furthermore, this domain contains the enzymatic machinery for cleavage of peptide bonds, the specific recognition site for protein substrates, and the site for interaction with specific protein inhibitors that regulate enzymatic activity. The blood clotting proteases are serine proteases, a class of enzymes with a common mechanism of enzymatic action that requires the catalytic triad of serine, aspartic acid, and histidine within the active site. The catalytic domain of the blood clotting proteases has an active site and an internal core nearly identical to that of trypsin.[62] The molecular surfaces surrounding the enzyme active site are responsible for defining the extended substrate-binding site of the enzyme. Solution of the crystal structure of human α-thrombin has emphasized the structural homology between throm-

bin and other well-characterized serine proteases.[63] Two patches of positively charged amino acids close to the C-terminal B-chain helix form the presumed heparin-binding site and a secondary fibrinogen-binding site.[64] Interaction of the A and B chains is stabilized by charged residues. A deep canyon-like active site cleft probably contributes significantly to the narrow substrate specificity of thrombin.[63,64]

Other Domains

Other motifs that appear within the proteins involved in hemostasis include the aromatic amino acid stack domain, the apple domains observed in factor XI, and the fibronectin type I and type II domains. The functions of these domains are unknown.

Components of the Intrinsic and Extrinsic Pathways

Factor XII

The factor XII gene, located on chromosome 5, contains 14 exons and 13 introns (Fig. 118–5).[58] Exon I encodes the signal peptide, exon II encodes a segment with no structural homology with other proteins, exons III and IV code for a region homologous with the type II fibronectin structure, exons V and VII each encodes EGF domains, exon VI encodes a fibronectin finger domain that intervenes between the EGF domains, and exons VIII and IX each encodes a kringle domain. The trypsin-like catalytic domain, including the activation region, is encoded by the remaining exons X to XIV. The gene organization of the catalytic domains parallels that of urokinase, factor XI, and tPA. The factor XII mRNA is 2.4 kb in length.[58,65] The mature plasma form of factor XII is composed of 596 amino acid residues in a single polypeptide chain.[58,65]

Factor XII, also known as *Hageman factor,* is the first component of the intrinsic pathway. As such, it is a component of the contact phase of activation of blood coagulation observed in vitro. This protein does not appear to have a physiologic role in hemostasis in vivo, as patients lacking this protein do not have a bleeding disorder. Indeed, the propositus, John Hageman, died of a pulmonary embolism following a fall. The protein circulates in the blood as a single-chain proenzyme of 80,000 molecular weight.[66,67] Factor XII is a glycoprotein, with carbohydrate attached to Asn230 and Asn414. Other glycosylation sites include Thr280, 286, 309, 310, and 318 and Ser289. The surface-binding properties of factor XII, specifically enhancement of the rate of factor XII activation by negatively charged surfaces, may be mediated by the positively charged amino acid sequence His-Lys-Tyr-Lys, a structure common to factor XII and kininogen.[68] The factor XII concentration in plasma is approximately 30 μg/mL. Factor XII has a plasma half-life of 2 days.[69]

Factor XI

The gene for factor XI, an intrinsic pathway component, contains 15 exons and 14 intervening sequences (see Fig. 118–5).[70] Exon I encodes a 5′ untranslated sequence, whereas exon 2 encodes a signal peptide. Four repeat sequences are each encoded by two exons: repeat 1 by exons III and IV, repeat 2 by exons V and VI, repeat 3 by exons VII and VIII, and repeat 4 by exons IX and X. The four apple domains play a role in protein recognition. High–molecular-weight kininogen has binding sites on the apple 1, 2, and 4 domains. Factor IX binds to the apple 2 and 3 domains. Factor XIIa binds to the apple 4 domain. The trypsin-like domain, responsible for the proteolytic function of the enzyme form of the zymogen, is encoded by exons XII to XV. Factor XI has a molecular weight of 160,000[71] and is composed of two identical chains bound together by disulfide bonds.[72] Factor XI circulates in the blood as a disulfide-lined homodimer at a concentration of 5 μg/mL. It has a biologic half-life of approximately 3 days.[73]

The crystal structure of human factor XI at 2.9 Å reveals the four apple domains in a structure resembling a flat saucer.[74] A cavity in the center of the structure is lined with basic and aromatic amino acids. The protease domain has a structure typical of serine proteases. The apple domains form a circular platform around the base of the protease domain.

Factor IX

Factor IX plays a critical role in blood coagulation (see Chapter 124). Its gene, adjacent to the factor VIII gene, is located on the X chromosome. Defects in this gene, both major and minor, are the cause of hemophilia B (see Chapter 125). This gene is 34 kb in length, contains eight exons,[75] and has a structure that is highly homologous with the structures of factors VII and X and protein C genes (see Fig. 118–5). These genes are sufficiently similar to suggest that they are derived ancestrally from a common related gene. Factor IX is encoded on a 2.8-kb mRNA transcript. The factor IX gene is regulated by a liver-specific *cis*-activating element that binds to the liver-specific transcription factors CCAAT enhancer-binding protein (C/EBP) and nuclear factor 1 (NF-1). The NF-1 binding site is located at −99 to

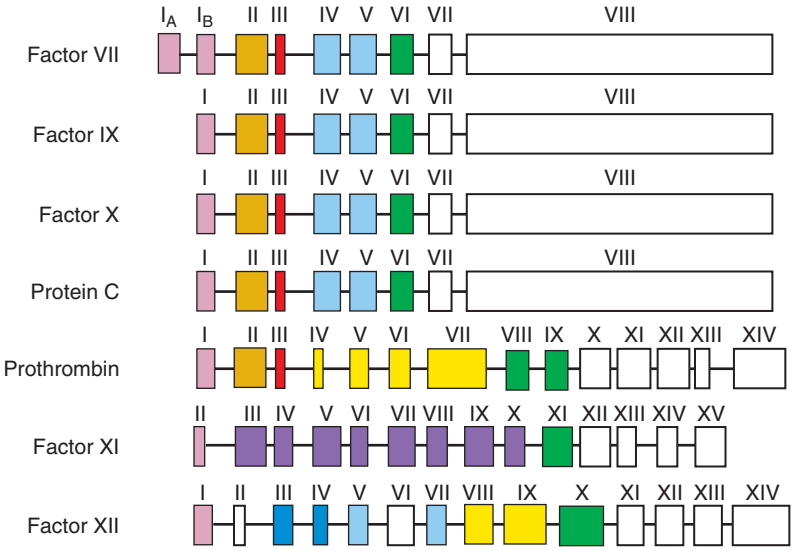

Figure 118–5 Gene structures among the blood coagulation and regulatory serine proteases. Exons are shown schematically according to scale. Introns (thin lines) are not drawn to scale. *(Modified from Furie B, Furie BC: The molecular basis of blood coagulation. Cell 53:505, 1988.)*

−76 upstream of the transcriptional start site.[76] The EBP-binding site is located close to the transcription initiation site. An androgen-responsive promoter element in the factor IX gene explains the curious phenotype of factor IX Leyden (see Chapter 124).[77]

The mature protein, with a molecular weight of 56,000, requires vitamin K for its synthesis and contains 12 γ-carboxyglutamic acid residues. The fully carboxylated form of the protein binds to calcium ions and to membrane surfaces in the presence of calcium ions. Factor IX contains metal-binding sites, defined by γ-carboxyglutamic acid,[78] and another class of metal-binding site that is a component of the EGF domain.[79,80] The site within the EGF domain is defined in part by Asp64, a residue that is partially β-hydroxylated. Factor IX is a glycoprotein containing N- and O-linked sugars. Factors IX and IXa bind to phospholipid membranes composed of phosphatidylserine-phosphatidylcholine.[31,81] This interaction requires both Ca^{2+} and fully carboxylated factor IX.[81] The x-ray structure of porcine factor IXa in the absence of calcium demonstrates the relationship of the two EGF domains and the serine protease domain; however, the Gla domain is partially disordered and not defined.[82] The nuclear magnetic resonance-derived structure of human factor IX Gla domain in the presence of calcium supports, as a first approximation, a model of the Gla domain based upon that of prothrombin.[49,83] The crystal structures of the Gla domain confirm the similarity of this domain in all of the vitamin K–dependent proteins.[50,51]

Expression of phospholipid-binding properties involves two metal-dependent conformational transitions.[81] The calcium-stabilized conformer expresses a phospholipid-binding site that is located at the N-terminus of the protein.[84] Factors IX and IXa bind to activated platelets but not to resting platelets.[85,86] However, there is no evidence for a protein-based receptor for factor IX on the platelet surface. Factor IXa, but not factor IX, binds to factor VIIIa on the surface of activated platelets. The factor VIIIa-binding site includes regions of the second EGF domain and the serine protease domain.[87] The endothelial cell-binding site of factor IX resides in the Gla domain.[88] Collagen on the surface of endothelial cells defines this factor IX-binding site.[89,90] However, the biologic role of this site remains uncertain. The factor IX concentration in plasma is approximately5 μg/mL. This protein has a plasma half-life of approximately 24 hours.[91] As with other proteins of this molecular size, it partitions between the intravascular and extravascular spaces. A comprehensive review of the structure of the factor IX gene and the protein it encodes is given in Chapter 124.

Factor VIII

Factor VIII is a critical cofactor required for normal blood clotting (see Chapter 123). Defects in the factor VIII gene that lead to a deficiency in factor VIII are the cause of hemophilia A. The factor VIII gene is 186 kb in length and is divided into 26 exons (see Fig. 123–1).[92,93] As such, it is one of the largest genes known. Located on the X chromosome, it is near the locus of the factor IX gene. Factor VIII is synthesized as a single polypeptide chain, including a 19-residue signal peptide; in its mature form it contains 2332 amino acid residues.[92,93] Although this protein is synthesized by many cell types, the liver is a major site of synthesis.[94] The glycosylated protein A is estimated to have a molecular weight of 330,000. The protein sequence of factor VIII demonstrates marked sequence homology with factor V, another protein cofactor.[95] Factor VIII circulates in the blood as a heterodimer composed of two polypeptide chains derived from the original single chain. These two chains, including one of relative molecular weight (M_r) 80,000 and one of M_r varying between 90,000 and 200,000, are derived from the COOH-terminus and the NH_2-terminus of the single-chain precursor, respectively. Their interaction is Ca^{2+} dependent. A region of the C2 domain defines the membrane-binding properties of factor VIII and the site of interaction with von Willebrand factor (vWF).[96] The A1 domain interacts with the A3 domain, thus linking the heavy and light chains.[97] Although membranes including phosphatidyl-L-serine are required for factor VIII interaction, phosphatidylethanolamine enhances membrane binding.[98,99] The orientation of factor VIII bound to phospholipid vesicles has been determined by electron microcroscopy.[100] In its circulating form, factor VIII is inactive or minimally active as a cofactor in blood coagulation. It circulates in the blood at very low concentration (100 ng/mL) bound to vWF. Its plasma half-life is approximately 8 to 12 hours.[101] Factor VIII is converted into its active cofactor form by the proteolytic cleavage of two or more peptide bonds within the protein by thrombin. The structure and function of factor VIII are described in detail in Chapter 123.

Factor X

The factor X gene, located on the long arm of chromosome 13 adjacent to the factor VII gene, is composed of eight exons and is 22 kb in length (see Fig. 118–5).[102] The organization of this gene is identical to that of the factor IX gene. Exon I encodes the signal peptide, exon II the propeptide/γ-carboxyglutamic acid-rich domain, exon III the short aromatic amino acid stack domain, exons IV and V the two EGF domains, exon VI the activation region, and exons VII and VIII the catalytic domain. The 5′ end of the factor X gene is linked to the 3′ end of the factor VII gene.[103] The liver-specific promoter element FXP1-binding site was located −63 to −42 bp upstream of the factor X gene, whereas other promoter elements, FXP2 and FXP3, span −215 to −149 and −457 to −351, respectively.[103] After transcription, the factor X mRNA of approximately 1.5 kb includes a short 3′ untranslated region following the stop codon.[104,105] The polyadenylation signal is located within the 3′ end of the coding sequence. Factor X, with a molecular weight of 56,000, is synthesized as a single polypeptide chain.[102,105] However, factor X as isolated from plasma is composed of two polypeptide chains, a heavy chain with a molecular weight of 38,000[106–108] and a light chain with a molecular weight of 18,000.[109,110] These chains are linked by a single disulfide bond. The Arg-Lys-Arg sequence at residues 139 to 141 in the single polypeptide chain appears very susceptible to intracellular or extracellular proteolysis, yielding the predominant two-chain form.[102,105] The light chain of factor X includes 11 γ-carboxyglutamic acid residues at positions 6, 7, 14, 16, 19, 20, 25, 26, 29, 32, and 39 in the human protein. A single β-hydroxyaspartic acid residue is located in the first EGF domain at residue 63. Bovine factor X contains both asparagine-linked carbohydrate at Asn36 and threonine-linked carbohydrate at Thr300.[111] Like prothrombin, the asparagine-linked sugars contain NeuAca263Galβ163(NeuAca266)GlcNAc in the outer chain. The two EGF domains are important for binding to the cofactor, factor Va. The second EGF domain can support factor Va binding but at reduced affinity,[87] suggesting a role for the first EGF domain in this interaction as well.[112]

Factor X is a calcium-binding protein that interacts with membrane surfaces in the presence of calcium. It contains both low-affinity and high-affinity metal-binding sites,[113] occupancy of which leads to conformational changes and expression of membrane-binding properties.[114] Like the other vitamin K–dependent proteins, factor X binds preferentially to acidic phospholipid surfaces.[115,116] Bound factor X is an extrinsic membrane protein in that no component of it is embedded within the membrane. The three-dimensional structure of bovine factor X lacking the Gla domain has been determined by x-ray crystallography and demonstrates marked structural homology with trypsin and the other serine proteases involved in blood coagulation.[117,118] The N-terminus of the Gla domain of factor X shows little stable structure in the absence of Ca^{2+}.[119] However, the structure of the Gla domain of factor X determined when bound to factor X binding protein from a snake venom indicates marked structural homology with other Gla domains.[48] Furthermore, the Gla domain of factor X in the presence of Mg^{2+} assumes a novel conformation, distinct from that in the presence of Ca^{2+}.[120] The Gla domain linked to the first EGF domain shows little interaction between the two domains, but the orientation of these domains is altered by the presence of calcium ions.[121]

The plasma concentration of factor X is maintained at approximately 10 μg/mL. Factor X has a half-life in plasma of approximately 36 hours.[91]

Factor VII

The factor VII gene is 13 kb in length and is located on the long arm of chromosome 13, immediately adjacent to the factor X gene.[122,123] The coding region is found on nine separate exons (see Fig. 118–5). Preprofactor VII is synthesized via two alternative forms. In one form, incorporating exon IB encoding for the signal peptide factor VII arises from a gene whose gene organization is identical to that of the factor IX gene. In a second form, exon IA directs the coding of the signal peptide instead of exon IB. In this form, preprofactor VII has a polypeptide extension of the NH_2-terminus that elongates the signal peptide/propeptide from 38 to 60 residues. Exon II encodes the propeptide and γ-carboxyglutamic acid-rich domain, and exon III encodes the short aromatic amino acid stack domain, a segment common to all vitamin K–dependent proteins. Exons IV and V each encodes one of the EGF domains. The catalytic domain is coded by exons VI to VIII, with the activation peptide encoded within exon VI. The mRNA for factor VII is approximately 2.4 kb in length,[124] with a 3′ untranslated region 1.0 kb in length and a poly(A) tail located after the stop codon.

Factor VII is a component of the extrinsic pathway of blood coagulation. It forms a complex with tissue factor to generate an enzyme complex that activates factor X. Human factor VII, with a molecular weight of 50,000, circulates in plasma as a single-chain zymogen containing 406 amino acid residues.[124] The NH_2-terminal domain includes 11 γ-carboxyglutamic acid residues at positions 6, 7, 14, 16, 19, 20, 25, 26, 29, 34, and 35 in bovine factor VII.[125] Site-specific mutagenesis of some residues in the Gla domain leads to markedly enhanced membrane binding.[126] Asp63 is partially β-hydroxylated. Factor VII is a glycoprotein that contains 13% carbohydrate. The structure of the complex of the active site-inhibited factor VIIa and extracellular domain of tissue factor has been determined by x-ray crystallography.[47] Salient general features of this complex include extensive "embracing" of extended conformations of one protein by the other. This interaction involves multiple domains and multiple contact sites within each domain. The structure of the calcium-stabilized Gla domain is homologous to that of prothrombin and factor IX.

In contrast to other proenzymes involved in blood coagulation, factor VII circulates in the blood in two forms: the inactive zymogen factor VII and the enzymatic active factor VIIa.[6] Factor VII is a zymogen, with no enzymatic activity prior to cleavage.[127] The concentration of factor VIIa is low but sufficient to generate significant factor X-activating activity when the factor VIIa forms a complex with newly exposed tissue factor. The factor Xa formed can activate factor VII to factor VIIa, increasing the amount of factor VIIa available during tissue injury. This model would allow significant amplification of thrombin formation via the extrinsic pathway.

Factor V

Factor V is a plasma glycoprotein with a molecular weight of 330,000. This protein is a critical cofactor that in its activated form facilitates activation of prothrombin by factor Xa. Factor V is a single-chain protein that circulates in the blood in a precursor, inactive cofactor form. The factor V gene, located on chromosome 1 at 1q21–25, encodes a 7-kb mRNA, which itself encodes a prefactor V including a 28-amino–acid-residue signal peptide and a mature protein composed of 2196 amino acid residues.[128,129] The gene contains 25 exons that range in size from 72 to 2820 bp[130] and resembles the factor VIII gene in organization. The heavy-chain region is composed of two domains with notable structural homology, termed the *A domain.* The light-chain region is composed of another A domain and two homologous C domains. The heavy-chain region and light-chain region are joined by a connecting region known as the *B domain.* The A1-A2-B-A3-C1-C2 domain structure is also present in factor VIII.[92] The conversion of factor V into the procoagulant factor Va is a stepwise process related to cleavages adjacent to Arg709, Arg1018, and Arg1545 by either thrombin or factor Xa.[131,132] A single site adjacent to Arg1545 in human factor V is critical for generation of biologically active factor Va.[131] Factor Va is inactivated by cleavage of peptide bonds adjacent to Arg306, Arg506, and Arg679 by activated protein C.[133] Ca^{2+} plays a role in the stabilization of the heavy chain and light chain of factor V.[134] Disruption of this Ca^{2+} binding site by mutagenesis leads to a destabilized factor Va following thrombin activation of factor V, presumably through dissociation of the heavy and light chains.[135] Protein S and phospholipid membranes are critical for this reaction.[136]

Although the liver appears to be the primary site of synthesis of factor V, megakaryocytes also synthesize this protein. In addition to its presence in plasma, factor V is a component of the α granules in megakaryocytes and subsequently in platelets[137] and is secreted on platelet stimulation with specific agonists. Factors V and Va bind to two classes of binding sites on the surface of platelets.[138] However, the higher-affinity binding sites interact specifically with factor Va and not with factor V. The plasma concentration of factor V is 10 μg/mL, and its plasma half-life is approximately 12 hours.[139]

Prothrombin

The prothrombin gene is located on chromosome 11.[140] It is 21 kb in length and is composed of 14 exons, each encoding all or part of a functional domain of prothrombin (see Fig. 118–5)[141]: signal peptide (exon I), propeptide/γ-carboxyglutamic acid-rich domain (exon II), aromatic amino acid stack domain (exon III), two kringle domains (exons IV–VII), activation region (exons VIII and IX), and catalytic domain (exons X–XIV). The introns vary considerably in size, from 84 bp for the intron between exons VIII and IX to 9447 bp for that between exons XII and XIII. Although the structure of prothrombin is homologous with those of factors IX, X, and VII and protein C, the prothrombin gene demonstrates only partial homology with the genes of these proteins. Exons I to III are shared by all these proteins, but prothrombin contains exons IV to VII encoding the kringle domains and has a homologous serine protease domain composed of seven exons, in contrast to the two exons found in the factor IX gene family. Prothrombin mRNA is 2.1 kb in length and includes a 5′ untranslated region greater than 150 bp, a 1.8-kb open reading frame, and a 97-bp 3′untranslated region. The prothrombin gene contains a weak promoter before the transcription initiation site and liver-specific enhancer element spanning approximately 900 bases upstream from the transcription initiation site. This site interacts with hepatic nuclear factor 1.[142,143]

Prothrombin is a plasma glycoprotein with a molecular weight of 72,000.[57,144,145] As with all the blood clotting proteins, prothrombin is synthesized with a hydrophobic signal peptide from residues −43 to −19. After translocation to the rough endoplasmic reticulum, the signal peptide is removed by a signal peptidase. The propeptide, containing the γ-carboxylation recognition site,[42] includes residues −18 to −1. During protein synthesis but after γ-carboxylation, this peptide is removed by an intracellular propeptidase. The mature prothrombin that circulates in the plasma is composed of 579 amino acid residues arranged in a single polypeptide chain. The 10 γ-carboxyglutamic acid residues are located in the Gla domain of human prothrombin at residues 6, 7, 14, 16, 19, 20, 25, 26, 29, and 32. Carbohydrate represents approximately 10% of the mass of prothrombin. *N*-Asparagine–linked carbohydrate is attached to Asn78, Asn100, and Asn373 in bovine prothrombin,[146] and human prothrombin likely contains carbohydrate at the homologous amino acids. Complex asparagine-linked oligosaccharides include NeuAca2 63Galβ163(NeuAca266)GlcNAc. The short aromatic amino acid stack domain has a significant α-helical structure and serves to link the Gla domain to two kringle domains,[45] which are similar to structures found in factor XII, plasminogen, and tPA and are defined

structurally by the pattern of disulfide bonds. These domains are important for protein complex formation with factor Va. The remainder of prothrombin, accounting for approximately half the protein structure, represents the catalytic domain. This region includes the activation domain that is critical for conversion of zymogen into the active enzyme and the trypsin-like region that possesses protease activity. Prothrombin has no coagulant activity in its zymogen form and must be converted to thrombin in order to participate in blood coagulation.

The metal-binding properties of prothrombin are conferred by γ-carboxyglutamic acid residues.[147] Abnormal (des-γ-carboxy) prothrombin, lacking γ-carboxyglutamic acid, does not bind to Ca^{2+} and does not interact with membrane surfaces in the presence of calcium.[147,148] Prothrombin binds Ca^{2+} and other metal ions via two classes of metal-binding sites[149–152] and, on metal binding, undergoes conformational changes leading to expression of membrane-binding properties.[114,153,154] Concomitantly, neoantigens are exposed on the metal-stabilized conformers of prothrombin.[155–158] Prothrombin is an extrinsic membrane-binding protein. In the presence of calcium ions, a surface of the prothrombin–metal complex interacts with phospholipid vesicles; a marked preference for acidic phospholipids, specifically phosphatidylserine, has been demonstrated. The N-terminal third of the protein contains the ω loop, and within it the hydrophobic patch;[45] this region is buried within the membrane.[159] Salient features of a model of prothrombin–membrane interaction include the presence of an appropriately charged pocket for the phosphoserine of phosphatidylserine in the Gla domain, electrostatic interaction of the carboxyl group of the serine head group with the γ-carboxyglutamic acid-calcium network of the Gla domain, formation of salt bridges between the positively charged arginine and lysine side chains with the phosphate oxygens, and alignment of the fatty acid tail of phosphatidylserine with the hydrophobic patch of the Gla domain (Fig. 118–6).[160]

The plasma concentration of prothrombin is approximately 100 μg/mL.[161,162] The plasma half-life of prothrombin is approximately 3 days.[91,163]

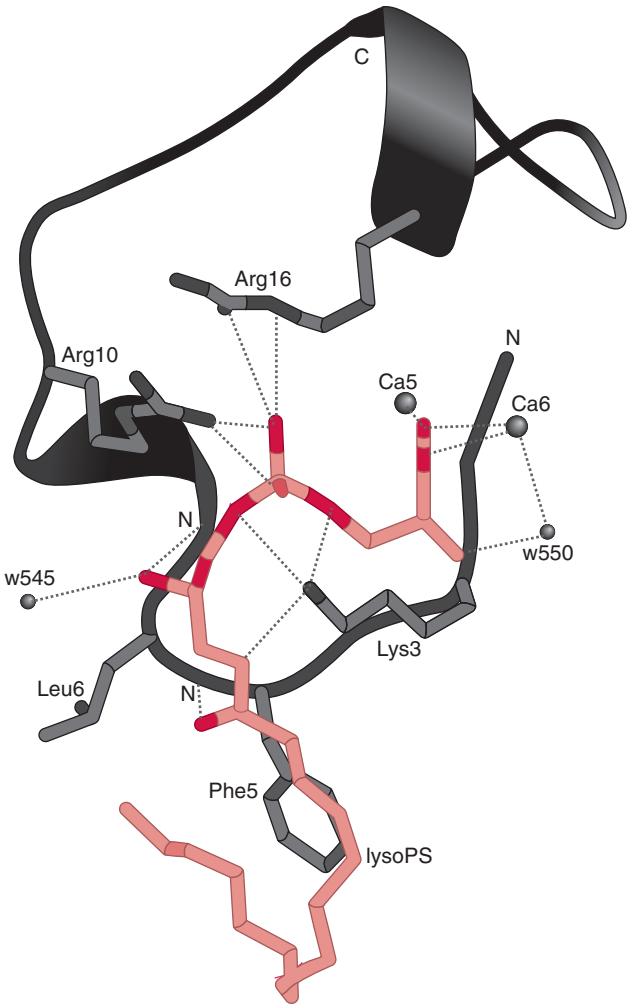

Figure 118–6 Interaction of phosphoserine head group of phospholipid with prothrombin. The hydrogen bonds and salt bridges between atoms in lysophosphatidylserine and the prothrombin-calcium ion complex are indicated as dashed lines (gray). The side chains of Lys3, Phe5, Leu6, Arg10, and Arg16, bound Ca^{2+} ions 5 and 6, and the backbone amide nitrogens of Leu6 and Gla7, N, are labeled. The lysophosphatidylserine (lysoPS) is pink. The phosphate oxygens and carbonyl oxygens labeled red. The Gla domain of prothrombin is black.

Fibrinogen

Fibrinogen is the most abundant plasma protein involved in blood coagulation. At a plasma concentration of 2 to 3 mg/mL, it represents approximately 2% of the total plasma proteins. In addition, platelets contain fibrinogen within their α granules. Variant forms likely arise via posttranslational modifications or protein degradation. Fibrinogen, unique among the blood clotting proteins, is encoded by three separate genes, each of which encodes one of the three subunits. These three genes, located on chromosome 4, are clustered on a 50-kb region.[164] The fibrinogen genes are organized with the α-chain gene 10 kb upstream of the γ-chain gene, which in turn is 13 kb upstream of the β-chain gene. The α-, γ-, and β-chain genes contain nine, five, and eight exons, respectively. The regulation of these genes is coordinated at the transcriptional level by the synchronous production of three separate mRNA species.[165]

Fibrinogen is a structural protein that circulates in the plasma in a functionally inert precursor form. Its conversion to fibrin leads to polymerization of fibrin and to formation of a fibrin clot. Human fibrinogen has a molecular weight of approximately 340,000. It is composed of three pairs of polypeptide chains: two Aα chains, two Bβ chains, and two γ chains.[166] The α, β, and γ chains demonstrate significant structural homology within their amino acid sequences, suggesting their evolutionary origin from a common ancestral gene.[167–169] The Aα chain has a molecular weight of 63,500 and contains 610 amino acid residues. The Bβ-chain has a molecular weight of 56,000 and contains 461 amino acid residues. The γ-chain has a molecular weight of 47,000 and contains 411 amino acid residues. The Aα, Bβ, and γ chains are covalently linked through disulfide bonds. The disulfide bonds near the N-terminal regions of these polypeptide chains link the three chains to each other; they also link the two Aα chains together and the two γ-chains together. This region is known as the *disulfide knot.* Electron micrographs of fibrinogen show a trinodular molecule.[170] X-ray crystal structures of fibrinogen provide insight into the mechanism by which fibrin self-assembles.[171,172] Crystal structures of fragment D consist of a coiled-coil region and two homologous globular regions.[173] Crystal structures of the N-terminal fragment E region show marked symmetry of design.[174] The crystal structure of the C-terminal fragment of the γ chain reveals a mechanism for electrostatic steering that guides the alignment of the fibrin monomers during polymerization.[175] The plasma half-life of fibrinogen is approximately 3 to 5 days.[176]

Factor XIII

Factor XIII is a zymogen of a cysteine transglutaminase that circulates in the blood. It is composed of two peptide subunits, the A chain (M_r 75,000) and the B chain (M_r 80,000).[177] Factor XIII has a molecular weight of 320,000. It is a tetrameric structure with two A chains and two B chains held together noncovalently. After binding to Ca^{2+},[178] factor XIII ($\alpha_2\beta_2$) is activated to its enzyme form factor XIIIa ($\alpha_2\beta_2$) by thrombin through cleavage of the bond between

Arg37 and Gly38 in the A chain, thus releasing an activation peptide with a molecular weight of 4500. Factor XIIIa contains a free sulfhydryl group at the active site on the A chain and functions as a transamidase in cross-linking glutamic acids and lysine residues. The concentration of factor XIII in plasma is approximately 60 μg/mL. Platelet factor XIII is composed of only A chains in the form of the dimer A_2. Enzymatically, the platelet and plasma forms of factor XIIIa are equivalent.

Tissue Factor

Tissue factor is an integral membrane protein with a molecular weight of approximately 43,000. It is located on the plasma membrane of most vascular cells.[25,179] This protein, which is a receptor for factor VII, is required for initiation of blood coagulation through the extrinsic pathway. Factor VII binding to tissue factor is calcium dependent. Tissue factor is a transmembrane protein composed of 263 amino acid residues.[26,27] The three-dimensional structure of the extracellular domain is known, both alone[180] and in complex with factor VIIa.[47] A short hydrophobic domain of 23 amino acids represents the membrane-spanning region (Fig. 118–7). The N-terminal domain of 219 amino acid residues is a dominant component of the protein and is oriented extracellularly. A short, 21-residue C-terminal cytoplasmic domain contains palmitate and stearate bound through a thioester bond to a cysteine residue.[181] The transmembrane and C-terminal cytoplasmic domain are essential for full coagulant activity. Full biologic activity can be restored to the extracellular domain when soluble truncated tissue factor engineered with a histidine-tag is associated with metal-chelating lipids within the membrane surface.[182] By raising tissue factor off the membrane surface using protein domain spacers, the orientation of tissue factor to the membrane was shown to be critical for factor X activation but not important for conversion of factor VII to factor VIIa.[183] These results emphasize that formation of the tissue factor/factor VII binary complex is independent of membrane participation, whereas formation of the tissue factor/factor VIIa/factor X ternary complex requires membrane participation.

Tissue factor is expressed constitutively in most nonvascular cells. In monocytes and endothelial cells, expression of tissue factor is associated with cell stimulation.[184–186] Tissue factor in blood accumulates in the developing thrombus[12] and is delivered to the thrombus via microparticles in a mechanism that is P-selectin and PSGL-1 dependent.[13] The tissue factor gene is 12.4 kb in length and is composed of six exons.[187]

von Willebrand Factor

vWF is a multimeric glycoprotein that is present in the plasma, within the α granules of platelets, and in the Weibel-Palade bodies of endothelial cells (see Chapter 128). The gene for vWF is located on chromosome 12 and is approximately 176 kb in length.[188] The gene includes 52 exons that encode a signal peptide, a large propolypeptide (M_r 80,000), and the mature vWF monomer (M_r 225,000).[189] A 9-kb mRNA encodes a precursor form of the protein, synthesized as a single polypeptide chain containing 2813 amino acid residues.[189–192] Pro-vWF undergoes posttranslational modification involving initial formation of dimers, which undergo multimerization via a process that is dependent on the presence of the intact propeptide.[193,194] The high-molecular-weight vWF multimers vary in size up to approximately 10 million, with the largest forms displaying the most potent biologic activity.

Crystal structures of domains of vWF have provided insight into the organization of the protein. The structure of the A3 domain complexed to antibody indicates the location of the collagen-binding site.[195] Site-specific mutagenesis allowed mapping of this region.[196] The N-terminus of glycoprotein Ibα wraps around the A1 domain of vWF, providing two contact interfaces.[197] Gain-of-function mutations in vWF, as in type IIB von Willebrand disease, show the structural correlates of increased affinity between glycoprotein Ibα and vWF.[198]

Two critical biologic roles are fulfilled by vWF. First, it can mediate the adhesion of platelets to the injured vascular wall. Adhesion occurs through simultaneous binding of vWF to its receptor glycoprotein Ib on platelet surfaces and to collagen in the subendothelium. In addition to being constitutively secreted from endothelial cells, vWF is stored in the Weibel-Palade bodies of endothelial cells and released on stimulation of granule release.[199] As a plasma carrier protein, vWF binds noncovalently to and stabilizes factor VIII and circulates in the blood as a factor VIII/vWF complex. Factor VIII binds stoichiometrically to the vWF subunit.[200] Under physiologic conditions, however, most of the factor VIII-binding sites on mature vWF are unoccupied.

SYNTHESIS OF BLOOD COAGULATION PROTEINS

Biosynthesis of Vitamin K–Dependent Blood Clotting Proteins

Four of the plasma proteins involved in blood coagulation—prothrombin, and factors IX, X, and VII—require vitamin K for their synthesis. These proteins contain between 10 and 12 residues of γ-carboxyglutamic acid[201,202] within the first 45 residues of their NH_2-termini (Fig. 118–8). They represent a unique class of calcium-binding proteins that assemble on membrane surfaces in the presence of Ca^{2+}. These proteins are synthesized in a precursor form, which includes a typical signal peptide and a propeptide that intervenes between the signal sequence and the mature NH_2-terminus of the protein. Following translocation through the rough endoplasmic reticulum, specific glutamic acid residues in the prozymogen are selectively γ-carboxylated.

Vitamin K–dependent carboxylation is catalyzed by a membrane-bound γ-carboxylase located in the endoplasmic reticulum. In the presence of reduced vitamin K, molecular oxygen, carbon dioxide,

A short transmembrane domain is rich in hydrophobic amino acids. The cytoplasmic domain, extending from residues 243 to 263, contains a free sulfhydryl (SH) group, which undergoes esterification to palmitate or stearate.

Cell 53:505, 1988.)*

and the protein precursor substrate, specific glutamic acids adjacent to the γ-carboxylation recognition site on the propeptide are converted to the corresponding γ-carboxyglutamic acids. The vitamin K–dependent carboxylase catalyzes both the formation of γ-carboxyglutamic acid from glutamic acid and vitamin K epoxide from vitamin K, which indicates the coupling of these two processes (see Chapter 130).[203] The vitamin K–dependent carboxylase is a single-chain protein with a molecular weight of 94,000 that is composed of a single polypeptide chain of 758 amino acids.[203–206] The carboxylase can be expressed in insect cells otherwise lacking carboxylase activity.[207] The vitamin K–dependent carboxylase includes sulfhydryl groups at the active site.[208] Cysteines critical for carboxylation may include Cys99 and Cys450,[209] although the precise cysteines in the active site remain controversial.[210]

The propeptide within the vitamin K–dependent proteins directs γ-carboxylation. This region demonstrates sequence homology among proteins that contain γ-carboxyglutamic acid (Fig. 118–9),[211,212] an observation that has suggested a role for the propeptide in carboxylation. Site-specific mutagenesis has shown that factor IX species lacking the 18-residue propeptide or containing point mutations at conserved residues −16 or −10 within the propeptide eliminate γ-carboxylation.[42] Analogous studies of prothrombin have demonstrated the importance of amino acids at residues −18, −17, −15, and −10 in the propeptide of prothrombin. Deletion mutants of proprotein C lacking residues in the −17 to −12 portion of the propeptide also are associated with impaired γ-carboxylation.[213] These results demonstrate that the propeptide contains a recognition element, termed the *γ-carboxylation recognition site,* which designates the vitamin K–dependent proteins for γ-carboxylation. This propeptide is required for carboxylation. Furthermore, expression of a cDNA construct in which the propeptide is adjacent to a glutamic acid-rich region of thrombin leads to carboxylation of these glutamic acid residues.[43] Thus, the propeptide is sufficient to support carboxylation, and no other components within the substrate are required, except to improve efficiency of carboxylation.

Peptides containing a complete propeptide sequence and carboxylatable glutamic acid residues are efficiently carboxylated, with a K_m of approximately 3 μM.[214,215] In contrast, peptides without the γ-carboxylation recognition site or with a truncated site are poor substrates for the carboxylase. Glutamic acid, but not aspartic acid, is a substrate for the carboxylase. Based on the predicted structure of the propeptide of factor X, an 18-residue peptide stimulates the carboxylation of the pentapeptide FLEEL (Phe-Leu-Glu-Glu-Leu) by the partially purified carboxylase by approximately eightfold.[216]

The propeptide of prothrombin contains the carboxylation recognition site on its N-terminus and the propeptide cleavage site at the C-terminus. This peptide incorporates a 10-residue amphipathic α helix, from residues −3 to −13.[217] This helix serves as an extension to expose the carboxylation recognition site (Fig. 118–10). In contrast to factor IX, profactor IX cannot be activated to its enzymatically active form and does not bind to acidic membranes even though it is fully carboxylated.[218] The propeptide plays three roles in the synthesis of the vitamin K–dependent proteins: (a) via the γ-carboxylation recognition site, the propeptide signals for carboxylation of adjacent glutamic acid residues; (b) the propeptide inhibits premature zymogen activation and membrane binding during intracellular processing; and (c) the propeptide activates the vitamin K epoxidase activity of the carboxylase.[219]

The propeptide contains a sequence adjacent to the sessile bond that is characteristic of many proproteins and prohormones: Arg-X-Arg/Lys-Arg at residues −4 to −1, where propeptide cleavage occurs between −1 and +1. The propeptidase enzyme responsible for cleavage probably is PACE/furin,[220] a constitutively expressed protease located in the trans-Golgi region that cleaves substrates with adjacent basic amino acid residues. Site-specific mutagenesis of profactor IX has emphasized the importance of Arg–1, the lack of importance of the side chain of residue −3, and the effect of mutation of residue −2 on the efficiency of cleavage.[221]

During synthesis of vitamin K–dependent proteins, the signal peptide contains a recognition element that directs the partially syn-

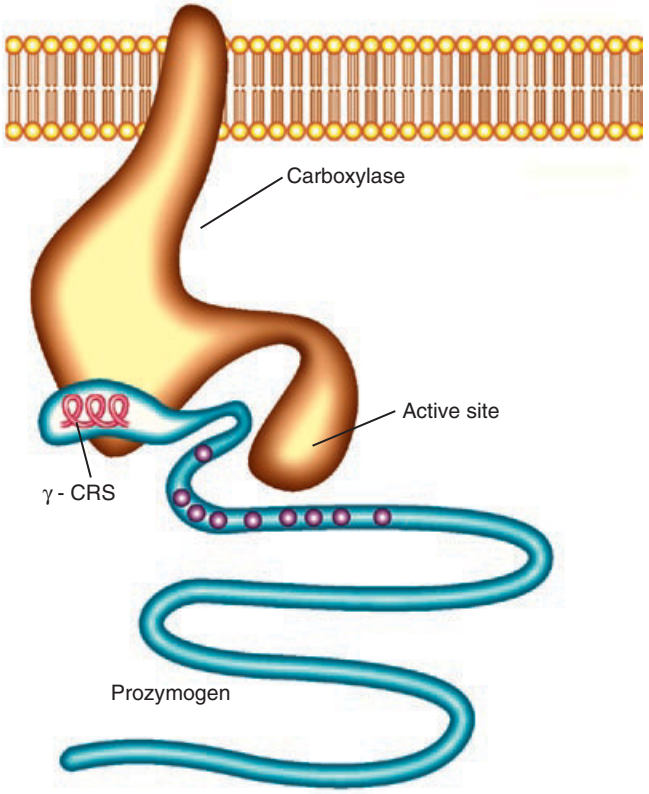

Figure 118–10 Vitamin K–dependent carboxylase. The precursors of the vitamin K–dependent blood clotting proteins, which contain the γ-carboxylation recognition site (γCRS) within the propeptide, bind to carboxylase through this recognition site. Glutamic acids are converted to γ-carboxyglutamic acids by carboxylase in the presence of vitamin K, oxygen, and carbon dioxide. *(Modified from Furie B, Furie BC: The molecular basis of blood coagulation. Cell 53:505, 1988.)*

thesized protein to the endoplasmic reticulum (Fig. 118–11). With cleavage of the signal peptide, the carboxylation recognition site on the propeptide is expressed. The vitamin K–dependent carboxylase is anchored to this region and modifies all the glutamic acids within a given proximity to the recognition site. After carboxylation, the protein is transported to the Golgi apparatus, where the propeptide undergoes cleavage. Final processing of the protein is completed in the Golgi compartment.

Posttranslational β-Hydroxylation

An unusual amino acid, *erythro*-β-hydroxyaspartic acid, is located in the NH_2-terminal EGF domains of protein C[222] and factors IX, X, and VII. *Erythro*-β-hydroxyasparagine also has been identified in protein S.[223] These amino acids are formed by posttranslational hydroxylation of aspartic acid and asparagine. Their function remains unknown, although they may be involved in defining the metal-binding properties of these proteins.

Unlike posttranslational γ-carboxylation, β-hydroxylation of factor IX is not directed by the propeptide, nor does this process require vitamin K or concomitant γ-carboxylation. β-Hydroxylation occurs in domains homologous to the EGF precursor in certain vitamin K–dependent proteins,[223] as well as in proteins outside this family, including the complement proteins Clr and Cls, thrombomodulin, uromodulin, and the low-density lipoprotein recepto.[223–227] A consensus sequence encompassing the β-hydroxylated aspartic acid and asparagine residues within a number of EGF domains has been noted by Stenflo et al.[223]: Cys-X-Asp/Asn-X-X-X-X-Phe/Tyr-X-Cys-X-Cys.

EGF domains that lack the consensus sequence do not contain this posttranslational modification. The hydroxylation is catalyzed by aspartyl β-hydroxylase, an enzyme that requires 2-ketoglutarate and Fe^{2+}.[226] This reaction is blocked by agents that inhibit 2-ketoglutarate–dependent dioxygenases.[228]

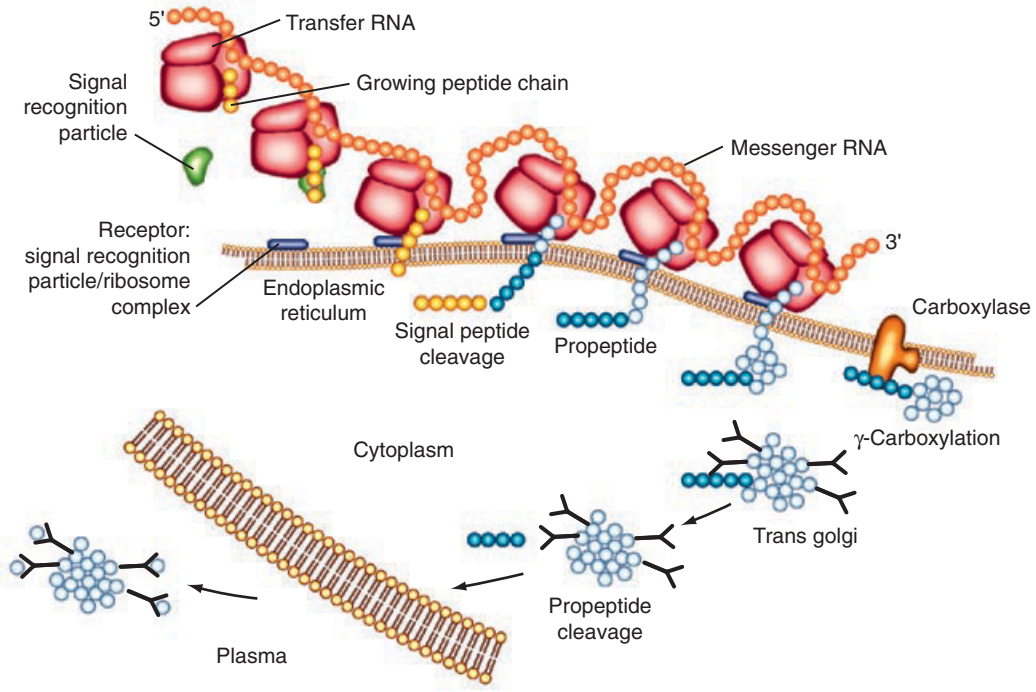

Figure 118–11 Biosynthesis of the vitamin K–dependent blood coagulation proteins. Signal recognition particle binds to the signal peptide, thus directing this complex to the endoplasmic reticulum. Signal peptide directs translocation to the luminal aspect of the endoplasmic reticulum. After signal peptide cleavage by signal peptidase, propeptide is expressed. This region, containing the γ-carboxylation recognition site, binds to the vitamin K–dependent carboxylase. Specific glutamic acids are converted to γ-carboxyglutamic acids by this enzyme. Propeptide is removed in the trans-Golgi region. *(Modified from Furie B, Furie BC: The molecular basis of blood coagulation. Cell 53:505, 1988.)*

Von Willebrand Factor Multimerization

vWF is synthesized as a single polypeptide chain containing a signal peptide, a large propolypeptide (M_r 80,000), and the mature vWF (M_r 225,000). During synthesis, the mature vWF forms a dimer, which multimerizes to the high-molecular-weight, biologically active forms critical for cellular adhesion. Synthesis of vWF takes place in endothelial cells and megakaryocytes. In endothelial cells, vWF is secreted via a constitutive pathway involving mainly dimeric forms. In addition, the regulated pathway involves storage of vWF in Weibel-Palade bodies, within which vWF undergoes multimerization and subsequently cleavage of the propolypeptide. Endothelial cells degranulate under specific stimuli, leading to secretion of vWF. The propolypeptide is required for multimerization[193,194] and is further required for directing vWF to the Weibel-Palade bodies.[229]

ACTIVATION OF BLOOD COAGULATION

Mechanism of Extrinsic Activation

Activation of blood clotting through the tissue factor pathway plays a dominant physiologic role in hemostasis. Tissue factor, a cellular receptor for factors VII and VIIa, is present on most cell surfaces. Expression of tissue factor activity is constitutive on most nonvascular cells and is inducible via de novo synthesis in cells within the blood or on the blood vessel wall. In addition, blood-borne tissue factor circulates in the blood at low concentration. There appear to be two distinct pathways of blood coagulation. In one pathway of hemostasis that follows tissue injury and laceration of blood vessels, nonvascular cells become exposed to blood, leading to contact of nonvascular cell tissue factor with flowing blood. Immediate formation of a complex of tissue factor on the cell surface with factor VIIa from the blood then follows. The formation of this complex initiates the tissue factor pathway, culminating in the generation of thrombin and the formation of a fibrin clot.

An alternate pathway of blood coagulation is P-selectin dependent.[11] This pathway is initiated by vessel wall injury but does not require exposure of flowing blood to tissue factor on nonvascular cells. Rather, tissue factor in the circulating blood, present at very low concentration and possibly inactive, accumulates in the developing thrombus.[12] This tissue factor is present on leukocyte microparticles, along with PSGL-1, and is concentrated on activated platelets within the developing thrombus through platelet P-selectin.[13] The developing thrombus, initiated by endothelial cell damage, contains platelets, tissue factor and fibrin.[1]

Activation of Factor VII

Both pathways involve initiation of fibrin formation via tissue factor. Tissue factor, at a critical concentration, triggers a series of biochemical events in the blood coagulation cascade.

$$\text{Factor VII} \xrightarrow{\text{FVIIa/TF}} \text{Factor VIIa}$$

Through its extracellular domain, tissue factor forms a catalytic complex with factor VIIa in the presence of Ca^{2+}.[29,179] Low amounts (10–100 pM) of factor VIIa are present in normal plasma.[6] With tissue factor as a cofactor, factor VIIa can autocatalyze the activation of factor VII to factor VIIa.[230–232] Deletion of the membrane-anchoring region of tissue factor abolishes autoactivation of factor VII but not cofactor function in the activation of factor X or factor IX.[233] The tissue factor/factor VIIa complex acts on factor IX and factor X, leading to the generation of factor IXa and factor Xa, respectively. Factor Xa is able to feed back to convert more factor VII to factor VIIa, thereby amplifying the initiation of clotting.[7] Activation of factor VII involves cleavage of the Arg152-Ile153 bond, leading to a form of factor VIIa composed of a light chain (M_r 20,000) and a heavy chain (M_r 30,000) linked by a disulfide bond (Fig. 118–12).[20,234,235] This reaction is greatly enhanced by the presence of tissue factor and phospholipid vesicles.[19,236,237] Activation of factor VII is associated with expression of the catalytic triad within the heavy chain, His41, Ser192, and Asn90, common to the active site of all serine proteases. Although the potential for factor Xa-mediated and factor VIIa-mediated amplification of this pathway is apparent, the nature of the protease that generates constitutive factor VIIa in plasma is unknown.

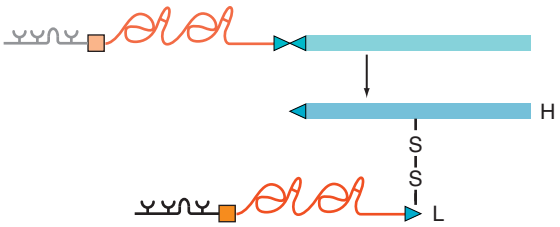

Figure 118–12 Factor VII activation. The zymogen factor VII is composed of a single polypeptide chain. Activation of factor VII to factor VIIa involves cleavage of the bond between Arg152 and Ile153 by factor Xa or factor VIIa. Light (L) chain and heavy (H) chains are linked by a disulfide bond.

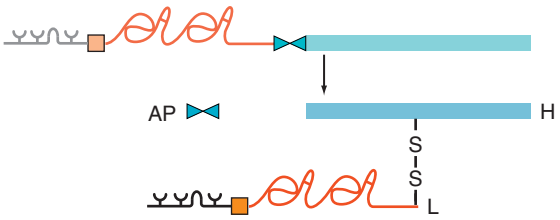

Figure 118–13 Factor IX activation. The zymogen factor IX is composed of a single polypeptide chain. Activation of factor IX to factor IXa involves cleavage of two peptide bonds. Factor IXa contains a light (L) chain and a heavy (H) chain linked by a disulfide bond. An activation peptide (AP) is released during the activation process.

Activation of Factor IX

Activation of factor IX proceeds via the tissue factor pathway in vivo. In vitro (e.g., in the clinical laboratory), the intrinsic pathway is activated via factor XIa:

$$\text{Factor IX} \xrightarrow{\text{TF/factor VIIa or factor XIa}} \text{Factor IXa}$$

Factor IX can be activated through the extrinsic pathway.[15] The factor VIIa/tissue factor complex activates both factor IX and factor X in reactions that require Ca^{2+}. Although the kinetics of factor IX activation by factor XIa and by factor VIIa/tissue factor differ, both enzymes cleave the same peptide bonds and generate the same structural form of factor IXa.

Activation of factor IX by factor XIa, in contrast to the activation of the other vitamin K–dependent blood clotting proteins or the activation of factor IX by factor VIIa tissue factor (which occur on membrane surfaces), takes place in the solution phase. Membrane surfaces, including those of artificial phospholipid vesicles or platelets, do not accelerate the generation of factor IXa. The reaction has an absolute requirement for Ca^{2+}.[238] Factor IX is activated by the cleavage of two internal peptide bonds: the Arg145–Ala146 bond and the Arg180–Val181 bond (Fig. 118–13).[239,240] A factor IXa light chain (M_r 18,000), from residues 1 to 145, and a factor IXa heavy chain (M_r 27,000), from residues 181 to 416, are generated by the proteolytic activation. These chains remain covalently attached through a single disulfide bond. An activation peptide, from residues 146 to 180, is cleaved from factor IX during activation.

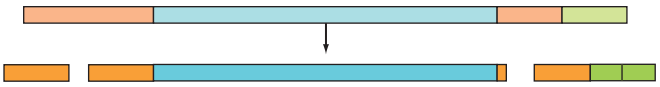

Figure 118–14 Activation of factor VIII, an inactive cofactor composed of a single polypeptide chain. Factor VIII is converted to its active cofactor form, factor VIIIa, by cleavage of two, and possibly three, peptide bonds to generate a heavy chain and a light chain noncovalently linked in the presence of Ca^{2+}.

Like factor IX, factor IXa binds to phospholipid vesicles in the presence of calcium ions and binds to calcium and other metal ions. Activation of factor IX to factor IXa leads to the expression of a factor VIII-binding site and active enzyme site with full coagulant activity. Cleavage of Arg180–Val181 is required for at least partial expression of the factor VIII-binding site; cleavage of Arg145–Ala146 in addition to Arg180–Val181 leads to full enzymatic and cofactor binding activity.

Activation of Factor X

Factor X, at the confluence of the intrinsic pathway and the extrinsic pathway, may be activated by the factor IXa/factor VIIIa complex (tenase complex) or by the factor VIIa/tissue factor complex.

$$\text{Factor X} \xrightarrow{\text{factor IXa/factor VIIIa or factor VIIa/TF}} \text{Factor Xa}$$

The tenase complex, composed of factor IXa and factor VIIIa, requires factor VIII in its active cofactor form (factor VIIIa). Factor VIII expresses either no or minimal cofactor activity but is converted to factor VIIIa by the cleavage of two or possibly three peptide bonds (Fig. 118–14).[241] Factor VIII, a heterodimer composed of a heavy chain that varies in molecular weight from 90,000 to 200,000 and a light chain with a molecular weight of 76,000, is a substrate for thrombin, an enzyme that cleaves at least four peptide bonds within factor VIII. Anion binding site I on thrombin binds to factor VIII.[242] Cleavage of peptide bonds at Arg372–373 and at Arg1686–1689 is required for factor VIII activation.[241] The resulting factor VIIIa contains polypeptide chains of molecular weights 50,000 (derived from the heavy chain), 43,000, and 73,000 (derived from the light chain; see Chapter 123).[243] Factors VIII and VIIIa bind tightly to phospholipid vesicles and to activated platelets.[30,37]

$$\text{factor VIII} \xrightarrow{\text{thrombin}} \text{factor VIIIa}$$

Factor IXa binds to factor VIIIa that is bound to phospholipid membranes and activated platelets. Formation of this enzyme complex is required for activation of factor X on a physiologically relevant time scale.[244] Binding of Na^+ to factor IXa in the tenase complex increases its biologic activity by approximately 12-fold.[245] Similarly, mutation of Glu13 to Ala in factor VIII enhances cofactor interactions with the tenase complex.[246] In the absence of direct structural data, modeling of the tenase complex has suggested multiple interactions between the domains of factor IXa and factor VIIIa.[247] The interface between the second EGF domain and the protease domain of factor IXa contributes to both factor VIII binding and factor X activation.[248]

Alternatively, factor VIIa in complex with tissue factor on cell surfaces can activate factor X on a physiologically relevant time scale. The formation of this complex requires Ca^{2+}.

Factor X, a zymogen with no coagulant activity, is converted to its active enzyme form, factor Xa, by cleavage of a single polypeptide bond between Arg51 and Ile52 in the heavy chain (Fig. 118–15). This cleavage is catalyzed either by the complex of factor IXa and factor VIIIa on membrane surfaces in the presence of Ca^{2+} or by the complex of factor VIIa and tissue factor on membrane surfaces in the presence of Ca^{2+}.[249,250] An activator without physiologic relevance, the coagulant protein of Russell viper venom (RVV) often is used for

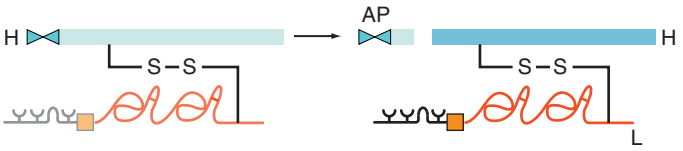

Figure 118–15 Factor X activation. Factor X is composed of two chains, a heavy (H) chain and a light (L) chain, linked by a disulfide bond. Activation of factor X to factor Xa requires cleavage of a single peptide bond on the heavy chain. AP, activation peptide.

clinical laboratory measurements in a test known as the Stypven or RVV time.[251] The activation peptide remains associated with factor Xa[252] but, with the exception of the C-terminal amino acids, does not contribute to the initial formation of a complex with tenase. Although zymogen activation results in a major functional change in the protein, only subtle structural changes in factor X are associated with the development of enzymatic activity.[253] Expression of enzymatic activity involves the catalytic triad common to all serine proteases—His 93, Asp138, and Ser233—in the heavy chain of bovine factor X.

Factor Xa is inhibited by specific plasma protease inhibitors, including antithrombin III and α_2 macroglobulin.[254] These inhibitors probably are scavengers in that they neutralize the potent coagulant activity of any factor Xa that flows past the site of tissue injury. The ternary structure of the antithrombin III/factor Xa/heparin complex reveals that heparin induces an allosteric transition in antithrombin III, thus facilitating the interaction of antithrombin III with the protease domain and active site of factor Xa.[255]

The tissue factor pathway is regulated by a protease inhibitor, tissue factor pathway inhibitor (TFPI).[256–259] The gene for this protein is located on chromosome 2 and includes nine exons.[260,261] This inhibitor, with a molecular weight of 34,000, contains three tandem Kunitz-type protease inhibitor domains.[262] TFPI binds factor Xa directly and inhibits factor VIIa/tissue factor activity in a reaction that appears to involve the formation of a factor Xa/TFPI/factor VIIa/tissue factor complex.[263] Generation of this complex downregulates activity of the tissue factor pathway.

Generation of Thrombin: Assembly of the Prothrombinase Complex

Conversion of prothrombin to thrombin is mediated by the enzyme action of factor Xa and the cofactor factor Va in a complex formed on membrane surfaces. The factor Xa/factor Va complex that is formed on membranes in the presence of Ca^{2+} is known as the "prothrombinase" complex because it serves to act on prothrombin as substrate (Fig. 118–16).

$$\text{prothrombin} \xrightarrow{\text{factor Xa/factor Va}} \text{thrombin}$$

The factor Xa/factor Va/membrane complex has many structural and functional parallels with the factor IXa/factor VIIIa/membrane complex. Factors V and Va are extrinsic membrane-binding proteins. Interaction of these factor V forms with membranes is independent of Ca^{2+} or other metal ions. Factor V binds with high affinity to phospholipid vesicles rich in phosphatidylserine,[264–267] to activated platelets,[138,268] and to microparticles derived from activated platelets.[38,269]

Factor V circulates in the blood as an inactive cofactor or as a cofactor with low intrinsic activity. It is converted to its active cofactor form, factor Va, by the hydrolysis of three peptide bonds, Arg709–Ser710, Arg1018–Thr1019, and Arg1545–Ser1546, by thrombin or factor Xa (Fig. 118–17).[270–273] Anion binding site I on thrombin binds to factor V.[242] These cleavages generate a heavy chain

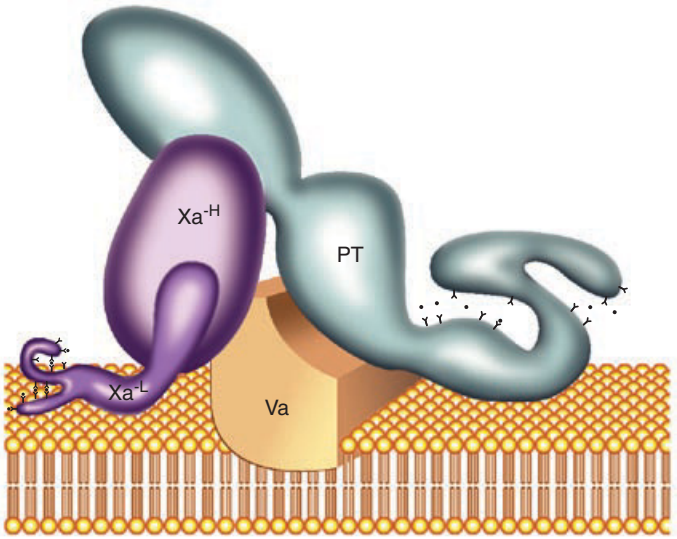

Figure 118–16 Model for the macromolecular complex associated with zymogen activation. A central feature of the proteins involved in blood coagulation is their assembly on membrane surfaces. Interaction of Ca^{2+} with the γ-carboxyglutamic acids on vitamin K–dependent proteins leads to the exposure of a membrane-binding site on these proteins. Assembly of these proteins on membranes in a geometry defined by the protein cofactor facilitates enzyme–substrate interaction. The protein cofactor likely plays an important regulatory role in this complex. Factor Xa, enzyme (L, light chain; H, heavy chain); prothrombin (PT), substrate; factor Va, cofactor; l, Ca^{2+}; U, γ-carboxyglutamic acid; lipid-binding sites in black. *(Modified from Furie B, Furie BC: The molecular basis of blood coagulation. Cell 53:505, 1988.)*

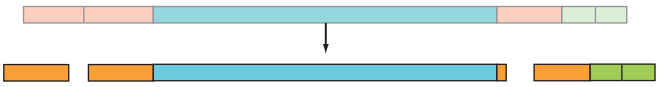

Figure 118–17 Activation of factor V, an inactive cofactor composed of a single polypeptide chain. Factor V is converted to its active cofactor form, factor Va, by the cleavage of two or possibly three peptide bonds to generate a heavy chain and a light chain noncovalently linked in the presence of calcium ions.

(M_r 110,000) and a light chain (M_r 78,000) that are linked noncovalently in the presence of Ca^{2+}. A three-dimensional computational structural model of factor Va has been described.[274]

$$\text{factor V} \xrightarrow{\text{thrombin}} \text{factor Va}$$

In the presence of Ca^{2+}, a complex of factors Xa and Va forms on phospholipid vesicles. Formation of the prothrombinase complex involves three steps: (a) binding of factor Va to membrane surfaces, (b) binding of factor Xa to membrane surfaces, and (c) interaction of membrane-bound factors Va and Xa.[32] Although factor Xa can activate prothrombin directly in the absence of Ca^{2+}, factor Va, and membrane surfaces, the rate of activation is very slow and irrelevant on a physiologic time scale. IN contrast, the rate of prothrombin activation by the prothrombinase complex is approximately 300,000 times as high as the rate of activation by factor Xa.[32]

Although phospholipid vesicles serve as a model system for studying prothrombinase complex formation on platelets, the details of formation of the complex on the two surfaces may vary. Factor Va binds to specific sites on the platelet surface, defining the formation of the prothrombinase complex. Factor Va appears to be the factor Xa receptor on platelets.[275,276] Factor Xa binds to platelets, leading to the expression of prothrombinase activity.[277] Furthermore, factor Va binds to endothelial cells, monocytes, and lymphocytes, facilitating assembly of the prothrombinase complex.[278–281]

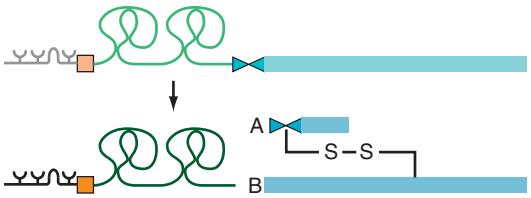

Figure 118–18 Activation of prothrombin, which is composed of a single polypeptide chain. Its activation to thrombin involves cleavage of two or possibly three peptide bonds. Thrombin, the active enzyme, is composed of two chains, the A chain and the B chain, linked by a disulfide bond.

Prothrombin is converted to thrombin by the prothrombinase complex. Although multiple fragments can be generated by the action of prothrombinase on prothrombin, two or possibly three peptide bonds are necessarily cleaved in generating thrombin, a two-chain enzyme with a molecular weight of 38,000 (Fig. 118–18).[282–285] Cleavage of the Arg271–Thr272 or Arg286–Thr287 bond in the presence of plasma proteins yields fragment 1 ≅ 2 (M_r 43,000) or fragment 1 ≅ 2 ≅ 3 (M_r 45,000), respectively, both derived from the NH_2-terminus of human prothrombin.[286,287] With these cleavages, prethrombin 2 (M_r 38,000) or prethrombin 2 with a 13-residue NH_2-terminal extension is generated. Cleavage of the Arg322–IIe323 bond in prothrombin generates meizothrombin and in prethrombin 2 generates both the A chain (M_r 5,000) and the B chain (M_r 32,000) of thrombin, linked by a single disulfide bond. A small peptide, Asp-Tyr-Asp-Tyr-Gln, based on a sequence in the C-terminus of the factor Va heavy chain, inhibits the pathway that generates meizothrombin.[288,289] In contrast to thrombin, meizothrombin has enzymatic activity toward small substrates but does not convert fibrinogen to fibrin.[290] Meizothrombin can be converted to thrombin in the presence of factor Va. The charge relay system, common to the trypsin-like serine proteases, is located at His365, Asp419, and Ser527.

Effector cell protease receptor 1, a receptor for factor X, has a molecular weight of 65,000. It is widely distributed on cells and recognizes a portion of the EGF domain exposed upon zymogen activation of factor X.[291] This receptor is exposed on the platelet surface only upon platelet activation and participates in prothrombinase assembly on cell surfaces.[292]

Thrombin is inhibited by antithrombin III. This inhibition is greatly accelerated by heparin (see Chapter 111).

Conversion of Fibrinogen to Fibrin

$$\text{fibrinogen} \xrightarrow{\text{thrombin}} \text{fibrin} + \text{fibrinopeptide A} + \text{fibrinopeptide B}$$

Fibrinogen circulates as a plasma protein in a biologically inactive form. It is converted to fibrin as a consequence of the cleavage of peptide bonds in both the Aα and the Bβ chain by the enzyme thrombin (Fig. 118–19). Thrombin is specific for the Arg16–Gly17 bond in the Aα chain. Cleavage of this bond releases fibrinopeptide A, a peptide containing 16 amino acid residues from the Aα chain, thereby generating a new amino terminus on the α chain. Thrombin also is specific for the Arg14–Gly15 bond in the Bβ chain, cleavage of which releases fibrinopeptide B, a 14-amino acid peptide, from the Bβ chain, thereby generating a new amino terminus on the β chain. Thus, the covalent structures of fibrinogen and fibrin are identical except for the removal of two fibrinopeptide A and two fibrinopeptide B fragments from fibrinogen.

Upon generation, the fibrin monomer homopolymerizes to form long strands known as *protofibrils* (Fig. 118–20). Both fibrinogen and fibrin are characterized by a trinodal domain structure, with a linear D-E-D domain organization. After removal of the fibrinopeptides,

binding sites within the central E domain of the fibrin monomer bind to sites on the D domain of the γ chain of another fibrin monomer.[170] This yields a half-staggered noncovalent complex between two monomeric units.[293] Addition of a third monomer in a half-staggered orientation facilitates the end-on-end interaction of the D domains of two adjacent monomers. Through these two intermolecular interactions, E domain–D domain and D domain–D domain, two-stranded protofibrils are formed. Only after the protofibrils have become sufficiently long is their lateral association—a necessary event in the formation of thick fibrin fibrils—observed.

The polymerized form of fibrin contains fibrin monomers that are noncovalently bound to each other. Thus, the fibrin strands are unstable. Through the action of factor XIIIa, the α and γ chains of adjacent fibrin strands are covalently cross-linked to yield a form of fibrin that is not easily disrupted. Factor XIIIa, a transglutaminase, catalyzes the condensation of lysine residues on one chain and glutamic acid residues on a second chain.[294] Factor XIII, an inactive precursor, is a plasma protein that is converted to its active form, factor XIIIa, by the proteolytic action of thrombin.

Although many details of blood coagulation remain unclear, there has been considerable definition of the structure and function of participating components and of the special role that cell membranes play in complex formation. The rapid generation of thrombin, with concomitant platelet activation and fibrin clot formation, is localized to the region of tissue injury.

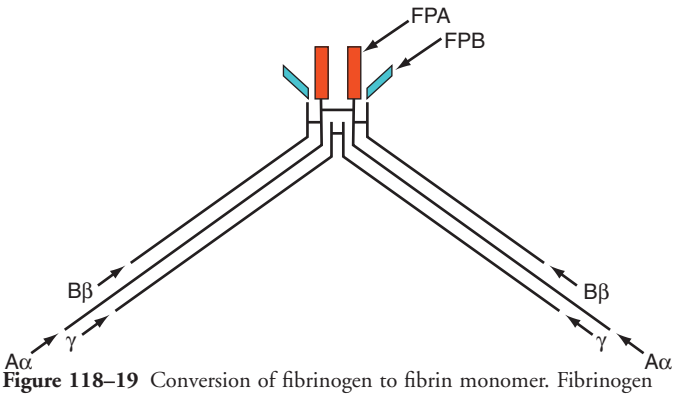

Figure 118–19 Conversion of fibrinogen to fibrin monomer. Fibrinogen is composed of three chains, Aα, Bβ, and γ, arranged as a heterodimer, $A\alpha_2\beta_2\gamma_2$. The conversion of fibrinogen to fibrin, $\alpha_2\beta_2\ \gamma_2$, requires cleavage of peptide bonds to release fibrinopeptide A and fibrinopeptide B.

Contact Phase of Blood Coagulation: Activation of Factors XII And XI

Patients with factor XII, prekallikrein, or high-molecular-weight kininogen deficiency have no bleeding phenotype despite prolonged partial thromboplastin time. These proteins are not required for hemostasis (i.e., rapid generation of fibrin clot). However, these proteins may play a role in fibrinolysis, thrombosis, and fibrin formation during inflammation and wound healing.

Prekallikrein, with a molecular weight of 100,000, is partly bound to high-molecular-weight kininogen in plasma. It is converted to kallikrein, the active enzyme form of the protein, by factor XIIa. Kallikrein, a serine protease, is composed of two subunits, a heavy chain of molecular weight 52,000 and a light chain of molecular weight approximately 35,000. The active site resides on the light chain, whereas the heavy chain binds to high-molecular-weight kininogen.[295] In plasma, kallikrein is inactivated by α_2 macroglobulin and by C1 inhibitor.[296,297]

High-molecular-weight kininogen, with a molecular weight of 120,000, is a plasma protein that participates in contact activation. High-molecular-weight kininogen accelerates the rate of surface-dependent activation of factor XII[298] and the rate of prekallikrein activation by activation products derived from factor XIIa.[299]

Factor XII, a zymogen of molecular weight 80,000, is composed of 596 amino acids in its circulating form.[58,65] It is activated to factor XIIa by plasma kallikrein (Fig. 118–21, *A*).[300–302]

$$\text{factor XII} \rightarrow \text{factor XIIa}$$

This reaction is greatly accelerated by the presence of high-molecular-weight kininogen and by contact with negatively charged surfaces such as glass and collagen. Activation of factor XII to generate factor XIIa involves cleavage of the peptide bond between Arg353 and Val354. A heavy chain (M_r 50,000) composed of 353 amino acid residues binds to negatively charged surfaces and is derived from the NH_2-terminus of factor XII. This chain contains the EGF domains, the kringle domain, and the fibronectin type I and type II domains. A light chain (M_r 30,000) composed of 243 amino acid residues

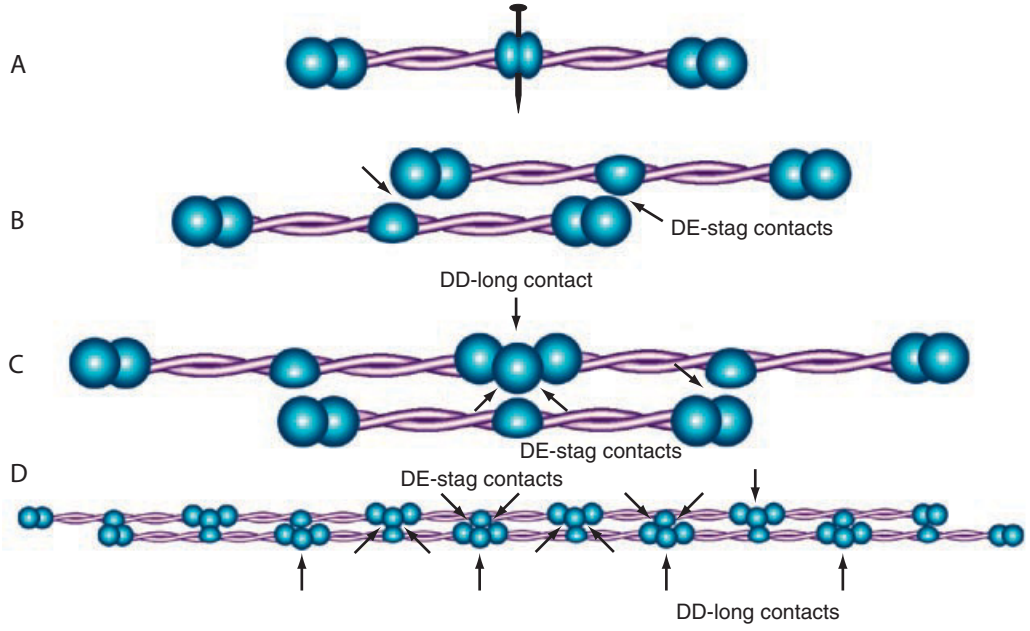

Figure 118–20 Formation of fibrin strands. **A,** Fibrin forms a staggered dimer **(B)**. **C,** Addition of another fibrin monomer end on end yields a trimer. **D,** Continued addition of fibrin monomer generates the fibrin strands.

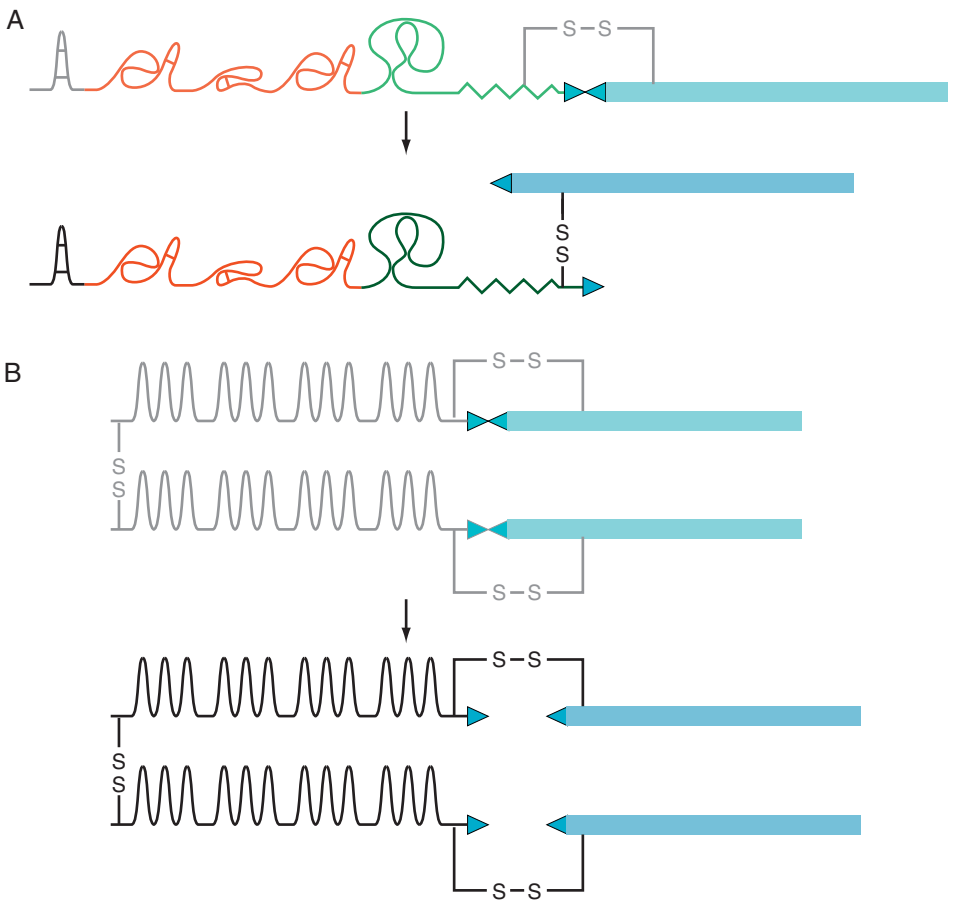

Figure 118–21 Contact phase of blood coagulation. **A,** Factor XII, a zymogen composed of a single polypeptide chain, is converted to its active form, factor XIIa, by cleavage of a single peptide bond. Kallikrein catalyzes this reaction, and the rate of the reaction is greatly accelerated by high-molecular-weight kininogen and by contact with negatively charged surfaces. The light chain of factor XIIa contains the enzyme-active site. **B,** Factor XI, composed of a homodimer formed by two identical subunits, is converted to factor XIa by the enzyme factor XIIa. Each subunit is cleaved to yield a heavy chain and a light chain; the latter contains the enzyme-active site.

contains the catalytic domain, which is common to serine proteases. The catalytic triad includes His393, Asp442, and Ser544. The light chains and heavy chain are linked by disulfide bonds. Factor XIIa functions to convert factor XI to its activated form, factor XIa, and to convert prekallikrein to kallikrein (see Fig. 118–21B).

$$\text{factor XI} \xrightarrow{\text{factor XIIa}} \text{factor XIa}$$

Factor XI is composed of two identical polypeptide chains, each of molecular weight 80,000, connected by a disulfide bond. Factor XI is converted to its enzymatic form, factor XIa, by proteolytic cleavage of the Arg369–Ile370 bond in each chain (see Fig. 118–21, *B*). The heavy chain (M_r 50,000), derived from the amino terminus, and the light chain (M_r 30,000) remain attached through a disulfide bond. Data suggest that thrombin is the physiologically relevant activator of factor XI. The catalytic domain of factor XIa resides on the light chain. The catalytic triad common to all serine proteases includes His44, Asp93, and Ser188.

Factors XI and XIa bind to platelets[303,304] but not to endothelial cells.[305] Whether factor XI–platelet interaction has a physiologic role and whether factor XIa on platelets activates factor IX in the solid phase are uncertain.[306]

CHAPTER 119

MOLECULAR AND CELLULAR BASIS OF FIBRINOLYSIS

H. Roger Lijnen and Désiré Collen

OVERVIEW OF THE FIBRINOLYTIC SYSTEM

The fibrinolytic system in mammalian blood plays an important role in the dissolution of blood clots and in the maintenance of a patent vascular system. The fibrinolytic system (Fig. 119–1) contains an inactive proenzyme, plasminogen, which can be converted to the active enzyme, plasmin, which degrades fibrin into soluble fibrin degradation products. Two immunologically distinct physiologic plasminogen activators have been identified in blood: tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA). Inhibition of the fibrinolytic system may occur at the level of the plasminogen activators, by specific plasminogen activator inhibitors (plasminogen activator inhibitor 1 [PAI-1] and plasminogen activator inhibitor 2 [PAI-2]), or at the level of plasmin, mainly by α_2 antiplasmin. Some physicochemical properties of the main components of the fibrinolytic system and their gene organization are summarized in Tables 119–1 and 119–2. tPA-mediated plasminogen activation is primarily involved in the dissolution of fibrin in the circulation,[1] whereas uPA binds to the specific cellular receptor for urokinase plasminogen activator (uPAR), resulting in enhanced activation of cell-bound plasminogen. The main role of uPA is induction of pericellular proteolysis during tissue remodeling and repair, macrophage function, ovulation, embryo implantation, and tumor invasion.[2]

Regulation and control of the fibrinolytic system is mediated by specific molecular interactions among its main components and by controlled synthesis and release of plasminogen activators and plasminogen activator inhibitors, primarily from endothelial cells. Disorders of the fibrinolytic system may result from impaired activation (i.e., thrombotic complications) or from excessive activation (i.e., bleeding tendency).

PROTEIN STRUCTURE OF THE MAIN COMPONENTS

The enzymes of the fibrinolytic system are serine proteases; their active site consists of a "catalytic triad" composed of the amino acids serine, aspartic acid, and histidine. This active site is located in the C-terminal serine protease domain, and the N-terminal regions contain one or more functional domains, such as the finger domain (homologous to the fingers in fibronectin), the epidermal growth factor-like domain, and kringle domains. Inhibitors of the fibrinolytic system are grouped into the serpin (serine proteinase inhibitor) superfamily. Serpins have in their C-terminal region a specific reactive site peptide bond that is cleaved by their target enzyme, resulting in release of a peptide from the inhibitor and formation of an inactive enzyme–inhibitor complex (see Table 119–1).

Human plasminogen is a 92-kd, single-chain glycoprotein consisting of 791 amino acids. It contains 24 disulfide bridges and five homologous kringles. All plasminogen activators convert plasminogen to plasmin by cleavage of a single Arg561-Val562 peptide bond. The two-chain plasmin molecule is composed of a heavy chain containing the five kringles (N-terminal part of plasminogen) and a light chain (C-terminal part) containing the catalytic triad, composed of His603, Asp646, and Ser741.[3] Native plasminogen has N-terminal glutamic acid ("Glu-plasminogen") but is easily converted by limited plasmic digestion to modified forms with N-terminal lysine, valine, or methionine, commonly designated "Lys-plasminogen." Plasminogen kringles contain lysine binding sites that mediate the specific binding of plasminogen to fibrin and the interaction of plasmin with α_2 antiplasmin. They play a crucial role in the regulation of fibrinolysis.[4]

tPA is a 70-kd serine protease, originally isolated as a single polypeptide chain of 527 amino acids.[5] However, native tPA contains an N-terminal extension of three amino acids (Gly-Ala-Arg-). tPA is converted by plasmin to a two-chain form by hydrolysis of the Arg275-Ile276 peptide bond. In contrast to the single-chain precursor form of most serine proteases, single-chain tPA is enzymatically active. The N-terminal region of tPA is composed of several domains with homologies to other proteins: a finger domain, including residues 4–50; an epidermal growth factor domain consisting of residues 50–87; and two kringles, including residues 87–176 and 176–262. The region constituted by residues 276–527 represents the serine protease part with the catalytic site, composed of His322, Asp371, and Ser478. These distinct domains in tPA are involved in several functions of the enzyme, including its binding to fibrin, fibrin-specific plasminogen activation, rapid clearance in vivo, and binding to endothelial cell receptors. Binding of tPA to fibrin is mediated by the finger and the second kringle domains.[6] The tPA molecule comprises three potential *N*-glycosylation sites at Asn117, Asn184, and Asn448.

Single-chain urokinase plasminogen activator (sc-uPA) is a 54-kd glycoprotein containing 411 amino acids.[7] On proteolytic cleavage of the Lys158-Ile159 peptide bond, the molecule is converted to the two-chain derivative two-chain urokinase plasminogen activator (tc-uPA). The catalytic triad is located in the C-terminal polypeptide chain and is composed of Asp255, His204, and Ser356. The N-terminal chain contains an epidermal growth factor domain (residues 5–49) and one kringle domain. A low-molecular-mass tc-uPA (33 kd) can be generated with plasmin by hydrolysis of the Lys135-Lys136 peptide bond after previous cleavage of the Lys158-Ile159 bond.

uPAR, the specific cell surface receptor for uPA, is a heterogeneously glycosylated protein of 50 to 60 kd, synthesized as a 313-amino-acid polypeptide, anchored to the plasma membrane by a glycosylphosphatidylinositol (GPI) moiety. The uPAR molecule is composed of three related structural domains. One of the domains, the N-terminal domain, is involved in binding uPA. It binds all forms of uPA containing an intact growth factor domain.[8]

α_2 Antiplasmin is a 70-kd, single-chain glycoprotein containing approximately 13% carbohydrate. The molecule consists of 464 amino acids and contains two disulfide bridges.[9] α_2 Antiplasmin is a serpin with reactive site peptide bond Arg376-Met377. Its concentration in human plasma is approximately 70 μg/mL (approximately 1 μM). α_2 Antiplasmin is synthesized primarily in a plasminogen-binding form that becomes partially converted in circulating blood to an inactive form that lacks a 26-residue peptide from the C-terminal end. The inhibitor is cross-linked to the fibrin α chain when blood is clotted in the presence of calcium ions and factor XIIIa; Gln14 is involved in this cross-linking.[10]

PAI-1 is a 52-kd, single-chain glycoprotein consisting of 379 amino acids. It is a serpin with reactive site peptide bond

Table 119–1 Properties of Main Components of the Fibrinolytic System

Component	M_r	Carbohydrate Content (%)	No. of Amino Acids	Catalytic Triad	Reactive Site	Plasma Concentration (μg/mL)
Plasminogen	92,000	2	791	—	—	200
Plasmin	85,000	2	±715	His603, Asp646, Ser741	—	—
tPA	68,000	7	530 (527)[a]	His322, Asp371, Ser478	—	0.005
uPA	54,000	7	411	His204, Asp255, Ser356	—	0.008
uPAR	55,000				—	—
	60,000	±35	313			—
α_2 Antiplasmin	70,000	13	464	Arg376–Met377	70	
PAI-1	52,000	ND	379	—	Arg346–Met347	0.05
PAI-2	47,000	ND	393	—	Arg358–Thr359	<0.005
TAFI	60,000	23	401		—	5

[a]The numbering of amino acid residues usually is based on the initially determined incorrect value.
ND, not determined; PAI-1, plasminogen activator inhibitor 1; PAI-2, plasminogen activator inhibitor 2; TAFI, thrombin activatable fibrinolysis inhibitor; tPA, tissue plasminogen activator; uPA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor.

Table 119–2 Gene Organization and Chromosome Location of Main Components of the Fibrinolytic System

Component	Symbol	Gene (kb)	mRNA (kb)	Exons	Chromosome
Plasminogen	*PLG*	52.5	2.9	19	6q26–q27
tPA	*PLAT*	32.7	2.7	14	8p12-p11
uPA	*PLAU*	6.4	2.4	11	10q24
uPAR	*PLAUR*	23	1.4	7	19q13.1–q13.2
α_2 Antiplasmin	*PLI*	16	2.2	10	17p13
PAI-1	*PLANH1*	12.2	2.4/3.2	9	7q21.3–q22

PAI-1, plasminogen activator inhibitor 1; PAI-2, plasminogen activator inhibitor 2; TAFI, thrombin activatable fibrinolysis inhibitor; tPA, tissue plasminogen activator; uPA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor.

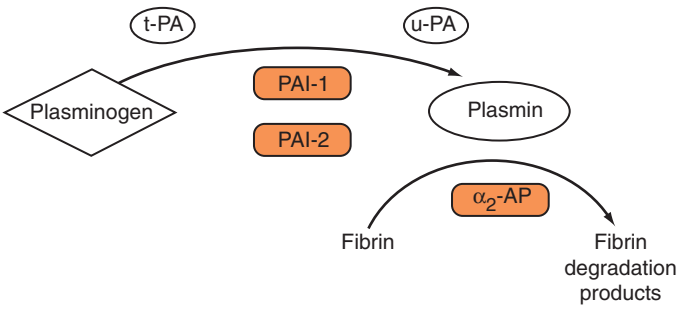

Figure 119–1 Schematic representation of the fibrinolytic system. α_2-AP, α_2 antiplasmin; PAI, plasminogen activator inhibitor; t-PA, tissue plasminogen activator; u-PA, urokinase plasminogen activator.

Arg346-Met347.[11] PAI-1 is stabilized by binding to S-protein or vitronectin.[12]

PAI-2 exists in two different forms with comparable kinetic properties: a 47-kd intracellular nonglycosylated form and a 60-kd secreted glycosylated form.[13] PAI-2 is a serpin[14] containing 393 amino acids with reactive site Arg358-Thr359. The function of intracellular PAI-2 is unclear because its main target enzyme (uPA) occurs extracellularly.

The 60-kd thrombin activatable fibrinolysis inhibitor (TAFI) is a carboxypeptidase B-like enzyme that is primarily produced by the liver and circulates at approximately 75 nM, but the normal variation is wide.[15] The circulating active enzyme has a very short half-life, and only a small fraction of the protein must be activated for normal function. Efficient activation is achieved by the thrombin–thrombomodulin complex.[16]

GENE STRUCTURE OF THE MAIN COMPONENTS

The plasminogen (*PLG*) gene is located on chromosome 6q26–q27, close to the gene for apolipoprotein(a).[17] The 19 exons are separated by 18 introns following the general GT-AG rule. A signal sequence is encoded by the first exon, an activation peptide and each of the five kringles are encoded by two exons, and the remaining six exons code for the intervening sequence and for the protease domain. Several common polymorphisms have been identified, of which the two most common variants observed in all races are *PLGA* and *PLGB*.[18]

The gene for tPA contains 14 exons and is located on chromosome 8, bands p12-p11.[19,20] The intron–exon organization suggests that assembly occurred according to the "exon shuffling" principle, whereby the distinct structural domains are encoded by a single exon or by adjacent exons. An Alu insertion/deletion polymorphism was identified; the homozygous insertion polymorphism is associated with enhanced tPA release under stress conditions.[21]

The uPA gene is located on chromosome 10q24. It contains 11 exons, and the intron–exon organization closely resembles that of the tPA gene.[22] However, some exons are missing in the uPA gene,

which accounts for the absence of a finger domain and a second kringle.

The gene for uPAR is located on chromosome 19. It consists of seven exons and six introns, extending over 23 kb.[23,24] Constitutive expression of the uPAR gene is dependent on the −141 to −61 region.

The gene for α_2 antiplasmin is located on chromosome 17p13. It is 16 kb and contains 10 exons.[25] The N-terminal region of the protein, which comprises the fibrin cross-linking site, is encoded by exon IV, whereas both the reactive site and the plasminogen binding site in the C-terminal region are encoded by exon X.

The PAI-1 gene is located on chromosome 7, bands q21.3-q22. It is 12.2 kb and consists of nine exons.[26] As a result of alternative polyadenylation yielding an additional 3′ untranslated region, an mRNA species of 3.2 kb occurs in addition to a region of 2.4 kb. A single 4G/5G polymorphism in the promoter region appears to play an important role in regulation of PAI-1 gene expression, with the 4G allele associated with higher PAI-1 levels.[27]

The gene for PAI-2 is located on chromosome 18q22.1. It spans 16.5 kb and contains eight exons.[28] The gene structure of PAI-2 is different from that of PAI-1 but similar to that of the chicken ovalbumin gene.

The gene for TAFI is located on chromosome 13. It contains 11 exons and spans 48 kb of genomic DNA.[29] Several polymorphisms in the TAFI gene have been claimed to explain the wide normal range of concentrations, but no strong correlations with disease have been established.[30]

MECHANISM OF INHIBITION OF PLASMIN BY α_2 ANTIPLASMIN

α_2 Antiplasmin forms an inactive 1:1 stoichiometric complex with plasmin. Inhibition involves two consecutive reactions: a fast, second-order reaction producing a reversible inactive complex, followed by a slower first-order transition resulting in an irreversible inactive complex. The second-order rate constant of inhibition is very high ($2–4 \times 10^7\ M^{-1}\ s^{-1}$), but this high inhibition rate depends on the presence of free lysine binding sites and a free active site in the plasmin molecule and on the availability of a site complementary to the lysine binding site (plasminogen binding site) and of the reactive site peptide bond in the inhibitor. The half-life of plasmin molecules generated at the fibrin surface, which have their lysine binding sites and active site occupied, is two to three orders of magnitude longer than that of free plasmin.[31]

MECHANISM OF ACTION OF TISSUE PLASMINOGEN ACTIVATOR

In the Presence of Fibrin

tPA is a poor enzyme in the absence of fibrin, but the presence of fibrin strikingly enhances the activation rate of plasminogen.[32] Optimal stimulation is only obtained after early plasmin cleavage in the C-terminal Aα chain and the N-terminal Bβ chain of fibrin, yielding fragment X polymer.[33] Kinetic data support a mechanism in which fibrin provides a surface to which tPA and plasminogen adsorb in a sequential and ordered manner, yielding a cyclic ternary complex.[16] Formation of this complex results in enhanced affinity of tPA for plasminogen (K_m 0.16 μM compared with 65 μM without fibrin), yielding up to three orders of magnitude higher catalytic efficiency for plasminogen activation (Fig. 119–2). In agreement with this mechanism, the increase in fibrin stimulation after formation of fibrin X polymers is associated with enhanced binding of tPA and plasminogen, which is mediated in part by C-terminal lysine residues generated by plasmin cleavage. Interaction of these C-terminal lysines with lysine binding sites on tPA and plasminogen may allow improved alignment as well as allosteric changes of the tPA and plasminogen moieties, enhancing the rate of plasminogen activation.[33]

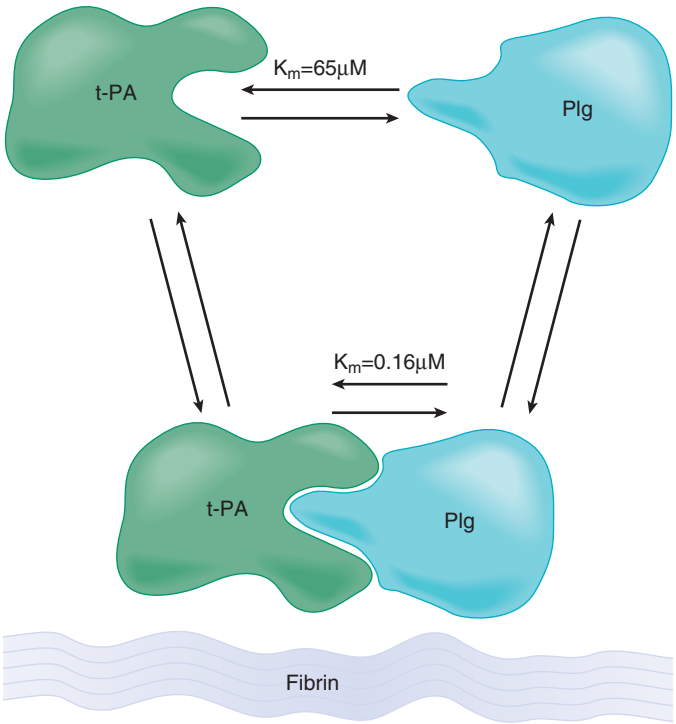

Figure 119–2 Schematic representation of molecular interactions regulating fibrin-specific activation of the fibrinolytic system by tissue plasminogen activator (t-PA). t-PA in circulating plasma in the absence of fibrin has low affinity for its substrate plasminogen (K_m = 65 μM), and no efficient plasminogen activation occurs. t-PA binds specifically to fibrin, and the bimolecular t-PA–fibrin complex has high affinity for plasminogen (K_m = 0.16 μM). Plasminogen binds to the binary t-PA–fibrin complex and is activated to plasmin at the fibrin surface. In loco generated plasmin is protected from rapid inactivation by α_2 antiplasmin. Plg, plasminogen.

Lipoprotein(a) competes with plasminogen for binding to fibrin, suggesting that elevated lipoprotein(a) levels impairs physiologic fibrinolysis.[34]

TAFI inhibits fibrinolysis by downregulating the cofactor functions of partially degraded fibrin. This effect most likely is mediated by removal of newly exposed C-terminal lysine residues that are generated on plasmin cleavage of fibrin.[35]

AT THE CELL SURFACE

A striking analogy exists between the role of fibrin and that of cell surfaces in plasminogen activation.[36] Many cell types bind plasminogen activators and plasminogen, resulting in enhanced plasminogen activation and protection of bound plasmin from inhibition by α_2 antiplasmin.

Most cells bind plasminogen by its lysine binding sites with high capacity but relatively low affinity. Gangliosides as well as a class of membrane proteins with C-terminal lysine residues such as α enolase play an important role in binding of plasminogen to cells.[37] The catalytic efficiency of tPA for activation of cell bound plasminogen is approximately 10-fold higher than in solution, possibly as a result of conversion of the plasminogen conformation to the more readily activatable "Lys-plasminogen-like" structure.[38] Vascular cells have the capacity to regulate pericellular fibrinolysis by modulating the expression of plasminogen receptors; enhanced receptor occupancy results in enhanced plasminogen activation by tPA.[39]

A 40-kd membrane protein (related to annexin II) was proposed as the functional tPA receptor on human umbilical vein endothelial

cells.[40] Cell surface–bound tPA retains its enzymatic activity and is protected from inhibition by PAI-1. Assembly of plasminogen and plasminogen activators at the endothelial cell surface provides a focal point for plasmin generation and may play an important role in maintaining blood fluidity and nonthrombogenicity.

Cellular receptors also may play a role in the rapid clearance of tPA from the circulation. Circulating tPA (half-life 5–6 minutes in humans) may interact with several receptor systems in the liver. Liver endothelial cells have a mannose receptor that recognizes the high mannose-type carbohydrate antenna on kringle 1, and liver parenchymal cells contain a calcium-dependent receptor that interacts with the finger and epidermal growth factor domains of tPA.[41] Parenchymal cells also contain a high-affinity receptor for uptake and degradation of tPA–PAI-1 complexes, which also binds free tPA albeit with lower affinity; this receptor, called *low-density lipoprotein receptor-related protein* (LRP), is identical to the α_2-macroglobulin receptor.[42]

MECHANISM OF ACTION OF UROKINASE PLASMINOGEN ACTIVATOR

In the Presence of Fibrin

In contrast to tc-uPA, sc-uPA displays very low activity toward low-molecular-weight chromogenic substrates. sc-uPA appears to have some intrinsic plasminogen activating potential, which represents less than 0.5% of the catalytic efficiency of tc-uPA.[43] In plasma in the absence of fibrin, sc-uPA is stable and does not activate plasminogen; in the presence of a fibrin clot, sc-uPA but not tc-uPA induces fibrin-specific clot lysis.[44] sc-uPA is an inefficient activator of plasminogen bound to internal lysine residues on intact fibrin but has a higher activity toward plasminogen bound to newly generated C-terminal lysine residues on partially degraded fibrin. The fibrin specificity of sc-uPA does not require its conversion to tc-uPA but is mediated by enhanced binding of plasminogen to partially digested fibrin.[45]

AT THE CELL SURFACE

The binding of sc-uPA to uPAR on the cell surface was claimed to be crucial for its activity under physiologic conditions. Binding results in strongly enhanced plasmin generation due to effects on activation of plasminogen and on feedback activation of sc-uPA to tc-uPA by generated plasmin. Both effects critically depend on cellular binding of plasminogen. Cell-associated plasmin is protected from rapid inhibition by α_2 antiplasmin, which further favors the activation of receptor-bound sc-uPA. This system can be efficiently inhibited by PAI-1 and PAI-2 (Fig. 119–3). A model based on uPAR-dependent complex formation has been proposed, which would allow initiation of plasminogen activation by the low intrinsic activity of sc-uPA.[46] However, the observation that direct anchorage of uPA to the cell surface (using a GPI-anchored uPA mutant) leads to potentiation of plasmin generation equivalent to that observed in the presence of uPAR suggests that uPAR only functions to localize uPA at the cell surface.[47] In transgenic mice, an uPAR-independent function of uPA has been demonstrated in fibrin clearance and in arterial neointima formation.[48]

MECHANISMS OF INHIBITION OF PLASMINOGEN ACTIVATORS

Multiple mechanisms are involved in the rapid inhibition of tPA in human plasma. PAI-1 is a specific rapid-reacting inhibitor of tPA, which is present at low concentrations in normal plasma but at higher concentrations in many clinical conditions.[49] tPA is inhibited slowly by α_2 antiplasmin, α_1 antitrypsin, and C1 inhibitor. The main mechanism of removal of tPA from the blood, however, is clearance by the liver. In healthy volunteers and in patients with acute myocardial infarction, the initial half-life of tPA is 4 to 6 minutes.[50]

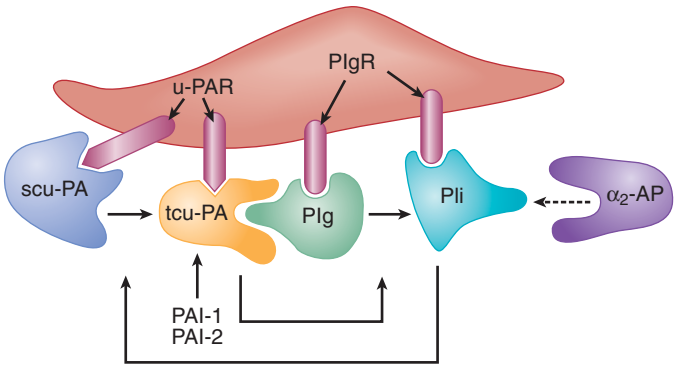

Figure 119–3 Plasminogen activation by urokinase plasminogen activator (u-PA) at the cell surface. The u-PA bound to its cellular receptor (u-PAR) efficiently converts plasminogen (Plg) bound to its cellular receptor (PlgR) to plasmin (Pli), which is protected from rapid inhibition by α_2 antiplasmin (α_2-AP). Plasmin converts u-PAR–bound single-chain urokinase plasminogen activator (scu-PA) to a two-chain derivative (tcu-PA), resulting in enhanced plasminogen activation. Receptor-bound tcu-PA, but not scu-PA, is inhibited by plasminogen activator inhibitor 1 (PAI-1) and plasminogen activator inhibitor 2 (PAI-2).

In human plasma, tc-uPA is also slowly inhibited by several proteinase inhibitors, including α_2 macroglobulin, α_1 antitrypsin, antithrombin III, α_2 antiplasmin, and plasminogen activator inhibitor 3 (PAI-3, which is identical to activated protein C inhibitor). More specific and rapid inhibition occurs by PAI-1 and PAI-2. In contrast to tc-uPA, sc-uPA is not inhibited by plasma protease inhibitors. The main mechanism of removal of uPA from the blood is hepatic clearance.[51] In patients with acute myocardial infarction, sc-uPA shows a biphasic disappearance rate with an initial half-life in plasma (after infusion) of approximately 4 minutes.[52]

PAI-1 reacts with single-chain and two-chain tPA and with tc-uPA but not with sc-uPA.[53] PAI-1 inhibits its target proteinases by formation of a 1:1 stoichiometric reversible complex, followed by covalent binding between the hydroxyl group of the active site serine residue of the proteinase and the carboxyl group of the P1 residue at the reactive center ("bait region") of the serpin. Highly positively charged regions in tPA (residues 296–304)[54] and in uPA (residues 179–184)[55] are involved in the rapid interaction. A molecular form of intact PAI-1 has been isolated that does not form stable complexes with tPA but is cleaved at the P1-P1′ peptide bond ("substrate PAI-1").[56] Examination of the crystal structure of the cleaved substrate variant using radiographs shows that it has a new β strand (s4A) formed by insertion of the N-terminal portion of the reactive site loop into β-sheet A subsequent to cleavage.[57] Inhibitory PAI-1 may convert not only to latent PAI-1, which can be reactivated, but also to substrate PAI-1, which may be irreversibly degraded by target proteases, including tPA, uPA, and thrombin.[56] PAI activity is very rapidly cleared from the circulation by the liver, with a reported half-life of 7 minutes in rabbit.[58]

PAI-2 inhibits tc-uPA approximately 10-fold slower than PAI-1. PAI-2 efficiently inhibits two-chain tPA and less efficiently inhibits single-chain tPA; it does not inhibit sc-uPA.[53]

MODULATION OF CELL-ASSOCIATED PROTEOLYTIC ACTIVITY BY MATRIX METALLOPROTEINASES

Several regulatory molecular interactions appear to exist between the fibrinolytic and matrix metalloproteinases (MMP) systems, but their exact (patho)physiologic role remains to be elucidated.

MMP-3 (stromelysin 1) specifically cleaves uPA, removing its uPAR binding sequence and resulting in downregulation of cell-associated uPA activity.[59] Several MMPs, including MMP-3, MMP-7, MMP-9, and MMP-12, cleave plasminogen, generating an angiostatin-like fragment containing the receptor-binding domains.[60–62] These MMPs may downregulate cellular fibrinolysis by reducing the amount of activatable cell-bound plasminogen.[63] MMP-3 and MMP-7 also degrade fibrinogen and cross-linked fibrin,[64,65] whereas the catalytic domain of MMP-11 cleaves fibrinogen but not fibrin.[66] The main physiologic inhibitors of the fibrinolytic system, α_2 antiplasmin and PAI-1, are also specifically cleaved by MMP-3, resulting in their neutralization.[67,68]

Inactivation of PAI-1 may be relevant in view of the findings that it plays a role in cell adhesion and migration, independent of its antiproteolytic activity, as a result of high-affinity binding to vitronectin that competes with uPAR-dependent or integrin-dependent binding of cells to the extracellular matrix. Cleavage of PAI-1 by MMP-3 may represent a mechanism decreasing the antiproteolytic activity of PAI-1 and impairing the competitive inhibitory properties on cell adhesion and migration by reducing the binding of cleaved PAI-1 to vitronectin.[68] Plasmin contributes to activation of pro-MMPs secreted by several cell types and thereby may play a role in multiple phenomena requiring extracellular proteolysis, such as atherosclerosis, restenosis after vascular injury, aneurysm formation, and myocardial ischemia.[69]

CONCLUSION

Fibrinolysis is regulated by specific molecular interactions between its main components. Activation of plasminogen by tPA is enhanced in the presence of fibrin or at the endothelial cell surface. uPA binds to the specific cellular receptor uPAR, resulting in enhanced activation of cell-bound plasminogen. Inhibition of fibrinolysis occurs at the level of the plasminogen activators or at the level of plasmin. Assembly of fibrinolytic components at the surface of many cell types by binding to specific receptors provides a mechanism for generation of localized cell-associated proteolytic activity. This may be modulated by interaction with other proteolytic systems, such as MMPs.

CHAPTER 120

REGULATORY MECHANISMS IN HEMOSTASIS: NATURAL ANTICOAGULANTS

Björn Dahlbäck and Johan Stenflo

In the absence of an anticoagulant, blood drawn into a test tube clots completely. In the serum that forms, all enzymes participating in coagulation have been activated, and all fibrinogen has been converted to fibrin. In contrast, the coagulation that occurs in vivo after vascular injury is a precisely regulated process.[1–3] This process depends on a delicate balance between coagulation and anticoagulation.[4–6]

INITIATION OF COAGULATION

Blood coagulation is initiated by endothelial cell damage. The damage leads to exposure of the integral membrane glycoprotein tissue factor, which triggers the coagulation process.[1–3,7] Tissue factor is synthesized and expressed by macrophages/monocytes in the adventitia of blood vessels as well as by fibroblasts and keratinocytes in the skin. Healthy endothelial cells that line the luminal side of blood vessels do not express tissue factor activity. However, endothelial cell tissue factor expression can be induced by inflammatory cytokines.

Tissue factor forms a noncovalent complex with activated factor VII that readily cleaves peptidyl substrates and activates factor VII to activated factor VII. Factor VII binds to tissue factor with approximately the same affinity as activated factor VII.[3] Once bound, factor VII is rapidly activated by small amounts of activated factor VII, thrombin, activated factor X, or cellular proteases. The activated factor VII then activates trace amounts of the zymogens factor IX and factor X to the corresponding proteases activated factor IX and activated factor X. Activated factor VII bound to tissue factor is approximately four orders of magnitude more efficient at activating factors IX and X than unbound activated factor VII (Fig. 120–1). This is due to a tissue factor-induced increase in the catalytic constant of activated factor VII and to membrane binding of the substrates factor IX and factor X. Activated factor X leaving the surface of a tissue factor-bearing cell (e.g., a macrophage) is rapidly inactivated by tissue factor pathway inhibitor (TFPI) and by antithrombin, whereas activated factor IX and thrombin are inhibited more slowly. These reactions are often referred to as the *initiation phase of blood coagulation*.[8]

Trace amounts of activated factor IX and thrombin are formed adjacent to platelets bound to subendothelial collagen. The thrombin molecules bind with high affinity to the platelet receptor GP1b and cleave the platelet membrane protein protease-activated receptor 1 (PAR1). Cleavage of PAR1 promotes exocytosis of the platelet granules, which results in exposure of phosphatidylserine-rich cell membranes and release of coagulation components, including factor V/activated factor V and fibrinogen. The phosphatidylserine-containing membranes interact with vitamin K-dependent coagulation factors (factor VII, factor IX, factor X, and prothrombin; Fig. 120–1). Any unactivated factor V released from the platelets is activated by thrombin. These steps are referred to as the *amplification phase* of blood coagulation.[8] Phospholipid-bound protein complexes are formed on the platelet membrane between the cofactors activated factor VIII and activated factor V, and their respective proteases, that is, activated factor IX and activated factor X. Much larger amounts of thrombin are formed than in the initiation phase.[3,9] The process, termed the *propagation phase,* culminates with thrombin-mediated cleavage of fibrinogen, which converts it to fibrin that is deposited at the site of injury.

The tissue factor molecule consists of an N-terminal, extracellular part with two immunoglobulin-like domains.[10,11] There is one disulfide bond in the N-terminal domain and one in the C-terminal domain. The latter bond is adjacent to the cell membrane and is exposed to solvent.[11] The transmembrane region of tissue factor is followed by a short intracellular cytoplasmic tail that has a single Cys residue that is acetylated by stearic or palmitic acid.

Two populations of tissue factor are present on the surface of macrophages. In addition to the active structure that forms an enzymatically active complex with activated factor VII/factor VII there is a second form of tissue factor referred to as *latent* or *cryptic.* Activated factor VII in complex with latent tissue factor cleaves peptidyl bonds but activates factor VII very slowly.[12] The activity of tissue factor appears to be regulated by the conformation of the tissue factor domain that is adjacent to the cell membrane, as revealed by the state of oxidation of the disulfide bond that links Cys186 and Cys209. This disulfide bond is oxidized in the active form and reduced in the latent/cryptic form. The reduction/oxidation state of the disulfide bond appears to be regulated by the extracellular pool of protein disulfide isomerase.[13]

Tissue factor is involved in intracellular signaling.[14] Activated factor X in the ternary activated factor VII–tissue factor–activated factor X complex activates the protease-activated receptors PAR1 and PAR2, which mediate intracellular signaling leading to production of inflammatory cytokines. The in vivo importance of PAR activation at this level compared to activation that is mediated by thrombin remains to be elucidated.

PROCOAGULATION AND ANTICOAGULATION

The coagulation system is balanced in two principally different manners. The protein C anticoagulant system can be regarded as an anticoagulant counterpart of the coagulation system. It is triggered by thrombin, which activates the regulatory protein, protein C, to activated protein C (APC), a serine protease that degrades activated factor V and activated factor VIII by limited proteolysis. In addition there are the two protease inhibitors TFPI, a Kunitz-type inhibitor, and antithrombin, a member of the serine protease inhibitor family (serpins).

Tissue Factor Pathway Inhibitor

The prime inhibitor of activated factor VII is the 46-kd TFPI.[4,15] TFPI is produced by microvascular endothelial cells as well as by monocytes/macrophages.[16] A fraction of TFPI in blood plasma circulates in complex with low-density lipoprotein and high-density lipoprotein. TFPI bound to lipoproteins has less anticoagulant effect than the free form. Also, a fraction of TFPI is noncovalently associated with endothelial cell glycosaminoglycans and can be released by heparin.

TFPI contains three Kunitz-type domains and a C-terminal region that is rich in cationic amino acid residues. There are two alternatively spliced forms of the inhibitor, TFPIα and TFPIβ.[17] The TFPIβ form lacks the Kunitz-3 domain and the region that is C-terminal of this domain in TFPIα. Instead, another C-terminal domain mediates

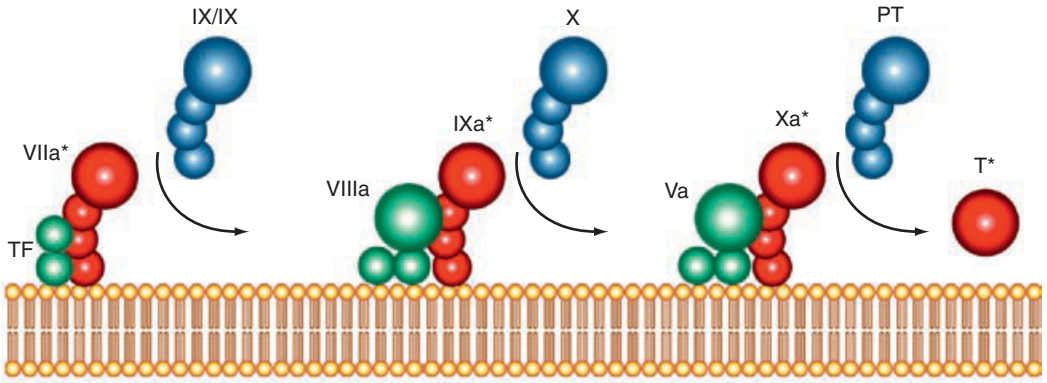

Figure 120–1 Schematic representation of the initiation and propagation of blood coagulation. Blood coagulation is initiated by the exposure of tissue factor (TF) to circulating blood. Factor VII/activated factor VII (VIIa) binds to tissue factor and activates either factor IX (IX) or factor X (X). The activated factor IX (IXa) and activated factor X (Xa) form membrane-bound complexes with their respective cofactor, activated factor VIII (VIIIa) and activated factor V (Va), which activate factor X and prothrombin (PT), respectively. Thrombin is efficiently generated from prothrombin by the activated factor X/activated factor V complex. Thrombin has multiple functions. It activates platelets and several coagulation factors, such as factor VIII, factor V, factor XI, and factor XIII. In addition it converts fibrinogen to fibrin, which constitutes the blood clot.

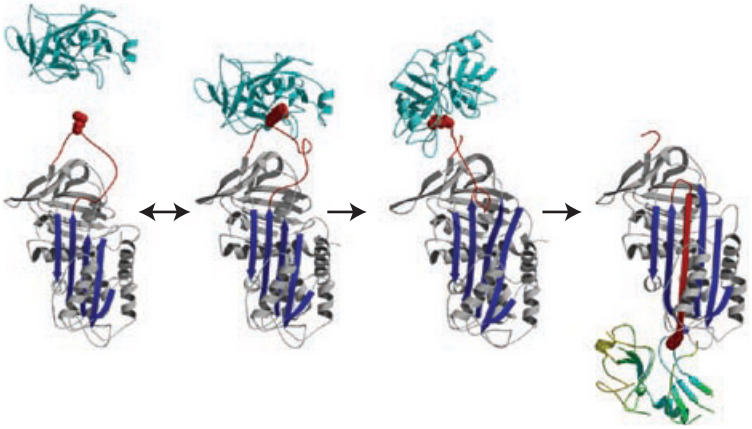

Figure 120–2 Complex formation between a serpin and an enzyme. Inactivation of trypsin by antitrypsin is shown. The mechanism of inhibition is the same for thrombin inhibition by antithrombin (AT). To the left are shown the serpin with the major β-sheet A in blue and the reactive center loop with the scissile bond residue in red. The second section shows the formation of a Michaelis complex between the inhibitor and the enzyme, which results in the formation of a covalent complex between inhibitor and enzyme. The third section shows the complex with the cleaved reactive center loop. The final event is insertion of loop 4 (red) with linked enzyme into the β-sheet A with concomitant denaturation and inactivation of the enzyme (section 4). *(Modified from Huntington JA: Shape-shifting serpins—Advantages of a mobile mechanism. Trends Biochem Sci 31:427, 2006.)*

noncovalent interaction with cellular glycosylphosphatidylinositol. TFPIβ appears to account for most of the tissue factor-activated factor VII inhibitory activity. It is more heavily glycosylated than TFPIα, particularly with respect to sialic acid.

Inhibition of activated factor VII by TFPI can proceed via two pathways. Activated factor X that has been activated by, for example, tissue factor-activated factor VII, is bound to and inhibited by TFPI. In the next step, TFPI-activated factor X complex binds activated factor VII–tissue factor, forming an inactive quaternary complex. Inhibition also can take place by interaction of the activated factor VII–tissue factor-activated factor X complex with TFPI. The tissue factor-activated factor VII complex binds to the Kunitz-1 domain, whereas activated factor X binds to the Kunitz-2 domain of TFPI. The C-terminal cationic residues mediate binding to cell surface heparinoids. These cationic residues are also required for binding to heparin. Thus, heparin treatment releases TFPI from the cell surface. Heparin also seems to form a template for the interaction between activated factor X and TFPI. The tissue factor–activated factor VII complex is cleared from the circulation within a few minutes.[18] Protein S has been shown to have a stimulatory effect on the inhibition of activated factor X by tissue factor.

TFPI-2, a homologue of TFPI, also inhibits tissue factor-activated factor VII.[19] It is expressed in umbilical vein endothelial cells, placenta, and liver. Whether it is involved in the regulation of blood coagulation is unknown.

Serpins

The serine protease inhibitors (serpins) compose a large group of homologous proteins that inhibit trypsin, thrombin, and numerous other serine proteases.[20] The most important serpins in blood coagulation are antithrombin and heparin cofactor II. Antithrombin inhibits activated factor IX, activated factor X, and thrombin, whereas heparin cofactor II inhibits only thrombin. The mechanism of inactivation of a serine protease is the same for all members of the family and can be described as a suicide substrate inhibition mechanism.[20–23]

Serpin-mediated enzyme inhibition is initiated by protease cleavage of the reactive site loop of the inhibitor and formation of an acyl intermediate between the active site of the enzyme and the carboxyl group at the site of cleavage (Fig. 120–2). Once this covalent bond is formed, en route to cleavage of the peptide bond, the reactive site loop with attached enzyme is promptly translocated to the opposite pole of the inhibitor by means of insertion of the reactive site loop as strand 4 into β-sheet A of the serpin.[24,25] This process leads to distortion of the active site of the enzyme and its immediate inactivation. The rate of translocation and hence denaturation of the target enzyme is critical to the process.

The importance of specific regions of antithrombin is illustrated by the functional defects associated with mutations in loops 3 and 5, loops that are adjacent to the inserted loop. These mutations lead to a reduced rate of insertion of the cleaved loop with attached enzyme

into β-sheet A. As a result, the acyl intermediate that links enzyme and inhibitor is cleaved with subsequent release of the active enzyme from the cleaved inhibitor.[26]

The rate of inactivation of thrombin by antithrombin in solution is relatively slow. This is due to partial incorporation of the reactive center loop into β-sheet A (see Fig. 120–2).[27] Binding of antithrombin and thrombin to heparin brings the target molecules in proximity and activates antithrombin by removing the partially inserted reactive center loop from β-sheet A. The thrombin–antithrombin complex that is formed has lower affinity for heparin and for endothelial cell glucosaminoglycans (GAGs) than does free antithrombin. It dissociates from the GAGs and is subsequently rapidly removed from the circulation by mononuclear cells ($t_{1/2}$ <5 minutes).[18,22] Heparin, a heterogeneous and negatively charged GAG, is found in mast cell granules, but it is not a normal constituent of blood.[28] Endogenous GAGs are bound to endothelial cells both on the luminal and the abluminal side, although most is bound on the abluminal side. It is estimated that approximately 10% of the endothelial cell GAGs can catalyze complex formation between thrombin and antithrombin.

In heparin obtained from porcine intestines, only a small fraction is active as an anticoagulant. In modern preparations of heparin that are intended for therapeutic use in clinical medicine, the fraction that is active as an anticoagulant has been enriched. Unlike heparin-catalyzed inactivation of thrombin by antithrombin, inactivation of activated factor X does not depend on bridging of activated factor X and antithrombin to heparin but results solely from a heparin-induced conformational change in antithrombin that makes it more reactive with activated factor X.[27] Modern preparations of heparin for clinical use often consist of low–molecular-weight heparin that particularly catalyzes inactivation of activated factor X by antithrombin.

Antithrombin deficiency increases the risk for venous thrombosis (see Chapter 134).[29] It is found in approximately 1 : 3000 persons in the general population and in 1% to 3% of patients with venous thrombosis.[30] Although heparin cofactor II is a specific thrombin inhibiting serpin, its function in vivo is unknown. A few patients with deficiency of the inhibitor have been identified, but no symptoms have been associated with this deficiency.[31]

PROTEIN C SYSTEM

The protein C system exerts its anticoagulant effect by regulating the activities of activated factor VIII and activated factor V, which are cofactors in the tenase and prothrombinase complexes, respectively.[5,32,33] The severe thrombotic disease purpura fulminans, which affects homozygous protein C-deficient individuals in the neonatal period, shows the vital importance of this anticoagulant system. Multiple proteins are involved at different points of the protein C pathway, for example, those that participate in activation of protein C, those supporting the proteolytic activity of APC, and those that inhibit APC (Table 120–1 and Fig. 120–3). Protein C, the key component of the system, is a vitamin K-dependent zymogen of a serine protease that is efficiently activated on the surface of endothelial cells by thrombin bound to thrombomodulin.[33] APC cleaves a limited number of peptide bonds in activated factor V and activated factor VIII, thus providing specific and efficient inhibition of the coagulation pathway. Protein S and the intact form of factor V stimulate the activity of APC. Protein S is sufficient for inactivation of activated factor V, whereas regulation of activated factor VIII requires the synergistic APC cofactor function of both protein S and factor V.[32] In human plasma, protein S is present in two forms: 30% to 40% is free; the rest is bound to C4b-binding protein (C4BP), a regulator of the classical complement pathway. Only free protein S functions as APC cofactor.[34–36] Three protease inhibitors, protein C inhibitor, α_1 antitrypsin, and α_2 macroglobulin, inhibit APC activity in human plasma. However, the half-life (approximately 20 minutes) of APC in circulation is relatively long as the inhibition of APC is slow.[34] The protein C pathway has been found to have anti-inflammatory and antiapoptotic effects.[33,37–39] Moreover, APC has been launched as therapy for patients with severe septic shock and multiple organ failure, resulting in improved survival.[33,37,40–42]

IMPORTANCE OF ENDOTHELIUM IN INITIATION OF THE PROTEIN C PATHWAY

Protein C is a multidomain molecule composed of a γ-carboxyglutamic acid residue (Gla)-rich domain, two epidermal growth factor (EGF)-like domains, a short activation peptide, and the serine protease domain.[34,43] Thrombin is the physiologic activator of protein C, but without its cofactor thrombomodulin it is very inefficient in activating protein C. The high affinity binding of thrombin to thrombomodulin results in greater than 1000-fold amplification of the rate of protein C activation. Thrombomodulin not only functions as an efficient cofactor to thrombin in the activation of protein C but also inhibits the procoagulant properties of thrombin. Thus, thrombomodulin transforms thrombin from a procoagulant to an anticoagulant enzyme. A membrane protein on endothelial cells, endothelial protein C receptor (EPCR), provides another 20-fold stimulation of the thrombin/thrombomodulin-mediated activation of protein C in vivo.[44] The stimulatory effect of EPCR depends on interaction between the Gla domain of protein C and EPCR, which helps orient

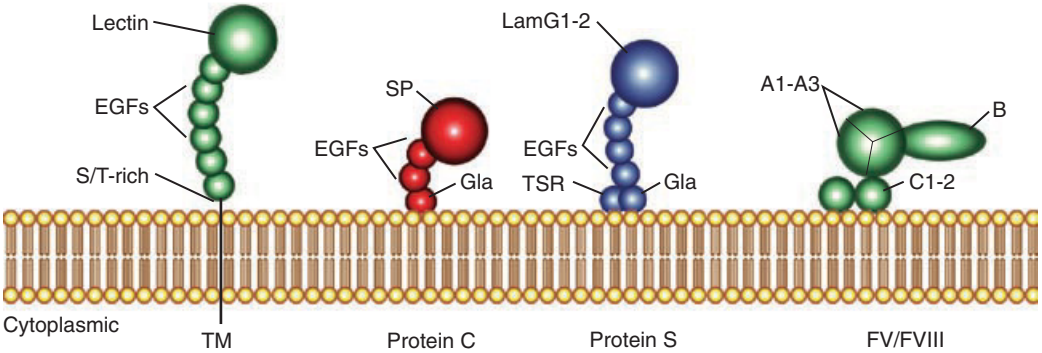

Figure 120–3 Schematic representation of several components of the protein C system. Many multidomain proteins are involved in the protein C system. The domain organization of thrombomodulin (TM), protein C, protein S, and factor V/factor VIII (FV/FVIII) is shown. The following domains are found in the proteins: epidermal growth factor-like domain (EGF); serine/threonine-rich domain of thrombomodulin (S/T-rich), which carries a chondroitin sulfate side chain; serine protease domain (SP); vitamin K-dependent γ-carboxyglutamic acid-rich domain (Gla), which binds calcium and negatively charged phospholipid membranes; and A, B, and C domains of factor V/factor VIII, which attain similar molecular arrangement. During activation of factor V and factor VIII, the B domains are cleaved off and dissociate from the active molecules. TSR, thrombin-sensitive region.

Table 120–1 Components of the Protein C Anticoagulant Pathway

Protein (Amino Acids)	Molecular Mass (kd)	Subunits (Amino Acids)	Domains	Special Functions
Protein C (417)	62	Light chain (155) Heavy chain (262)	Gla, 2 EGFs AP and SP	Zymogen to APC; anticoagulant, antiinflammatory, and antiapoptotic protease, which cleaves factor V/activated factor V and activated factor VIII and PAR1
Protein S (635)	75	Single chain	Gla, TSR, 4 EGFs, SHBG (2 LamG domains)	Cofactor to APC; cofactor to tissue factor pathway inhibitor; binds C4b-binding protein; binds to apoptotic cells; stimulates phagocytosis
Thrombomodulin (554)	75	Single chain	Lectin, hydrophobic, 6 EGFs, S/T-rich, transmembrane, cytoplasmic tail	In membrane of all endothelium; cofactor to thrombin in activation of protein C and thrombin activatable fibrinolysis inhibitor; antiinflammatory
Endothelial protein C receptor (221)	50	Single chain	MHC/CD1	In membrane of endothelium; binds Gla domain of protein C; stimulates protein C activation by thrombin–thrombomodulin and PAR1 cleavage by APC
Factor V (2196)	330	Single chain	A1, A2, B, A3, C1, C3	Precursor to procoagulant activated factor V and to anticoagulant APC; cofactor in activated factor VIII degradation
Factor VIII (2332)	330	Heavy chain (1313) Light chain (684)	A1, A2, B, A3, C1, C3	Precursor to procoagulant activated factor VIII; cofactor in the tenase complex
C4b-binding protein (4078)	570	7 α chains (549) 1 β chain (235)	8 CCPs 3 CCPs	α Chains are cofactors to factor I, an enzyme regulating the complement system; β chain binds to protein S
Protein C inhibitor (387)	60	Single chain	Serpin	Inhibitor of APC and other proteases; stimulated by heparin
α_1 Antitrypsin (394)	60	Single chain	Serpin	Inhibitor of APC and other proteases

The total numbers of amino acids in the mature proteins are given in parenthesis. The molecular masses are approximate and include posttranslational modifications such as carbohydrate side chains. Factor VIII is synthesized as single chain but processed to two chains with heterogeneity of heavy chains; the number of amino acids refers to the longest heavy chain of factor VIII. References to different proteins and their properties are given in the text; some of the information is derived from protein databases available on the Internet. http://www.ncbi.nlm.nih.gov/; http://www.expasy.org/

APC, activated protein C; EGF, epidermal growth factor; Gla, γ-carboxyglutamic acid; PAR, protease-activated receptor 1; S/T-rich, serine/threonine-rich; TSR, thrombin-sensitive region.

protein C to the thrombin–thrombomodulin complex (Fig. 120–4). Thrombomodulin is present in the membranes of essentially all vascular endothelial cells. In the capillaries, the ratio between the cell surface and blood volume reaches its peak. As a consequence, the high concentration of thrombomodulin in the capillary circulation ensures that thrombin binds to thrombomodulin ($K_d = 0.5$ nM) and activates protein C.[33,45,46]

Thrombomodulin is a type I membrane protein containing multiple domains: an N-terminal type C lectin domain followed by six EGF-like domains, a Ser/Thr-rich region containing a chondroitin sulfate side chain, a transmembrane section, and a short cytoplasmic tail (see Fig. 120–3).[33,45,46] Thrombin binds to EGF-5 and EGF-6, whereas EGF-4 interacts with a positively charged cluster in the serine protease domain of protein C.[33,45,47–51] EPCR binds the Gla domain of protein C, which makes protein C accessible to the activating thrombin–thrombomodulin complex.[33,44] EPCR is a member of the major histocompatibility class 1/CD1 family and a type I membrane protein. It contains two α helices and an eight-stranded β sheet, which together form a phospholipid-binding groove. The ability of EPCR to bind phospholipid is important for interaction with the Gla domain of protein C.[52] Thrombomodulin has another important anticoagulant property as its chondroitin sulfate side chain stimulates the inhibition of thrombin by antithrombin and protein C inhibitor.[33]

The thrombin–thrombomodulin complex can also activate the fibrinolysis inhibitor thrombin activatable fibrinolysis inhibitor (TAFI), a carboxypeptidase B that is present in plasma. Activated TAFI removes C-terminal lysine residues from fibrin. Because these lysines constitute a binding site for plasminogen during its activation by tissue plasminogen activator, TAFI inhibits fibrinolysis.[45,53] TAFI also inhibits anaphylatoxins C3a and C5a, suggesting that activation of TAFI by thrombin–thrombomodulin has antiinflammatory consequences.

ACTIVATED PROTEIN C INHIBITS COAGULATION THROUGH CLEAVAGE OF ACTIVATED FACTOR V AND ACTIVATED FACTOR VIII

Factors V and VIII share the domain structure A1-A2-B-A3-C1-C2, with the A domains arranged in a triangular pattern (see Fig. 120–3).[32,54] Activation of factors V and VIII by thrombin releases the carbohydrate-rich B domains from the activated factor V and activated factor VIII which are thus composed of the A1-A2-A3-C1-C2 domains. The high-affinity binding sites for the enzymes activated factor IX and activated factor X are located in the A2 and A3 domains of activated factor VIII and activated factor V, respectively.[55–60] In both activated factor VIII and activated factor V, the C2 domains contain the major sites for phospholipid binding, with some contributions from the C1 domains.[61–64] Molecular models of the A domains of activated factor V and activated factor VIII have been created based on their homology with ceruloplasmin.[65–70] Moreover, three-dimensional structures of APC-cleaved bovine-activated factor V (lacking the A2 domain) and of the C2 domains of both activated factor V and activated factor VIII have been determined.[71–73] The structure of the C1 domain of factor VIII has been predicted by homology and a model of phospholipid-bound activated factor VIII created.[67] These three-dimensional structures, together with experimental results, have made possible the creation of models of both the tenase and the prothrombinase complexes; models that improve our understanding of the molecular interactions involved in two of the important enzymatic reactions of blood coagulation.[59,60]

In human activated factor V, three sites are cleaved by APC: at positions Arg306, Arg506, and Arg679 (Fig. 120–5).[32,54] Cleavage at Arg506 results in partial loss of activated factor X cofactor activity and is kinetically favored over cleavage at Arg306.[32,74–77] Arg306 cleavage results in complete loss of activated factor V activity due to dissociation of the A2 fragments.[78] Regulation of activity of the tenase complex by APC encompasses cleavage of human activated factor VIII at Arg336 and Arg562.[58,79] This reaction is more complex than the degradation of activated factor V because, in addition to protein S, the nonactivated form of factor V serves as an APC cofactor.[32,80,81] In vivo, the concentration of factor VIII is much lower than that of factor V. The complicated task of regulating the highly efficient tenase complex in the presence of a large molar excess of the competing APC substrate factor V/activated factor V may explain the requirement for two APC cofactors.[32,58,79] To serve as an APC cofactor in the regulation of activated factor VIII in the tenase complex, factor V must be cleaved at Arg506 by APC.[32,81,82]

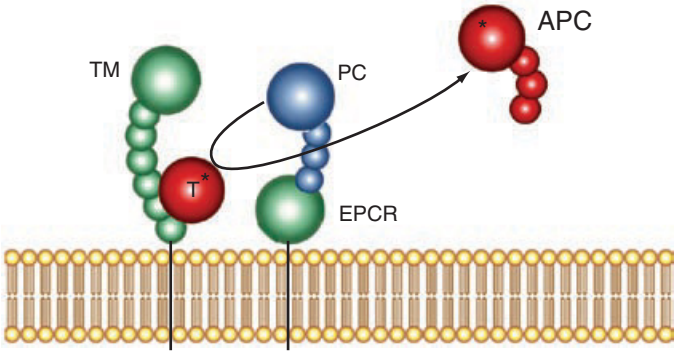

Figure 120–4 Schematic model of the molecular interactions involved in activation of protein C (PC). Thrombin binds to thrombomodulin (TM) with high affinity and efficiently activates protein C. The endothelial protein C receptor (EPCR) interacts with the γ-carboxyglutamic acid (Gla) domain of protein C and helps orient protein C to the thrombin–thrombomodulin complex. The activated protein C (APC) dissociates and leaves room for a new protein C molecule to be activated.

MULTIPLE FUNCTIONS OF VITAMIN K-DEPENDENT PROTEIN S

Protein S consists of an N-terminal Gla domain, a thrombin-sensitive region, four EGF-like domains, and two laminin G-type domains (see Fig. 120–3).[34,35,43] The Gla domain of protein S binds negatively charged phospholipid membranes, and protein S and APC form a membrane-bound complex (Fig. 120–6) that cleaves factor V/activated factor V and activated factor VIII. Several parts of protein S are important for its interaction with APC, including the Gla domain, the thrombin-sensitive region, and the EGF-1 and EGF-2 domains.[34,35,83] During degradation of activated factor VIII, the two laminin G-type domains play a role in the synergistic APC cofactor activity of protein S with factor V.[34,35,84]

Protein S has anticoagulant activity that is independent of APC. According to one hypothesis, direct binding of protein S to activated factor X and activated factor V inhibits the prothrombinase complex.[85,86] Protein S can also function as a cofactor to TFPI in regulation of the tissue factor pathway.[87]

The interaction between protein S and the complement regulatory protein C4BP in human plasma suggests that protein S plays a role in control of the complement system.[34–36] C4BP has an octopus-like structure, with seven identical α chains and a single β chain (see Fig. 120–6).[36] Each α chain can bind a C4b (activated complement protein C4) molecule and convert it into a substrate for factor I, a complement regulatory enzyme in blood. Thus, C4BP is an important regulator of the classical complement pathway. The binding site for protein S is located in the β chain of C4BP.[36,88] In protein S, the interaction site for C4BP is located in the two LamG domains.[89,90] During apoptosis, negatively charged phospholipid is exposed on the surface of cells to which protein S binds. The bound protein S is important for phagocytosis of the apoptotic cell. The molecular mechanisms are unclear but presumably involve an interaction between protein S and the receptors on the surface of the phagocytes.[91,92] In contrast to free protein S, binding of the protein S–C4BP complex to the apoptotic cell surface has been found to inhibit the phagocytic process, suggesting that C4BP blocks the site on protein

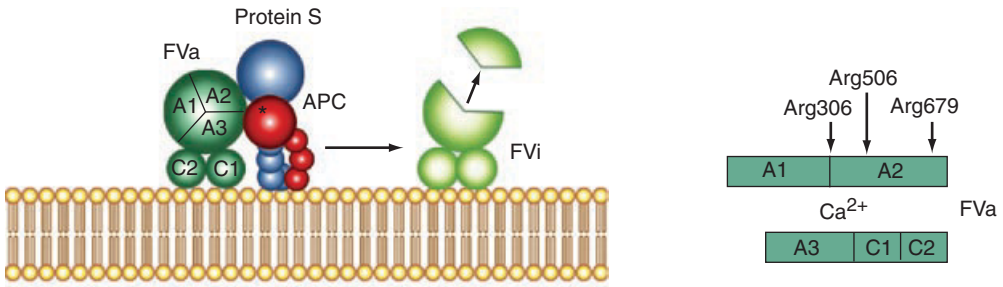

Figure 120–5 Schematic model of the degradation of factor Va (FVa) by activated protein C (APC). Degradation of activated factor V by APC in the presence of protein S, which serves as an APC cofactor. APC cleaves factor V at three sites, Arg306, Arg506 and Arg679, which results in dissociation of degradation fragments from the activated factor V molecule and loss of activated factor V activity.

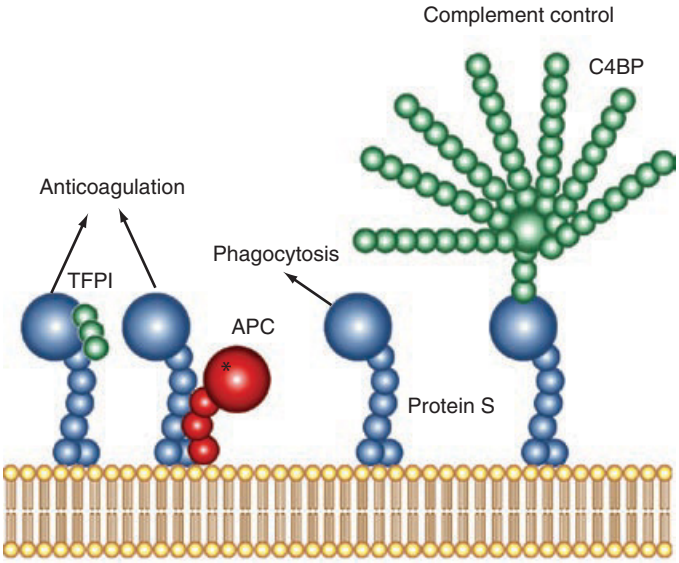

Figure 120–6 Multiple functions of protein S. Protein S binds to negatively charged phosphatidylserine, which is exposed on the surface of cells in certain situations, such as during apoptosis. Protein S has important anticoagulant functions, being a cofactor to both activated protein C (APC) and tissue factor pathway inhibitor (TFPI). Both the free and the C4b-binding protein (C4BP) bound forms of protein S interact with the membrane surface via the γ-carboxyglutamic acid (Gla) domain. The octopus-like shape of C4BP is illustrated with six long α chains and a short β chain that interacts with protein S. This provides the potential for local regulation of both coagulation and the complement (e.g., on apoptotic cells). In addition, the bound protein S stimulates phagocytosis of apoptotic cells.[92]

S interacting with the surface receptors.[93] Binding of protein S and protein S–C4BP complexes to the surface of apoptotic cells may be important for local control of coagulation and complement pathways.

ANTIINFLAMMATORY AND ANTIAPOPTOTIC EFFECTS OF THE PROTEIN C PATHWAY

Several of the proteins of the protein C pathway exert biologic effects other than those strictly referred to as anticoagulant. For example, the lectin domain of thrombomodulin has antiinflammatory effects due to downregulation of nuclear factor-κB and mitogen-activated protein kinase pathways.[46,94] Thrombomodulin also decreases leukocyte adhesion and extravasation, effects that also have been associated with protein C.[94,95] Antiinflammatory and antiapoptotic effects of APC have been demonstrated both in vivo and in vitro. These effects depend on the presence of EPCR and are due to APC-mediated cleavage of PAR1 (Fig. 120–7).[33,37–39,44] PAR1 is a G-coupled protein belonging to the large group of receptors with seven transmembrane spanning regions. PAR1 is primarily known to be cleaved by thrombin, and the novel N-terminus that appears after proteolysis activates the receptor and triggers intracellular signaling events.[96] The antiapoptotic effects of APC have been demonstrated in cultured human umbilical vein endothelial cells in which APC inhibits nuclear factor-κB activation.[38,97] In addition, the gene expression profile was switched toward an antiinflammatory and antiapoptotic direction after treatment of human umbilical endothelial cells (HUVEC) with APC and apoptosis-related genes were suppressed. Genes that decrease proinflammatory signaling pathways and those that are antiapoptotic were instead upregulated. In another study, human APC was shown to inhibit staurosporine-induced apoptosis in the EAhy926 cell line.[98]

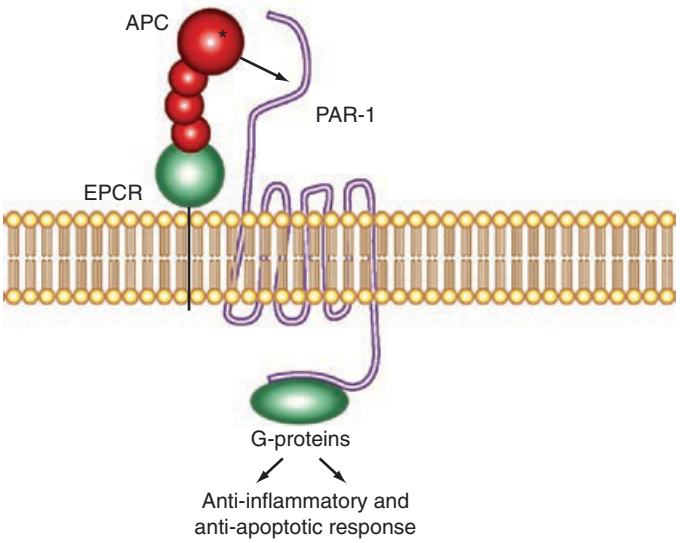

Figure 120–7 Activated protein C (APC) bound to endothelial protein C receptor (EPCR) activates protease-activated receptor 1 (PAR-1). The γ-carboxyglutamic acid (Gla) domain of APC binds to EPCR, which helps orient the active site of APC (marked with asterisk) toward a sensitive peptide bond in PAR-1. PAR-1 spans the membrane seven times, and the cytoplasmic portion of PAR-1 interacts with G proteins. Cleavage of PAR-1 by APC creates a novel N-terminus, which binds and autoactivates the PAR-1 molecule. Intracellular G proteins that are bound to PAR-1 are stimulated and generate the antiinflammatory and antiapoptotic responses of APC.

In a stroke model in mice, APC was shown to be neuroprotective and to protect cultured cortical neurons.[99–101] Similar effects were observed after administration of protein S.[102] Whether the beneficial effects of APC and protein S in vivo are due to direct cytoprotective effects on the neurons or are mediated by improved blood flow, antiinflammatory effects, or decreased apoptosis of endothelial cells remains to be elucidated. Many unresolved questions related to the APC-mediated effects on PAR1 in vivo remain, for example, why does thrombin that is several orders of magnitude[103] more potent than APC in cleaving PAR1 not have the same protective effects as APC?[104]

Not all antiinflammatory properties of APC are dependent on EPCR and PAR1. For example, APC inhibits monocyte activation by interferon γ, phorbol 12-myristate 13-acetate (PMA), and endotoxin-induced pathways resulting in decreased production of tumor necrosis factor α and interleukin 1, selective prevention of downregulation of certain membrane receptors (CD11b, CD14, and CD18), and decreased cell surface exposure of tissue factor.[103,105] APC is also found to stabilize monocyte chemoattractant protein 1 mRNA, a chemokine that is controlled by activation of nuclear factor-κB.[106]

SEVERE SEPSIS AND THE PROTEIN C PATHWAY

During sepsis, the blood coagulation system is activated by tissue factor. The septic challenge induces expression of tissue factor on endothelium and monocytes/macrophages in response to cytokines (e.g., tumor necrosis factor, interleukin 1, interleukin 6).[37,107,108] In severe cases, disseminated intravascular coagulation, microvascular thrombosis, circulatory collapse, organ failure, and shock develop. Protein C in plasma is consumed in septic shock, which can worsen the disease if the concentration of APC decreases. This can result from reduced expression of thrombomodulin and EPCR on endothelium, with detrimental effects on activation of protein C. In a sepsis model in baboons, infusion of a sublethal dose of *Escherichia coli* resulted in more severe disease if APC activity or protein C activation was inhibited.[37,109] Likewise, inhibition of binding of protein C or APC to EPCR exacerbated the septic response to *E. coli* infu-

sion.[110,111] The role of protein S is illustrated by the aggravated effects of sublethal *E. coli* infusion that follow inhibition of protein S by either monoclonal antibodies or C4BP (the latter binds free protein S).[112,113] Beneficial effects of APC infusion were demonstrated in the sepsis model in baboons. The observed prevention of shock and disseminated intravascular coagulation may depend not only on the anticoagulant activity of APC but also on the antiinflammatory effects.[114] APC has also been attempted for treatment of sepsis in humans. In the PROWESS study (1690 patients with severe sepsis), recombinant APC (drotrecogin alfa [Xigris]) resulted in a 19.4% reduction in the relative risk of death and an absolute reduction of 6.1% (30.8% mortality at 28 days in the placebo group vs 24.7% with APC).[41] Further evidence for the efficacy of APC in the treatment of severe sepsis was obtained in the open-label trial ENHANCE.[115] However, in the more recent ADDRESS study of patients with severe sepsis and low risk of death (defined by an Acute Physiology and Chronic Health Evaluation [APACHE I]) score <25 or single-organ failure), no beneficial treatment effects were observed, which argues against the use of APC in such patients.[116] Thus, it appears that APC treatment is efficient in patients with very severe sepsis (APACHE score >25 or multiple-organ failure) when protein C and APC reach very low levels, whereas no beneficial effects of treatment are seen for milder forms of sepsis. The critical factor for the therapeutic effect of APC may be the endogenous level of APC, suggesting that methods for determining the generation of APC in vivo, such as measuring APC directly[117] or indirectly as APC–protein C inhibitor complexes,[118] may have a role in deciding which patients will benefit from treatment with APC.

PROTEIN C PATHWAY AND VENOUS THROMBOSIS

The severe microvascular thrombotic disease of the neonatal period affects individuals with complete inherited protein C deficiency. This disorder demonstrates that the protein C system is vitally important for keeping the blood fluid. In the general population, the prevalence of defective protein C alleles is approximately 1:600; thus, complete deficiency affects approximately 1:200,000 to 1:300,000 newborn babies.[6] The lifelong imbalance between procoagulant and anticoagulant pathways in individuals with heterozygous protein C deficiency is associated with an approximately fivefold increased risk of venous thrombosis (see Chapter 134). Similar thrombosis risk affects patients with heterozygous protein S deficiency; together the two defects account for at most 5% to 10 % of patients with venous thrombosis in western societies (see Chapter 134). Higher prevalences have been reported from Japanese and Chinese studies.[119] The most common genetic risk factor for venous thrombosis in Caucasians is the Arg506 to Gln mutation (factor V Leiden), which causes the condition known as APC resistance. The mutation is found in 20% to 40% of thrombosis patients.[5,6,120,121] The procoagulant activity of factor V is not affected by the mutation, whereas two reactions of the anticoagulant protein C system are affected. Activated factor V Leiden cannot be cleaved at position 506 by APC because of the mutation, but cleavage at the other sites Arg306 and Arg679 are unaffected. In addition, degradation of activated factor VIII is affected by the factor V Leiden mutation because cleavage at Arg506 in factor V is important for the anticoagulant activity of factor V.[32] The relative importance of these two defective reactions, that is, degradation of activated factor V and activated factor VIII, for expression of the prothrombotic phenotype is not known.

The factor V Leiden mutation is found only in individuals with Caucasian background; it is absent or very rare in Asians, Australian Aboriginals, and black Africans. This is explained by the fact that the mutation only occurred once in human history; thus, factor V Leiden is the result of a founder effect, and the mutation is approximately 20,000 to 25,000 years old.[122] With few exceptions, the prevalence of factor V Leiden in European populations exhibit a north to south gradient, with the highest prevalence (10%–15%) in the north and lowest prevalence (approximately 2%) in the south. In United States, the prevalence is approximately 5% in the north and somewhat lower in the south due to differences in ethnic background in the population.[6,121] The relative risk of thrombosis in heterozygous individuals is increased approximately fivefold, whereas homozygotes carry a 50-fold increased risk (see Chapter 134). The factor V Leiden mutation is not a risk factor for arterial thrombosis. Women with factor V Leiden have reduced risk for bleeding after delivery, which may offer a major survival benefit in human history.[120] Moreover, factor V Leiden is suggested to be a positive survival factor in sepsis of either man or mice.[123–125] Thus, the factor V Leiden allele has provided a survival advantage during evolution, which explains its high prevalence in certain populations.

CHAPTER 121

CLINICAL EVALUATION OF HEMORRHAGIC DISORDERS: THE BLEEDING HISTORY AND DIFFERENTIAL DIAGNOSIS OF PURPURA

Barry S. Coller and Paul I. Schneiderman

The initial evaluation of patients with hemorrhagic problems involves obtaining a detailed history of bleeding symptoms and analyzing any current hemorrhagic lesions, which most often occur on the skin. This chapter focuses on the bleeding history and the differential diagnosis of purpuric skin lesions that may reflect an underlying hemorrhagic or nonhemorrhagic disorder.

THE BLEEDING HISTORY

General Principles

The bleeding history forms the basis of the diagnosis and therapy of hemorrhagic disorders. In order to maximize its value, several basic principles of eliciting and interpreting this information deserve emphasis.

1. Many normal, healthy people consider their bleeding and bruising excessive. For example, using standardized, self-administered questionnaires, Miller et al.[1] found that 23% of the normal population had "positive" bleeding histories, and Wahlberg et al.[2] reported that a remarkable 65% of healthy women and 35% of healthy men answered "yes" to the question: "Do you suffer from a bleeding disorder?" (Table 121–1).[2] Similarly, Plug et al.[3] found that 61% of normal females reported having gum bleeding, 44% reported having nosebleeds, 17% reported having bruising, and 9% reported having prolonged bleeding from small wounds.

2. Patients with profound coagulation disorders invariably have dramatically abnormal bleeding histories, although surprisingly they may not volunteer the information unless specifically questioned.

3. Patients with mild to moderate abnormalities may not have excessive bleeding symptoms or may not recognize subtle symptoms as abnormal, even though they are at risk for developing excessive bleeding if exposed to severe hemostatic challenges. In the study by Miller et al.,[1] 35% of patients with heterozygous von Willebrand disease had negative bleeding histories, and in the study by Wahlberg et al.[2] approximately 54% of the men and 38% of the women with either von Willebrand disease or a platelet function defect failed to identify themselves as suffering from a bleeding disorder (see Table 121–1).

Identifying the group of patients with milder defects and distinguishing them from the normal population require considerable skill and experience and cannot be done with certainty. In fact, given the low frequency of hemorrhagic disorders in the population and the high false-positive rate in the normal population, the task is formidable. For example, if one uses the values of 65% and 100% for the sensitivity of the bleeding history and 77% for its specificity derived from the studies of Miller et al.[1] and Castaman et al.[4] and assumes a prevalence of ten patients with von Willebrand disease in a population of 1000,[5] the predictive accuracy of a positive history is a dismal 3% to 4%. Thus, in a population of 1000 people, either seven or 10 patients with von Willebrand disease with positive histories (65% or 100% of 10) would need to be differentiated from the 228 normal individuals with positive histories (23% of 990) (see Chapter 129).

4. A search for objective confirmation of subjective symptoms provides important information in assessing the severity of the patient's disorder. This is especially important in obtaining a bleeding history because some patients are extremely sensitive to even minor hemorrhagic problems, whereas other patients ignore major problems. Specific objective indicators are discussed with each group of symptoms, but overall indicators include the following: (a) visits to physicians for bleeding problems, along with any laboratory data obtained; (b) need for transfusion of whole blood, packed red blood cells, plasma, platelets, or coagulation factor concentrates; and (c) history of documented anemia and/or physician-prescribed iron therapy.

5. A medication history is incomplete without specific questions concerning aspirin, herbal remedies, dietary supplements, or medications available without prescription that may affect coagulation or platelet function because patients may not recognize these agents as medications. Similarly, it is important to inquire about vitamin tablets that may contain vitamin K in patients taking oral anticoagulants. Hormone replacement therapy and birth controls pills can affect hemostasis.[6,7]

6. Although self-administered questionnaires with yes or no answers facilitate data collection and statistical analysis,[1,2,8,9] obtaining the maximal amount of useful information requires a dialogue between patient and physician. This allows the physician a chance to assess whether the patient truly understands what is being asked, to refine the questions in response to the initial answers, and to follow up on potentially important data that are revealed only as the discussion proceeds.

7. A constellation of hemorrhagic symptoms, rather than any single symptom, is most helpful in suggesting the etiology of the disorder. Thus, spontaneous hemarthroses and muscle hemorrhages are highly suggestive of severe hemophilia, whereas epistaxis, gingival bleeding, and menorrhagia are more commonly found in patients with thrombocytopenia, platelet disorders, or von Willebrand disease (see Chapters 125 and 129).

8. Excessive bruising and bleeding may be a manifestation of diseases of the blood vessel rather than diseases of coagulation or platelets. In patients with impressive bleeding histories but no abnormalities in coagulation or platelets, a high index of suspicion is needed for hereditary hemorrhagic telangiectasia (HHT), Cushing disease, scurvy, Ehlers-Danlos syndrome, and other systemic disorders. In patients whose hemorrhagic symptoms are confined to the skin, consideration must be given to a wide range of dermatologic disorders.

9. The diagnostic value of any single hemorrhagic symptom varies according to the disorder. In studies of hemophilia carriers[10] and of patients with von Willebrand disease or platelet function abnormalities,[2] the individual questions were ranked on the basis of their ability to discriminate between patients and normals. The results from the hemophilia carrier study are given in Table 121–2, and the results of other studies are detailed later in the chapter. Because the patterns of hemorrhage differ with different hemorrhagic disorders, the diagnostic value of any given question will differ as well. For example, a positive response to the question about long bleeding after tooth extractions had a higher sensitivity in the study of patients with von Willebrand disease and platelet disorders[2] (see Table 121–1) than in the study of hemophilia carriers (see Table 121–2).[10]

10. A dietary history is important in patients taking oral anticoagulants because intake of vitamin K will affect the response to medication (see Chapters 130 and 135). In order to maintain a con-

	Males		Females	
Question	***Normals (n = 23)***	***Patients[b] (n = 24)***	***Normals (n = 20)***	***Patients[b] (n = 21)***
Do you suffer from a bleeding disorder?	35	46	65	62
Bleeding from the gums?	52	67	50	67
Long bleeding after tooth extraction?	4	21	10	24
Skin bleeding?	0	13	15	10
Long bleeding from small wounds?	13	25	10	10
Tendency to bruises?	22	25	55	62
Spontaneous bruises?	0	4	40	48
Nose bleeding?	57	63	85	57
Blood coughed up or vomited?	9	13	5	10
Metrorrhagia?	—	—	55	42
Muscle bleeding?	4	13	15	0
Blood in the urine?	0	8	10	10
Joint bleeding?	0	0	0	10
Blood in the stool?	13	8	5	10
Treated with vitamin K?	0	4	10	19
Treated with plasma or blood transfusion?	0	4	0	0

[a]Values are percent of normal patients and percent of patients with von Willebrand disease, platelet abnormalities, or antithrombin III deficiency answering "yes" to indicated questions. Subjects were given a choice of "yes," "no," and "don't know." The percentage answering "no" and "don't know" varied considerably from question to question.

[b]The patient group consisted of 16 persons with von Willebrand disease, 27 with a variety of qualitative platelet abnormalities, including aspirin-like defects (n = 9), isolated abnormal collagen-induced aggregation (n = 12), and isolated abnormal arachidonic acid-induced aggregation (n = 6), and 2 with antithrombin III deficiency.

stant level of anticoagulation, the dietary intake of vitamin K must remain constant.[11] The absolute amount of vitamin K intake is less important, so it is reasonable to permit the patient free choice of diet with the proviso that, once selected, it remain reasonably constant.[12] If the patient wishes to change diets, it is important to monitor the level of anticoagulation more carefully. Patients should be instructed that food additives, such as fish oils, may contain vitamin K. Patients who are not taking food by mouth are at particularly high risk for developing vitamin K deficiency, especially if they are also taking broad-spectrum antibiotics because the latter decrease the vitamin K contribution from bacteria in the gastrointestinal tract (see Chapter 130).[13,14] The combination of decreased oral intake and antibiotic therapy is quite common in patients with bowel disorders during the preoperative and early postoperative periods. Because vitamin K is required on a daily basis despite its fat solubility, significant depression of coagulation factors can occur within several days and lead to excessive operative and/or postoperative bleeding.

11. Potentially confounding pharmacologic and medical influences must be considered in evaluating the history. For example, pregnancy, use of birth control pills, and hormone replacement therapy can variably increase von Willebrand factor levels in some patients with mild to moderate forms of the disease.[6,7,15] Thus, because von Willebrand factor levels decrease soon after parturition, the risk of bleeding actually may increase after delivery and remain high for several weeks thereafter. Similarly, because the stress of surgery or pregnancy can lead to thrombocytopenia in type 2B von Willebrand diseases, bleeding may be especially severe at those times.[16–18]

12. Assessing excessive bleeding in the newborn is especially difficult. For example, some neonates with Glanzmann thrombasthenia

have only minimal symptoms at birth, and the symptoms of von Willebrand disease may be masked by an increase in von Willebrand factor as a result of the stress involved in the delivery. Similarly, a significant number of hemophilic neonates do not have hemorrhagic symptoms in the first weeks of life. Large cephalhematomas may be due to birth trauma, but if they continue to progress after delivery, hemophilia or a vitamin K-dependent factor deficiency should be considered. Delayed bleeding from the umbilical stump should raise the possibility of factor XIII deficiency or a fibrinogen abnormality (quantitative or qualitative).

13. Hemostatic competence during previous severe hemostatic challenges provides particularly valuable data. Thus, a mild bleeding diathesis may not become clinically manifest until the patient experiences a major hemostatic challenge. As a result, it is more difficult to exclude the presence of a mild defect in patients who have not had a significant hemostatic challenge.

Documenting the History

Table 121–3 contains a bleeding history form. It is designed to be filled out by the physician during discussions with the patient. Use of such a form ensures that the major symptoms are elicited and recorded in a standardized manner. The form itself is made a part of the patient's permanent record. Other bleeding history reporting forms have been developed, and their relative value is discussed here, along with general scales of bleeding severity, after considering each of the bleeding symptoms in more detail.[9,19–22]

Evaluating Individual Bleeding Symptoms

Epistaxis

Bleeding from the nose is one of the most common manifestations of platelet disorders and von Willebrand disease. It also is the most common symptom of HHT. At the same time, a large fraction of the normal population has experienced one or more nosebleeds. Thus, when a group of normal subjects was presented with the question, "Nose bleeding?" on a self-administered questionnaire, 57% of the men and 85% of the women answered "yes" (see Table 121–1). To obtain more meaningful data, it is important to inquire about the frequency of nosebleeds and whether the nose bleeding occurs spontaneously or only with trauma. The latter may not always be appreciated because some individuals habitually and subconsciously traumatize their mucous membranes when they use their fingers to remove crusted secretions from their nose. If the bleeding is confined to a single nostril, it more likely is due to a localized vascular abnormality than to a systemic coagulopathy. In northern locales, nosebleed with nonhematologic etiologies is more likely to occur in the dry winter months, especially with use of forced air heating systems that dry out the mucous membranes. It is important to ascertain the effects of aging on epistaxis because many individuals with no discernible abnormalities have childhood epistaxis that disappears after puberty, whereas patients with HHT usually suffer increasingly severe epistaxis with increasing age. Therefore, the age of onset of epistaxis in HHT may provide prognostic information. The length of time for the bleeding to stop gives valuable insight into the severity of the episodes. Objective information can be obtained by inquiring as to whether the epistaxis was severe enough to require evaluation by a physician, and, if so, whether packing, cautery, or transfusions were considered necessary to control the bleeding.

Gingival Hemorrhage

Bleeding from the gums is another common symptom of platelet disorders and von Willebrand disease. It often is the first sign of hemostatic compromise in patients who develop thrombocytopenia after chemotherapy. Interestingly, patients with long-standing hemorrhagic disorders may not recognize that their gingival bleeding is excessive because they assume that everyone bleeds from their gums on a daily basis. In fact, occasional, but not perennial, gum bleeding is very common among the normal population, with 52% of normal males and 50% of normal females answering "yes" to the question, "Bleeding from the gums?" in the study by Wahlberg et al.[2] Therefore, it is important to establish the frequency with which the patient's gum bleeding occurs and whether the bleeding is spontaneous, as the vast majority of normal persons will experience gum bleeding only after the trauma of tooth brushing. If spontaneous gum bleeding occurs during the night, patients may notice blood-tinged stains on their pillowcase. Daily gum bleeding with tooth brushing may or may not be abnormal, depending on whether the patient has gingival disease and whether a hard-bristle or soft-bristle tooth brush is used. Because routine tooth scaling to remove plaque performed by dental hygienists is a significant hemostatic challenge, it is useful to inquire whether the patient was told that he or she bled excessively after this procedure. Finally, some patients have oral mucous membrane bleeding in the form of blood blisters as another manifestation of a hemorrhagic diathesis, most commonly due to severe thrombocytopenia. Such blisters have a predilection to form on the inner surface of the cheek at sites that are traumatized by the teeth.

Skin Hemorrhage

Petechial lesions characteristically appear as crops or showers of lesions in dependent portions of the vasculature. However, the integrity of the microvasculature depends on a variety of vascular and extravascular factors. Therefore, it is not surprising that patients with similar platelet or coagulation disorders show considerable variability in the appearance of petechial lesions. For example, when infants cry, they increase the pressure in the veins draining the face, and in some patients with platelet disorders such as Glanzmann thrombasthenia this may be sufficient provocation to bring out petechial lesions.

Bruising is one of the most difficult symptoms to evaluate because patients vary greatly in their recognition and response to the symptom. Thus, patients who always bruise excessively, even without trauma, may assume that this is normal because they have experienced it all their lives, whereas normal individuals who bruise only rarely may become very concerned about a single large bruise associated with trauma. Bruising is more common in women than in men. For example, 22% of normal men and 55% of normal women responded affirmatively to the question, "Tendency to bruises?," and none of the normal men but 40% of the normal women indicated that they had "spontaneous bruises." Therefore, it is necessary to define better the nature of the bruising so as to determine whether the bruising is part of a hemorrhagic diathesis.

The dermatologic literature recognizes the female easy bruising syndrome (purpura simplex) as one in which women have excessive bruising in relationship to their menstrual cycle, although the time in the cycle when the bruising is excessive varies among women.[23] This diagnosis should be entertained only after excluding other etiologies. Variations in von Willebrand factor levels have been reported during the menstrual cycle, presumably reflecting the effects of estrogen, and this is one potential contributing cause (reviewed by Kujovich[24]). However, not all studies found cyclical variations and not all studies found the same patterns during the menstrual cycle.[24] If there are no underlying hematologic or nonhematologic causes,[25] it is appropriate to reassure the patient that she is unlikely to be at risk of excessive hemorrhage, even with more severe hemostatic challenges such as surgery. It is inappropriate, however, to tell the patient that there is nothing wrong with her, because this can be misinterpreted to suggest that the physician thinks she inappropriately sought medical attention for a trivial matter. These patients clearly do have an abnormality that can be quite frightening, even though at present the molecular basis of the defect has not been identified biochemically.

It is important to try to establish whether the patient's hemorrhagic response is excessive when measured against the inciting

Table 121–3 Form for Documentation of Bleeding History

1. Epistaxis

trauma. Thus, spontaneous bruising is most likely to be pathologic, and the patient should be asked specifically whether bruises appear even without any recognized antecedent trauma. Unfortunately, patients vary significantly in appreciating when they have been traumatized. For example, mothers of children who are old enough to be physically active, but still young enough to be held in the mother's arms, may be so focused on other matters that they do not realize that they are being repeatedly kicked. Similarly, normal toddlers and youngsters who are physically active commonly have bruises on their legs and arms.

The location of a bruise may offer indirect evidence of its relationship to trauma. The vast majority of traumatic events occur on exposed sites on the arms and legs. Therefore, if the patient suffers repeated bruises on unexposed sites on the trunk or back, these are more likely to be either spontaneous or in response to minimal trauma. The size of the bruise may also give some indication of the extent of bruising. It is best to provide patients with some size standards that they can relate to, such as "dime-sized," "silver-dollar-sized," or "as large as your palm." When assessing bruise size, it is important to remember that bruises often spread during the resolution phase. With severe bruises there may be hemorrhage into the bruise, resulting in very dark discoloration and the appearance of a raised "knot" in the center of the bruise; such bruises tend to be particularly painful.

The color of the bruise may also be significant. Fresh bruises associated with hemorrhagic phenomena tend to be dark purple, so-called "black-and-blue marks"; they evolve into shades of yellow-green as they resolve. By contrast, patients with senile purpura or Cushing syndrome commonly have bruises that are much redder in appearance. Since easy bruising may be the presenting symptom of Cushing syndrome, it is important to have a high index of suspicion for this disorder in younger patients whose bruises simulate the appearance of senile purpura. Another color variant worth distinguishing is the jet black central area and violaceous-erythematous surrounding area characteristic of warfarin-induced skin necrosis. This thrombotic disorder has a predilection for fatty tissues such as the breasts; it can be mistaken for a hemorrhagic abnormality because of the bruise-like quality of the lesion and the association with oral anticoagulant use.

Bruises usually take 10 days to 2 weeks to resolve, depending on the extent of the bruise. When patients indicate that their bruises take months to resolve or that they have required casting of a limb in order for the bruising to stop, consideration should be given to the poorly understood entity of psychogenic purpura.[26–29]

Tooth Extractions

Bleeding in response to tooth extraction can provide extremely important information. The hemostatic challenge varies, however, with the type of tooth removed; molar extractions are usually the severest tests of hemostasis. Objective information can be obtained about the duration and extent of bleeding by asking about the need to reconsult the dentist for packing, suturing, or even transfusion of blood products. A deep injection given to achieve anesthesia of the lower jaw by nerve block is a particularly dangerous hemostatic challenge since hemorrhage from such an injection may extend down into the neck and compromise the airway.

Bleeding from Minor Cuts

In our society, shaving nicks are the most common minor cuts suffered, and patients with platelet disorders or von Willebrand disease usually bleed excessively from them. If a patient uses an electric razor or a depilatory, it is worthwhile asking whether a razor blade was ever used and, if so, why the switch was made. Although it is difficult to obtain objective information about bleeding after razor nicks, it may be helpful to ask whether the patient delays leaving home in the morning because of persistent oozing from these wounds or whether they leave home with small pieces of tissue paper still attached to their bleeding wounds. It is also useful to instruct the patients that direct pressure for 5 minutes is usually much more effective than tissue paper, since rebleeding is very common when the latter is removed. Patients with purpura secondary to amyloidosis may paradoxically choose to switch from an electric razor to a blade razor because the pressure of the electric razor causes more purpura than razor nicks.

Bleeding from Major Trauma

In the absence of previous surgery, the extent of bleeding in response to major trauma furnishes the most reliable information about future hemostatic risk. In order to assess the appropriateness of the bleeding, the details of the injury must be determined. The need for sutures and transfusions provides objective information. Excessive bleeding due to thrombocytopenia or platelet dysfunction tends to occur immediately, whereas excessive bleeding due to coagulation abnormalities may be delayed. It is especially important to know whether aspirin or other antiplatelet agents were taken after the trauma to alleviate pain.

Hemoptysis

Hemoptysis is virtually never the presenting symptom of a bleeding disorder and is rare even with serious bleeding disorders. Thus, a comprehensive search for an anatomic abnormality or an underlying infectious or neoplastic disease is required, even if the patient has a systemic coagulopathy. Patients with bleeding diatheses may, however, have blood-tinged sputum in association with acute respiratory tract infections. Occasionally, a patient with an upper respiratory tract infection associated with a postnasal drip may also complain of hemoptysis, even though the true source of blood is in the upper airway.

Hematemesis

As with hemoptysis, hematemesis is virtually never the presenting symptom of a hemostatic disorder, and thus a search for an anatomic basis is mandatory. Hemostatic defects may, however, contribute significantly to gastrointestinal bleeding, as in patients with liver disease and esophageal varices, or patients with gastritis secondary to aspirin ingestion.

Hematuria

Urinary tract bleeding is also virtually never the first symptom of a hemostatic disorder and thus a full investigation to define an anatomic defect is required. Hemostatic defects may, however, exacerbate hematuria caused by other disorders; thus, patients with urinary tract infections that might ordinarily produce microscopic hematuria may instead develop gross hematuria. Normal subjects may also develop gross hematuria with urinary tract infections. Since women are much more likely to contract such infections, it may explain why none of the normal men but 10% of the normal women complained of blood in their urine in the study by Wahlberg et al. (see Table 121–1).[2] Even among patients with platelet disorders and von Willebrand disease, however, only 8% of the men and 10% of the women complained of hematuria (see Table 121–1).[2]

Hematochezia

Hemorrhoids are the most common cause of hematochezia, but more serious, less common, causes need to be excluded. In the study by Wahlberg et al.,[2] 13% of normal men and 5% of normal women

complained of blood in the stool (see Table 121–1). Although a systemic coagulopathy may exacerbate hematochezia, one should not ascribe the bleeding to the coagulopathy itself without extensive evaluation. Von Willebrand disease, platelet abnormalities, and both inherited and acquired forms of angiodysplasia may all be associated with severe recurrent episodes of hematochezia and often the search for discrete bleeding sites is frustrating and inconclusive. Associations between von Willebrand disease and both angiodysplasia and HHT have been reported,[30] but current information does not support a genetic link between von Willebrand factor and any of the recognized genetic forms of HHT.[31,32] It is more likely, therefore, that having von Willebrand disease makes the hemorrhage associated with vascular anomalies more severe, increasing the probability that the patient will come to medical attention.

Melena

It is important to make certain that the patient understands precisely what is meant by the term melena, because many patients will answer "yes" to a question about black stools when, on further questioning, it is clear that their stools are really dark brown. The black rubber tubing of a stethoscope is a good visual prompt for making this clear. Objective evidence of gastrointestinal hemorrhage can be obtained by explicitly asking whether the patient's stool ever tested positive for occult blood and whether the patient ever underwent endoscopy. As with the other sources of gastrointestinal bleeding, melena is virtually never the presenting symptom of an inherited hemostatic defect. Recurrent episodes of melena may occur, however, in patients with serious hemorrhagic abnormalities or angiodysplasia, and on occasion can even be lethal. Objective data on fecal occult blood tests, previous hospitalizations, the results of endoscopic studies, and the need for blood replacement should also be obtained.

Central Nervous System Bleeding

Severe thrombocytopenia (<5,000–10,000 platelets/μl) is associated with increased risk of central nervous system hemorrhage, including both diffuse petechial lesions and gross hemorrhagic strokes. The latter may occur spontaneously or after just minimal head trauma. It is of interest that spontaneous central nervous system hemorrhage is exceedingly rare in Glanzmann thrombasthenia.[33]

Venipuncture Site Bleeding

Patients with diffuse intravascular coagulation, hyperfibrinolysis, thrombocytopenia, or qualitative platelet disorders characteristically bleed for a long time after venipunctures, whereas patients with coagulation disorders do not. Delayed bleeding, however, may occur in the latter group. Virtually all of the prolonged venipuncture bleeding can be prevented, or at least minimized, by applying direct pressure to the venipuncture site for at least five minutes and then observing the uncovered site for at least one minute for evidence of continual bleeding.

Ophthalmologic Bleeding

Subconjunctival hemorrhages are associated with both platelet and coagulation abnormalities. Activities that increase venous pressure, such as uncontrollable crying in infants, or prolonged Valsalva movements or strangulation, may, however, be sufficient to elicit conjunctival hemorrhages in otherwise normal individuals. These maneuvers will also exacerbate the hemorrhages in patients with hemostatic disorders. Severe thrombocytopenia may also lead to retinal hemorrhage. Many other disorders that are not associated with hemostatic defects can, however, also lead to retinal hemorrhages as a result of damage to the vasculature, including multiple myeloma, retinal vein thrombosis, diabetes, sickle cell anemia, some forms of age-related macular degeneration, and leukemic leukostasis. Orbital hemorrhage is more commonly associated with hemophilia than platelet disorders.

Menses and Ovarian Bleeding

Menorrhagia is defined as loss of more than 80 ml of blood per cycle.[34,35] Assessing the severity of menstrual flow based on the patient's subjective estimation or the number of sanitary napkins or tampons used is generally unreliable because women vary greatly in their perception of excessive bleeding and their hygienic practices.[36] It is usually more helpful to establish the number of days of heavy flow and the total number of days for an average menstrual period; if the former is greater than 3 and/or the latter is greater than 6 or 7, it is likely that the menstrual bleeding is excessive. It may also help to ascertain whether the bleeding is heavy enough to require especially large sanitary napkins or to require curtailment of ordinary activities. Pictorial charts may help quantify blood loss.[35] Objective data include whether a physician 1) prescribed birth control pills to control the bleeding, 2) told the patient she was anemic, 3) prescribed iron, 4) performed a dilatation and curettage (D&C) to assess the bleeding, 5) was forced by circumstances to perform an emergency hysterectomy to secure hemostasis, and/or 6) performed an elective hysterectomy or endometrial ablation as preventive measures. When menorrhagia is confirmed by direct measurement of menstrual blood loss and no gynecologic cause is identified, a search for a hemostatic defect is indicated. In fact, the frequency of von Willebrand disease in patients with menorrhagia has been estimated as 5–20% (reviewed by Kujovich[24]).

Ovarian bleeding at the time of ovulation may be excessive in patients with platelet abnormalities, particularly Glanzmann thrombasthenia. It may result in severe abdominal pain, especially if blood is released into the peritoneal cavity, and may cause damage to the ovary. Repeated events can lead to reduced fertility.[37]

Pregnancy and Delivery

A detailed history of bleeding with each pregnancy should be obtained, including objective data regarding the need for transfusions, dilatation and curettage, iron therapy, and/or hysterectomy. It is useful to specifically ask if the patient's doctor commented on her bleeding being excessive at delivery, even if none of the objective criteria were met. A history of recurrent spontaneous abortion may be part of the antiphospholipid antibody syndrome, which may include lupus-like anticoagulants, anticardiolipin antibodies, and/or false-positive serologic tests for syphilis (see Chapter 133). The suspicion of this syndrome should be even greater if recurrent spontaneous abortions occur after the first trimester. Recurrent spontaneous abortions also have been reported in association with abnormalities of fibrinogen[38] and factor XIII,[39] presumably due to abnormal stability of placental attachment.

Hemarthroses

Joint bleeding is the hallmark of the hemophilias and is extremely rare in all other hemostatic defects except severe von Willebrand disease. Because joint bleeding usually is not associated with discoloration, patients may not appreciate that their symptoms are caused by hemorrhage. Therefore, it is important to inquire specifically about pain, swelling, and limitation of motion rather than merely asking about bleeding into the joints. Pain is the most sensitive indicator and may be the only manifestation.

Surgical Procedures

The details of each surgical procedure should be recorded, including any statements made by the surgeon about the extent of bleeding. In

general, the onset of excessive bleeding postoperatively due to coagulation abnormalities may be delayed for hours to approximately 1 day, whereas excessive bleeding due to platelet disorders or thrombocytopenia usually manifests as diffuse oozing intraoperatively or immediately postoperatively. Emphasis should be placed on ascertaining whether any blood products were administered. Specific questioning about tonsillectomy (which is a severe hemostatic challenge because of the large raw surface produced) and appendectomy may be required because some patients forget about these operations, especially if they were performed many years before. It is helpful to ask how long the patient was hospitalized with each operation because delayed discharge may have been due to excessive bleeding. The hospital records should be secured because they may contain important clinical and laboratory data that the patient never knew or forgot.

Circumcision and Umbilical Stump Bleeding

Congenital bleeding disorders, particularly the hemophilias, may cause excessive bleeding at circumcision as their first manifestation. Delayed bleeding from the umbilical stump or after circumcision is said to be particularly suggestive of factor XIII deficiency,[40] but factor VIII or factor IX deficiency also can produce delayed bleeding.

Telangiectasias

Patients may manifest a wide range of telangiectatic lesions, ranging from pinpoint erythematous dots that blanch when compressed to classic cherry angiomata ranging in size up to several centimeters. The vast majority of the otherwise normal population will demonstrate an increase in skin telangiectasias with aging, often associated with the development of papular cherry angiomata. The latter may have a distinctive blue appearance if present in the deeper layers of the skin. Patients with HHT usually have progressively more severe disease as they age. What constitutes the minimal criteria for HHT is not clear; some otherwise normal persons with no clinical manifestations in their early years develop easy bruising in association with skin telangiectasias in their later years. The classic hallmarks of HHT include epistaxis and tongue telangiectasias, but lesions may be present in virtually every organ, manifesting as space-occupying lesions, sources of bleeding, or sources of arteriovenous shunting. On physical examination, the lesions may be much more subtle than the florid examples found in most textbooks. A careful search of the integument is necessary, focusing on the face, chest, shoulders, legs, and under the nails. Lesions are commonly found on the vermilion border of the lips and under the tongue, even when the tip of the tongue is not involved. It is important to distinguish the lesions of HHT from the spider telangiectasias associated with liver disease and pregnancy. The latter have a more splotchy appearance, are concentrated on the shoulders, chest, and face, and have a more serpiginous quality.

Disorders Affecting Connective Tissue

If Ehlers-Danlos syndrome is considered in the differential diagnosis, it is useful to inquire specifically as to whether the patient was "double jointed" as a child or had unusually distensible skin. However, in type IV Ehlers-Danlos syndrome, which is marked by ecchymoses and easy bruisability, joint hypermobility may be confined largely to the fingers, and the skin, although thin and translucent, may be only mildly hyperextensible.[41] More obvious abnormalities, such as lens dislocations, should be apparent. Questions regarding common skin manifestations of Cushing syndrome should be posed, including rounded faces, purple striae, truncal obesity, and fat deposition in the back of the neck. Old photographs of the patient may be extremely helpful in deciding whether facial changes are new. The medication history should provide information on whether the patient is taking glucocorticosteroids.

Wound Healing

Although abnormal wound healing is not a common problem in patients with hemostatic disorders, defects have been reported in association with factor XIII deficiency and fibrinogen abnormalities. Patients with Ehlers-Danlos syndrome and Cushing disease and those taking glucocorticosteroids are likely to have had abnormal wound healing.

Medications

The dose of each prescription and nonprescription drug taken by the patient should be recorded. Specific questions should cover aspirin and other antiplatelet agents, birth control pills, vitamins, herbal remedies, and dietary supplements because these drugs may not be appreciated as medications by the patient. Iron therapy in the past should be noted because it may provide information on previous episodes of anemia due to blood loss.

Family History of Bleeding

A pedigree going back at least one or two generations should be recorded, with emphasis on hemorrhagic and/or thrombotic manifestations for each member. A specific question regarding parental consanguinity should be included because patients may not realize that this is important information. Details about the cause of death for each deceased individual should be obtained.

Immunization History

Because patients with hemostatic disorders may need blood products, it is important to know whether the patient previously was vaccinated against hepatitis B. Vaccination should be considered for all those who have not been vaccinated or whose immunity has decreased below the recommended threshold.

Standardized Questionnaires and Hemorrhage Assessment Instruments

Questionnaires

Rodeghiero et al.[19] developed a physician-administered questionnaire encompassing a range of questions very similar to those included in Table 121–3, with instructions on how to determine when a symptom should be recorded as trivial. In general, the average and most severe manifestations of each symptom are recorded. They also developed a bleeding score to reflect the severity of each symptom. They used the results from 84 symptomatic patients with type 1 von Willebrand disease, 42 type 1 von Willebrand disease obligate carriers who had not sought medical attention, and 215 age- and sex-matched controls to validate the original bleeding score. The symptomatic patients and obligate carriers had similar values for factor VIII (44% and 42%), von Willebrand factor antigen (27% and 27%), and ristocetin cofactor activity (19% and 19%), indicating their biochemical equivalence. The authors analyzed the usefulness of the bleeding history for diagnosing type 1 von Willebrand disease based on both the number and intensity of the bleeding symptoms. Of a possible 10 bleeding symptoms for females and eight for males, fewer than 1% of the controls reported having three hemorrhagic symptoms, 7% reported having two symptoms, and 77% reported having none. In contrast, only 12% of affected patients had no symptoms, 27% had one, 19% had two, 23% had three, and 20% had four or more symptoms. The obligate carriers had results similar to those of the patients, indicating that they suffered similar bleeding symptoms, reinforcing that individuals vary considerably in whether they seek medical attention for hemorrhagic symptoms of equivalent severity. Using a cutoff of three

Table 121–4 Comparison of Different Clinical Criteria for Diagnosis of von Willebrand Disease Developed by Rodeghiero et al.[19]

Criteria	Sensitivity (%)	Specificity (%)
1. Qualitative (>2 symptoms)	50.0	99.5
2. Quantitative (score >3 in males or >5 in females)	64.2	99.1
3. Mixed: criteria 1 and 2	45.2	100
4. Mixed: criterion 1 or 2	69.1	98.6
5. CART model	80.1	91.6

CART, classification and regression tree analysis.

From Rodeghiero F, Castaman G, Tosetto A, et al: The discriminant power of bleeding history for the diagnosis of type 1 von Willebrand disease: An international, multicenter study. J Thromb Haemost 3:2619, 2005.

or more hemorrhagic symptoms, the sensitivity and specificity for diagnosing the obligate carriers were 50.0% and 99.5% (Table 121–4); a cutoff of two or more symptoms would have produced 76.1% sensitivity and 92.1% specificity.

The intensity of the bleeding symptoms, as reflected in the bleeding history scores, correlated with the presence of von Willebrand disease, whether in the affected patient group or the obligatory carrier group (Table 121–4). The diagnostic likelihood ratios differed among the symptoms, with the highest ratios for the questions about cutaneous hemorrhage and excess bleeding with surgery, tooth extraction, or childbirth (Table 121–5). The absence of bleeding with certain provocations may also provided very valuable information. Thus, the absence of bleeding after tooth extractions made it very unlikely that the individual had von Willebrand disease (negative diagnostic likelihood ratio 0.29). The authors found variable increases in sensitivity and specificity when combining both the number and severity of symptoms (see Table 121–4). Application of classification and regression tree analysis (CART) improved the diagnostic sensitivity but decreased the specificity. Classification and regression tree analysis suggested that an efficient strategy for diagnosing or excluding von Willebrand disease consisted of first asking if the individual had undergone tooth extraction. For those who had not or who did not have excess bleeding after tooth extraction, a subsequent negative response to a question about cutaneous bleeding would exclude von Willebrand disease with reasonable probability. In patients with either excess bleeding after tooth extraction or cutaneous bleeding, further laboratory evaluation for von Willebrand disease would be appropriate.

This bleeding history questionnaire subsequently was administered to 712 subjects from 144 families with von Willebrand disease and analyzed with a modified bleeding symptom score (Table 121–6).[20] Three or more hemorrhagic symptoms were present in 79% of index cases and 57% of affected family members. The median bleeding scores for 195 controls, 295 unaffected family members, 273 affected family members, and 144 index cases were −1, 0, 4, and 9, respectively. Figure 121–1A shows the bleeding scores, Fig. 121–1B the odds ratios for individual symptoms, and Fig. 121–1C the correlations of bleeding symptoms with levels of von Willebrand factor antigen, factor VIII, and ristocetin cofactor activity. There was an inverse correlation between bleeding score and each of these laboratory tests. Of note, the mucocutaneous bleeding score, obtained by summing the scores for spontaneous bleeding symptoms, was similar to ristocetin cofactor activity and von Willebrand factor antigen levels in predicting bleeding after tooth extraction but superior to factor VIII values. The mucocutaneous bleeding score was superior to all of the laboratory values in predicting surgical bleeding. The authors concluded that bleeding after minor wounds and cutaneous bleeding were most valuable diagnostically, whereas postpartum hemorrhage, gastrointestinal bleeding, and oral bleeding did not discriminate patients from unaffected family members (Fig. 121–1B).

The data in this study[20] are similar to those in the initial report by Rodeghiero et al.,[19] with the notable exception of postpartum hemorrhage, which was a useful discriminator in the first study but not in the second study. They also identified symptom clusters, including epistaxis with postsurgical or oral bleeding, and cutaneous bleeding with menorrhagia in affected patients. Finally, they noted that index cases had more severe symptoms than did affected family members, despite similar von Willebrand factor laboratory values, suggesting that the index cases may have additional factors compromising their hemostasis. Support for the presence of prohemorrhagic factors in the families was deduced from the slightly elevated bleeding scores in the unaffected family members relative to normal controls (see Fig. 121–1A). Most recently, thus group has applied a Bayesian approach to the diagnosis of type 1 von Willebrand disease, integrating the bleeding score with the von Willebrand factor level and the family history.[8]

Sramek et al.[9] created a self-administered bleeding history questionnaire and analyzed its usefulness in two separate situations: (a) discriminating between individuals referred to a hematologist for evaluation who did and did not have a bleeding disorder, and (b) identifying whether individuals with no known bleeding disorder did or did not have a bleeding disorder. To achieve these goals, they sent questionnaires to 222 patients with a proven bleeding disorder, 134

Table 121–5 Diagnostic Values of Bleeding Scores[a] for Hemorrhagic Symptoms in the Questionnaire Developed by Rodeghiero et al.[19] When Applied to Obligatory Carriers of Type 1 von Willebrand Disease and Healthy Controls

Symptoms	Score 0	1	2	3	Diagnostic Likelihood Ratio
Menorrhagia					
Obligatory carriers	5	4	7	5	4.3
Affected	11	6	9	7	
Controls	101	3	9	8	
Surgical Bleeding					
Obligatory carriers	11	3	6	3	19.1
Affected	26	0	9	7	
Controls	170	2	1	1	
Tooth Extraction Bleeding					
Obligatory carriers	7	5	16	0	13.2
Affected	13	8	24	1	
Controls	171	3	7	0	
Epistaxis					
Obligatory carriers	17	14	11	0	5.1
Affected	38	32	9	3	
Controls	192	20	3	0	
Cutaneous Bleeding					
Obligatory carriers	11	20	9	2	19.1
Affected	25	35	19	2	
Controls	207	8	0	0	
Bleeding from Wounds					
Obligatory carriers	21	17	2	2	10.2
Affected	45	31	3	5	
Controls	205	9	0	1	
Postpartum Bleeding					
Obligatory carriers	7	3	3	1	13.3
Affected	9	6	3	5	
Controls	102	1	2	0	

The bleeding score values for obligatory carriers differed from those of controls for each symptom (all $P < 0.001$) but not from those of affected patients (all $P \geq 0.10$). For each symptom, the number of individuals from each group with the indicated score values is indicated, along with the diagnostic likelihood ratio of the question for differentiating obligatory carriers and affected patients from controls.

[a]Score varies from 0 for no symptom or trivial severity to 3 for severe hemorrhage.

From Rodeghiero F, Castaman G, Tosetto A, et al: The discriminant power of bleeding history for the diagnosis of type 1 von Willebrand disease: An international, multicenter study. J Thromb Haemost 3:2619, 2005.

Table 121–6 Bleeding Symptoms Score Developed by Tosetto et al.[20]

	Score					
Symptom	***–1***	***0***	***1***	***2***	***3***	***4***
Epistaxis	—	No or trivial (<5 min)	>5 or >10 min	Consultation only	Packing or cauterization or antifibrinolytic	Blood transfusion or replacement therapy or desmopressin
Cutaneous	—	No or trivial (<1 cm)	>1 cm and no trauma	Consultation only		
Bleeding from minor wounds	—	No or trivial (<5 min)	>5 or >5 min	Consultation only	Surgical hemostasis	Blood transfusion or replacement therapy or desmopressin
Oral cavity	—	No	Referred at least one	Consultation only	Surgical hemostasis or antifibrinolytic	Blood transfusion or replacement therapy or desmopressin
Gastrointestinal bleeding	—	No	Associated with ulcer, portal hypertension, hemorrhoids, angiodysplasia	Spontaneous	Surgical hemostasis, blood transfusion, replacement therapy, desmopressin, antifibrinolytic	
Tooth extraction	No bleeding in at least two extractions	None done or no bleeding in one extraction	Referred in <25% of all procedures	Referred in >25% of all procedures, no intervention	Resuturing or packing	Blood transfusion or replacement therapy or desmopressin
Surgery	No bleeding in at least two surgeries	None done or no bleeding in one surgery	Referred in <25% of all surgeries	Referred in >25% of all procedures, no intervention	Surgical hemostasis or antifibrinolytic	Blood transfusion or replacement therapy or desmopressin
Menorrhagia	—	No	Consultation only	Antifibrinolytics, pill use	Dilatation and curettage, iron therapy	Blood transfusion or replacement therapy or desmopressin or hysterectomy
Postpartum hemorrhage	No bleeding in at least two deliveries	No deliveries or no bleeding in one delivery	Consultation only	Dilatation and curettage, iron therapy, antifibrinolytics	Blood transfusion or replacement therapy or desmopressin	Hysterectomy
Muscle hematomas	—	Never	Posttrauma, no therapy	Spontaneous, no therapy	Spontaneous or traumatic, requiring desmopressin or replacement therapy	Spontaneous or traumatic, requiring surgical intervention or blood transfusion
Hemarthrosis	—	Never	Posttrauma, no therapy	Spontaneous, no therapy	Spontaneous or traumatic, requiring desmopressin or replacement therapy	Spontaneous or traumatic, requiring surgical intervention or blood transfusion
Central nervous system bleeding	—	Never	—	—	Subdural, any intervention	Intracerebral, any intervention

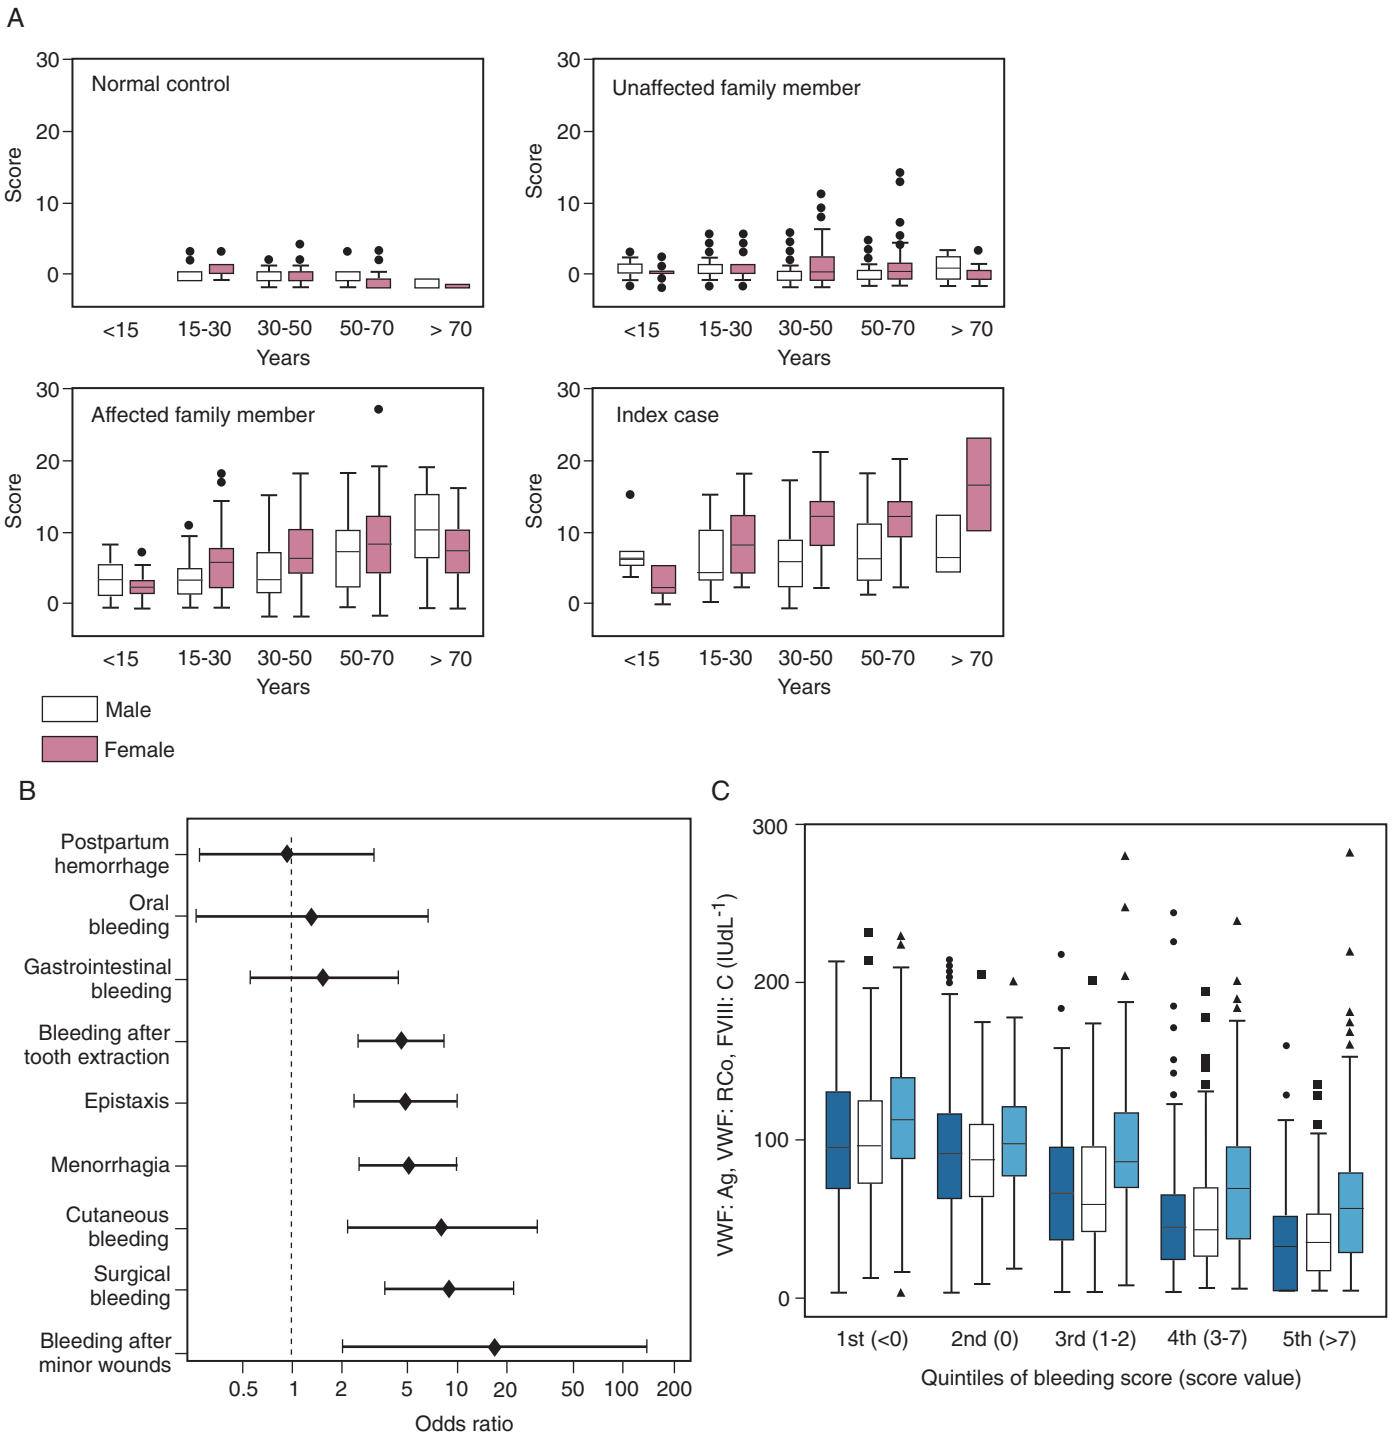

Figure 121–1 Application of a standardized bleeding history assessment questionnaire for diagnosing von Willebrand disease in 195 controls, 295 unaffected family members, 273 affected family members, and 144 index cases.[20] **A,** Bleeding score and age in families with von Willebrand disease and in normal controls. For each category, the boxes represent the 50% of subjects centered around the median. Age is presented on the X-axis. **B,** Association between bleeding symptoms and type 1 von Willebrand disease in the enrolled families in an age-adjusted logistic model. Index cases were excluded from the analysis. A bleeding symptom was considered in the model for a symptom-specific score >1. For each bleeding symptom, the graph reports the logistic estimate and its 95% confidence interval. **C,** Association between bleeding score and levels of von Willebrand factor antigen (VWF:Ag; dark gray boxes), factor VIII coagulant activity (F VIII:C; white boxes), and ristocetin cofactor activity (VWF:RCO, light gray boxes). For each quintile of bleeding score, the boxes span from the 25th to the 75th percentile. Center line represents the median value. *(From Tosetto A, Rodeghiero F, Castaman G, et al: A quantitative analysis of bleeding symptoms in type 1 von Willebrand disease: Results from a multicenter European study (MCMDM-1 VWD). J Thromb Haemost 4:766, 2006.)*[8]

patients referred for evaluation of a bleeding disorder who were found to have no bleeding disorder, and 341 healthy volunteers. Questionnaires were analyzed for both the number and severity of different symptoms. Of note, 70% of the patients with mild von Willebrand disease, 95% of the patients with platelet dysfunction, and 75% of the patients referred for evaluation who were determined to not have a bleeding disorder were women. The questions with the highest univariate positive likelihood ratios (LR+) for distinguishing individuals referred to a hematologist who did, from those who did not, have a bleeding disorder were profuse bleeding with tonsillectomy/adenoidectomy (10.1), muscle bleeding (3.4), joint bleeding (2.5), family member with bleeding disorder (2.4), and profuse bleeding after surgery (2.1). The questions with the lowest negative likelihood ratio (LR–), and thus the best negative predictive values, were profuse bleeding with tooth extraction (0.3) and family member with established bleeding disorder (0.5). The questions with the highest odds ratios (LR+/LR–) by both univariate (shown) and multivariate (not shown) analysis were those about profuse bleeding with tonsillectomy/adenoidectomy (16.2), profuse bleeding with tooth extraction (6.7), and family member with bleeding disorder (5.0). Despite the apparent value of some of these questions, when the overall data were analyzed by receiver operating characteristic curves, the bleeding history was judged to have only minimal discriminatory power for separating referred individuals with, from those without, bleeding disorders. Adding data on the severity of the bleeding symptoms did not improve the test performance meaningfully.

When the bleeding questionnaires of individuals with bleeding disorders were compared to those of healthy controls to simulate the value of the questionnaire as a screening instrument prior to surgery or other invasive procedures, the questions with the highest positive likelihood ratios were those regarding family members with bleeding disorders (34.9), profuse bleeding from small wounds (27.2), profuse bleeding with tonsillectomy/adenoidectomy (16.9), and having a family member with bleeding symptoms (12.9). The questions with the lowest likelihood ratios, and thus the greatest negative predictive values, were those regarding profuse bleeding with tooth extraction (0.2), profuse menstruation (0.3), easy bruising (0.4), and profuse bleeding after surgery (0.4). The questions with the highest odds ratios were those related to family member with a bleeding disorder (97.5), profuse bleeding with small wounds (67.2), and profuse bleeding with tooth extraction (39.4). Receiver operating characteristic curve analysis indicated that the bleeding history had high discriminatory power in separating those with and without a bleeding disorder, either without or with information on the severity of bleeding.

Questions that were weak discriminators in both of the comparisons were those related to profuse bleeding at delivery, hematuria, and hematochezia. The authors noted the differences between their findings and those of Wahlberg[8] with regard to the discriminating value of questions related to dental and surgical bleeding and the presence of a family member with a bleeding disorder and ascribed them to the possible use of prophylactic interventions and the choice of the control population (nonaffected relatives) in the study by Wahlberg.

The bleeding history questionnaire developed by Sramek et al.[9] subsequently was applied to the analysis of bleeding in 274 carriers of hemophilia and 245 noncarrier family members.[3] Carriers were more likely than noncarriers to have (a) required treatment after tooth extraction (relative risk [RR] 23.2), tonsillectomy/adenoidectomy (RR 9.9), or other surgery (RR 2.3); (b) had prolonged bleeding (>5 minutes) from small wounds (RR 2.2) or with nosebleeds (>10 minutes; RR 4.5); or (c) had prolonged (>3 hours) bleeding after tooth extraction (RR 2.3), tonsillectomy/adenoidectomy (RR 1.8), or surgery (RR 2.6). When the results from all participants were analyzed as a function of clotting factor level (0–40, 41–60, and >60 IU/mL), similar increases in bleeding symptoms were observed in individuals with clotting levels less than 40 IU/mL and those with levels between 40 and 60 IU/mL, relative to individuals with levels greater than 60 IU/mL, demonstrating an increased likelihood of symptoms even in those in the 40 to 60 IU/mL group.

Nosek-Cenkowska et al.[22] administered a bleeding history questionnaire to 251 children and their parents prior to tonsillectomy or adenoidectomy and then excluded the results from the 21 patients who had laboratory or clinical evidence of a bleeding disorder. The remaining group was considered to be normal and compared to a group of 31 patients with platelet disorders or von Willebrand disease. The questions that best discriminated between the normals and the patients were those regarding easy bruising (24% vs 67%), bruising every other week (36% vs 68%), bruises confined to areas of trauma (61% vs 39%), bruises affecting more than one part of the body (5% vs 39%), presence of large bruises (>2 inches) at least several times per year (4% vs 30%), hematoma under a bruise (3% vs 22%), nosebleeds (39% vs 69%), nosebleeds at least once per week (3% vs 23%), prolonged nosebleeds (>20 minutes; 4% vs 47%), and relatives with bleeding disorders (44% vs 68%).

Hemorrhage Assessment Instruments

A number of scales of bleeding severity have been developed to standardize reporting of (a) efficacy of prohemostatic agents, (b) surgical or resuscitative interventions, (c) hemostatic impact of an underlying disease, or (d) toxicity of anticoagulants, antiplatelet agents, or chemotherapeutic agents (reviewed by Koreth et al.,[21] Table 121–7). These scales can be characterized by their intraobserver and interobserver consistency (reliability), correlation with a meaningful outcome (validity), sensitivity, and objectivity. Because bleeding manifestations vary considerably depending on the nature of the defect, the scales may differ in usefulness depending on the hemostatic mechanism affected. In general, scales used to quantify bleeding in bone marrow transplantation and/or cancer therapy use broad categories and subjective criteria. They are used primarily to assess the toxicity of treatments and thus are geared to adverse event reporting rather than the delivery of medical care. Bleeding scales used to assess the severity of bleeding associated with immune thrombocytopenia focus on mucocutaneous hemorrhage because this is the most common bleeding manifestation and thus the most valuable for assessing the effect of new therapies. Similarly, multiple scales have

Table 121–7 Scales Used to Assess Clinical Hemorrhage

Primary Use	Scales
1. Bone marrow transplantation toxicity Cancer chemotherapy toxicity	Nevo et al.[403,404]; Miller et al.[405]; Tornebohm et al.[406]; Gmur et al.[407]; Rebulla et al.[408]; National Cancer Institute [Common Terminology Criteria for Adverse Events (CTCAE) 2.0 and 3.0][409]
2. Immune thrombocytopenia	Buchanan and Holtkamp[410]; Buchanan and Adix[411]; Medeiros and Buchanan[412]; Banchette et al.[413]; Lacey and Penner[414]; Bolton-Maggs and Moon[415]
3. von Willebrand disease	ISTH Provisional Consensus[416]; Hospital for Sick Children[416]; Rodeghiero et al.[19]; Tosetto et al.[20]
4. Hemophilia and other coagulation disorders	Multiple Clinical Trials Scales (reviewed in Koreth et al.[21]); World Federation of Hemophilia[417]; Manco-Johnson et al.[418]
5. Hemorrhagic effects of anticoagulants, antiplatelet agents, and fibrinolytic agents	Multiple Clinical Trials Scales (reviewed in Koreth et al.[21]); Salzman et al.[419]; Landefeld et al.[42–44]; Graafsma et al.[420]

Adapted from Koreth R, Weinert C, Weisdorf DJ, Key NS: Measurement of bleeding severity: A critical review. Transfusion 44:605, 2004.

been used to assess the efficacy of different therapies in hemophilia and other coagulation defects; these have focused on joint hemorrhage because it is the most common manifestation of bleeding in hemophilia. Many other scales have been used to assess the hemorrhagic effects of anticoagulants, antiplatelet agents, and fibrinolytic agents used in treating cardiovascular diseases. The Landefeld bleeding severity index, which combines objective evidence of blood loss (by combining data on blood replacement therapy and decreases in hematocrits) and subjective assessment of severity, has been applied in a large number of studies.[42–44] Few attempts have been made to assess the clinical usefulness of these scales or to compare them to each another. However, in one study of hemorrhage associated with percutaneous coronary intervention, the Global Use of Strategies To Open Occluded Coronary Arteries (GUSTO) scale was found to correlate better with clinical outcome than the laboratory-based Thrombolysis In Myocardial Infarction (TIMI) scale.[45] A scale that captures minor bleeding episodes has also been proposed as being more meaningful for assessing long-term antiplatelet therapy.[46] There has been disagreement about whether hemorrhagic toxicity should be evaluated separately from the efficacy of the cardiovascular intervention or combined with it to establish a single composite endpoint. To date, no validated instruments equate the medical significance of hemorrhagic toxicity with efficacy, and because such assessments are intrinsically subjective, broad agreement by either physicians or patients on how to equate them is unlikely. Thus, at present, it appears best to maintain the separation so that efficacy and toxicity can be judged independently.

Summary

Obtaining the details of the bleeding history requires insight into the mechanisms and manifestations of the different hemorrhagic disorders as well as an appreciation of the patient's perceptions of symptoms. Whenever possible, objective data should be obtained to provide a more comprehensive and credible picture. Although obtaining a complete bleeding history may seem tedious, it is well worth the effort because the patient's previous responses to hemostatic challenges are much better predictors of the patient's likelihood of bleeding excessively than are the patient's routine laboratory values. In fact, in one study, routine screening assays of coagulation and platelets failed to detect any clinically significant abnormalities in more than 100 preoperative patients with normal bleeding histories.[47] Although the clinical value of routine laboratory tests for screening for coagulation abnormalities remains uncertain despite many studies of the topic, there is strong consensus on the central role of the bleeding history in evaluating hemostatic risk.[48]

DIFFERENTIAL DIAGNOSIS OF HEMORRHAGIC DERMATOLOGIC LESIONS

Skin hemorrhage is defined as the indiscriminate extravasation of blood cells out of the vasculature and into the skin, subcutaneous tissue, or both. The amount of blood leaking from the vessel determines the size of the lesion, with minute amounts producing pinpoint red lesions less than 2 mm in size (petechiae), and larger amounts producing purpuric lesions (2 mm to 1 cm) or frank ecchymoses (>1 cm).[23] Despite these precise definitions, conventional usage often groups purpuric lesions and ecchymoses under the term *purpura,* and the general group of disorders that produce such lesions is often referred to as *the purpuras.* All these lesions can be readily differentiated from simple erythema and telangiectasias, in which the blood remains confined within the vasculature, because these latter lesions will blanch if direct pressure is applied to them. This can be easily demonstrated using a glass slide. True purpura may demonstrate partial blanching with direct pressure, but a nonblanchable component will remain. The color of the lesion depends on the size and location of the hemorrhage as well as the time since the extravasation occurred. Initially, superficial lesions are bright red or deep red, and deeper lesions have more of a purple appearance. With time, the lesions evolve into deep purple, brown, orange, or blue-green discolorations.

The general mechanisms by which extravasation of blood from the vasculature can occur is depicted schematically in Fig. 121–2. The integrity of the blood vessel depends on (a) the competence of the hemostatic system in combating the basal level of ongoing vas-

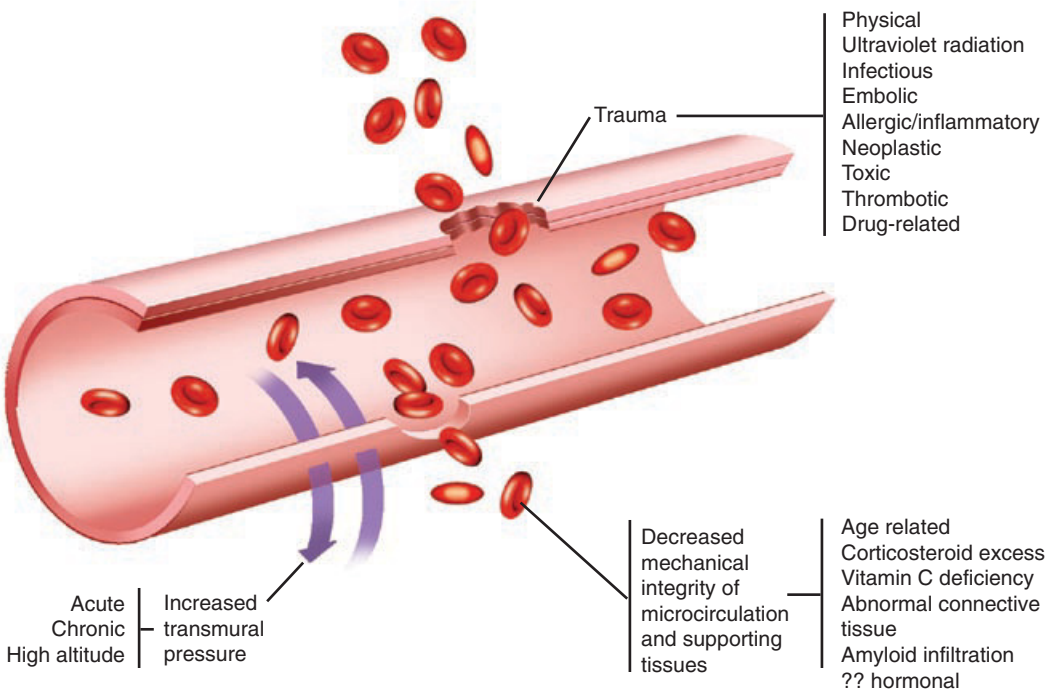

Figure 121–2 Mechanisms of nonpalpable purpura.

Table 121–8 Differential Diagnosis of Purpura

True Purpura

I. Hemostatic Defects

A. Platelet abnormalities
  1. Quantitative
  2. Qualitative

B. Coagulation abnormalities

II. Nonhemostatic Defects—Vascular Purpura

A. Nonpalpable purpura
  1. Increased transmural pressure gradient
    a. Acute (Valsalva, coughing, vomiting, high altitude, weight lifting)
    b. Chronic—Venous stasis
  2. Decreased mechanical integrity of microcirculation and supporting tissues
    a. Age related (infancy and actinic purpura)
    b. Glucocorticoid excess—Cushing syndrome and glucocorticoid therapy
    c. Vitamin C deficiency (scurvy)
    d. Abnormal connective tissue—Ehlers-Danlos syndrome
    e. Amyloid infiltration of blood vessels[a]
    f. Colloid milium
    g. ?Hormonal—Female easy bruising syndrome (purpura simplex)
    h. Lorenzo's oil
    i. MELAS syndrome
  3. Trauma to blood vessels
    a. Physical
      1) Injuries
      2) Child abuse
      3) Factitial purpura
    b. Ultraviolet Radiation
      1) Purpuric sunburn
      2) Solar purpura
    c. Infectious
      1) Bacterial[a]
      2) Rickettsial
      3) Fungal[a]
      4) Viral
      5) Parasitic
    d. Embolic
      1) Infectious organisms[a]
      2) Atheroemboli (cholesterol crystal emboli)
      3) Fat emboli
    e. Allergic and/or inflammatory
      1) Serum sickness
      2) Pigmented purpuric eruptions
      3) Pyoderma gangrenosum
      4) Contact dermatitis
      5) Familial Mediterranean fever
    f. Neoplastic[a]
    g. Metabolic
      1) Erythropoietic porphyria
      2) Calciphylaxis
    h. Immunoglobulin related (hyperglobulinemic purpura of Waldenström and light-chain vasculitis)
    i. Drug related[a]
    j. Thrombotic
      1) Disseminated intravascular coagulation
      2) Warfarin (coumarin)-induced skin necrosis
      3) Protein C or protein S deficiency, factor V Leiden, prothrombin G20201A
      4) Purpura fulminans
      5) Paroxysmal nocturnal hemoglobinuria[a]
      6) Antiphospholipid antibody syndrome
      7) Hemangioma with thrombocytopenia and consumptive coagulopathy (Kasabach-Merritt syndrome)
  4. Unknown cause—Psychogenic purpura

B. Palpable purpura
  1. Cutaneous vasculitis
    a. Systemic vasculitides[b]
    b. Paraneoplastic vasculitis
    c. Henoch-Schönlein purpura
    d. Acute hemorrhagic edema of infancy
    e. Livedoid vasculitis
    f. Idiopathic
    g. Urticarial
  2. Cryoglobulinemia
  3. Cryofibrinogenemia
  4. Primary cutaneous diseases

Nonpurpuric Disorders Simulating Purpura

I. Disorders with telangiectasias

A. Cherry angiomas
B. Hereditary hemorrhagic telangiectasia
C. Chronic actinic telangiectasia
D. Scleroderma
E. CREST syndrome
F. Ataxia-telangiectasia
G. Chronic liver disease
H. Pregnancy-related telangiectasia

II. Kaposi sarcoma and other vascular sarcomas[c]

III. Fabry disease

IV. Neonatal extramedullary hematopoiesis

V. Angioma serpiginosum

[a]May also have a palpable purpuric component.
[b]May also have a nonpalpable purpuric component.
[c]May also have a purpuric component, either nonpalpable or palpable.
CREST, calcinosis cutis, Raynaud syndrome, esophageal motility disorder, sclerodactyly, telangiectasia; MELAS, mitochondrial myopathy, encephalopathy, lactic acidosis, stroke-like episodes.

cular trauma, (b) the integrity of the blood vessel itself and its surrounding tissues, and (c) the transmural pressure gradient tending to drive blood out of the vessel. Even if all these systems are functioning normally, however, serious trauma of diverse etiologies may be sufficient to cause hemorrhagic extravasation.

A classification of disorders producing skin hemorrhage is given in Table 121–8.[23,49] It is organized primarily according to etiology, but a division is made between lesions that are palpable and those that are not palpable because palpability can be readily determined at the bedside and therefore has important practical significance in developing a differential diagnosis. Although the specific mechanism(s) producing palpability is poorly understood, one hypothesis is that a lesion becomes palpable when a generalized increase in vascular permeability secondary to an inflammatory process results in marked extravasation of plasma proteins with the development of extravascular coagulation leading to fibrin deposition. Support for such a mechanism comes from studies showing that the palpable induration accompanying delayed hypersensitivity reactions can be diminished by administration of oral anticoagulants.[50] Alternatively, palpability may be secondary to extensive cellular infiltration, as in certain inflammatory or malignant disorders.

Purpuric lesions secondary to hemostatic defects, including thrombocytopenia and abnormal platelet function, were described in the section. Evaluating Individual Bleeding Symphoms.

Figure 121–3 Valsalva petechiae.

Figure 121–4 Stasis purpura (palpable).

Figure 121–5 Actinic purpura.

Nonpalpable Purpura

Increased Transmural Pressure

Acute

The clinical picture of minute petechiae of the face (especially the eyelids; Fig. 121–3), neck, and upper chest may be seen after prolonged Valsalva maneuvers, crying, coughing, vomiting, childbirth, weight lifting, generalized seizures, vigorous exercise, thoracoabdominal compression, child abuse, bungee jumping, or spirometry.[51–54] A similar syndrome can be found in newborns with umbilical cord strangulation. For the child being evaluated for abuse, the presence of petechiae with or without bruising may indicate an increased likelihood of nonaccidental injury.[55] Lesions on the lower extremities, especially in the elderly, may be due to acute venous stasis from venous insufficiency, compression of the inferior vena cava (as occurs with an aortic aneurysm), or wearing of tight clothing or stockings. Occasionally, such dependent purpura may be palpable (Fig. 121–4), even in the absence of microscopic inflammation.

Purpura may accompany an increase in transmural pressure due to reduced extravascular pressure rather than increased intravascular pressure. Thus, suction purpura may result from application and/or careless removal of electrocardiographic leads, "cupping" devices used during religious rituals, rubber suction cups on toys, sitting in the bathtub,[56] or gas masks; kissing accompanied by suction also may leave its mark.[57] Cutaneous petechiae have been described in mountain climbers ascending higher than 3,800 m above sea level,[58] and petechiae and hemorrhagic bullae have been observed in the external auditory canals of pilots who fly at high altitudes.[59]

Chronic

As a result of humans assuming an upright posture, venous pressure is greater in the lower than the upper extremities. This increased pressure makes the lower extremities more vulnerable to loss of vascular integrity. Thus, the first signs of petechiae due to hemostatic defects commonly, but not universally, appear at the ankles. Moreover, other common cutaneous disorders, such as drug rashes, contact dermatitis,[60] and sunburn, often progress to become petechial and purpuric over the lower extremities. Chronic venous stasis of the lower extremities, due either to venous valvular incompetence or chronic use of tight-fitting garments, exacerbates this phenomenon and can convert subclinical insults of diverse etiologies into frank purpura. Thus, recurrent episodes of extravasation of red blood cells lead to the development of purpuric and yellow brown macules, the latter due to the persistent presence of hemosiderin.

Decreased Mechanical Integrity of Microcirculation and Supporting Tissues

Age Related (Infancy and Actinic Purpura)

Approximately one fourth of normal infants younger than 1 year have some petechiae,[61] and this may reflect vascular incompetence.

At the other end of the age spectrum, chronic solar damage and decreased collagen, elastin, and ground substance due to advanced age may result in the development of characteristic red to purple purpuric patches on the extensor surfaces of the forearms and hands (actinic purpura; Fig. 121–5). The skin accompanying actinic purpura is particularly thin and lacks elasticity, making it especially susceptible to tears induced by shearing forces.[62] Owing to the decreased healing capacity that accompanies aging, the purpuric changes may take months to resolve. Interestingly, the syndromes of premature aging, such as progeria, Werner syndrome, and acrogeria, all may give rise to acral purpuric changes identical to those of purpura in the elderly.[58]

Glucocorticoid Excess (Cushing Syndrome and Glucocorticoid Therapy)

The patches of purpura in Cushing syndrome are classically described as appearing on the extensor surfaces of the forearms, but they may appear on both the flexor and extensor aspects of both the upper and lower extremities. As with actinic purpura, the lesions have a very characteristic bright red appearance, and the skin is fragile.[23] Shearing stress is often the immediate cause of the purpura, and the patches may last for weeks to months. Use of potent fluorinated topical glucocorticosteroids, either with or without occlusive dressings, may result in cutaneous atrophy and purpura.[63] Glucocorticosteroids administered parenterally, orally, or by inhalation may produce similar changes. Microscopy reveals loss of dermal connective tissue with thinning of the epidermis.

Vitamin C Deficiency (Scurvy)

Follicular keratosis, petechiae, and perifollicular purpura with entrapped corkscrew hairs of the arms, legs, back, and buttocks are the characteristic findings of vitamin C deficiency (Fig. 121–6). After 2 to 3 months of inadequate vitamin C intake, swelling, pain, and purpura develop, followed by larger ecchymoses and hemorrhagic

Figure 121–6 Scurvy.

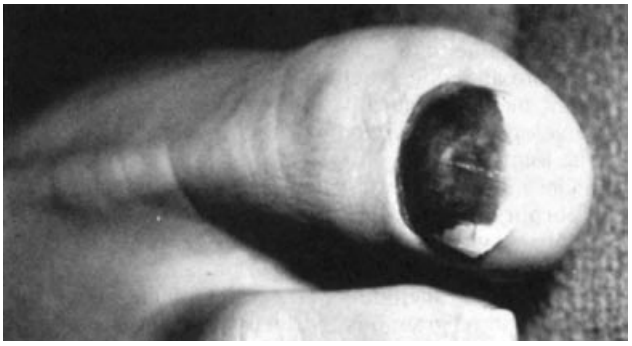

Figure 121–7 "Tennis toe": subungual hemorrhage.

ulcers on the legs and mucous membranes.[64,65] Hemorrhagic gingivitis or stomatitis may occur. Conjunctivitis, myalgias, arthralgias, and bone pain result from localized hemorrhage. Subsequently, woody edema and hyperpigmentation of the legs remain as sequelae of chronic ascorbate deficiency.[66] Scurvy has been reported in the setting of liver transplantation.[67] The prevalence of vitamin C deficiency in hospitalized patients may be as high as 16%.[68]

Abnormal Connective Tissue—Ehlers-Danlos Syndrome

Easy bruising is one of the most prominent features of Ehlers-Danlos syndrome type IV, which is most commonly caused by a defect in the gene for type III collagen. However, bruising also may be seen in the other types. Milder forms of Ehlers-Danlos syndrome that do not meet the diagnostic criteria for the more classic forms have been described, and mild to moderate bruising may be seen in these patients.[69] When evaluating patients for this heterogenous group of connective tissue disorders, it is important to assess the elasticity of the skin, the extensibility of the joints, and the presence of associated abnormalities such as high-arched palate and pectus excavatum. Patients with type IV Ehlers-Danlos syndrome may manifest only joint hyperextensibility of the fingers and modest skin elasticity despite having ecchymoses and easy bruising; However, the skin is thin and translucent.[41] Arterial rupture and intestinal perforations are serious complications of this form of Ehlers-Danlos syndrome.[41] Patients with Marfan or Noonan syndrome also may have mild bleeding tendencies and increased capillary fragility.

Amyloid Infiltration of Blood Vessels

Mucocutaneous manifestations may be prominent in primary systemic amyloidosis associated with plasma cell dyscrasias.[70] Histologic examination demonstrates extensive infiltration of blood vessel walls with amyloid, resulting in increased vascular fragility. As a result, minimal trauma can produce hemorrhagic lesions ("pinch purpura"), and petechiae occur readily with increased transmural pressure (e.g., after Valsalva maneuver or proctoscopy), especially when the amyloid infiltrates the blood vessels in the eyelids and face (postproctoscopic periorbital purpura). A variety of cutaneous lesions can occur in patients with primary systemic amyloidosis, including brown- to tan-colored translucent papules, plaques, nodules, and bullae; these all may become hemorrhagic, either spontaneously or after minimal trauma. An enlarged scalloped tongue with peripheral indentations secondary to pressure from the adjacent teeth is frequently seen. Alopecia and nail changes are less common skin manifestations.

Colloid Milium

Colloid milium is a cutaneous disorder seen in patients with chronic ultraviolet light exposure. It is characterized clinically by translucent yellow papules and plaques and histologically by deposition of upper dermal amorphous eosinophilic material (similar in appearance to amyloid). Lesions of colloid milium may become purpuric after minimal trauma.[71]

?Hormonal—Female Easy Bruising Syndrome (Purpura Simplex)

The female predominance and the frequent association with phases of the menstrual cycle suggest that the female easy bruising syndrome (purpura simplex) is due to hormonal effects on the blood vessel and/or its surrounding tissues.[23] Antibody-mediated platelet dysfunction has been implicated in some patients.[25] Concomitant use of aspirin or other nonsteroidal antiinflammatory drugs may inhibit platelet function and contribute to the severity of the symptoms. Patients complain of frequent purpuric and ecchymotic lesions with minimal trauma. Patients with this entity usually are not at increased risk for hemorrhage from more severe hemostatic challenges such as surgery, but other potentially more serious hemostatic defects must be excluded.

Lorenzo's Oil

Purpura from a defect in vessel wall function has been seen in a patient receiving Lorenzo's oil (glycerol trioleate and glycerol trierucate).[72]

MELAS Syndrome

MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, stroke-like episodes) syndrome encompasses a group of disorders characterized by one or more enzymatic defects of aerobic metabolism that lead to morphologic changes of mitochondria in multiple organs. Recurrent crops of purpuric macules of the palms and soles have been described in association with MELAS syndrome.[73]

Trauma to Blood Vessels

Physical

Any form of injury, if severe enough, can damage blood vessels sufficiently to cause skin hemorrhage. Thus, it is important to know in detail the extent of the injury before deciding whether the skin hemorrhage is consistent with the magnitude of the trauma.[51] Traumatic lesions usually have well-defined margins. Depending on the etiology (e.g., occupational, accidental, recreational), the pattern may be annular or circumferential (e.g., paintball[74] or baseball injury), linear or loop shaped (e.g., child beating), or subungual (e.g., running shoe injury; Fig. 121–7). The lesions associated with child abuse often include both cutaneous purpura and petechiae of the genitalia, as well as the bulbar and palpebral conjunctivae, the latter reflecting strangulation, smothering, or both.[75,76] Patients with factitial, or self-

Figure 121–8 Ecthyma gangrenosum.

inflicted, purpura usually have medium- to large-sized lesions on the lower extremities, but other sites may be involved as well. They characteristically express indifference to the bruises. Crush injury may result in petechiae of the face, neck, and chest, sparing the skin of the central chest ("brassier sign").[77] Treatment of cutaneous vascular anomalies with a 585-nm pulsed dye laser can result in purpura.[78,79]

Ultraviolet Radiation

Acute severe sunburn can have a petechial component if the damage is sufficiently extensive. Petechial eruptions on the legs and trunk have been described after just brief exposures to natural sunlight (solar purpura).[80,81] Neonates with hyperbilirubinemia after transfusion may develop transient purpuric patches at sites of maximal exposure to blue light phototherapy, perhaps related to an interaction between the light and circulating porphyrins.[82]

Infectious

Bacterial, viral, fungal, rickettsial, protozoal, and parasitic infections all may produce purpura as a primary clinical manifestation.[83,84] In one study of children with fever and petechiae, approximately 10% had bacterial sepsis and approximately 50% had viral upper respiratory tract infections.[85] The pathogenesis of infectious purpura often is complex and may include direct vascular invasion by the organism, diffuse intravascular coagulation, immune complex vasculitis, Schwartzman-like phenomenon, septic emboli, and/or direct toxic effects on the vasculature. Although characteristic patterns of purpura have been described for the different agents, overlap between the patterns is common.

Gram-negative sepsis with *Pseudomonas* species, *Klebsiella* species, or *Escherichia coli* produces characteristic lesions of ecthyma gangrenosum, which begin as plaque-like areas of edema and erythema with subsequent nodule formation surmounted by irregular purpura (Fig. 121–8). The central area of purpura often is bullous and surrounded by concentric areas of normal skin and a thin band of erythema. Erosions and ulceration may occur. Lesions may be single or multiple, and the palms and soles occasionally may be involved. The differential diagnosis of ecthyma gangrenosum includes fungal sepsis due to *Candida* species, drug eruptions, cryoglobulinemia, Sweet syndrome, pyoderma gangrenosum, necrotizing vasculitis, polyarteritis nodosa, hyperviscosity syndrome, and leukemic infiltrates.[86]

Meningococcemia initially produces erythematous papules, but these soon evolve into stellate purple to slate-gray purpuric lesions (Fig. 121–9). Approximately 5% to 10% of children with fever and petechiae have meningococcemia.[85,87] One useful differentiating finding is that children with purpura confined to the distribution of the superior vena cava are much less likely to have meningococcemia than are those with more generalized purpura.[88] The combination of purulent meningitis and petechiae strongly suggests that *Neisseria meningitides* is the etiologic agent.[89] Acrocyanosis and symmetric peripheral gangrene may ensue and are thought to be due to disseminated intravascular coagulation (DIC). The purpura of meningococcemia may be due to direct vascular invasion by the organism or an endotoxin-induced Shwartzman reaction. Microvascular thrombosis is a common pathologic finding, and the importance of thrombosis in the pathophysiology is reinforced by the observation that, in small clinical series, administration of antithrombin III concentrates,[90] recombinant tissue plasminogen activator,[91] or protein C[92,93] improved outcome. In chronic intermittent meningococcemia, an immune complex dermatitis may develop, characterized by hemorrhagic papulovesicles over the joints.

Figure 121–9 Meningococcemia.

Figure 121–10 Acute bacterial endocarditis.

The classic rash of scarlet fever characteristically features linear purpuric lines in the skin folds (Pastia lines). Streptococcal pharyngitis has been reported to produce perioral, neck, and truncal petechiae in a small percentage of patients.

Bacterial sepsis, including acute and subacute bacterial endocarditis due to gram-positive or gram-negative organisms, may cause purpuric macules, papules, hemorrhagic bullae, erosions, and/or ulcers (Fig. 121–10). Some patients with endocarditis have antineutrophil cytoplasmic antibodies (ANCA), one of the manifestations of vasculitis, thus blurring the distinction between primary vasculitis and sepsis.[94]

Widespread ecchymoses and ischemic infarction of the skin are characteristic findings in purpura fulminans, which most commonly is associated with streptococcal, staphylococcal, pneumococcal, and meningococcal bacteremia but also may be caused by other bacteria,

Figure 121–11 Rocky Mountain spotted fever.

Figure 121–12 Schamberg pigmented purpuric eruption.

viruses, and fungi. The first manifestations of pneumococcal sepsis in asplenic patients may be facial petechiae and purpura, accompanied by acral cyanosis or livedo reticularis.[95] Whipple disease caused by *Tropheryma whipplei* presents rarely with nonthrombocytopenic, nonpalpable purpura.[96]

Splinter hemorrhages of the nails occur in subacute bacterial endocarditis, but they also can be seen in normal individuals following trauma or in patients with trichinosis, peptic ulceration, hypertension, malignancies, severe rheumatoid arthritis, and a number of dermatologic conditions. Thus, the specificity of splinter hemorrhages as a sign of endocarditis is limited.[97,98]

Rickettsial infections, including Rocky Mountain spotted fever (Fig. 121–11) and epidemic typhus, typically produce an array of cutaneous changes ranging from urticarial macules to petechiae, ecchymoses, and areas of hemorrhagic necrosis. Although the characteristic lesion of Lyme borreliosis is a nonpurpuric annular expanding plaque (erythema migrans), the central aspect of this lesion may contain a purpuric macule, papule, or hemorrhagic bulla.

Patients with either disseminated fungal infections (e.g., cryptococcosis, zygomycosis, candidemia, alternariosis, histoplasmosis, aspergillosis)[99,100] or locally invasive fungal diseases (e.g., mucormycosis) may have necrosis, purpura, and/or petechiae early in the course of the illness.[101] Viral infections may have primary purpuric eruptions as their presenting manifestations. Human parvovirus B19 infection has been described as causing a petechial or confluent purpuric rash on the buttocks, axilla, and/or chest,[102] a generalized petechial and purpuric eruption,[103,104] or petechiae limited to the genital area[105] or perioral region and chin (acropetechial syndrome).[106] Palatal petechiae may accompany the exanthem.[107]

One characteristic pattern of infectious purpura is papular purpuric gloves and socks syndrome. This disorder of adolescents and young adults is characterized by well-demarcated symmetric pruritic or painful acral edema and erythema, confluent petechial/purpuric papules and plaques of the hands and feet, oral erythema and erosions, swelling of the lips and tongue, and angular or erosive cheilitis. The inner thighs, inguinal region, buttocks, elbows, and knees may be involved. Systemic manifestations include fever, fatigue, myalgias, anorexia, lymphadenopathy, and arthralgias. The disorder is seen most commonly in association with infections caused by parvovirus B19 but also may be seen with measles virus,[108] cytomegalovirus, Coxsackie B6, rubella, human herpes virus 6, or human herpes virus 7.[109–113]

Patients with virus-associated hemophagocytic syndrome may present with petechiae and purpura.[114] Hanta virus-associated hemorrhagic fever with renal syndrome is transmitted to humans by wild rodents. Signs include fever, acute renal failure, headache, vomiting, and prostration associated with mucocutaneous petechiae, ecchymoses, facial flushing, periorbital edema, and conjunctival and palatal petechiae.[115]

Purpura may be the initial manifestation of parasitic infections, especially in the immunocompromised host. Migration of filariform larvae of *Strongyloides stercoralis* typically produces rapidly progressive abdominal thumbprint linear and reticulated purpura on a background of petechiae; the periumbilical region usually is most severely affected.[116–118] The disorder frequently is fatal. Disseminated *Pneumocystis jiroveci* infections in patients with AIDS may demonstrate purpuric papules and nodules that resemble the lesions of Kaposi sarcoma (see Kaposi Sarcoma and Other Vascular Sarcomas).[119]

Embolic

Atheroemboli with prominent cholesterol crystals, usually originating from atherosclerotic lesions in the aorta, produce a constellation of cutaneous findings, including acral petechiae and purpura, livedo reticularis, nodules, unilateral peripheral ulcers, and bilateral cyanosis and gangrene.[120] Distal pulses are present, and occasionally the emboli are seen in the retinal circulation as refractile interruptions in the column of arterial blood. The syndrome is seen most frequently in older men on anticoagulation or after vascular repair procedures. A high predilection for the pancreas makes elevated serum amylase levels a common accompanying laboratory finding.

Fat embolism may occur 2 to 3 days after severe external trauma or following liposuction. Initial findings include petechiae of the skin folds of the neck and axillae, upper extremities, chest, and/or conjunctivae. The full syndrome consists of hyperthermia, respiratory distress, retinal fat emboli, neurologic symptoms, and pulmonary infiltrates.[121] Emboli from left atrial myxomas may cause acral purpura; necrosis, livedo reticularis, or red papules; splinter hemorrhages; palpable purpura; claudication; peripheral cyanosis; leg ulcers; and/or Raynaud phenomenon.[122] Septic emboli from pseudoaneurysms following percutaneous transluminal coronary angioplasty due to *Staphylococcus aureus* have produced a syndrome of palpable purpura, petechiae, and livedo reticularis.[123]

Allergic and/or Inflammatory

In serum sickness, morbilliform or urticarial eruptions are the most common manifestations. Linear or serpiginous bands of erythema along the sides of the hands and feet may be seen at the margins of the palmar or plantar surfaces.[102] In patients who are thrombocytopenic, purpura usually appears within these linear bands. The eruption often heralds onset of the syndrome. Immunologic evaluation of biopsy material often demonstrates immunoglobulin and complement deposits.

The pigmented purpuric eruptions,[119,124–127] including Schamberg disease, Majocchi disease, and others, are a poorly understood group of disorders characterized by petechiae and purpura on a background of light to dark brown or orange hyperpigmentation (Figs. 121–12 to 121–14). Telangiectasias may or may not be present. Scaling, lichenification, and atrophy are seen occasionally. These eruptions characteristically involve the lower extremities but also may be seen on the arms or trunk; occasionally they are found on the palms and soles.[128] They are not associated with any systemic manifestations. Systemically administered medications (e.g., hydrochlorothiazide, diltiazem, pseudoephedrine, glipizide, and acetaminophen) have been implicated as the cause in some patients,[129,130] as have chronic dental infections.[131] Histologically, extravasation of red blood cells,

Figure 121–13 Majocchi pigmented purpuric eruption.

Figure 121–14 Lichen aureus.

hemosiderin deposits within macrophages, and a perivascular lymphohistiocytic infiltrate with endothelial cell swelling are seen. The pathogenesis of these disorders is not established, but suggested mechanisms include increased capillary fragility with rupture of capillaries in the papillary dermis, aneurysmal dilation of the microvasculature, and abnormal cellular immune responses to an unknown antigen.[132] Involved skin contains activated helper T cells and keratinocytes that stain positive for antigenic markers associated with receptors for effector immune cells.[133] Cutaneous T-cell lymphoma can produce lesions simulating those found with the pigmented purpuric eruptions.[134] Other disorders that must be included in the differential diagnosis are purpuric clothing dermatitis, sensitivity to food additives, lichen nitidus,[135] and hyperglobulinemic purpura of Waldenström.

Pyoderma gangrenosum is a destructive, necrotizing ulceration of the skin presenting as a nodule, pustule, or hemorrhagic bulla. Lesions occur on the calves, thighs, buttocks, and face. Lesions heal with atrophic and cribriform scars. Pyoderma gangrenosum may occur in association with inflammatory bowel disease, rheumatoid arthritis, other polyarthritic and vasculitic syndromes, blood dyscrasias, leukemia, lymphoma, and multiple myeloma. A superficial hemorrhagic bullous form occurs with acute leukemia or other myeloproliferative disorders.

Allergic or irritant contact dermatitis to clothing, rubber, woolen garments, elastic, benzoyl peroxide, dyes, balsam of Peru,[136] eutectic mixture of local anesthetics (EMLA),[137] or detergent whiteners may result in purpuric eruptions that simulate the pigmented purpuric eruptions.[138]

Familial Mediterranean fever is a recessively inherited autoinflammatory disease associated with mutations in the MEFV gene, which codes for the protein pyrin.[139] Petechial or palpable purpuric lesions on the face, trunk, and extremities have been described in a minority of children with familial Mediterranean fever; the lesions usually resolve spontaneously.[140] True vasculitis has been frequently observed in patients with familial Mediterranean fever.[141,142] The protracted febrile myalgia syndrome of familial Mediterranean fever consists of fever, severe paralyzing myalgias, abdominal pain, diarrhea, arthritis and arthralgias, and transient palpable purpuric eruptions mimicking Henoch-Schönlein purpura.[143,144]

Figure 121–15 Letterer-Siwe disease (Langerhans cell histiocytosis).

Figure 121–16 Histiocytosis X.

Intraabdominal inflammatory diseases such as acute pancreatitis, ruptured ectopic pregnancy, and perforated duodenal ulcer may result in periumbilical purpura (Cullen sign). Similarly, purpura of the flanks (Grey Turner sign) may be an indicator of retroperitoneal hemorrhage. In Langerhans cell histiocytosis, purpuric papules are observed in the seborrheic areas of the scalp, flexures, and groin in children and may be generalized in adults.[145,146]

Neoplastic

Infiltration of the skin in the Langerhans cell histiocytosis group of disorders, including Letterer-Siwe disease and histiocytosis X, can result in the development of a petechial and purpuric papular and crusted dermatitis of the seborrheic areas of the scalp, flexures, and groin (Figs. 121–15 and 121–16). This disorder most commonly affects children but has been reported in adults as a generalized dermatitis.[145,146] Cutaneous T-cell lymphoma may produce cutaneous lesions similar to those seen in the pigmented purpuric eruptions.[147] Similarly, skin infiltrations in patients with leukemias, lymphomas, and plasma cell disorders can produce red to purple papules that simulate purpura.[148] T-cell prolymphocytic leukemia characteristically demonstrates facial edema, purpura, and lesional symmetry.[149] Adult T-cell leukemia may demonstrate purpura at sites of the malignant infiltrate.[150] Patients with hemophagocytic lymphohistiocytosis, a disorder of cytokine dysfunction and uncontrolled activation of T lymphocytes and histiocytes, demonstrate facial erythema and edema, purpura, and morbilliform eruptions.[151]

Metabolic

Patients with erythropoietic protoporphyria may develop purpuric lesions of the dorsum of the hands in areas of edema and erythema after ultraviolet light exposure. Damage to endothelial cells has been postulated as the mechanism of extravasation of red blood cells.[152]

Calciphylaxis is a syndrome consisting of vascular and subcutaneous calcification in patients with secondary hyperparathyroidism due to end-stage renal failure.[153] Livedoid hemorrhagic necrosis may be observed in these patients. Subcutaneous and vascular calcifications

Figure 121–17 Waldenström hyperglobulinemic purpura.

Figure 121–18 Acral cyanosis in disseminated intravascular coagulation.

may follow calcium gluconate infusions or may accompany chronic hypercalcemia. They may result in cutaneous necrosis and hemorrhage, typically in a speckled or vascular pattern.

Relapsing showers of petechiae on the trunk and extremities are observed in infants with ethylmalonic aciduria, a metabolic disorder associated with acral cyanosis, chronic diarrhea, and progressive central nervous system dysfunction.[154,155]

Patients with primary hyperoxalosis (deficiency of hepatic alanine-glyoxylate transaminase) may develop a syndrome of necrotizing livedo reticularis, renal failure, and cardiomyopathy.[156]

Immunoglobulin-related (Hyperglobulinemic Purpura of Waldenström and Light Chain Vasculopathy)

Macular or slightly raised discrete or confluent purpuric lesions with hemosiderin staining are the classic cutaneous findings of benign hyperglobulinemic purpura of Waldenström (Fig. 121–17), a syndrome that occurs most often on the legs of women aged 20 to 40 years.[126,157] Palpable purpura is rare. Precipitating factors include increased hydrostatic pressure, hyperviscosity, and low temperatures.[158,159] The polyclonal increase in globulins (mostly IgG1) can be associated with Sjögren syndrome,[160] systemic lupus erythematosus, polymyositis, rheumatoid arthritis, myeloma, thymoma, sarcoid, or multiple sclerosis. Because patients may have recurrent crops of purpuric lesions, pigmented purpuric eruptions must be excluded. Histologically, acute inflammatory cells, red blood cells, and arteriolar necrosis predominate. Elevated serum levels of IgG, IgA, and IgM may be observed.[161] Circulating immunoglobulin-containing complexes may be present.[162] Many patients have antibodies to Ro/SSA,[163] and children born to women with hyperglobulinemic purpura of Waldenström have been reported to develop congenital heart block.[164]

A vasculopathy due to deposition of λ light-chain crystals can produce nonpalpable purpura, hemorrhagic vesicles, ischemic necrosis of the extremities, and rapidly progressive renal failure.[165] Intravascular λ light chains can be observed on direct immunofluorescence of skin, and monoclonal λ light chains are present in the serum.

Drug Related

Petechial and purpuric reactions can be observed after administration of a variety of drugs, including aspirin, alclofenac, allopurinol, atropine, belladonna, bismuth, carbamazepine, carbimazole, carbromal, chloral hydrate, chlordiazepoxide, cimetidine, desipramine, disopyramide, doxepin, fenbufen, gefitinib (epidermal growth factor receptor inhibitor),[166] gold salts, indomethacin, iodides, isoniazid, meclofenamate sodium, mefenamic acid, menthol, mercury, morphine, naproxen, nitrofurantoin, penicillamine, penicillin, phenacetin, phenytoin, piperazine, piroxicam, pyrazolone derivatives, quinine, quinidine, sulfonamides, sulindac, thiouracils, and tolmetin.[167] Topical application of EMLA cream has been reported to result in purpura at the site of application.[168] The mechanism for at least some of these reactions is presumed to be allergic hypersensitivity.

Thrombotic

Disseminated Intravascular Coagulation. DIC may result from a variety of different insults, many of which have the common denominator of producing hypotension (see Chapter 132). The etiologies of DIC include sepsis, severe trauma, malignancy, obstetric conditions, vascular malformations, toxins, immune-mediated disorders, and shock, cardiac arrest, and heat stroke.[169] Because endothelial cells are active metabolically, hypotension can produce widespread ischemia and endothelial cell damage. The damage can expose subendothelial surfaces, which in turn can initiate an uncontrolled thrombotic response that ultimately selectively depletes coagulation factors and platelets. Alternative mechanisms for initiating the process involve the effects of endotoxin and other mediators, such as interleukin (IL)-1 and tumor necrosis factor, on endothelial cell and monocyte procoagulant activity. This is achieved, at least in part, by induction of tissue factor expression, increased synthesis of tissue plasminogen activator inhibitor, and decreased production of both thrombomodulin and tissue plasminogen activator. Abnormalities of the protein C anticoagulant pathway also are present.[170] Severe deficiency of von Willebrand factor-cleaving protease (ADAMTS13) has been reported in patients with sepsis-induced DIC and may contribute to the renal failure found in association with DIC.[171]

Given the potential for both thrombotic and hemorrhagic manifestations, the diverse skin manifestations are not surprising. The most common skin findings of DIC are acral cyanosis (Fig. 121–18) and variable petechial, purpuric, and ecchymotic lesions (Fig. 121–19). The competence of the fibrinolytic system to digest deposited fibrin determines the extent of tissue compromise. In the most severe cases, acral hemorrhagic gangrene can occur.[83] The presence of peripheral gangrene may be an important consideration in the often difficult decision to use heparin for treatment of the syndrome. The clinical and laboratory differential diagnosis of DIC includes thrombotic thrombocytopenic purpura, chronic DIC (Trousseau syndrome), fulminant hepatic failure, and the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome.[169]

Warfarin-Induced Skin Necrosis. Skin necrosis affects 0.01% to 0.1% of all patients receiving warfarin (Coumarin) and can appear anytime from day 2 to day 14 (usually days 3–6) of therapy.[172,173] Patients who are deficient in protein C appear to be at high risk because the disorder is thought to be due to a temporary imbalance between the procoagulant and anticoagulant vitamin K factors.[174–177] Warfarin-induced skin necrosis begins suddenly as painful erythematous patches (Fig. 121–20) that become edematous and indurated and rapidly progress to irregularly hemorrhagic and necrotic plaques, nodules, and bullae. Eventually large tumid indurations and infarcts occur with eschar formation and sloughing (Fig. 121–21).[178,179] The syndrome is more common in women than in men. The lesions often develop in the skin overlying fatty areas, such as the buttocks, thighs, and breasts. In men, involvement of the penis has been reported.[172] Lesions may be symmetric and widely distributed; occasionally they

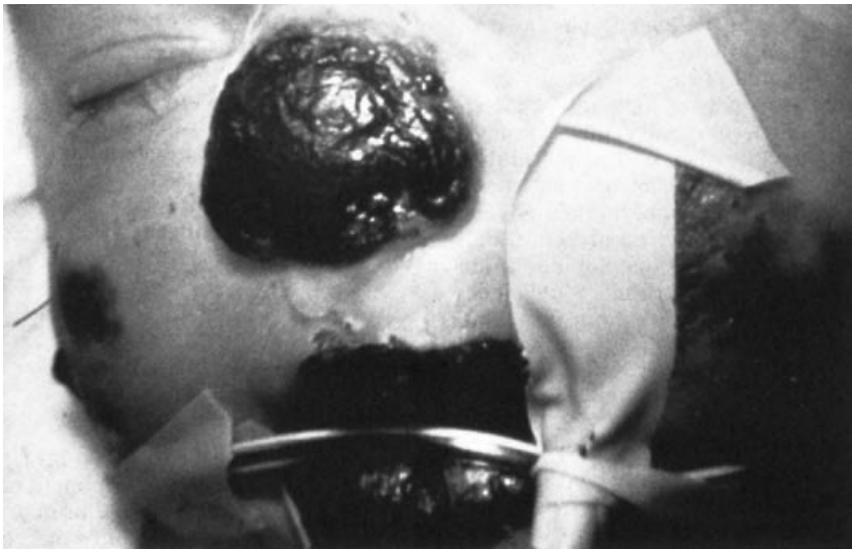

Figure 121–19 Lesion in disseminated intravascular coagulation.

Figure 121–20 Warfarin-induced skin necrosis.

Figure 121–21 Warfarin-induced skin necrosis.

are severe enough to require surgical intervention.[180,181] Histologically, fibrin and platelet thrombi are observed in the dermal and subcutaneous vasculature. In one study, tumor necrosis factor was identified in the lesions, and endothelial cell adhesion molecules were upregulated.[182] The lesions of warfarin-induced skin necrosis can be differentiated from hemorrhagic lesions due to excessive warfarin administration by the presence of the nearly black eschar in the center of the necrotic zone and by histologic examination. Ancillary differentiating points in favor of warfarin-induced skin necrosis include predilection for the female gender, absence of an excessively prolonged prothrombin time, and temporal relationship to the start of warfarin therapy.

Protein C or Protein S Deficiency, Factor V Leiden, Prothrombin G20201A. Homozygous protein C deficiency[183,184] and compound heterozygosity for protein C deficiency[185] have been reported to produce diffuse purpuric and ecchymotic skin lesions suggestive of chronic DIC and purpura fulminans (see Purpura Fulminans).[177,186,187] Widespread venous thrombosis usually accompanies the skin lesions, and central nervous system thrombosis and blindness can occur. The skin lesions and venous thrombosis respond rapidly to therapy with plasma. Long-term therapy may require careful introduction of oral anticoagulants.[188] Replacement therapy with protein C concentrate has been successful.[189,190] Cutaneous necrosis similar to that observed with warfarin-induced skin necrosis has been reported in association with acquired protein C deficiency due to liver disease, malabsorption, antibiotic administration, or autoantibodies to protein C.[191] Infants with homozygous protein S deficiency or resistance to activated protein C due to homozygous factor V Leiden have demonstrated neonatal recurrent purpura fulminans.[192,193] An association between purpura fulminans and combined prothrombotic abnormalities (prothrombin G20201A, factor V Leiden, inherited or acquired protein S deficiency) has been reported in a number of patients, raising the possibility that one or more of these mutations predisposes individuals to infection-related purpura fulminans (see Purpura Fulminans).[194–196] Varicella infection can be accompanied by transient development of autoantibodies to protein S, protein C, or other coagulation proteins, but the development of such antibodies is not predictive of purpura fulminans.[197,198]

Purpura Fulminans. Purpura fulminans is the term given to the most profound cutaneous manifestation of DIC. It is characterized by fever, hypotension, and progression from acral erythema and edema to petechiae, purpura and localized ecchymoses, and ultimately massive, widespread ecchymoses[199,200] and hemorrhagic bullae with progression to infarction of the skin (Fig. 121–22).[201] Widespread arterial and venous thrombosis often accompanies these manifestations. Clinically, purpura fulminans mimics catastrophic antiphospholipid antibody syndrome.[202] Purpura fulminans is associated with a high mortality rate (>50%). It is triggered most commonly by infection with *N. meningitides, Streptococcus pneumoniae,* or *Haemophilus influenzae* in adults or children[203] but may be initiated by any of the infectious agents discussed in Infectious Trauma to Blood Vessels.[83,204] *Staphylococcus aureus*-associated purpura fulminans has been described.[205] The pathogenesis of purpura fulminans is postulated to include a Schwartzman reaction precipitated by endotoxin in gram-negative infections and exotoxin in gram-positive infections mediated by tumor necrosis factor α and IL-1, resulting in consumption of the anticoagulant proteins C and S and antithrombin III.

Patients with sepsis-induced purpura fulminans characteristically have very low levels of protein C.[206] Postvaricella purpura fulminans

Figure 121–22 Purpura fulminans following herpes zoster.

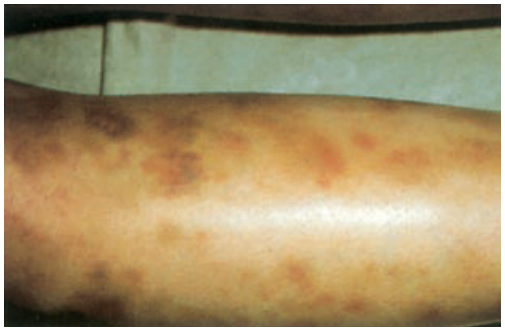

Figure 121–23 Psychogenic purpura.

is associated with acute transient deficiencies of protein C, protein S, or antithrombin III.[207] Anti-protein S antibodies may be transiently present.[208]

Purpura fulminans may occur without antecedent infections.[209] Homozygous protein S, protein C deficiency, or factor V Leiden can produce essentially the same pattern in the neonate,[187] and heterozygous, doubly heterozygous, or acquired abnormalities in these proteins, as well as the prothrombin G20210A mutation, may predispose individuals to develop infection-related purpura fulminans (see Protein C or Protein S Deficiency, Factor V Leiden, Prothrombin G20201A).[194–196] An association between hereditary angioedema, the factor V Leiden mutation, and purpura fulminans has been proposed.[210] Clinically, the syndrome of purpura fulminans most often begins as skin discomfort, followed by erythema, edema, and petechiae. Thereafter painful symmetric purple-gray papules and plaques surrounded by an advancing red border develop. Finally, massive widespread ecchymoses, symmetric, hemorrhagic necrosis, and bulla formation of the arms and legs, abdomen, thighs, and buttocks are seen.[199,200] Head and neck involvement is uncommon, and mucous membranes usually are spared. Ultimately the lesions may progress to gangrene, often with autoamputation of the digits. Associated symptoms and signs include prostration, fever, and edema of the extremities; death is not uncommon. In children, purpura fulminans most commonly follows bacterial infections with the meningococcus, pneumococcus, or group A β-hemolytic streptococcus, or viral infections with varicella or upper respiratory viruses.[211] Treatment with fresh frozen plasma may dramatically improve prognosis.[212] Successful adjunctive treatment of acute infectious purpura fulminans in children and adults with activated protein C has been described.[213,214]

Histopathology reveals hemorrhagic necrosis of the dermis with thromboses of the capillaries and small blood vessels. Fibrinoid necrosis of vessel walls and perivascular granulocytic infiltrates have been described.

The differential diagnosis includes thrombotic thrombocytopenic purpura, allergic or septic vasculitis, postinfectious thrombocytopenia, homozygous protein C or S deficiency, warfarin-induced necrosis, antiphospholipid antibody syndrome, paroxysmal nocturnal hemoglobinuria, and dermal hemorrhage.

Paroxysmal Nocturnal Hemoglobinuria. Occasional patients with paroxysmal nocturnal hemoglobinuria (see Chapter 30) may develop erythematous patches with dusky centers that enlarge to form painful plaques of erythema with central necrosis.[215–217] Hemorrhagic bullae, ulcerations, petechiae, ecchymoses, palpable purpura, and eschar formation may develop. Histologically, intravascular thrombi are seen in the absence of vasculitis.

Antiphospholipid Antibody Syndrome. The antiphospholipid antibody syndrome (see Chapter 131), whose cardinal manifestations are a tendency to thrombosis, thrombocytopenia, and fetal wastage,[218] is often associated with cutaneous manifestations. They are highly variable and may include purpura, ecchymoses, widespread cutaneous necrosis with thrombi within the microvasculature (similar to that seen in purpura fulminans), livedo reticularis, peripheral ischemia and gangrene, leg ulcers, pyoderma gangrenosum-like lesions, dermographism, acrocyanosis, Raynaud phenomenon, urticaria, diffuse alopecia, porcelain white scars, painful skin nodules, subungual splinter hemorrhages, pterygium unguium, and acral red to purple macules.[219,220] A subset of microangiopathic antiphospholipid syndrome may include thrombotic thrombocytopenic purpura, HELLP syndrome, and catastrophic antiphospholipid syndrome (Asherson syndrome).[221,222]

The antibody profile of patients with antiphospholipid antibody syndrome includes IgG and IgM antibodies directed against β_2-glycoprotein I, IgM antibodies to factor VII/activated factor VII, and lupus anticoagulant-type antibodies.[223]

Hemangioma with Thrombocytopenia and Consumptive Coagulopathy (Kasabach-Merritt Syndrome). The Kasabach-Merritt syndrome is defined by the presence of a reddish or purple mass in a neonate or young infant in association with widespread ecchymoses, thrombocytopenia, and a "localized" consumptive coagulopathy.[224] The large mass is a vascular lesion (kaposiform hemangioendothelioma or tufted angioma) in which platelets deposit and coagulation is initiated.[224] Management of such lesions requires stabilization of hemostasis and removal or ablation of the lesion.[224]

Unknown Causes—Psychogenic Purpura

Psychogenic purpura is the term given to a poorly understood disorder characterized by severe recurrent erythema, swelling, pain, and ecchymoses. It affects women much more commonly than men (Fig. 121–23).[26–29,225,226] Patients usually experience pain before or at the time the bruise appears, and the bruising often is so extensive that the patient loses use of the limb during the healing process. In the most severe cases, the patient becomes bedridden. Attempts to identify the etiology have been unsuccessful. Some studies have implicated allergic reactions to blood cells or DNA.[26,28,29,227–230] Localized neurogenic release of fibrinolytic activity in the skin also has been proposed as a mechanism linking the psychological and dermal components of the syndrome.[231] Psychological profiles of patients with this disorder have demonstrated widespread abnormalities,[26,232] raising the possibility of self-inflicted trauma, a view supported by the healing that usually accompanies casting. Whether this is the cause in all cases is far from certain, so it is best to continue to classify the etiology as unknown.

Palpable Purpura

Cutaneous Vasculitides

Patients with lupus erythematosus, dermatomyositis, scleroderma, rheumatoid arthritis,[233] and Sjögren syndrome,[234,235] as well as patients with systemic large and small vessel vasculitis (including urticarial or hypocomplementemic vasculitis,[236] polyarteritis nodosa,[237] micro-

Figure 121–24 Rheumatoid vasculitis.

Figure 121–25 Wegener granulomatosis.

scopic polyangiitis,[238–240] Wegener granulomatosis,[241] Behçet disease, Churg-Strauss angiitis,[242] rheumatoid vasculitis, relapsing polychondritis, or undefined vasculitis[243]) may have an array of vasculitic purpuric lesions, including petechiae, papules (palpable purpura), ecchymoses, hemorrhagic bullae, splinter hemorrhages, and periungual hemorrhages (Figs. 121–24 and 121–25).[162,244–254] In microscopic polyangiitis, purpuric skin lesions are present in 15% to 50% of patients.[240] In Sjögren syndrome, approximately 25% of patients have vasculitis with palpable purpura.[234] Nonpurpuric cutaneous lesions may be present, including ulcers, subcutaneous nodules, livedo reticularis, erythema of the face and hands, erythematous plaques, telangiectasias,[255] oral ulcers, and facial edema.[240] Early in the evolution of vasculitis, immune complexes, histamine, thrombin, IL-1, interferon γ, and substance P activate endothelial cells, resulting in release of plasminogen activators and development of urticarial lesions. Late in the process, activated neutrophils release tumor necrosis factor α, proteases, and oxygen free radicals, leading to perturbations of endothelial cells, decreased fibrinolytic activity, microvascular thrombosis, and tissue hypoxia and ischemia, which become manifest as palpable purpura.[256]

Drugs,[257] alcohol,[258] immunoadsorption therapy,[259] and infections are common causes of small vessel (hypersensitivity) vasculitis.[260] Clinical findings include palpable purpura, joint symptoms, and systemic and cutaneous vasculitis. Bacterial infections with staphylococci, streptococci, *Mycobacterium leprae, Mycobacterium tuberculosis,* and others are often associated with vasculitic lesions.[261,262] Subacute bacterial endocarditis due to *Streptococcus viridans* or other organisms may be associated with circulating immune complexes that produce cutaneous and/or systemic leukocytoclastic vasculitis. These syndromes may be accompanied by the development of cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) in association with antiproteinase-3 antibodies.[94,263] Viruses associated with vasculitis include HIV, hepatitis B, hepatitis C, and parvovirus. Hepatitis B is strongly associated with polyarteritis nodosa.[264] Parvovirus has been reported in association with polyarteritis nodosa, Wegener granulomatosis, and Henoch-Schönlein purpura.[265] The tetrad of necrotizing vasculitis, chronic hepatitis C infection, hypocomplementemia, and cryoglobulinemia is a late manifestation of hepatitis C infection.[266]

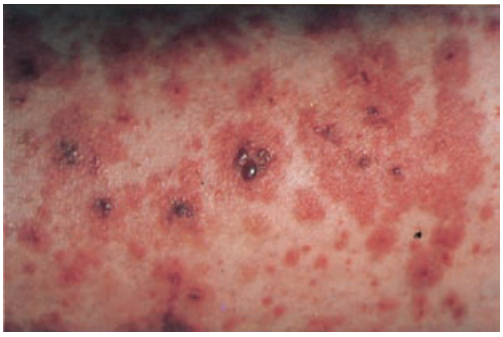

Figure 121–26 Henoch-Schönlein purpura.

α_1-Antitrypsin deficiency has been described in association with manifestations of systemic vasculitis, including cutaneous involvement resembling that observed in microscopic polyarteritis, Wegener granulomatosis, and Henoch-Schönlein purpura.[267,268]

Paraneoplastic vasculitis is a syndrome of petechiae, palpable purpura, urticaria, maculopapular lesions, leg ulcers, and/or erythema multiforme seen in association with a number of different solid tumors, hairy cell leukemia, and other lymphoproliferative or myeloproliferative disorders.[269–274] An increased prevalence of solid tumors and lymphoid malignancies has been reported in patients with ANCA-positive vasculitis.[275] In some cases, the cutaneous lesions precede the diagnosis of the malignancy or signal recurrence of the malignancy.

Henoch-Schönlein purpura is the most common leukocytoclastic vasculitis of young children between the ages of 2 and 10 years,[276–278] with a peak age of onset between 4 and 7 years.[279] Adults also are affected, sometimes in association with an underlying malignancy,[280–282] most commonly leukemia and cancer of the lung and prostate.

Palpable purpuric lesions, abdominal pain, and arthritis of the knees and ankles occur together and are the most common findings. However, other organs, including the testicle,[283] may be involved as well. Acute and chronic renal disease is an important associated finding and is more common in adults.[284,285] Adults may have a more severe clinical syndrome compared with children.[284,286,287] There is an increased incidence in males[288,289] and a seasonal increase during the winter months. Many precipitating factors have been implicated, including infections[290] such as streptococcal pharyngitis,[291] staphylococcal sepsis,[292] meningococcal disease,[293] *Bartonella henselae*,[294,295] *Haemophilus parainfluenza*, parvovirus B19,[296] and hepatitis A. In children with Henoch-Schönlein purpura who develop nephritis, mesangial deposition of nephritis-associated plasmin receptor (a group A streptococcal antigen) has been observed.[297] *Helicobacter pylori* has been implicated in the gastrointestinal manifestations of the disease.[298]

Environmental chemicals and toxins, insect bites, physical trauma, familial Mediterranean fever, and malignancies all have been anecdotally reported to be associated with Henoch-Schönlein purpura.[280,299–301]

Genetic predisposition to, or protection from, development of Henoch-Schönlein purpura has been linked to specific major histocompatibility and complement loci.[302–305] Familial cases of Henoch-Schönlein purpura have been described,[306] and inducible nitric oxide synthase polymorphisms have been associated with susceptibility to Henoch-Schönlein purpura.[307]

Clinical presentations of Henoch-Schönlein purpura include explosive onset over the legs and buttocks of urticarial papules and plaques, with or without purpura (Fig. 121–26), palpable purpura, or hemorrhagic vesicles or bullae.[308–310] Larger stellate, reticulate, and necrotic lesions may occur (Fig. 121–27). Often a striking accentuation of palpable purpura demarcated at, and below, the sock line is seen.[311] Occasionally, ecchymotic lesions resembling child abuse are present, but the lesions of Henoch-Schönlein purpura usually are strikingly symmetric. Such lesions are predominantly seen on the arms, hands, and/or face.

Figure 121–27 Leukocytoclastic vasculitis.

Henoch-Schönlein purpura is thought to be an immune complex disease, with 50% of patients producing IgA rheumatoid factor.[312] IgA-containing immune complexes, including IgA ANCA,[313,314] are detectable in many patients, especially during the early phases of the syndrome.[312,315,316] IgA antiendothelial cell antibodies have been identified in the acute stage of Henoch-Schönlein purpura and may directly activate endothelial cells to produce IL-8.[317] Elevated levels of IgA anticardiolipin antibodies have been reported in children[318] and adults.[319] IgA molecules of some patients with Henoch-Schönlein purpura have been reported to be deficient in sialic acid, an abnormality that may enhance their tendency to aggregate and form macromolecular complexes.[288] The following have all been reported in patients with Henoch-Schönlein purpura: increased levels of von Willebrand factor, an indicator of endothelial cell damage; increased vascular endothelial growth factor; increased intracellular adhesion molecule 1 and vascular cell adhesion molecule 1[320]; attenuated vascular endothelium-dependent relaxation[321]; increased levels of tumor necrosis factor α, leptin, and nitrite[322]; increased plasma levels of matrix metalloproteinase 9[323]; hypocomplementemia[324]; decreased levels of factor XIII[325] (which may be used to support the diagnosis[326]); elevated levels of markers of hypercoagulability[327]; increased numbers of transforming growth factor (TGF)-β–secreting T cells[318]; increased levels of IL-6 associated with thrombocytosis[328]; and increased urinary excretion of tumor necrosis factor α, interleukin 1β, and leukotriene E_4.[329–331] Elevated levels of IL-5 and eosinophilic cationic protein, as well as specific polymorphisms of vascular endothelial growth factor and paired box gene 2 (PAX2), may be associated with development of nephritis.[332–334] Prolonged rash, proteinuria greater than 1g/day, hypertension, and renal impairment at presentation all are unfavorable prognostic indicators.[335–337]

There is no standard therapy for Henoch-Schönlein purpura or the associated IgA renal disease,[338] but there have been numerous conflicting anecdotal reports and nonrandomized retrospective analyses of therapy with systemic glucocorticoids,[339,340] immunosuppressive agents, intravenous γ globulin,[341] and plasmapheresis.[342]

Acute hemorrhagic edema of infancy may mimic Henoch-Schönlein purpura. However, it occurs only in children between the ages of 4 months and 2 years, and its manifestations are exclusively cutaneous. It is characterized by sudden onset of fever, tender iris-like or medallion-like large purpuric cutaneous lesions, and peripheral edema.[343–345] Occasionally reticulate purpura, tender necrotic lesions of the ears, and/or urticaria are observed. The lesions occur on the cheeks, eyelids, ears, extremities, and genitalia and must be differentiated from the cutaneous findings of child abuse, Sweet syndrome, Kawasaki disease, septic emboli, drug eruption, meningococcemia, and hemorrhagic erythema multiforme.

Approximately 10% of adults with leukocytoclastic vasculitis have been reported to demonstrate livedoid superficial plaques, with multifocal areas of hemorrhage or necrosis and reticulate margins connecting adjacent lesions.[346] The blood vessels in these lesions contain deposits of IgA and C3. Smooth-margined purpuric papules with uniform hemorrhage may show IgA but more frequently demonstrate IgG or IgM vascular deposits.

Figure 121–28 Cryoglobulinemia.

Recurrent cutaneous eosinophilic necrotizing vasculitis is characterized by papular, purpuric, and necrotic cutaneous lesions of the legs and feet. Angioedema and arthralgias are common.[347,348] Cutaneous leukocytoclastic vasculitis has been associated with sarcoidosis.[349]

Exercise-induced purpura is a recurrent form of leukocytoclastic vasculitis occurring in marathon runners and long-distance walkers (usually women) in whom erythematous, urticarial, and/or purpuric plaques appear on the lower legs above the malleoli.[350,351] These itching, burning, or painful plaques spare the region compressed by socks. This syndrome also has been called "golfer's vasculitis."[352]

Cryoglobulinemia

Cryoglobulins are cold-precipitable proteins found in plasma or serum. Single component cryoglobulins may be IgG, IgM, or IgA.[353] These cryoproteins may be idiopathic in origin or may occur with Waldenström macroglobulinemia, myeloma, lymphoma, benign paraproteinemias, or visceral leishmaniasis.[322] Mixed cryoglobulins usually are composed of a rheumatoid factor IgM complexed with a monoclonal or polyclonal IgG. Less frequently, IgG or IgA antibodies have anti-IgG activity. Mixed cryoglobulins may be seen as an idiopathic phenomenon or in association with a wide variety of subacute and chronic disorders, most particularly infection with hepatitis C virus (HCV). In fact, it has been reported that 80% to 90% of patients with mixed cryoglobulinemia are positive for anti-HCV antibodies.[354] The immune complexes are commonly composed of HCV and anti-HCV, along with either an IgA or IgM rheumatoid factor.[355,356] T_H1 cytokines have been implicated in the clinical presentation of patients with HCV-induced cryoglobulinemia.[357,358] The clinical triad of purpura, weakness, and arthralgias is characteristic of mixed cryoglobulinemia. Clinical lesions of cryoglobulinemia include the intermittent appearance of acral hemorrhagic necrosis (Fig. 121–28), palpable purpura, livedo reticularis, subungual hemorrhage (Fig. 121–29), urticaria, leg ulcerations, Raynaud phenomenon, and erythema multiforme-like lesions.[162,359–363] Monoclonal cryoglobulins may crystallize and result in livedo reticularis with purpuric necrosis, destructive arthropathy, and malignant hypertension.[364] Rituximab[365] and the combination of prednisolone and the Japanese immunosuppressive reagent mizoribine[366] have been reported to be effective therapy in select groups of patients.

Cryofibrinogenemia

Cryofibrinogenemia indicates the presence in the blood of an abnormal cold-precipitable protein indistinguishable from fibrinogen or fibrin. Essential (primary) cryofibrinogenemia occurs in association

Figure 121–29 Subungual hemorrhage due to cryoglobulins.

Figure 121–30 Hereditary hemorrhagic telangiectasia.

with DIC. Secondary cryofibrinogenemia may occur with neoplastic, thromboembolic, or infectious disorders. Cutaneous manifestations include sensitivity to cold, purpura, hematoma, livedo reticularis, cyanosis, ulcerations, erythema, urticaria, gangrene, acral blisters, and Raynaud phenomenon.[367–369] The lesions are most commonly observed on the acral areas, including the distal extremities, buttocks, nose, and ears.

Primary Cutaneous Diseases

Allergic contact dermatitis to poison ivy, allergic hypersensitivity to drugs, acne vulgaris, insect bites (especially blackfly bites), dermatitis herpetiformis, pityriasis rosea, and other primary cutaneous disorders may present with purpuric papules and vesicles mimicking septic and vasculitic lesions.[370,371]

NONPURPURIC DISORDERS SIMULATING PURPURA

Disorders With Telangiectasias

Cherry Angiomas

Cherry angiomas are the common papular, brightly erythematous lesions seen on the trunk and extremities of middle-aged and older men and women. They are produced by capillary loop aneurysms.[372] The lesions progress with age and may produce easy bruising because they have an increased tendency to bleed with trauma. On occasion, the lesions have a striking black appearance, mimicking malignant melanoma. Pinpoint or smaller cherry angiomas may be present in large numbers and may mimic petechiae. They may increase the risk of developing purpura in patients taking warfarin.

Hereditary Hemorrhagic Telangiectasia

HHT, also known as Osler-Weber-Rendu syndrome, is an autosomal dominant disorder with an estimated frequency of at least 1 : 8000–50,000, manifested by widespread dermal, mucosal, and visceral telangiectasias.[373–376] One form of the disorder, characterized by a high frequency of symptomatic pulmonary arteriovenous malformations and cerebral abscesses, has been identified as being due to abnormalities in the endothelial protein endoglin (ENG; HHT1).[375] This protein, whose gene is on the long arm of chromosome 9, mediates the response of endothelial cells to members of the TGF-β family.[377] A number of mutations involve the production of truncated forms of the receptor, opening up the possibility of a dominant negative mechanism to explain the autosomal dominant inheritance pattern.[378] A second form of the disease has been linked to the activin receptor-like kinase 1 gene (ACVRL1; ALK-1; HHT2) on chromosome 12, which is also a cell surface receptor for the TGF-β superfamily of ligands.[377,379,380] Dominant negative effects of mutations of ACVRL1 have been identified in zebrafish vascular development.[381] The TGF-β activated kinase 1 (TAK1) may be one of the important downstream molecules mediating the effects of TGF-β on vascular development, as mouse embryos deficient in TAK1 develop vascular lesions akin to those observed in HHT.[382] Other forms of the disease have been linked to loci on chromosome 5q (HHT3), chromosome 7p14 (HHT4), and a region of chromosome 3 containing the TGF-βII receptor.[379,383] An association between juvenile polyposis and HHT has been reported in patients with mutations in SMAD4 (MADH4), a protein in the TGF-β activation pathway.

The pathophysiology of the disorder has been studied by computer reconstruction of cutaneous telangiectasias based on serial sections.[372] Focal dilation of postcapillary venules is followed by connections to dilated arterioles, initially through capillaries, and later directly. Perivascular mononuclear cell infiltrates also are observed. The vessels of HHT show a discontinuous endothelium and an incomplete smooth muscle cell layer. The surrounding stroma lacks elastin. Thus, the bleeding tendencies are thought to be due to mechanical fragility of the abnormal vessels.

Clinically, venous lakes and papular, punctate, mat-like, and linear telangiectasias appear on all areas of the skin and mucous membranes, with a predominance of lesions on and under the tongue and on the face, lips (Fig. 121–30), perioral region, nasal mucosa, fingertips, toes, and trunk.[384] Recurrent epistaxis is a nearly universal finding in patients with this disorder; symptoms almost always worsen with age. Thus, the severity of the disorder often can be gauged by the age at which the nosebleeds begin, with the most severely affected patients developing recurrent epistaxis during childhood. Cutaneous changes usually begin at puberty and progress throughout life. Bleeding can occur in virtually every organ, with gastrointestinal, oral, and urogenital sites most common. In the gastrointestinal tract, the stomach and duodenum are more common sites of bleeding than is the colon. Hepatic and splenic arteriovenous shunts, as well as intracranial, aortic, and splenic aneurysms, may occur. Pulmonary arteriovenous fistulae are associated with oxygen desaturation, hemoptysis, hemothorax, brain abscess, and cerebral ischemia due to paradoxical emboli. Cirrhosis of the liver has been reported in some families.

Therapy for HHT remains problematic, consisting of laser treatment for cutaneous lesions; split-thickness skin grafting, embolization of arteriovenous communications, or hormonal therapy (estrogen or estrogens plus progesterone) for epistaxis; pulmonary resection or embolization for pulmonary arteriovenous malformations; and hormonal therapy and laser coagulation for gastrointestinal lesions.[373,385,386] The nasal vasculature pattern may help to predict the response to laser therapy versus septodermaplasty.[387] Resurfacing the nasomaxillary cavity with radial forearm fasciocutaneous free flaps has been reported to be effective in patients with refractory epistaxis.[388] The antifibrinolytic agents ε-aminocaproic acid and tranexamic acid have been reported to be beneficial in controlling hemorrhage[389,390] but negative results with antifibrinolytic therapy also have been reported.[391,392] Improvement in lesions has been reported in cases using an antagonist to vascular endothelial growth factor,[393] and sirolimus and aspirin.[394]

Figure 121–31 Telangiectatic mats.

Figure 121–32 CREST syndrome.

Chronic Actinic Telangiectasias, Scleroderma, CREST Syndrome, Ataxia Telangiectasia, Chronic Liver Disease, and Pregnancy-Related Telangiectasias

Telangiectasias from chronic actinic damage (Fig. 121–31), and telangiectatic mats seen in scleroderma and CREST (calcinosis cutis, Raynaud syndrome, esophageal motility disorder, sclerodactyly, telangiectasia) syndrome (Fig. 121–32) may be easily confused with purpura as well as the lesions of vascular nevi and HHT. Angiokeratoma corporis diffusum, ataxia telangiectasia, and spider telangiectasias associated with chronic liver disease also must be differentiated. One point of differentiation is that spider telangiectasias have a central, prominent, easily blanchable feeding vessel with several smaller telangiectasias emanating from the central vessel. Spider telangiectasias seen in patients with chronic liver disease are distributed from the head to the nipple line and correlate with the risk of bleeding from esophageal varices.[395]

KAPOSI SARCOMA AND OTHER VASCULAR SARCOMAS

The epidemic form of Kaposi sarcoma found among some patients infected with HIV is easily confused with purpuric (Fig. 121–33) and ecchymotic (Fig. 121–34) lesions as well as some of the pigmented purpuric eruptions (Fig. 121–35).[396] Oral lesions of epidemic Kaposi sarcoma also may mimic petechiae and purpura (Fig. 121–36). Similarly, angiosarcoma may present as a purple to brown plaque resembling purpura (Fig. 121–37).

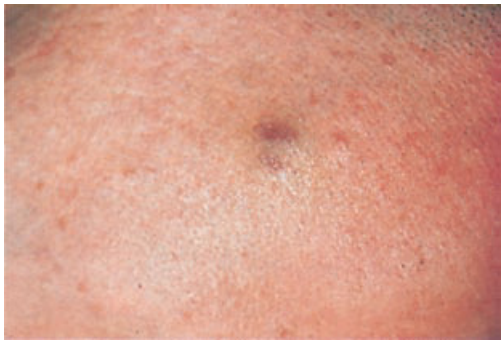

Figure 121–33 Kaposi sarcoma (AIDS).

Figure 121–34 Kaposi sarcoma (AIDS).

Figure 121–35 Kaposi sarcoma (AIDS).

FABRY DISEASE

Fabry disease (angiokeratoma corporis diffusum) is an X-linked inherited disorder of glycolipid metabolism with deficiency of the enzyme α-galactosidase A.[397] Accumulation of glycolipid throughout the body leads to cutaneous, renal, ophthalmologic, cardiac, and central nervous system manifestations. Angiokeratoma corporis diffusum lesions are pinpoint to 4-mm deep red, blue, or black macules or papules (Fig. 121–38). These nonblanchable lesions are distributed over the trunk, extremities, and genitalia. In mild cases, lesions are localized to the thighs, scrotum, or periumbilical region. Grouping of lesions may occur. Superficial corneal dystrophy and varicosities of the bulbar conjunctivum are commonly seen (Fig. 121–39). Replacement therapy with recombinant human α-galactosidase A is available.[397]

Figure 121–36 Kaposi sarcoma (AIDS).

Figure 121–37 Angiosarcoma.

NEONATAL EXTRAMEDULLARY HEMATOPOIESIS (BLUEBERRY MUFFIN BABY)

Infants with congenital infections with toxoplasmosis, rubella, cytomegalovirus, Coxsackie B2 virus, or parvovirus B19, Rh incompatibility, hereditary spherocytosis, or twin transfusion syndrome may have dark red, blue, or blue-gray macules and/or papules at birth or within the first 48 hours of life.[398,399] The lesions contain sites of extramedullary hematopoiesis and are found most commonly on the scalp, neck, and trunk but may be widely distributed. The lesions fade into tan- or copper-colored macules by 8 weeks of age. Infants born with neuroblastoma, rhabdomyosarcoma, leukemia, or Langerhans cell histiocytosis[400] may present with lesions that have a similar appearance.

ANGIOMA SERPIGINOSUM

Angioma serpiginosum is a livedoid vascular nevoid lesion showing pinpoint vascular ectasias on a background of erythema.[23,401,402] The lesion blanches partially with pressure and is not petechial. Capillary microscopy demonstrates punctate dilated capillaries. Lesions usually are seen on the legs and buttocks of women but may occur anywhere; they commonly expand during childhood and regress with age.

CHAPTER 122

LABORATORY EVALUATION OF HEMOSTATIC AND THROMBOTIC DISORDERS

Alvin H. Schmaier

The clinical laboratory evaluation is an integral part of the diagnosis and management of patients with hemostatic/thrombotic disorders. A clinical hematologist when challenged by patients with hemostatic/thrombotic disorders is as good as the laboratory that serves him or her for diagnosis and management. This chapter provides a critical practical approach to the diagnosis and management of bleeding and clotting disorders. The chapter discusses how clinicians use the clinical coagulation laboratory for management of patients with hemostatic and thrombotic disorders. The latter activity is a new use of laboratory resources for what until the present era has mostly been a diagnostic facility.

Physiologic hemostasis is the sum of protein (coagulation, fibrinolytic, and anticoagulation) and cellular (platelets, endothelial cells, and leukocytes) elements working in concert to staunch the bleeding at sites of vascular injury without occlusive thrombosis. The coagulation system leads to thrombin formation. The role of the fibrinolytic system is to lyse clot formed by thrombin. The role of the anticoagulation system is to regulate all the enzymes of the coagulation and fibrinolytic systems so that no excess clotting or bleeding occurs. The sum of these elements leads to the hemostatic plug (Fig. 122–1). Thus, the present approach to patients with bleeding disorders is to evaluate the hemostatic, fibrinolytic, and anticoagulation proteins and platelet number and function that contribute to this process. For decades the proteins of the hemostatic system have been referred to as the "coagulation cascade" based on the waterfall hypothesis of Ratnoff and Davies[1] and MacFarland,[2] who almost simultaneously reported a sequence of proteolytic reactions starting with factor XII (Hageman factor) activation and ending with formed thrombin proteolyzing fibrinogen to form a clot. However, at the onset, this hypothesis for physiologic hemostasis was untenable because it was known that factor XII deficiency is not associated with bleeding.[3] By the mid-1970s, the cofactors for factor XII activation (prekallikrein and high-molecular-weight kininogen) were identified, and deficiencies of these proteins also were not associated with a bleeding state.[4–6] In 1977, Osterud and Rappaport[7] recognized that factor VIIa is able to activate factor IX to factor IXa. Later, Broze et al.[8] recognized that the kinetics of tissue factor pathway inhibitor were such that, under physiologic circumstances, the factor VIIa/tissue factor complex cannot directly activate factor X but must go through factor IX activation. If this is the case, how does factor XI, whose deficiency is associated with bleeding, become activated independent of factor XIIa? In 1991, Gailani and Broze[9] showed that formed thrombin cycles back to activate factor XI, resulting in amplification of activation of thrombin formation. Presently, physiologic hemostasis is believed to be an interacting system initiated by factor VIIa and tissue factor activation and amplification of several zymogens that become serine proteases (Fig. 122–2; see Chapter 118). Although this has become a cohesive hypothesis for physiologic coagulation activation, clinical laboratory testing of the proteins of coagulation is not based on this current understanding—it follows the Ratnoff and Davies hypothesis.

The clinical laboratory assays used to examine the proteins of the coagulation system are based on the original surface-activated coagulation cascade hypothesis.[1,2] Although these tests do not represent physiologic hemostasis, they still are useful for diagnosis of defects in coagulation proteins and potential bleeding disorders. Thus, the clinician must understand the distinction between physiologic coagulation, fibrinolysis, and anticoagulation and the diagnostic tests that are used to measure these systems. The first part of this chapter describes the assays used to measure bleeding disorders. Understanding these assays is a practical approach to recognizing a potential bleeding abnormality in a patient. The second part of this chapter provides an overview of an approach to the laboratory diagnosis of thrombosis risk and discusses use of the clinical coagulation laboratory for monitoring activated coagulation states.

When faced with a bleeding patient, the hematologist must use an analytic diagnostic approach to determine its etiology. Most recognized bleeding states are caused by one of three defects: a defect or deficiency in a plasma protein, a defect in platelet number or function, or a defect in platelet–vessel wall interactions (i.e., an abnormality in the adhesive interactions between platelets and the vessel wall), as in defects associated with the presence or function of von Willebrand factor.

When approaching the diagnosis of a coagulation protein defect in a patient, understanding the mechanism is paramount. Any coagulation protein defect can be a true protein deficiency, an abnormal protein that cannot participate in its physiologic function(s), or an inhibitor to the active site of the protein or one that induces enhanced clearance of the protein. In general, inhibitors to a coagulation protein are immunoglobulins, although abnormal production of endogenous heparin, fibronectin, or cryoglobulins has been reported as the source of acquired inhibitors to coagulation proteins.[10] An abnormal coagulation protein can result from missense, deletion, or translocations of its DNA. Last, enhanced clearance of coagulation proteins usually occurs as a result of an antibody–protein complex that is recognized as foreign and thus removed from the circulation.[11] The resultant increased clearance of the protein results in a deficiency of the protein. Thus, clinical laboratory testing, when available, should focus on measuring the presence of the protein by antigen and its functionality by a variety of assays in order to recognize all of these mechanistic possibilities.

In general, hemarthrosis and spontaneous soft-tissue and intramuscular hemorrhage characterize defects of plasma protein, such as hemophilia A and B (factors VIII and IX deficiency). Soft-tissue petechiae, purpura, or ecchymosis characterizes von Willebrand disease or platelet number or functional disorders. However, distinguishing the potential mechanism for bleeding can be difficult. History and physical examination are important components of the hemostatic workup (see Chapter 121) but are inadequate for specific diagnosis of bleeding or clotting disorders. Thus, the clinical laboratory is essential for definitive diagnosis of a bleeding disorder in patients.

CLINICAL SCREENING ASSAYS IN HEMOSTATIC TESTING TO DETECT COAGULATION PROTEIN DEFECTS

In the practice of clinical hemostasis, there are no good global assays for measuring physiologic tissue factor-initiated hemostasis. The three assays most commonly used to examine the coagulation system are (a) the activated partial thromboplastin time (aPTT) induced by surface (contact) activation of the system, (b) the prothrombin time (PT) induced by the addition of excess tissue factor, and (c) the thrombin clotting time (TCT). In the aPTT assay, surface or contact

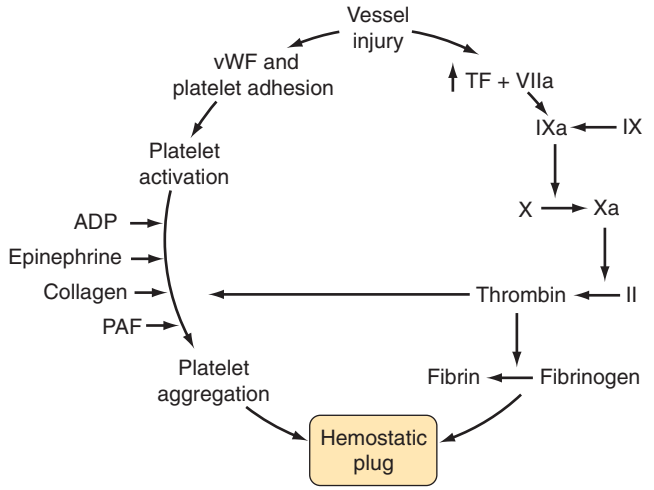

Figure 122–1 Schematic diagram of hemostasis. When a vessel is injured, platelets adhere to the injury site via von Willebrand factor (vWF). Upon adherence, the platelets are activated and release their granule contents. Released adenosine diphosphate (ADP) and exposed collagen recruit more platelets to the injury site. Simultaneously at the site of injury, tissue factor (TF) is upregulated and with activated factor VII activates factor IX to activated factor IX and, sequentially, factor X to activated factor X and prothrombin to thrombin. Thrombin stimulates more platelets, enhancing the platelet plug. Thrombin also proteolyzes fibrinogen to form fibrin monomer, which then polymerizes into a fibrin clot. These events occur on or about the activated platelet surface. PAF, platelet-activating factor. (Adapted from Schmaier AH, Thornburg C, Pipe, S: Coagulation and fibrinolysis. In Henry's Clinical Diagnosis and Management by Laboratory Network. Eds McPherson and Pincus. 21st Edition Elsevier, Philadelphia, PA, 2007, pp 729–745.

activation of the coagulation system occurs because factor XII associates with negatively charged substances in the reagent such that the protein actually stretches to allow expression of its active site, autoactivating factor XII to initiate a cascade of proteolytic reactions seen in the coagulation system.[12–14] These phenomena are the basis of the Ratnoff and Davies hypothesis for activation of the coagulation system. This test measures more proteins (factor XII, prekallikrein, high-molecular-weight kininogen) than those necessary for physiologic hemostasis. In the PT assay, addition of excess tissue factor creates an unphysiologic change in the normal stoichiometric relationship of coagulation factors, thereby allowing factor VIIa to overcome the inhibitory effect of tissue factor pathway inhibitor and favoring direct activation of factor X to factor Xa without the usual physiologic requirement to proceed through factor IX activation. In the TCT assay, exogenous thrombin is added to examine the integrity of its major substrate fibrinogen.

When all three assays are performed simultaneously on a sample of plasma, the results indicate almost all of the diagnostic categories for a bleeding state. It is most useful when performing diagnostic evaluations to perform a complete evaluation of the patient at one time rather than a series of piecemeal studies. Patient conditions usually are dynamic, so piecemeal evaluations often miss evolving clinical states. The three screening tests are performed as follows:

1. *Activated partial thromboplastin time (aPTT).* To perform this common coagulation assay, equal parts of a negatively charged surface and phospholipid mixture and patient plasma are incubated for more than 5 minutes. Calcium chloride 30 mM is added to recalcify citrated plasma, and the time required for clot formation is measured. The aPTT assay assesses the coagulation proteins of the so-called intrinsic system and the common pathways (Fig. 122–3).[15]
2. *Prothrombin time (PT).* To perform this assay, tissue thromboplastin (animal derived or recombinant human tissue factor) and phospholipids and patient plasma are incubated for more than 5 minutes. The plasma then is recalcified by the addition of $CaCl_2$ 30 mM, and the time required for clot formation is measured. The PT assay assesses the coagulation proteins of the so-called extrinsic system and the common pathway (see Fig. 122–3).[16] The sensitivity of the assay is based on likeness of the tissue factor to human tissue factor used in the assay (see Interpretation of Screening Tests of the Coagulation System).
3. *Thrombin clotting time (TCT).* To perform this assay, purified thrombin is added to plasma to determine the time for clot formation. It is a direct measure of the conversion of fibrinogen

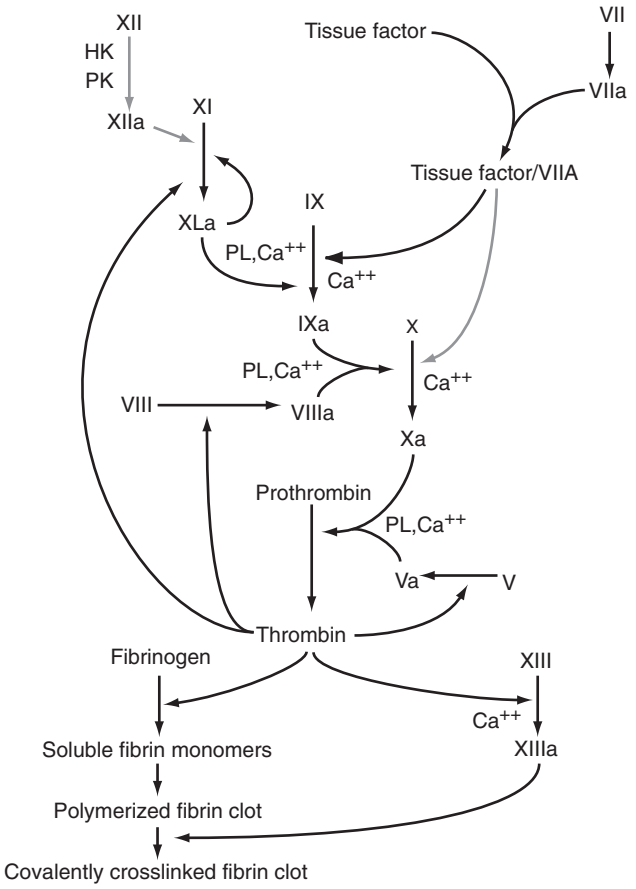

Figure 122–2 Schematic diagram of physiologic hemostasis. Formation of the tissue factor-activated factor VII complex (TF/VIIa) results in factor IX activation to activated factor IX (IXa). TF/VIIa does *not* normally directly activate factor X. Formed activated factor IX activates factor X to activated factor X (Xa) in the presence of activated factor VIII (VIIIa), which must have been formed from some prior thrombin activation of factor VIII). Activated factor X in the presence of activated factor V (Va) activates prothrombin to thrombin (IIa). Thrombin proteolyzes fibrinogen to form a fibrin clot. If more thrombin is needed, thrombin can activate factor XI to activated factor XI (XIa), which then activates more factor IX to activated factor IXa, which makes more activated factor X and thrombin. If more thrombin-induced clot formation is needed, thrombin also activates carboxypeptidase U to form a thrombin activatable fibrinolysis inhibitor (TAFIa) that inhibits fibrinolysis. Factor XI also can be activated by activated factor XII, which is formed secondarily by the constitutive activation of prekallikrein (PK) in the presence of high-molecular-weight kininogen (HK) by the endothelial cell enzyme prolylcarboxypeptidase. These latter mechanisms are *not* constitutive for physiologic hemostasis. However, in nonphysiologic states such as sepsis, clot formation in the intravascular compartment, or cardiopulmonary bypass, activated factor XII can activate factor XI to initiate hemostasis with thrombin formation. This latter mechanism is the basis of the activated partial thromboplastin time, a major screening test for hemostatic disorders. (Adapted from Schmaier AH, Thornburg C, Pipe, S: Coagulation and fibrinolysis. In Henry's Clinical Diagnosis and Management by Laboratory Network. Eds McPherson and Pincus. 21st Edition Elsevier, Philadelphia, PA, 2007, pp 729–745.

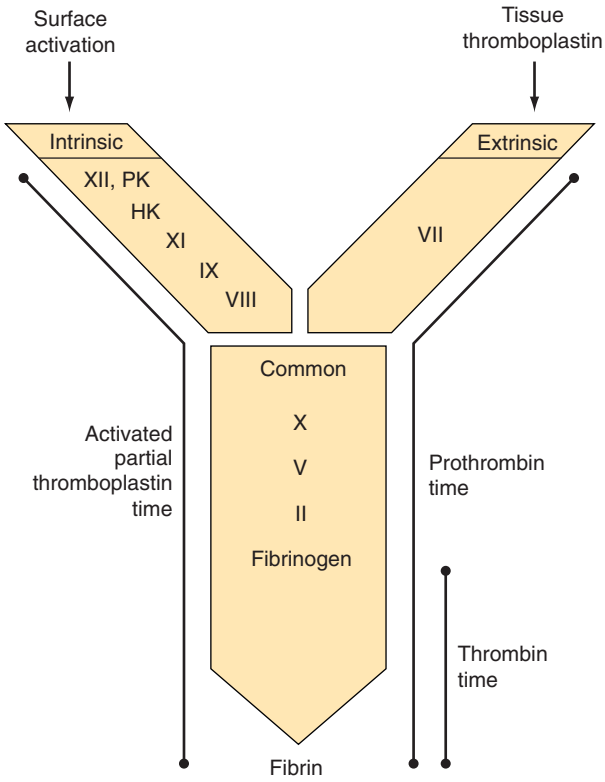

Figure 122–3 Organization of the coagulation system based on current screening assays. The intrinsic coagulation system consists of the proteins factors XII, XI, IX, and VIII and prekallikrein (PK) and high-molecular-weight kininogen (HK). The extrinsic coagulation system consists of tissue factor and factor VII. The common pathway of the coagulation system consists of factors X, V, and II and fibrinogen (I). The activated partial thromboplastin time requires the presence of every protein except tissue factor and factor VII. The prothrombin time (PT) requires tissue factor, factors VII, X, V, and II, and fibrinogen. The thrombin clotting time only tests the integrity of fibrinogen. (Adapted from Schmaier AH, Thornburg C, Pipe, S: Coagulation and fibrinolysis. In Henry's Clinical Diagnosis and Management by Laboratory Network. Eds McPherson and Pincus. 21st Edition Elsevier, Philadelphia, PA, 2007, pp 729–745.

to fibrin (see Fig. 122–3). When performing this assay, it is essential to use the minimal amount of α thrombin (3000 U/mg specific activity) that will reproducibly "clot" fibrinogen, usually 4 to 6 U/mL, aiming for approximately 20 seconds with pooled normal plasma to achieve maximal sensitivity for a clinically useful assay.[17,18] This assay is distinguished from the clottable fibrinogen assay (Clauss assay) by the amount of thrombin used (≈50 U/mL in the Clauss assay).[17,19]

The results of these assays allows the 40-year-old cascade hypothesis to guide the clinician to a practical differential diagnosis of what protein(s) may be affected based on the results of the screening tests. In the coagulation cascade hypothesis, coagulation proteins are classified as members of the intrinsic system, the extrinsic system, or the common pathway (see Fig. 122–3).

All coagulation assays examine the rate of clot formation. In these assays, a sequence of proteolytic reactions take place, leading to thrombin formation and its proteolysis of fibrinogen. Proteolysis of fibrinogen results in clot formation with precipitation of soluble proteins that are detected by either increased impedance or turbidity or decreased optical clarity, based on the instrumentation used to measure the result. Any defect along the pathway to clot formation will give an abnormal result. Furthermore, because a series of reactions must occur to result in the final clot formation, any substance (e.g., inhibitory antibodies, heparinoids, anticoagulants) that interferes with the assay downstream from a specific factor's activity will lead to an abnormal result. For example, a potent inhibitor to factor VIII will give an abnormal factor XI or IX coagulant assay. A deficient or abnormal fibrinogen will affect the results of the aPTT and PT assays even though the levels of all the coagulation factors are normal.

INTERPRETATION OF SCREENING TESTS OF THE COAGULATION SYSTEM

When diagnosing potential bleeding disorders, the coagulation cascade hypothesis and its grouping of coagulation proteins are used to interpret the screening tests for coagulation proteins for various deficiencies or abnormalities in the coagulation proteins (see Fig. 122–3).

The in vitro event of factor XII autoactivating in the aPTT assay initiates the sequence of reactions of the coagulation cascade.[1,2] The aPTT assay measures all the proteins of the so-called intrinsic coagulation protein system (factor XII, prekallikrein, high-molecular-weight kininogen, factor XI, factor IX, and factor VIII) and the proteins of the so-called common pathway (factors X, V, II, and fibrinogen). It is important to realize that coagulation proteins decrease to different levels before the various screening assays show an abnormality. For example, most commercial aPTT reagents detect a decrease in factor VIII when the protein level decreases to 35% to 45% of normal (i.e., 0.35–0.45 U/mL). Alternatively, factor XII and high-molecular-weight kininogen at levels of 10% to 15% of normal will only just begin to show abnormalities on the aPTT assay.[20,21] Similarly, factor VII levels below 35% to 40% will begin to be detected on the PT assay. The sensitivity of the screening tests in detecting specific abnormalities varies with the factor being tested, the commercial reagent used in the assay, and equipment platform for measurement. Ideally, each clinical laboratory should know the level of decrease for each coagulation factor that is detected by an abnormal aPTT or PT by their current equipment and reagents being used.[22]

The PT assay measures the so-called extrinsic protein coagulation pathway of coagulation, which consists of activated factor VII (factor VIIa) and the proteins of the common pathway (factors X, V, II, and fibrinogen).[16] The PT assay also is used as a monitor for patients taking warfarin.[23,24] In this capacity, its result reporting has been modified so that it can be interpreted universally. Because of the plethora of commercially available PT reagents and instruments for assay, it is impossible for physicians to know normal values for the PT from any given laboratory. A convention called the international-ized normalized ratio (INR) was developed to standardize the reporting of PT for patients taking warfarin.[23] INR = (patient's PT/mean laboratory control PT)^{ISI}, where ISI (international sensitivity index) for a reagent is a measure of the responsiveness of a given thromboplastin to reduction of the vitamin K-dependent coagulation factors. The reliability of PT becomes less with increasing ISI of the thromboplastin as the therapeutic range for PT diminishes.[24] It is provided by each manufacturer based on the degree of variation of the thromboplastin from the World Health Organization (WHO) reference thromboplastin that has an arbitrarily assigned value of 1, as determined by z, the logarithm of a PT per second determined with the WHO standard, and x, the logarithm of PT in seconds determined with the test preparation, according to the equation $z = a_1 + b_1x$, where $b_1 = m + \text{square root of } m^2 + 1$ and $a_1 = z - b_1x$ (see Pollar[24] for meaning of m in these equations). Manufacturer determination of ISI requires a minimum of 20 normal donors and 60 samples of patients stable on warfarin therapy with INRs between 1.5 to 5.0.[24] The higher the ISI, the less sensitive the thromboplastin. Human recombinant thromboplastin gives an ISI value of approximately 1.0. In practice, the term INR has become common parlance to describe all PT changes from normal. In reality, it should be used only to characterize the degree of PT prolongation of a plasma sample from a patient on warfarin.

Table 122–1 Laboratory Evaluation of Abnormalities of Coagulation Protein: aPTT and PT Screening Tests

Long aPTT, Normal PT	Long PT, Normal aPTT	Long aPTT and PT
Associated with Bleeding	Factor VII (rare)	**Think Medical States (Common)**
Factor VIII (male only)		
Factor IX (male only)	Slight defects[b] in factors X, II, and V and dysfibrinogenemias	Anticoagulants
Factor XI		Disseminated intravascular coagulation
Antibodies to factor VIII		Liver disease
Amyloid adsorbed factor IX		Vitamin K deficiency
		Massive transfusion
Not Associated with Bleeding		Antibodies to factor V
Factor XII	**Single Factor Deficient**	
Prekallikrein	Perform specific inhibitor assay	**Common Pathway**
High-molecular-weight kininogen		**Deficiencies (rare)**
Lupus anticoagulant		Factor X, V, II
Single Factor Deficient		Dysfibrinogenemias
Perform specific inhibitor assay		
		Single Factor Deficient
		Perform specific inhibitor assays
Multiple Factors Deficient		
Pan inhibitors,[a] e.g., lupus anticoagulant, immunoglobulin		**Multiple Factors Deficient** Pan inhibitors

[a]Pan inhibitors: General description of a nonspecific inhibitor that can be an immunoglobulin (e.g., lupus anticoagulant, myeloma protein) or natural substance (heparin, fibronectin, amyloid) that binds coagulation proteins and interferes with their function.
[b]Occurs with more sensitive PT reagents, international sensitivity index ≈ 1.0.
aPTT, activated partial thromboplastin time; PT, prothrombin time.

TCT only measures the ability of exogenous thrombin to proteolyze (clot) fibrinogen. It only assesses fibrinopeptide A and B release from fibrinogen and fibrin polymerization. Prolonged TCTs as indicated by values outside the 95% confidence interval for the time to clot of a population of 20 or more normals suggest reduced fibrinogen levels or abnormal fibrinogen function.

Knowing what each test measures, the following approach can be used to evaluate bleeding risk in patients who have prolonged values in one or more of these assays (Table 122–1). For example, if a patient has an isolated prolonged aPTT, determination of the patient's risk to bleed begins with the addition of historical information (see Chapter 121). If isolated prolongation of the aPTT is associated with bleeding, then the differential diagnosis in decreasing likelihood of frequency is factor VIII, factor IX, or factor XI deficiency. Factor VIII and IX deficiencies are sex linked and usually are seen only in males; factor XI deficiency is autosomal recessive and is seen in males and females (see Chapters 123 to 126 for a full discussion). If the aPTT alone is prolonged and the patient has no history of bleeding, the most common cause is a lupus anticoagulant (see Chapter 131). The specific proteins of the so-called intrinsic coagulation system associated with a prolonged aPTT but no bleeding history in decreasing frequency are factor XII, prekallikrein, and high-molecular-weight kininogen deficiency (Table 122–2). All of these defects are autosomal recessive and rare. Knowing about these latter three proteins is essential to evaluating a prolonged aPTT, even though the patient is not at bleeding risk. It also is important to recognize these protein defects so that patients do not undergo unnecessary plasma replacement therapy. Information indicates that factor XII contributes to the extent of thrombosis independent of hemostasis.[25] Factor XII activation contributes to the extent of clot formation of induced arterial thrombus by fibrin, platelets, or other material that function as negatively charged surfaced for autoactivation.[25–27]

Table 122–2 Clinical Peculiarities of Coagulation Protein Screening Tests

Long aPTT, normal or long PT, *no bleeding*	Normal aPTT, PT, *with bleeding*
Long APTT only	
Factor XII deficiency	Factor XIII deficiency or inhibitor
Prekallikrein deficiency	α_2-Antiplasmin deficiency or defect
High-molecular-weight kininogen	Plasminogen activator inhibitor deficiency or defect
Lupus anticoagulant	α_1-Antitrypsin Pittsburgh defect
Long aPTT and PT	
Dysfibrinogenemia with fibrinopeptide B release defect	
Lupus anticoagulant	

aPTT, activated partial thromboplastin time; PT, prothrombin time.

Individuals can have acquired disorders that inhibit specific coagulation factors and increase their risk for bleeding. The clinical laboratory phenotype of these patients depends on the protein to which the coagulation protein inhibitor is directed. The most common severe acquired coagulation protein inhibitor is a spontaneous antibody inhibitor to factor VIII that is seen in both males and females (see Chapter 131). Patients with the disorder present with bleeding and a long aPTT. Characteristically, this inhibitor is seen in elderly patients, patients with B-cell malignancies, patients with connective

tissue disorders such as systemic lupus erythematosus, and women postpartum. Patients are managed acutely with replacement therapy (high-dose factor VIII, activated vitamin K-dependent coagulation factor concentrates, or recombinant factor VIIa), but long-term management may require immunosuppression with cyclophosphamide (Cytoxan) and prednisone and/or rituximab.[28,29] Management decisions in these patients are influenced by the severity of bleeding and the height of the titer of the inhibitor to factor VIII as determined by the Bethesda assay.[30–32]

Alternatively, an isolated PT prolongation associated with bleeding usually indicates factor VII deficiency (see Chapter 127). Patients usually have partial VII defects as a true deficiency is incompatible with life.[33] At times, defects in some common pathway proteins (fibrinogen and factors II, V, and X) may first appear as an isolated PT prolongation; if severe, these latter protein defects will yield prolonged PT and aPTT results. The reason for the former is that certain more sensitive PT reagents first detect the defect before the aPTT. Recombinant tissue factor-based PT reagents with an ISI value approaching "I" constitute these more sensitive PT reagents.[24]

In general, defects in the common pathway proteins (fibrinogen, and factors II, V, and X) usually result in a prolonged PT and aPTT. When confronted with laboratory results of prolonged PT and aPTT, the hematologist should first not consider the specific proteins mentioned but rather should address the differential diagnosis for medical states such as anticoagulation therapy, disseminated intravascular coagulation (DIC), liver disease, vitamin K deficiency, and massive transfusion.[34,35] These general medical conditions are the most common causes of abnormal results in the two screening tests. Anticoagulation, unless the patient is faking medical illness, and massive transfusion are excluded by history.[36] Vitamin K deficiency is rare except in patients who are receiving warfarin therapy, are nutritionally depleted alcoholics, are having IV replacement without vitamins, have bacterial overgrowth in the gastrointestinal tract as result of antibiotic therapy, or, very rarely, have defects in transport proteins or enzymes for metabolism (see Chapter 130). Liver disease has several mechanisms that contribute to prolonged aPTT and PT. Prekallikrein, factor VII, and factor V are the first proteins to be decreased in liver disease. Abnormal fibrinogens often are produced in liver disease.[37] TCT detects defects in fibrinopeptide A and B release as well as polymerization defects. The reptilase time uses a snake venom enzyme to "clot" fibrinogen by liberating only fibrinopeptide A.[38] An abnormal TCT with a normal reptilase time indicates a fibrinopeptide B release defect, an abnormality that gives very long aPTT and PT values but is not associated with bleeding (see Table 122–2).[18] The reptilase time also will not be altered by the presence of heparin and can be used to determine if long aPTT and TCT are due to heparin.[36]

In addition to these general medical conditions, acquired disorders can present with the clinical laboratory phenotype of a long PT and aPTT. Acquired deficiencies or inhibitors are also seen in a number of medical conditions. Systemic amyloidosis is associated with decreases in plasma factor X or IX as a result of adsorption of the coagulation proteins onto the amyloid protein.[39] In the former condition, PT and aPTT may be affected; in the latter, only aPTT is affected. Hypergammaglobulinemic states seen with multiple myeloma or Waldenström macroglobulinemia (immunoglobulin M) can be associated with pan inhibitors to coagulation protein function.[40] Dysfibrinogenemias are common in these patients because fibrinogen binds immunoglobulin.[18] These phenomena are recognized by performing specific factor assays against the one or more proteins affected at multiple dilutions of the patient's plasma. In general, as the factor assay is performed at lower dilutions (e.g., 50%, 25% and 10% of normal plasma), the degree of inhibition of the coagulation factor reduces, suggesting that as the plasma is diluted, the effect of the inhibitor is lost. This coagulation test pattern is characteristic of a specific inhibitor to a coagulation protein.

Another acquired inhibitor that influences coagulation protein reactions is the lupus anticoagulant (see Chapter 131). This inhibitor represents antibodies directed to epitopes of proteins bound to certain phospholipids.[41] Lupus anticoagulants variably interfere with aPTT and PT. Detection of the degree of interference depends on the nature of the commercial reagent. Characteristically, a lupus anticoagulant will have a greater effect on a coagulation assay as the reagents, not protein, in the assay are diluted out.[42] For example, the degree of prolongation of PT or aPTT in a plasma sample will be greater at 1:50 dilution and 1:500 dilution of the assay reagent in a patient with a lupus anticoagulant than in a patient with a specific inhibitor to a coagulation protein.[42,43] In the latter case, the inhibitor level will change only when the patient's plasma, not the reagent for the assay, is diluted. Specific criteria have been developed to recognize lupus anticoagulants.[41,44,45] In general, assays that have some dilution of the coagulation reagent (dilute PT or tissue thromboplastin inhibition assay, dilute aPTT, dilute Russell viper venom time, or kaolin clotting time) are useful but are not specifically diagnostic for the condition.[41,43,44] Correction of the defect with excess phospholipids or platelet membranes is an additional characteristic of the disorder noted on clot-based assays.[41,46] However, no clot-based assay is diagnostic for lupus anticoagulants. All criteria also emphasize that the diagnosis is one of exclusion.[41,46]

FACTOR-SPECIFIC COAGULATION PROTEIN TESTING

All specific coagulation factor assays of the intrinsic system (XII, prekallikrein, high-molecular-weight kininogen, factors XI, IX, and VIII) are measured on one-stage assays using aPTT as its assay platform.[47,48] These assays became readily available because of accessibility of specific factor-deficient plasma. For example, a factor VIII assay uses a mixture of aPTT reagent, factor VIII-deficient plasma, and patient (test sample) plasma. After incubation for more than 5 minutes, the time to clot is initiated by recalcification with calcium chloride. All coagulation factors of the extrinsic system and common pathway (factors VII, X, V, and II) are measured in assays using PT as its platform.[47,48] For example, a factor X assay is a mixture of PT reagent that contains tissue factor (thromboplastin), factor X-deficient plasma, and patient (test sample) plasma. After incubation for more than 5 minutes, the time to clot is initiated by addition of calcium chloride. The amount of factor present in a given patient sample is determined by comparing the patient sample against a standard curve made with 10% to 100% normal plasma using the factor-deficient plasma and PT reagent.

Coagulation-based assays are sensitive and specific. They are simpler to perform than antigen assays for each of the coagulation proteins. Additional assays such as TCT and reptilase time specifically examine the integrity of fibrinogen.[17,38] Coagulation-based assays examine the function of the protein, antigen assays establish its presence, and, combined, these assays may detect protein with reduced function. Such a situation commonly arises when examining fibrinogen. The most useful means for determining the presence of an abnormal fibrinogen (dysfibrinogenemia) is to measure clottable fibrinogen and fibrinogen antigen on the same sample.[18,49] If fibrinogen clottability is less than 90% the amount of fibrinogen antigen, the protein produced probably is functionally abnormal.[37,49]

In addition to clot-based assays, the modern coagulation laboratory performs antigen assays for various proteins, which is important in the diagnosis of abnormal proteins.[49] Chromogenic assays also are used to measure certain enzymes (factor VIII, factor Xa, thrombin, plasmin, activated protein C) and various plasma protease inhibitors (antithrombin, α_2 antiplasmin, C1 inhibitor). The ability to neutralize the enzymatic activity of factor Xa or thrombin is a useful way to assay for the plasma level of anticoagulants, such as heparin, low molecular weight heparins, or for heparinizing which inhibit factor Xa or hirudin, argatroban a biualirudin which inhibit thrombin.[50]

PRACTICAL APPROACH TO THE BLEEDING PATIENT WITH A COAGULATION PROTEIN DEFECT

Patients with abnormal results on coagulation assays can be evaluated by the differential diagnosis of an isolated aPTT abnormality, PT abnormality, or both. When presented with a prolonged coagulation

assay, the differential diagnosis often is between a true deficiency and an inhibitor to a specific coagulation protein. Two approaches can be used to obtain a specific diagnosis.

A common practice when approaching the problem of determining specific coagulation factor defects begins with a mixing test of patient and normal plasma. Mixing studies based on PT or aPTT are interpreted based on the fact that a 50% level of any coagulation factor alone gives normal PT and aPTT values. Both of these screening assays have hyperbolic curves, that is, a decrease in any one factor does not lead to a linear prolongation of either of the two assays. At 50% levels of any coagulation factor, global clotting assays will fall in the normal range.[51] Only with values less than 50% of specific factors will PT and aPTT begin to prolong. The sensitivity of PT and aPTT to prolongation with lowering of clotting factors varies depending on the factor and the reagent made by the manufacturer.[22] Thus, if patient plasma is mixed 1:1 with normal plasma, PT or aPTT should be normal if no factor is present in the patient plasma. If the mixture does not correct to normal, something in the patient plasma may be interfering with function of the protein in normal plasma.

Because screening assays for inhibitors are not standardized, a mixing study is a weak assay fraught with misinterpretation and, in many ways, is a much less attractive initial approach. Almost no studies provide evidence-based laboratory procedures for inhibitor screening assays. Some approaches to the use of mixing studies were developed for testing for lupus anticoagulants, which have their own peculiar aspects.[43–46] Critical issues in performing mixing studies is the ratio of patient plasma to normal plasma (1:1 to 4:1), the time of incubation from mixing to assay (immediate to 2 hours), and the assays used for measuring results (PT, aPTT). One critical investigation examined the sensitivity and specificity of mixing studies for assessing factor deficiencies and anticoagulants.[52] Patient and normal plasma were incubated at 37°C for 1 hour before assay in a ratio of 1:1 or 4:1 patient to normal plasma. On an aPTT mix of 1:1 with percent correction of 70% to 75% calculated using a specific formula (see reference for formula), the sensitivity and specificity in recognizing a factor deficiency or anticoagulant were 100% and 33% or 33% and 100%, respectively. When the percent correction was 50% calculated from a ratio of 4:1 patient to normal in the plasma mix for the aPTT, the sensitivity and specificity in recognizing a factor deficiency or anticoagulant improved to 88% and 100% or 100% and 88%, respectively.[52] Likewise, on a PT mix of 1:1 with a percent correction of 70% to 75% calculated using a specific formula (see reference for formula), the sensitivity and specificity in recognizing a factor deficiency or anticoagulant were 95% and 50% or 50% and 95%, respectively. When the percent correction was greater than 40% calculated from a ratio of 4:1 patient to normal in the plasma mix for the PT, the sensitivity and specificity in recognizing a factor deficiency or anticoagulant improved to 96% and 100% or 100% and 96%, respectively.[52] Further studies showed that assay after an immediate mix versus 1-hour incubation at 37°C had lower sensitivity and specificity. These investigations show the variability of mixing studies test performance and their "usefulness" in translating their information into meaningful diagnostic data. Once the presence of an inhibitor is determined, factors assays must be performed to isolate the specific protein to which the inhibitor is directed. Furthermore, specific inhibitor studies are needed to confirm the diagnostic impression and determine titer.

As a second initial approach to diagnosis of a specific coagulation protein defect, the specific defect of a prolonged coagulation assay can be obtained by performing all relevant coagulation factor assays indicated by the abnormal PT and aPTT. If any one test value is decreased, then a specific coagulation factor inhibitor assay for that factor can be performed. One can argue that an excess number of specific assays is being performed, but in most developed clinical institutions, these assays are automated and can be performed more efficiently in batch fashion than piecemeal with sequential ordering. The value of such an approach is the shortened time to a specific factor diagnosis. If more than one factor is found to be low using such an approach, then efforts are made to determine the global reason for the result. Finding a single factor decrease by any initial approach requires more effort to perform the specific assays and determine if there are inhibitors to that factor. One general approach to a specific inhibitor study can be performed by mixing various ratios of patient plasma to normal plasma (e.g., 1:1, 2:1, 4:1, 1:2, 1:4), incubating the samples for 2 hours at 37°C, and then assaying the level of the specific factor in the mixture.[53] Simultaneously, the patient plasma and normal plasma used in the mixing study are incubated under the same conditions. At the time of assay, the percent activities of the specific factor under study in the normal plasma, patient plasma, and each of the mixtures are obtained. If the *observed value* at any given ratio of patient plasma to control plasma is less than the calculated *expected value* of mixing the two plasmas in the various ratios (e.g., 1:1, 2:1, 1:2, etc.), then one can conclude that an inhibitor present in patient plasma transferred to the normal plasma sample. For example, if there is 100% activity (1 U/mL) of the factor being studied in an undiluted sample, a 1:1 dilution of normal plasma with factor-deficient plasma should give an activity level of approximately 50%. If the same normal plasma was incubated 1:1 with patient plasma and the activity was 32%, one should conclude that something in the patient plasma transferred and inhibited the factor's activity in normal plasma, which is the definition of an inhibitor. This approach is a general, nonquantitative method for assessing a coagulation factor inhibitor. A specifically quantitative method for determining inhibitors to any coagulation factor can be developed for all coagulation factors using a modification of specific inhibitor assays used to characterize factor VIII inhibitors.[30–32] This approach is preferred because it standardizes assay performance and method for reporting inhibitor assay results. Given the vagaries of general mixing studies for inhibitors, my approach has been to determine if a single coagulation factor is affected when the screening tests are abnormal and then determine if there is a specific inhibitor to the activity of that factor using a standardized approach to a specific factor inhibitor assay.[30–32]

SCREENING TESTS USED TO RECOGNIZE PATIENTS WITH DISORDERS OF PLATELET NUMBER OR FUNCTION

Recognition of platelet function disorders is critical to any hemostatic evaluation (see Chapters 129, 141, and 142). Knowing the platelet count is essential because thrombocytopenia alone may increase bleeding risk. Obtaining a detailed medication history from patients is important in order to realize the mechanism of action of each medication and its possible influence on assays for platelet function. It is clinically not useful to document abnormal platelet function in a patient taking interfering medication. Screening tests for platelet function testing have been developed; each has advantages as well as disadvantages. The screening tests for platelets are as follows:

1. *Platelet count.* This assay measures the number of platelets in 1 μL of blood. It is used to exclude a quantitative platelet defect as the cause of a bleeding disorder. Causes of thrombocytopenia are discussed in Chapters 32 and 138 to 140.
2. *Bleeding time.* To perform this assay, the forearm is pierced, and the time until bleeding stops is measured. Specific devices have been manufactured to perform this assay, which assesses platelet number or function. The bleeding time is a very qualitative assay influenced by technique, skin characteristics, and platelet count.[54] It should only be performed by experienced technologists. In general, it should not be performed on any patient with a platelet count less than 100,000/μL because a low platelet count alone can lead to prolongation of the bleeding time. The bleeding time assay is not a good predictor of surgical bleeding.[55,56] It is seldom useful when performed on a hospitalized patient. However, in the outpatient setting for an individual who has a bleeding history and is not taking any medications, an abnormal bleeding time may provide useful information. It can predict whether more costly von Wille-

brand factor studies and platelet aggregation and secretion studies will be useful for the diagnosis of a bleeding state. If thrombocytopenia is not present, the differential diagnosis of the long bleeding time includes von Willebrand disease and platelet function defects. Patients with Ehlers-Danlos syndrome, osteogenesis imperfecta, and scurvy may have variable prolongation of bleeding times that are not necessarily due to platelet dysfunction.[57–59]

3. *High-shear platelet function analyzers.* Several automated platelet function analyzers have come into use as screening tests for platelet function abnormalities, replacing the bleeding time as a diagnostic assay. Each method is unique to and should be evaluated against the wide range of congenital and acquired platelet function disorders before it is accepted as a screening assay. One product, the platelet function analyzer PFA-100 (Siemens, Deerfield, IL), has been best evaluated and is most widely used.[60,61] In citrated whole blood, the PFA-100 measures the "closure time" required for platelets to adhere to agonist-coated membranes and aggregate under high sheer stress (5000–6000 s^{-1}). It is a novel technology and not analogous to the bleeding time or light transmission platelet aggregometry. Two cartridges are available: collagen–ADP and collagen–epinephrine-coated membranes. Platelet function is measured as a function of the time needed to occlude the aperture, termed "closure time." Abnormal closure times are longer than the mean values of laboratory-specific values for normals. Each laboratory that uses this technology must determine its own normal values because of influences of different collection tubes and anticoagulant concentrations. Test results can only be interpreted as normal or abnormal. The assay does not make a specific diagnosis (e.g., von Willebrand disease). The PFA-100 may be useful to screen for individuals with von Willebrand disease, Glanzmann thrombasthenia, and Bernard-Soulier syndrome but may be less sensitive to primary platelet secretion defects and storage pool disorders.[62–66] Any abnormality detected by the PFA-100 requires specific testing for von Willebrand disease and platelet function disorders for diagnosis.

INTERPRETATION OF SCREENING TESTS OF PLATELET FUNCTION

Abnormalities on one or more of the screening tests in a patient with a normal platelet count usually suggests von Willebrand disease or a defect in platelet function. Of note, von Willebrand disease or platelet function defects leading to bleeding can be present even with one or both of the screening assays is normal. At present, no screening assay can exclude the diagnosis of von Willebrand disease or a platelet function defect. If the clinical history is compelling but the screening tests are normal, more definitive von Willebrand factor or platelet function testing is needed. Likewise, if a screening test for platelet function abnormalities is abnormal, the consulting physician has the onus to diagnose or exclude von Willebrand disease or a platelet function defect. Thus, once medication or nonprescription drug use is excluded, more sophisticated, specifically diagnostic studies for von Willebrand disease and a platelet function defect are needed for most patients requiring invasive procedures. In general, one of 10 patients in this diagnostic category have a platelet function defect. The majority of individuals fall into the category of von Willebrand disease. Von Willebrand disease is discussed in Chapters 128 and 129. Its diagnosis is made by abnormal studies of von Willebrand antigen, von Willebrand factor activity (ristocetin cofactor assay and/or collagen binding assay), and von Willebrand factor multimers. Some patients with von Willebrand disease also have a reduced factor VIII assay, presenting with a long aPTT. Certain subtypes of patients with von Willebrand disease (type IIB or platelet-type) have a lower threshold to agglutinate and aggregate to ristocetin (0.3–0.6 mg/mL) in platelet-rich plasma; normal individuals do not respond to this concentration of ristocetin. However, all normals respond to 1.0 mg/mL and higher concentrations of ristocetin added to platelet-rich plasma.

In addition to evaluation for von Willebrand disease, individuals with an abnormal bleeding time or PFA-100 result may require evaluation with platelet aggregation studies. Two forms of platelet aggregation studies are available: light transmission aggregometry in platelet-rich plasma and impedance aggregometry in platelet-rich plasma or whole blood. Light transmission aggregometry in platelet-rich plasma is the gold standard of platelet function testing[67]; impedance aggregometry is less well characterized.[68] Whole-blood impedance aggregometry to some extent is a screening study as well. When performed in conjunction with platelet secretion, either of ATP or serotonin, light transmission aggregometry can be diagnostic of several well-characterized platelet function defects and can characterize defects in others (see Chapters 141 and 142). The procedures for light transmission aggregometry have been reviewed.[69–71] Because of the wide variability in how light transmission aggregometry is performed in clinical laboratories, efforts are being made to develop minimal standards for the performance of platelet function testing in clinical laboratories.[72,73] In light transmission aggregometry, the absence of platelet aggregation in response to physiologic platelet agonists is indicative of Glanzmann thrombasthenia (defects in integrin $\alpha_{IIb}\beta_3$), whereas absent agglutination/aggregation in response to ristocetin suggests Bernard-Soulier syndrome (defects in glycoproteins Ib, IX, and V) or von Willebrand disease. Platelet storage pool disorders can be diagnosed if platelet light transmission aggregometry is performed simultaneously with studies that include measurement of proteins within or released from platelet α or dense granules or measurement of granule membrane proteins (e.g., P-selectin) that become surface expressed after cell activation. Platelet activation defects, such as that induced by aspirin, can be diagnosed as well using this combination of techniques (see Chapters 141 and 142). Finally, with appropriate monoclonal antibodies, flow cytometry can be useful in measuring the surface expression of platelet glycoproteins and the activation state of the cell.[74]

BLEEDING DISORDERS NOT RECOGNIZED BY SCREENING TESTS FOR COAGULATION PROTEINS OR PLATELETS

A few rare bleeding disorders are not recognized by routine blood coagulation and platelet screening tests (see Table 122–2). These entities include, in order of frequency, factor XIII defects, α_2-antiplasmin defects, plasminogen activator inhibitor 1 defects, and α_1-antitrypsin Pittsburgh. Factor XIII deficiency can be congenital or acquired, especially after isoniazid therapy.[75] α_2-Antiplasmin defects and plasminogen activator inhibitor 1 defects produce hyperfibrinolytic states as a result of reduced inhibition of plasmin and tissue plasminogen activator or urokinase, respectively.[76,77] α_2-Antiplasmin deficiency can be acquired in acute leukemia or other activated coagulation states.[78] Deficiency or abnormal forms of plasminogen activator inhibitor 1 also are associated with a bleeding state.[77] α_1-Antitrypsin Pittsburgh is an exceedingly rare bleeding disorder caused by a mutation in antitrypsin that results in potent thrombin inhibition, preventing clot formation.[79]

OTHER ACTIVITIES FOR HEMOSTASIS LABORATORIES

Thrombosis Evaluation

In addition to the diagnosis of bleeding disorders, the hemostasis laboratory is important in the evaluation of prothrombotic states (see Chapter 134). Evaluation of prothrombotic states serves the patient in many ways. In individuals with idiopathic thrombosis, recognition of a specific molecular or protein defect may be important in determining the duration of anticoagulant therapy. Certain prothrombotic states (e.g., antithrombin, protein C, and protein S deficiencies,

antiphospholipid antibody syndrome) may confer higher risk for recurrence and thus suggest long-term anticoagulation after the first event. Recognition of less severe prothrombotic states (e.g., factor V Leiden and prothrombin 20210 polymorphisms, functional defects in fibrinogen and plasminogen) do not in themselves confer high risk for thrombosis but when conjoined with another risk factor may confer higher risk. Knowing this information helps patients engage in risk modification activity (e.g., stop taking oral contraceptives). Finally, 18% of patients without a family history of thrombosis and 30% to 40% of patients with a family history may have an identifiable molecular or protein risk factor for venous thrombosis.[80] This information helps many patients deal with anticoagulant management issues after they present with idiopathic thrombosis.

Monitoring Acute Hemostatic and Thrombotic Conditions

In addition to the diagnosis of hemostatic and thrombotic disorders, the coagulation laboratory has the function of monitoring patient therapy. Patients receiving unfractionated heparin (UFH) and warfarin are monitored by aPTT and PT, respectively. New monitoring roles are being established for these facilities. This section is divided into two parts: monitoring of anticoagulation therapy and measurement of activated coagulation.

Anticoagulation monitoring is an increasingly larger activity of hemostasis laboratories. In addition to UFH and warfarin monitoring using clot-based assays, low-molecular-weight heparin monitoring is an important activity in the hospitalized patient. This monitoring is especially important in patients who are obese, in those who have renal function compromise, and in patients prior to elective surgery.[81] Anti-factor Xa assays for monitoring low-molecular-weight heparins can be developed against each agent using the WHO's low-molecular-weight heparin for the standard curve.[50] Similarly, there is interest in developing clinical assays in addition to the aPTT for monitoring direct thrombin inhibitors, such as argatroban hirudin or bivalirudin as antifactor IIa chromogenic assays.[50]

Monitoring of activated coagulation states and their amelioration with treatment is another activity of the specialized hemostatic laboratory. The classic activated coagulation state is DIC (see Chapter 132). DIC is a clinicopathologic state associated with tissue destruction as a result of infectious, traumatic, obstetrical, malignant, and connective tissue disorders. The two forms of clinical presentation are an *acute* form that is a hyperfibrinolytic state and a *subacute* form that is more indolent. In the acute form, aPTT and PT are elevated, and the fibrinogen and platelet count are low. In the subacute form, aPTT, PT, and platelet may be normal or slightly, low and fibrinogen can be normal or even elevated. Finding a prolonged PT and aPTT with a reduced fibrinogen and platelet count usually indicates DIC in the hospitalized patient until proven otherwise.[82] This clinical laboratory phenotype of DIC most probably results from a secondary hyperfibrinolytic state and is the form of DIC most commonly recognized. The biochemical diagnosis of DIC then is simplified to finding evidence of simultaneous thrombin and plasmin formation. The D-dimer is a plasmin-proteolyzed fragment of insoluble, cross-linked fibrin.[83,84] It is a confirmatory assay for DIC in the appropriate clinical condition. Insoluble fibrin results from thrombin cleavage of soluble fibrinogen and cross-linking of fibrin by thrombin/activated factor XIII. Presently, a scoring system to aid in the diagnosis of DIC is available.[85] D-Dimer elevation characterizes DIC but is not specific for it. It is positive in patients in postoperative states, with resolving hematomas, and after large-vessel or pulmonary thrombosis. A positive D-dimer also has become an adjunct to the clinical diagnosis of pulmonary embolism.[86] Heparin-induced thrombocytopenia is another coagulation laboratory activation state. Laboratory diagnosis and monitoring the effectiveness of therapy for heparin-induced thrombocytopenia is discussed in detail in Chapter 140.

CHAPTER 123

STRUCTURE, BIOLOGY, AND GENETICS OF FACTOR VIII

Geoffrey Kemball-Cook, John H. McVey, and Edward GD Tuddenham

Factor VIII is a key cofactor in blood coagulation. Absence of functional factor VIII in plasma results in the serious bleeding disorder hemophilia A, which affects approximately one in 10,000 live births (see Chapter 125). Although hemophilia A has been regarded as a good candidate for gene therapy, traditional treatment of hemophilia consists of factor VIII replacement using plasma-derived or recombinant factor VIII products. Developments in factor VIII biochemistry have improved our understanding of how factor VIII interacts with other macromolecules in the performance of its normal procoagulant (clotting) function and how naturally occurring mutations result in the spectrum of clinical phenotypes found in hemophilia A (see box on Plasma Protein Factor VIII).

FACTOR VIII STRUCTURE AND FUNCTION

For successful normal human hemostasis, both tissue factor/activated factor VII-dependent initiation of clotting and factor VIII-dependent amplification of this initial response are absolutely required. Initiation of blood coagulation generates small quantities of activated factor IX and factor X. However the factor VIII-dependent mechanism catalyzes conversion of factor X to factor Xa far more efficiently, thus dramatically amplifying the events triggered by the tissue factor-dependent pathway.[1] This factor VIII-dependent amplification is indispensable for maintaining hemostasis, as shown by the fact that absence of circulating functionally active factor VIII causes the coagulation disorder hemophilia A.

Coagulation is a complex network of interactions (see Chapter 118). Factor VIII is proteolytically activated in the early stages of clotting to activated factor VIII. It is released from its plasma carrier protein, von Willebrand factor (vWF), and then complexes with and functions as a cofactor for the serine protease factor IXa. The membrane-bound complex (the so-called *tenase complex*) activates factor X to factor Xa.[2] Factor Xa thus produced can participate in a similar complex ("prothrombinase") with activated factor V for proteolytic conversion of prothrombin into thrombin, the key enzyme of the coagulation cascade that generates insoluble fibrin from soluble fibrinogen. It is possible that the procoagulant membrane surface on which the tenase complex assembles is provided by activated platelets,[3] although this has not been proven. Although detailed understanding of the assembly and function of these membrane-associated complexes is lacking, it is clear that a major role of the membrane surface is to concentrate components of the tenase and prothrombinase complexes, limit their diffusion to two dimensions, and provide the optimal spatial orientation of the components. For the factor VIII-dependent complex, this results in a large increase in factor Xa generation resulting from lowering the Michaelis constant (K_m) for factor X[2,4] and increase in the catalytic constant of the reaction (k_{cat}).[5]

Factor VIII Structure

Factor VIII is a large plasma protein with a predicted molecular mass of approximately 270 kd in the absence of additional posttranslational glycosylation. Inspection of the predicted linear amino acid sequence of the factor VIII molecule (mature sequence 2332 amino acid residues after removal of the signal peptide) demonstrates a clear domain organization consisting of three homologous A domains, two homologous C domains, and the unique large B domain, together with three short highly acidic sequences *a1, a2,* and *a3.* These sequences are arranged in the order (N-terminus to C-terminus) A1-*a1*-A2-*a2*-B-*a3*-A3-C1-C2 (Fig. 123–1).[6,7] Much evidence from a large range of proteins of known structure strongly indicates that such homologous domains fold independently from each other and thus are structurally distinct. This domain structure is similar to that of the homologous factor V,[8] except that factor V lacks the three short acidic peptides. The A domains have approximately 40% identity with each other and with the A domains of factor V, as well as with the three-A-domain proteins ceruloplasmin (Cp) and hephaestin. The C domains are homologous to several proteins, including the lipid-binding lectin discoidin I. The C domains also exhibit 40% identity to the C domains of factor V. The B domains of factors VIII and V do not show any sequence conservation with each other or with any other known protein.[9] However, they show strong similarities in two other respects: overall size and high density of N-linked glycosylation.

These sequence data provide clear indications that factors VIII and V are derived from a common ancestor, which itself was derived from a three-A-domain progenitor for all four related A-domain proteins.[10,11]

Prior to secretion into plasma, factor VIII is proteolytically processed within the cell to a series of metal ion-linked heterodimers produced by cleavage at the B-*a3* junction and by a number of additional cleavages within the B domain.[12] These cleavages generate the heavy chain composed of A1 (1-336: mature protein numbering), *a1* (337-372), A2 (373-719), and *a2* (720-740) with variable lengths of B (741-1648), and the light chain composed of *a3* (1649-1689), A3 (1690-2019), C1 (2020-2172), and C2 (2173-2332). Thus, circulating factor VIII in vivo consists of a heavy chain of variable molecular mass (e.g., from 90 kd, when only the A1-A2 domains are present, to 220 kd when the full-length B domain is present) and a light chain of 76 kd.[13]

Much is known from genetic and biochemical approaches. However, in order to relate further information about structure–function relationships in factor VIII and to interpret mutations, information on the three-dimensional structure of the protein is required. X-ray crystallography can give the highest resolution but requires large amounts of pure protein and successful crystallization of the target protein. Nuclear magnetic resonance also is high resolution, requires smaller amounts of protein, and does not require crystallization, but the factor VIII molecule is too large for this technique. However, these techniques can be applied to individual domains of factor VIII.

Electron microscopy either of individual protein molecules or of ordered arrays can provide medium-resolution structural information. Finally, homology modeling can be used to predict the structure of a domain or group of domains based on an existing high-resolution structure for a related protein.

Election microscopy studies at very low resolution led to characterization of the size and shape of factor VIII molecules in solution.[14,15] A globular core of approximately 12-nm diameter with a rod-like protrusion, suggested to be the B domain, up to 50 nm long, was defined. Fluorescence energy transfer studies also suggested close association of light chain and heavy chain.[16]

Plasma Protein Factor VIII

The plasma protein factor VIII is essential for rapid blood clotting. The absence of functional factor VIII is the cause of the bleeding disorder hemophilia A, which affects one in 5,000 male births.

Homology modeling was used in an attempt to generate useful models for part of the factor VIII molecule. Homology modeling required the availability of high-resolution structures for proteins or domains homologous to all or part of the factor VIII molecule. The first model, based on the crystal structure of the protein nitrite reductase, which has three domains rather distantly related to the factor VIII A domains, suggested a "triangular" structure for these domains in factor VIII.[17] Shortly afterward, a crystal structure of the related protein human Cp was produced.[18] This was used as the basis for construction of an improved A-domain homology model confirming the triangular layout and providing a revised arrangement for the

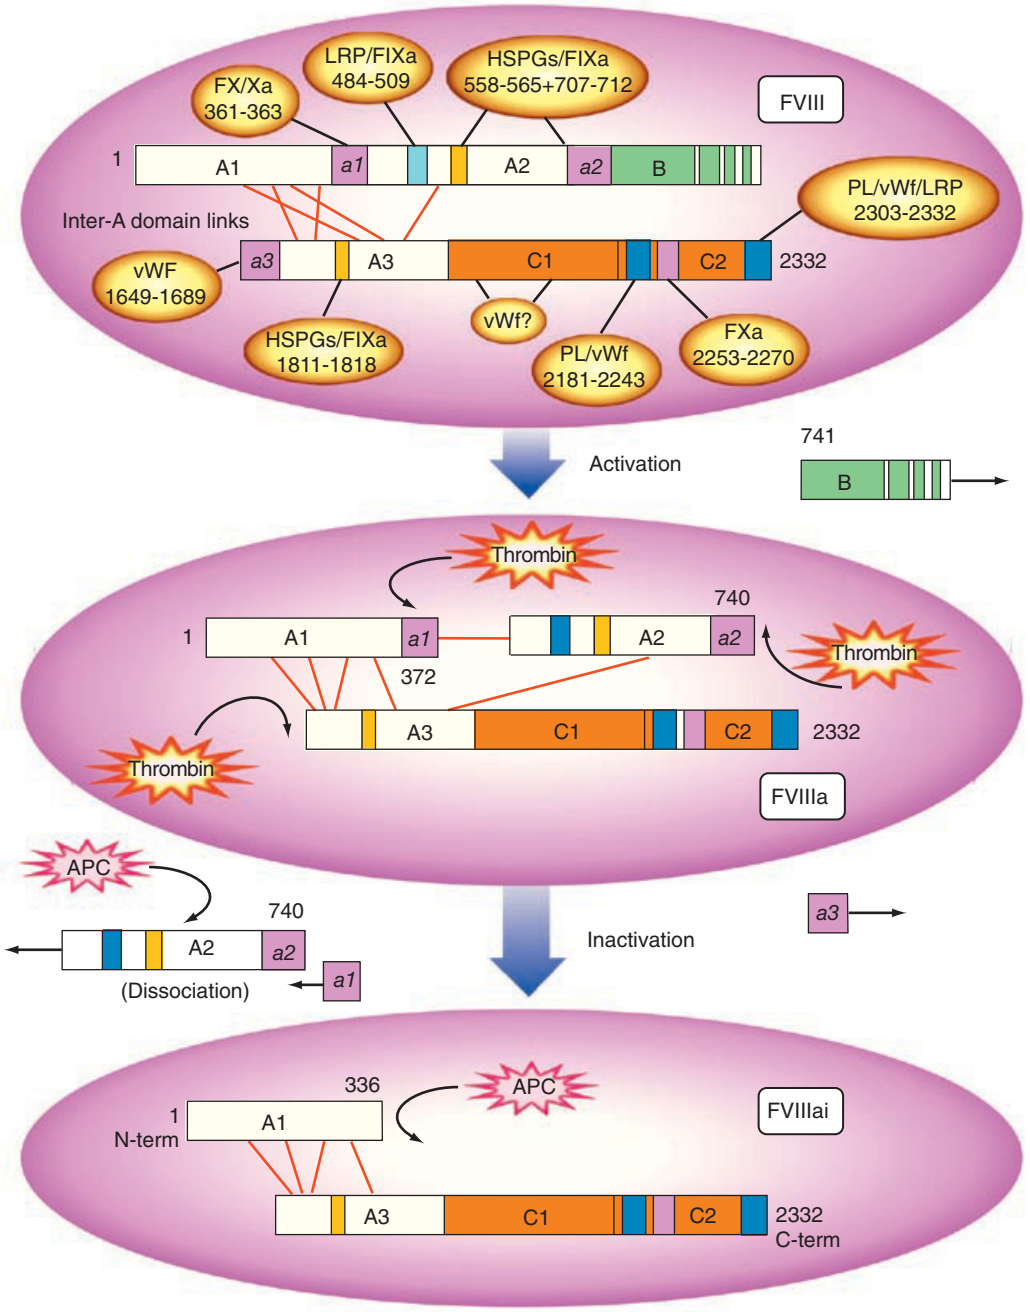

Figure 123–1 Factor VIII domain structure and functional regions, proteolytic activation by thrombin, and subsequent inactivation by subunit dissociation or activated protein C cleavage. Prior to activation, factor VIII circulates as a two-chain noncovalently linked heterodimer held together by electrostatic and hydrophobic interaction between the A domains. The regions of factor VIII involved in binding various macromolecules are indicated. Activation of factor VIII by cleavages at positions 372, 740, and 1689 releases the B domain and acidic peptide *a3*, generating the factor VIIIa heterotrimer. Here the A2 subunit is weakly associated with the stable A1/A3-C1-C2 heterodimer through electrostatic interactions. Following activation, inactivation of factor VIIIa proceeds either by spontaneous dissociation of the A2 domain or by proteolytic cleavage by APC after residues 336 and 562 in A1 and A2, respectively. LRP, low-density lipoprotein receptor-related protein; PL, phospholipid; vWf, von Willebrand factor.

orientation of the subdomains, together with more reliable detail of the structure.[19] This model, together with the growing online database of hemophilic mutations,[20] was used to investigate structure–function in factor VIII as well as for direct experimental studies with recombinant factor VIII variants.

Electron microscopic studies of arrays of factor VIII molecules adhering to a phospholipid monolayer defined the overall shape of the factor VIII molecule at low resolution and provided information on factor VIII–phospholipid interaction.[21] Contemporaneously, a high-resolution crystal structure for the factor VIII C2 domain was derived, obtained with highly purified recombinant C2 domain. Although preliminary homology models had been constructed previously for the factor VIII C domains,[22] this was the first high-quality structural information available for either C domain. For the first time, hemophilic mutations could be unambiguously studied at high resolution in part of the factor VIII molecule; in addition, a plausible mechanism for the interaction of factor VIII with a membrane via the C2 domain was derived.[23]

Because the C1 and C2 domains of factor VIII are closely related by homology, a homology model for the factor VIII C1 domain was generated that facilitated analysis of factor VIII functions.[24] In further studies, the C1 and C2 structures were combined with refined electron microscopic array data to produce a five-domain factor VIII structure (A1-A2-A3-C1-C2) bound to a phospholipid membrane.[25] This factor VIII model satisfied a large number of detailed biochemical and biophysical criteria and thus was used for a number of detailed studies of both naturally occurring hemophilic variants and in vitro mutagenesis. A draft molecular model for the factor VIIIa-IXa complex on the phospholipid membrane was produced by manually docking the factor VIII model with the crystal structure of factor IXa.[13] This model for the complex is consistent with many existing data, including defined binding sequences on both proteins. This basic tenase model was adopted for various mutation/mutagenesis studies.[26,27] Since the release of this model, a crystal structure for part of the related factor Va molecule lacking the A2 domain has been reported.[28] In addition, detailed combined modeling/docking methods have generated further hypothetical models of tenase that can be used to test hypotheses of function.[29] Most recently two groups have solved the crystal structure of B-domainless human factor VIII, confirming the predicted triangular arrangement of the three A domains, associated with tow C domains suggested to interact side-by-side with phospholipid membranes following activation.[29a,29b] The availability of these structures facilitates both close analysis of hemophilia-causing mutations together with the design of altered factor VIII molecules with greater stability or potency.

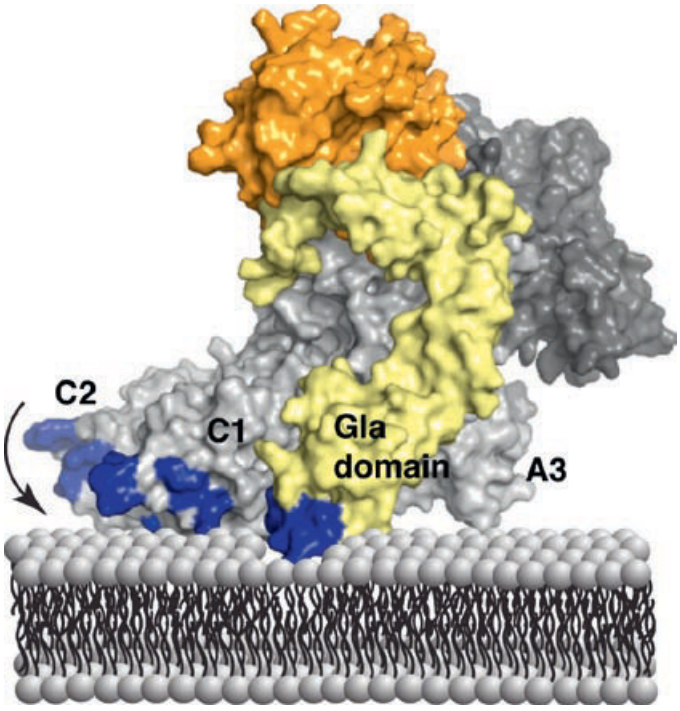

Figure 123–2 Model of the factor IXa-factor VIIIa complex. The complex of factor VIIIa (heavy chain [dark grey] and light chain [light grey and grey]) and factor IXa (heavy chain [orange] and light chain [yellow] includes four putative membrane binding sites: the bases of C1 and C2 domain, the A3 domain loop of factor VIII and the Gla domain of factor IXa [blue]. Possible interactions of the factor IXa-factor VIIIa complex with phospholipid membrane surfaces are illustrated.[29a]

Mechanisms of Factor VIII Action

Activation of Factor VIII

Factor VIII circulates in plasma as an inactive pro-cofactor and must be activated to factor VIIIa by specific proteolytic cleavages for full activity. After initiation of coagulation, factor VIII is activated by two major physiologic activators: factor Xa and thrombin. The cleavages resulting in factor VIII activation by thrombin and factor Xa have been defined.[30] Both proteases cleave the factor VIII molecule after Arg372 (between *a1* and A2), after Arg740 (between *a2* and B) within heavy chain, and after Arg1689 (between *a3* and A3) within light chain, yielding noncovalently linked A1-*a1*, A2-*a2*, and A3-C1-C2 fragments, which remain associated as heterotrimeric factor VIIIa (see Fig. 123–1). The short acidic *a3* peptide is lost. Because the *a3* region bears an important vWF-binding site, removal of *a3* by cleavage at Arg1689 promotes release of factor VIIIa from vWF and a substantial increase in factor VIIIa affinity for platelets.[31] In addition, cleavage at Arg1689 is required for generation of the maximal cofactor activity of factor VIIIa.[32]

Removal of *a3* leads to a 10-fold decrease in the association rate constant and a 160-fold increase in the dissociation rate constant of interaction of factor VIIIa with vWF in comparison with non-activated factor VIII[33] and a 1600-fold decrease in factor VIIIa affinity for vWF, enabling factor VIIIa to bind to a membrane surface and to factor IXa during assembly of the tenase complex. The A1 and A3 domains retain a metal ion-mediated interaction, and this relatively stable A1/A3-C1-C2 dimer is more weakly associated with the separate A2 domain through electrostatic interactions. The role of individual metal ions and amino acids in the association for factor VIII domains has been extensively studied.[26,34,35]

Information on the factor VIII sites responsible for binding of these activators is available. An important factor Xa-binding site was localized to C2 residues 2253-2270[36] and a site responsible for thrombin-catalyzed cleavage at Arg1689 in the light chain assigned to the C2 domain of factor VIII.[37] Residues 361-363 in the acidic peptide *a1* have been implicated in binding factor Xa during activation of factor VIII.[38] In addition, sites in A1 and A2 are associated with cleavage at Arg740.[39]

Inactivation of Factor VIII

Clotting in response to injury must be rapid but also localized in both place and time, because uncontrolled thrombin generation would risk intravascular thrombosis. Thus, factor VIIIa activity is degraded by two separate processes, resulting in an inactivated cofactor often referred to as *factor VIIIai* (see Fig. 123–1).

First, spontaneous dissociation of the A2 domain from the factor VIIIa heterotrimer in the absence of any further cleavage of factor VIIIa results in loss of factor VIIIa procoagulant function, and hemophilic mutations at the A2 interdomain interface display more rapid dissociation. This mechanism appears to be the primary cause of the rapid downregulation of tenase activity in vivo.[40] Second, specific proteolytic cleavage by activated protein C after Arg336 and Arg562 effectively destroys the procoagulant modulation of factor VIIIa of the factor IXa active site in the tenase complex.[41] However, this

appears to be only a secondary mechanism of factor VIIIa control,[42,43] in contrast to the profound effect of activated protein C cleavage at homologous sites in factor Va.

Because dissociation of A2 from the noncovalently linked factor VIIIa heterotrimer appears to limit the duration of factor VIII action in vivo, one strategy for maximizing the potency of administered recombinant factor VIII is to delay or even abolish this dissociation. A novel approach to achieve this goal is to engineer a novel disulfide link between cysteine residues in the A2 and A3 domains. This approach has shown promise in laboratory testing.[44,45] Although A2 dissociation is abolished, the mutant factor VIII molecules can be inactivated by activated protein C.

Interactions of Factor VIII with Components of Hemostasis

Factor VIII Interactions in the Tenase Complex

Three specific and essential interactions enable the cofactor activity of factor VIIIa in the assembled intrinsic tenase complex: with the enzyme factor IXa, the substrate factor X, and the membrane upon which the tenase complex assembles.

The factor VIIIa light chain bears an important factor IXa binding site ($K_d \approx 15$ nM) within A3 domain residues 1811-1818,[46,47] and this largely enables the high-affinity interaction between factors VIIIa and IXa, although the sequence is not involved in modulation of the factor IXa active site. The exact region of factor IXa involved is not clear; however, the site is included within the factor IXa light chain formed of its γ-glutamyl carboxylic acid (Gla)-epidermal growth factor 1 (EGF1)-EGF2 domains. In addition, cleavage of the factor IX zymogen is required, and the Ca^{2+} binding site in the EGF1 domain and EGF1-EGF2 salt bridge must be intact.[48,49] An interaction with the N-terminal Gla domain of factor IXa was suggested.[50]

The A2 domain also interacts with factor IXa directly through residues 330-338 in the factor IXa protease domain.[51,52] Although the affinity of factor IXa for isolated A2 is low ($K_d \approx 300$ nM), this interaction enables the cofactor activity of factor VIIIa, as interaction of the A2 domain with the factor IXa protease domain amplifies its enzymatic activity.[53] The A2 domain contains three amino acid sequences that are involved in interaction with factor IXa (see Fig. 123–1): 558-565,[54] 707-712,[55–57] and 484-509.[58] The 558-565 sequence has been modeled as an extended interface with the factor IXa protease domain helix.[52] In addition, a full FVIII-FIXa clocked structure using crystal structures of B-domainless FVIII and porcine FIXa has been constructed (Ngo et al, 2008).

The functionally important A2 sites that affect factor IXa enzymatic activity apparently are exposed only upon cleavage within the factor VIIIa heavy chain at Arg372, by either factor Xa or thrombin.[59] Recruitment of the light chain and A2 sites with factor IXa stabilizes factor VIIIa within the tenase complex, where factor IXa serves as a bridge linking the A2 subunit and A1/A3-C1-C2 heterodimer[60]; this delays spontaneous inactivation of factor VIIIa heterotrimer due to dissociation of A2.[40,61] The effect of the cleavages at Arg372 in the heavy chain and Arg1689 within the light chain on the assembly of the functional tenase complex has been studied by fluorescence anisotropy with active site-labeled factor IXa.[32,59,62] The anisotropy increase induced by a factor VIII molecule with cleaved light chain (HC/A3-C1-C2) was significantly higher than that observed for factor VIII with intact light chain (HC/LC) and comparable to that for factor VIIIa.[32] That anisotropy change correlates with modulation of the factor IXa active site by factor VIII suggested that removal of the acidic sequence *a3* following cleavage at Arg1689 is required for optimal interaction of factor VIIIa with factor IXa. These studies also indicated that maximal stimulation of the factor IXa active site by factor VIIIa requires cleavage between A1 and A2 at Arg372 in addition to removal of *a3*.[53,59] Addition of factor X led to a further marked increase in anisotropy, suggesting that factor X also contributes to optimal orientation of the factor IXa active site in the assembled tenase complex.[53]

Limited information defines the factor VIII site(s) involved in interaction with the factor X, the zymogen substrate of the tenase complex. One site has been localized to *a1* (residues 337-372) based on the ability of the corresponding synthetic peptide to inhibit factor X binding to the isolated A1 domain and also on chemical cross-linking of this peptide with factor X.[63] This factor X interactive site subsequently was narrowed down to *a1* residues 349-372.[64] The *a1* peptide facilitates substrate binding into the complex, as cleavage of factor VIIIa by activated protein C (releasing the *a1* fragment) and mutation of acidic residues in the sequence 361-363 both raised the K_m for factor X.[65,66]

The factor VIII heavy chain does not appear to contribute to factor VIII membrane binding. The factor VIII light chain is important for interaction with phospholipids[67] and is entirely responsible for their interaction at high affinity. Activation of factor VIII to factor VIIIa by thrombin increases this affinity.[31] A conformational change occurs within the C2 domain associated with factor VIIIa release from vWF after loss of the *a3* peptide, resulting in a 10-fold increase in its affinity for phospholipid membranes.[31] The plasma concentration of factor VIII is approximately 1 nM, so decrease of the K_d for factor VIIIa–phospholipid interactions to a comparable nanomolar level (0.4–1.1 nM)[31] suggests that conditions favorable for factor VIIIa association with membranes may result after factor VIII activation at the site of coagulation.

Studies with synthetic factor VIII peptides suggested that the major factor VIII light chain sequence involved in phospholipid binding is located within the C2 domain at residues 2303-2332, as peptides encompassing this region inhibited factor VIII–phospholipid binding.[68,69] Binding localization to the C2 region 2181-2243 of various antibodies that prevent factor VIII–phospholipid interaction suggested it should contain factor VIII residues critical for interaction with phospholipid.[70] The 1.5-Å x-ray structure of the human factor VIII C2 domain further implicated this factor VIII region in phospholipid binding, as analysis of the structure suggested that three hydrophobic projections or "feet" formed by the side chains of Met2199/Phe2200, Val2223, and Leu 2251/Leu2252 might penetrate into the hydrophobic interior of the membrane bilayer.[23,71]

Interaction of factor VIII requires phospholipid surfaces with negatively charged head groups (e.g., phosphatidylserine). Thus, four basic residues were postulated to stabilize factor VIII–phospholipid binding by electrostatic interaction with such head groups (Arg2215, Arg2220, Lys2227, and Lys2249) because they lie close to the "feet."[25] Further direct analysis of factor VIII–phospholipid binding by electron crystallography permitted the resolution of five functional domains of factor VIII (A1, A2, A3, C1, and C2) on a phospholipid surface and strongly supported the contribution of these three loops, together with a fourth, Trp2313-His2315, in forming the phospholipid-interacting region.[25] Thus, two of the first three loops lie in the implicated 2181-2243 sequence and the fourth loop within the implicated 2303-2332 sequence. Predictions based on the x-ray structure of C2 and electron crystallographic studies of factor VIII were supported by alanine mutagenesis of the residues composing the hydrophobic "feet" Met2199/Phe2200 and Leu 2251/Leu2252, which strongly reduced the affinity of factor VIII for phospholipid.[72] In parallel with this effect on factor VIII–phospholipid binding, these mutations reduced factor VIII affinity for vWF, indicating that these two residues are important contributors to factor VIII–vWF interaction. Interestingly, the recent crystal structures of B-domainless FVIII suggest that both C1 an C2 contribute hydrophobic residues to phospholipid interaction in a side-by-side fashion (Ngo et al, 2008).

Interactions with von Willebrand Factor

von Willebrand factor is a large multimeric plasma protein composed of identical subunits of 220 kd (see Chapter 128). In the circulation, factor VIII molecules interact via the factor VIII light chain with vWF in a tight noncovalent complex with K_d of approximately 0.4 nM.[33,73] This complex is required for maintaining the normal

factor VIII level in plasma. Binding to vWF reduces premature assembly of the tenase complex prior to factor VIII activation and prevents factor VIII inactivation by activated protein C, factor IXa, and factor Xa. Deficiency of vWF leads to a secondary deficiency of factor VIII[74,75] due to a lack of its protection from proteases and faster clearance from the circulation.

The factor VIII light chain contains at least two regions directly involved in binding to vWF (see Fig. 123–1): the acidic sequence *a3* (residues 1649-1689) preceding the A3 domain,[33,76] and one or more sequences within the C1 and C2 domains. Synthetic peptide studies had suggested that the sequence 2303-2332 in C2 was involved in both vWF and phospholipid binding,[33,68] and this was supported by the finding that the purified 2303-2324 peptide assumed an amphipathic helical conformation, in free solution, with affinity for phospholipid membranes.[69] However, x-ray crystallography of the C2 domain showed unambiguously that the 2303-2332 sequence lies largely within the domain core,[23] so such a helical structure is very unlikely, although individual residues within the sequence still could be important.

Involvement of the C1 domain in addition to C2 was demonstrated by the fact that vWF binding was affected by mutation of three C1 residues (Tyr2105, Arg2116, and Ser2119) in hemophilia A patients[77] and that Arg2150 in C1 also is associated with vWF interaction.[78–80] In addition, isolated C1-C2 fragment was shown to interact much more tightly with vWF than does the isolated C2 domain.[81] This finding suggests that vWF interaction is mediated by contributions from the *a3* peptide, C1, and C2, oriented to form a combined surface for interaction with either vWF or the phospholipid surface.[25] Although the heavy chain does not appear to interact directly with vWF, it is required for maximal affinity of factor VIII–vWF interaction, as affinity of the whole factor VIII molecule for vWF is 10-fold higher than for isolated light chain.[33]

Loss of the acidic *a3* peptide following factor VIII activation by thrombin promotes factor VIIIa dissociation from vWF, as *a3* is also suggested to be required for maintaining the C2 conformation optimal for vWF binding. A conformational change within the C2 domain upon removal of *a3* was indicated by a reduction in affinity of thrombin-cleaved light chain, compared to intact LC, for an anti-C2 monoclonal antibody NMC-VIII/5 that is conformationally sensitive.[33] Additional evidence for this conformational change was obtained using another antibody with a discontinuous epitope composed of two portions of the C2 domain, residues 2227-2241 and 2259-2279.[82] This antibody binding to these spatially close but distinct regions of C2 may account for its ability to "lock" the C2 conformation, thus preventing conformational changes within C2 induced by removal of *a3*. Affinity of factor VIIIa for vWF in the presence of the conformation-specific antibody (K_d 36 nM)[83] was 20-fold higher than in its absence (K_d 640 nM).[33] This confirms that after factor VIII activation by thrombin, the C2 domain undergoes a conformational change that is required for complete release of factor VIIIa from vWF.

Biosynthesis and Metabolism of Factor VIII

Factor VIII Biosynthesis and Processing

Expression profile analysis suggests expression in a variety of different tissues, with the highest levels of factor VIII mRNA detected in the liver and kidney.[84] Further evidence from liver transplantation in humans and dogs demonstrating restoration of normal levels of factor VIII in subjects with hemophilia A suggested the liver was the major site of synthesis. However, the cell type within the liver responsible for factor VIII synthesis is unclear. Synthesis of factor VIII has been attributed to hepatocytes, sinusoidal endothelial cells, and Kupffer cells. However, more recent data suggest the major cell type responsible for factor VIII synthesis are the liver sinusoidal endothelial cells, as these cells secrete active factor VIII when maintained in vitro,[85] and after transplantation in vivo these endothelial cells corrected the phenotype of hemophilia A mice.[86,87]

Much insight into the biosynthesis of factor VIII has come from analysis of expression in heterologous cell types with the purpose of producing recombinant factor VIII for therapeutic purposes.[88] In addition, characterization of the molecular defects responsible for the autosomal recessive bleeding disorder associated with combined deficiency of factors V and VIII revealed the importance of intracellular trafficking in the biosynthesis of factor VIII.[89]

The B domain of factor VIII can be deleted without loss of factor VIII procoagulant activity.[90] Expression cassettes encoding B-domain–deleted recombinant factor VIII resulted in significantly higher levels of mRNA over equivalent full-length recombinant factor VIII expression cassettes, resulting in higher levels of recombinant factor VIII protein synthesis. However, the levels of recombinant factor VIII secreted into the media did not increase proportionately, suggesting intracellular interactions were limiting efficient secretion.[91,92] Recombinant factor VIII is cotranslationally translocated into the lumen of the endoplasmic reticulum (ER) where it folds and assembles into tertiary structures. These reactions are facilitated by enzymes and molecular chaperones that interact with folding intermediates of recombinant factor VIII.

As the nascent protein chain enters the ER lumen, the sequence is scanned for asparagine residues in the consensus Asn-X-Ser/Thr motif, and preassembled core glycans are covalently added. Sequential trimming of two glucose residues allows the peptide to associate with the ER chaperones calnexin and calreticulin,[93] which associate with other luminal factors including members of the protein disulfide isomerase family. This most probably creates a protected environment that allows correct folding and formation of appropriate disulfide bonds. Release from calnexin/calreticulin is followed by cleavage of the innermost glucose residue from the N-glycan core. The structure of the released peptide is checked and a terminal glucose residue is added back onto the N-glycan core of polypeptides that have not folded correctly, allowing it to reassociate with the calnexin/calreticulin system in an attempt to acquire the native conformation. Another important protein chaperone in recombinant factor VIII expression is immunoglobulin heavy-chain binding protein BiP (GRP78 [78-kd glucose-regulated protein]).[94–96] BiP has an ATPase domain and interacts with recombinant factor VIII through an 11-residue hydrophobic β sheet that occurs within the homologous type 1 copper ion binding site in the A1 domain of factor VIII. Mutation of amino acid residue Phe309 within the β sheet to serine increased secretion of recombinant factor VIII several-fold and reduced the ATP requirement, suggesting that BiP plays a role in copper ion binding to recombinant factor VIII.[97]

A significant amount of recombinant factor VIII within the ER never transits to the Golgi compartment due to a failure to fold correctly. Improperly folded recombinant factor VIII proteins are targeted for ER-associated degradation by translocation back across the ER membrane to the cytosol where proteosomal degradation takes place.

If after release from chaperones recombinant factor VIII has folded correctly, then it will exit the ER. Studies of the molecular defect responsible for combined deficiency of factor V and factor VIII revealed that mutations lay in the genes encoding two proteins: either LMAN1 (also known as ERGIC 53) or MCFD2.[98–102] LMAN1 and MCFD2 form a stable complex that serves as a cargo receptor for efficient transport of factor V and factor VIII from the ER to the Golgi via COPII-coated vesicles.[103] The B domain of factor VIII appears to be the primary determinant of LMAN1-MCFD2 binding, most probably through mannose residues in the heavily glycosylated B domain as LMAN1 contains a carbohydrate recognition domain that binds mannose residues. MCFD2 contains two calcium ion-binding EF hands and interacts with LMAN1 in a calcium ion-dependent manner. MCFD2 is important in the efficient recruitment of factor VIII to LMAN1 and therefore ensures efficient ER export. The overall biosynthetic process in the ER and Golgi is shown in Fig. 123–3.

In the Golgi apparatus, factor VIII is further posttranslationally modified by proteolytic cleavage within the B domain at positions 1313 and 1648, modification of the *N*-linked oligosaccharides to

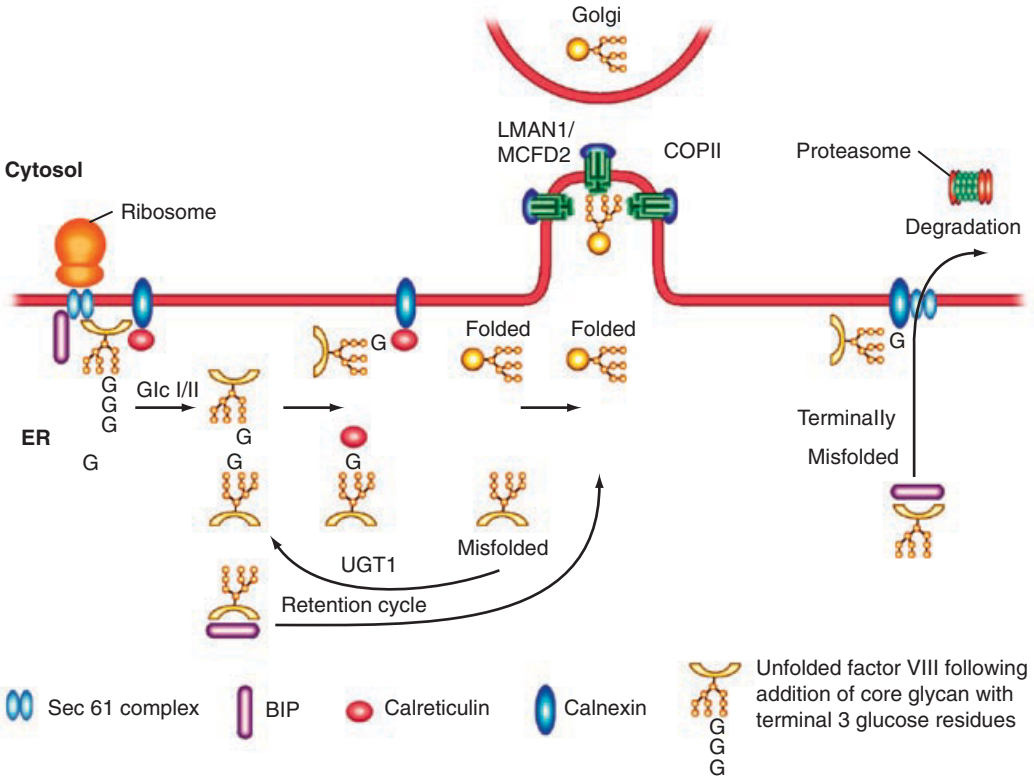

Figure 123–3 Biosynthesis of factor VIII. The proposed pathway of translation and trafficking through the endoplasmic reticulum (ER) to the Golgi compartment is indicated. Newly synthesized factor VIII is cotranslationally modified by addition of N-linked core glycans in the ER. Newly synthesized factor VIII associates with chaperones (calnexin, calreticulin, and immunoglobulin heavy-chain binding protein [BiP]) and their accessory proteins that aid the folding of the protein into its native conformation. Quality control mechanisms ensure misfolded protein is not transported from the ER but is retained to allow further refolding attempts. Terminally misfolded protein is transported to the cytosol for degradation by the proteasome. Correctly folded factor VIII is recruited to COPII vesicles by MCFD2 and LMAN1 for efficient transport to the Golgi.

complex types, addition of *O*-linked carbohydrate, and sulfation of six tyrosine residues.[104]

Low-Density Lipoprotein Receptor-Related Protein and Factor VIII Clearance

Factor VIII turnover in plasma and the mechanisms responsible are relatively poorly characterized. A key role in factor VIII catabolism has been found for low-density lipoprotein (LDL) receptor-related protein (LRP),[105–107] a broad-specificity hepatic clearance receptor.[108] The wide spectrum of plasma ligands for LRP includes blood clotting and fibrinolytic proteins such as factor Xa,[109,110] factor IXa,[111] tissue factor pathway inhibitor, the thrombin–antithrombin complex, plus plasminogen activators and their complexes with plasminogen activator inhibitor.[108]

LRP is one member of the LDL receptor family of structurally related endocytic receptors, in humans also containing LDL, very-low-density lipoprotein (VLDL), gp330/megalin, and apolipoprotein E receptor 2.[108,112] Mature LRP is a noncovalently linked heterodimer made up of a 515-kd extracellular ligand binding subunit and an 85-kd transmembrane/cytoplasmic subunit. Ligand binding to LRP occurs via the cysteine-rich LDL receptor class A (LDLRA) repeats featuring a highly conserved patch of negatively charged amino acid side chains that interact with positively charged ligand residues.

The involvement of LRP in factor VIII catabolism and clearance rests on the findings that (a) factor VIII is able to bind to purified LRP, (b) factor VIII is efficiently internalized and degraded by LRP-expressing cell lines, and (c) factor VIII plasma half-life in a mouse model could be prolonged threefold by blocking LRP with its classical antagonist, the 39-kd receptor-associated protein.[106,113] At least two separate factor VIII regions are involved in LRP interaction: one within the light-chain C2 domain[105] and the other one within heavy-chain A2 domain mapped to the 484-509 sequence.[106] This A2 site is inaccessible unless factor VIII is proteolytically activated to factor VIIIa,[114] probably serving to maintain plasma factor VIII levels during normal circulation. The C2 site of factor VIII has not been finely mapped but likely shares vWF-binding residues, as an anti-C2 monoclonal antibody that inhibits LRP–factor VIII binding also inhibits its binding to vWF.[105,115]

Taken together, these findings suggest that, in the normal circulation, where factor VIII will be complexed with vWF, only the A2 LRP-binding site would be exposed and thus mediate factor VIII clearance. This hypothesis was supported experimentally by showing that catabolism by LRP-expressing cells, both of the isolated A2 domain and of factor VIII from its complex with vWF, showed similar kinetics.[116]

The importance of the C2 site for LRP-mediated factor VIII clearance derives from comparison of factor VIII catabolism by LRP-expressing cells in the presence and absence of vWF. Purified isolated factor VIII in which the C2 site is exposed was internalized and degraded twice as efficiently as factor VIII complexed with vWF.[106] The C2 site may be similarly exposed in vivo in patients with severe von Willebrand disease who have no circulating plasma vWF. In such patients, infused factor VIII had a half-life three times shorter than either normal subjects[117–119] or hemophilia A patients, who also have normal plasma vWF levels.[120] The role of LRP in accelerated clearance of factor VIII in the absence of vWF is consistent with studies in vWF-deficient mice. Preadministration of receptor-associated protein inhibited clearance of factor VIII.[75,107]

Proteolytic activation to factor VIIIa also leads to exposure of the C2 site upon dissociation of factor VIII from vWF. Thus, exposure of both A2 and C2 LRP-binding sites in factor VIIIa (A1/A2/A3-

C1-C2) may be important for LRP-mediated regulation of factor VIIIa levels at the site of vascular injury.[121] Factor VIIIa is an unstable heterotrimer owing to rapid dissociation of A2 from the A1/A3-C1-C2 fragments,[122] so the fact that both isolated A2 domain[116] and the A3-C1-C2 cleaved light chain of factor VIII[121] can be efficiently cleared by LRP-expressing cells suggests the existence of an LRP-mediated pathway for clearance of both constituents of activated factor VIII in vivo, enabled via the A2 and C2 LRP-binding sites. Because two other protein components related to the tenase complex, factor Xa and factor IXa, also are LRP ligands,[109,111] LRP may have a role in regulation of tenase activity at the site of coagulation by reducing the levels of factor IXa, for which factor VIIIa serves as a cofactor, and the product of tenase, factor Xa, capable of activating factor VIII.

A mechanism for "preconcentrating" factor VIII near the cell surface has been suggested, as actual factor VIII–LRP interaction has an affinity only of K_d 60 to 116 nM.[105,106] LRP-mediated endocytosis is facilitated for many LRP ligands by cell surface heparan sulfate proteoglycans, which are a major glycoprotein component of the extracellular matrix. LRP-mediated clearance of factor VIII from its complex with vWF is promoted by heparan sulfate proteoglycans.[116] Simultaneous blocking of both LRP and heparan sulfate proteoglycans confirmed a synergistic effect in factor VIII clearance, as a more significant prolongation of factor VIII half-life was seen in mice (5.5-fold) than with blocking of LRP alone (3.3-fold). The heparan sulfate proteoglycan-binding site in factor VIII has been localized within A2 domain residues 558-565,[116] which also bind factor IXa. Use of a factor V/factor VIII chimeric molecule also suggested that another factor IXa-binding site in factor VIII A3, residues 1811-1818, binds significantly to heparan sulfate proteoglycans.[123] Thus, the catabolic pathway of factor VIII may involve initial binding of factor VIII/vWF complex to heparan sulfate proteoglycans, which concentrate the complex on the cell surface and present it to LRP, followed by LRP-mediated catabolism of factor VIII.

FACTOR VIII GENETICS AND GENOMICS

Factor VIII Genomics

The human factor VIII gene *F8* is located on the X chromosome at band q28 and consists of 26 exons spanning 186,933 base pairs (bp)[124] (reference genomic sequence GI 67083285, reverse complement 498-187430 bp). The exons range in size from 69 bp (exon 5) to 3106 bp (exon 14); the vast majority are between 69 and 250 bp in length. The 25 introns vary considerably in size, ranging from 207 bp (intron 17) to 32,849 bp (intron 22). The encoded mRNA is 9030 nucleotides in length (reference mRNA sequence GI 10518504), including a 171-nucleotide 5′ untranslated region and a 1803-nucleotide 3′ untranslated region. The 7053-nucleotide sequence encoding the 2351-amino-acid primary translation product is split across all 26 exons. Exon 1 encodes the 19-amino-acid secretory leader and the first 29 amino acids of the A1 domain. The remainder of the A1 domain is encoded by exons 2-8, the A2 domain is encoded primarily by exons 9-13, with a short segment and the acidic sequence *a2* encoded on the large exon 14 that primarily encodes the B domain. The most 3′ segment of exon 14 encodes *a3* and the start of A3, with the remainder of A3 encoded by exons 15-19. The C1 and C2 domains are encoded by exons 20-23 and 24-26, respectively.

Intron 22 of the *F8* gene contains three additional transcribed genes: *F8A*, *F8B,* and *H2AFB1*. These genes are contained within a 9.5-kb segment of intron 22 known as *int22h-1* that is present as multiple copies (*int22h*-2 and *int22h*-3) approximately 400 kb telomeric of *F8*. *F8A*, a gene devoid of introns, is transcribed in the opposite direction to *F8* on the complementary strand.[125] It is abundantly transcribed in a wide variety of tissues, and the 40-kd protein is associated with huntingtin (Htt), the aberrant protein in Huntington disease, and therefore is also known as Htt-associated protein 40 (HAP40).[126] It acts as an adaptor protein linking Htt with the GTPase Rab5, a key regulator of endocytosis.[127] *F8B* is transcribed in the same direction as *F8* and uses a unique 5′ exon spliced to exons 23-26 of *F8*. It encodes a putative protein, with eight novel amino acids followed by the C2 domain of factor VIII. Its function is unknown. No *F8B* gene is known to exist in mice, as only one copy of the *int22h* interval is present extragenic to *F8*. However, overexpression of a transgene encoding F8B produced multiple eye defects in transgenic mice.[128] The *H2AFB1* gene is transcribed in the opposite direction to F8 and encodes a member of the histone H2A B1 family.

The 1.2 kb of 5′ flanking region of the *F8* gene that includes most of the 5′ untranslated region contains numerous transcription factor binding sites. Functional analysis of a series of 5′ deletion constructs linked to a luciferase reporter gene following transient transfection of liver-derived cell lines showed that most of the upstream sequence was dispensable for liver-specific expression.[129,130] A fragment of 215 bp containing 109 bp of 5′ flanking sequence and 106 bp of 5′ untranslated sequence contained all the necessary elements for maximal expression. This fragment contains binding sites for the transcription factors C/EBP, nuclear factor-κB (NF-κB) and HNF1 and mutation analysis demonstrated a key role for HNF1 in transcriptional regulation. Factor VIII is known to increase under conditions that induce the acute phase response. Functional deletion/mutation analysis has shown this requires the NF-κB and C/EBP binding sites located in the 5′ untranslated region.[131]

Biochemical evidence, molecular cloning data, and comparative sequence analysis support the existence of all components of the coagulation network in jawed vertebrates and suggest that it evolved before the divergence of teleosts more than 430 million years ago.[10,11] The *F8* gene has been cloned and sequenced in a variety of vertebrates, ranging from mammals to birds and bony fish (teleosts). Comparative analysis of the gene organization in *Fugu rubripes* (Japanese puffer fish) and *Danio rerio* (zebrafish) with the human gene indicates an identical genomic organization with conservation of the exon–intron boundaries, with the exception of exon 14, which is much smaller due to a reduction in the size of the B domain. The introns in *Fugu F8* gene are condensed, with sizes ranging from 69 to 461 bp, accounting for the considerably smaller size (9.2 kbp vs 186.9 kbp) of the *Fugu* ortholog. Expansion of the human *F8* is due, in part, to the presence of repetitive elements within introns in the human *F8* gene that are not present in the *Fugu F8* gene. Approximately 70% of the human *F8* gene (129 kbp) consists of repetitive elements such as SINES (65), LINES (102), LTRs (50) and other DNA (21) elements. None of these repeat elements are found in the coding sequences; however, two are located in the 3′ untranslated region.

Hemophilia A

Genetic Disorders

Hemophilia A is an X-linked single gene bleeding disorder resulting from mutations in or close to the *F8* gene, which leads to loss of the circulating plasma coagulation protein factor VIII or production of a defective variant. The factor VIII protein was first purified 25 years ago.[132] Cloning of the *F8* gene was accomplished soon after[124] and was followed by descriptions of the mutations in many patients with hemophilia A.[133–135]

F8 gene defects associated with hemophilia A can be divided into two classes: (a) large gene rearrangements, insertions, and deletions, and (b) small mutations affecting only a small number of nucleotides. All types of defects may result in severe disease, but the single most clinically important defect is a recurrent large gene rearrangement (an "inversion") involving *F8* intron 22, which results in approximately 45% to 50% of *all* severe disease cases of hemophilia A worldwide.

The worldwide online hemophilia A mutation database[20] (http://europium.csc.mrc.ac.uk) lists more than 2800 individual reports of *F8* variants, including all insertion/deletions and single-base DNA replacements. In some cases, assessment of the severity of disease associated with a mutation casts light on the functional aspects of

Table 123–1 Summary of Mutation Data Available from Analysis of 2853 Individual Reports in the Online Hemophilia A Database[20]

		Reported Clinical Severity				Reported Inhibitor Status	
Hemophilia A Mutations	**Unique Reports**	***Severe (%)***	***Moderate (%)***	***Mild (%)***	***Variable (%)***	***Positive (%)***	***Negative (%)***
Total Unique Mutations	1221	718 (67)	123 (11)	212 (20)	23 (2)	171 (19)	727 (81)
Unique Single-Base Variants	809	369 (52)	105 (15)	206 (29)	23 (3)	78 (13)	513 (87)
Missense	583	204 (40)	92 (18)	187 (37)	23 (5)	44 (10)	391 (90)
Stop	131	112 (97)	4 (3)	0 (0)	0 (0)	31 (31)	69 (69)
Splice	95	53 (66)	9 (11)	19 (23)	0 (0)	3 (5)	53 (95)
Unique Insertions	80	67 (91)	5 (7)	2 (3)	0 (0)	16 (26)	46 (74)
Small (<50 bp)	75	63 (92)	5 (7)	1 (1)	0 (0)	15 (25)	45 (75)
Large (>50 bp)	5	4 (80)	0 (0)	1 (20)	0 (0)	1 (50)	1 (50)
Unique Deletions	332	282 (95)	13 (4)	4 (1)	0 (0)	77 (31)	168 (69)
Small (<50 bp)	197	157 (93)	9 (5)	4 (2)	0 (0)	31 (22)	113 (78)
Large (>50 bp)	135	125 (97)	4 (3)	0 (0)	0 (0)	46 (46)	55 (55)

The distribution of these mutations among severe, moderate, and mild disease, and relation to inhibitor status where known, are given. Human factor VIII gene *(F8)* inversions invariably result in severe disease but are not included in the database because of their high redundancy. Inversions are responsible for approximately 45% of all severe disease.

Hemophilia A database[20] from http://europium.csc.mrc.ac.uk.

Online Hemophilia A Database

The worldwide online hemophilia A mutation database (http://europium.csc.mrc.ac.uk) lists more than 2800 individual reports of *F8* variants, whether directly submitted to the database or derived from published reports.

Inversions and Severe Hemophilia

Half of all cases of severe hemophilia A worldwide are caused by spontaneous homologous recombination resulting in inversion of part of the *F8* gene.

factor VIII protein. Inversions are omitted from the database because they are almost entirely identical both genetically and phenotypically and therefore are highly redundant. A summary of mutations listed in the online database is given in Table 123–1 (see box on Online Hemophilia A Database).

Gross Genetic Changes

A mutation hotspot specific to hemophilia A is the recurrent rearrangement responsible for 50% of all severe cases in which homologous recombination of a sequence within intron 22 of the *F8* gene and two extragenic and telomeric copies of the sequence results in an inversion that disrupts the *F8* gene.[136,137]

Inversions (IVS 22 and IVS 1)

Half of all severe hemophilia A is caused by spontaneous homologous recombination resulting in inversion of the *F8* gene (Fig. 123–4). Two types of inversion involving a sequence in intron 22 and either the proximal (*int22h-2*) or the distal (*int22h-3*) of two extragenic copies of this sequence were thought to be responsible for the two forms of inversion observed in hemophilia A patients.[138] However, genomic sequence data following the completion of the DNA sequence of the human X chromosome[139] indicate that recombination leading to inversion can occur only between intron 22 and distal copies of the sequence.[140] Recombination between intron 22 and the proximal copies of the sequence would be predicted to lead to duplication and deletion because they are in the same orientation to each other. The new sequence information also revealed that *int22h-2* and *int22h-3* form the arms of a large palindrome. Therefore it has been suggested that recombination occurs between the arms of the palindrome, creating alleles where either the *int22h-2* or the *int22h-3* occupies the proximal position, thus explaining the observed rearrangements[141,142] (see box on Inversions and Severe Hemophilia).

A second inversion found in 5% of severe hemophilia A cases involves a 1-kb sequence in intron 1 (*int1h-1*) and a repeated copy (*int1h-2*) 140 kb telomeric of the *F8* gene between the *C6.1A* and *VBP1* genes. The inversion results in the production of two chimeric mRNAs that compose either exon 1 of the *F8* gene and exons 2-6 of the *VBP1* gene or exons of the *C6.1A* gene and exons 2-26 of the *F8* gene. The inversion causes severe hemophilia A because the coding sequence for factor VIII (exons 2-26) is downstream of the translation stop codon of the *C6.1A* gene.[143,144]

Large Insertions and Deletions

Approximately 5% of patients with hemophilia A have large deletions (>50 base pairs). The online mutation database[20] (http://europium.csc.mrc.ac.uk) lists 137 individual deletions of varying size scattered throughout the *F8* gene. Few of the deletions have been mapped at the nucleotide level. Deletions usually are associated with a severe bleeding phenotype, although four cases are reported to be associated with a moderate bleeding phenotype. The observed clinical phenotype most probably is due to in-frame joining of the exons flanking the deletion during mRNA processing.

Insertions of large elements in the *F8* gene are a rare cause of hemophilia A; only five such events have been reported.[20] Two involve insertion of LINE repetitive elements, which are members of the class of transposable elements, also known as interspersed repeats, that are the largest single component of mammalian genomes. LINEs mobilize by an ancient reverse transcription mechanism shared with the group II introns of mitochondria and eubacteria.[145] Two of the other insertions described in the *F8* gene involve Alu repeat elements, members of the SINE family of short interspersed nucleotide elements that lack the ability to retrotranspose autonomously but can coopt LINE machinery for their replication.

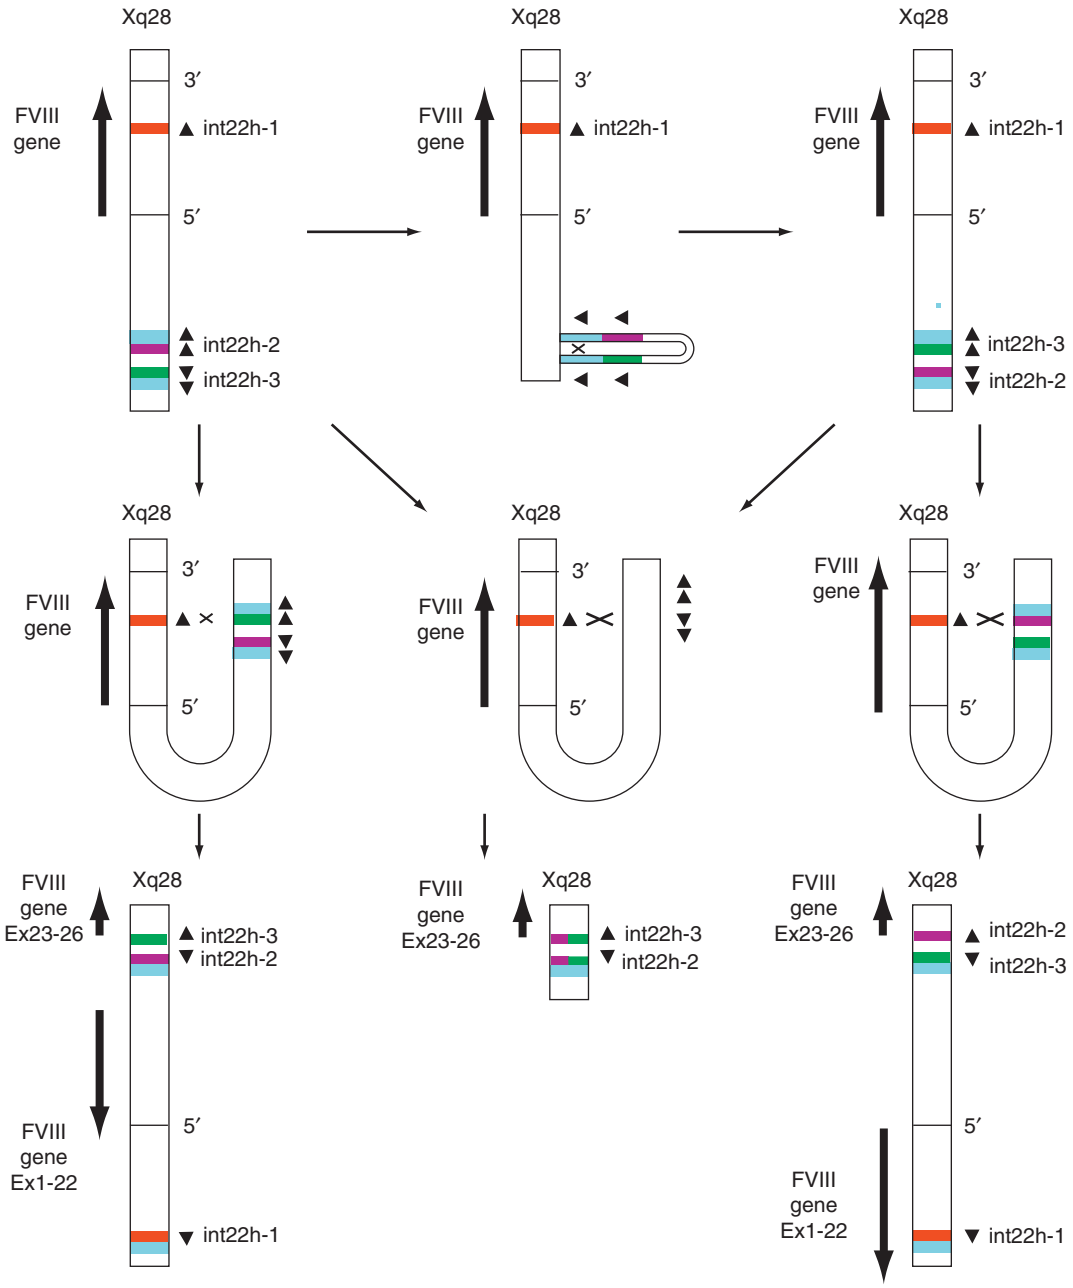

Figure 123–4 Inversions in Xq28 causing hemophilia A. Proposed mechanism causing polymorphic inversion and recombination between *int22h* repeats leading to inversion of the *F8* gene. The *F8* gene is indicated by the large arrow. Inversions disrupting the *F8* gene result from recombination between *int22h-1* region (in intron 22 of the *F8* gene) and either *int22h-2* or *int22h-3*, which lie 400 kb distal to *F8*. The three copies of the *int22h* sequence are indicated by the red, purple, and green boxes, and their orientation relative to the intron 22 copy is indicated by the arrowhead. The distal copies (*int22h-2* and *int22h-3*) are in opposite orientation to each other and are flanked by a large imperfect palindrome, indicated by blue boxes. Proposed recombination between the arms of the palindrome would generate alleles where either the *int22h-2* or the *int22h-3* is most telomeric and in the opposite orientation to *int22h-1*. The consequences of the recombination between the *int22h-1* and either *int22h-3* or *int22h-2* in the distal position leading to inversion are indicated to the left and right of the figure, respectively. The consequence of the recombination between the *int22h-1* and either *int22h-2* or *int22h-3* (indicated by the checkered colors) in the proximal position, leading to deletion rather than inversion, is indicated in the center of the figure.

Other Rearrangements

Two examples of duplication of parts of the *F8* gene causing hemophilia A have been described. In one case, a 23-kb sequence in intron 22 is duplicated and inserted between exons 23 and 24 in one of the maternal *F8* genes. This was presumed to be unstable and led to deletion of 39 kb of DNA including exons 23-25, thus causing hemophilia A in the patient' son.[146] The other duplication, of exon 13 was identified in a cohort of northern Italian patients in which it was found to be responsible for mild hemophilia A in 32% of subjects from the area.[147,148] The duplication is associated with a mild bleeding phenotype because exon skipping of one of the duplicated exons during mRNA processing leads to production of a wild-type factor VIII mRNA. More recently, a complex genetic rearrangement consisting of a 15.5-kb deletion/16-bp insertion located 0.6 kb from a 28.1-kb deletion/263-kb insertion at Xq28 has been described in a patient with hemophilia A. Although this arrangement affects the copy number of several genes, with deletion of part of the *F8* gene and the *FUNDC2* gene and duplication of the *FAM11A*, *HSFX1*, *MAGEA9,* and *MAGEA11* genes, the patient exhibits no clinically detectable phenotype other than hemophilia A.[149]

Small Mutations

This category of disease-causing mutations includes single-base replacements resulting in an amino acid change ("missense") or the introduction of a new stop codon ("nonsense" or "stop"). Occasionally, such a base change occurs at or near an mRNA splice junction, resulting in skipped exons or premature truncation of the protein ("splice" variants). Included in this category are small insertion/deletion events, commonly defined as involving less than 50 bases, and frequently involving a single base. These defects usually cause frameshifts in the DNA sequence, generating novel stop codons downstream.

In general these mutations result from small-scale errors of DNA replication that are not successfully repaired. The spectrum of clinical severity and presence of inhibitors depends strongly on the type of small mutation and its location.

As of 2007, more than 1800 individual reports of single-base substitutions are given in the online hemophilia A database.[20] Some are recurrent, but more than 800 *unique* single-base variants are listed as being causative of disease. Even for a large protein of 2332 amino acids, this is an extraordinarily rich database of functional disorder in a single protein. Annotations in the database include factor VIII clotting activity and circulating factor VIII antigen (factor VIII:Ag) levels, clinical severity, antifactor VIII inhibitor status, and journal reference for each report.

To date, the unique single-base substitution variants are made up of 583 unique missense mutations that result in an amino acid substitution, 131 unique stop mutations, and 90 unique splice variants. The distribution of these mutations among severe, moderate, and mild disease, and relation to inhibitor status where known, are given in Table 123–1. Table 123–2 lists the distribution of the mutations by *F8* exon. Exon 14 is approximately 10 times larger than the average size of the other exons, so it has a much higher burden of causative mutations generally, although missense mutations actually are relatively poorly represented when normalized per kilobase of coding sequence, reflecting the dispensability of the B domain for functional activity.

Table 123–2 Summary of the Distribution of Mutations in the Online Hemophilia A Database[20] by *F8* Exon

Single-Base Substitutions: Missense, Nonsense, and Splice Mutations

Table 123–1 shows the stratification of unique single-base substitution mutations by clinical severity and antifactor VIII inhibitor status. Missense mutations and splice variants are associated with all disease severities, unlike stop mutations, which result almost exclusively in severe disease as usually no protein circulates.

In approximately 590 single-base substitution cases of reported known inhibitor status, 78 (13%) are reported as inhibitor positive. Most of these are associated with severe disease, indicating a likely role for regular replacement therapy in the development of an antibody response. Stop mutations result in a higher proportion of cases with positive inhibitor status (31/100 [31%]) in comparison to the missense mutation group in which only 10% (44/435) are inhibitor positive. Only three of 56 cases report the presence of an inhibitor in the splice variant group, an unexplained low incidence.

For stop mutations, a skewed pattern of inhibitor development in relation to exon number is seen. Of 30 unique stop mutations associated with the generation of antifactor VIII antibodies in vivo, none are found in exons 1-7 and only four in the first 13 exons. The reasons are unknown, although various hypotheses have been formulated for this distribution of inhibitor-positive cases (see Chapter 126).[150,151]

Many single-base mutations occur numerous times in different populations; 32 unique mutations have been reported independently on 10 occasions or more, with six of those reported independently over 25 times. Enhanced predisposition to replication errors at the local chromatin level clearly is involved, whether caused by the CpG dinucleotide "hotspot" effect (i.e., CG→TG), by specific sequence motifs, or by other local factors.

Within these groups with an identical mutation, the variabilities of clinical phenotype and factor VIII activity level are notable. For example, the mutation Arg1997→Trp has been reported 34 times in unrelated families, with factor VIII activity varying from less than 1% to 5% of normal plasma values, and clinical severity varying from severe to mild. This variability suggests that besides the defined disorder in the *F8* gene, additional factors must be controlling factor VIII activity. Other genes do affect factor VIII levels. Detailed studies of a small number of families with the rare clotting disorder of combined factor V–factor VIII deficiency have demonstrated that mutations in at least two genes coding for proteins involved in glycoprotein trafficking in the ER and Golgi apparatus result in reductions in the secreted levels of both factor V and factor VIII. Other causes of variation are undefined.

With a three-dimensional structure for factor VIII or its domains, structural rationales for defects in function can be attempted. The many missense mutations in the database can be a fertile area for correlating factor VIII function with protein structure and explaining how these small changes in protein sequence result in clinical disease.

Knowing circulating factor VIII antigen levels as well as factor VIII activity levels is necessary in order to make interpretations about factor VIII function in plasma or about the ability of a variant molecule to be secreted. A plasma activity of 5% of normal associated with a hemophilic missense mutation might result from either a molecule that is present at a normal 100% antigen level but is dysfunctional (i.e., cross-reactive material [CRM]-positive) or a poorly secreted or unstable yet functionally normal molecule that circulates at the 5% level (i.e., CRM-negative).

The abolition of existing cysteine residues known to be involved in disulfide bridge formation is associated with low levels or an absence of factor VIII molecules in the plasma of patients. von Willebrand factor interaction is impacted by mutations in the *a3* peptide at Tyr1680 and in the C1 residues Tyr2105, Arg2116, Ser2119, and Arg2150, either directly or indirectly. In all these cases, the effect is a reduction of circulating levels of factor VIII protein, which appears otherwise functionally normal, and mild to moderate hemophilia usually results.

In some cases, antigen values are normal, whereas activity values are grossly reduced or undetectable. This finding indicates that, in these patients, hemophilia is caused by generation of a functionally inactive molecule that circulates normally. This small class of missense mutations gives strong clues as to which amino acids or regions are crucial for functional interactions in this molecule, and structure–function relationships have been suggested by several groups based on CRM-positive mutations.[19,152–155]

Because factor VIII can express its procoagulant function only after specific proteolytic cleavages, modifications of the relevant proteolytic sites (e.g., Arg372→Cys/His, Ser373→Pro/Leu, Arg1689→Cys) would severely reduce or even abolish this activity. In fact, these mutations all result in normal circulating factor VIII protein levels with functional activity of 12% or below. Arg1689→His has a milder effect on function, with a mean activity value of 23% from seven reports.

Alternatively, modifying interactions with one of the functionally important ligands of factor VIII (e.g., factor IXa, factor X, phospholipid membrane) by mutation would reduce functional activity. In the case of factor IXa binding, two mutations associated with very low factor VIII activity and normal antigen levels are N-glycosylation variants. Ile566→Thr leads to a new glycosylation site at Asn564, at a factor IXa binding site. Met1772→Thr predicts a new N-glycosylation at Asn1770, also close to a factor IXa binding region. These novel glycosylations appear to hinder the functional association of the two proteins.

Because factor VIIIa instability is mediated by the dissociation of the A2 domain from the A1 and A3 domains, for other variants, amino acid changes impacting the stability of the proteolytically activated heterotrimeric factor VIIIa itself, via the interdomain interfaces, might reduce functional integrity sufficiently to cause clinical disease. Examples have been experimentally confirmed.[156,157]

Approximately one third of all hemophilic missense mutations cause the clinical phenotype by generating a dysfunctional molecule that circulates normally in plasma. The remaining mutations are associated with defective factor VIII secretion or stability.

Small Deletions and Insertions

The mutation database lists both *F8* deletions and the less common insertions. Together they can be termed "indels." *F8* indels have been divided into large and small. In general, large indels involve stretches of hundreds or many thousands of DNA bases, whereas most small indels result from deletion or insertion of a single base.

The database lists 296 individual small deletion reports (defined as smaller than 50 bases deleted), comprising 197 unique small deletions of which approximately 50% are of single bases. Small deletion reports outnumber those of large deletions by 2:1. Overall inhibitor development is lower than expected at 22% of all unique cases, compared to values of approximately 30% for insertion frameshifts and nonsense point mutations.

A small but significant number of small deletion variants occur with high frequency in unrelated families across the world, as seen with some small insertions. Almost all of these multiple reports are of deletions of a single adenine base (A) in a consecutive run of As. For example, there are more than 50 separate reports of an A deletion in a run of nine As at codons 1191-1194, which also is a "hot spot" for single-base insertions. Most patients with this mutation are severely affected, so it is a highly significant cause of disease.

Small deletions are found throughout the factor VIII sequence and generally cause frameshifts followed by chain termination as a result of generation of novel termination signals and a truncated protein product. Almost all are associated with severe disease. However, as also found with small insertions, there are a small number of moderate or mild cases, often associated with "A runs" with predicted truncated protein product. It is postulated that some low-level miscopying in this region results in generation of small amounts of mRNA with the correct wild-type sequence, allowing synthesis of sufficient functional protein to moderate the clinical phenotype.

In a small number of rare in-frame deletions, a multiple of three bases is deleted. Most of these occurrences are predicted to result in deletion of a single amino acid. Some are associated with detectable factor VIII activity and protein, indicating that the deletion has been accommodated in the protein structure. Deletions of two or four amino acids are associated with severe disease.

Insertion events causing hemophilia are much less frequent overall than are deletions (see Table 123–1). An additional difference in the mutation spectrum between the two types of indel events is that large insertions are extremely rare events, unlike large deletions. Of the 144 individual insertion reports in the hemophilia A database, only five feature more than a few bases in total. The dominant group of small insertions are composed of just 75 unique insertion events, the vast majority of which are less than 10 bp in length. Insertions of an additional adenine base at the site of a run of adenines accounts for most of the repetitious reports, for example, more than 27 separate unrelated cases of insertion of an A into a run of eight As at codons 1439-1441, and another 14 cases of insertion of A into a run of nine As at codons 1191-1194. Runs of As in the *F8* cDNA are relatively common, and these insertions, and small deletions at the same loci, are thought to result from uncorrected DNA polymerase slippage during replication.

The vast majority of insertions cause frameshifts and result in severe hemophilia (see Table 123–1). However, similar to the situation with small deletions, a small number of "A-run" insertion cases are associated with low but measurable factor VIII activity levels and only moderate clinical severity. This situation probably is the result of a small percentage of normal mRNA molecules being produced by "corrective" slippage errors on the mutant template during transcription.

Promoter Mutations

Mutations in the 5′ flanking sequence of the *F8* gene responsible for hemophilia A are extremely rare. Only two sequence variants in this region have been identified, both associated with mild bleeding phenotypes. One patient was asymptomatic until age 53 years, when he suffered abdominal bleeding while undergoing anticoagulation therapy for heart insufficiency. The other patient had no spontaneous bleeding into joints and muscles but suffered bleeding complications only after surgery.[158] The functional consequences of these mutations are not fully characterized.

Clinical Aspects

Inhibitors and Gene Deletions

The presence of a severe gene lesion preventing factor VIII expression is strongly associated with the development of alloantibodies to factor VIII introduced via replacement therapy. The most severe gene lesions affecting *F8* are large deletions, and patients with this genotype very frequently develop inhibitors. Of 98 patients with deletions larger than 50 bp, 44 had inhibitors (45%). This is a higher percentage than for any other class of gene lesion[151] but still not a predictable event, perhaps because intravenous infusion is a weak route to immunization in the absence of adjuvant, and the infused material will bind to its natural carrier vWF, which is present at normal levels in the circulation of the recipient.

Carrier Detection and Antenatal Diagnosis

For every affected male with an X-linked recessive disorder in the population there are approximately two carriers of the disease. However, the number of putative carriers related to a case likely is at least double that figure and often much higher, although the prior risk of being a carrier decreases with genetic distance from the proband. In practice this works out to approximately five females requesting carrier determination for every affected male in a static population.

Prior to the era of widespread gene sequencing, the first step in carrier detection was to estimate the ratio of plasma factor VIII activity to vWF antigen. The mean for noncarrier females is a ratio of 1.0, whereas the mean for carriers of hemophilia A is 0.5. There is wide individual variation in this ratio due to random X inactivation, but performing this phenotypic test still is clinically useful and important because a proportion of carrier females have sufficiently low factor VIII levels to be classified as bleeding carriers, with the phenotype of mild hemophilia. Rarely as a result of processes that interfere with X inactivation of the mutation-bearing allele, girls with severe hemophilia are born. Another potentially confusing factor in the interpretation of factor VIII : vWF ratios is the presence of a von Willebrand disease allele segregating in the same kindred as one affected by hemophilia A (Fig. 123–5).

The next step in carrier status determination uses linkage markers; a highly informative set located within *F8* is available.[159] Combination of the dinucleotide repeat polymorphisms in introns 13 and 22 with single nucleotide polymorphisms in introns 18 and 22 gives heterozygosity and therefore useful information in approximately 90% of carriers in most populations from diverse ethnic groups. Therefore, linkage analysis is uninformative for approximately 10% of families. It now is common practice to perform direct mutation detection by sequencing to track the disease allele in hemophilia A families. Other reasons for using this approach are that issues of paternity are circumvented, intermediate family members are not required to conclusively demonstrate linkage, and the mutation itself can provide useful information about clinical phenotype when it is not known from the affected relative. If the potential carrier herself is the only available member of the kindred and if she is heterozygous for a known or plausible novel mutation in her *F8* gene, her status is at once resolved (see Fig. 123–5). In approximately 2% of cases of severe and moderate hemophilia A, no mutation can be found in the coding regions usually sequenced. Linkage then is the only method available for carrier determination.

Antenatal diagnosis is offered to carriers of hemophilia A based on direct mutation analysis or on linkage analysis if the mutation is not known from DNA extracted from a chorionic villus sample taken at approximately 12 weeks of gestation. Before then, determining whether the conceptus is male or female is possible by noninvasive testing of maternal blood Y chromosome DNA at approximately 10 weeks. If the conceptus is female, then chorionic villus sampling with its risk of pregnancy loss (≈1% in experienced centers) is not needed. Preimplantation diagnosis of hemophilia has been successfully demonstrated with selection of embryos for transfer that are not affected.[160]

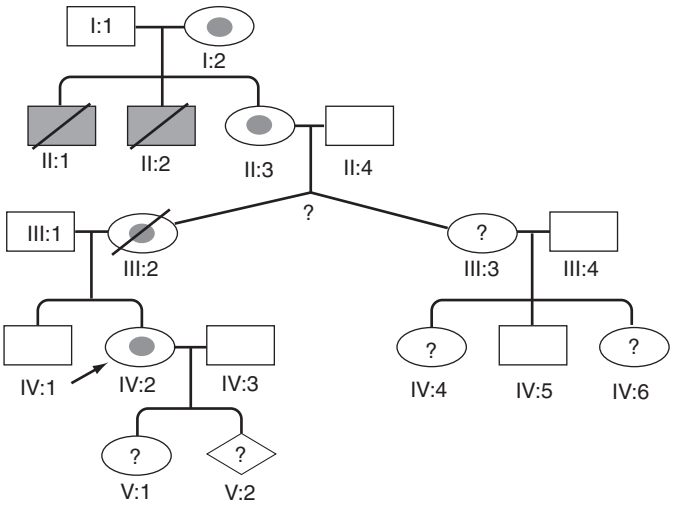

Figure 123–5 Sequencing the *F8* gene to correct diagnosis in a hemophilia A carrier. The proband (IV:2, arrow) was recalled for reevaluation of her original diagnosis of mild von Willebrand disease. Review of her family tree and phenotypic data (two antecedent males died of bleeding; factor VIII activity 33 IU/mL; von Willebrand factor antigen 63 IU/mL) suggested that she had been misclassified and that she might be a hemophilia A carrier. Sequencing of her *F8* gene showed her to be heterozygous for Arg372→Cys, a known cause of moderately severe hemophilia A. Although pregnant and carrying a male conceptus (according to Y chromosome analysis of maternal blood), she elected to continue the pregnancy and to be managed at delivery with appropriate precautions for the possibility of an affected infant. Because it now is clear that her mother was an obligate carrier, the surviving twin sister (III:3) almost certainly is a carrier (they were said to be identical), and her two daughters (IV:4 and IV:6) also are putative carriers as is the proband's daughter (V:1). Of note, both male relatives died of bleeding at a young age, and no DNA was available from them. Hence, sequencing of the putative carrier's *F8* gene was the only option for resolution of both the diagnosis and the inheritance in this family. The question mark indicates status is unconfirmed.

CHAPTER 124

BIOCHEMISTRY OF FACTOR IX AND MOLECULAR BIOLOGY OF HEMOPHILIA B

David A. Roth, Steven J. Freedman, and Bruce Furie

Factor IX is a plasma protein with a molecular weight of 56,000. Synthesis of factor IX by the liver requires vitamin K. Factor IX participates in an intermediate phase of the blood coagulation pathway (see Chapter 118). Activated factor XI (factor XIa) or activated factor VII (factor VIIa) complexed with tissue factor can activate factor IX. In complex with factor VIIIa on membrane surfaces, activated factor IX (factor IXa) then activates factor X. The critical importance of factor IX is emphasized by the phenotype of hemophilia B, a hereditary disease characterized by factor IX deficiency.

In 1952, factor IX was discovered to be distinct from factor VIII by the observation that the clotting time corrected after mixing the plasmas from two unrelated patients with hemophilia.[1,2] Hemophilia B, or Christmas disease, is an X-linked disorder defined by a hereditary decrease in factor IX activity. The molecular defect leading to factor IX deficiency in the index patient has been shown to be a point mutation, with a substitution of Cys206 to serine in the catalytic domain.[3] Hemophilia B accounts for approximately 12% of the total cases of hemophilia. The disease is variable in phenotype, and the degree of bleeding severity usually correlates with the level of factor IX activity present in the patient's plasma. As anticipated from the variable phenotypes of hemophilia B and the similarity of phenotypes within each particular family, hemophilia B is caused by a variety of genetic defects. It is estimated that one third of cases of hemophilia B arise from spontaneous mutations.

GENE STRUCTURE AND REGULATION

The factor IX gene is located on the tip of the long arm of chromosome X at Xq27.1,[4] close to the factor VIII gene. The gene is 34 kb in size and was derived ancestrally from a precursor of the prothrombin gene, like other genes encoding vitamin K-dependent proteins.[5] The factor IX gene contains eight exons (Fig. 124–1), which range in size between 25 and 1935 nucleotides, and seven introns, which range in size from 188 to 9473 nucleotides. The messenger RNA (mRNA) comprises a 205-base pair (bp) 5′ untranslated region, a 1383-bp preprofactor IX region that encodes for a 461-amino-acid precursor protein, and a 1392-bp 3′ untranslated region.[6–8] Exons I, II, and III encode the prepro leader sequence, the γ-carboxyglutamic acid (Gla) domain, and the aromatic amino acid stack domain. Exons IV and V encode the two consecutive epidermal growth factor (EGF)-like domains. Exons VI, VII, and VIII encode the activation peptide and the serine protease catalytic domain.

Regulation of the factor IX gene is mediated by elements in the 5′ untranslated region, intron sequences, and the 3′ untranslated region. The 5′ proximal region extending to −270 contains the minimal promoter sequence required for maximal factor IX expression.[9,10] Multiple promoters exist within this region, including a CAAT box at −238 and a TATA box at −181.[11,12] A transcription start site has been defined at approximately −176.[9] Multiple negative regulatory elements (silencers) that suppress gene expression exist upstream of −416. One such silencer consists of a promoter (−766 to −417) oriented in the reverse direction of the factor IX promoter activity.[12] Experiments using transgenic mice indicate that the introns of factor IX are required for its expression in vivo.[13] Furthermore, expression vectors that include the first intron of the factor IX gene produce sevenfold to ninefold higher levels of mRNA than vectors lacking this sequence.[14] The 3′ untranslated region contains polyadenylation signal sequences that are important in normal gene expression. A 653-bp deletion of this region has been found in a mild form of hemophilia B.[15]

Factor IX levels increase with age.[16] Longitudinal analysis of human factor IX gene expression patterns in transgenic mice identified two *cis*-acting elements that control age-dependent levels of circulating factor IX.[17] AE5′ (age-regulatory element in the 5′ end) resides between −770 and −802 of the 5′ untranslated region and is responsible for age-stable expression of the human factor IX gene. The other element, AE3′, is found in the middle of the 3′ untranslated region and causes age-associated increases in factor IX, most likely by stabilizing factor IX mRNA.

Factor IX Leyden is a form of hemophilia B characterized by a severe bleeding disorder during childhood; factor IX activity and antigen levels are less than 1%.[18] With the onset of puberty or with the administration of androgen therapy,[19] factor IX levels rise to 30% to 60% of normal, and the hemophilia phenotype disappears (Fig. 124–2). In normal individuals, factor IX levels increase modestly after puberty.[20] Analysis of factor IX genes from patients with various pedigrees with the factor IX Leyden phenotype demonstrated 11 unique point mutations clustered in a region between nucleotides −40 to +20.[11] A transgenic mouse with a mutation at +13 in the factor IX promoter shows age-dependent, male-specific expression of factor IX, mimicking the factor IX Leyden phenotype.[21] Several transcription factors that bind within or immediately upstream of the factor IX Leyden promoter region have been identified.[11,22,23] For example, CCAAT/enhancer-binding protein binds between +1 and +18,[22] and hepatic nuclear factor 4 binds between −19 and −27.[24,25] CCAAT/enhancer-binding protein α and Ets factor GA-binding protein (GABPα/β) bind between −195 and −220, which lies upstream of the Leyden promoter region.[26] Binding of these two transcription factors enhances transactivation of the factor IX gene by two proline- and acidic-amino-acid-rich (PAR) proteins, D-site-binding protein and hepatic leukemia factor.[26,27] Studies have also demonstrated transcriptional activation of the factor IX gene after cotransfection of hepatocytes with the androgen receptor and the CCAAT/enhancer binding protein, and androgen receptor binding to the proximal factor IX promoter was disrupted by mutation at nucleotide −26.[28] Levels of many of these transcription factors rise at different time points during development. Thus, they may play an important role in the developmental expression of the factor IX gene through wild-type and factor IX Leyden promoters.

SYNTHESIS OF FACTOR IX

Factor IX is synthesized in the hepatocyte as a precursor protein. It then undergoes a series of intracellular posttranslational modifications and is secreted as a zymogen (Fig. 124–3). The coding sequence of the factor IX gene encodes two peptides that are removed prior to secretion of the mature factor IX into the blood: a 28-residue signal peptide that directs the nascent peptide chain to the endoplasmic reticulum and an 18-residue propeptide between the signal peptide and the mature amino terminus of factor IX.[8] The signal peptide is cleaved cotranslationally by the signal peptidase. The propeptide contains the γ-carboxylation recognition site that directs

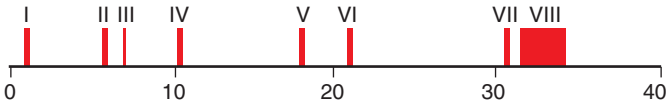

Figure 124–1 Structure of the factor IX gene and encoded factor IX domains. The factor IX gene includes eight exons and seven introns. Exons 1 to 8 are represented as solid bars and designated with roman numerals I to VIII.

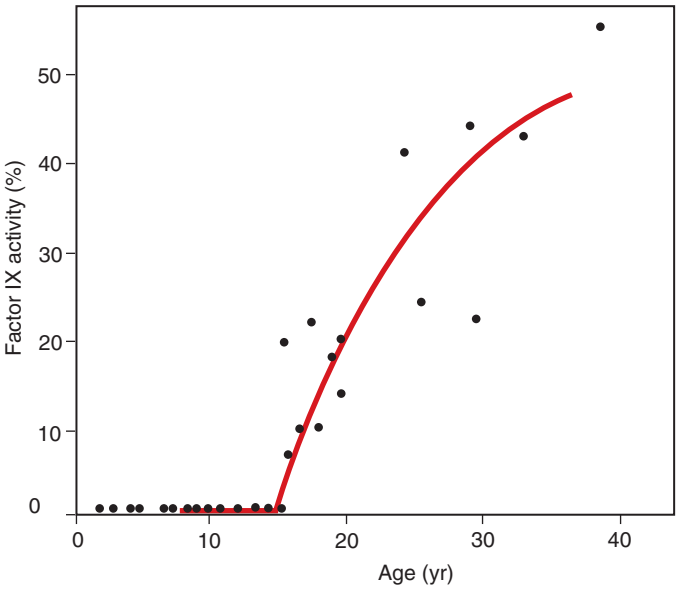

Figure 124–2 Factor IX Leyden. Changes in the plasma factor IX level as a function of age. (From Briet E, Bertina RM, van Tilburg NH, Veltkamp JJ: Hemophilia B Leyden: A sex-linked hereditary disorder that improves after puberty. N Engl J Med 306:788, 1982.)

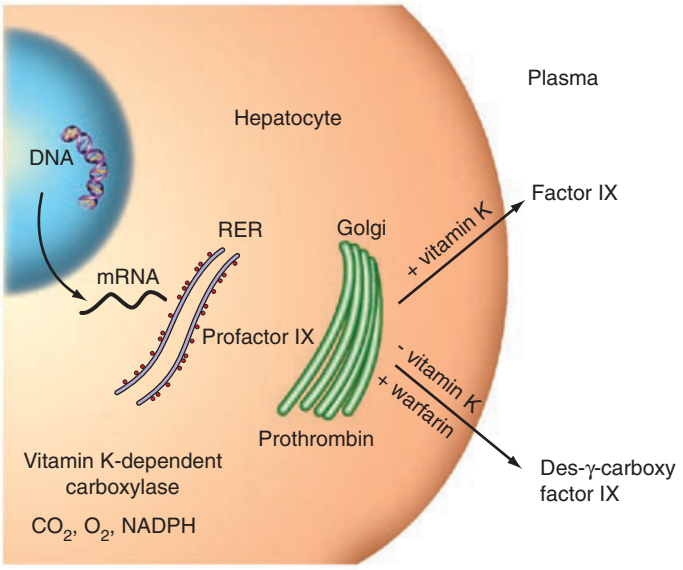

Figure 124–3 Biosynthesis of factor IX. Factor IX is synthesized in the liver in a precursor form. The signal peptide is responsible for translocation of the nascent peptide chain to the endoplasmic reticulum. Profactor IX undergoes posttranslational processing, including γ carboxylation, glycosylation, β hydroxylation, disulfide bond formation, and propeptide cleavage. γ Carboxylation requires molecular oxygen, reduced vitamin K, and carbon dioxide in the presence of the vitamin K-dependent γ carboxylase.

γ carboxylation of the adjacent glutamic acid residues in the Gla domain of mature factor IX.[29] This recognition element is defined by amino acids −18, −17, −16, −14, and −10 toward the amino terminus of this region.[30] The vitamin K-dependent carboxylase binds to the γ-carboxylation recognition site within the propeptide.[29–32] The carboxylation reaction, catalyzed by the carboxylase, requires a reduced form of vitamin K (vitamin KH_2), molecular oxygen, carbon dioxide, and the factor IX precursor uncarboxylated profactor IX, which contains glutamic acid residues.[33] The carboxylase is an enzyme with a molecular weight of 94,000 that is sufficient to carboxylate a precursor substrate in the presence of the necessary cofactors.[34–37] The carboxylase is a membrane protein, and its catalytic activity resides on the luminal side of the rough endoplasmic reticulum.[38,39] Multiple glutamic acids are carboxylated within a single precursor upon interaction with the carboxylase.[40] The Gla residues bind calcium, and this in turn facilitates membrane binding by factor IX and factor IXa.

Aspartic acid 64 within the first EGF-like domain undergoes β hydroxylation in the rough endoplasmic reticulum. From the cDNA sequences of factor IX,[7,8] factor X,[41] protein C,[42,43] protein S,[44] and factor VII,[45] it is apparent that specific aspartic acid residues in precursor forms of these proteins undergo β hydroxylation posttranslationally. Stenflo et al.[46] suggest that a consensus sequence consisting of Cys-X-Asp/Asn-X-X-X-Phe/Tyr-X-Cys-X-Cys signals this event. Factor IX contains approximately 0.4 moles of β-hydroxyaspartic acid per mole of factor IX.[47,48] This modified amino acid is formed from aspartic acid by a posttranslational process catalyzed by the α-ketoglutarate–dependent dioxygenase[49] aspartyl β-hydroxylase.[50,51] Mutants lacking Asp64 have decreased calcium binding, which suggests that β-hydroxyaspartic acid is involved in calcium binding. However, detailed studies using nuclear magnetic resonance spectroscopy failed to show a significant difference in calcium binding between β-hydroxylated and non–β-hydroxylated factor IX peptides.[52] Furthermore, recombinant factor IX expressed in the presence of dipyridyl, *o*-phenanthroline, or pyridine 2,4-dicarboxylate, which are inhibitors of 2-ketoglutarate–dependent dioxygenases, retains full activity.[53] These data are consistent with the hypothesis that Asp64 is required for full functional activity, but β hydroxylation is not.

Bovine and human factor IX are glycoproteins that contain approximately 17% carbohydrate by weight. The first EGF-like domain is glycosylated at two *O*-linked glycosylation sites. Xyl α(1 → 3) Glcβ1 → *O*-Ser and Xyl α(1 → 3) Xyl α(1 → 3) Glcβ1 → *O*-Ser saccharides are glycosidically linked to Ser53.[54] A tetrasaccharide NeuAc α(2 → 6) Gal β(1 → 4) GluNAc β(1 → 3) Fucα1 → *O*-Ser is linked to Ser61.[55–57] A putative UDP-glucose:protein *O*-glucosyltransferase that makes *O*-glucose modifications in EGF repeats has been identified.[58] A second heavily glycosylated portion of factor IX is the activation peptide (Ala146-Arg180). It is glycosylated at two *N*-linked and two *O*-linked glycosylation sites.[59] Asn157 and Asn167 are fully glycosylated. Thr159 and Thr169 are partially glycosylated. Additional posttranslation modifications including sulfation of Tyr155 and phosphorylation of Ser158 have been identified. Although these modifications on factor IX have no effect on specific coagulant activity, tyrosine sulfation may influence in vivo recovery of factor IX.[60]

Profactor IX, including the propeptide and factor IX sequence, undergoes carboxylation in the endoplasmic reticulum. Profactor IX, even in its fully carboxylated form and in contradistinction to factor IX, is not capable of binding to membrane surfaces.[61] Presumably this property prevents factor IX from being retained inside the cell, where high levels of calcium ions within the endoplasmic reticulum could support factor IX–membrane interaction. Profactor IX undergoes additional posttranslational processing, including disulfide bond formation and glycosylation, characteristic of other secreted plasma proteins. The propeptide is cleaved as a late processing event.[8,62,63] Furin or a furin-like converting enzyme cleaves peptide

bonds at a site adjacent to the sequence RXRR, where X can be any amino acid and R is arginine.[64] Bristol et al.[65] used site-directed mutagenesis to define a hierarchy of the efficiency of cleavage given different paired amino acids at the P1 and P2 positions: Lys-Arg > Arg-Arg > Thr-Arg > Arg-Lys > Lys-Lys >> Lys-Thr. γ Carboxylation precedes propeptide cleavage.[65]

The carboxyl terminus of factor IX contributes to intracellular factor IX stability and cellular secretion. Mutant factor IX with substitutions in amino acids 403 to 415 are degraded and secreted only at low levels when expressed in a hepatoma cell line.[66] Addition of proteosome inhibitors to this system leads to increased intracellular mutant factor IX concentrations and recovery of factor IX secretion.[66] Consistent with these observations, naturally occurring mutations in the carboxyl terminus of factor IX lead to hemophilia B with severely depressed factor IX protein levels in the plasma.[67]

STRUCTURE OF FACTOR IX

Human factor IX is a single-chain glycoprotein composed of 415 amino acids (Fig. 124–4).[7,8,68] It has a molecular weight of 56,000.[69,70] Factor IXa is composed of a light chain of molecular weight 18,000 and a heavy chain of molecular weight 28,000.[71] The structure of porcine factor IX has been determined by x-ray crystallography in the absence of calcium ions.[72] The protein resembles a tulip in which the amino terminal Gla domain represents the bulb, the two EGF domains represent the stalk, and the catalytic domain represents the flower (Fig. 124–5).

PROPEPTIDE

The propeptide directs γ carboxylation of profactor IX and then is cleaved to yield factor IX. The propeptide includes an amphipathic α helix with a hydrophobic face and a hydrophilic face.[73] The carboxylation recognition site is located proximal to this helix. This recognition site binds the amino-terminal third of the carboxylase.[74,75] Curiously, the propeptide also interacts with a region of the carboxylase having sequence homology to itself. This region of the carboxylase between residues 495 and 513 has been named the "internal propeptide."[74,76,77] Mutations in the propeptide have been documented as the cause of some forms of hemophilia B. Diuguid et al.[62] determined the size of the propeptide of factor IX by analysis of a mutant factor IX, factor IX Cambridge. This mutant has an 18-residue amino-terminal extension due to mutation of Arg–1 to a serine, precluding propeptide cleavage by the propeptidase furin. Concurrently, Bentley et al.[63] evaluated factor IX Oxford 3, a mutant factor IX in which Arg–4 is mutated to glutamine; this mutation also prevents propeptide cleavage. Similar mutations have been described, each characterized by the complete absence of factor IX activity and the presence of the 18-residue propeptide extension.[78–81] Of the several proteins studied,[62,78,82,83] there is a partial defect in γ carboxylation of factor IX. Because of the failure of propeptide cleavage, these profactor IX mutants cannot bind to phospholipid vesicles, nor can they be activated by factor XIa. In fact, the propeptide prevents binding of profactor IX to membranes even if profactor IX is fully carboxylated.[61] These data and the marked sequence homology of this domain in Gla-containing proteins led to the proposal that the propeptide participates in γ carboxylation.[84] Using site-specific mutagenesis and a heterologous mammalian expression system, Jorgensen et al.[29] and Rabiet et al.[48] demonstrated that factor IX lacking the 18-residue propeptide was not carboxylated in vivo. Similarly, point mutations at −16 (Phe → Ala) or −10 (Ala → Glu), both positions highly conserved in the propeptides of the vitamin K-dependent proteins, inhibited γ carboxylation. These results demonstrated that the propeptide contains a recognition element, designated the γ-carboxylation recognition site, that signals γ carboxylation of vitamin K-dependent proteins during hepatic biosynthesis. The propeptide is sufficient to direct γ carboxylation when engineered immediately amino terminal to an unrelated glutamic acid-rich region of prothrombin.[85]

γ-Carboxyglutamic Acid Domain

The amino-terminal Gla domain of human factor IX includes 12 Gla residues, located at positions 7, 8, 15, 17, 20, 21, 26, 27, 30, 33, 36, and 40.[86,87] The Gla domain defines some of the critical calcium-binding sites of the protein and is required for the interaction of factor IX with membrane surfaces in the presence of calcium ions.[88] At present, naturally occurring mutations have been described for nine of the 12 Gla residues. Patients with these mutations have moderate to severe hemophilia, an observation emphasizing the functional importance of these residues.[67] In contrast, factor IX, which lacks Gla36 and Gla40, Gla residues that are not found in other vitamin K-dependent blood coagulation proteins, maintains full function.[89,90] In the absence of calcium, the Gla domain consists of three well-defined structural elements linked by a flexible polypeptide backbone.[90] The three structural elements are a short amino-terminal ω loop (residues 6–9), a hexapeptide loop formed by a disulfide bridge between cysteines 18 and 23, and a carboxyl-terminal α helix (residues 37–46). The hexapeptide loop is essential for factor IX function, as evidenced by the fact that factor IX Zutphen (Cys18 → Arg) cannot form the Ca^{2+}-dependent conformation and results in severe hemophilia.[91] When bound with calcium, the Gla domain folds in a manner that exposes the ω-loop–containing hydrophobic residues Leu6 and Phe9 on the surface. This region forms at least part of the phospholipid-binding site in factor IX (see Membrane-Binding Properties below).[92,93] The Gla domain also interacts directly with the light chain of factor VIII.[94]

EPIDERMAL GROWTH FACTOR-LIKE DOMAINS

Two consecutive EGF-like domains bridge the amino-terminal Gla domain/aromatic amino acid stack and the carboxyl-terminal serine protease domain in factor IXa. The EGF domains are approximately 50 amino acids long and have three conserved disulfide bonds. The three-dimensional structures of these domains closely resemble that of other EGF domains and contain two antiparallel β sheets.[72,95,96] The carboxyl-terminal end of the first EGF domain fills a hydrophobic pocket at the amino-terminal end of the second EGF domain.[97] Only the first of the two EGF domains binds calcium ions and provides one of two high-affinity calcium-binding sites outside of the Gla domain.[96] The other high-affinity calcium-binding site resides in the serine protease domain.[98] The importance of this calcium-binding site for factor IX function is illustrated by mutations of Asp47 and Asp64 (factor IX Alabama) that disrupt calcium binding and cause hemophilia B.[99–102] Engineered mutations of Asp64 have widespread effects on factor IXa function, including assembly into the tenase complex and enzymatic activity for its substrate factor X.[103]

Analysis of EGF peptides and mutants helps to define the function of these domains in factor IX and factor IXa. The isolated first EGF domain inhibits factor Xa generation by intact factor IXa in the presence or absence of factor VIIIa, and it can be directly cross-linked to Gla domainless factor X.[104,105] Alanine scanning mutagenesis of the second EGF domain shows that residues 102 to 108 bind factor X.[106] Data using EGF chimeras, deletions, and point mutants indicate that the first EGF domain directly interacts with tissue factor in the factor VIIa/tissue factor complex.[107,108] Mutation of Gly48 → Arg in factor IX Tainan and factor IX Malmo are poorly activated by factor VIIa/tissue factor.[109] Substitution of Arg94 in the second EGF domain with a serine, a naturally occurring hemophilia B defect, introduces an *O*-linked carbohydrate that attenuates factor IX activation by both factor XIa and the factor VIIa/tissue factor complex.[110] Alanine scanning mutagenesis of the second EGF domain shows that residues 89 to 93 are involved in factor VIIIa binding. In contrast, studies with factor IX chimeras in which the first EGF domain is replaced with the first EGF domain of other coagulation proteins suggest that this region does not interact with factor VIIIa.[111,112] However, Asp64 mutations in factor IX affect binding to the factor VIII light chain.[113] Thus, both EGF domains are involved in protein–protein

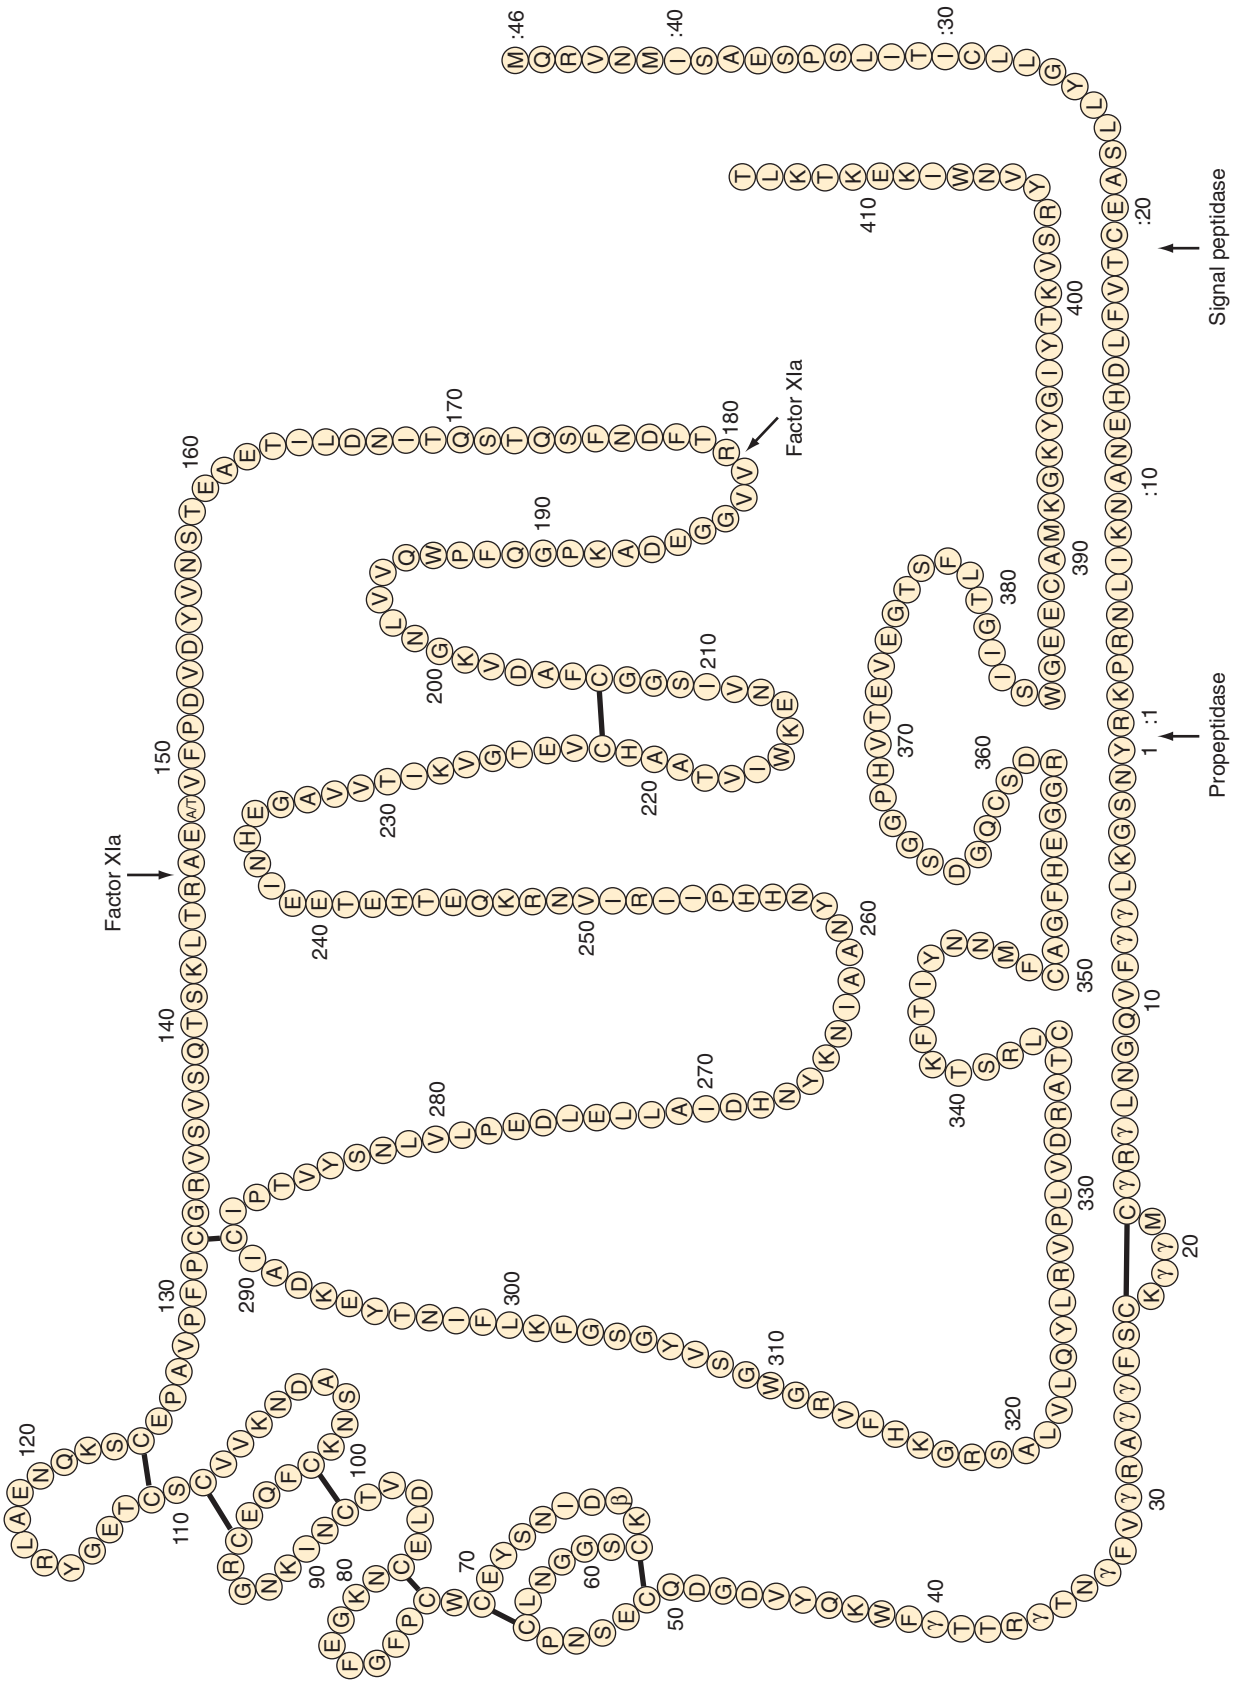

Figure 124–4 Amino acid sequence of factor IX. The preprofactor IX sequence includes the signal peptide, propeptide, γ-carboxyglutamic acid domain, aromatic amino acid stack domain, two EGF domains, and the serine protease domain. Amino acids are designated by the one-letter code. β, β-hydroxyaspartic acid; γ, γ-carboxyglutamic acid; EGF, epidermal growth factor.

The cysteines of the hexapeptide disulfide loop, residues 18 and 23, are labeled by residue number, and the disulfide bond is indicated. The side chains of the conserved aromatic residues of the aromatic amino acid stack domain are displayed and labeled by residue number. EGF 1, first epidermal growth factor-like region; EGF 2, second epidermal growth factor-like region; Gla, γ-carboxy glutamic acid-containing region; NMR, nuclear magnetic resonance; SP, serine protease-containing region.

interactions that contribute to factor IX activation and factor IXa function.

SERINE PROTEASE DOMAIN

The carboxyl-terminal portion of factor IX demonstrates marked sequence homology with zymogens of serine proteases, such as trypsin and chymotrypsin. This region is 235 amino acids long and contains, in latent form, the enzyme active site of factor IXa. The mechanism of factor IX activation involves limited proteolysis through cleavage of two peptide bonds that release the activation peptide between residues Ala146 and Arg180. Consequently, the serine protease domain is within the heavy chain of factor IXa. The enzyme active site is common to all serine proteases and contains the enzymatic machinery for the hydrolysis of peptide bonds. The classic catalytic triad is composed of factor IXa residues His221, Asp269, and Ser365. An extended substrate-binding site surrounds the active site and defines the high substrate specificity of factor IXa for protein substrates.[114]

CALCIUM-BINDING PROPERTIES

Factor IX binds to metal ions. As with the other vitamin K-dependent proteins, there are two classes of metal-binding sites: high affinity and low affinity.[114,115] Occupation of these two classes of metal-binding sites leads to two sequential conformational changes in these proteins.[116,117] The first conformational change can be induced by calcium, magnesium, and many other divalent cations. The second conformational change is induced only by calcium ions. Fab fragments of conformation-specific antibodies, directed against factor IX after it has undergone the conformational transition that is calcium ion selective, block the binding of factor IX to phospholipid vesicles and the activation of factor IX by factor XIa. These findings suggest that the conformer achieved only in the presence of calcium is necessary for expression of a phospholipid-binding site and for binding of factor IX by factor XIa.[117]

The binding of calcium to the Gla domain involves formation of an internal calcium-binding pocket formed by the amino-terminal nine Gla residues. The binding results in the formation of a calcium-carboxylate network with an exposed amino-terminal hydrophobic loop.[92,93] The crystal structure of the factor IX Gla domain shows that six calcium ions are coordinated by Gla residues. However, it is possible that other calcium ions bind to low-affinity sites not detectable by x-ray crystallography. The binding of calcium to the first EGF-like domain is mediated by a consensus sequence including Asp47, Asp49, Gln50, Asp64, and Tyr69. Asp47, Gln50, and Asp64 residues interact directly with calcium.[97,99,104] Astermark et al.[118] demonstrated that the individual Gla and EGF domains bind calcium ions, but the intact Gla–EGF domain unit binds calcium ions with even higher affinity. Another high-affinity calcium-binding site in the heavy chain of factor IX involving residues 235, 237, 240, and 245 has been described.[98]

MEMBRANE-BINDING PROPERTIES

The interaction of factor IX and factor IXa with phospholipid membranes has been studied using phospholipid vesicles.[101] Factor IX affinity for phosphatidylcholine-phosphatidylserine membranes is independent of the phosphatidylserine concentration above 20% to 30%.[119] K_d of approximately 1 to 2 μM has been measured. Factor IX binds to vesicles in the presence of Ca^{2+} but not in the presence of Mg^{2+} or ethylenediaminetetraacetic acid (EDTA). Furthermore, des-γ-carboxy factor IX does not interact with phospholipid vesicles, even in the presence of Ca^{2+}. These results emphasize the importance of the Gla domain in defining phospholipid-binding properties. Several lines of experimental evidence indicate that the amino-terminal region of the Gla domain is the phospholipid-binding site (Fig. 124–6). First, Leu6 and Phe9 form a hydrophobic surface patch as demonstrated in the human factor IX Gla domain solution and crystal structures.[92,93] Second, these residues can be directly cross-linked to phospholipids.[120] Third, the Mg^{2+}-coordinated Gla domain, which does not bind phospholipid membranes, lacks a well-ordered hydrophobic surface patch.[120] Fourth, this patch is part of the epitope for an antifactor IX antibody that inhibits phospholipid binding.[93] Finally, and most convincingly, the homologous region in the prothrombin : Ca^{2+}: phosphoplipid ternary complex crystal structure directly interacts with phospholipid membranes.[121] Other structural

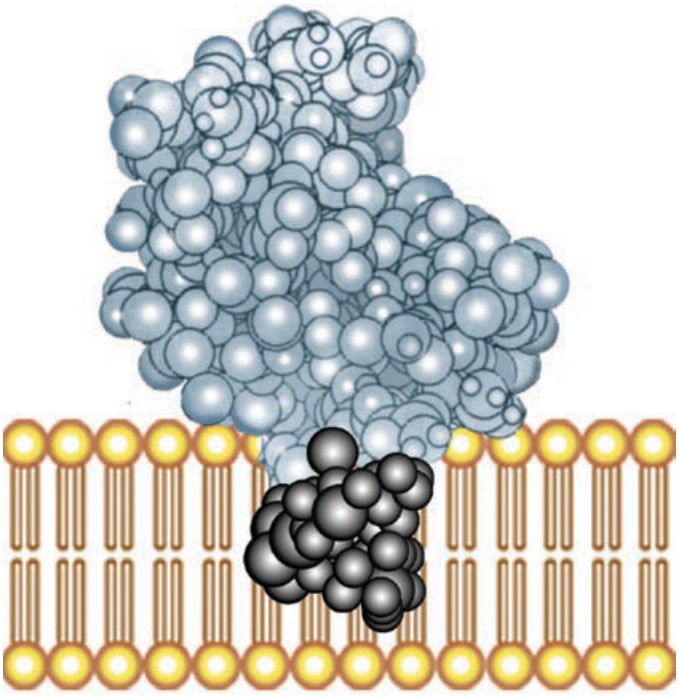

Figure 124–6 Model of the interaction of factor IX and phospholipid membrane. The hydrophobic residues (black) that form the hydrophobic patch in the phospholipid-binding site of factor IX are buried in the phospholipid bilayer. The phosphatidylserine binds specifically through electrostatic interactions with amino acid side chains of the γ-carboxyglutamic acid (Gla) domain.

similarities between factor IX and prothrombin interactions with phospholipid membranes may be present.

Factors IX and factor IXa bind to bovine aortic endothelial cells and compete for the same site.[122–124] K_d binding constants ranging between 127 pM and 7.4 nM have been reported. Factor IXa binding to endothelial cells is greater in the presence of both factor VIII and factor X.[125] Interaction of factor IX with endothelial cells is inhibited by a Gla peptide corresponding to residues 1 to 42 of factor IX.[126] K_i for this interaction is approximately 0.05 μM. A chimeric protein in which the Gla domain of protein C is replaced with that of factor IX is able to bind endothelial cells.[127] These results suggest that the endothelial binding site resides within the Gla domain. More specifically, factor VII can be converted to a protein that binds endothelial cells if Gla domain residues 3 to 11 are replaced with those of factor IX.[128] However, Gla peptides corresponding to residues 1 to 14 and 1 to 24 do not compete with intact factor IX for binding to endothelial cells.[129] Because purified natural variants of factor IX with mutations within the hydrophobic stack domain or the first EGF-like domain do not compete effectively with wild-type factor IX for binding to endothelial cells, the functional integrity of the Gla domain in the interaction with endothelial cells depends on these regions.[130] Interestingly, factor IX can bind to collagen IV with K_d of 6.8 nM, which approximates the binding affinity of factor IX to endothelial cells.[124] In this study, mutant factor IX containing Lys5 → Ala or Val10 → Lys could not compete with wild-type factor IX binding to collagen IV. Further support for collagen IV as the endothelial cell-binding site is provided by data by Gui et al.,[131] who showed that factor IX binds to endothelial cell collagen IV surfaces in vivo.

Activated platelets, but not resting platelets, bind factors IX and IXa.[132,133] Factor IX and factor IXa have some common binding sites on activated platelets. There are 250 to 300 sites per platelet for factor IX and 500 to 600 sites per platelet for factor IXa. The interaction of factor IXa with platelets is mediated at least in part by the Gla domain.[134] A synthetic peptide from residues 4 to 11 in the Gla domain inhibits factor IXa binding to platelets.[135] Studies using chimeras in which the second EGF domain of factor IX/IXa is replaced with the second EGF domain of factor X or factor VII exhibited decreased binding to platelets, suggesting that the second EGF domain plays a role in platelet binding.[136,137] In the presence of saturating concentrations of factors VIIIa and X, the K_d of factor IXa (0.5 nM) binding is five times lower than that of factor IX alone.[138,139]

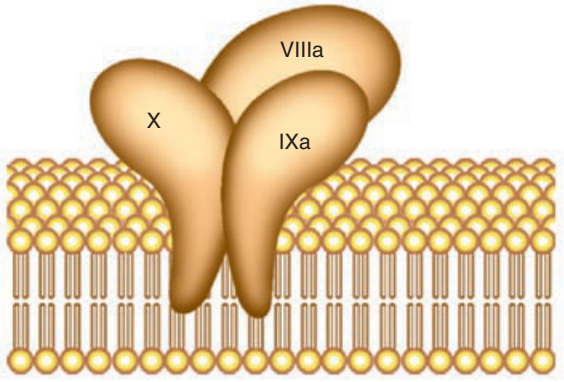

Figure 124–7 Model of the structure of the tenase complex. The tenase complex (the enzyme complex capable of activating factor X to factor Xa) includes factor IXa as enzyme and factor VIIIa as cofactor bound to the membrane surface. The substrate factor X interacts with factor IXa, factor VIIIa, and the membrane.

FORMATION OF THE TENASE COMPLEX

Assembly of factor IXa and factor VIIIa on phospholipid membranes constitutes the tenase complex (Fig. 124–7). Factor IXa and factor VIIIa interact on phospholipid membrane surfaces with a K_d of 2 nM at a 1 : 1 molar stoichiometry.[140] The affinity of factor IXa for factor VIIIa is increased 10-fold in the presence of phospholipid. A specific role for phosphatidylethanolamine in the formation of the tenase complex on phospholipid surfaces has been demonstrated.[141] The rate of bond cleavage (k_{cat}) leading to the formation of factor Xa is increased 1500-fold by the presence of phospholipid.[142] Activation of factor IX to factor IXa leads to the expression of a factor VIII-binding site and active enzyme site with full coagulant activity.[143] Factor VIIIa binds more tightly to factor IXa than does factor VIII.[140] A conformational change in the factor IXa active site is induced by factor VIIIa, thus providing a structural basis for enhancement of factor IXa activity upon cofactor binding.[144]

Factor IX domains are involved in protein–protein interactions that facilitate tenase complex formation. The affinity of a naturally occurring factor IX mutant (Gly12 → Arg) for factor VIIIa is 172-fold less than that for wild-type factor IX, suggesting a role for the Gla domain in formation of the tenase complex.[145] Both EGF domains of factor IXa interact with factor X, and the second EGF domain interacts with factor VIIIa. Helix 330 in the protease domain of factor IXa interacts with residues 558 to 565 in the A2 subunit of factor VIIIa.[146]

ACTIVATION OF FACTOR IX BY THE INTRINSIC PATHWAY

Factor IX is a proenzyme with no catalytic activity. It is activated to factor IXa, formally known as factor IXaβ, by factor XIa in the presence of calcium, or by factor VIIa/tissue factor in a reaction that occurs on a membrane surface and in the presence of calcium (Fig. 124–8). The kinetics of factor IX activation by factor VIIa/tissue

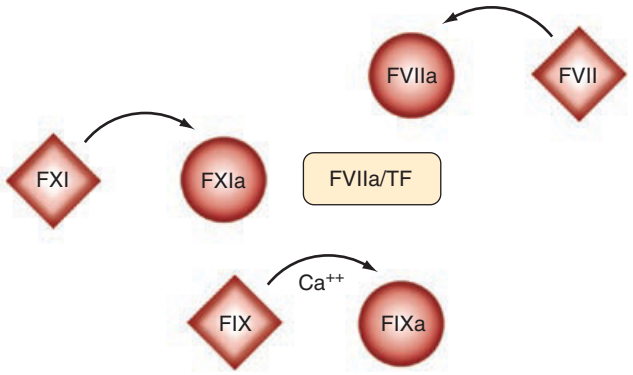

Figure 124–8 Pathways of factor IX activation. Factor IX is activated independently by either factor XIa or factor VIIa/tissue factor. Factor XIa can activate factor IX in the absence of membrane surfaces, but calcium ions are required. The complex of factor VIIa and tissue factor on membrane surfaces in the presence of calcium ions also converts factor IX to its active enzyme form.

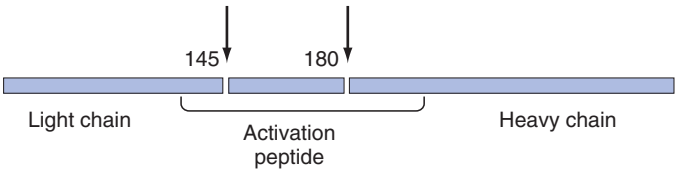

Figure 124–9 Activation of factor IX by limited proteolysis. The zymogen factor IX has no enzymatic activity. Upon cleavage of the peptide bonds adjacent to Arg145and Arg180, enzymatically active factor IXa is generated. Cleavage of these peptide bonds is associated with expression of enzyme activity and a factor VIIIa binding site.

factor and factor XIa are comparable. In contrast to the other vitamin K-dependent blood clotting proteins, membrane surfaces, including phospholipid vesicles or cell surfaces, do not enhance factor IX activation by factor XIa. When factor IX is activated by factor XIa, two peptide bonds are cleaved: one bond located at Arg145-Ala146 and the other bond at Arg180-Val181 (Fig. 124–9).[147] With release of the internal carbohydrate-rich activation fragment (M_r 11,000) from residues 146 to 180, the factor IXa light chain (M_r 17,000) and heavy chain (M_r 28,000) remain bound by a single disulfide bond (see Fig. 124–4). The enzyme active site is located on the heavy chain. Cleavage of factor IX appears to occur via a processive mechanism in which both cleavages are made by factor XIa before factor IXa is produced.[148] The protease from Russell viper venom activates factor IX to factor IXaα by cleaving only the Arg180-Val181 bond.[71]

Factor IX Chapel Hill (Arg145 → His), the first factor IX mutation to be defined at the molecular level, is the prototype of a genetic defect in which activation of a zymogen is impaired due to the mutation of an arginine preceding a sessile bond.[138] It has minimal coagulant activity.[100] Factors IX Chicago-2 (Arg145 → His)[139] and factor IX Albuquerque (Arg145 → Cys)[149] have mutations at the same site. In both of these mutations, loss of the arginine at position 145 precludes cleavage of the sessile bond separating the factor IX light chain from the activation peptide. Failure to cleave this bond, but normal cleavage of the Arg180-Val181 bond, produces factor IXaα, which activates factor X very slowly. The active site of factor IXa is formed, however, as demonstrated by its ability to cleave synthetic substrates normally.[150] Cleavage of the Arg145-Ala146 bond exposes a binding site for factor VIIIa. Conversely, factor IXα, an intermediate with a cleaved Arg145-Ala146 bond but a noncleaved Arg180-Val181 bond, binds factor VIII normally but cannot generate factor Xa from factor X.[151] Factor IX mutants at position 180 include factor IX Hilo (Arg180 → Gln), factor IX Milano (Arg180 → Gln), factor IX Deventer (Arg180 → Trp), and factor IX Nagoya (Arg180 → Trp), all of which result in hemophilia Bm, a type of hemophilia in which the patient's mutant factor IX causes a marked prolongation of the ox brain prothrombin time. This phenotype results because factor IX Bm variants are more effective inhibitors of the factor VIIa/tissue factor complex-induced activation of factor X than is wild-type factor IX.[152,153] Factor IX Novara (Val181 → Phe)[153] and factor IX Tokyo (Val182 → Ala)[154] also result in the hemophilia Bm phenotype, whereas factor IX Kashihara (Val182 → Phe) results in hemophilia B.[155,156]

Activation of factor IX by factor XIa is highly metal selective, with optimal activation only in the presence of Ca^{2+} and suboptimal activation in the presence of Sr^{2+}.[103,157] K_m for activation of factor IX by factor XIa without calcium is 18 μM, and k_{cat} is 2.4 min^{-1}. In the presence of calcium, K_m is decreased to 2 μM, and k_{cat} is increased to 10.4 min^{-1}.[158,159] Although the proteolytic activity of factor XIa is present on the light chain, the heavy chain of factor XIa is responsible for Ca^{2+}-dependent acceleration of factor IX activation.[159,160] The region of the factor XIa heavy chain that interacts with factor IX has been localized to residues 134 to 172 in the heavy chain of factor XI.[161] Interestingly, conformation-dependent, Ca^{2+}-specific antifactor IX antibodies, which inhibit phospholipid binding, also inhibit factor IX activation by factor XIa.[116] Based on this observation, it was proposed that the phospholipid-binding site and factor XIa-binding site on factor IX overlap. In support of this hypothesis is the finding that if the factor IX Gla domain, which binds Ca^{2+} and phospholipid, is either decarboxylated or replaced with the factor VII Gla domain in factor IX, then activation by factor XIa is attenuated.[162] Unexpectedly, the isolated Gla domain (residues 1–47), which binds phospholipid and is recognized by conformation-dependent, Ca^{2+}-specific antifactor IX antibodies, did not inhibit factor XIa activation of factor IX.[163] Therefore, the Gla domain is necessary but not sufficient for factor XIa binding. As such, other data implicate a role for the neighboring EGF domain. For example, activation of factor IX New London (Pro50 → Glu) by factor XIa is abnormally slow.[164] Also, a monoclonal antibody directed against the first EGF domain of factor IX inhibits its activation by factor XIa.[165]

ACTIVATION OF FACTOR IX BY THE EXTRINSIC PATHWAY

Factor IX is also activated by factor VIIa and tissue factor (see Fig. 124–8).[142,166] This reaction, which is dependent on calcium ions, is characterized by K_m of 0.3 μM.[167,168] The k_{cat} for this reaction is between 13 and 68 min^{-1}.[167,168] Structure–function studies indicate that both of the factor IX EGF domains may be involved in binding the factor VIIa/tissue factor complex. The relative importance of factor IX activation by factor XIa or the factor VIIa/tissue factor complex was evaluated by measuring the level of the factor IX activation peptide in patients with factor VII and XI deficiencies.[169] A significant reduction in the baseline levels of the factor IX activation peptide was noted in patients with factor VII deficiency but not in patients with factor XI deficiency compared with normal controls. Furthermore, administration of recombinant factor VIIa to patients deficient in factor VII resulted in significant elevations of the factor IX activation peptide.[170] Almus et al.[171] evaluated activation of factors IX and X by the factor VIIa/tissue factor complex in an umbilical vein model. In this system, activation of factors IX and X occurs at the same rate. These studies, along with the observation that patients with factor XI deficiency have variable bleeding, suggest that the factor VIIa/tissue factor complex initiates blood clotting. A revised model for blood coagulation was proposed whereby the factor VIIa/tissue factor complex initiates blood clotting and thrombin activation of factor XI maintains it.[172]

ENZYMATIC ACTIVITY OF FACTOR IXa

Activation of factor X by factor IXa has been evaluated under multiple experimental conditions. Calcium by itself accelerates factor IXa activation of factor X, but it has a more important role in allowing for forma-

tion of the tenase complex on membrane surfaces. The presence of both factor VIIIa and Factor IXa on membrane surfaces greatly accelerates activation of factor X, whereas the presence of only one of these cofactors alone has a minimal effect.[173,174] The k_{cat} for factor X activation by factor IXa in the presence of factor VIIIa but without phospholipid vesicles is 0.058 min^{-1}. The same reaction without factor VIIIa but with phospholipid vesicles has k_{cat} of 0.095 min^{-1}, whereas in the presence of factor VIIIa and phospholipid vesicles the reaction is greatly accelerated, with k_{cat} of 1740 min^{-1}.[132] Activation of factor X by factor IXa is also supported by activated platelets and endothelials cells. The k_{cat} for factor X activation on activated platelets is 1240 min^{-1}, which is very close to the k_{cat} for factor X activation in the presence of phospholipid vesicles. The rate of activation of factor X on endothelial cells is approximately one sixth the rate on activated platelets.[175]

Physiologic inhibitors of factor IXa circulate in plasma. Factor IXa is inhibited by antithrombin III, which forms a 1:1 stoichiometric complex with factor IXa as well as other activated coagulation factors. This reaction is accelerated approximately 1000-fold by the addition of heparin.[176–179] Some factor IX Bm variants with mutations at the amino terminus of the heavy chain or within the catalytic domain are unable to bind antithrombin III.[153] Protease nexin 2, an amyloid β-protein precursor containing a Kunitz-type protease inhibitor domain, is an even more potent inhibitor of factor IXa than is antithrombin III.[180,181] However, it is present in plasma at only picomolar concentrations. Nonetheless, the protease nexin 2 is an α-granule component of platelets and may achieve physiologically significant concentrations in areas of platelet degranulation.[182]

Mutations within the catalytic domain of factor IX also decrease enzymatic activity. A mutation of IIe397 → Thr has been recognized in many hemophilia B families, including factor IX Vancouver,[183] factor IX Long Beach,[184] and factor IX Los Angeles.[185] This defect is near, but not within, the active site of factor IXa. It may alter the extended substrate-binding site for factor X. Likewise, factor IX Angers (Gly396 → Arg)[186] and factor IX Lake Elsinore (Ala390 → Val)[187] also interfere with enzymatic activity. Factor IX Bergamo (Pro368 → Thr) is adjacent to Ser365, the active site serine, so not unexpectedly it ablates enzymatic activity.[153]

MOLECULAR BASIS OF HEMOPHILIA B

An updated comprehensive list of naturally occurring factor IX mutations causing hemophilia B can be found in the Hemophilia B Mutation Database (version 13; www.kcl.ac.uk/ip/petergreen/haemBdatabase.html). This list is compiled from 2891 patient entries and includes various types of mutations, including 91 gross deletions or insertions, 211 short deletions and insertions, one triple mutation, 34 double mutations, and the remainder single mutations. Of note, this database overrepresents mutations causing a more severe bleeding phenotype, and certain mutations are overrepresented due to a founder effect, whereas double mutants are underrepresented due to incomplete gene sequencing. Gross deletions and nonsense mutations cause severe, antigen-negative hemophilia B (Figs. 124–10 and 124–11).[188,189] The other mutations produce decreased factor IX antigen, activity, or both (Fig. 124–11). Approximately one third of cases of hemophilia B are cross-reacting material positive [CRM(+)]; the factor IX antigen level is normal or mildly reduced, but the mutant protein has defective activity. Mutations have been described

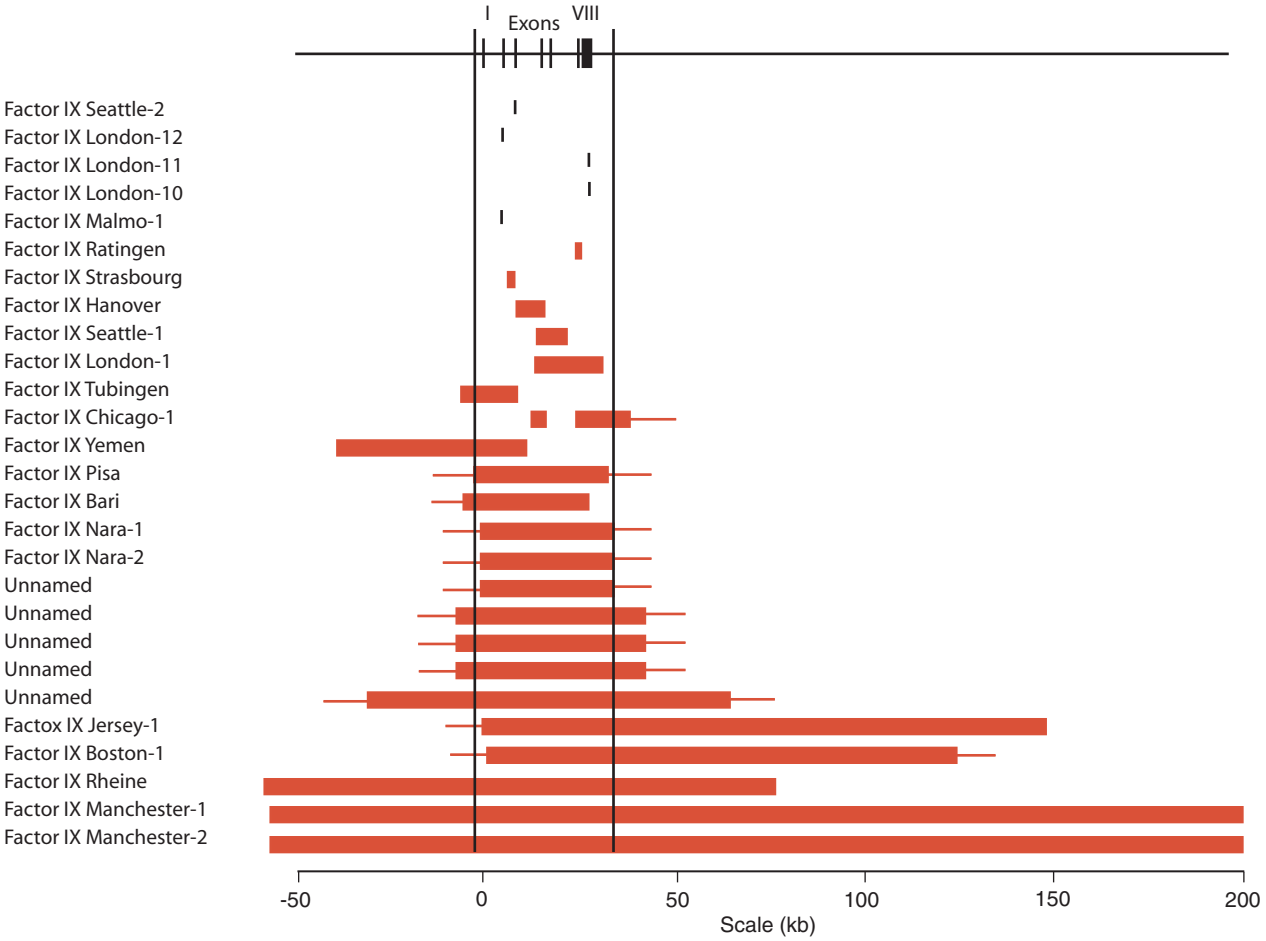

Figure 124–10 Factor IX gene deletions as a cause of hemophilia B. Almost 150 deletions are reported in the hemophilia B mutation database, of which a representative set is illustrated here. Deleted portions of factor IX gene are indicated by light blue rectangles; an uncertain extent of deletion is indicated by blue lines. The factor IX gene (exons 1–8) is shown in black.

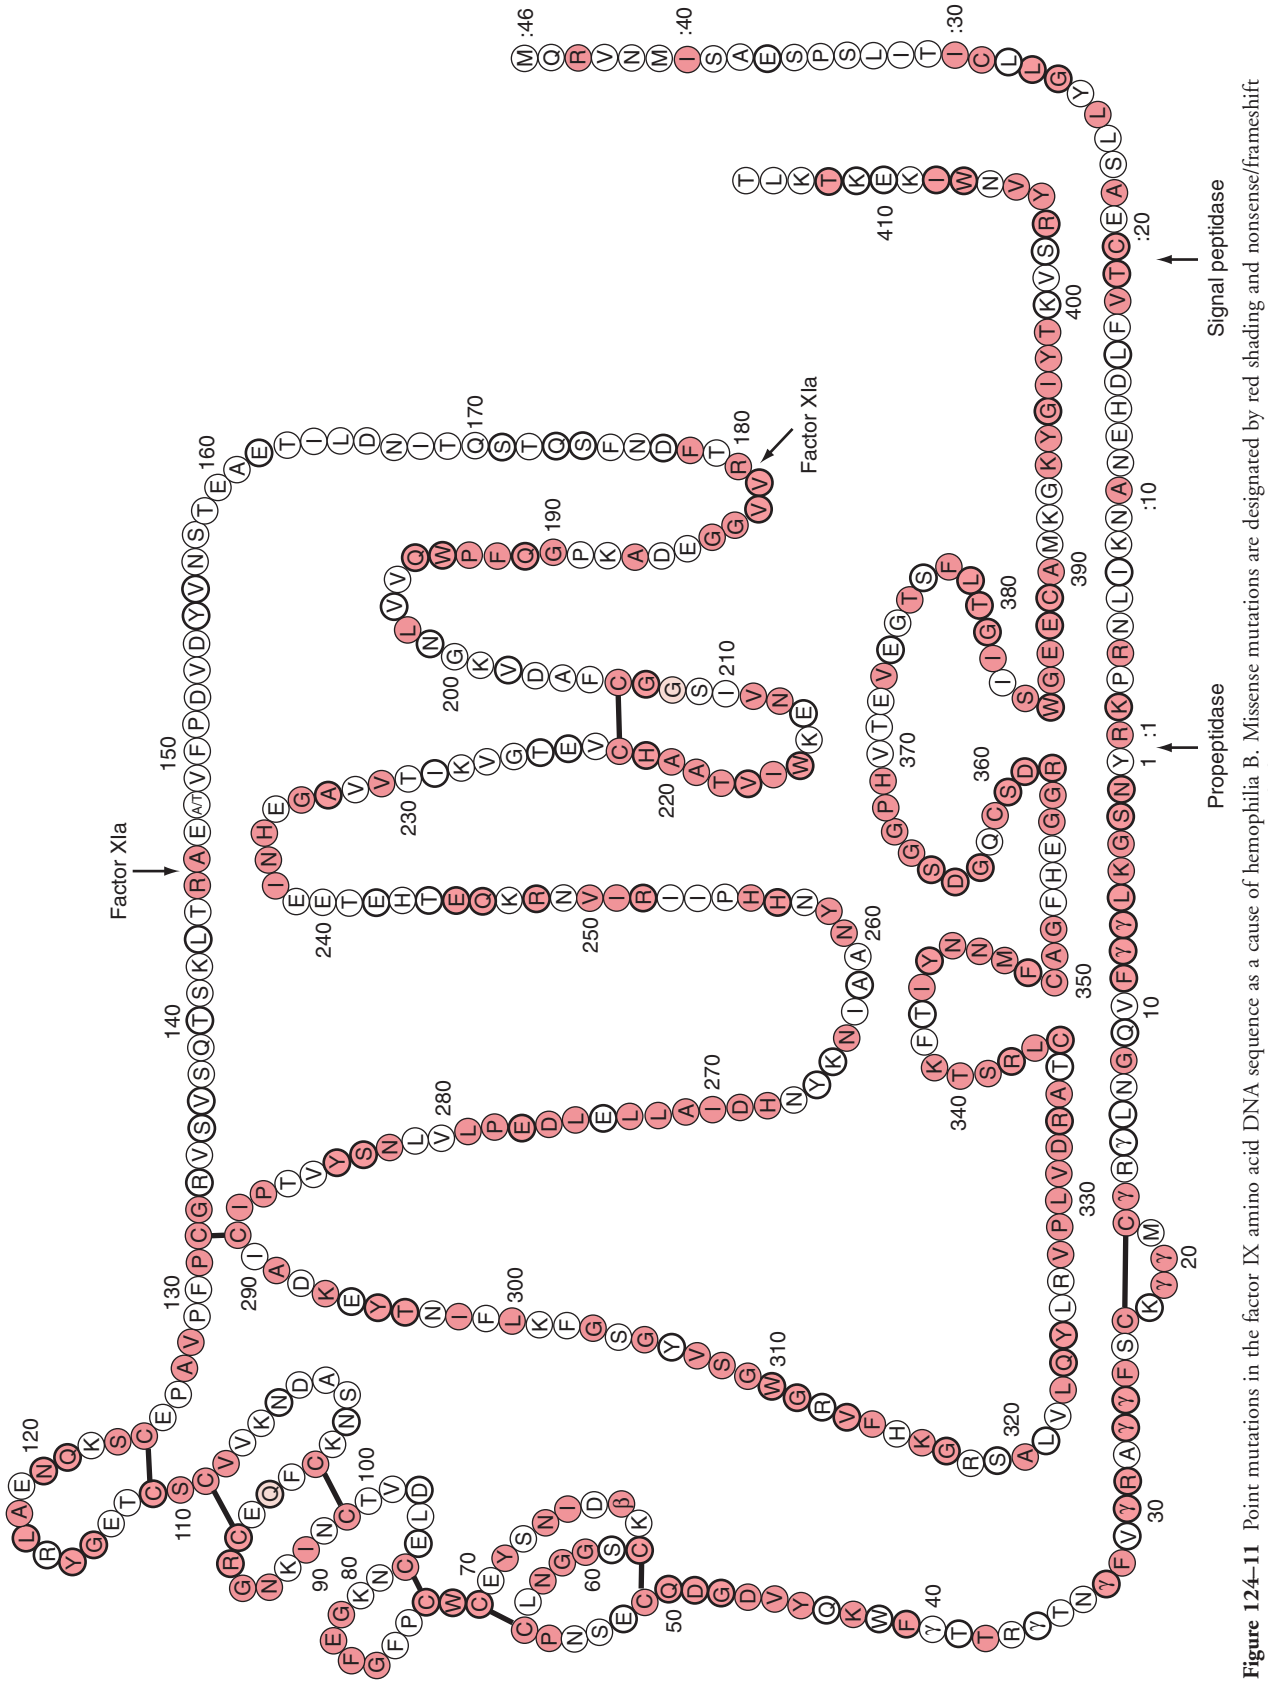

Figure 124–11 Point mutations in the factor IX amino acid DNA sequence as a cause of hemophilia B. Missense mutations are designated by red shading and nonsense/frameshift mutations are designated by a black bold circle. Amino acids are designated by the one-letter code. β, β-hydroxyaspartic acid; γ, γ carboxyglutamic acid.

in all regions of the factor IX gene, including the regulatory regions, the exon-encoding protein domains, and even the poly A tail. Mutations are overrepresented in exons IV and VIII, which encode the calcium-binding EGF domain and catalytic domain, and are underrepresented in exons I and VI, which encode the signal and activation peptides. Mutations have been described for nine of the 12 Gla residues and for all of the 22 cysteines, emphasizing the importance of these residues for factor IX structure and function.

Mutations causing antigen-negative hemophilia B (i.e., mainly gross deletions and nonsense mutations) are associated with antifactor IX antibodies in response to replacement therapy with factor IX.[188] In a series of 62 families with hemophilia B, a family member in approximately one third of families exhibiting deletions or nonsense mutations developed an inhibitor.[190] Slightly less than 2% of patients reported in the Hemophilia B Mutation Database developed inhibitors. Therefore, not all patients without factor IX antigen develop inhibitors in response to replacement therapy.[191,192] Conversely, some patients with antifactor IX antibodies do not possess gross gene deletions.[80,193] In at least one case, antibodies developed in an antigen-positive patient.[193] Thus, the lack of circulating factor IX protein is not the only factor controlling the development of an immunologic response to factor IX replacement therapy.

Numerous examples of repeat factor IX mutations in unrelated families have been reported. To date, 962 unique molecular events and 91 gross deletions or insertions are reported among the 2891 patient entries in the Hemophilia B Mutation Database; the rest are repeats. Several groups have postulated that the CpG dinucleotide sequence is a mutational hotspot.[194–196] The CpG sequence is a component of four of the six arginine codons. As a mutational hotspot, it may represent an important cause of the development of spontaneous point mutations. Furthermore, using a mathematical model, the 20 CpG dinucleotides in the factor IX coding sequence showed an observed mutation rate 150 times the rate expected for the predicted transition rate.[197] Of 51 single base-pair substitutions found in one study, 27 were at CpG dinucleotides, which represents a 38-fold excess for mutations at these sites.[198] In another study, point mutations at CpG dinucleotides were estimated to be increased by 77-fold over the expected rate.[199]

In patients with mutant plasma proteins, the mutation of arginine to another amino acid appears to be common. Insofar as internal point mutations likely will destabilize protein structure and lead to markedly diminished circulating protein levels, patients preselected for circulating mutant protein antigen are likely to have amino acid substitutions on the protein surface. Proteases of the trypsin family use arginines located on the protein surface to hydrolyze adjacent bonds during protein processing and zymogen activation. For instance, hemophilia Bm results from mutation of Arg180 to a variety of other amino acids that prevent carboxyl-terminal cleavage to release the activation peptide. Thus, given the functional importance of arginines, these mutations appear to lead to phenotypically obvious defects in protein function.

Hemophilia B is diagnosed by the finding of isolated, hereditary factor IX deficiency. Factor IX deficiency may be observed by prolongation of the activated partial thromboplastin time and by failure of plasma from these patients to correct the clotting time of factor IX-deficient plasma. A low level of factor IX activity combined with a lifelong history of bleeding or a family history of bleeding secures the diagnosis. The level of factor IX antigen present in the plasma of each patient permits characterization of the hemophilia as antigen negative or antigen positive. Within a particular cohort, the factor IX activity level usually is constant, reflecting that each family displays the same genetic defect and that each defect is associated with a particular phenotype.

The bleeding disorder associated with moderate or severe hemophilia B and the sex-linked nature of the disorder make genetic counseling for affected persons and potential carriers an important issue. Carrier analysis has been performed by differentiating between factor IX activity and factor IX antigen levels. However, this method at best is only 80% effective, partially because of the preponderance of mutations yielding markedly diminished factor IX antigen and partially because of "lyonization," which causes differential levels of inactivation of the X chromosome carrying the mutant gene.[200]

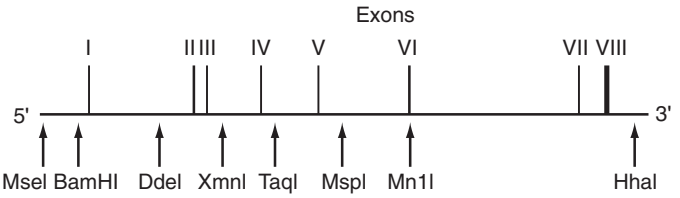

Figure 124–12 Restriction fragment length polymorphisms in the factor IX gene.

With knowledge of the sequence of the factor IX gene, it is possible to probe for the precise genetic defect among potential carriers. To determine whether a person is a hemophilia B carrier, genomic DNA is isolated from the potential carrier and key family members. If the genetic defect for a particular cohort is known, the DNA of potential carriers can be screened using stringent hybridization to oligonucleotide probes to detect whether these individuals carry that genetic defect. This method is compromised by the fact that as many as one third of hemophilia cases in any generation arise from new mutations.

Of greater usefulness for diagnosing carriers is restriction fragment length polymorphism linkage analysis (Fig. 124–12). Factor IX genes are amplified by polymerase chain reaction (PCR), and the PCR products are analyzed by restriction enzyme digestion and gel electrophoresis. PCR amplification allows prenatal diagnosis using fetal DNA samples obtained through amniocentesis or chorionic villus sampling. Cosegregation of a specific polymorphism that creates a restriction enzyme site within or adjacent to the factor IX gene and the hemophilic mutation is used as indirect evidence for carrier state. Several polymorphisms have been described within and adjacent to the factor IX gene, and they are informative in more than 90% of families (Fig. 124–12).[201] Ethnic variation in the frequency of polymorphisms makes restriction fragment length polymorphism analysis more useful for determining carrier state in some populations (e.g., Caucasians) compared with others (e.g., Asians).[202,203] Other limitations include the lack of an informative polymorphism for any individual pedigree, the absence of key family members for analysis, and the problem of genetic recombination. Perhaps a more generally applicable technique is conformation-sensitive gel electrophoresis.[204] Amplification of the factor IX gene by PCR, followed by conformation-sensitive gel electrophoresis, and DNA sequencing or restriction enzyme digestion should facilitate rapid identification of a hemophilia B mutation in suspected carriers and their fetuses.

CHAPTER 125

CLINICAL ASPECTS AND THERAPY FOR HEMOPHILIA

Margaret V. Ragni, Craig M. Kessler, and Jay Nelson Lozier

[I]f the first son of a woman is circumcised and he dies and the second son is circumcised and he dies, you must not circumcise the third son. . . . Additionally, the sons of the woman's sister should not be circumcised but the sons of her brother can be circumcised.

The Talmud (Yebamot 64b)

The existence of a sex-linked hereditary coagulopathy was first recognized and the disorder first described in the Talmud in the fifth century. This entity eventually was labeled "haemorrhaphilia" (love of bleeding) in 1828.[1] By means of early crude assays developed at the end of the nineteenth century, the clotting times of plasma from persons with hemophilia were found to be greatly prolonged compared with the clotting times in nonbleeders.[2] Mixing two sources of hemophilic plasma sometimes corrected the abnormality in vitro.[3] By 1947, the defect in hemophilia had been attributed to a single deficient plasma protein, which was required for platelet utilization and thromboplastin generation.[4,5] Shortly thereafter, the recognition by Pavlovsky[6] that the plasma of some hemophilic patients could correct the in vitro or in vivo defects of other patients having a clinically identical bleeding disorder led to recognition of the existence of multiple types of hemophilia. The clinical entity related to the protein defect described by Brinkhous[4] and Quick[5] was termed *hemophilia A* and was shown to be related to deficiency of factor VIII (antihemophilic factor or antihemophilic globulin). The other type was termed *hemophilia B* and was shown to result from factor IX deficiency (antihemophilic factor B, plasma thromboplastin component, or Christmas factor, named after a patient with factor IX deficiency).[7,8] These two types of hemophilia are similar clinically and have identical hereditary patterns (sex-linked recessive).

The pathophysiology of hemophilia A and hemophilia B is based on the insufficient generation of thrombin by the factor IXa/factor VIIIa complex through the intrinsic pathway of the coagulation cascade. Formation of the tissue factor/factor VIIa complex is the initiating event in mammalian hemostasis and is triggered immediately after vascular injury, when factor VII in plasma interacts with tissue factor in the membranes of cells that are extrinsic to the vasculature. The fact that factor IX, not factor X, is the preferred substrate for the tissue factor/factor VIIa complex indicates that the intrinsic and extrinsic pathways of blood coagulation are not as distinct as initially proposed in the "waterfall" or "cascade" models of the 1960's.[9–14] A scant amount of thrombin is generated, enough to activate platelets and to cleave factor VIII from its pro-cofactor form to yield its active cofactor form (see Chapter 123). In turn, the factor IXa/VIIIa "tenase" complex assembles on membrane surfaces to activate factor X. Deficiencies of either factor VIII or IX lead to ineffective hemostasis due to inadequate thrombin generation.

EPIDEMIOLOGY

Accurate estimates of the incidence and prevalence of hemophilia depend on the reliable diagnosis and differentiation of hemophilia A and B from von Willebrand disease and other, less common congenital bleeding disorders. Hemophilia A and hemophilia B are clinically identical and must be distinguished from von Willebrand disease, which is due to decreased von Willebrand factor (vWF) activity.[15] Hemophilia A is four to six times more common than hemophilia B,[16–31] and mutations that cause hemophilia occur throughout the genes for factor VIII[32] and factor IX.[33] Based on worldwide surveys of patients with hemophilia, the annual incidence of hemophilia A has been estimated at approximately 1:5000 male births (Table 125–1).[16–28,31,34] The incidence of hemophilia B is estimated at approximately 1:30,000 male births.[30]

The prevalence of hemophilia indicates the number of patients alive with the disease at a given point in time. Hemophilia A and hemophilia B are observed in all ethnic and racial groups. Although some studies suggest a lower prevalence in the Chinese population and a higher prevalence among Caucasians,[35,36] the demographics of hemophilia mirror the general population (Table 125–2).[37]

The prevalence of hemophilia varies with age. The peak prevalence occurs in the second or third decade of life,[16–28] likely due to underdiagnosis or delayed diagnosis of mild hemophilia in young individuals[38,39] and excess mortality in older individuals with severe disease. As the overall fitness of patients with hemophilia improves with advances in therapy[40] and as the rate of detection of mild cases increases, a corresponding overall increase in both the true and the observed prevalence of hemophilia is likely.[41] In the developing world, the diagnostic rate is much lower, even that for severe disease.[31] The epidemic of acquired immunodeficiency syndrome (AIDS), although devastating to infected persons, has been predicted to have a transitory and relatively modest effect on the future prevalence of hemophilia.[36,42,43] Carrier testing and prenatal diagnosis (see box on Carrier Detection and Prenatal Diagnosis in Hemophilia) have not had a great impact on the incidence of hemophilia, because a substantial number of cases are the result of unanticipated new mutations. Furthermore, not all known female carriers undergo prenatal diagnostic testing, and most pregnant carriers diagnosed with a hemophilic fetus do not opt for pregnancy termination.[22,23,28,44,45]

The hemophilias are more common than autosomal recessive bleeding disorders because disease manifests in the first male to inherit a defective factor VIII or factor IX allele, unlike recessive diseases, which require inheritance of two defective alleles and may have an incidence of 1:500,000 to 1:2,000,000.[46] Consanguinity is not a typical feature of families in which hemophilia occurs, in contrast with autosomal recessive bleeding disorders.[46] Hemophilic females are exceedingly rare because the 50% factor levels typical of carriers protect against bleeding so that most carriers are asymptomatic. However, among hemophilic females doubly heterozygous for the disease who inherit the affected gene from a carrier mother and an affected father, postpartum bleeding is common.[47] Some female carriers may be affected as a result of unequal inactivation (lyonization) of factor VIII or factor IX alleles, hemizygosity for all or part of the X chromosome, or other mechanisms.

Three degrees of clinical severity correspond to the level of plasma coagulant factor activity. Persons with factor VIII or factor IX levels less than 1% of normal have severe hemophilia characterized by frequent spontaneous bleeding into joints and soft tissues as well as prolonged bleeding with trauma or surgery. Patients with 1% to 5% of normal levels have a moderate course characterized by occasional spontaneous bleeding and excessive bleeding with surgery or trauma. Levels greater than 5% of normal seem to protect against spontaneous bleeding, although excessive bleeding with surgery or trauma occurs.

Table 125–1 Prevalence, Incidence, and Severity of Hemophilia in Various Countries

Population	Hemophilia A			Hemophilia B		
	Prevalence (per 100,000 Males)	*Annual Incidence (per 10,000 Males)*	*Severe Disease (% of Cases)*	*Prevalence (per 100,000 Males)*	*Annual Incidence (per 10,000 Males)*	*Severe Disease (% of Cases)*
United States	20.6	—	60%	5.3	—	44%
Sweden	10.7–11.1	1.4	30%–40%	2.6–3.2	0.3	28%–32%
Greece	10.7–12	1.9	38%–58%	1.6–2.0	0.4	52%–60%
Spain	5.7	—	—	0.9	—	—
United Kingdom[a]	9.5–15.7	—	44%–61%	1.0–2.8	0.4	52%–60%
Finland	5.4	0.7	63%	3.2	—	19%
Netherlands[b]	14.5	—	(40%)	2.6	—	(40%)
Italy[a]	8.2	—	65%	1.5	—	70%
Canada	11.6	—	34%	2.7	—	24%
Japan	6.5	—	—	1.4	—	—
India[c]	2.4	—	45%	0.6	—	—

[a]Severe disease is defined as coagulant factor activity levels <1% of normal, except in the United Kingdom and Italy, where severe disease includes coagulant factor activity levels <2% of normal.
[b]Percent severe disease reported for the Netherlands is the overall average for hemophilia A and B combined.
[c]Figures for India do not reflect an estimated 43% underreporting of cases.
Data from references 16–28, 31, 34.

Table 125–2 Prevalence of Hemophilia in Various Racial Groups in the United States[a]

Combined Prevalence of Hemophilia A and B in Various Racial Groups

Racial Group	Prevalence (Cases/100,000 Males)
White	13.4
African American	12.3
Hispanic American	11.4

Racial Distribution of Patients with Hemophilia A and B

Group	Hemophilia A	Hemophilia B
White	71.7%	69.6%
African American	12.6%	17.2%
Hispanic American	7.8%	4.7%
Other/unknown	7.9%	8.4%

[a]The prevalence for each group is derived by dividing the number of cases of hemophilia A and B by the total number of males in a six-state region (Colorado, Georgia, Louisiana, Massachusetts, New York, and Oklahoma) from 1993 to 1994. The distribution of hemophilia A and B in various groups is derived from the number of cases of hemophilia A or B in each group divided by the total number of cases of hemophilia A and B.

Data from Soucie JM, Evatt B, Jackson D: Occurrence of hemophilia in the United States. The Hemophilia Surveillance System Project Investigators. Am J Hematol 59:288–294, 1998.

In patients with severe or moderate disease, the disorder is readily diagnosed because of spontaneous bleeding and joint disease, but mild hemophilia is substantially underdiagnosed. The proportion of hemophilia A patients with severe disease differs among series, ranging from 30% to 80% of cases, with 60% in the largest series (see Table 125–1). The proportion of cases that are severe is lower in hemophilia B, ranging from 20% to 45%.[16–28] Hemophilia treatment/referral centers may be more likely to diagnose mild and moderate disease that might otherwise be missed in a community hospital where subtle bleeding abnormalities cannot be analyzed with sophisticated laboratory testing.

GENETIC ASPECTS

Hemophilia A demonstrates sex-linked inheritance, by virtue of the location of the factor VIII gene on the long arm of the X chromosome (Xq28).[48] The factor IX gene also is located on the long arm of the X chromosome, at Xq27.[49] Accordingly, males bearing a defective allele on their single X chromosome are affected with hemophilia, the severity of which is determined by the particular mutation. Hemophilic males do not transmit the gene to their sons except under extraordinary circumstances,[50] but all of their daughters are obligate carriers for hemophilia. The diagnosis of mild hemophilia may be significantly delayed in females, even in those with a family bleeding history.[38] Although female carriers usually are not affected, they can become symptomatic with hemophilia via a number of mechanisms.[51]

Carriers with a defective allele on one X chromosome and a normal allele on the other X chromosome may undergo X chromosome inactivation, or *lyonization* (described by Mary Lyon), which results in unequal inactivation of alleles so that the defective (hemophilic) allele is expressed in preference to the normal allele. The lyonization process may be the result of random X-chromosome inactivation[52–54] or may be nonrandom in some cases (i.e., a distinct tendency for inactivation of the normal X allele is seen in all females from the same kindred).[55] Females who have hemophilia due to this process are said to be *lyonized carriers*. The phenotype in the lyonized carrier is no more severe than in the hemophilic male in such families, because any expression from the normal allele in such carriers will ameliorate the hemophilia phenotype. Accordingly, symptomatic lyonized carriers are seen only in hemophilic kindreds in which the male phenotype is symptomatic.

Other mechanisms for female hemophilia include homozygosity for the defective factor VIII allele and hemizygosity for the defective gene. Homozygosity may occur as the result of mating between a hemophilic male and a female carrier. This mechanism may be inferred if multiple hemophilic sons are born to a hemophilic woman, which has been confirmed in one case through detailed genetic analysis of the kindred.[56] Hemizygosity for the X chromosome may occur in females who have the 45,XO (Turner syndrome) karyotype limited to cells that synthesize factor VIII or

Carrier Detection and Prenatal Diagnosis in Hemophilia

Carrier testing and prenatal diagnosis can be offered to women who are related to obligate carrier females or males with hemophilia and who are interested in childbearing. It also may be important to other members of the family to ascertain the mechanism of mutation of the factor VIII or factor IX genes. For instance, germline mutation in a maternal grandfather has different implications for maternal aunts of a patient with hemophilia than does germline mutation in the mother of the patient. This analysis is especially pertinent in de novo cases of hemophilia.

Prenatal diagnosis may be useful even when pregnancy termination is not acceptable based on moral or ethical grounds. For instance, a prenatal diagnosis of hemophilia may be an indication for cesarean section and perinatal factor replacement and may allow more time for psychological preparation of the parents before delivery. Conversely, ruling out hemophilia as soon as possible is advantageous to parents of a normal child.

Accuracy rates greater than 90% for carrier detection and 95% for prenatal diagnosis have been achieved in laboratories having special expertise in blood coagulation testing using assays for factor VIII, factor IX, and von Willebrand factor. Sampling of fetal blood for factor activity cannot be performed before approximately 16 weeks of gestation, however, and procoagulant proteins in amniotic fluid may give spurious coagulant activity on coagulation factor assays. Furthermore, maternal factor IX (but not factor VIII) is found in amniotic fluid, which may contaminate fetal blood samples, making prenatal diagnosis of hemophilia B more difficult than diagnosis of hemophilia A. Phenotypic diagnosis of carriers may be misleading in females with extreme inactivation of the X chromosome with the abnormal factor VIII or factor IX allele. Analysis of factor VIII levels in potential carriers must take into account the age of the woman as well as ABO blood type, which affects the normal range of factor VIII and von Willebrand factor levels. Despite these limitations, phenotypic analysis still is useful as an adjunct to genotypic analysis and may be the only option when key family members are not available for genetic analysis.

Genotypic analysis requires either that the specific gene defect be known or that the carrier be heterozygous for at least one DNA polymorphism within, or closely linked to, the gene in question. DNA from the affected male must be available for analysis if the genetic defect is not known in advance. Prenatal diagnosis by genotypic analysis has advantages over phenotypic analysis. Results are not affected by X inactivation, blood type, or factor levels. Because less material is needed for genetic analysis, the test can be performed during the first trimester (e.g., chorionic villus sampling at 12 weeks of gestation).

When a carrier is heterozygous for a restriction fragment length polymorphism and the DNA of the hemophilic male is available for analysis, it is possible to determine which restriction fragment length polymorphism is associated with the gene defect. Fetal DNA can be characterized for the presence of the restriction fragment length polymorphism to determine whether or not an allele associated with the defective gene has been inherited. The analysis of fetal DNA is a probabilistic venture because of a (small) chance of recombination between the marker site and the actual gene defect. Accordingly, the best markers for analysis are within the gene (and therefore less likely to be subject to recombination with the defect) or very close to the gene of interest. When the specific gene defect is known, the analysis becomes deterministic.

Polymerase chain reaction amplification of DNA and denaturing gradient gel electrophoresis analysis may facilitate rapid screening of mutations in the known coding sequence for factor VIII. However, this analysis does not account for intervening sequences, which compose the vast majority of the gene. If the known male with hemophilia A is not available for analysis or if informative polymorphisms are not observed in the carrier female, analysis of the fetal DNA for the common intron 22 inversions, responsible for almost half of all severe cases of hemophilia A, may be useful.

IX (somatic mosaicism)[51,57] or in all cells as a consequence of a germline event (Turner syndrome).[58]

One report documents a female carrier who inherited an affected factor VIII allele from her mother (an unaffected carrier) and an X isochromosome from her nonhemophilic father. In this case, expression of factor VIII from the isochromosome was defective, and the daughter displayed severe hemophilia A.[59] In another case, a structurally abnormal X chromosome deleted at the tip (Xq27) distal to a normal factor IX gene resulted in inactivation of that chromosome, and expression from the other X chromosome revealed a defective factor IX gene for which the affected female was a carrier. As a consequence, she demonstrated severe hemophilia B.[60]

Evaluation of "hemophilia" in a female should begin with testing for von Willebrand disease as well as autosomal recessive coagulation factor deficiencies associated with a bleeding phenotype. In hemophilic females, karyotyping is necessary not only to rule out Turner syndrome but also to rule out a male (46,XY) karyotype associated with testicular feminization, which has been described in hemophilia A.[61,62]

No single mutation is responsible for hemophilia, in contrast with cystic fibrosis, sickle cell anemia, and Duchenne muscular dystrophy, which are caused by either one or a limited number of mutations. Hundreds of point mutations, deletions, and inversions that cause hemophilia have been described throughout the factor VIII and factor IX genes (see Chapters 123 and 124).[30,63]

An inversion of the factor VIII gene accounts for approximately 40% of cases of severe hemophilia A. Because of the presence of a transcribed gene (*F8A*) within intron 22 of the factor VIII gene[64] and at least two nontranscribed copies of the *F8A* gene lying telomeric to the factor VIII gene, homologous recombination can occur during spermiogenesis.[65] With this mechanism, the first 22 exons of the factor VIII gene are inverted with respect to the last four exons, resulting in a defective truncated factor VIII transcript that lacks functional factor VIII. This inversion may occur with either of the extragenic copies of *F8A* and can be detected and differentiated by restriction fragment length polymorphism analysis on Southern blot preparations.[66] A similar mechanism has been described in dogs with hemophilia A but not in mice, perhaps because dogs have multiple copies of the *F8A* gene and mice have only the single copy in intron 22.[67–69] Because of the high incidence of the intron 22 inversion in patients with severe hemophilia A, testing for this rearrangement should be the first step in carrier and prenatal testing, before sequence analysis of the large factor VIII cDNA/gene. In humans, the inversion usually is the result of a recombination event during spermiogenesis in the maternal grandfather of the person who represents the index case.[70]

Careful analysis of factor IX gene mutation patterns in Caucasian,[71] Asian,[72] Hispanic,[73] and Amerindian[74] populations indicates that hemophilia B results from similar endogenous processes (e.g., deamination of CpG dinucleotides) rather than from environmental mutagens. Although no single common gene defect causes hemophilia B, haplotype analysis indicates that point mutations derived from three "founder" patients account for approximately 25% of all cases of hemophilia B in North America.[75]

ETIOLOGY AND PATHOGENESIS

The hallmark of hemophilia is bleeding into joints (hemarthrosis), which is painful and leads to chronic inflammation and joint destruction similar to those seen in rheumatoid arthritis. Abnormal bleeding originates from the subsynovial venous plexus underlying the joint capsule, where a lack of thromboplastic activity has been demonstrated.[76] The high degree of factor Xa inhibitory activity conveyed by the tissue factor pathway inhibitor synthesized by human synovial cells also may predispose hemophilic joints to bleeding,[77] which may explain the impressive hemostatic response after intravenous administration of recombinant factor VIIa for acute hemarthroses in patients with factor VIII inhibitors.[78,79]

Untreated, inadequately treated, or recurrent joint bleeds result in chronic synovial and intraarticular pathology produced by the toxic effects of hemosiderin and release of proteolytic enzymes (e.g., elastase, collagenase) from the cellular blood components. As synovial iron from recurrent bleeding accumulates, the c-*myc* and *mdm*-2 oncogenes are induced, resulting in synovial cell proliferation.[80,81] Synovial hypertrophy, hemosiderin deposition, fibrosis, and damage to cartilage progress until subchondral bone cyst formation becomes apparent radiographically. Abnormal mechanical forces of weight bearing on these joints exacerbate the damage, which ultimately results in permanent deformities with subluxation, misalignment, loss of mobility, occasional ankylosis, and unequal extremity lengths. Once hemophilic arthropathy compromises one joint, destruction may be precipitated in another joint as a result of unusual and increased stresses placed on it to compensate for the dysfunction of the damaged joint.

Radiologically and clinically, hemophilic arthropathy evolves through five stages (Fig. 125–1). Stage 1 consists of intraarticular and periarticular swelling due to acute bleeding. The joint structure appears normal. Stage 2 is associated with loss of bone density around the joint and epiphyseal hypertrophy secondary to chronic synovial inflammation. Stage 3 is characterized by progression of the epiphyseal hypertrophy with widening of the intercondylar notch. The articular cartilage surfaces are not affected until stage 4, when secondary joint space narrowing becomes apparent. Stage 5 is characterized by advanced cartilage erosion, loss of joint space, joint fusion, and development of fibrosis of the joint capsule.

Because radiographic and clinical examinations frequently underestimate the extent of joint disease, new approaches to evaluation are being introduced.[82] Magnetic resonance imaging (MRI)[83,84] permits better discrimination of changes in the cartilage, synovium, and joint space and earlier detection of synovial hypertrophy than possible by physical examination or radiography (Fig. 125–2).

CLINICAL PRESENTATION

The clinical presentations of patients with hemophilia A and with hemophilia B are indistinguishable. Hemophilia, especially severe disease with less than 1% of normal factor activity, is readily diagnosed, especially in patients with a family history of hemophilia. The diagnosis of hemophilia usually is made on the basis of unusual bleeding symptoms early in life, and the age at first bleeding episode varies with the severity of disease. Infants with severe disease typically present with their first bleeding between 12 and 18 months (despite undetectable factor VIII or factor IX activity). The first manifestations of disease in mild hemophilia may be seen at age 2 to 5 years.[14,39,85] Severe hemophilia most often manifests as easy bruising. Mild to moderate disease more often is associated with bleeding after trauma or dental procedures.[14] Spontaneous hemarthroses occur in individuals with severe disease but are rare before age 9 months, when weight bearing and walking begin.[14]

Coinheritance of "prothrombotic" genes such as factor V Leiden or prothrombin A20210 may mitigate the severity of bleeding, if not arthropathy, in patients with severe hemophilia A.[86,87] These mutations or protein C deficiency may delay the onset of clinically significant bleeding associated with severe hemophilia A[88] or render a more moderate phenotype, as demonstrated in a hemophilia mouse model heterozygous or homozygous for factor V Leiden.[89] In contrast, the occurrence of combined coagulation factor deficiencies (e.g., type 1 von Willebrand disease with hemophilia) may render the phenotype more severe.[90]

That the trauma of childbirth does not cause intracranial hemorrhage more often than it does is remarkable, although some infants may be born with hemophilia A as a result of de novo mutation and die of intracranial hemorrhage at birth undiagnosed. A study of the modes of delivery and prenatal complications in 117 moderately or severely affected infants (those with hemophilia A and B) shows that the risk of serious bleeding in conjunction with normal vaginal delivery is small (<3.8%).[91–93] Vacuum extraction is a major risk factor for subgaleal or cephalic hematomas, and cesarean section does not eliminate the risk of intracranial hemorrhage. In addition, forceps deliveries and prolonged labor increase the risk of intracranial bleeds (Fig. 125–3).[94] Use of fetal scalp electrodes and fetal blood sampling for intrapartum monitoring of affected neonates does not appear to cause bleeding complications.[95]

It is often assumed that excessive bleeding with circumcision is usual for hemophilic infants. In fact, such bleeding occurs in less than half of severely affected infants after circumcision.[85] Of note, those who bleed are circumcised several days later than those who do not bleed. Thus, failure to bleed excessively with circumcision does not rule out hemophilia.

Although the individual with severe hemophilia may bleed from any anatomic site after negligible or unnoticed trauma, intraarticular and intramuscular bleeds are the most common clinical symptoms of severe and moderate hemophilia, yet they rarely occur before the child begins to ambulate. In fact, the most common *presenting* manifestations of hemophilia A and B in one series of patients were soft-tissue bleeds in 41%, bleeding associated with intramuscular injections and surgery in 16%, and oral bleeding from tongue or lip biting in 11%,[96] 14% of which were severe enough to require transfusion of packed red blood cells.

Soft-tissue hemorrhages advance along tissue planes, and blood loss may be extensive and even life threatening because the bleeding is not confined to a closed space (e.g., the joint capsule) as in hemarthrosis. Intracranial hemorrhage was the leading cause of death before the AIDS epidemic and remains the most common hemorrhagic cause of death. Hematuria and gastrointestinal tract bleeding are common. Retroperitoneal bleeding (Fig. 125–4), although uncommon, may occur spontaneously, with extension downward along the psoas muscle through the inguinal canal into the thigh or dissection upward along the vertebral muscles even as far as the neck.

Isolated hemorrhage into a closed space such as the forearm may lead to a compartment syndrome, which is characterized by severe pain with compromise of nerve function and blood flow. Without factor replacement and surgical decompression, compartment hemorrhage may lead to permanent neuropathy, tissue necrosis, or even loss of limb. Compartment syndromes of the forearm may be caused even by venipuncture at the antecubital fossa, and patients should be alert for this uncommon but devastating complication of phlebotomy.

The extreme examples of soft-tissue hemorrhage, which are common in severe hemophilia A, are less common in moderate or mild disease. Moderate or mild disease may not be detected until adulthood (e.g., during dental extraction), when unexplained bleeding, such asa hematoma initially regarded as a recurrent "pulled muscle," prompts evaluation. Routine preoperative laboratory tests may reveal a prolonged activated partial thromboplastin time (aPTT) that triggers further testing, leading to a diagnosis of hemophilia. Some patients with mild disease serve in the military or engage in other hazardous pursuits, only to have hemophilia diagnosed later in life.

Intraarticular bleeding becomes problematic usually between the ages of 2 and 3 years. It occurs most prominently in the knees, followed by the elbows and ankles. Bleeding into the shoulders, hips, and wrists is less common, although trauma may precipitate bleeding in any joint. Bilateral involvement may occur but is uncommon.[97]

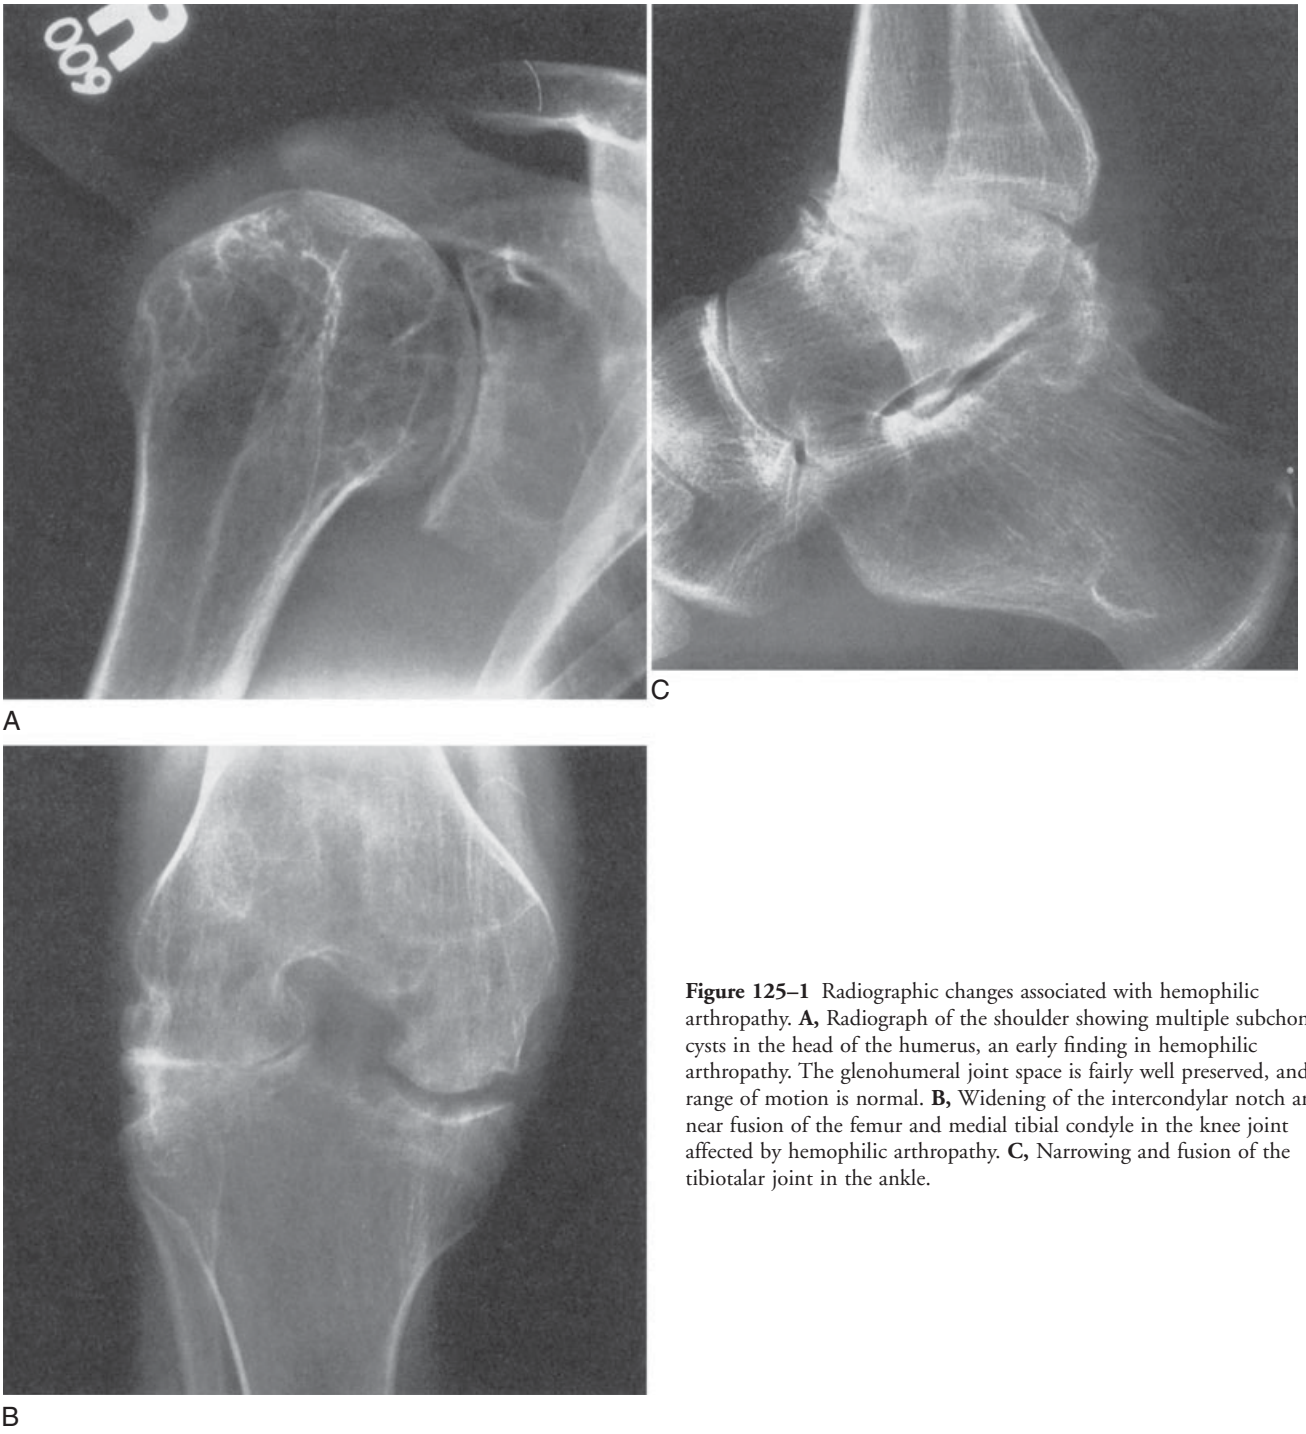

Figure 125–1 Radiographic changes associated with hemophilic arthropathy. **A,** Radiograph of the shoulder showing multiple subchondral cysts in the head of the humerus, an early finding in hemophilic arthropathy. The glenohumeral joint space is fairly well preserved, and range of motion is normal. **B,** Widening of the intercondylar notch and near fusion of the femur and medial tibial condyle in the knee joint affected by hemophilic arthropathy. **C,** Narrowing and fusion of the tibiotalar joint in the ankle.

In acute hemarthroses, a tingling or burning sensation often precedes the onset of intense pain and swelling. Joint mobility is compromised by pain and stiffness, and the joint is maintained in a flexed position. In most cases, replacement of the deficient clotting factor gradually reverses the pain, and once the bloody joint effusion resorbs, joint range of motion and function are regained.

Chronic hemophilic arthropathy often is painful with weight bearing and normal use, but frequently the pain is related to the arthritic changes in the joint. Pain may disappear or subside once the joint becomes ankylosed. Muscle atrophy around the joints may lead to further instability, loss of use, valgus deformities, and increased bleeding due to loss of cushioning around the joint and uncoordinated function among muscle groups. Individuals with factor VIII and factor IX levels greater than 20% of normal rarely develop hemophilic arthropathy, even if they had experienced previous bleeds, as reported in 6% to 20%.[98]

Socioeconomic and other health issues may affect the severity and degree of disability associated with hemophilic joint disease. Obesity, which is not uncommon in individuals with hemophilia, significantly worsens joint range of motion.[99] Whether higher body mass index in hemophilic men occurs because of immobilization, sedentary lifestyles, or inability to work due to recurrent bleeds is a major focus of current hemophilia care. In addition, the place of care may influence outcomes: those who receive care outside a hemophilia treatment center have significantly lower quality of life and shorter lifespans than those who receive care from experienced, knowledgeable staff at a hemophilia center.[40]

LABORATORY EVALUATION

The severity, frequency, and location of bleeding in patients with hemophilia are determined by the plasma concentration of factor VIII or factor IX. Typically, the same degree of severity exists within families, and little fluctuation of coagulation factor levels occurs within an individual over time. Exceptions include Heckathorn syndrome,[100] in which factor VIII levels vary within affected family members; moderate or mild hemophilia A, in which factor VIII levels vary as acute-phase reactants with exercise and inflammation; and the unusual hemophilia B variant factor IX Leyden,[101] in which reduced factor IX levels progressively rise after puberty, eventually approaching the normal range (3%–4% increase per year through adolescence). This rise has been attributed to the effects of androgenic steroids on the mutated promoter region of the factor IX gene in affected patients.[102,103]

Factor VIII and factor IX levels are assayed against a normal pooled plasma standard, which is designated as 100% activity, equivalent to that of 1 U/mL of factor VIII or factor IX. The normal range of factor VIII and factor IX levels varies between 50% and 150%, although increases in either factor are associated with pregnancy and aging. Use of estrogen-containing contraceptives and replacement therapies produce substantially higher rises in factor VIII than in factor IX. In the normal healthy premature and term neonate, factor IX (but not factor VIII) levels typically are 20% to 50% of normal and rise to nearly normal adult levels within 6 months. This situation is attributed to hepatic immaturity at birth. In congenital factor VIII or factor IX deficiencies, persons with undetectable activity (<0.01 U/mL) will experience the most severe and frequent spontaneous bleeding complications, whereas those with higher levels will manifest moderate (with 2%–5% of normal activity) or mild (>5% of normal activity) symptomatology.

The whole blood clotting time, results of the prothrombin consumption test, and aPTT are abnormal in hemophilia A and B because of intrinsic pathway coagulation protein deficiencies. Various other laboratory techniques are available for specific determination of factor VIII and factor IX activities. The one-stage assay based on aPTT is most commonly used because of its reproducibility, simplicity, and low cost. In Europe, use of a chromogenic assay is advocated for determination of factor VIII levels and has been

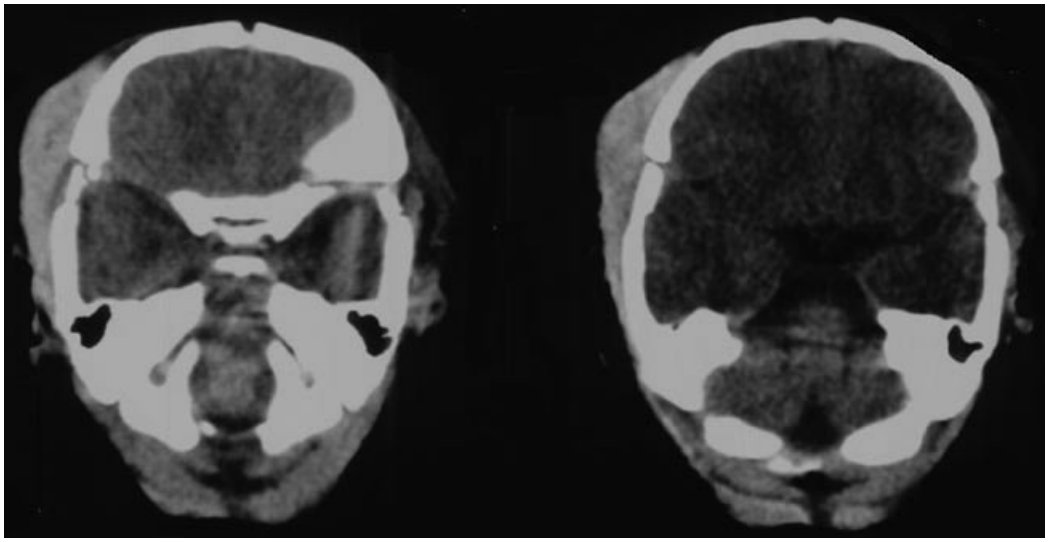

Figure 125–3 Subgaleal bleed in 2-day old male infant with severe hemophilia A. Computed tomographic scan shows a large right subgaleal hematoma. The infant was born by spontaneous vaginal delivery, without assistance of forceps or vacuum, with Apgar scores of 8 and 10. The presentation was breech, and delivery was difficult. He developed edema of the right eye and right face and hemoglobin 6.4 gm% in the first day of life. He received two units of blood and factor VIII concentrate. At age 4 months he developed an inhibitor, anti-factor VIII 50 Bethesda units, as had two older affected siblings before him.

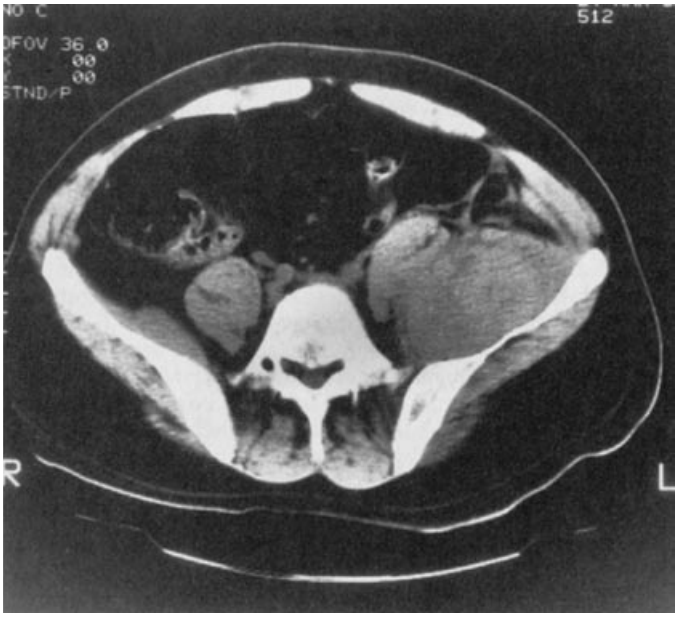

Figure 125–4 Retroperitoneal hemorrhage involving the iliopsoas muscle of the left iliac fossa in a patient with hemophilia A and a high-titer inhibitor.

adopted by the European Pharmacopoeia and the International Society on Thrombosis and Haemostasis,[104] but this assay is much less commonly used in the United States. Factor VIII assays performed by chromogenic techniques and by the aPTT method in patients receiving recombinant factor VIII concentrates (particularly B domain-deleted products) give consistently different results. Values determined by the chromogenic substrate method are approximately twice as high as those determined by the one-stage aPTT method.[104,105] The laboratory discrepancy is based on the relative amount of phospholipid in the activating reagent for the one-stage assay compared with the chromogenic assay, as well as modifications to the activation time in the chromogenic assay as performed in some laboratories.

The wide variety of aPTT reagents, standards, assay methods, and laboratories used to perform current one-stage and chromogenic assays[106] complicates both the pharmacokinetics and dosing of factor concentrates. For these reasons, use of product-specific standards in place of plasma standards has been recommended, with better agreement on product recoveries, for example, with B-domain–deleted factor VIII, which differs in structure and half-life from full-length factor VIII.[107] Adopting product standards for such assays may improve patient care by providing more accurate factor levels and avoiding breakthrough bleeds.[108] An alternate assay, the thrombin generation assay, measures peak thrombin generation, total thrombin generated, and $t_{1/2}$ max (time to half maximum) thrombin generation.[109,110] Because the thrombin generation assay provides absolute values and requires no standards, it may provide more accurate postinfusion values as well as better detection of low factor levels.[110] Preliminary data from study of a more global assay that incorporates clot formation and fibrinolysis may provide better risk assessment than provided by standard clotting time assays.[111]

Hemophilia A usually can be differentiated from von Willebrand disease in the laboratory by the presence of normal or increased vWF antigen and ristocetin cofactor activity.[112] Of note, the rare von Willebrand 2N variant, in which the vWF protein does not bind factor VIII, may be phenotypically identical to severe hemophilia A except for its autosomally transmitted inheritance pattern.[113,114] Specialized assays for measuring the factor VIII-vWF protein-binding characteristics and genetic testing for the specific point mutations involved are necessary to diagnose this entity. Bleeding times or closure times, which are prolonged in von Willebrand disease, are normal in persons with hemophilia. However, prolonged bleeding times have been documented in patients with hemophilia A and B in the absence of abnormal platelet aggregation assays or following the surreptitious use of aspirin or nonsteroidal antiinflammatory drugs (NSAIDs) in several series of patients.[115,116] Although there is no obvious explanation for this phenomenon, bleeding times tend to be more prolonged when the Simplate device is used and correlate with severity of bleeding events, platelet IgG levels, circulating immune complexes, and vascular injury. The effects of concurrent hepatitis or human immunodeficiency virus (HIV) infection have not been evaluated.

Most individuals with severe factor VIII or factor IX deficiency (<1% activity) have undetectable levels of the corresponding factor antigen when assayed against a specific antibody: they are designated cross-reactive material-negative [CRM(–)]. In contrast, moderately and mildly affected patients may have normal or slightly reduced levels of antigen [CRM(+)].[117] The clinical significance of CRM(–) versus CRM(+) status remains unclear; however, it has been conjectured that CRM(–) persons are more likely than those who are CRM(+) to develop alloantibodies directed against their specific clotting protein defect.[118] A special subset of CRM(+) hemophilia B, hemophilia B_M, is associated with an abnormal factor IX protein that prolongs the prothrombin time when an ox or bovine (rather than human) brain source of thromboplastin is used. This product of point mutations in the factor IX gene possesses decreased coagulation function and acts as a competitive inhibitor of factor VIIa.[119,120]

Although the presence of an inhibitor to factor VIII or factor IX is clinically suspected when a bleeding episode fails to respond to an adequate dose of factor concentrate, laboratory confirmation is critical to the diagnosis and subsequent treatment strategy. For alloantibody inhibitors (associated with congenital defect) or autoantibody inhibitors (associated with previously normal coagulation), if the initial aPTT is prolonged, aPTT determination should be repeated after incubation of the patient's plasma with normal plasma at 37°C for 1 to 2 hours. If the prolonged aPTT does not correct, the presence of an inhibitor should be evaluated through specific clotting factor assays performed in multiple dilutions and subsequently quantified according to the Bethesda method (see Chapter 126). The clotting factor against which the inhibitor is directed will remain persistently and equally deficient at all dilutions, whereas the apparent activity of other factors will increase as the inhibitor is diluted out.[121,122] Increasing dilutions of the patient's plasma are incubated with an equal volume of normal plasma (standardized to contain 1 U/mL) for 2 hours at 37°C until a residual factor activity level falls within 25% to 75% of the control mixture of normal plasma and buffer. A standard curve is estab-lished, which defines 1 Bethesda unit (BU) as a measure of the inhibitor potency that results in 50% neutralization of factor VIII or factor IX activity in the pooled normal plasma.[123] The Nijmegen modification of the Bethesda method, which eliminates the pH-dependent variation of factor VIII activity in the incubation mixtures of the Bethesda assay and uses immunodepleted factor VIII-deficient plasma, increases the specificity of the assay in the very low range of factor VIII antibody inhibitor titers. This assay usually is reserved for research protocols because titers of the clinically relevant inhibitors typically are greater than 5 to 10 BU.[124] By convention, a titer greater than 0.6 BU is considered positive for the presence of an inhibitor. Inhibitors present at less than 5 BU are termed low-titer inhibitors and usually are not associated with anamnestic responses when sources of the specific clotting factor protein are administered. Inhibitors present at greater than 10 BU are defined as high-titer inhibitors and often are associated with anamnestic responses. The most sensitive means for detecting an inhibitor antibody is measurement of a decrease in the recovery and half-life of factor VIII in vivo.

DIFFERENTIAL DIAGNOSIS

Considerations in the differential diagnosis of hemophilia include congenital bleeding disorders such as von Willebrand disease, platelet disorders (e.g., Glanzmann thrombasthenia), and deficiency of various other coagulation factors such as factor V, VII, X, or XI or fibrinogen.[44] In addition are autoimmune syndromes in which antibodies to factor VIII may spontaneously develop, leading to "acquired hemophilia."[125]

The diagnosis of hemophilia is made on the basis of family history, bleeding symptoms, and findings on physical examination and laboratory evaluation. The hallmarks of severe hemophilia include prolonged bleeding with surgical procedures, trauma, or dental extraction, as well as hemarthroses and spontaneous bleeding into soft tissues. The last of these conditions distinguishes severe hemophilia A from von Willebrand disease and platelet disorders, in which soft-tissue hemorrhage and hemarthropathy are uncommon (except in severe, type 3 von Willebrand disease). In addition, a family history indicating autosomal dominant transmission is characteristic of von Willebrand disease rather than hemophilia, which has a sex-linked recessive pattern of inheritance. Family history may be unrevealing in de novo presentations of hemophilia.

Severe hemophilia A is not clinically distinguishable from severe hemophilia B by either historical features (bleeding symptoms) or findings on physical examination; the two must be distinguished by specific assays for factor VIII and factor IX. Accurate diagnosis of hemophilia A and hemophilia B is critical for appropriate clinical management. Autosomally inherited disorders of coagulation factors V, VII, X, and XI and fibrinogen also must be diagnosed by specific coagulation factor assays.[46]

Mild hemophilia A may be difficult to distinguish from von Willebrand disease because factor VIII levels tend to be depressed in the latter, and prolongation of the bleeding time (characteristic of von Willebrand disease but not hemophilia) is not reliably present. Specific assays for vWF and analysis of the vWF multimeric pattern by gel electrophoresis may distinguish the two disorders. Repeat testing is sometimes required to make a definitive diagnosis in the case of von Willebrand disease, especially mild (type 1) forms of the disease (see Chapters 128 and 129).

TREATMENT

Factor Replacement Therapy

The key to treatment of bleeding in hemophilia is replacement of the missing coagulation protein to achieve hemostasis. The dose and choice of product are influenced by the severity of disease, the site and severity of the bleeding, and the clinical scenario. The patient's weight, inhibitor antibody status, and treatment history (especially with respect to exposure to bloodborne pathogens) also are important. The annual cost of factor replacement therapy for an adult receiving weekly treatments may range from $20,000 to $100,000, and the cost for patients with inhibitors may be greater, particularly for those undergoing immune tolerance induction protocols. Therefore, patients are best managed in a comprehensive hemophilia center, where multispecialty expertise and ancillary support services for diagnosis, therapy, and management are in place. The comprehensive hemophilia center also serves as a resource for patients with related bleeding disorders such as von Willebrand disease. Replacement therapy involves educating the patient and his or her family in self-infusion techniques, the cornerstone of home-based treatment.

Guidelines for replacement therapy have been determined empirically over many years; however, the minimal doses of clotting factor replacement for adequate hemostasis have not been established (Tables 125–3, 125–4, 125–5, and 125–6). Typically, hemostasis for minor bleeding can be achieved at plasma factor levels of 25% to 30% of normal (0.25–0.30 U/mL), whereas severe bleeding requires at least 50% of normal activity. Surgical procedures and life-threatening bleeding require targets of 75% to 100% of normal activity. For factor VIII replacement, each unit of factor VIII per kilogram of body weight is assumed to raise the plasma level by 2% (0.02 U/mL). Thus, injection of 1750 U of factor VIII will provide for an incremental rise of 50% (0.5 U/mL) of normal (1750 U/70 kg × 0.02 U/mL), which then declines according to the pharmacokinetics associated with factor VIII. This calculation estimates the peak level, and in critical bleeding situations common practice involves doubling the initial dose to ensure that the trough level after one half-life exceeds the desired value. Because factor VIII has a half-life of 8 to 12 hours, repeat dosing at least two or three times daily is

required to maintain the desired factor VIII level. One half of the initial dose is given every half-life (i.e., every 8–12 hours) to maintain the desired factor VIII level.

Similar calculations can be made for dosing factor IX concentrates. Factor IX demonstrates a volume of distribution approximately twice that of factor VIII because of equilibration with the extravascular extracellular fluid compartment (in which factor VIII does not exchange) and a half-life of approximately 24 hours. One unit of factor IX administered per kilogram of body weight results in a 1% (0.01 U/mL) increment in the circulating factor IX level in plasma. Thus, 3500 U of factor IX provides an incremental rise of 50% of normal (0.5 U/mL; 3500 U/70 kg × 0.01 U/mL). For low-purity, low specific activity factor IX preparations, it is best to aim for a maximum level of 50% of normal to avoid the thrombotic complications that have occurred with these preparations. This is not a problem with the highly purified, high specific activity factor IX preparations.

A recovery rate 20% lower than expected has been observed in approximately 30% of patients who receive recombinant factor IX. This finding may have implications for therapy for acute bleeding, so patients should undergo a baseline pharmacokinetic study with the factor IX preparation of choice. The initial dose is adjusted accordingly, as are subsequent maintenance doses of factor IX, which are given every 18 to 24 hours.[118] For replacement therapy for hemophilia A or B, subsequent dosing is adjusted on the basis of measured factor levels. The duration of treatment is determined by the rapidity of pain relief and recovery of range of motion of an affected joint or resolution of a hematoma. For major surgery, replacement therapy usually is continued for at least 10 to 14 days to allow for efficient wound healing and scar formation. This is consistent with data showing that impaired coagulation delays wound healing in hemophilia B mice related to greater iron deposition that is thought to induce angiogenesis in wound sites.[126] This emphasizes the importance of factor replacement in achieving early and rapid hemostasis as well as wound healing after trauma or surgery.

Intermittent bolus infusions of factor concentrates have been used successfully for treatment and prophylaxis for many years. However, pharmacokinetics may vary between products and patients, and the wide fluctuations in factor levels during therapy may make management difficult (see box on Choice of Factor Concentrate). Continuous infusion protocols have been developed, which reduce factor use, facilitate laboratory monitoring of factor levels (because laboratory values reflect a steady state rather than a peak or a trough), and decrease the overall cost of therapy. This approach has been associated with excellent hemostasis and safety and has been used with factor VIII, factor IX, porcine factor VIII, recombinant human factor VIIa, and activated prothrombin complex concentrates for therapy for patients with inhibitors. Some studies note a 30% to 75% decrease in the use of concentrate with continuous infusions administered in the surgical setting and report a progressive decrease in the plasma clearance of coagulation factors.[122,138,139] Most high-purity preparations maintain more than 80% of initial activity 3 to 7 days after reconstitution.[140] A typical continuous infusion protocol begins with a bolus designed to achieve 100% of normal levels followed by an infusion of 2 U/kg/hour. The results of factor VIII or factor IX assays obtained thereafter are used to guide changes in the infusion regimen. Typically, if the measured factor level is low, the infusion rate can be increased or a small bolus given to bring the levels up to the desired value. Addition of small amounts of heparin (1–5 U/mL of infusion

Table 125–3 Guidelines for Replacement Dosing with Factor VIII and Factor IX

	Desired Plasma Level (% of Normal)		Initial Dose (IU/kg body weight)		
Type of Lesion	***Factor VIII***	***Factor IX***	***Factor VIII***	***Factor IX***	**Duration of Therapy (Days)**
Mild (often spontaneous) hemarthrosis	30%	20%–30%	15	20–30	q8–12h over 1–2 days for factor VIII q12–24h over 1–2 days for factor IX (often only one dose required)
Superficial hematoma Oropharyngeal or dental Severe epistaxis Persistent hematuria					
Major central nervous system trauma or hemorrhage; lumbar puncture or epidural anesthesia	80%–100%	80%–100%	>50	50	q8–12h over at least 10–14 days for factor VIII q12h over at least 10–14 days for factor IX
Surgery					High-purity products are recommended to avoid thrombotic complications
Retroperitoneal hemorrhage Dental extraction with nerve block Severe gastrointestinal bleeding					Continuous infusion with high-purity products recommended to avoid peak and trough level fluctuations and to save on overall use of factor concentrate

solution) may reduce the incidence of local thrombophlebitis at the venous access site.

The pharmacokinetics of factor products are different in children than in adults: children have lower factor VIII recovery and shorter half-life.[141] Recovery appears to be highly correlated with body surface area, whereas half-life is strongly correlated with vWF levels. These findings suggest the need for pharmacokinetics studies in children to assure the adequacy of prophylaxis and the treatment regimen, especially before surgery.[141] Use of ideal weight for height, age, and gender also has been advocated to assist dosing in obese children and adults.[142]

Benefits and Risks of Use of Factor Preparations

Bloodborne Pathogens

Until the availability of recombinant factor VIII products in the late 1980s and recombinant factor IX in the late 1990s, patients with hemophilia received thousands of units of concentrates derived from plasma obtained from tens of thousands of donors. Patients who received these products prior to 1985, when viral inactivation procedures were introduced, were infected by various transfusion-transmitted infectious agents, including HIV, hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis G virus, and parvovirus B19. Virtually all patients who received plasma-derived concentrates before 1985 have been infected with

Choice of Factor Concentrate

The choice of factor concentrate is based on safety, as there is no difference in efficacy among the preparations, whether recombinant or plasma derived. Since implementation of viral attenuation methods in the manufacture of these products, no seroconversions to HIV, HBV, or HCV with any plasma-derived product have been reported. Because there remains the possibility of transmission of HIV-1, HIV-2, hepatitis B or C virus, nonlipid-enveloped viruses, hepatitis A virus, and parvovirus B19 despite viral inactivation and viral filtration methods, recombinant factor VIII and factor IX concentrates are recommended as first-line treatment of all individuals with hemophilia, regardless of HIV or HCV serostatus (see Bloodborne Pathogens). If plasma-derived products are used, high-purity products are preferred over lesser-purity products. For example, plasma-derived coagulation factor IX is recommended over plasma-derived prothrombin complex concentrates or their activated prothrombin complex concentrates because of potential thromboembolic risk with the latter product. Recombinant products also are preferred in prophylaxis regimens.

Among the 15% to 25% of affected patients who develop inhibitors, those with high-titer antibodies may require immune tolerance induction to neutralize the inhibitor; once eradicated, factor VIII can be used effectively to achieve hemostasis (see Chapter 126). Until tolerance is achieved, however, hemostasis in inhibitor patients is achieved with recombinant factor VIIa, activated prothrombin complex concentrates, or porcine factor VIII concentrates. The latter are generally less effective than recombinant factor VIII or IX concentrates are in noninhibitor patients, which is not surprising given that the former agents fall short of the normal thrombin-generating activity possible with the latter agents.[127] A prospective crossover comparison study of recombinant factor VIIa and activated prothrombin complex concentrate factor VIII inhibitor bypass activity for treatment of hemarthroses in subjects with high-responding factor VIII or IX inhibitors found neither agent to be superior.[128] Porcine factor VIII is effective, however, only in patients with low antiporcine factor VIII titers. As might be expected, titers of antiporcine factor VIII typically rise a few days after its administration, but there may be an important window of opportunity to achieve hemostasis with this agent, for example, in surgery, prior to development of an anamnestic response. The high rate of endogenous porcine parvovirus in swine has been a problem for production of plasma-derived porcine factor VIII products, and a recombinant product is under development. Prophylaxis in inhibitor patients may be effective with use of several different agents, including factor VIII inhibitor bypass activity and recombinant factor VIIa.[129] Immune tolerance induction, which neutralizes factor VIII inhibitors, is generally performed with recombinant factor VIII, although plasma-derived vWF concentrate has shown superior efficacy in some patients.[130,131] Immunosuppression with cyclosporine,[132] mycophenolate,[133] and rituximab[134,135] have shown efficacy as single agents in tolerance induction, although only in small studies. Preliminary results with rituximab indicate tolerance can be maintained for 12 or more months, potentially providing the opportunity for treatment with factor VIII during elective surgery. A phase II clinical trial of rituximab in inhibitor patients through the NHLBI Transfusion Medicine Hemostasis Clinical Trials Network (TMH-CTN) should help determine the efficacy, safety, and durability of this modality. Inhibitor formation is a T-cell–dependent immune response, suggesting the potential usefulness of a dendritic cell vaccine approach. In the hemophilia A murine model, factor VIII-pulsed dendritic cells have led to successful tolerance induction and prevented an anamnestic response on rechallenge with factor VIII.[136,137]

All replacement therapy options should be discussed with the patient or the family. Patient preferences must be given serious consideration because extensive scientific data are not always available to determine the "best" treatment and because of the wide variation in cost among the clotting factor concentrates. Regardless of product choice, elective major surgery should be approached with great caution and performed in a major hemophilia treatment center with expertise in hemophilia management and with a wide range of products available should one prove ineffective.

HCV, with 60% genotype 1, the predominant phenotype of United States donors. The HCV genotype 1 is characterized by a poorer response to interferon-ribavirin antiviral therapy and more frequent progression to hepatic failure.[143] HCV infection is characterized by asymptomatic hepatic transaminasemia, which may be either intermittent or persistent. Spontaneous clearance may occur in up to 20% of infected patients, primarily in those with hepatitis B coinfection acquired before age 2 years and those with HCV coinfection since 1983.[144] Progression to liver failure occurs in approximately 10% to 20% of HCV-seropositive patients with 20 to 25 years of exposure, and hepatitis C liver disease is the leading cause of morbidity and mortality in this population.[145,146] Among those coinfected with HIV, there is persistent HCV replication, high HCV RNA viral load, advanced fibrosis, and more rapid liver disease progression, with a 3.7-fold increased relative risk of end-stage liver disease.[145] Risk factors for liver disease progression in hemophilia include age at HCV exposure, hepatitis B surface antigenemia, HIV coinfection, and alcohol use. This latter risk factor underscores the importance of avoiding or minimizing alcohol use in this group.

Liver biopsy, the standard for determining the extent of liver damage and degree of fibrosis, is not commonly performed in patients with hemophilia.[147] Although percutaneous liver biopsy has been complicated by bleeding,[148] the less invasive transjugular liver biopsy, which accesses the liver via the jugular vein, appears to be safe in patients with hemophilia when performed under factor coverage.[147,149]

Treatment with interferon-ribavirin antiviral therapy leads to durable viral suppression in fewer than 50% of patients, just as in nonhemophilic subjects. However, among those with HIV–HCV coinfection, significantly fewer respond (≤20%), and hepatotoxicity is not uncommon.[145,150] Therapy, if successful, may not only prevent liver disease progression but also development of hepatocellular carcinoma,[151,152] which is associated with chronic HCV and HBV infections.

For patients with HIV–HCV coinfection there is increasing evidence that HIV antiviral therapy, or highly active antiretroviral therapy (HAART), reduces the severity of liver disease progression,[153] presumably related to HIV viral load reduction. For those who develop end-stage liver disease, liver transplantation is becoming the standard of care for coinfected individuals just as for HIV-negative/HCV-positive individuals,[150] although not all centers perform the procedure, and some assign lower priority to those with HIV infection. Even if accepted onto a waiting list, coinfected patients are more likely to die preoperatively of severe bacterial sepsis and multiorgan failure.[154] Recognition of the signs and symptoms of end-stage liver disease and early referral to hepatologists and transplant surgeons are essential for optimal care. Yet, coinfected patients may not receive standard HIV or HCV antiviral therapy or be referred to a hepatologist. If patients do receive a donor organ, which cures the hemophilia,[155–157] hepatitis C is difficult to eradicate because it recurs in all HCV-positive liver transplant recipients,[153] underscoring the need for better hepatitis C treatment.

The risks of horizontal transmission of HCV from the infected hemophiliac to his sexual partner or subsequent vertical transmission of HCV to the unborn fetus appear to be minimal (<3%), unless the patient and the pregnant female are coinfected with HIV. In that case, vertical HIV transmission is more likely than is HCV infection,[158] although the risk of HIV transmission to sexual

partners is greatly reduced by HAART and the absence of a detectable HIV viral RNA.

Hepatitis B is a problem of the past for patients with hemophilia as a result of testing of plasma donors for hepatitis B surface antigen and routine administration of recombinant hepatitis B vaccine shortly after birth. HBV titers from prior vaccination may disappear with the progression of AIDS; in these patients, vaccination should be repeated. Of the HBV-seropositive patients who were exposed to the virus in concentrates administered before 1985, approximately 5% are chronic carriers of hepatitis B surface antigen. In these patients, development of progressive hepatic failure or hepatocellular carcinoma is more likely, and they are susceptible to coinfection with the hepatitis D virus ("deltavirus"), which accelerates liver failure.

Although HAV transmission is not considered an important bloodborne pathogen, HAV seroconversions have been detected in hemophiliacs who received high-purity concentrates treated with solvent detergent.[159] HAV in plasma pools containing one or more transiently viremic donors are not susceptible to currently available viral inactivation processes because HAV is a nonenveloped virus. Thus, manufacturers of plasma-derived concentrates now screen prospective donors and donor pools by polymerase chain reaction testing for viral nucleic acids to minimize the risk of transmission of HAV (as well as HIV-1 and HIV-2, HBV, and HCV). The HAV vaccine series is recommended for all seronegative hemophilic children older than 2 years and is effective by both the intramuscular and subcutaneous routes.[160] The immune response to the vaccine of HIV-seropositive patients should be checked because booster doses may be needed.

Hepatitis E is not transmitted through plasma-derived concentrates. This is in contrast to hepatitis G virus, a human flavivirus distantly related to HCV. Approximately 15% to 25% of hemophiliacs who received nonviral attenuated concentrates are seropositive for hepatitis G virus, compared with 3% of healthy blood donors.[161] Hepatitis G virus appears to be susceptible to the same viral inactivation processes used for HCV and other lipid-enveloped viruses and should not be a substantial threat to hemophiliacs.

Human parvovirus B19, a single-stranded DNA virus, is associated with fifth disease (erythema infectiosum) in children, transient aplastic anemia in patients with chronic hemolytic diseases, and chronic bone marrow aplasia in patients with AIDS. Through transplacental transmission, B19 parvovirus can induce hydrops fetalis and fetal loss. Because infection is ubiquitous and frequently asymptomatic in healthy adults, viremia often is undetected. The prevalence of B19 viremia in normal blood donor populations ranges up to 1:1000,[162] ensuring that most large plasma pools used to make factor concentrates are contaminated with virus. The seroprevalence of hemophiliacs treated repeatedly with plasma-derived concentrates approaches 80% even in those who have received only viral-attenuated products deemed safe from HCV and HIV.[163,164] This is considerably higher than observed in age-matched control groups (approximately 40% seroprevalence). Previous exposure to B19 parvovirus is not affected by age, type or severity of hemophilia, HIV status, $CD4^+$ lymphocyte counts, or purity of the plasma-derived concentrate.[165] Although a few anecdotes describe pure red cell aplasia or pancytopenia, the long-term consequences of parvovirus infection in hemophilia are not established. To date, parvovirus B19, a nonlipid-enveloped virus, has been resistant to inactivation by all available heating and solvent-detergent techniques, used alone or in combination, in the manufacture of concentrates.[166] Adjunctive nanofiltration steps have been implemented for additional viral depletion. Of concern to many physicians who care for patients with hemophilia is the fact that parvovirus B19 is representative of other nonlipid-enveloped viral pathogens (known or unknown) that might contaminate plasma-derived concentrates. These compelling considerations have served as the rationale for administering only recombinant factor VIII or factor IX to parvovirus B19-seronegative patients, previously untreated hemophiliacs, or pregnant carriers. The viruses responsible for West Nile fever and severe acute respiratory syndrome are lipid-enveloped and should be excluded from the plasma-derived concentrates by currently available viral attenuation processes. Furthermore, donor screening procedures and specific virus testing likely will help exclude these pathogens from plasma-derived products.

Other agents potentially transmissible through plasma-derived transfusion include SEN virus, TT virus, both of which cause hepatitis; human herpesvirus 8; simian foamy virus; coronavirus of the severe respiratory syndrome, and prion variant Creutzfeldt-Jakob, which causes the human form of bovine spongiform encephalopathy.[167]

The causative agent of the progressive dementia and spongiform encephalopathy characteristic of Creutzfeldt-Jakob disease (CJD) has been considered infectious since the mid 1960s; however, its transmissibility through the transfusion of blood or blood components remains controversial. Because it cannot be detected in asymptomatic donors, is resistant to chemical and physical inactivation, and does not induce antibodies in carriers, which could be a marker of exposure, CJD prions remain a theoretical threat to individuals using plasma-derived concentrates. CJD is not known to be transmitted to humans by blood components, and no CJD-related deaths are known or reported in hemophilia or other heavily transfused populations.[168] The possibility of bloodborne transmission, however, has not been completely excluded because of its decades-long incubation period prior to symptomatic disease.

A variant form of CJD (vCJD) that causes a neurologic disorder similar to bovine spongiform encephalopathy, a prion disease of cattle, has been recognized in nonhemophilic individuals in the United Kingdom. Between 1995 and 2006, 200 individuals worldwide developed vCJD, including three individuals in the United States who acquired vCJD through blood cell transfusion outside the United States.[169] vCJD has not been transmitted through plasma-derived clotting factor,[168] although it remains a potential risk. The Food and Drug Administration has evaluated the potential for transmission of vCJD by plasma-derived factor VIII concentrates from subclinically infected donors that might be inadvertently included in source plasma. The conclusion was that all U.S.-licensed products probably achieve a 4 $\log_{10}$ reduction of vCJD during manufacture (www.fda.gov/ohrms/dockets/ac/06/briefing/2006-4271B1-01.pdf). The clearance of prions from factor VIII products is hindered because factor VIII is purified from cryoprecipitate, and current manufacturing processes do not inactivate or destroy prions. Prion clearance is entirely the result of partitioning away from intermediates and final product during manufacture and is not as robust as viral clearance measures capable of 10 $\log_{10}$ reduction, for instance. Based on these data, the risk of vCJD transmission via plasma-derived clotting factor concentrates is estimated to range from 1:9.4 billion per person-year, based on episodic treatment, to 1:15,000 per person-year, based on daily treatment.[170] The risk, although low, has contributed to patient preference for recombinant products only and for elimination of animal proteins from the manufacturing process to the greatest extent possible. Monitoring and surveillance for CJD and vCJD in individuals receiving blood products and clotting factor concentrates continues.[170]

Noninfectious Complications of Replacement Therapy

Other than infectious complications, clotting factor concentrates produce few clinically significant adverse reactions. Transfusion-associated anaphylaxis is rare, although anaphylaxis to factor IX concentrates in persons with severe hemophilia B in close association with the development of a factor IX inhibitor has been reported.[171] Genetic analysis reveals complete deletion or rearrangements of the factor IX gene in most affected patients. Induction of immune tolerance to factor IX has not been generally successful, and these patients may be predisposed to developing nephrotic syndrome.[172] Any plasma-derived or recombinant factor IX concentrate is capable of producing such a complication; treatment of bleeding events with

recombinant human factor VIIa is the only effective alternative. Urticarial reactions and low-grade fevers can be treated with antihistamines and acetaminophen.

Thrombotic Complications of Replacement Therapy

Thrombotic complications with use of factor VIII concentrates have not been commonly reported. However, low-purity factor IX complex concentrates have been associated with occurrence of thrombotic complications when infused repeatedly in large amounts. Similar complications have been reported with administration of the activated factor IX complex concentrates used in inhibitor patients. Disseminated intravascular coagulation, deep vein thrombosis, pulmonary embolism, and fatal or life-threatening acute myocardial infarction in young men and boys have been described.[173–175] The introduction of high-purity plasma-derived and recombinant factor IX preparations has virtually eliminated this thrombogenicity, and in vivo studies show little or no rise in the surrogate markers of coagulation activation (e.g., fibrinopeptide A, prothrombin fragment 1.2). Thrombotic events have been reported with use of recombinant factor VIIa,[176,177] including local phlebitis if the drug is administered in small peripheral veins.[178]

Adjunctive Therapeutic Measures

In most persons with mild or moderate hemophilia A, the expense of replacement therapy can be reduced and exposure to bloodborne pathogens eliminated through administration of desmopressin (desamino-8-arginine vasopressin [DDAVP]), a pharmacologic analogue of the hormone 8-arginine vasopressin. DDAVP usually is administered intravenously or intranasally as a spray, with subsequent rise in factor VIII coagulant activity adequate to achieve hemostasis for surgical procedures or symptomatic bleeding. Peak factor VIII activity two to five times baseline level typically is observed within 30 minutes after intravenous infusion of DDAVP (0.3 μg/kg of body weight) and within 60 minutes after intranasal delivery 150 μg per nostril of metered spray: one puff in one nostril for those <50 kg and one puff in each nostril for those ≥50 kg). Because of the variability in individual response, potential candidates for this form of treatment should be tested in advance of its use to provide hemostasis. Dosing can be repeated at 8- to12-hour intervals; however, a progressive tachyphylaxis frequently occurs, making DDAVP less useful for long-term hemostatic support in the postoperative period. Furthermore, the antidiuretic effects of the drug may produce water intoxication and severe hyponatremia, particularly if free water intake is not restricted. Seizure activity is uncommon but has been reported, predominantly in small children and the elderly, but it may occur at any age. Monitoring of fluids and serum sodium levels should minimize these risks. Virtually all patients experience transient facial flushing; mild headaches and minimally decreased blood pressure occasionally are noted. DDAVP should be used cautiously in elderly men with risk factors for coronary or cerebral arterial thrombosis because of an apparent increased risk for angina pectoris, myocardial infarction, or stroke after administration. This may be due to DDAVP-mediated release of supranormal vWF protein multimers from endothelial cells, which promote platelet adhesion in conditions of high shear stress. DDAVP also stimulates the release of tissue plasminogen activator from endothelial cells, potentially producing fibrinolysis at the site of hemostasis. Therefore, for treatment or prevention of mucosal surface bleeding (e.g., dental, gastrointestinal, or vaginal [in carriers]), antifibrinolytic agents should be added immediately before administration of DDAVP and continued for 5 to 7 days thereafter. Similarly, adjunctive administration of antifibrinolytic agents, such as ε-aminocaproic acid or tranexamic acid, in combination with clotting factor concentrates enhances control of bleeding during and after dental surgery in patients with hemophilia A. Use of these agents should be reserved for patients with hemophilia B who are receiving high-purity factor IX preparations because any thrombotic tendency induced by low-purity materials may be exacerbated by inhibition of fibrinolysis.
