The typical HS patient is relatively asymptomatic. As noted in the earliest descriptions of HS, mild jaundice can be the only symptom of the disease. Splenomegaly gradually develops in most patients, with the spleen occasionally reaching large dimensions. Anemia is usually mild to moderate but can occasionally be absent because of compensatory bone marrow hyperplasia.

Mild Forms and Carrier State

In some families, anemia is absent, the reticulocyte count is normal or only minimally elevated, laboratory evidence of hemolysis is minimal or absent,[46–48] and the changes in red blood cell shape can be mild, escaping detection on the peripheral blood film. The presence of HS is detected only by osmotic fragility testing or during evaluation of a relative with a more symptomatic form of the disease. Some patients are first diagnosed during transient viral infections such as infectious mononucleosis or parvovirus infection, during pregnancy, or even in the seventh to ninth decades of life as the bone marrow's ability to compensate for hemolysis wanes.

Severe and Atypical Forms

The relatively uncommon patients with nondominant forms of HS can present with a severe life-threatening hemolysis early in life.[1,3,6]

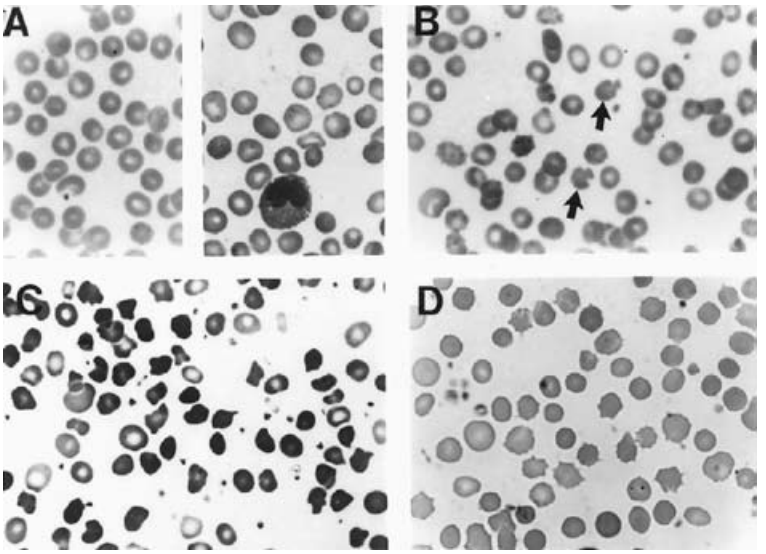

Figure 46–3 Blood films from patients with hereditary spherocytosis (HS) of varying severity. (**A**) Two blood films of typical moderately severe HS with a mild deficiency of red blood cell spectrin and ankyrin. Although many cells have a spheroidal shape, some retain a central concavity. (**B**) HS with pincerlike red blood cells (**arrows**), as typically seen in HS associated with band 3 deficiency. Occasional spiculated red blood cells are also present. (**C**) Severe atypical HS caused by a severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have irregular contour. (**D**) HS with isolated spectrin deficiency caused by a β-spectrin mutation. Some of the spherocytes have prominent surface projections resembling spheroacanthocytes.

Some patients can be transfusion dependent during early infancy and childhood. The underlying molecular defects include severe spectrin or band 3 deficiency.

Hereditary Spherocytosis and Nonerythroid Manifestations

In most HS cases, the clinical manifestations are confined to the erythroid lineage, probably because many of the nonerythroid counterparts of the red blood cell membrane proteins (eg, spectrin and ankyrin) are encoded by separate genes or because some proteins (eg, protein 4.1R, β-spectrin, ankyrin) are subject to tissue-specific alternative splicing. However, several HS kindreds have been reported with a cosegregating neurologic or muscular abnormality, such as a degenerative disorder of the spinal cord, cardiomyopathy, or mental retardation. The observation that both erythrocyte ankyrin and β-spectrin are also expressed in muscle, brain, particularly the cerebellum, and spinal cord raises the possibility that these HS patients may have a defect in one of these proteins. This hypothesis is further supported by studies of *nb/nb* mice, a mouse model of HS caused by an ankyrin mutation.[42] These mice develop a neurologic syndrome with a progression that coincides with the loss of ankyrin from the Purkinje cells of the cerebellum.[49]

Mutations of band 3 without HS have been described in patients with distal renal tubular acidosis.[50] Most patients with heterozygous mutations of band 3 and HS have normal renal acidification. The exceptions are two kindreds with co-inherited HS and renal acidification defects because of band 3 mRNA processing mutations, band $3^{Pribram}$, and band $3^{Campinas}$.[51,52] The pathogenesis of the renal tubular acidosis in these cases is unknown.

Laboratory Evaluation

Most HS patients have either a mild to moderate anemia or no anemia at all, reflecting the facts that the hemolytic rate can be very mild and that the hemolysis is fully compensated for by increased red blood cell production, as evidenced by reticulocytosis. Some patients, however, particularly those with nondominantly inherited HS, are severely anemic, with hemoglobin concentrations as low as 4 to 6 g/dL.

Despite the increased percentage of reticulocytes with a larger volume than mature red blood cells, the mean corpuscular volume (MCV) of HS red blood cells is often low normal or even slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is usually increased (>35 g/dL), together reflecting mild cellular dehydration.

The finding of an MCHC > 35.4 g/dL combined with an elevated red blood cell distribution width (RDW) >14% has been found to be an excellent screening test for HS.[50] Another screening method measures MCV by light scattering and provides a histogram of hyperdense erythrocytes (MCHC > 40 g/dL) claimed to identify nearly all HS patients.[53–55] These hyperdense erythrocytes can be detected with newer laser-based blood counters or using aperture impedance analysis available in many clinical laboratories.

Evidence of accelerated red blood cell destruction, as indicated by increased lactate dehydrogenase and unconjugated bilirubin levels and by decreased haptoglobin, as well as by reticulocytosis, is present in typical HS patients. However, these abnormalities can be absent in individuals with a mild form of the disease.

Blood Film

In a typical case of HS, spherocytes are readily identified by their characteristic shape on the peripheral blood film (Fig. 46–3). They lack central pallor, their mean cell diameter is decreased, and they appear more intensely hemoglobinated, which reflects both altered red blood cell geometry and increased cell density. In a three-dimensional view, some spherocytes have a spherostomatocytic shape that is occasionally appreciated on the peripheral blood film. In mild forms of the disease, the peripheral blood smear can appear normal because the loss of surface area can be too small to be appreciated by blood smear evaluation; the cells appear as "fat" disks rather than as true spherocytes.

Additional morphologic features have been described in some HS patients (see Fig. 46–3). A subset of HS patients whose red blood cells are deficient in band 3 protein have some pincerlike red blood cells on the peripheral blood film, a finding that is both sensitive and specific for this HS subset,[25] However, pincerlike cells disappear after splenectomy. Surface spiculations or acanthocytic spherocytes have been described in cases of HS associated with defects in β-spectrin.[12,13] Frequent sphero-ovalocytes and stomatocytes were reported in Japanese patients with protein 4.2 deficiency.[29]

Osmotic Fragility

The osmotic fragility test (Fig. 46–4) measures the in-vitro lysis of red blood cells suspended in solutions of decreasing osmolarity. The

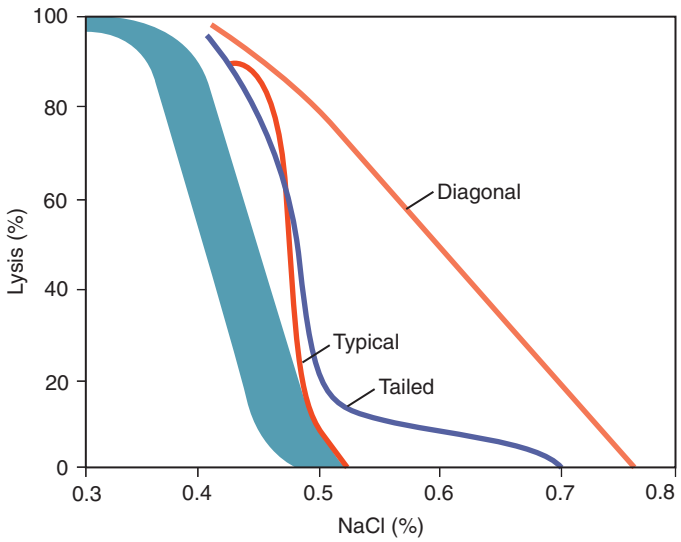

Figure 46–4 Characteristic osmotic fragility curves in hereditary spherocytosis (HS). The typical curve of increased osmotic fragility is the most common finding. The tailed curve reveals a second population (a tail) of very fragile erythrocytes conditioned by the spleen. This tail disappears after splenectomy. The diagonal curve is seen in patients with severe HS. *(Modified from Dacie J: Hereditary spherocytosis (HS). In The Haemolytic Anaemias, 3rd ed, vol 1. Edinburgh, Churchill Livingstone, 1985, p 134.)*

normal red blood cell membrane is unstretchable and is virtually freely permeable to water. Thus, the cell behaves as a nearly perfect osmometer in that it increases its volume in hypotonic solutions progressively until a "critical hemolytic volume" is reached. At this point, the red blood cell membrane ruptures, and hemoglobin escapes into the supernatant solution. As a result of the loss of membrane and the ensuing surface area deficiency, the critical hemolytic volume of spherocytes is considerably lower than that of normal red blood cells. Consequently, these cells hemolyze more than normal red blood cells when suspended in hypotonic sodium chloride (NaCl) solutions. However, a finding of increased osmotic fragility is not unique to HS and is also present in other conditions associated with spherocytosis on the peripheral blood film, such as autoimmune hemolytic anemia.

The slight dehydration of hereditary spherocytes (which in other conditions is associated with decreased osmotic fragility) has no appreciable effect on HS osmotic fragility because of the overriding effect of the markedly diminished cell-surface area. In fact, the densest, most dehydrated cells exhibit the greatest increase in osmotic fragility.

The osmotic fragility curve often reveals uniformly increased osmotic fragility. A "tail" of the osmotic fragility curve can be present in nonsplenectomized HS subjects, indicating a subpopulation of particularly fragile red blood cells conditioned by splenic stasis. This subpopulation of cells disappears after splenectomy.[48] In subjects with mild HS, osmotic fragility can be normal and abnormalities can only be found after incubation that further augments the loss of surface area; however, the sensitivity of the incubated osmotic fragility test can be outweighed by a loss of its specificity. The relative contributions of cell dehydration and surface area deficiency can be accurately determined by osmotic gradient ektacytometry, available only in specialized laboratories.

Autohemolysis and Other Tests

Red blood cell autohemolysis, the spontaneous hemolysis of red blood cells incubated under sterile conditions without glucose, was previously advocated as a sensitive test for the detection of HS. This test is being used less frequently and is probably no more sensitive than the incubated osmotic fragility test. Other tests described in the literature such as the glycerol lysis test, the pink test, hypertonic cryohemolysis, and the skeleton gelation test, are not widely used in the United States. The former two tests, which employ glycerol to retard the osmotic swelling of red blood cells, are preferred by some laboratories because they are easy to perform and can be adapted to microsamples. Cryohemolysis testing remains popular in Europe.[56]

The observations that most spherocytes are deficient in band 3 (see Fig. 46–1) and that eosin-5'-maleimide (EMA) covalently binds band 3 and Rh-related proteins with a 1:1 stoichiometry have been used in a screening test in which binding of fluorescently-labeled EMA to erythrocytes is followed by flow cytometric quantitation. This method is fast and simple and appears to have both high sensitivity and specificity.[57] Like osmotic fragility (OF) and cryohemolysis, other erythrocytes abnormalities such as abnormalities of erythrocyte hydration and variants of dyserythropoietic anemia can also yield abnormal results.

Detection of the Underlying Molecular Defect

Because the most common finding in erythrocytes of patients with HS is a deficiency of one or more of the membrane proteins, initial studies often include sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) solubilized red blood cell membrane proteins followed by densitometric quantitation. The results are expressed as ratios of individual red cell membrane proteins to band 3. This technique reveals abnormalities in approximately 70% to 80% of patients, defining the distinct biochemical phenotypes discussed previously. Direct quantitation of membrane proteins by radioimmunoassay is superior to densitometric quantitation and permits accurate measurement of the copy number of the individual proteins per red blood cell. The importance of the latter approach is heightened by the fact that the loss of band 3 can overestimate the spectrin/band 3 or ankyrin/band 3 ratios and, consequently, underestimate the extent of protein deficiencies. As less band 3 is lost after splenectomy, densitometric measurements are more reliable in splenectomized patients.

Subsequent strategies to search for the underlying defect are complex. Studies of protein function, readily employed in the detection of spectrin mutations in cases of HE and HPP (see Pathobiology of the Red Blood Cell Lesion), have been disappointing in detecting abnormalities in HS, with the exception of HS characterized by a weakened β-spectrin-protein 4.1R interaction. Studies of membrane protein synthesis and assembly, using either reticulocytes or erythroblasts derived from peripheral blood burst-forming units in vitro, have been used but they are insensitive in detecting mild to moderate abnormalities in membrane protein synthesis and assembly and are technically cumbersome to perform.

Genetic linkage analysis has been employed in cases of HS, but it suffers from the disadvantages of the need to study large kindreds and its lack of usefulness in studying patients with de-novo mutations. Because of the large sizes of the HS genes, mutation-screening techniques have been developed. Polymerase chain reaction–based mutation screening techniques include single-strand conformational polymorphism analysis and denaturing high-performance liquid chromatography.[20,44] Both techniques identify candidate regions in HS genes of affected patients. These regions are then subjected to nucleotide sequence analysis for detection of the precise genetic defect. Combinations of techniques have been employed in the search for ankyrin gene mutations.[58]

Complications

Gallstones

Bilirubin stones are found in approximately 50% of patients with HS, often even in those with a very mild form of the disease.[3] Gall-

stones have occasionally been detected during infancy, but they are most likely to occur in children and young adults.[59] The coinheritance of Gilbert syndrome markedly increases the risk for gallstones in HS patients.[60] Because of the high incidence of gallstones, HS patients should be periodically examined by ultrasonography for the presence of gallstones, beginning early in childhood.

Crises

True hemolytic crises are relatively rare and only occasionally reported in association with infections. Aplastic crises during viral infections are largely attributable to infection by parvovirus B19.[61] This infection (erythema infectiosum, fifth disease) manifests with fever, chills, lethargy, malaise, nausea, vomiting, abdominal pain with occasional diarrhea, respiratory symptoms, muscle and joint pains, and a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities. The virus selectively infects erythroid precursors and inhibits their growth.[62] The ensuing anemia, often profound, can be the first manifestation of HS.[63] Multiple family members with undiagnosed HS who are infected with parvovirus have developed aplastic crises at the same time. Infection with parvovirus is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, hydrops fetalis, and fetal demise.

Rarely, at least in developed countries, patients present with megaloblastic crises caused by folate deficiency. This typically occurs in patients with increased folate demands, such as those recovering from an aplastic crisis, pregnant women, and the elderly. Megaloblastic crisis in pregnancy has been reported as the first manifestation of HS. Folate supplementation (1 mg/day) is recommended for all patients with HS.

Other Complications

In patients with more severe forms of HS, other complications include gout, leg ulcers, or chronic dermatitis of the legs that heal after splenectomy and symptoms of expanded erythroid space, including paravertebral or renal pelvic masses of extramedullary hematopoiesis, which can mimic an underlying neoplasm. Several cases of hemochromatosis in HS patients have been reported. In some, iron overload resulted from repeated transfusions; in others, the patients had two genetic defects, one involving HS and the other involving a hemochromatosis carrier state.[64] Other rare complications include thrombosis, spinocerebellar degenerative syndromes, movement disorders, myopathy, and hypertrophic cardiomyopathy.

More than a dozen cases of HS and hematologic malignancy, including myeloproliferative disorders, multiple myeloma, and leukemia, have been reported. It is unknown if long-standing hematopoietic stress predisposes to the development of these secondary disorders or if they occurred randomly.

Differential Diagnosis

Because of the relatively asymptomatic presentation of HS, this diagnosis should be considered during an evaluation for unexplained splenomegaly, unconjugated hyperbilirubinemia of unknown cause, gallstones at a young age, severe anemia during pregnancy, or transient anemia during acute infections. The diagnosis of HS can be missed in mild forms of the disease, because spherocytosis might not be apparent on the peripheral blood film. An osmotic fragility test of incubated red blood cells usually provides a diagnostic answer. Autoimmune hemolytic anemia (AIHA) should be ruled out by a negative Coombs test.

More typical forms of HS, characterized by relatively uniform spherocytosis with increased MCHC, are usually easily distinguished from other disorders manifesting with spherocytosis, such as immune hemolytic anemias and unstable hemoglobins. In some patients, the spherostomatocytes in the rare Rh null syndrome and the intermediate syndromes of hereditary stomatocytosis can be confused with HS red blood cells.

Spherocytosis is transiently improved, and both the osmotic fragility and hemolysis are normalized in patients with obstructive jaundice. This is because of an expansion of red blood cell surface area that follows an increased uptake of phospholipids and cholesterol from the abnormal plasma lipoproteins. In normal red blood cells, this leads to target cell formation; in HS, spherocytes are transformed to discocytes. Spherocytosis and the increased osmotic fragility of HS red cells are likewise improved by iron deficiency, but the red blood cell life span remains shortened. In addition, coexistence of β-thalassemia trait and HS partially corrects the HS phenotype.

Therapy and Prognosis

Splenectomy

Splenectomy is curative in almost all patients with typical forms of HS, as red blood cell survival is normalized, and anemia and hyperbilirubinemia are corrected. Spherocytosis and the increase in osmotic fragility persist, but the tail of the osmotic fragility curve, indicating the presence of a subpopulation of cells conditioned by the spleen, disappears. In patients with severe, nondominantly inherited HS, splenectomy produces a dramatic clinical improvement, but hemolysis is only partially corrected.[14,15]

Several weeks to months before splenectomy, patients should be immunized with polyvalent vaccine against pneumococcus as well as vaccines against *Haemophilus influenzae* type b and meningococcus.

Indications for Splenectomy

Risks and benefits should be considered carefully in HS patients before splenectomy is performed. A multitude of factors influence the decision for splenectomy in HS patients, including the risk of overwhelming postsplenectomy sepsis, the emergence of penicillin-resistant pneumococci, and the potentially increased risk of cardiovascular disease and pulmonary hypertension later in life.[65–69] Indications for splenectomy include growth retardation, skeletal changes, symptomatic hemolytic disease, anemia-induced compromise of vital organs, the development of leg ulcers, or the appearance of extramedullary hematopoietic tumors. Whether to perform splenectomy in patients with moderate HS without any of the above factors remains controversial.

Because of an increased frequency of postsplenectomy infection in young children, splenectomy should not be performed earlier than 3 to 5 years of age.

Operative Considerations

When splenectomy is warranted, laparoscopic splenectomy has become the procedure of choice in many centers.[70,71] Laparoscopic splenectomy has been associated with less postoperative discomfort, a quicker return to preoperative diet and activities, a shorter hospitalization time, decreased costs, and smaller scars. Early complications of splenectomy include local infection, bleeding, and pancreatitis. In general, the morbidity rate of splenectomy is lower in patients with HS than with other hematologic diseases. However, the benefits of surgery must be weighed against possible complications, such as postsplenectomy infections, including the postsplenectomy sepsis syndrome. Although these complications are rare and their frequency is likely to diminish further with appropriate vaccinations, the indiscriminate performance of splenectomy in all HS patients with splenomegaly is unwarranted.

Subtotal (Partial) Splenectomy

Partial splenectomy has been suggested for infants and young children with severe HS, anemia, and poor growth with the goals of palliating anemia and decreasing transfusion requirements while pre-

serving splenic function.[72–74] The goal of this operation is to decrease hemolysis while maintaining splenic phagocytic function. It has been so far performed in a few hundred patients with stable increase in hemoglobin levels and decrease in reticulocyte counts. The volume of splenic tissue left behind ranges from 10 to 30 mL. Although initial data are promising, it is not clear whether the remaining splenic tissue will effectively prevent postsplenectomy sepsis. In addition, regrowth of the splenic remnant has been reported in most patients, which can eventually lead to recurrence of HS and another operative procedure.[75]

After splenectomy, prophylactic antibiotics for at least 5 years are recommended by some practitioners, and for life by others.

Postsplenectomy Failures

Postsplenectomy failures are caused either by the presence of an accessory spleen missed during surgery (accessory spleens were found in 17%–39% of all patients)[76] or by the presence of another superimposed red blood cell disorder such as pyruvate kinase deficiency. The recurrence of hemolytic anemia several years after splenectomy should raise the suspicion of development of splenunculi, resulting from autotransplantation of splenic tissue during surgery. The presence of an accessory spleen or splenunculus is suggested by the absence of both Howell-Jolly bodies and the "pitted" cells with crater-like surface indentations readily seen by interference contrast microscopy.[77] A definitive confirmation of splenosis is made by a radiocolloid liver-spleen scan or by a scan using chromium (Cr)-labeled heated red blood cells, which are taken up by the ectopic splenic tissue.

Genetic Counseling

After a patient is diagnosed with HS, family members should be examined for the presence of HS. A history, physical examination for splenomegaly, complete blood count with indices, reticulocyte count, examination of the peripheral blood smear for spherocytes, and biochemical evaluation including bilirubin and haptoglobin levels should be obtained for available close relatives.

HEREDITARY ELLIPTOCYTOSIS AND RELATED DISORDERS

Definition, Prevalence, and History

Hereditary elliptocytosis designates a group of inherited disorders that have in common the presence of elliptical red blood cells on peripheral blood films.[78] Elliptocytosis was first described by Dresbach in 1904,[79] and its heritability was firmly established by Hunter.[80] Subsequent reports have revealed a considerable heterogeneity of clinical expression and have defined several distinct syndromes, including HPP and SAO.[1,6]

Hereditary elliptocytosis is common in people of African and Mediterranean ancestries. In the US population, the prevalence of HE is approximately 3 to 5 per 10,000.[81] The true incidence of HE is unknown because its clinical severity is heterogeneous and most patients are asymptomatic without anemia.[82] HE is considerably more frequent in areas of endemic malaria. In equatorial Africa, the prevalence of common HE has been estimated at between 0.6% and 1.6%. Worldwide, HE appears to be more common among people of African origin. In Southeast Asian populations, the prevalence of SAO, a variant of HE, is as high as 30%.[83]

The molecular basis of HE remained obscure until a defect of membrane skeletal proteins was suggested. Subsequently, defects in the erythrocyte membrane proteins α-spectrin, β-spectrin, protein 4.1R, glycophorin C, and band 3 were described.

On the basis of red blood cell morphology, HE can be divided into three major groups (Fig. 46–5). Common HE, a dominantly inherited condition, is morphologically characterized by biconcave

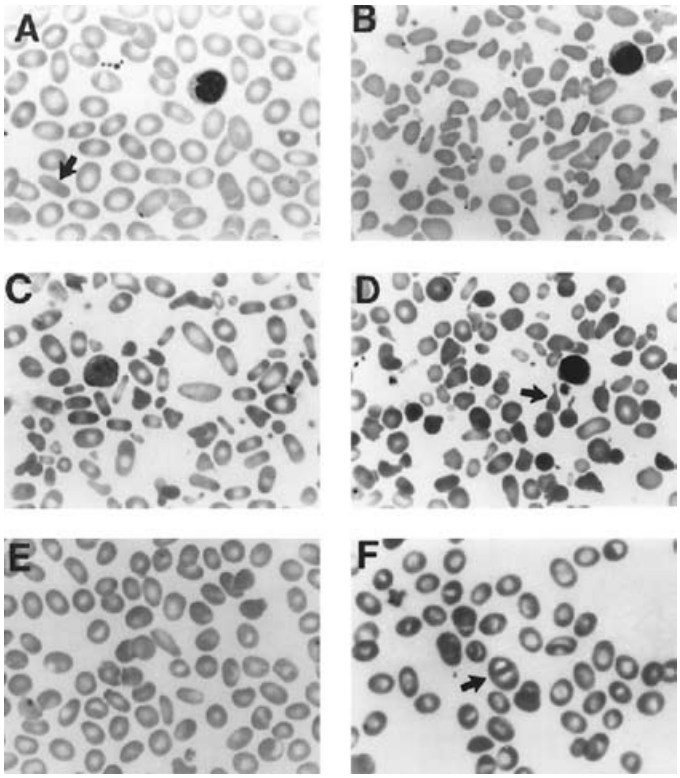

Figure 46–5 Blood films of subjects with various forms of hereditary elliptocytosis (HE). (**A**) Simple heterozygote with mild common HE. Note the predominant elliptocytosis with some rod-shaped cells (*arrow*) and virtual absence of poikilocytes. (**B**) Simple heterozygote with severe common hemolytic elliptocytosis. Note the numerous small fragments and poikilocytes. (**C**) "Homozygous" common HE because of doubly heterozygous state for two mutant α-spectrins. Both parents have mild HE. Note the many elliptocytes as well as numerous fragments and poikilocytes. (**D**) Hereditary pyropoikilocytosis. The patient is a double heterozygote for a structural α-spectrin mutant and a presumed α-spectrin synthetic defect. Note the prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only few elliptocytes are present. Some poikilocytes are in the process of budding (*arrow*). (**E**) Spherocytic HE (hereditary ovalocytosis). Most red blood cells are oval rather than truly elliptical. Many oval cells are "fat," lacking a central concavity, the feature distinguishing spherocytic HE from common HE. (**F**) Southeast Asian ovalocytosis (Melanesian). Most cells are oval, some containing either a longitudinal slit or a transverse ridge (*arrow*).

elliptocytes and, in some patients, rod-shaped cells. The clinical severity of common HE is highly variable, ranging from an asymptomatic condition to a severe recessively inherited hemolytic anemia, including hemolytic HE and HPP, in which the blood film reveals numerous red blood cell fragments, microspherocytes, and poikilocytes. Spherocytic HE, also called hemolytic ovalocytosis, is a much less common condition in which both round "fat" ovalocytes and spherocytes are present on the blood film. SAO, a disorder highly prevalent in the malaria-belt of Southeast Asia and the Pacific, is characterized by rigid, spoon-shaped cells that have either a longitudinal slit or a transverse ridge.

Common Hereditary Elliptocytosis

The possibility that the primary lesion of HE and HPP erythrocytes resides in the proteins of the red blood cell membrane skeleton was first raised by the findings of thermal instability of HPP spectrin, retention of the elliptical shape in HE membrane skeletons, disintegration of membrane skeletons after exposure to shear stress, defective self-association of spectrin dimers to tetramers, altered susceptibility

of spectrin to tryptic digestion, and a deficiency of the membrane skeleton proteins spectrin and protein 4.1R. Gene cloning and determination of the primary structure of these proteins was soon followed by reports of mutations in the genes encoding erythrocyte membrane proteins.

Etiology

Spectrin Mutations

The most common defects in HE, found in approximately two-thirds to three-quarters of all patients, are mutations of α- or β-spectrin.[1,6,78,84] Both α- and β-spectrin are elongated flexible molecules consisting of triple helical repeats connected by nonhelical segments. These polypeptides are associated side-to-side in an antiparallel position, forming a flexible, rod-like αβ heterodimer in which the NH_2-terminus of α-spectrin and the COOH-terminus of β-spectrin form the head region of the heterodimer.[84,85] Spectrin heterodimers associate head-to-head to form spectrin tetramers, the major structural subunits of the membrane skeleton. Spectrin tetramers, in turn, are interconnected into a highly ordered two-dimensional lattice through binding, at their distal ends, to actin oligomers with the aid of protein 4.1R.[86]

The contact site between the α- and β-spectrin chains of the opposed heterodimers is a combined "atypical" triple helical repetitive segment in which the first two helices are contributed by the COOH-terminus of β-spectrin, whereas helix 3 is the first helical segment of α-spectrin. Spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that under physiologic conditions strongly favors spectrin tetramers.[87,88] Most α-spectrin defects are at or near the NH_2-terminus of α-spectrin, which is involved in the heterodimer contact (the so-called αI domain defined by limited tryptic peptide mapping; see the discussion under Laboratory Evaluation),[84] and impair the self-association of spectrin into tetramers. Most α-spectrin mutations are point mutations.[78,84] These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin.

Elliptocytogenic β-spectrin mutations are COOH-terminal point mutations or truncations that disrupt the formation of the combined β triple-helical repetitive segment and consequently the self-association of spectrin heterodimers to tetramers.[78,84] All of these mutations open a proteolytic cleavage site residing in the third helix of the combined repetitive segment, which gives rise to a 74-kd αI peptide.

Although most spectrin mutations reside in the vicinity of the αβ-spectrin self-association site, a few mutations remote from the self-association site have been described. These mutations are asymptomatic in the simple heterozygous state but cause hemolytic anemia, which can be severe, in homozygous patients.[89–91] Unlike mutations located in the self-association contact site which are predicted to disrupt the conformation of the local protein structure,[92] mutations outside this region are predicted to perturb long range protein-protein interactions, disrupting the positively coupled, cooperative interactions of αβ spectrin self-association, spectrin-ankyrin interactions, and ankyrin-band 3 interactions.[93,94] One HE-associated mutation in a linker region remote from the self-association contact site disrupted the stability propagated from one spectrin repeat to the next.[93,94]

Protein 4.1R Mutations

Another group of elliptocytogenic mutations, although much less common than spectrin mutations, are quantitative or qualitative defects of protein 4.1R.[78] Protein 4.1R is a multifunctional protein that contains several important sites of protein interactions, including the spectrin-binding domain, where 4.1R binds to the distal end of the spectrin αβ heterodimer, markedly increasing the binding of spectrin to oligomeric actin, and the basic NH_2-terminal domain, where 4.1R interacts with glycophorin C, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of spectrin to the membrane.[85,86]

Studies of 4.1R mRNA from normal red blood cells revealed 4.1R isoforms resulting from complex tissue and developmental-stage specific patterns of alternate mRNA splicing.[95–99] Alternate translation initiation sites are present in the protein 4.1R mRNA. When an upstream AUG is used, isoforms greater than 80 kd are synthesized. During erythropoiesis, this upstream AUG is spliced out and a downstream AUG is used, leading to the production of the 80-kd mature erythroid protein 4.1R isoform.[96] On SDS-PAGE, protein 4.1R is resolved into two bands of different sizes: 4.1a and 4.1b. The larger band, 4.1a, is typically found in normal red blood cells, whereas the shorter one, 4.1b, represents the major isoform of reticulocytes. The 4.1b isoform is converted into the 4.1a isoform by deamidation of Asn 502.

A partial deficiency of protein 4.1R is associated with mild, dominantly inherited HE, whereas a complete deficiency (a homozygous state) leads to a severe hemolytic disease.[100,101] Homozygous 4.1R(–) erythrocytes fragment more rapidly than normal at moderate sheer stresses, an indication of their intrinsic instability.[102] Membrane mechanical stability can be restored by reconstituting the deficient red blood cells with protein 4.1R or the protein 4.1R/spectrin/actin-binding site.[103] Homozygous protein 4.1R(–) erythrocytes also lack p55 and have only 30% of the normal content of glycophorin C. These homozygous 4.1R(–) erythrocytes, as well as glycophorin C(–) Leach erythrocytes, demonstrate decreased invasion and growth of *Plasmodium falciparum* in vitro.

Mutations associated with protein 4.1R deficiency have included deletions that include the exon encoding the erythroid transcription start size and mutations of the transcription initiation codon.[78] Qualitative defects of protein 4.1R protein include deletions and duplications of the exons encoding the spectrin-binding domain, leading either to truncated or elongated forms of protein 4.1R. Electron microscopic studies of homozygous 4.1R(–) erythrocyte membranes revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, suggesting that protein 4.1R plays an important role in maintenance not only of the skeletal network but also of the integral proteins of the membrane structure.[104]

Glycophorin C Deficiency

Glycophorin C (GPC) has been found absent because of a variety of molecular defects.[105] In contrast to other forms of HE, which are dominantly inherited, heterozygous carriers are asymptomatic, with normal red blood cell morphology, and homozygous subjects have no anemia and only mild elliptocytosis apparent on the peripheral blood film.

GPC deficiency with elliptocytosis, the so-called Leach phenotype,[106] caused by reduced expression of GPC, should be distinguished from the immunochemically defined phenotypes Gerbich and Yus, in which abnormal glycoproteins are formed that can functionally substitute for normal GPC and preserve the normal red blood cell shape. The Leach phenotype is usually caused by a large deletion of genomic DNA (~7 kb) that removes exons 3 and 4 from the GPC/GPD locus. In one patient, the Leach phenotype was caused by a frameshift mutation.

GPC-deficient subjects are also partially deficient in protein 4.1R and lack p55, presumably because these proteins form a complex and recruit or stabilize each other on the membrane.[107] It has been speculated that the protein 4.1R deficiency in Leach erythrocytes is the cause of the elliptocytic shape. In contrast, subjects deficient in glycophorin A, the major transmembrane glycoprotein, are asymptomatic.

Pathobiology of the Red Blood Cell Lesion

Most of the elliptocytogenic mutations of spectrin reside within, or in the vicinity of, the spectrin heterodimer self-association site, dis-

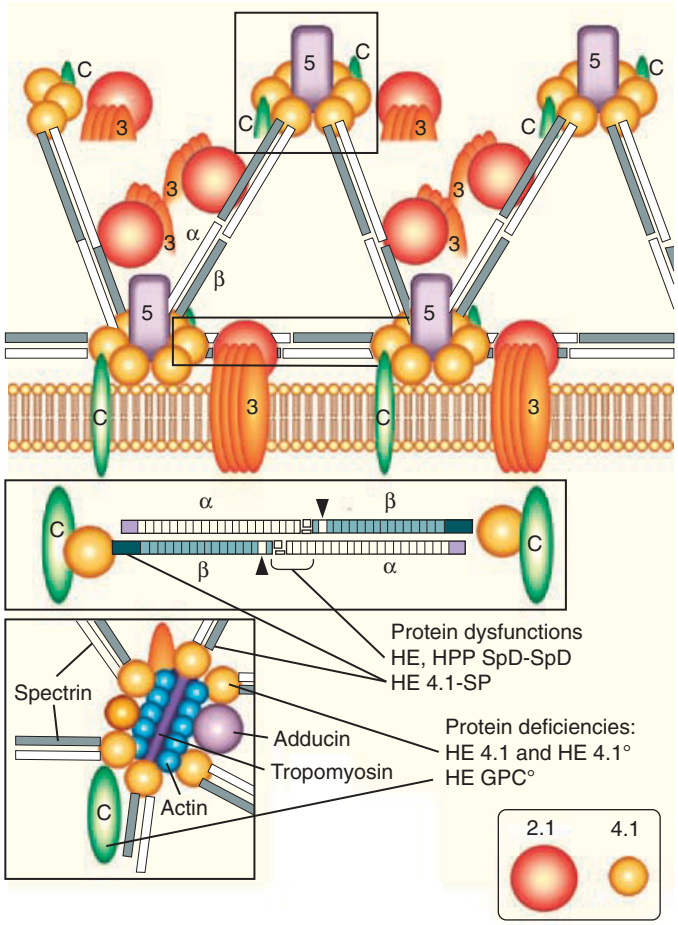

Figure 46–6 Schematic representation of the molecular assembly of the membrane skeleton and the molecular defects in hereditary elliptocytosis HE and hereditary pyropoikilocytosis (HPP). Spectrin is composed of α- and β-spectrin heterodimers (SpD) that associate in their head regions into tetramers. At their distal ends, SpD bind to the junctional complexes of oligomeric actin (band 5) and protein 4.1. Additional proteins found in the junctional complex, such as adducin, tropomyosin, and protein 4.9, are shown in the lower enlarged area. The membrane skeleton is attached to transmembrane proteins by interactions of β-spectrin with ankyrin (protein 2.1; [*black arrow*] designates the ankyrin-binding site in β-spectrin), which in turn binds to the cytoplasmic domain of band 3, and by linkage of protein 4.1 to glycophorin C. The known protein dysfunctions in HE and HPP include (1) defects of the SpD head region because of a mutation of either α- or β-spectrin, causing impaired assembly of SpD into tetramers, and (2) defects of proteins of the junctional complex such as a qualitative or quantitative defects of protein 4.1R or glycophorin C.

rupting this region and consequently disrupting the two-dimensional integrity of the membrane skeleton (Fig. 46–6). These defects are detected by ultrastructural examination of the membrane skeleton, which reveals disruption of a normally uniform hexagonal lattice. Consequently, membrane skeletons are mechanically unstable, as are whole cell membranes and the cells.[108] In patients with severely dysfunctional spectrin mutations or patients homozygous or doubly heterozygous for spectrin mutations, the membrane instability is sufficient to cause red blood cell fragmentation with hemolytic anemia under conditions of normal circulatory shear stress.

The pathobiology of the elliptocytic shape is less clear. Red blood cell precursors in common HE are round, and the cells become progressively more elliptical as they age in vivo.[109,110] Red blood cells subjected to shear stress in vitro, or red blood cells flowing through microcirculation in vivo, have an elliptical or parachute-like shape, respectively. It is possible that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape because the weakened spectrin heterodimer contacts facilitate skeletal reorganization, which follows axial deformation of cells resulting from application of a prolonged or excessive shear stress. This reorganization is likely to involve breakage of the unidirectionally stretched protein connections followed by the formation of new protein contacts that preclude the recovery of a normal biconcave shape.[87] This process has been shown to account for permanent deformation of irreversibly sickled cells.[111]

In HPP, the recessively inherited form of HE characterized by severe hemolysis, red blood cells have two abnormalities.[112,113] They contain a mutant spectrin that characteristically disrupts spectrin heterodimer self-association, and they are also partially deficient in spectrin, as evidenced by a decreased spectrin/band 3 ratio. In some HPP cases, this biochemical phenotype is a consequence of a double heterozygous state for an elliptocytogenic α-spectrin mutation and a defect involving reduced α-spectrin synthesis. Such synthetic defect of α-spectrin is fully asymptomatic in the heterozygous carrier, because under normal conditions, the synthesis of α-spectrin is approximately three to four times greater than that of β-spectrin.

When present in conjunction with an elliptocytogenic mutation of α-spectrin, such a synthetic defect augments the expression of the mutant spectrin. Because the elliptocytogenic α-spectrin mutants are often unstable, the combination of the two defects leads to spectrin deficiency in the cells. Other HPP subjects are homozygous or doubly heterozygous for one or two elliptocytogenic spectrin mutations, respectively.[84] In such cases, the spectrin deficiency may be a consequence of spectrin instability that reduces the amount of spectrin available for membrane assembly. Furthermore, in red blood cells containing a high fraction of unassembled dimeric spectrin, the spectrin deficiency may in part be related to the stoichiometric ratio of one ankyrin copy per one spectrin tetramer (ie, two spectrin heterodimers). Consequently, only approximately one-half of spectrin heterodimers succeed in attaching to the ankyrin-binding sites. The phenotype of HPP, characterized by the presence of fragments and elliptocytes, together with evidence of red blood cell surface area deficiency (as reflected by the presence of microspherocytes on the peripheral blood film), suggests that the membrane dysfunction involves both vertical interactions (a consequence of spectrin deficiency) and horizontal interactions involving the elliptocytogenic spectrin mutation.

The red blood cell lesion in protein 4.1R deficiency shows similarities in regard to cell shape and membrane stability to the above elliptocytogenic mutations of spectrin, suggesting that the deficiency principally affects the spectrin-actin contact (see Fig. 46–6) rather than the skeleton attachment to glycophorin C via protein 4.1R (a vertical interaction).[108]

The molecular basis of elliptocytosis and the mechanical instability of glycophorin C-deficient red blood cells are not fully understood. However, recent studies suggest that the deficiency of glycophorin C is not directly responsible for the altered mechanical properties. Instead, the mechanical instability appears to be related to a concomitant partial deficiency of protein 4.1R, as evidenced by a full correction of membrane instability by introduction into the cells of protein 4.1R or its spectrin-binding peptide, which facilitates the contact of β-spectrin to actin. The superimposed deficiency of protein 4.1R is likely to be related to the fact that glycophorin C serves as an attachment site for protein 4.1R to the membrane, recruiting protein 4.1R to the red blood cell membrane. The effects of these defects on the mechanical stability of glycophorin C-deficient cells appear to be relatively minor, because glycophorin C-deficient subjects have no detectable hemolytic anemia and the mechanical properties of the red blood cells are normal when tested by micropipette aspiration.

Inheritance

In most patients, HE is inherited as an autosomal dominant disorder. The clinical severity is highly variable among different kindreds (reflecting heterogeneous molecular lesions) and, to a lesser extent,

within a given kindred, presumably because of other genetic or acquired defects that modify disease expression.[6,78] Occasionally, HE is inherited as an autosomal recessive condition from an asymptomatic parent who carries the same molecular defect of spectrin as the HE offspring. In one kindred with a submicroscopic chromosome X deletion, inheritance was X-linked.[114]

The inheritance of the related disorder HPP is autosomal recessive: one of the parents carries the α-spectrin mutation and either is asymptomatic or has mild HE, whereas the other parent is fully asymptomatic and has no abnormalities detectable by current biochemical approaches. However, several HPP patients have recently been studied who were doubly heterozygous for two α-spectrin mutations; in the heterozygous parents, these mutations were either silent or expressed as mild HE.

Clinical Manifestations

In view of the striking molecular heterogeneity of common HE, it is not surprising that the clinical spectrum of this disorder is variable, ranging from an asymptomatic trait without hemolysis to a life-threatening hemolytic anemia.

Mild Hereditary Elliptocytosis and Asymptomatic Carrier State

In most of these subjects, HE is found accidentally during evaluation of the peripheral blood film. Although some HE subjects have a mild compensated hemolytic anemia, others do not have any evidence of hemolysis, their red blood cell survival is normal, and the peripheral blood film may reveal only modest (≥15%) elliptocytosis. The molecular basis of mild HE is heterogeneous, and the reported molecular defects include both α- and β-spectrin mutations, partial deficiency of the 4.1R protein, and the absence of glycophorin C. Some individuals carrying the spectrin mutation are completely asymptomatic, including normal red blood cell morphology; this is often the case in one of the parents of a patient with HPP.

Hereditary Elliptocytosis with Sporadic Hemolysis

Worsening of hemolysis together with the appearance of poikilocytes on the peripheral blood film has been reported in patients with hypersplenism, infections, or vitamin B_{12} deficiency, as well as in those with microangiopathic hemolysis such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura.[115] In the latter two conditions, worsening hemolysis can be caused by microcirculatory damage superimposed on the underlying mechanical instability of the red blood cells.

Hereditary Elliptocytosis with Neonatal Poikilocytosis

Neonatal offspring of parents with mild HE present with symptomatic hemolytic anemia and a marked poikilocytosis.[116,117] During the first year of life, the hemolysis and poikilocytosis abate, and the clinical picture transforms into that of mild HE. Such patients typically carry one mutant α-spectrin allele. The severity of the molecular defect, in terms of the percentage of spectrin dimers and the amount of mutant spectrin in the cells, is the same in the neonatal period as it is later in life. The worsening of hemolysis in the neonatal period has been attributed to the presence of fetal hemoglobin, which binds poorly to 2,3-diphosphoglycerate (2,3-DPG).[118] The ensuing elevation of free 2,3-DPG levels has a marked destabilizing effect on the spectrin-protein 4.1R-actin interaction, thereby further destabilizing the membrane skeleton.

Hereditary Elliptocytosis with Chronic Hemolysis

Patients with HE with chronic hemolysis present with moderate to severe hemolytic anemia with elliptocytes and poikilocytes on peripheral blood film; some require splenectomy. In some of the kindreds, the hemolytic HE has been transmitted through several generations. In some kindreds, not all of the HE subjects have chronic hemolysis; some have a mild hemolysis only, presumably because of another genetic factor modifying the disease expression.

Homozygous and Compound Heterozygous Hereditary Elliptocytosis

Several HE individuals have been described who were apparent homozygotes for the HE gene.[116–120] These individuals were found to be either homozygotes or compound (double) heterozygotes for one or two α- or β-spectrin mutations.[6,78] The clinical severity is variable, from a relatively mild hemolytic anemia to a severe, life-threatening disease,[119–121] depending on the severity of the underlying molecular defect and in some cases is indistinguishable from HPP.

Hereditary Pyropoikilocytosis

Under the term HPP, Zarkowsky and colleagues described an autosomal recessive severe hemolytic anemia with striking micropoikilocytosis and thermal instability of red blood cells.[122] It is now established that HPP represents a subtype of common HE, as evidenced by the coexistence of both HE and HPP in the same family and by the presence of the same molecular defect of spectrin.[112,113,123,124] Unlike HE subjects carrying the spectrin mutation, the red blood cells of HPP subjects are also partially deficient in spectrin. Typically, one parent of the HPP offspring carries an α-spectrin mutation whereas the other parent is fully asymptomatic and has no detectable biochemical abnormality. In many such patients, the asymptomatic parent carries a silent "thalassemia-like" defect of spectrin synthesis, enhancing the relative expression of the spectrin mutant and leading to a superimposed spectrin deficiency in the HPP offspring. Subsequent studies of the original kindred reported by Zarkowsky revealed that defective spectrin synthesis from the null allele was caused by a splicing mutation of the α-spectrin gene.[125] Some HPP subjects inherited two α-spectrin mutations; either their parents were hematologically normal or one had mild HE. In these HPP subjects, spectrin deficiency may be related to instability of the mutant spectrin. The thermal instability of spectrin originally reported as diagnostic of HPP is not unique for this disorder;[122] it is also found in HE subjects carrying this α-spectrin mutation, in the homozygous and in the heterozygous states. HPP is seen predominantly in black subjects, but it has also been diagnosed in Arabs and whites.

Molecular Determinants of Clinical Severity

The severity of hemolysis in common HE often varies not only among different kindred but within a given family as well. The two principal determinants of severity of hemolysis are the spectrin content of the cells and the percentage of dimeric spectrin in the crude spectrin extract. The fraction of dimeric spectrin in such extracts in turn depends on several factors. The first of them is the degree of dysfunction of the mutant spectrin. Typically, mutations that are either within or near the combined αβ triple helical repetitive segment representing the spectrin heterodimer self-association site produce a more severe clinical phenotype and a more severe defect of spectrin function than those seen with point mutations in the more distant triple helical repeats.[100] Second, the percentage of the dimeric spectrin depends on the fraction of the mutant spectrin in the cells, which in turn is determined by the gene dose (eg, simple heterozygote versus homozygote or double heterozygote) or the presence of other genetic defects such as the presence, in *trans*, of a defect leading to a reduced α-spectrin synthesis in some subjects with HPP.

The low-expression α-spectrin allele α^{LELY} is the best-characterized abnormality affecting spectrin content and clinical severity. Initially, a polymorphism of the αV domain, $\alpha^{V/41}$, was identified in HE patients who, when they inherited $\alpha^{V/41}$ in *trans*, had more severe HE than expected. Subsequently, an amino acid substitution of exon 46,

Leu1857Val, and partial skipping of exon 46, linked to the $\alpha^{V/41}$ polymorphism, were identified as the characteristics of the α^{LELY} allele.[126] These abnormalities are located within the site at which spectrin monomers assemble into heterodimers (the spectrin heterodimer nucleation site). In-vitro studies suggest that the inability of α-spectrin chains to assemble into the mature membrane skeleton is because of a combination of decreased αβ dimer-binding affinity and increased proteolytic cleavage of the mutant α-spectrin chains.[127] The presence of α^{LELY} in *trans* diminishes the propensity of the otherwise normal allele to associate with the corresponding β-chain, favoring the attachment of the elliptocytogenic α-spectrin allele. Conversely, coexistence of the α-spectrin mutation in *cis* and the mutation involving the α-spectrin nucleation site diminishes the propensity of the mutant allele to be incorporated into the spectrin heterodimer, thereby ameliorating the clinical severity of this mutation. The α^{LELY} allele is clinically silent by itself, even when inherited in the homozygous state, probably because α-spectrin is normally synthesized in three- to fourfold excess.

Laboratory Evaluation

Blood Film and Laboratory Evidence of Hemolysis

A careful blood smear evaluation is essential for the diagnosis of HE and for the classification of the disorder into the three major subtypes outlined earlier (see Hereditary Elliptocytosis and Related Disorders, Definition, Prevalence, and History and Fig. 46–5). In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is characteristically minimal or absent, with the exception of spherocytic elliptocytosis, in which the presence of round "fat" ovalocytes is associated with accelerated red blood cell destruction. In patients with hemolytic forms of common HE, poikilocytosis is characteristically found on the blood film. In severe forms of HE, particularly in homozygous HE, many red blood cells circulate as cell fragments, producing a marked decrease in MCV. The finding of red blood cell fragments together with a striking microspherocytosis and often only occasional elliptocytes is characteristic of HPP (see Fig. 46–5).

Osmotic, Thermal, and Mechanical Fragility

Osmotic fragility is increased in HPP, in spherocytic elliptocytosis, and in HE subjects with poikilocytosis apparent on the peripheral blood film.[128] In patients with a mild common HE without poikilocytosis on the peripheral blood film, osmotic fragility is normal.

Thermal instability of red blood cells was originally reported by Zarkowsky and colleagues as a characteristic feature of HPP.[122] It reflects thermal instability of the mutant spectrin: In normal red blood cells, spectrin is denatured and red blood cells fragment at 50°C (122°F). HPP red blood cells fragment and their spectrin denatures at 41°C (105.8°F). However, the diagnostic value of this test is limited, because thermal instability of red blood cells is also noted in HE red blood cells containing mutant spectrin. In contrast, an occasional patient with otherwise typical HPP may have normal thermal stability of red blood cells and spectrin. Red blood cells in common HE have unstable membranes and membrane skeletons when subjected to shear stress.

Electrophoretic Separation of Solubilized Membrane Proteins

In HE and HPP, SDS-PAGE can reveal proteins of abnormal mobility, the origin of which can be subsequently identified by Western blotting (eg, truncated α- or β-spectrins in HE and HPP, or elongated or truncated forms of the 4.1R protein, and a partial or, rarely, complete deficiency of the 4.1R protein in HE).[84] In HPP, SDS-PAGE reveals a partial deficiency of spectrin, as indicated by a decreased spectrin/band 3 ratio. Spectrin deficiency, in conjunction with an elliptocytogenic spectrin mutation affecting the spectrin heterodimer contact, is invariably found in cases of HPP.

Nondenaturing Gel Electrophoresis of Low Ionic Strength Spectrin Extract

Analysis of the ratio of tetrameric and dimeric spectrin in the low ionic strength extracts reveals the most common functional abnormality in HE (ie, weakened self-association of spectrin heterodimers into tetramers).[111] Because the spectrin dimer-tetramer interconversion has a high activation energy, it is kinetically immobilized at near 0°C (32°F). Consequently, the percentage of spectrin dimers and tetramers in the 0°C (32°F) crude spectrin extract reflects the relative distribution of these species in the red blood cell membrane in situ. Mutations of α- or β-spectrin residing within or near the αβ-spectrin heterodimer self-association site invariably lead to an increase in the fraction of dimeric spectrin (normal range, 5 ± 2.5%) in the crude 0°C (32°F) spectrin extract.

Tryptic Peptide Mapping of Spectrin and the Detection of the Underlying DNA Defect

As reviewed elsewhere,[84] tryptic digestion of spectrin under controlled conditions followed by electrophoretic separation gives rise to highly reproducible tryptic peptide patterns. Among these peptides, the 80-kd αI domain peptide representing the self-association site of the normal α-spectrin is the most prominent one. Nearly all α- or β-spectrin mutations reported are associated with a formation of tryptic peptides of abnormal size and mobility that are generated instead of the normal 80-kd αI domain peptide. The cleavage sites of the most common abnormal tryptic peptides were mapped and found to reside in the third helix of a given triple helical repetitive segment. The reported mutations reside in the vicinity of these cleavage sites either in the same helix or, less commonly, in helix 1 or 2 of a given repetitive segment. Consequently, tryptic peptide mapping remains a powerful tool with which to map the site of the underlying spectrin mutation, which can be subsequently defined by polymerase chain reaction amplification and sequencing of the respective region of the genomic DNA or cDNA.

Differential Diagnosis

Various acquired and inherited conditions can be associated with elliptocytosis and poikilocytosis, including iron deficiency, thalassemias, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndromes, and pyruvate kinase deficiency. The percentage of elliptocytes in these conditions is seldom greater than 60%. However, this is not diagnostically useful, because some HE subjects can have a relatively low percentage of elliptocytes. In normal subjects, the percentage of elliptocytes is not greater than 5%, although in earlier reports it was listed as high as 15%. Previous diagnostic criteria of HE, based on the percentage of elliptocytes, such as 25%, 33%, or 40%, and their axial ratio, do not appear useful. The most reliable differentiation of HE from the above-mentioned conditions is based on a positive family history rather than on the percentage of elliptocytes.

Treatment and Prognosis

As in the case of HS, red blood cells from patients with more severe forms of HE are retained by the spleen, producing a marked engorgement of splenic pulp. Consequently, patients with symptomatic hemolysis benefit from splenectomy.[128] This procedure is virtually never indicated in heterozygotes with autosomal dominant HE because most do not have clinically significant hemolytic anemia. If hemolysis is still active after splenectomy, folate should be administered daily. Recommendations for antibiotic prophylaxis, immunizations, and monitoring for intercurrent illnesses are similar to those noted earlier for HS patients before and after splenectomy. Serial interval ultrasonographic investigations to detect gallstones should be performed in patients with significant hemolysis.

Spherocytic Elliptocytosis

Spherocytic elliptocytosis, which shares features of HS and HE, has been designated spherocytic HE, HE with spherocytosis, or hereditary hemolytic ovalocytosis. The diagnosis is based on the simultaneous presence of elliptical red blood cells and spherocytes or "fat," round sphero-ovalocytes in the peripheral blood film (see Fig. 46–5). In contrast to common HE, cells of other shapes, such as rod-shaped cells, poikilocytes, and fragments, are absent. Importantly, hemolysis, despite relatively mild alterations in red blood cell morphology, and increased osmotic fragility are the main diagnostic features distinguishing this disorder from common HE.

The molecular basis of classic spherocytic HE is unknown. However, patients with mutations, particularly truncations at the C-terminus of β-spectrin, have many of the clinical features of spherocytic HE and probably represent an example of this disorder.[84,129] Patients who lack glycophorin C have rounded, smooth elliptocytes and could be classified as having a mild, recessively inherited variant of spherocytic HE. Finally, some patients with recessively inherited defects of protein 4.2 can display some features of spherocytic HE, particularly mild ovalostomatocytosis.[29]

Southeast Asian Ovalocytosis

Southeast Asian ovalocytosis is characterized by the presence of oval red blood cells, many containing one or two transverse ridges or a longitudinal slit (see Fig. 46–5). The condition is widespread in certain ethnic groups of Malaysia, Papua New Guinea, the Philippines, and Indonesia.[83,130] Numerous functional abnormalities of ovalocytes have been reported, including increased red blood cell rigidity, decreased osmotic fragility, increased thermal stability, resistance to shape change by echinocytogenic agents, and a reduced expression of many red blood cell antigens. A remarkable feature of ovalocytes is their resistance to in-vitro invasion by several strains of malaria parasites, including *Plasmodium falciparum* and *Plasmodium knowlesi*. Moreover, in areas of endemic malaria, the ovalocytic subjects have reduced numbers of intracellular parasites in vivo.[83,131,132] In these regions, there is a decrease in the prevalence and in the disease severity of malaria in patients with SAO compared with control subjects.[133]

All SAO individuals are heterozygotes for two band 3 gene mutations in *cis*: the deletion of nine codons encoding amino acids 400 through 408 from the boundary of the cytoplasmic and membrane domains of band 3, and the 56 Lys to Glu substitution. The 56 Lys to Glu substitution represents an asymptomatic polymorphism known as band 3 Memphis. The SAO phenotype is associated with a tighter binding of band 3 to ankyrin, increased tyrosine phosphorylation of the band 3 protein, inability to transport sulfate anions, and a markedly restricted lateral and rotational mobility of band 3 protein in the membrane.[134–138]

Laboratory Evaluation

The finding of 30% or greater of oval red blood cells on the peripheral blood film, some containing a central slit or a transverse ridge, in the context of a notable absence of clinical and laboratory evidence of hemolysis in a subject from the above-noted ethnic groups is highly suggestive of the diagnosis. A useful screening test is the demonstration of the resistance of ovalocytes or their ghosts to changes in shape produced by treatments that produce spiculation in normal cells, such as metabolic depletion or exposure of ghosts to salt solutions. In contrast to normal red blood cells, which form spicules in response to such stimuli, SAO red blood cells or ghosts do not change shape after these treatments. The mechanism of this resistance to changes in shape is not clear, and it may reflect the high rigidity of the red blood cell membrane.

Because the underlying cause of SAO is the deletion of 27 bases from the band 3 gene, isolation of genomic DNA or reticulocyte cDNA with subsequent amplification of the deletion-containing region appears to be the most specific test for establishing the diagnosis of SAO.[136] Interestingly, this mutation appears to be lethal in the homozygous state, as large screens of individuals from indigenous areas have only identified heterozygotes.[139]

Molecular Basis of Southeast Asian Ovalocytosis Membrane Rigidity and Malaria Resistance

The red blood cells of SAO are unique among axially deformed cells in that they are rigid and hyperstable rather than unstable. The SAO mutation is the first example of a defect of an integral membrane protein leading to red blood cell membrane rigidity, an observation previously attributed to properties of the membrane skeleton. The basis of the increased rigidity is unclear.

The molecular basis of malaria resistance of SAO red blood cells is likely related to altered properties of the band 3 protein, which serves as one of the malaria receptors, as evidenced by the inhibition of in-vitro invasion by band 3-containing liposomes. In normal red blood cells, the invasion process is associated with a marked membrane remodeling that involves redistribution of intramembrane particles that contain band 3 protein. Such particles cluster at the site of parasite invasion, forming a ring around the orifice through which the parasite enters the cell. The invaginated red blood cell membrane, which surrounds the invading parasite, is free of intramembrane particles. The reduced lateral mobility of band 3 protein in SAO red blood cells may preclude band 3 receptor clustering, thereby preventing the attachment of the parasites to the cells. Decreased exchange of anions across the red blood cell membrane has also been proposed to contribute to the resistance of ovalocytes to malaria invasion. In addition, SAO red blood cells consume ATP at a higher rate than normal cells, and the partial depletion of ATP levels in ovalocytes has been suggested to account, at least in part, for the resistance of these cells to malaria invasion in vitro.

Acanthocytosis and Related Disorders

Acanthocytes (from the Greek *acantha*, "thorn") or spur cells are red blood cells with prominent thorn-like surface protrusions that vary in width, length, and surface distribution. Spur cells must be distinguished from echinocytes (Greek *echinos*, "urchin") or burr cells, characterized by multiple small projections that are uniformly distributed throughout the cell surface (Fig. 46–7). Acanthocytes should also be distinguished from keratocytes ("horn" red cells) that have few massive protuberances.

Acanthocytosis was first described in cases of abetalipoproteinemia and subsequently in severe liver disease, the chorea-acanthocytosis syndrome, the McLeod blood group phenotype, and other conditions. The molecular mechanisms leading to acanthocytosis in abetalipoproteinemia and severe liver disease have been extensively studied and have been attributed to changes in composition of membrane lipids and their altered distribution between the two hemileaflets of the lipid bilayer.

Spur Cell Hemolytic Anemia of Severe Liver Disease

Spur cell hemolytic anemia is an uncommon ominous complication of severe liver disease that is manifested by rapidly progressive hemolytic anemia and acanthocytes on the peripheral blood smear.

Pathobiology

The human red blood cell membrane contains nearly equal amounts of free (unesterified) cholesterol and phospholipids.[140] The free cholesterol in the plasma readily equilibrates with the red blood cell

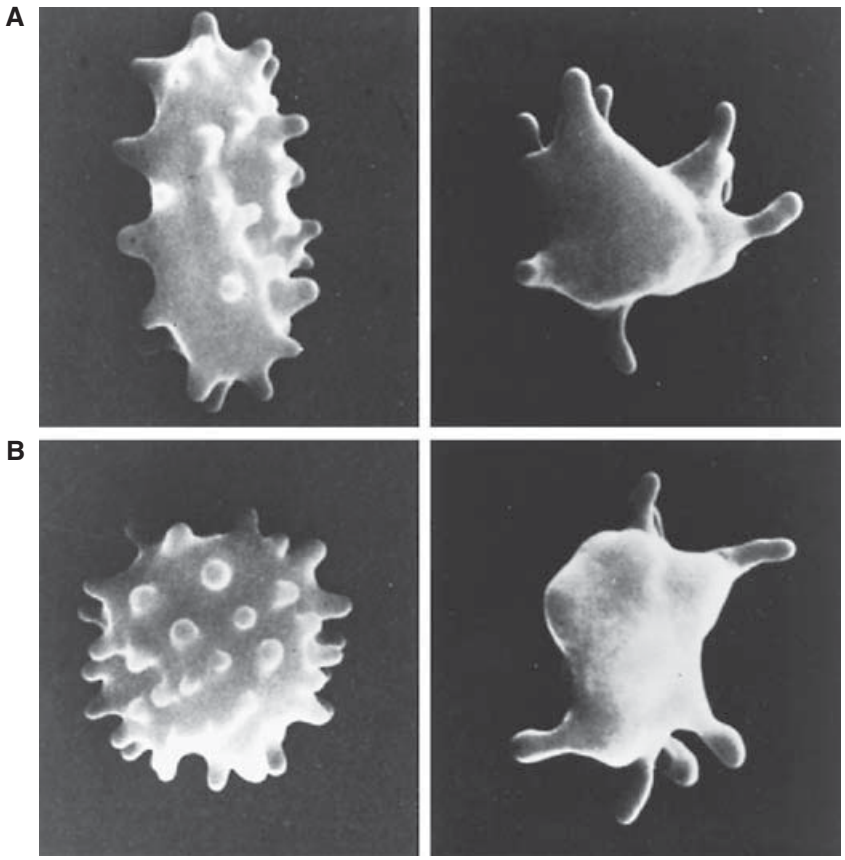

Figure 46–7 Morphologic differences between acanthocytes (**A**) and echinocytes (**B**) as demonstrated by scanning electron microscopy. *(Adapted from Bessis M: Red Cell Shapes: An Illustrated Classification and Its Rationale. New York, Springer-Verlag, 1973.)*

membrane cholesterol pool. This is in contrast to esterified cholesterol, which cannot be transferred from plasma into the red blood cell membrane. The plasma of patients with severe liver disease contains abnormal lipoproteins that have a high free cholesterol/phospholipid ratio. The excess free cholesterol readily partitions into the red blood cell membrane, leading to a marked increase in free cholesterol in the cells. Consequently, normal cells can develop a spur cell shape after their transfusion into a patient with severe liver disease or after incubation with the liver disease patient's plasma or cholesterol-enriched liposomes.

Spur cell formation involves two steps (Fig. 46–8). The first step is evident in red blood cells of splenectomized subjects with spur cell hemolytic anemia: Red blood cells have an expanded surface area with irregular contour and targeting, reflecting accumulation of free cholesterol in the membrane. This extra cholesterol accumulates preferentially in the outer bilayer leaflet, as suggested by findings of increased accessibility of cholesterol to cholesterol oxidase and a selective decrease in lipid fluidity of the outer hemileaflet of the lipid bilayer.

The second step in acanthocyte formation involves red blood cell remodeling by the spleen. As a result, red blood cells become spheroidal, and the surface projections are considerably longer and more irregular (see Fig. 46–8). The end result of these processes is poorly deformable red blood cells with long bizarre projections that are readily trapped in the spleen, which is often markedly enlarged because of passive congestion because of underlying portal hypertension.[141] Cholesterol also alters membrane permeability and interacts with several membrane skeletal proteins, but the role of these changes in spur cell lesions is unclear.

Clinical Manifestations

Most patients with chronic liver disease have a mild to moderate anemia related to gastrointestinal blood loss, iron and folic acid deficiencies, or hemodilution or as a direct effect of alcohol on red blood cell precursors.[142] Peripheral blood smears from these patients often reveal target cells that are particularly prominent in obstructive jaundice.

In some patients, particularly those with end-stage liver disease, anemia rapidly worsens and spur cells appear in high percentage in the peripheral blood. This is accompanied by worsening jaundice, rapid deterioration of liver function, hepatic encephalopathy, and hemorrhagic diatheses. A similar clinical syndrome has been described in patients with advanced metastatic liver disease, cardiac cirrhosis, Wilson disease, fulminant hepatitis, and infantile cholestatic liver disease. The development of spur cell hemolytic anemia is an ominous sign in most patients, predicting a survival seldom exceeding weeks to months.[143] In theory, splenectomy could provide a marked improvement, because the spleen is the major sequestration site of nondeformable acanthocytes; in reality, splenectomy is seldom considered because of severity of the underlying liver disease.

Abetalipoproteinemia

Definition and History

Bassen and Kornzweig first described an association of acanthocytosis with atypical retinitis pigmentosa, progressive ataxic neurologic disease, and a "celiac disease" later attributed to fat malabsorption. Subsequently, several investigators reported a congenital absence of β-lipoprotein, accounting for the diverse manifestations of the disorder.

Pathobiology

This autosomal recessive disorder has been detected in people of diverse ethnic backgrounds. The primary molecular defect involves a

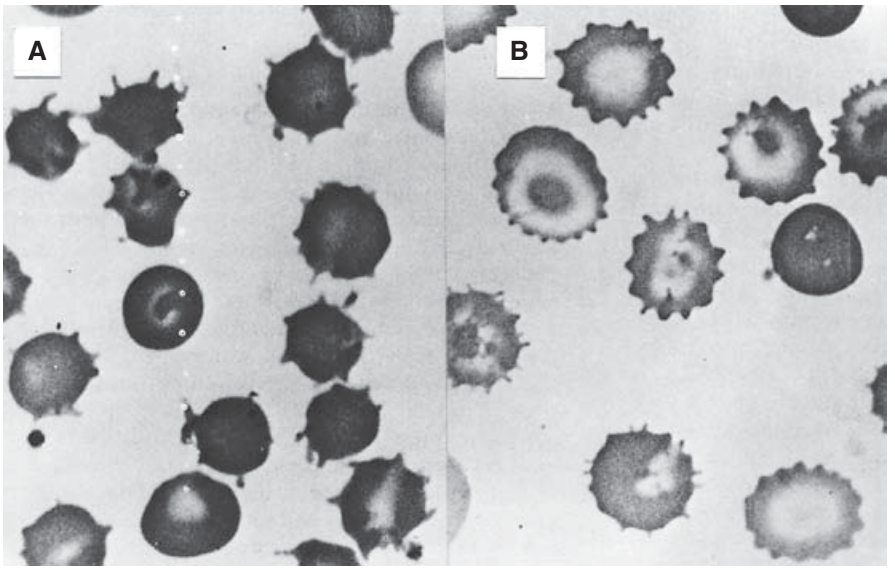

Figure 46–8 Blood film of a patient with liver cirrhosis and spur cell anemia before (**A**) and after (**B**) splenectomy. The latter smear demonstrates the effect of cholesterol acquisition leading to targeting (indicating increase in surface area) and irregularities in cell contour. The conditioning effect of the spleen (smear A) is demonstrated by the spheroidal shape of the cells and the remodeling of the spicules. *(From Cooper RA, Kimball DB, Durocher JR: The role of the spleen in membrane conditioning and hemolysis of spur cells in liver disease. N Engl J Med 290:1279, 1974.)*

congenital absence of β-apolipoprotein in plasma.[144] The B apoproteins (B100 and B48) are generated by alternate transcription of a single gene residing on the short arm of chromosome 2. Their deficiency is secondary to defective cellular secretion of the apoprotein by liver cells, caused either by aberrant posttranslational processing or by defective aposecretion. In some patients, this is because of qualitative or quantitative defects in the microsomal triglyceride transfer protein, which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces. Microsomal triglyceride transfer protein is the only tissue-specific component, other than apolipoprotein B, required for secretion of apolipoprotein B-containing lipoproteins. As a result, apoprotein B is absent in plasma, as are the individual lipoprotein fractions that contain this apoprotein. These lipoprotein fractions include chylomicrons and very-low-density lipoproteins that transport triglycerides, as well as the low-density lipoproteins that are products of very-low-density lipoproteins and transport cholesterol. Consequently, preformed triglycerides are not transported from the intestinal mucosa, and they are nearly absent in the plasma. Plasma cholesterol and phospholipids are markedly reduced, with a relative increase in sphingomyelin at the expense of lecithin.

As is the case in acanthocytosis of liver disease, the acanthocytic lesion is acquired from the plasma. Erythrocyte precursors are of normal shape, and the acanthocytic lesion develops as the cells mature and age in the circulation.[145] Normal cells acquire this shape when transfused into the recipient.

The most striking abnormality of red blood cell membrane lipids involves a net increase in sphingomyelin. Because plasma lipids readily exchange with the lipids of the red blood cell membrane, it is likely that this change simply mirrors the alterations in plasma lipid composition. In contrast to red blood cells in spur cell anemia of severe liver disease, the content of membrane cholesterol is normal or only slightly increased.[146]

The role of membrane lipids in the acanthocyte shape transformation was first established by findings of restoration of biconcave shape after extraction of lipids from the cell membrane by detergents.[147] The molecular basis of the acanthocytic shape is unknown, but several indirect observations suggest that it is related to an increase of the surface area of the outer hemileaflet of the lipid bilayer relative to the inner leaflet. Several other abnormalities have been noted in abetalipoproteinemia, including a decrease in plasma lecithin cholesterol transferase activity and an increased susceptibility of membrane and plasma lipids to oxidation as a result of malabsorption-induced deficiency of vitamin E. The contributions of these abnormalities to the acanthocyte red cell lesions are unknown.

Clinical Manifestations

This autosomal recessive disease can become evident in the first few months of life, manifested by fat malabsorption with normal absorption of other nutrients. Intestinal biopsy is diagnostic, revealing engorgement of mucosal cells with lipid droplets. Other features include retinitis pigmentosa and a progressive ataxia with intention tremors that usually develops at 5 to 10 years of age, progressing to death in the second or third decade of life. The hematologic manifestations are mild and include mild normocytic anemia with acanthocytosis (50%–90%) and normal or slightly elevated reticulocyte counts. Occasional patients can have more severe anemia resulting from the nutritional deficiencies (iron and folate) that accompany fat malabsorption. The treatment includes dietary restriction of triglycerides and supplementation with the lipid-soluble vitamins A, K, D, and E. Vitamin E can stabilize or even improve both the retinal and neuromuscular abnormalities.

Autosomal recessive abetalipoproteinemia should be distinguished from the homozygous form of familial hypobetalipoproteinemia. Although the clinical presentation of both disorders is similar, the latter disorder is milder, and the parents have occasional acanthocytes on the peripheral blood film, and their plasma low-density lipoproteins are decreased. The molecular lesions in familial hypobetalipoproteinemia involve a variety of apoprotein B gene mutations, leading to aberrant apoprotein B gene transcription or translation.

Varying degrees of acanthocytosis without anemia have also been described with isolated deficiency of apoprotein B100.

Neuroacanthocytosis Syndromes

The neuroacanthocytosis syndromes are a group of degenerative neurologic disorders with phenotypic and genetic heterogeneity that share the feature of acanthocytes on peripheral blood smear.[148] These disorders include chorea-acanthocytosis (ChAc), the X-linked McLeod syndrome (see McLeod Phenotype below) and several other neurodegenerative diseases including Huntington disease-like 2 (HDL2) caused by mutations in junctophilin-3 and pantothenate kinase-associated neurodegeneration (formerly known as Hallervorden-Spatz syndrome and its allelic variant syndrome—hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, pallidal degeneration [HARP]) caused by mutations in pantothenate kinase 2 (PANK2).[149,150]

Chorea-acanthocytosis syndrome is an autosomal recessive syndrome of adult onset that is manifest by multiple neurologic abnor-

malities, including limb chorea, progressive orofacial dyskinesia with tics, tongue-biting neurogenic muscle hypotonia, and atrophy. The hematologic manifestations are minimal and include a variable percentage of acanthocytes on the peripheral blood film without anemia and normal or only slightly decreased red blood cell survival.[151] The mechanism of acanthocytosis in this syndrome is unknown. Studies of plasma and red blood cell membrane lipids have revealed a high content of unsaturated fatty acids, presumably accounting for reduced red blood cell membrane fluidity. Additional abnormalities of uncertain significance include an uneven distribution of intramembrane particles, impaired phosphorylation of the erythrocyte actin-bundling protein dematin, abnormal accumulation of transglutaminase products, and altered function and structure of band 3.

Recently, the chorein gene (also known as CHAC or VPS13A-vacuolar protein sorting 13 homolog A) was cloned and mutations identified in affected patients.[152–154] Chorein does not belong to any known human gene family, and computer searches have not identified any known structural motifs or domains. The function of the chorein gene product remains unknown in either erythrocytes or the brain. In yeast, a chorein homologue is involved in protein sorting and transport.

McLeod Phenotype

The McLeod syndrome is characterized by a mild compensated hemolytic anemia with a variable percentage of acanthocytes on the peripheral blood film and, in some patients, late-onset myopathy or chorea.[155,156] The McLeod blood group phenotype is an X-linked anomaly of the Kell blood group system in which red blood cells, white blood cells, or both react poorly with Kell antisera. The affected cells lack Kx, the product of the *XK* gene, which appears to be a membrane precursor of the Kell antigens. The *XK* gene encodes a novel 444-amino acid integral membrane transporter. As expected, Kx is defective in McLeod patients. Male hemizygotes who lack Kx have variable acanthocytosis (8%–85%) and mild, compensated hemolysis. Because of the red blood cell mosaicism predicted by the Lyon hypothesis of X chromosome inactivation, female heterozygote carriers can have occasional acanthocytes on the peripheral blood film.[157] Lyonized women with more severe symptoms have been described.[158] Because of the susceptibility to alloimmunization, it is important to diagnose affected patients because if they are transfused, they can develop antibodies compatible only with McLeod red cells.

The McLeod syndrome has been reported in association with chronic granulomatous disease of childhood, retinitis pigmentosa, and Duchenne muscular dystrophy.[159] This association is caused by the close proximity of the genetic loci for these disorders in the p21 region of the X chromosome (Xp21), suggesting the occurrence of various manifestations because of contiguous gene syndromes. This may explain the occasional findings of either echinocytes or stomatocytes in Duchenne dystrophy, or a choreiform disorder in some subjects with the McLeod phenotype.

The Kell antigen consists of two protein components: a 37-kd protein that carries the Kx antigen, a precursor molecule necessary for the Kell antigen expression, and a 93 kd protein that carries the Kell blood group antigen.[156] Red blood cells with the McLeod phenotype have no detectable Kx antigen, and they have a marked deficiency of the 93 kd protein that carries the Kell antigen. McLeod red blood cells should be distinguished from Kell null (K_0) red blood cells, which have a normal shape. In K_0 cells, only the Kell antigen carrying the 93 kd glycoprotein is absent, whereas these cells have twice the amount of the Kx antigen. As in the other acanthocytic disorders, the surface projections of acanthocytes may be related to asymmetry of the surface area of the two lipid bilayer hemileaflets, as indicated by correction of the acanthocytosis by agents that expand the inner lipid layer, as well as the finding of an increased rate of exchange of phosphatidylcholine (localized preferentially in the outer lipid hemileaflet) with an exogenous source.

Acanthocytosis in Other Conditions

Two of eight subjects carrying the In phenotype, characterized by decreased expression of the Lutheran P1, I, and Aua blood group antigens, were reported to have acanthocytes on their peripheral blood smears. In one report, a dominantly inherited acanthocytosis was found in association with structural alterations of band 3 protein involving increased molecular size, restricted rotational diffusion, and a decrease in high-affinity binding sites for ankyrin.

Acanthocytes have also been noted in malnourished patients, including those with anorexia nervosa and cystic fibrosis. In these patients, red blood cell shape normalizes after restoration of the nutritional status. Likewise, a small number of cells with long spicules resembling acanthocytes are found in patients with hypothyroidism, after splenectomy, and with myelodysplasia.

Differentiation of Acanthocytes from Other Spiculated Red Blood Cells

Echinocytes (Burr Cells)

In contrast to acanthocytes, echinocytes, also called burr cells, have rather uniform surface projections. Although early echinocytic forms have a regularly scalloped cell contour, advanced forms of echinocytes have a spheroidal shape and the surface projections appear as short, narrow spikes (see Fig. 46–7). Although the finding of echinocytes on a peripheral blood film is often an artifact related to blood storage, contact with glass, or an elevated pH, several hemolytic anemias have been reported in association with echinocytosis on peripheral blood films. These conditions include mild hemolytic anemia in long-distance runners and in patients with hypomagnesemia and hypophosphatemia (presumably because of decreased intracellular ATP stores), uremia because of an unknown plasma factor, and pyruvate kinase deficiency.

Inspection of wet blood preparations (but not dried blood films) reveals echinocytosis in most patients with liver disease. In contrast to spur cells in patients with severe liver disease, these echinocytes have a normal cholesterol content, and the molecular abnormality may be related to the binding of abnormal echinocytogenic high-density lipoproteins to the red blood cell surface.

The mechanisms of echinocytosis in these diverse disorders are likely to be heterogeneous, as suggested by findings that many diverse factors, such as exposure of red blood cells to certain drugs, calcium loading, or ATP depletion, can induce the transformation of discocytes to echinocytes in vitro. However, in-vitro studies of the discocyte-echinocyte-stomatocyte equilibrium have suggested a possible common denominator. As discussed earlier, the lipid bilayer of normal red blood cells is asymmetric in lipid composition: The outer half of the lipid bilayer is relatively enriched in sphingomyelin and phosphatidylcholine, whereas the inner half is preferentially enriched in the negatively charged phosphatidylserine and phosphatidylethanolamine. Agents that preferentially bind to one or another class of these phospholipids dramatically influence red blood cell shape. Consequently, agents that preferentially accumulate in the outer half of the red blood cell lipid bilayer, expanding this lipid bilayer, produce an echinocytic shape, presumably by creating an asymmetry between the two surface areas of the two halves of the lipid bilayer (see Fig. 46–2). Conversely, agents that asymmetrically expand the inner half of the lipid bilayer, such as chlorpromazine, lead to stomatocytic shape transformation. In the case of echinocytes produced by ATP depletion or calcium loading, the altered phospholipid distribution between the two bilayer hemileaflets may be a consequence of calcium-induced phospholipid scrambling or a decrease in the activity of aminophospholipid translocase, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer leaflet to the inner hemileaflet.

Keratocytes, Bizarre Poikilocytes, and Schistocytes

Mechanical trauma of circulating red blood cells has occasionally produced bizarre shapes resembling acanthocytes, such as cells with horny projections (keratocytes). Some acanthocyte-like cells are also seen in splenectomized HE and HS subjects. Similar shape changes are seen in heated red blood cells, in which spectrin has been damaged by thermal denaturation, suggesting that these cells are bizarre poikilocytes rather than true acanthocytes.

RED BLOOD CELL MEMBRANE DISORDERS MANIFESTED BY TARGET CELL FORMATION

The common feature of target cells is an increase in the ratio of the cell surface area to cell volume. In microcytic red blood cells of patients with various forms of thalassemia and hemoglobinopathies, the increased surface-to-volume ratio, and consequently the target cell shape, reflect, at least in part, the relative abundance of cell-surface area. In liver disease and other disorders discussed subsequently, the target cell formation reflects an absolute expansion of the cell-surface area because of a net accumulation of membrane phospholipids and cholesterol.

Liver Disease

The presence of target cells in association with either normal or slightly increased cell volume is characteristically found in patients with obstructive jaundice, including various forms of liver disease associated with intrahepatic cholestasis. These target cells have a normal survival in the peripheral circulation and do not typically account for the anemias often encountered in patients with liver disease.

In these patients, target cell formation is a consequence of a net uptake of both free cholesterol and phospholipids into the red blood cell membrane from the plasma because of abnormalities in the cholesterol/phospholipid/protein ratios of low-density lipoproteins. Target cells have a decreased osmotic fragility, as the excess of membrane surface area leads to an increase in the critical hemolytic volume.

Lecithin Cholesterol Acyltransferase Deficiency

The lecithin-cholesterol acyltransferase (LCAT) enzyme catalyzes the transfer of fatty acids from phosphatidylcholine to cholesterol. It circulates in plasma as a complex with components of high-density lipoproteins.[160] LCAT deficiency is a rare autosomal dominant disorder manifested by hyperlipidemia, premature atherosclerosis, corneal opacities, chronic nephritis, proteinuria, mild anemia, and the presence of target cells on the blood film. The anemia is caused by mild hemolysis together with a diminished compensatory erythropoiesis. As in obstructive jaundice, the target cells in LCAT deficiency have a marked increase in both cholesterol and phospholipids. In addition, the membrane phosphatidylcholine is increased at the expense of sphingomyelin and phosphatidylethanolamine. Bone marrow aspiration and biopsy reveal the presence of sea blue histiocytes. Analysis of plasma lipoproteins reveals multiple abnormalities secondary to the underlying enzyme deficiency. Inherited LCAT deficiency should be distinguished from an acquired deficiency of this enzyme, which is found in patients with severe liver disease.

Stomatocytosis and Related Disorders

Stomatocytes were first described in a girl with dominantly inherited hemolytic anemia.[161] On blood films, her red blood cells contained a wide transverse slit or stoma (Fig. 46–9). In a three-dimensional view, these cells have a shape of a cup or a bowl. The slit-like appearance is an artifact that results from folding of the cells during blood smear preparation.

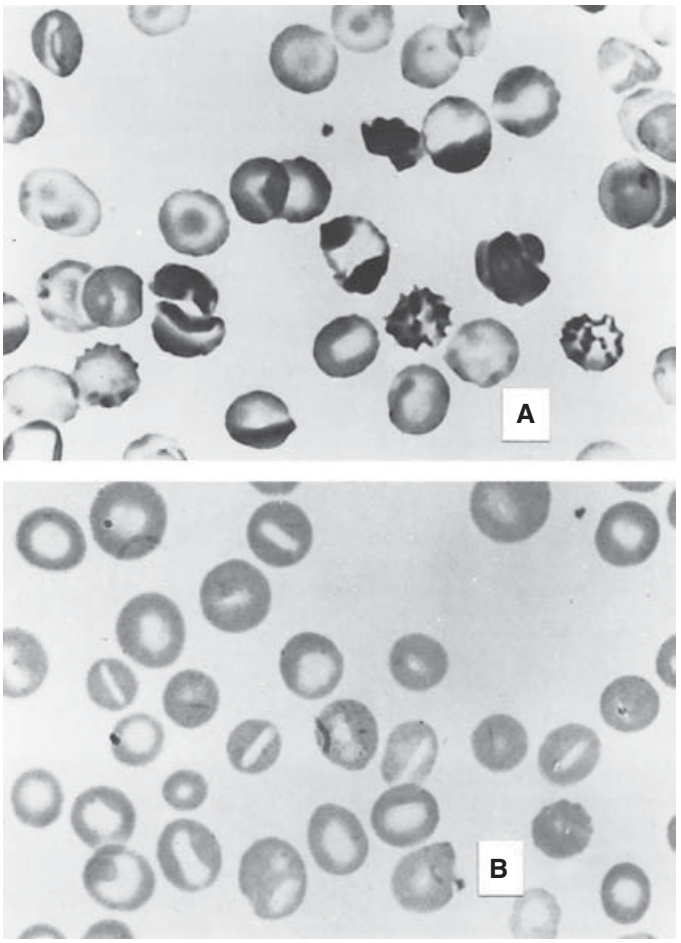

Figure 46–9 Peripheral blood smear of a patient with hereditary xerocytosis (desiccytosis) (**A**) and stomatocytosis (hydrocytosis) (**B**). *(From Lande WM, Mentzer WC: Haemolytic anaemia associated with increased cation permeability. Clin Haematol 14:89, 1985.)*

Stomatocytes are seen in a variety of acquired and inherited disorders. The latter are often associated with abnormalities in red blood cell cation permeability that lead to changes in red blood cell volume, which can be either increased (hence the designation hydrocytosis) or decreased (desiccytosis or xerocytosis), or, in some cases, near normal.[162–164]

There is no unifying theory to explain this morphologic abnormality. In vitro, stomatocytes can be produced by drugs that preferentially intercalate into the inner half of the asymmetric lipid bilayer, expanding its surface area relative to that of the outer half of the bilayer.

Hereditary Stomatocytosis-Hydrocytosis

Hereditary hydrocytosis designates a seemingly heterogeneous group of hereditary hemolytic anemias that are transmitted in an autosomal dominant mode in most patients.[163,164] The disorder is characterized by a moderate to severe hemolytic anemia with 10% to 30% stomatocytes (see Fig. 46–9), an elevated MCV, and a reduced MCHC. Osmotic fragility of red blood cells is markedly increased, as some of the swollen red blood cells approach their critical hemolytic volume. For unexplained reasons, red blood cell membrane lipids and, consequently, membrane surface area are also increased, but this increase in surface area is insufficient to correct the osmotic fragility of the red blood cells. Red blood cell deformability is decreased.

The principal cellular lesion involves a marked increase in intracellular sodium and water content with a mild decrease in intracellular potassium as a result of a marked sodium influx into the red blood cells. Despite a marked compensatory increase in active transport of sodium (Na) and potassium by the Na^+/K^+-ATPase (which normally maintains the low sodium and high concentrations in the cells) and an ensuing increase in glycolysis, the pump hyperactivity is unable to compensate for the vastly increased sodium leak. The molecular basis of this permeability defect is unknown. Stomatin (also known as band 7.2b), an integral membrane protein, is decreased or absent from the erythrocyte membranes of affected patients. This deficiency appears to be a maturational loss in the bone marrow and in the circulation, perhaps because of a defect in cellular trafficking.[165,166] Stomatin gene mutations have not been found in unrelated stomatocytosis patients deficient in this protein.[165]

Splenectomy can improve, but not fully correct, the hemolysis. In some patients, splenectomy can be deleterious or even contraindicated (see later),[167] perhaps because of altered endothelial cell adherence and membrane phospholipid asymmetry.[168]

Hereditary Xerocytosis and the Intermediate Syndromes

Hereditary xerocytosis or desiccytosis describes an autosomal dominant hemolytic anemia characterized by red blood cell dehydration and decreased osmotic fragility.[162,164] Affected individuals have characteristically moderate to severe hemolysis with an increased MCHC, reflecting cellular dehydration. Hydrops fetalis with fetal anemia or fetal ascites has been reported in a number of xerocytosis kindreds. Frequently, the MCV is mildly increased. In Coulter-type electronic counters, the conversion of pulse height (from the resistance of a cell passing through an electric field) to a cellular volume is dependent on cell shape. Xerocytes do not deform to the same degree as normal cells, which causes the MCV to be approximately 10% too high. The peripheral blood film (see Fig. 46–9) does not always reveal stomatocytes (which are more prominent on wet films), but frequently target cells, desiccocyte, and spiculated cells are seen. In some of the cells, hemoglobin is concentrated ("puddled") in discrete areas on the cell periphery.

The mechanism of cellular dehydration is unclear and complex, involving a net potassium loss from the cells that is not accompanied by a proportional gain of sodium. Consequently, the net intracellular cation content and cell water are decreased. In some reports, a decrease in red blood cell 2,3-DPG has also been noted. The gene for xerocytosis has been mapped to 16q23–q24.[169] A clinical syndrome of xerocytosis, perinatal ascites, and pseudohyperkalemia has been described.[162] Genetic studies of patients with this constellation of disorders and with isolated pseudohyperkalemia also show linkage to this region.

Some of the reported cases of hereditary stomatocytosis share features of both hereditary stomatocytosis and xerocytosis categorized as "intermediate" syndromes. These patients characteristically have both stomatocytes and some target cells on the peripheral blood smear. Osmotic fragility is either normal or slightly increased. Sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the red blood cell volume are either normal or slightly reduced. These cells were reported to have subnormal glutathione content. In some patients, red blood cells undergo in-vitro hemolysis at 5°C (41°F), hence the designation cryohydrocytosis.[170] A similar susceptibility to cold-induced cation permeability in which potassium and water loss predominates, and xerocytes instead of hydrocytes are present has also been described.

A study of stomatocytosis, spherocytosis, and spherostomatocytosis patients whose erythrocytes demonstrated significant cation leaks at 0°C (32°F)and in some cases, band 3-deficient membranes, revealed a series of missense mutations located in an intramembrane domain of band 3.[171] In-vitro studies suggest that these mutations convert band 3 from an anion exchanger to a nonselective cation leak channel.[171,172]

Several investigators have also reported a dominantly inherited hemolytic anemia with stomatocytosis, occasional target cells, spherocytes, and a decreased osmotic fragility in which the main red blood cell membrane abnormality involved a nearly 50% increase in phosphatidylcholine and a corresponding decrease in phosphatidyl-ethanolamine.[173] Because abnormalities in membrane phospholipid composition have not been systematically investigated, it is uncertain whether the disorder represents a distinct disease entity.

The results of splenectomy in this group of disorders are variable. In some patients the hemolytic anemia is improved, although often not fully corrected, by splenectomy, whereas in others the severity of the hemolysis is unchanged. Splenectomy should be carefully considered in patients with hereditary stomatocytosis. Several patients with stomatocytosis (both hydrocytosis and xerocytosis) have developed hypercoagulability after splenectomy, leading to catastrophic thrombotic episodes or chronic pulmonary hypertension.[167] Fortunately, the majority of persons with hereditary stomatocytosis are able to maintain an adequate hemoglobin level, so that splenectomy is not required.

Rh Deficiency Syndrome

Rh deficiency syndrome designates rare individuals who have either absent (Rh_{null}) or markedly reduced (Rh_{mod}) Rh antigen expression, mild to moderate hemolytic anemia associated with the presence of stomatocytes, and occasional spherocytes on the peripheral blood film. Hemolytic anemia is improved by splenectomy.

The Rh antigens are present in approximately 20,000 to 30,000 copies per cell and reside on minor transmembrane proteins with an electrophoretic mobility of 28 to 33 kd on SDS-PAGE. The Rh gene locus encodes two closely linked genes, one encoding the D polypeptide and the other encoding the Cc,Ee proteins, the antigenic expression of which is a consequence of alternate splicing of their pre-mRNA.[174]

Rh proteins are part of a multiprotein complex that includes two Rh proteins and two Rh-associated glycoproteins (RhAG). Other proteins that associate with this complex include CD47, LW, glycophorin B, and protein 4.2.[175] The Rh-RhAG complex interacts with ankyrin to link the membrane skeleton to the lipid bilayer. The Rh proteins share sequence homology to the Mep/Amt family of ammonium transporters in lower organisms and may participate in ammonium transport.[176]

Rh_{null} erythrocytes have no Rh antigen and have reduced or absent LW, Fy5, Ss, U, and Duclos antigens. Rh, RhAG, LW, glycophorin B, CD47, and protein 4.2 are also reduced or absent. Rh_{null} erythrocytes have increased osmotic fragility, reflecting a marked reduction in membrane surface area.[177] These cells are also dehydrated, as indicated by decreased cell cation and water content and increased cell density. The potassium transport and the Na^+/K^+ pump activity are increased, possibly because of reticulocytosis. Phospholipid asymmetry is also altered.

Although the clinical syndromes are the same, the genetic basis of the Rh deficiency syndrome is heterogeneous, and at least two groups have been defined. The *amorph type* is caused by defects involving the *RH30* locus encoding the RhD and RhE polypeptides. The *regulatory type* of Rh_{null} and Rh_{mod} phenotypes results from suppressor or *modifier* mutations at the *RH50* locus. When one chain of the Rh-RhAG complex is absent, the complex either is not transported to or is assembled at the membrane.

Familial Deficiency of High-Density Lipoproteins

Familial deficiency or absence of high-density lipoproteins (Tangier disease) because of mutations in ABCA1, a protein involved in cellular export of cholesterol, leads to accumulation of cholesterol esters in many tissues. Clinical manifestations include large orange tonsils,

hepatosplenomegaly, lymphadenopathy, cloudy corneas, and peripheral neuropathy.[178] Reported hematologic manifestations include a moderately severe hemolytic anemia with stomatocytosis and thrombocytopenia. Erythrocyte membrane lipid analyses reveal a low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in phosphatidylcholine at the expense of sphingomyelin.

Sitosterolemia

Sitosterolemia or phytosterolemia is a recessive disorder associated with elevated plasma levels of plant sterols.[179] Affected patients exhibit xanthomatosis and early onset premature cardiovascular disease. Reported hematologic manifestations include hemolytic anemia with stomatocytosis and macrothrombocytopenia.[180] Mutations in the transporters ABCG5 or ABCG8 lead to gastrointestinal hyperabsorption and decreased biliary elimination of plant sterols as well as altered cholesterol metabolism. Plant sterols are not synthesized endogenously in humans, but are passively absorbed in the intestine.[181] ABCG5 and ABCG8 actively pump plant sterols out of the intestinal cells back into the intestine and out of liver cells into bile ducts. It has been suggested that the stomatocytic phenotype is caused by intercalation of plant sterols into the inner leaflet of the lipid bilayer.

Acquired Stomatocytosis

Stomatocytes have been noted in diverse acquired conditions, including neoplasms, cardiovascular and hepatobiliary disease, alcoholism, and therapy with drugs, some of which are known to be stomatocytogenic in vitro. In some of these conditions, the percentage of stomatocytes on the peripheral blood smear can approach 100%. However, the clinical significance of this observation is unclear because stomatocytes are absent in most patients with the conditions listed. Furthermore, some stomatocytes can be found in normal individuals (3%–5%). The most consistent association is that of stomatocytosis and heavy alcohol consumption.

RED CELL MEMBRANE VARIANTS AND INFECTIOUS DISEASE

Viral, bacterial, and parasitic infection can all cause anemia. Multiple mechanisms leading to hemolysis have been described. As mentioned earlier in this chapter, parvovirus B19 selectively infects erythroblasts through interaction with globoside, which encodes the P blood group antigen and temporarily shuts down erythropoiesis.[62] Although this infection is tolerated well by healthy subjects, it can lead to severe, at times life-threatening, aplastic crises in patients with anemias because of premature erythrocyte destruction. As one might predict, parvovirus cannot invade erythroblasts of the rare p-negative individuals.[182]

Most infections cause hemolytic anemias triggered by several distinct, and at times overlapping, mechanisms. *Plasmodium, Babesia,* and *Bartonella* species directly attack the membrane and lyse the red cells. Some bacteria, such as *Clostridium perfringens,* elaborate hemolytic toxins or phospholipases that damage the membrane. Other infectious agents trigger occasional production of autoantibodies against red cell membrane components, which in turn leads to autoimmune hemolytic anemia. Finally, many sepsis syndromes are associated with anemia because of disseminated intravascular coagulation.

Malaria and the Erythrocyte Membrane

The red cell membrane defects described earlier in this chapter cause mild to severe hemolytic anemias. At the same time, many red cell membrane alterations have developed as a defense against microorganisms and parasites invading and lysing red cells. This is especially true for malarial parasites. Although four different species of the malaria parasite *Plasmodium*, including *P. falciparum, P. ovale, P. vivax,* and *P. malariae*, infect humans, almost all of the 1.5 to 2 million annual deaths caused by malaria are attributable to *P. falciparum*.

Because malaria coexisted with humans over the course of human evolution, it comes as no surprise that multiple erythroid genotypes were selected that confer some level of resistance to infection or mitigate disease severity. The ensuing heritable phenotypes include, among others, resistance to red cell adhesion and/or invasion, slower intraerythrocytic growth, decreased or increased adhesion of infected red cells to vascular endothelium or increased phagocytosis of parasitized red cells.

Malaria and other infections causing hemolytic anemias are described in more detail in chapters (37, 44) that also discuss hemoglobinopathies and red cell enzyme variants that reduce invasion and/or retard parasite growth. Consequently, we focus here on the heritable erythrocyte membrane alterations that developed as a defense against malaria.

Erythrocyte Preference

Two parasites, *P. vivax* and *P. ovale*, selectively infect reticulocytes, whereas *P. malariae* infect older erythrocytes. In contrast, *P. falciparum* infects red cells of all ages. This fact and the tendency of *P. falciparum*-infected erythrocytes to sequester in circulation explain the markedly higher severity of *P. falciparum* malaria.

Attachment and Invasion

Duffy Antigen

The *P. vivax* merozoite is completely dependent of attachment to the Duffy blood group antigen (also know as the Duffy antigen receptor for chemokines [DARC]) for erythrocyte invasion and, consequently, it cannot invade Duffy-negative red blood cells.[183] It has been hypothesized this is why the Duffy-negative phenotype is common in large areas of Africa. The Duffy-negative phenotype is caused by mutation in a GATA1 motif in the Duffy antigen gene promoter, preventing its expression in erythroid cells,[184] leaving its expression in other tissues intact. Elucidation of this mutation explained a longstanding conundrum of transfusion medicine: why individuals with the Duffy-negative phenotype never develop antibodies against the Duffy antigen.

Glycophorins

All major erythrocyte glycophorins, A, B, and C/D, are involved in attachment of *P. falciparum* to the red blood cell membrane. Consequently, invasion of *P. falciparum* into red cells from subjects lacking glycophorin A (En(a–)), glycophorin B (S-s-U-), or glycophorins C and D (Gerbich negative, Ge–) is diminished. As noted above, the Gerbich-negative phenotype is associated with mild, asymptomatic ovalocytosis.

Protein 4.1R and Spectrin

Deficiency of protein 4.1R or self-association defects of spectrin are associated with elliptocytosis of varying severity. Both phenotypes appear to reduce the red blood cell invasion.[185]

Band 3 and Southeast Asian Ovalocytosis

Conflicting explanations of the basis of the protective phenotype of Southeast Asian ovalocytosis (described above) from malaria have been described. Initial reports suggested that SAO erythrocytes were resistant to malarial invasion. These results were repeatedly ques-

tioned until recent studies demonstrated SAO cells to be resistant to invasion by the more virulent *P. falciparum* strains. This may explain the apparent contradiction with the reports of comparable parasitemias in SAO carriers and subjects with a normal red cell phenotype from Papua, New Guinea.

The protection from cerebral malaria afforded by SAO erythrocytes is likely because of reduced cytoadherence of SAO red cells to the cerebral vasculature. Under conditions of flow, *P. falciparum*-infected ovalocytes adhere more strongly than normal infected red cells to the endothelial receptor CD36.[186] As this receptor is not expressed in the brain, this raises a possibility that ovalocytosis protects from cerebral malaria by diminishing the number of parasitized red cells available for adhesion to the cerebral vasculature via alternative receptors. Moreover, ovalocytes appeared resistant to invasion by parasite strains that tend to bind to ICAM-1, the likely receptor for cytoadherence in the brain,[187] but the exact mechanism is not yet known.

Knops Blood Group System

Severe malaria, particularly cerebral malaria, has been associated with the formation of rosettes, clumps of cells formed by the adhesion of malaria-infected erythrocytes to complement receptor 1 (CR1) on uninfected erythrocytes. Identification of the Knops blood group antigens on CR1, followed by observations that frequencies of various Knops antigens varied significantly in whites and individuals of African ancestry, led to the hypothesis that some Knops group antigens might be protective from rosetting and severe malaria.[188] Case control studies with genotyping and/or flow cytometry have yielded conflicting results, but several have linked low-expression CR1 alleles with malaria resistance. Further studies have shown that the expression of CR1 and other complement proteins increase with age. Together, these data suggest that genetic and age-related differences in complement protein expression contribute to the variability observed in individuals with severe malaria.[189]

Although these erythrocyte membrane polymorphisms offer fascinating insight into natural defenses against one of the most serious diseases affecting humans, the mechanism of resistance to malaria has not been fully elucidated for any of them. Malaria has clearly had a profound impact on the genetic makeup of populations living in endemic areas and provided us with multiple clues about the host-parasite relationship. Better understanding of these natural defenses might eventually be converted into effective therapeutic interventions.

CHAPTER 47

AUTOIMMUNE HEMOLYTIC ANEMIA

Amy Powers and Leslie E. Silberstein

Autoimmune hemolytic anemia (AIHA) represents a spectrum of disorders in which antibodies against self-antigens on the erythrocyte membrane cause a shortened red blood cell (RBC) lifespan. The antigens targeted often have a high incidence so that both native and transfused RBCs are destroyed.[1] Three types of AIHA can be distinguished based on their serologic properties and clinical characteristics (Table 47–1). IgG warm autoantibodies bind to erythrocytes at 37°C (99°F) but fail to agglutinate the cells; cold agglutinins, almost always of the IgM isotype, clump RBCs at cold temperatures and occasionally lead to hemolysis; and the IgG Donath-Landsteiner antibody binds to RBC membranes in the cold and activates the hemolytic complement cascade when the cells are warmed to 37°C (99°F). All three can occur as an idiopathic (primary) disorder or can coexist with another disease (secondary). AIHA can follow administration of certain drugs (drug induced). This chapter refers to the hemolytic diseases associated with warm-reactive IgG autoantibodies as *warm autoimmune hemolytic anemia* (WAIHA), to the hemolytic anemias caused by cold-reactive IgM autoantibodies as *cold agglutinin disease*, and to the syndromes associated with the Donath-Landsteiner antibody as *paroxysmal cold hemoglobinuria* (PCH).

HISTORICAL BACKGROUND

PCH was the first recognized form of hemolytic anemia, probably because its clinical manifestation, the passage of black urine after exposure to the cold, was so striking. Descriptions of patients with attacks of hemoglobinuria after exposure to cold temperatures, including the case of a 10-year-old boy with chromaturie,[2] began to appear between 1854 and 1865 in the medical literature.[2,3]

The association of PCH with syphilis was first noted in 1884 by Gotze,[4] but nothing else of the cause of the disease was known until 1904, when Donath and Landsteiner[5] reported their landmark work. They described three cases of PCH in which an autolysin bound to the patient's RBCs in the cold, and a heat-labile serum factor (now known to be hemolytic complement components) lysed the sensitized erythrocytes when the temperature was raised to 37°C (99°F). They later proved the P antigen of RBCs to be the target in cases of both syphilitic and nonsyphilitic PCH.[6]

In 1908, Moreschi[7] developed the equivalent of the antiglobulin test, or what is now referred to as the *Coombs test*. He developed and tested it on animal RBCs. His animal studies were ignored for almost 40 years. The antiglobulin test, designed to detect nonagglutinating antierythrocyte antibodies on human cells, was introduced by Coombs et al.[8] in 1945. Within 1 year it was applied to the clinical diagnosis of AIHA.[9] Recognition of both idiopathic and secondary forms occurred early. In one of the first collections of 175 cases retrospectively studied by Dacie,[10] 71% were described as idiopathic, a number not very different today.

EPIDEMIOLOGY

The incidence of AIHA is estimated to be approximately 1:100,000 in adults[1] and less than 0.2:100,000[11] in children. It is less common than immune thrombocytopenia.[12] AIHA in teenagers and adults is more common in women than in men. The peak incidence in pediatric patients occurs in preschool-age children.[11] Boys are 2.5 times more likely to be affected than are girls.[13] In children, occurrences in patients younger than 2 years and older than 12 years are more likely to have a chronic unremitting course.[11] However, the majority of pediatric cases are acute in onset and self-limiting. Often these cases resolve within 6 months without treatment,[11] and the decision to treat is based on the degree of anemia and physiologic compromise. Approximately 50% to 70% of cases are idiopathic,[14] occurring at all ages, but the highest prevalence occurs in midlife. Some cases of AIHA are induced by drugs; others occur simultaneously with another autoimmune disease, particularly systemic lupus erythematosus. A substantial proportion of cases develop in patients with B-cell lymphoma or chronic lymphocytic leukemia (CLL). Treatment of the underlying malignancy often can resolve the AIHA.[15] In other instances, presumably by affecting T cells more than B cells, medications used to treat malignancies trigger the onset of hemolytic anemia.[16]

A retrospective analysis of 83 adult patients reviewed the epidemiology.[17] Sixty-seven percent of cases of AIHA occurred in women. Warm-reactive antibodies were the causative agent in 87% and cold-reactive in 13%. Of the WAIHA cases, 43% of antibodies were reactive with complement and IgG, 32% against IgG, and 25% against complement alone. Fifty-one percent of cases were secondary; systemic lupus erythematosus and non-Hodgkin lymphoma were each the primary diagnosis in 38% of those cases. The presence of hypogammaglobulinemia was significantly associated with non-Hodgkin lymphoma and prompted further workup, including chest and abdominal computed tomographic scans. The onset of hemolysis in this review preceded the diagnosis of lymphoma by a range of 22 to 66 months. No cases of PCH were reported in the review of these cases occurring between 1980 and 2000. Of the 15.6% of patients who died, 38% died of infectious complications and the same percentage of non-Hodgkin lymphoma, but none directly due to physiologic compromise of decreased oxygen-carrying capacity.

Few large studies of AIHA in children have been undertaken. A retrospective review of 100 cases of childhood AIHA (age range 6 months to 16 years) diagnosed over a 20-year period revealed a peak incidence in the first 4 years of life.[1] No sex predilection was observed. The majority of patients (64%) were diagnosed with WAIHA, whereas cold agglutinin disease and PCH accounted for 26% and 6% of children, respectively. A mixed type of AIHA was observed in four subjects. Overall, 54% of children had coexisting disease, including hematologic disorders, autoimmune disease, infection, and neoplasia. All cases of PCH were associated with a recent viral illness.[18]

WARM AUTOIMMUNE HEMOLYTIC ANEMIA

Pathophysiology

Immune Clearance of Erythrocytes

The serologic specificities of the autoantibodies that cause RBC destruction in patients with AIHA can be identical to the autoantibodies causing no discernible signs of hemolysis in healthy persons. Therefore, the pathogenicity of anti-RBC autoantibodies must depend on additional factors, including the amount of autoantibody, its avidity for the erythrocyte autoantigen, and its ability to fix complement.[19] Each of these factors may contribute independently and cumulatively to the erythrocyte lesion.

Table 47–1 Characteristics of Autoimmune Hemolytic Anemia

	Type of Autoimmune Hemolytic Anemia		
Characteristic	**Warm Autoimmune Hemolytic Anemia**	**Cold Agglutinin Disease**	**Paroxysmal Cold Hemoglobinuria**
Antibody isotype	IgG, rare IgA, IgM	IgM	IgG
Direct antiglobulin test (DAT) result	IgG and/or C3	C3	C3
Antigen specificity	Multiple, primarily Rh	i/I, Pr	P
Hemolysis	Primarily extravascular	Primarily extravascular	Intravascular
Common disease associations	B-cell neoplasia/lymphoproliferative, collagen–vascular	Viral, neoplasia	Syphilis, viral

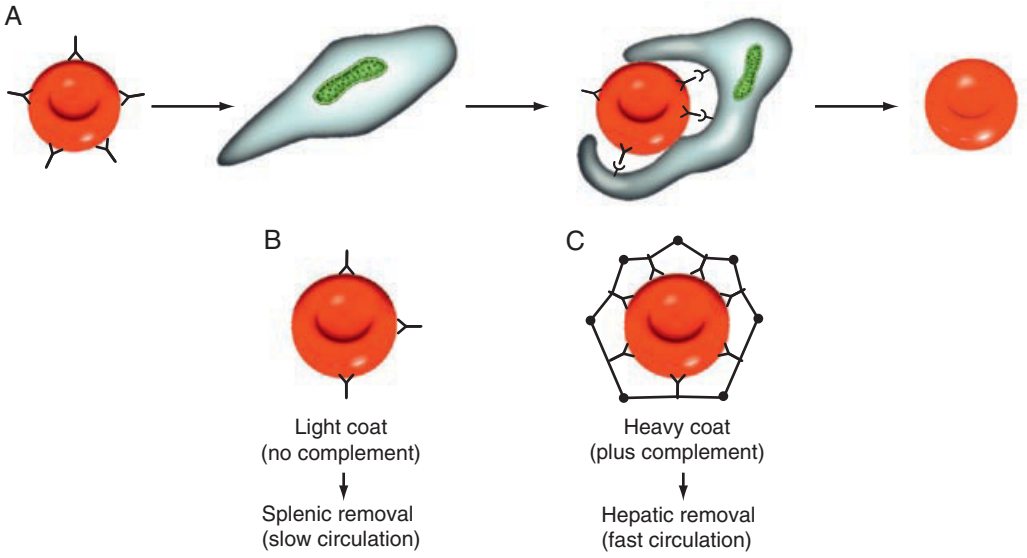

Figure 47–1 Mechanism of extravascular hemolysis in autoimmune hemolytic anemia. **A,** Macrophage encounters an IgG-coated erythrocyte and binds to it via its Fc receptors. Thus entrapped, the red blood cell (RBC) loses bits of its membrane as a result of digestion by the macrophage's ectoenzymes. The discoid erythrocyte transforms into a sphere. **B**, RBC lightly coated with IgG (and therefore incapable of activating the complement cascade) is preferentially removed in the sluggish circulation of the spleen. **C**, RBC with a heavy coat of IgG; thus, C3b (black circles) can be removed by both the spleen and the liver.

Immune hemolysis in vivo begins with opsonization by autoantibodies. The terminal effect can be destruction of the RBC directly within the circulation (intravascular hemolysis), removal of the cell from the circulation by tissue macrophages in the liver or spleen (extravascular hemolysis; Fig. 47–1), or both. The interaction of macrophages with RBCs coated with IgG and/or C3b occurs through receptors specific for the Fc portion of IgG (especially IgG1 and IgG3) and for C3b.[20,21] The presence of both IgG and C3b accelerates immune clearance,[22] suggesting that Fc and C3b macrophage receptors act synergistically.

Red Blood Cell Destruction

The macrophage may ingest an opsonized RBC entirely. More likely, proteolytic enzymes on its surface digest bits of the erythrocyte membrane producing a spherocyte, an RBC with the lowest possible surface area-to-volume ratio.[21] Spherocytes are less deformable and more susceptible to osmotic lysis than disk-shaped RBCs and thus are especially susceptible to hemolysis during their travels through the sluggish circulation of the splenic sinusoids. This is why the predominant mechanism of destruction of erythrocytes coated with IgG with or without C3b occurs extravascularly in cases of AIHA.

Macrophage-mediated mechanisms predominate in causing the lesion of AIHA, but the participation of cytotoxic lymphocytes (natural killer cells), which cause antibody-dependent cell lysis, has not been excluded. The efficiency of reticuloendothelial function probably also contributes to the degree of immune clearance and may account for exacerbations concurrent with viral or bacterial infections.[23,24]

Isotype Influence

Attachment of antibody to the surface of the RBC may lead to intravascular, extravascular, or no hemolysis. The degree of hemolysis is influenced by both the antigen and the antibody. The density and expression of the target antigen are important, as are the quantity, specificity, thermal amplitude, and ability to fix complement and bind tissue macrophages of the antibody.[1] Thus, the class or subclass of antibody attached is a crucial determinant of pathology. IgA, IgM, IgG1, and IgG3 can fix complement. If complement is activated through the C5 to C9 membrane attack complex, intravascular hemolysis occurs. Regulatory mechanisms at the level of C4b/C3b can arrest the cascade and prevent hemolysis.[25] IgG1 and IgG3 are recognized by Fc receptors of phagocytes and therefore can cause extravascular hemolysis.[1] RBCs coated with simply antibody or C3b are phagocytized by macrophages and destroyed extravascularly in the spleen and liver, respectively. IgG-coated cells are destroyed primarily in the spleen and IgM-coated cells in the liver.[14]

Under certain circumstances, IgM can activate complement and cause severe intravascular hemolysis. However, extravascular hemolysis predominates because the pathogenic effect is modulated by the RBC regulatory proteins decay accelerating factor (CD55) and membrane inhibitor of reactive lysis (CD59), which can eliminate hemo-

lysis.[1] Complement components remain attached to the RBC membrane after incomplete intravascular activation and cytolysis and are targets of the extravascular reticuloendothelial phagocytes.[1] IgM antibodies reacting optimally at 37°C (99°F) in the absence of IgG antibodies are exceedingly rare, yet they occur in 2% to 73% of cases of AIHA in conjunction with IgG antibodies. Although IgM antibodies usually mediate cold agglutinin disease and often have a more indolent course, cases of warm-reactive fatal IgM-mediated hemolysis have been reported in the literature.[26,27] These cases warrant very aggressive intervention. The reported surviving patient was treated with high-dose prednisone, intravenous Ig, and exchange transfusion.[27] Warm IgA hemolytic antibodies are reported in 14% to 21% of cases in combination with IgG antibodies.[28] Alone, their incidence is less than 0.2%.[28] This finding underscores the need to perform further testing for IgA or IgM autoantibodies in cases that are negative by the direct antiglobulin test (DAT) but clinically appear to be AIHA so that appropriate prompt management can be instituted.

The mechanism of IgA-mediated intravascular hemolysis is not completely understood. Complement activation by the classic and alternative complement pathways can be caused by IgA. In addition, Fc receptors for IgA have been discovered on human lymphocytes, granulocytes, and monocytes[29] and presumably mediate extravascular hemolysis.

Pathophysiology of Secondary AIHA

A CTLA-4 exon polymorphism has been associated with autoimmune diseases and was demonstrated to be present at a statistically significant increased prevalence in patients with AIHA, especially in cases secondary to CLL.[16,30] The CTLA-4 molecule is an important downregulator of T-cell antigen responses. The polymorphism with the substitution (Thr→Ala) at codon 17 appears to confer susceptibility to autoimmunity. AIHA occurs in patients with primary immune deficiencies, more commonly in patients with antibody defects such as common variable immunodeficiency and IgA deficiency. A number of other diseases also are complicated by AIHA (Table 47–2).[31]

As more diseases are treated with bone marrow and peripheral blood stem cell transplantation, the number of cases of posttransplant autoimmune hemolysis is expected to increase. A study of adult patients who received T-cell–depleted allogeneic bone marrow transplants revealed a 5% incidence of AIHA in patients surviving 6 months.[32] In a more recent study, the 3-year cumulative incidence of AIHA in a series of 272 adult hematopoietic stem cell transplant patients was 4.44%.[33] Factors associated with the development of AIHA in this population included transplant from an unrelated donor and the development of chronic extensive graft-versus-host disease.[33] The incidence in children is similar, with AIHA occurring in 6% of pediatric recipients undergoing unrelated donor hematopoietic cell transplantation.[34] The timing of development of AIHA after bone marrow transplantation depends on the antibody mediating the hemolysis, possibly because IgM reconstitutes earlier than IgG. In the posttransplant setting, three distinct mechanisms can account for hemolysis: true autoimmune hemolysis, immune hemolysis mediated by passenger lymphocytes, and immune hemolysis in the setting of chimerism and major blood group mismatch (Table 47–3).[35] Investigations to determine the cause of hemolysis will appropriately direct therapy, expected duration, and prevention.[35]

Clinical Findings

The clinical findings in WAIHA are variable. They are determined by the rate of hemolysis and the ability of the body to process breakdown products and mount a reticulocytosis. Some signs are associated with hyperdynamic circulation secondary to anemia and concomitant decreased oxygen-carrying capacity. They include hepatomegaly and, in more severe cases, pulmonary edema, lethargy, and obtundation. Splenomegaly can occur due to an increase in white pulp. Jaundice and fever are caused by cytokines and breakdown products. Rather than injury due to free hemoglobin, vasoconstriction and decreased renal perfusion lead to renal insufficiency.

The disease can occur acutely, with symptoms caused by rapidly developing anemia, or it can develop gradually in a relatively asymptomatic form. Occasionally, the blood bank provides the diagnosis through a positive antiglobulin test in a patient referred for transfusion therapy. Lymphadenopathy, fever, hypertension, renal failure, rash, petechiae, or ecchymoses should alert the physician to the possibility of a secondary AIHA and warrant a search for an underlying disease.

Table 47–2 Diseases Rarely Associated with Autoimmune Hemolytic Anemia

Collagen vascular disease
Rheumatoid arthritis
Scleroderma
Polyarteritis nodosa
Serum sickness
Sjögren syndrome
Lymphoreticular malignancy
Macroglobulinemia
Hodgkin lymphoma
Multiple myeloma
Mycosis fungoides
Other malignancy
Acute leukemia
Thymoma
Carcinoma (colon, kidney, lung, ovary)
Miscellaneous diseases
Myelofibrosis with myeloid metaplasia
Ulcerative colitis
Pernicious anemia
Thyroid disease
Ovarian cysts
Mucocutaneous lymph node syndrome (Kawasaki disease)
Evans syndrome (thrombocytopenia and hemolytic anemia)
Congenital immunodeficiency syndromes
Guillain-Barré syndrome
Primary biliary cirrhosis
Multiply transfused patients with hemoglobinopathies

Laboratory Evaluation

Differentiating AIHA from other forms of hemolytic anemia based on laboratory data alone may be difficult. The DAT, also known as the *Coombs test*, is considered pathognomonic of immune-mediated hemolysis. This assay detects the presence of IgG or complement bound to the RBC membrane (Fig. 47–2). In patients with severe AIHA, the DAT results may be strongly positive, but the strength of the reaction and titer of the autoantibody do not always predict the severity of disease. A false-negative result may be observed in some situations, including cases attributed to low-affinity autoantibodies and rare patients with IgA- or IgM-mediated hemolysis.

Rapid destruction of erythrocytes leads to other laboratory changes that are not specific for AIHA. These changes include increased serum levels of unconjugated bilirubin and lactate dehydrogenase and a reduction in plasma haptoglobin levels. Rare intravascular destruction of erythrocytes elevates the plasma free hemoglobin level and results in hemoglobinuria. In this situation, hemosiderinuria will follow in approximately 7 days when renal tubular epithelial cells containing absorbed iron exfoliate into the urine.

A positive DAT, confirmed with a specific anti-IgG reagent, is occasionally found in healthy people; approximately 1:10,000 blood donors has a positive antiglobulin test result without anemia or evi-

Table 47–3 Posttransplant Immune Hemolysis

	AIHA	Passenger Lymphocyte	ABO Rh mismatch
Mediated by	Donor lymphocytes	Donor memory B cells in solid organ or stem cells	Recipient Ab
Directed against	Donor RBCs	Recipient RBCs	Donor RBCs
Cause	T-cell dysfunction; immunomodulatory medications	GVHD-like reaction with production of Ab	Preformed Ab or Ab formed in response to donor tissue
Onset	2–25 months posttransplant	5–17 days	Acute-timing depends on preformed or newly formed Abs
Duration	Variable, depending on response to therapy	Usually resolves in 3 months	
Treatment options	Same as idiopathic AIHA	Compatible RBC transfusions, plasma or RBC exchange	Compatible RBC transfusion; immunosuppression
Prevention	None known	Prophylactic donor-compatible RBC transfusions	Removal of recipient Ab by plasma exchange or donor RBC purge

Ab, antibody; AIHA, autoimmune hemolytic anemia; GVHD, graft-versus-host disease; RBC, red blood cell.

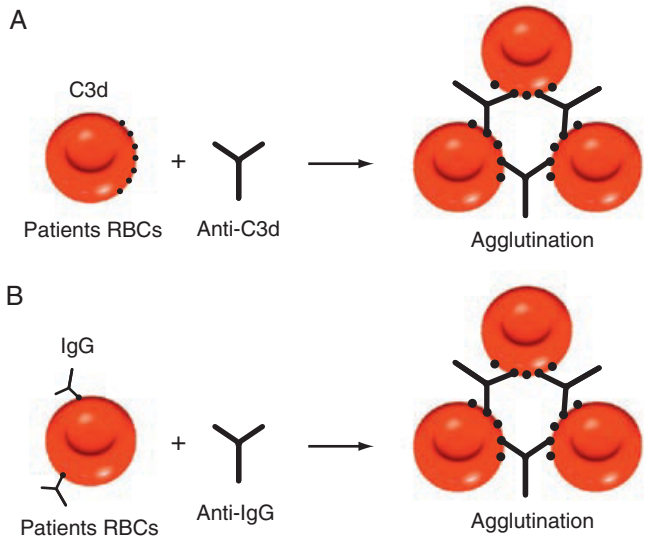

Figure 47–2 Direct antiglobulin test for detection of (**A**) erythrocyte-bound C3d or (**B**) IgG. Hemagglutination occurs when anti-C3d or anti-IgG can create a lattice structure by bridging sensitized red blood cells.

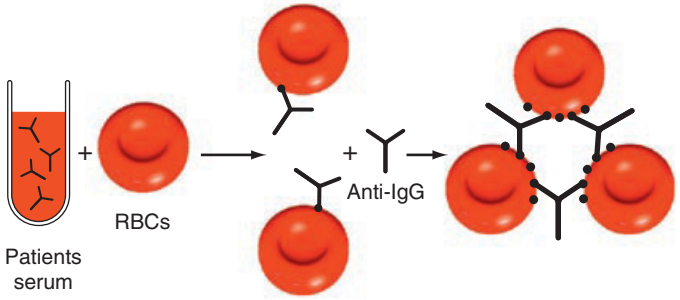

Figure 47–3 Indirect antiglobulin test for detection of antierythrocyte antibodies in serum. The patient's serum is mixed with a panel of normal red blood cells, some (or all) of which express the antigen(s) recognized by the serum antibodies. After the antibody-coated erythrocytes are washed, an anti-IgG reagent is added and hemagglutination occurs.

dence of increased hemolysis.[36] In approximately 10% of cases of AIHA, erythrocyte-bound C3b occurs in the absence of erythrocyte-bound IgG.

The unexpected report of a negative antiglobulin test result in a patient suspected of having AIHA is uncommon but may have several explanations. Technical errors are infrequent but can occur. Other rare causes are IgA and IgM autoantibodies or low-affinity IgG autoantibodies.[37] More commonly, the test is not sufficiently sensitive to detect small numbers of erythrocyte-bound IgG molecules; this occurs most often in cases of AIHA associated with a lymphoma or CLL. If the DAT result is positive, specific reagents are required to identify the erythrocyte-bound protein.

In approximately 80% of patients with AIHA, the autoantibodies are present in the serum as well as on the RBC membrane.[38] The indirect antiglobulin test (indirect Coombs test) detects the presence of these serum antibodies in the patient's serum (Fig. 47–3). The indirect antiglobulin test also detects alloantibodies induced by blood transfusion or maternal–fetal incompatibility. Alloantibodies have specificity for RBC antigens not present on the patient's native erythrocytes. Therefore, the DAT result is negative in cases of alloimmunization, unless the patient has been recently transfused. In this setting, alloantibodies may bind to the recently transfused RBCs and yield a positive DAT result. Therefore, an accurate transfusion history is essential in differentiating alloimmune from autoimmune hemolysis.

Laboratory findings also reflect the intensity of the hemolytic process, the ability of the body to process the RBC breakdown products, and the ability of the bone marrow to respond to the anemia. In fulminant cases, in which the RBC lifespan is less than 5 days, the anemia is severe, and erythropoiesis increases eightfold to 10-fold. As a result, the reticulocyte count rises, sometimes to levels greater than 40%. If the regenerative capacity of the bone marrow lags only slightly behind the rate of RBC destruction, a mild anemia with an elevated reticulocyte count occurs. If the gap is greater, severe anemia ensues. Inspection of the blood smear in a typical case reveals polychromatophilia, spherocytes, a few fragmented RBCs, nucleated RBCs, and occasionally erythrophagocytosis. Examination of the bone marrow, rarely indicated, shows erythroid hyperplasia, often with megaloblastoid features. Occasionally, RBC autoantibodies cause reticulocytopenia and dyserythropoiesis, thereby contributing to the severity of anemia.[39]

Patients with severe hemolytic anemia and markedly increased erythropoiesis occasionally develop folate deficiency and frank megaloblastosis. Growth of hematopoietic tissue in the bone marrow also leads to moderate increases in the white blood cell and platelet counts. The absence of reticulocytosis does not exclude the diagnosis

of AIHA but portends a serious prognosis.[40,41] The low count may be due to destruction of young erythrocytes by the autoantibody or a concurrent parvovirus B19 infection. This reticulocytopenia impairs the compensatory response, aggravates the severity of the anemia, and increases the need for RBC transfusions.

Therapy

General Principles

AIHA ranges from indolent to life threatening. Initiation of treatment and selection of the intervention (immediate transfusion vs attempts to modulate the immune system's production of autoantibody and destruction of antibody-coated RBCs) must begin with a thorough appraisal of symptoms and extent of the clinical compromise. The earliest historical records of treatment of acquired hemolytic anemia include splenectomy performed in 1911.[42] In 1950, the beneficial effect of corticotropin on AIHA in two patients with lymphoma was reported by Dameshek[43] and in a 5-year-old girl by Gardner.[44] Up until the last several years, treatment options changed little from these initial therapies.

Rapidly developing anemia with a hematocrit less than 20 requires urgent management. However, in the less aggressive forms of the disease, allowing physiologically compensated anemia rather than instituting treatment may be prudent. Management of AIHA depends in part on whether the disease is primary or secondary to disorders such as B-cell malignancies and systemic lupus erythematosus.[45] This also demands careful assessment before any treatment begins. In some cases of AIHA secondary to lymphoma or CLL, the pathogenic autoantibody (usually monoclonal) is secreted by neoplastic B cells. Combination chemotherapy or irradiation of the underlying malignancy often brings the hemolytic anemia under control.[46,47] In other cases, however, the autoantibodies (usually polyclonal) do not originate from the B-cell neoplasm but probably result from abnormal immune regulation instigated by the neoplastic B cells. Treatment of the latter type of secondary AIHA with immunosuppressive agents may improve the anemia, but it also can trigger an exacerbation.[48] Some chemotherapeutic agents and immunosuppressive medications interfere with T-cell function and thus can trigger autoimmune processes, including AIHA. Fludarabine and cladribine given as therapy for CLL precipitate autoimmune processes by interfering with the delicate balance between T- and B-cell functions.[16]

The ultimate goal of therapy is controlling the B-cell populations that secrete pathogenic autoantibodies. However, so little is known about such cells[49,50] that the currently available therapy is, by default, nonspecific. The desired therapeutic effect is eradication of the abnormal hemolytic process, not reversal of the serologic abnormalities. Indeed, the DAT result often remains positive in the face of hematologic recovery.

Transfusion

Some cases of AIHA are life threatening and necessitate transfusion with RBCs.[51] Severe anemia can cause high-output cardiac failure and subsequent pulmonary edema, somnolence, and even obtundation, which require immediate intervention with RBC transfusion. The hemoglobin at which these symptoms occur varies based on the rate of fall of hemoglobin, degree of cardiac compensation, and other underlying clinical features. Oxygen therapy can be prescribed but is no substitute for transfusion.

The clinician must recognize that the presence of autoantibodies will complicate and prolong the pretransfusion evaluation performed by the blood bank and that, despite a complete blood bank workup, the patient often will receive "cross-match incompatible" blood. In situations where transfusion is required, blood should not be withheld simply because it is not fully compatible.[52] However, transfusion should be administered with particular care and close monitoring.

Occasionally (1%–2% of cases), the relative specificity of autoantibodies can be demonstrated. This usually occurs within the Rh system, and RBCs lacking the corresponding Rh antigen survive better in vivo than those that express the antigen.[53] Specificities of IgG autoantibodies for other blood groups have been described.[54] Whether such relative specificity should be respected in the selection of donor units is controversial, as exposure to RBCs lacking the implicated antigen may increase the risk of alloimmunization in these patients.[55] An important practical point is that, with rare exceptions, the implicated autoantigens are present on all normal erythrocytes. Thus, in practice, all RBCs will be "incompatible." In addition, the blood bank must screen for alloantibodies that may be obscured by autoantibody reactions. Alloantibodies, usually with specificity for the Rh or Kell blood group system, occur in approximately 30% of patients with AIHA who have a history of blood group immunization by maternal–fetal incompatibility or previous transfusions.[56,57] These alloantibodies can escape notice in a patient with a positive result on the indirect antiglobulin test because of the concomitant presence in the serum of autoantibodies that react with virtually all normal RBCs. To detect suspected alloantibodies, adsorption techniques that use either the patient's own cells (autologous adsorption) or cells of known phenotype (heterologous adsorption) to remove autoantibodies from the serum are available.

A pretransfusion sample should be obtained for RBC phenotyping if possible. When available, some centers will provide these patients with RBCs that are phenotypically matched for common clinically significant antigens. Providing matched units decreases the rate of subsequent alloimmunization and prevents delayed hemolytic transfusion reactions.[58]

The preceding techniques should not be required as pretransfusion tests in patients with AIHA. Transfusions should never be delayed if the tests are not readily available or completed (see box on Hazards of Transfusion Therapy). However, standard antibody detection and identification tests with both the patient's serum and an eluate prepared from the patient's cells should be performed whenever possible. Titration of the eluate and the serum against RBCs of various Rh phenotypes can indicate an autoantibody specificity (or preference) within the Rh system. Some experts recommend that any such specificity be respected in selecting donor units.[59] RBC substitutes have been transfused in a few situations of severe hemolytic anemia and demonstrate benefit to the patients.[60] However, no RBC substitutes are approved by the United States Food and Drug Administration for routine clinical use.

Hazards of Transfusion Therapy

The idea that transfusion therapy represents a special hazard in patients with autoimmune hemolytic anemia has been overemphasized. Nevertheless, transfusions are not to be undertaken lightly in such patients. The decision to transfuse requires that the clinician and the blood bank work together. The clinician must supervise the transfusions and insist on close observation of the patient. An adverse reaction dictates additional laboratory tests, but even sophisticated serologic techniques do not ensure uneventful transfusions. Acute intravascular hemolysis can occur with no evidence of serologic incompatibility. In vivo compatibility testing with ^{51}Cr-tagged RBCs is of no value in the management of most patients.

Transfusion is warranted without delay and, if necessary, before all serologic tests are completed when cardiac or cerebral function is threatened. Alleviation of signs and symptoms of anemia usually can be accomplished with relatively small quantities of RBCs, as little as 0.5 to 1 units. Overtransfusion in the presence of high-output cardiac failure can easily lead to circulatory overload, another reason to justify careful observation of the patient during the transfusion.

Corticosteroids

Corticosteroids are first-line treatment for most patients with symptomatic unstable AIHA of either the idiopathic or the secondary form. The clinical response to prednisone results primarily from its ability to disable macrophages from clearing IgG, inactivated C3b, or C3b-coated erythrocytes. Corticosteroids interfere with both the expression and the function of macrophage Fc receptors. This probably is the earliest, and perhaps even the primary, mechanism of the ability of steroids to diminish the immune clearance of blood cells.[61–63] Prednisone can reduce autoantibody production but only after several weeks of therapy (see box on Prednisone Therapy).

The side effects of corticosteroids often preclude long-term use of high-dose therapy. The cushingoid features that develop can lead to patient noncompliance, especially in the adolescent population. The associated osteoporosis, myopathies, psychiatric changes, immunosuppression, and risk of gastric bleeding can warrant discontinuation.

Intravenous γ-Globulin

Intravenous γ-globulin has been found effective in managing selected cases of AIHA. The soluble IgG in the material may increase the lifespan of IgG-coated RBCs by saturating Fc receptors on macrophages. In a study of patients with AIHA associated with lymphoproliferative disorders, a long-term benefit was observed with a maintenance dose schedule of intravenous IgG given every 21 days. A decrease in antiglobulin titer found in these patients suggests a mechanism other than blockade of Fc receptors by intravenous IgG.[64]

Prednisone Therapy

Therapy can begin with prednisone (there is no clear advantage to alternative forms of corticosteroids) at a dose of 1 to 2 mg/kg/day in divided doses, depending on the severity of the disease. The physician can consider beginning with a lower dose (e.g., 0.6 mg/kg/day) in elderly patients, especially those who are immobilized or who already have osteoporosis, or in patients with infection or other mitigating complications. Whatever the amount selected, it should be continued until a response becomes evident, usually within 3 weeks, by a rise in the hematocrit and a fall in the reticulocyte count.

Autoimmune hemolytic anemia in children is likely to respond to prednisone with a durable remission. By contrast, permanent remissions are infrequent in adults. Therefore, therapy for adults requires a plan to manage (or prevent) relapse. Essential elements to consider in formulating the long-term management of a patient with autoimmune hemolytic anemia are the duration of treatment with the initial dose of prednisone and the rate of dosage reduction after a response has been achieved. The tapering schedule depends, in part, on the severity of the initial presentation and the prominence of side effects of treatment. In the absence of contraindications, prednisone is continued at the initial dose until the hemoglobin level reaches 10 g/dL or greater, by which time transfusions should no longer be necessary. Thereafter, the dose can be gradually reduced, usually at a rate of 5 to 10 mg/week. During this second phase of treatment, the divided daily prednisone dose can be consolidated into a single daily dose. If the remission remains stable after a dose of 10 mg/day is reached, further tapering over a 3- to 4-month period can proceed with caution. Some hematologists continue treatment for many months at low doses (e.g., 10 mg every other day), but the efficacy of this practice has not been established.

The mechanism of action of intravenous Ig was further elucidated in a murine model of immune thrombocytopenia.[59,65] The model demonstrated that the inhibitory Fc receptor FcγRIIB was necessary for intravenous Ig to confer protection against platelet destruction. This suggests that modulation of inhibitory signals is involved in other autoimmune diseases and could be investigated as a therapeutic target in AIHA.

Although intravenous γ-globulin Ig may be effective in managing selected cases of AIHA, it currently is not recommended for routine use in either acute or chronic treatment of AIHA. Intravenous Ig may be considered for treatment of severe life-threatening AIHA, in cases where AIHA is refractory to conventional treatment with corticosteroids, or possibly as a temporizing measure prior to splenectomy.[66,67] Although no controlled trials have been performed, published reports of intravenous Ig use in AIHA suggest a dose as high as 400 to 1000 mg/kg/day for successful clinical response.[67]

Splenectomy

For many years splenectomy has been used as therapy for AIHA.[68] Successful techniques for laparoscopic splenectomy have improved this therapeutic modality.[69] Indications for splenectomy include failure to respond to prednisone, dependence on prednisone dosages larger than 20 mg/day, or intractable side effects of the corticosteroid. The procedure can be highly effective, presumably by removing the major reticuloendothelial site of RBC destruction. An animal model demonstrated that IgG-coated RBCs are removed almost exclusively by the spleen.[70] In addition, the procedure eliminates many phagocytosing macrophages and autoantibody-producing B cells.

In most young adults with chronic AIHA, the question of splenectomy arises almost inevitably. However, in elderly patients with stable but incomplete remission, maintenance therapy with prednisone at a dose of 10 mg/day for an indefinite period may be the preferred alternative. There is a slight risk that overwhelming sepsis by encapsulated organisms can develop immediately or up to 25 years after splenectomy.[69] This risk is increased in the pediatric population, especially in patients younger than 6 years at the time of splenectomy, and a conservative approach to splenectomy in this age group is prudent. The risk of sepsis is lessened by immunization with pneumococcal and meningococcal vaccines, optimally administered at least 2 weeks preoperatively, and by prompt use of antibiotics for febrile illness.[71] Pediatric patients should complete the *Haemophilus influenzae* series of vaccines prior to undergoing splenectomy.

The response to splenectomy does not correlate with the age of the patient, presence or absence of an underlying B-cell disorder, strength of the antiglobulin test, prior response to prednisone, or pattern of sequestration of ^{51}Cr-labeled RBCs. Approximately 50% to 60% of patients with classic AIHA have a good-to-excellent initial response to splenectomy. They need less than 15 mg/day of prednisone to maintain an adequate level of hemoglobin.[72] Information regarding the clinical implications of an accessory spleen in patients with AIHA is meager. Faced with such a rare finding in a patient with relapse, many hematologists recommend its removal. The role of splenectomy in patients with mixed IgG, IgM, or mixed cold- and warm-reactive IgG antibodies is unclear.

Immunomodulatory Therapy

Most experience with immunosuppressive drugs for treatment of AIHA has been with alkylating agents (cyclophosphamide and chlorambucil) and thiopurines (azathioprine and 6-mercaptopurine; see box on Cytotoxic Drug Therapy).[73] The basis for the clinical use of these drugs is their inhibitory effect on the immune system, possibly affecting both B cells and T cells.[74] High-dose cyclophosphamide 50 mg/kg/day for 4 days induced durable remission (median follow-

Cytotoxic Drug Therapy

Administration of cytotoxic drugs is best reserved for refractory cases: symptomatic patients who have not responded to splenectomy, those in whom splenectomy is an unacceptable medical risk, patients who refuse the operation, and those who have serious side effects from corticosteroids. Cyclophosphamide (2 mg/kg/day) or azathioprine (1.5 mg/kg/day) should be continued for 3 months or more to ensure maximal inhibition of autoantibody synthesis. Less than half of patients treated with these drugs will respond with a rise in the hemoglobin that can be maintained in the face of substantially reduced doses of prednisone. This estimate may be overly optimistic, as negative or unfavorable results seldom are reported. Unfortunately, no controlled clinical trials of cytostatic agents for treatment of autoimmune hemolytic anemia have been conducted.

Cyclophosphamide and azathioprine, like prednisone, can induce numerous side effects. Early side effects include bone marrow suppression and impairment of the immune response (particularly T-cell–mediated immunity) and can occur concomitantly with therapy. After sustained administration, cyclophosphamide can damage ovarian function, inhibit spermatogenesis,[76–78] and cause bladder fibrosis.[79] Acute myeloid leukemia can develop years after administration.[80] By contrast, prolonged use of azathioprine has not been associated with a statistically significant increase in malignant diseases. All these considerations mandate careful monitoring of any patient treated with either cyclophosphamide or azathioprine.

Cyclosporine, a powerful T-cell modulator, has been used alone and in combination to elicit successful and sometimes durable remission in patients with AIHA and Evans syndrome.[81] Three of three patients with AIHA treated with cyclosporine achieved complete remission on initial doses of 2.5 mg/kg twice daily for 6 days then 3 mg/kg/day and 5 mg/day of prednisone for a median follow-up period of 49 months.[81] Mycophenolate mofetil successfully induced remission of AIHA complicating myelodysplastic syndrome.[82]

up 15 months) in 66% of patients treated.[75] This small refractory group of patients had been treated with a median of three other treatment regimens (range 1–7 other regimens).[74]

Rituximab Therapy

Rituximab is a chimeric anti-CD20 monoclonal antibody with a well-established favorable safety profile that has exciting possibilities for widespread clinical application in patients with autoimmune disease in general and AIHA specifically.[83,84] Several large trials of adult patients with non-Hodgkin lymphoma have demonstrated the efficacy and safety of rituximab.[84] Infusion-related side effects, including fever, respiratory distress, and hypotension, in a small population of lymphoma patients have been reported.[85,86] Massive cytokine release leads to this complication of infusion and is associated with high tumor burden.[87,88] No side effects have precluded completion of planned therapy in patients with autoimmune disease.[89] The occurrence and severity of side effects seem to be related to B-cell, and thus tumor, burden.[88] It has been anticipated and demonstrated that the side-effect profile is even more favorable in autoimmune disease patients with a lower level of B cells.[90] Other complications include long-term impairment of humoral immunity, which may be obviated with monthly infusions of intravenous Ig. Reactivation of hepatitis B[91] and parvovirus[92] and cases of some autoimmune diseases have been reported.

The mechanism of action of rituximab is multifaceted, complex, and incompletely understood. Rituximab induces cell death through complement-dependent lysis; antibody-dependent cellular toxicity; antibody-dependent phagocytosis mediated by Fc, complement, and phosphatidylserine receptors; direct antibody effects of CD20 ligation leading to inhibition of proliferation; apoptosis and sensitization to chemotherapy; and induction of active immunity.[83] Plasma cells are $CD20^-$. The response rate of patients with AIHA and thrombocytopenia suggests that earlier, $CD20^+$ B cells are producing antibody or that other as yet not clearly delineated mechanisms are affecting the disease remission. Reports that rituximab induces remission in patients with AIHA within 1 week to 3 months of first infusion suggest that the mechanism of action involves more than elimination of B cells. Table 47–4 summarizes selected case reports and small case studies of patients with both idiopathic and secondary AIHA treated with rituximab. The safety profile and response rate of this medication in patients with AIHA is favorable, which has prompted some experts in the field to attempt a trial of rituximab prior to splenectomy. A few cases of serious side effects, including *Pneumocystis carinii* pneumonia, varicella pneumonia,[93] *Escherichia coli* pyelonephritis,[94] and neutropenia.[95,96] have been reported.

Alemtuzumab Therapy

Use of alemtuzumab, a monoclonal antibody to the CD52 antigen, has been reported in idiopathic and secondary therapy-refractory AIHA.[97] Alemtuzumab binds both normal and malignant T and B lymphocytes and can cause cell death via complement fixation, antibody-dependent cell-mediated cytotoxicity, and apoptosis induction. Administration results in prolonged lymphocytopenia, and the resultant immunosuppression leads to increased susceptibility to infections for several months following cessation of therapy, requiring antiinfective prophylaxis.[98] Although experience with alemtuzumab for treatment of AIHA is limited, alemtuzumab may be beneficial for patients refractory to first-line treatments, including rituximab. In a recent study, five patients with CLL and AIHA were treated with alemtuzumab (30 mg three times weekly for 3–12 weeks) after not responding to conventional therapy; two patients were previously treated with rituxan.[99] All patients responded with a ≥2 g/dL rise in hemoglobin concentration and did not require further RBC transfusion requirement after a median of 5 weeks (range 4–7 weeks). They remained clinically stable without AIHA after a median of 12 months (range 2–13 months). Due to the demonstrated efficacy of alemtuzumab in the treatment of B-cell CLL, use of alemtuzumab may be considered before use of rituximab in patients with AIHA and progressive CLL in need of cytoreduction.[99] Further prospective studies of alemtuzumab in both idiopathic and secondary AIHA are needed.

Plasma Exchange

Because a single-volume plasma exchange replaces approximately 60% of the patient's plasma volume, the therapeutic advantage comes from removal of the IgG and/or IgM plasma antibodies mediating the hemolysis. Unfortunately, continuous antibody production and the large extravascular distribution of IgG limit the long-term efficacy of plasma exchange in patients with IgG-mediated AIHA. On cessation of therapy, the rate of return to pretreatment levels of autoantibody depends on the rate of autoantibody production.[100] A small retrospective case-control study showed no benefit from RBC transfusion following plasma exchange compared to RBC transfusion alone.[101] However, efficacy in IgG-mediated disease has been reported.[102] Occasional dramatic responses have been reported in patients being prepared for surgery or when plasma exchange was used as a temporizing measure after initiation of immunosuppressive therapy.[102,103] Therefore, this therapy should be reserved for patients who are unresponsive to transfusion and in critical condition because of rapid clearance of RBCs.

Table 47–4 Summary of Selected Studies and Case Report Data for Rituximab for Autoimmune Hemolytic Anemia

No. of Patients/Disease	Rituximab Dose (mg/m²)	Dosing Schedule	Response [% (n/N)]	Previous Regimens[a]	Splenectomy (n/N)	Follow-up Period (months)
15 Pediatric/idiopathic[171]	375	Weekly × 2–4	87 (13/15)	Two or more S, C, I, CyA, Az	2/15	7–28
1 Pediatric/SLE,[172] idiopathic[173]	375	Weekly × 2	100 (2/2)	S, C, I, CyA	0/2	5–7
6 Pediatric/idiopathic[94]	375	Weekly × 4 Weekly × 12 (2 patients)	100 (6/6)	S, I, Ph, CyA, Az	2/6	15–22
4 Pediatric/idiopathic[93]	375	Weekly × 4–6	100 (4/4)	S, V, CyA, Az, I, C, T	2/4	3–14
1 Pediatric/idiopathic[174]	375	Weekly × 4 then repeat	100(1/1)	S, I, C, CyA, ATG, Ph, Az	Yes	19

ATG, antithymocyte globulin; Az, azathioprine; BMT, bone marrow transplantation; C, cyclophosphamide; CAD, cold agglutinin disease; Chl, chlorambucil; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; Cl, cladribine; CLL, chronic lymphocytic leukemia; CR, complete remission; CyA, cyclosporine; D, dexamethasone; I, intravenous Ig; IFN, interferon; F, fludarabine; MM, mycophenolate mofetil; MP, mercaptopurine; Ph, plasmapheresis; PR, partial remission; S, corticosteroids; SLE, systemic lupus erythematosus; T, tacrolimus; V, vincristine; WAIHA, warm autoimmune hemolytic anemia; WAS, Wiskott–Aldrich synodrome.

Other Therapies

A few therapies for AIHA have been reported but are rarely used. They include infusion of vincristine-laden IgG-coated platelets,[9] use of danazol, an attenuated synthetic androgen,[104] and splenic irradiation.[105,106] In addition, B- and T-cell–depleted, allogenic and autogenic[107,108] bone marrow transplantation have been performed in extreme refractory cases of AIHA, with limited success. Erythropoietin has been used in some cases to increase RBC production in an attempt to decrease transfusion needs.

COLD AGGLUTININ DISEASE

Cold agglutinin disease refers to a group of disorders caused by antierythrocyte autoantibodies (e.g., cold agglutinins) that preferentially bind RBCs at cold temperatures (4°C–18°C [39°F–64°F]) and may or may not induce hemolysis. Virtually all sera from healthy individuals contain low-titer cold agglutinins, regarded as benign or harmless RBC autoantibodies and considered polyclonal. Similarly, cold agglutinins that arise after certain infections are polyclonal and usually benign. In rare cases, a transient form of cold agglutinin disease ensues and is thought to be produced as a result of random rearrangement of immunoglobulin gene segments and molecular mimicry of antigens on the surface of infective agents.[109] By contrast, monoclonal cold agglutinins are generally pathogenic and are derived from clonal B-cell expansions (as in idiopathic/chronic cold agglutinin disease), which may progress to frank lymphoma. Cold agglutinin disease develops in 1.1% to 4.9% of all cases of non-Hodgkin lymphoma.[110]

Pathophysiology

Immune Clearance of Erythrocytes

The pathogenic IgM autoantibody in cold agglutinin disease is highly efficient in activating the classic complement pathway on the erythrocyte membrane.[111,112] However, the thermal dependency of the antibody constrains its pathogenic effects. The autoantibody rapidly elutes off RBCs at the 37°C (99°F) temperature of the visceral circulation, but in the cool peripheral circulation of the hands and feet, the cold agglutinin remains on the erythrocyte membrane for at least a few seconds. That amount of time is sufficient to activate the complement cascade to the stage of C3b, which adheres to the RBC after it reenters the central circulation. In the hepatic circulation, C3b-coated RBCs encounter macrophages with receptors specific for C3b[113]; however, C3b sensitization is only a weak signal for activation

of phagocytosis. Hepatic clearance of C3b-coated RBCs requires 500 to 800 C3b molecules per RBC.[114] Thus, many C3b-coated cells escape into the systemic circulation, where the C3b inactivator system degrades C3b into C3dg, C3d, or both. The result is a cohort of erythrocytes coated with C3d, but not with the IgM autoantibody,[115] which have a near-normal survival in vivo, as macrophages bind to C3d with low avidity.[116] The DAT result remains positive, but little if any hemolysis occurs.[114]

These limits on the pathogenicity of cold agglutinins account for the subdued hematologic picture in most patients with cold agglutinin disease. However, if the regulatory C3b inactivator proteins are impaired, cleavage of RBC-bound C3b is limited, which permits completion of the complement cascade in the visceral circulation and results in severe extravascular hemolysis. Several patients with high titers of IgA cold agglutinins have been reported. These cases are not associated with cold agglutinin disease, which may relate to the lack of complement activation by IgA antibodies.[117]

Targets of Cold Agglutinin Disease

The antigenic specificity of cold agglutinins usually is identified by their degree of reactivity with RBCs from adults (blood group I) and cord blood (blood group i) (Fig. 47–4). The cold-reactive autoantibody produced after some cases of *Mycoplasma pneumoniae* infection has anti-I specificity,[118] whereas the antibody associated with infectious mononucleosis frequently, but not always, has anti-i specificity.[119,120] Antibody that agglutinates adult Group O cells with titers fourfold or greater than CORD RBCs at 4°C (39°F) is anti-I. The opposite results demonstrate anti-i.[121] Additional specificities have been identified by tests with rare adult RBCs that lack the I antigen or with enzyme-treated erythrocytes. Rarely cold agglutinins are specific for the A blood group antigen.[122]

Clinical Findings

The most common type of cold agglutinin disease, a chronic form characterized principally by a stable anemia of moderate severity and attacks of acrocyanosis precipitated by exposure to cold, constitutes approximately one third of all cases of immunohemolytic anemia. Cold agglutinins cause the cardinal abnormalities of the disease. The acrocyanosis stems from intraarteriolar agglutination of erythrocytes in the relatively cool tips of the fingers, feet, earlobes, and nose. Hemolytic anemia depends on the capacity of the cold agglutinins to initiate activation of the complement cascade on the surface of the RBC. Most patients with chronic cold agglutinin disease are in the fifth to eighth decades of life, and many of them have a B-cell neoplasm-lymphoma, Waldenström macroglobulinemia, or CLL. The cold agglutinin in those latter cases is monoclonal, almost always IgM-κ, and may manifest as a monoclonal band in the serum protein electrophoretic pattern. In the absence of a B-cell neoplasm, the spleen and lymph nodes are rarely enlarged; such findings warrant a search for the neoplasm. Some studies demonstrate that these patients have a relative paucity of complement. In the setting of intercurrent viral or bacterial illness, complement levels, and thus the degree of hemolysis, are increased.[123,124]

A second type of cold agglutinin disease, usually acute and always self-limited, occurs as a rare complication of several infectious diseases, most notably *M. pneumoniae* infection and infectious mononucleosis. Patients with this form of cold agglutinin disease are much younger than those with chronic cold agglutinin disease. Onset is abrupt, appearing as the infection wanes, and the anemia can be severe. Evaluation for *M. pneumoniae* infection should be considered in all cases of cold agglutinin–mediated hemolysis because prompt treatment of the pneumonia will resolve the hemolysis.[125] Most often, however, *M. pneumoniae* infections are not associated with pathologic hemolysis. The cold agglutinin titers are moderately elevated and are polyclonal.

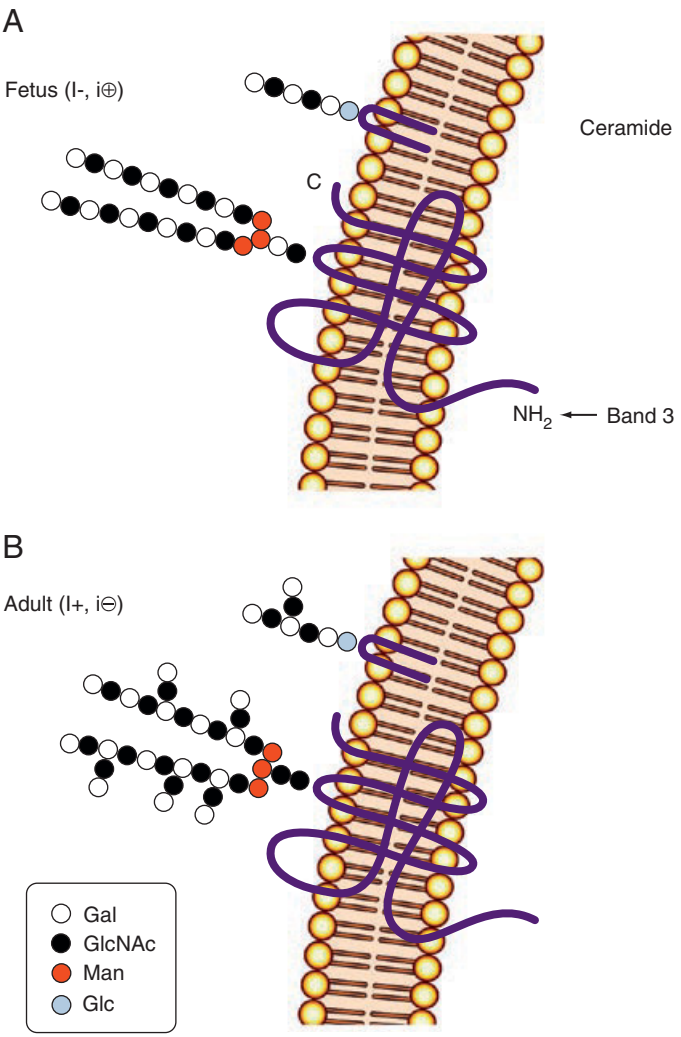

Figure 47–4 The I/i blood group system in (**A**) fetus and (**B**) adult. The fetus lacks the enzymes (branching enzymes) required to produce the branched forms of ceramide and the I antigen. The unbranched (fetal) and branched (adult) variants of the l antigen are immunochemically distinct structures. Shaded structure represents the erythrocyte membrane. The modified N-terminus of band 3 faces the interior of the red blood cell. *(From Hakomori S: Blood group ABH and Ii antigens of human erythrocytes: Chemistry, polymorphism, and their developmental change. Semin Hematol 18:39, 1981.)*

Laboratory Evaluation

The usual laboratory findings of hemolytic anemia (i.e., anemia, reticulocytosis, polychromatophilia, spherocytosis, erythroid hyperplasia in the bone marrow, and elevated serum bilirubin and lactate dehydrogenase levels) are generally not striking in patients with chronic cold agglutinin disease. Hemagglutination may be visible to the unaided eye in blood drawn from a patient with cold agglutinin disease and can interfere with automated blood counts. The agglutination usually can be seen on the peripheral blood smear (Fig. 47–5). The anemia often is mild and stable because the C3b inactivator in serum limits the extent of cold agglutinin–induced complement activation and phagocytosis. However, exposure to cold may greatly augment the binding of cold agglutinins, exceeding the restraints of the inactivator system. This can result in a sudden drop in hematocrit with complement-mediated intravascular hemolysis and renal failure.

In typical cases of chronic cold agglutinin disease, the cold agglutinin titer is very high (>1:10^5 and occasionally >1:10^6). The antibodies are most reactive in the cold, and hemagglutination disappears as

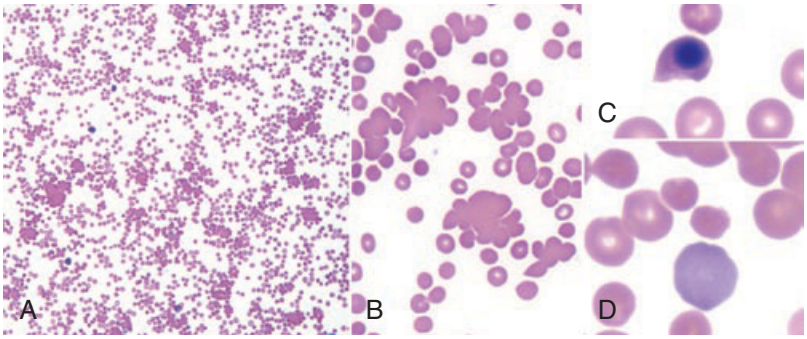

Figure 47–5 Peripheral smear in cold agglutinin disease. Low-power scan shows uneven distribution of red blood cells (**A**), which at slightly higher power (**B**) shows the red blood cells to be clumped together or agglutinated. This must be distinguished from rouleaux formation. High–power scan shows nucleated red blood cells (**C**), polychromatophilia, and microspherocytes (**D**).

the temperature rises toward 37°C (99°F). In some cases, however, the antibody has a high thermal amplitude, that is, it is reactive at relatively high temperatures and occasionally even at 37°C (99°F). Recognition of patients with high thermal amplitude cold agglutinins is important because they may respond to prednisone,[126] whereas patients with high-titer cold agglutinin disease usually do not. The thermal amplitude of the cold agglutinin, not the titer of the antibody, most accurately predicts the severity of disease. The DAT result is positive because of erythrocyte-bound C3d (see Pathophysiology above), but tests with anti-IgG reagents are negative. The indirect antiglobulin test, conducted at 37°C (99°F), is negative. In addition to monoclonal IgM cold agglutinins, IgG/IgM mixed cold agglutinins have been reported. Some patients with cold agglutinin disease have low titers of IgG and IgA cold agglutinins.

Transfusions and Cold Agglutinin Disease

Transfusion in a patient with cold agglutinin disease requires the same prudent safeguards observed with transfusions in patients with autoimmune hemolytic anemia. All compatibility tests must be performed at 37°C (99°F) and IgG-specific antiglobulin reagents used to avoid confusion with the serum cold agglutinin and the erythrocyte-bound C3d. Use of "inline" blood warmers is advisable, and more elaborate measures for performing the entire transfusion process at 37°C (99°F) occasionally are required. Hypothermia during cardiac surgery must be prevented, and special techniques must be used to avoid lowering the temperature of blood in the coronary arteries.

Therapy

Therapy for the cold agglutinin syndromes depends on the gravity of symptoms, serologic characteristics of the autoantibody, and any underlying disease. In the idiopathic, or primary, form of chronic cold agglutinin disease, prolonged survival and spontaneous remissions and exacerbations are not unusual. The anemia is generally mild, and the simple measure of avoiding exposure to cold temperatures can avoid exacerbations, especially when the cold agglutinin has a low thermal amplitude.

The purine analogue fludarabine has proved to be of therapeutic benefit in patients with chronic cold agglutinin disease.[127] However, WAIHA and immune thrombocytopenia purpura are documented side effects of this modality. Prednisone has been beneficial in rare cases showing relatively low titers of cold agglutinins of a high thermal amplitude or in which an IgG cold-reactive antibody is produced. However, prednisone is not useful therapy in most patients with primary IgM-induced cold agglutinin disease, and its administration should not be undertaken lightly, given the chronicity of the disease.[128] Plasma exchange may help as a temporary measure in acute situations.[129] Because 95% of IgM is intravascular and up to 80% of Igm can be removed by plasma exchange, plasma exchange should theoretically offer optimal and effective therapy. However, if the thermal amplitude of the antibody is such that agglutination occurs at room temperature, RBC agglutination within the cell separator and tubing can occur. In these situations, therapy may need to be initiated in a controlled, very high temperature setting of 37°C (99°F).[116] Splenectomy usually is ineffective because the liver is the dominant site of sequestration of RBCs heavily sensitized with C3b. In rare cases, however, patients with an enlarged spleen have responded to splenectomy. In some of these patients, a localized splenic lymphoma was found, whereas in others only lymphoid hyperplasia was evident. Rituximab, an anti-CD20 monoclonal antibody, has demonstrated some clinical effectiveness in cases of cold agglutinin disease (see Table 47–4). A prospective phase II study of patients with primary cold agglutinin disease reported a 54% response rate in 27 patients treated with 37 courses of rituximab.[13] Some of the patients who did not respond to the first course of four weekly doses of rituximab were treated with a combination of rituximab and interferon-α. Among the responses, one patient achieved complete remission and 19 partial remission. The complete remission was sustained at 42 months, although all but one of the patients with partial remission relapsed at a mean of 11 months.[130] It is essential to seek evidence of a B-cell neoplasm before initiating therapy for chronic cold agglutinin disease. Oral alkylating agents (chlorambucil or cyclophosphamide) help many patients with the secondary form of cold agglutinin disease because of their effect on the B-cell neoplasm, but only occasionally do they benefit patients with the primary form of the disease.[118,119,131,132] When cold agglutinin disease is part of an established B-cell malignancy, the severity of hemolysis often waxes and wanes in parallel with the activity of the neoplasm.

Transient cold agglutinin disease is a rare form that is always self-limited. Supportive measures, including transfusions and avoidance of cold, may suffice (see box on Transfusions and Cold Agglutinin Disease). Treatment of the *Mycoplasma* infection, if detected, shortens the duration and severity of hemolysis. Corticosteroids usually are not helpful, and splenectomy almost never is indicated.

PAROXYSMAL COLD HEMOGLOBINURIA

Epidemiology

PCH historically was associated with tertiary syphilis. This syphilitic variant is rarely seen today. PCH now is more commonly seen primarily in children after a viral or, much less commonly, a bacterial illness. Most commonly, the viral cause is not identified but the condition is associated with an upper respiratory tract infection. Case reports of PCH secondary to varicella infection[133] in adults and children have been reported.

In a review of 52 cases of PCH over a 37-year period, the median age at presentation was 5 years.[134] In a study of 100 children with onset of AIHA before age 16 years, six (6%) had PCH as defined by a positive Donath-Landsteiner test.[18] All six cases were associated with symptoms suggestive of an acute viral illness.

Pathophysiology

The IgG antibody responsible for PCH is found in the patient's serum by incubation of normal erythrocytes, fresh normal serum as a source of complement, and the patient's serum, first at 4°C (39°F)and then at 37°C (99°F), with appropriate controls. The target usually is the P blood group system,[135] which is a tetraglycosyl ceramide called *globoside*, although other targets have been reported.[136] The Donath-Landsteiner antibody fixes the first two components of complement in the cold and completes the cascade on warming to 37°C (99°F).[137]

Clinical Findings

Although the pathognomonic Donath-Landsteiner antibody often occurs in cases of tertiary or congenital syphilis, it generally does not cause hemolytic disease in this situation. On exposure to cold, an occasional patient experiences paroxysms of hemoglobinuria and constitutional symptoms: fever, back pain, leg pain, abdominal cramps, and rigors, followed by hemoglobinuria. In contrast, the postviral form of PCH[138,139] is characterized by constitutional symptoms with fulminant intravascular hemolysis and its associated signs of hemoglobinemia, hemoglobinuria, jaundice, severe anemia, relative reticulocytopenia,[134] and sometimes renal failure. The disease is self-limited, usually lasting 2 to 3 weeks, although it can be life threatening because of the degree of hemolysis and consequent anemia.

Laboratory Evaluation

The DAT finding almost always is negative, but occasionally weak reactions for erythrocyte-bound complement are manifested. The indirect antiglobulin test result is negative. The diagnosis depends on recognition of the clinical picture because tests for the Donath-Landsteiner antibody are not routinely performed.

Therapy

No specific treatment of PCH is available. Unlike the positive response to steroids of most IgG-mediated autoimmune diseases, prednisone is not useful. The best approach is supportive care, transfusions to alleviate symptoms, and avoidance of cold temperatures. The patient should be kept in a warm room, and transfusions should be given through a blood warmer. Unlike patients with cold agglutinin disease in whom the pathogenic antibody is IgM, PCH IgG antibody is less amenable to removal via plasma exchange. However, the literature reports a child with severe hemolysis secondary to the Donath-Landsteiner antibody in whom intravenous Ig, corticosteroids, and warming of the patient had failed, but in whom daily single-volume plasma exchange for 3 consecutive days immediately eliminated the need for further transfusions.[140]

DRUG-ASSOCIATED IMMUNE HEMOLYTIC ANEMIA

Drug-associated hemolytic anemia can be drug induced or drug dependent. The antibodies can be specific for RBC antigens alone or for RBC-bound drug.[1] Four distinct mechanisms are associated with the disorder. The first involves drug that can bind to the RBC membrane. The patient makes antibodies against the drug (e.g., penicillin) that combine with the erythrocyte-bound drug, opsonizing and preparing the RBC for destruction. Discontinuation of the drug brings the hemolytic anemia to a rapid halt because the antibodies have no specificity for antigens on the RBC membrane. Clues to the diagnosis are the appropriate clinical findings, a positive result on the DAT, a negative result on the indirect antiglobulin test, and failure of antibodies eluted from the patient's RBCs to bind to normal erythrocytes. The diagnosis is established when both the eluate and the patient's serum contain antibodies directed against the drug-coated cells. In the case of penicillin,[141] hemolytic anemia occurs only when large amounts are administered; in patients treated with lower doses, a positive DAT result without hemolytic anemia is not unusual because production of low-avidity IgG antipenicillin antibodies is a common event.

The second mechanism involves immune complexes. The offending drug, or drug metabolite, binds to a plasma protein, forming an immunogenic conjugate. An antibody to the conjugate, if one develops, usually is IgM. The antibody then binds to the immunogenic conjugate, forming an immune complex that adheres to RBCs. Through efficient activation of complement on the erythrocyte membrane, this process causes a clinical picture of intravascular hemolysis and concomitant hemoglobinemia, hemoglobinuria, and possible renal failure. This chain of events accounts for most reported examples of drug-induced immune hemolytic anemia. Reports on the nonsteroidal drug diclofenac have shown that AIHA is induced by sensitization to the glucuronide conjugate of the drug.[142]

Serologic findings with erythrocyte-bound immune complexes are similar to those of the first mechanism, except that the DAT reveals complement bound only to the RBC. The IgM antibody is presumed to be no longer present after complement activation. The patient's serum reacts with RBCs (lacking antidrug antibody) in the presence of the offending drug, and the eluate from the patient's RBCs generally does not react with normal erythrocytes.

The third mechanism involves in vivo sensitization to drugs by the formation of immunogenic drug–RBC complexes. In these cases, the specificity of the drug-induced antibodies not only is contributed by the drug (or its metabolites) but also is by defined RBC antigens, particularly of the Rhesus and I/i systems.[143]

The fourth mechanism involves the induction of authentic autoantibodies against RBCs by a drug. α-Methyldopa is the classic example.[144] The DAT result turns positive in as many as 20% of patients treated with α-methyldopa, but few of these patients develop hemolytic anemia. The antiglobulin test result may take several months to 1 year or more after the start of drug therapy to become positive. In patients with hemolytic anemia, discontinuation of the drug results in gradual cessation of the hemolytic anemia and disappearance of the autoantibody because the drug itself is not required for the hemolytic process but only for the initiation of antibody production. Curiously, the autoantibody usually is specific for antigens of the Rh system. The serologic findings are indistinguishable from those of primary AIHA and include a positive DAT result, usually a positive result on the indirect antiglobulin test, and an eluate that reacts with normal erythrocytes. Patients taking α-methyldopa often have other antibodies in addition to the RBC autoantibodies. The mechanism by which α-methyldopa induces autoantibodies is unknown but may involve effects on immunoregulatory T cells.

Drug-induced immune hemolytic anemia was commonly seen when penicillin was administered in large doses (i.e., >20 million units/day) and when α-methyldopa was widely used for treatment of hypertension.[59,145] The disease now is less common in clinical practice. Numerous drugs can induce hemolytic anemia. A 20-year retrospective review of 71 cases referred to an immunohematology reference laboratory revealed that 51% were due to cephalosporins and 15% were due to nonsteroidal antiinflammatory drugsS.[146] The remainder of cases included examples due to penicillin or penicillin derivatives, quinine, quinidine, probenecid, levofloxacin, cefoxitin (Mefoxin), carboplatin, and oxaliplatin.

UNUSUAL FORMS OF IMMUNE HEMOLYTIC ANEMIA

In certain cases, hemolytic anemia due to heteroantibodies or alloantibodies may be confused with AIHA. Some lots of antithymocyte globulin contain heterologous antihuman RBC antibodies, which can precipitate attacks of immune hemolysis.[147] Anti-A alloantibodies in some preparations of intravenous human γ-globulin have resulted

in RBC destruction,[148] and synthesis of alloantibodies by passenger B cells in transplanted livers and kidneys can cause a hemolytic anemia that masquerades as AIHA.[149]

IN VITRO AND ANIMAL MODELS OF POTENTIAL THERAPEUTIC INTERVENTIONS

Complement receptor 1 (CR1) negatively regulates B-cell antigen receptor–mediated activation.[82] The human recombinant soluble form of complement receptor 1 (sCR1) has been investigated in vitro and in vivo.[150] The in vitro alloimmune incompatibility model demonstrated inhibition of complement activation and abrogated hemolysis. In murine models, 10 mg/kg of sCR1 administered with human group O RBCs prevented alloimmunization and, in mice with preexisting anti-A antibodies, improved posttransfusion survival by 50%, reduced intravascular hemolysis, and decreased complement deposition. Further study is warranted to determine the appropriateness of phase I trials of human AIHAs resistant to standard therapies.

In vitro data suggest that an imbalance in T_H1/T_H2 cytokine production plays a role in AIHA. Decreased production of T_H1 cytokines, particularly interleukin (IL)-12, and increase in T_H2 cytokines, particularly IL-10, may play a role in the pathogenesis of AIHA.[151] Statistically significant differences in levels of T_H1/T_H cytokines were demonstrated in a study of 13 patients with AIHA compared with 13 control subjects.[152] Manipulation of the IL-10/IL-12 balance may offer potential therapeutic benefit.

NZB Mice

The inbred NZB mouse is genetically programmed to develop AIHA at approximately age 6 to 8 months (lifespan of a normal mouse is approximately 2 years). Antierythrocyte autoantibodies begin to appear at approximately age 3 months, and by 9 months the DAT result is positive in 60% to 80% of the animals. Typical signs of hemolytic anemia develop, with reticulocytosis, spherocytosis, shortened RBC survival time, and splenomegaly.[153]

Okamoto et al.[154] developed a transgenic murine model of AIHA. The symptoms in this model are variable, ranging from unaffected to severe anemia. The B1 cells have been demonstrated to mediate AIHA.[155] They are activated in both T-cell–dependent and T-cell–independent fashion.[156] B1 cells are distinct from B2 cells, the more prevalent B cells, in several ways. They preferentially locate in the peritoneal and pleural cavities, produce 50% of the natural serum IgM, and escape clonal deletion. IL-10 influences T-cell–proliferation of B1 cells, and continuous administration of anti–IL-10 monoclonal antibody depletes B1 but not B2 cells in murine models. B1 autoantibody production, but not spontaneous proliferation, is upregulated by IL-5.[155] The influence of T_H2 cytokines on the behavior of B1 cells in vivo[157] suggests possible avenues for treatment.

ORIGINS OF ANTIERYTHROCYTE ANTIBODIES

The vast improvement in our understanding of what prevents autoimmunization has not yet informed us of the mechanism that causes autoimmunization. Virtually nothing is known of the origins of warm-reactive IgG antierythrocyte autoantibodies, despite the availability of a thoroughly investigated, spontaneous animal model of the disease (the NZB mouse) and stocks of pathogenic autoantibodies, readily obtained from patients with the disease. A major impediment to advances in our perceptions of how AIHA originates is that the autoantigens are mostly unknown. Even in cases in which blood group specificity of the autoantibodies has been identified, the relevant structures have not been elucidated. Leddy et al.[158] succeeded in identifying four proteins on the RBC membrane that bind to antierythrocyte autoantibodies: the band 3 anion transporter, glycophorin A, and two polypeptides, probably related to the Rh family of antigens. Various combinations of these four autoantibody specificities were found in a group of 20 patients with AIHA.

The association of AIHA with systemic lupus erythematosus and immune thrombocytopenia (Evans syndrome), the induction of the disease by drugs that seem to perturb immune regulation, and the graft-versus-host model of AIHA all suggest, at least in some cases, antigen-independent activation of clones of B cells with the capacity to produce IgG anti-RBC autoantibodies. Such polyclonal B-cell activation may account for the production of antierythrocyte autoantibodies in patients with the acquired immunodeficiency syndrome.[118,159] Hypergammaglobulinemia and other signs of nonspecific activation of B cells are prominent in patients with human immunodeficiency virus infection.[160]

The immunologic basis of AIHA in patients with CLL or B-cell lymphoma is equally obscure.[161] In malignant diseases, there is indirect evidence that AIHA may be caused by immune dysregulation and not strictly malignant B-cell clone production of autoantibody. Malignancies can be complicated by AIHA prior to onset of disease or during remission and may not recur with relapse of the same malignant clone. In cases of CLL, the autoantibodies are IgG and often polyclonal,[162] whereas the malignant $CD5^+$ B cells of that disease generally produce only IgM antibodies that are monoclonal. Therefore, B cells other than those constituting the leukemia likely produce the autoantibodies. The large mass of $CD5^+$ B cells in patients with CLL might induce nonneoplastic $CD5^-$ B cells to produce IgG autoantibodies, perhaps by disturbing immunoregulatory idiotypic networks. Demonstration of the simultaneous presence of autoantibodies and antiidiotypic antibodies on RBCs in cases of AIHA[163] suggests that such networks may have a role in the disease.

In contrast to the antigens that incite warm autoantibodies, the structures of the autoantigens of cold agglutinin disease, the I/i system, are known (see Fig. 47–4).[164] This information has clarified our thinking about the immunology of this group of disorders. There is little reason to doubt that the very high levels of monoclonal cold agglutinins found in some patients with B-cell neoplasms are produced by the malignant cells. The demonstration that an idiotypic marker on monoclonal cold agglutinins could be detected not only on the patient's neoplastic B cells but also on 3% to 10% of normal B cells[165] supports the view that these autoantibodies are part of the normal immune repertoire. Malignant transformation of a cold agglutinin-producing B cell results in a lymphoma complicated by chronic cold agglutinin disease.

The basis of the association of PCH with syphilis may be antigenic mimicry, in which structural similarities between a microbial antigen and a self-antigen trigger an autoantibody response. In the case of PCH, the infecting organism, *Treponema pallidum*, should possess two antigenic determinants (epitopes): one recognized by T cells (the foreign epitope) and the other by self-reactive B cells (mimicking epitope). Donath-Landsteiner antibodies would be produced only by syphilitic patients whose class II major histocompatibility complex glycoproteins could present the foreign epitope in an immunogenic form to T cells. A similar mechanism could apply to postinfectious acute cold agglutinin disease, in which a cross-reaction involving antigenic determinants of *M. pneumoniae* and the I blood group substance has been incriminated.[166]

Structural analyses of monoclonal anti-I and anti-i autoantibodies from patients with B-cell neoplasms are beginning to yield important clues about the origins of chronic cold agglutinin disease. A striking observation is the repetitive use of the same immunoglobulin V_H gene, $V_{H4\text{-}34}$, in monoclonal IgM cold agglutinins, regardless of the anti-I or anti-i specificity of the autoantibody.[167,168]

From these results it appears that (a) the germline $V_{H4\text{-}34}$ heavy chain encodes the dominant specificity of monoclonal cold agglutinins, (b) the somatic mutations of the light chain genes of the cold agglutinins are the result of an immune response, and (c) the V_H CDR3 and the light chain confer fine specificity (e.g., for I or i) on the cold agglutinin and influence its affinity. These data make a convincing case that monoclonal cold agglutinins arise as the result of an immune response, perhaps an autoimmune response to an autoanti-

gen on erythrocytes. The results of these molecular studies of cold agglutinins complement other evidence favoring a role for antigen-mediated clonal selection in some types of B-cell neoplasms.

In contrast to monoclonal cold agglutinins associated with chronic cold agglutinin disease, the naturally occurring IgM cold agglutinins that are present in low titers in normal serum are not restricted to the $V_{H4\text{-}34}$ gene segment. Thus, naturally occurring low-titer cold agglutinins are associated with different genes of the V_{H3} family as well as the $V_{H4\text{-}34}$ gene.[169] Therefore, it appears that B-cell neoplasia is an important, but not exclusive, element in the association between $V_{H4\text{-}34}$ and cold agglutinins. The correlation with lymphomas has added interest because $V_{H4\text{-}34}$ has been independently linked to B-cell lymphomas that do not secrete cold agglutinins.[170] Both kinds of $V_{H4\text{-}34}$-related B-cell tumors may originate from an uncontrolled autoimmune response against I or i RBC antigens, one type lacking the capacity for secreting the cold agglutinin and the other able to secrete it as a monoclonal IgM immunoglobulin.

CHAPTER 48

EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIAS

Stanley L. Schrier and Elizabeth A. Price

By definition, extrinsic causes of hemolysis are abnormalities in the environment in which the red blood cells (RBCs), usually normal themselves, circulate. These abnormalities can be acute or chronic in nature. They can arise from congenital lesions but usually result from acquired lesions. Inherited anomalies of glucose-6-phosphate dehydrogenase (G6PD) deficiency which reduces the red cell's ability to deal with oxidative insults can leave red cells more vulnerable to environmental insults. Determination of hemolysis with various levels of compensation as the cause of an anemia is accomplished using the approaches described in Chapter 34. Signs of extrinsic hemolysis with minimal or no anemia can be valuable clues to diseases of other organ systems. Among the most important forms of extrinsic hemolytic anemia are those caused by immune mechanisms; these are discussed in Chapter 47.

Clinical and morphologic findings suggest the many misfortunes that can befall RBCs in their travels. They can be trapped in an abnormal marrow stroma network, sheared by jets in an abnormal heart, cut and fragmented by fibrin strands stretched across damaged areas in the microvasculature, or attacked by parasites. They can undergo stasis and perhaps metabolic depletion in giant hemangiomas or in an enlarged spleen. An abnormally functioning liver or kidney can cause a buildup of substances in plasma that alter RBC shape and metabolism. Drugs can cause oxidation or other metabolic damage. Oxidant injury provokes degradation of hemoglobin with the formation of hemichromes (see Drug-Induced Oxidative Hemolysis below). Degraded hemoglobin and hemichromes bind avidly to the cytoplasmic tail of the major transmembrane protein band 3 (see Chapter 46) and cause clustering of band 3 oligomers.[1] Immunoglobulins and complement then bind to the external membrane face over clusters of band 3, promoting immune destruction. Other membrane proteins may be subject to oxidative attack. Toxins, venoms, heat, and mechanical trauma can directly destroy the membrane. These agents may cause an alteration in the asymmetry of the phospholipid bilayer, causing phosphatidylserine to move from the inner leaflet of the membrane bilayer to the outer leaflet, where it can be recognized by macrophages.

In general, only the most devastating damage leads to direct intravascular destruction. Usually, the initial insult leads to an eventual change in the external portion of the RBC membrane, which causes macrophages to retard, hold, remove, or otherwise modify RBCs. Infection or inflammation can activate these macrophages. Some RBC changes are accompanied by a decrease in RBC deformability, which retards flow and thereby facilitates the action of macrophages on the affected RBC. All of these changes lead to extravascular hemolysis.

FRAGMENTATION HEMOLYSIS: MICROANGIOPATHY

Clinical Manifestations

Patients present with various degrees of hemolytic anemia and compensation, with evidence of RBC fragmentation on smear (Fig. 48–1 and see box on Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias). RBC removal is generally extravascular, with minimal or moderately decreased levels of haptoglobin. If RBC damage is sufficiently severe, signs of intravascular hemolysis may be present. Because of the underlying pathology, some of these syndromes show evidence of platelet removal, leading to thrombocytopenia. Occasionally, the underlying cause produces activation and depletion of procoagulant factors with consequent activation of the fibrinolytic system, consistent with disseminated intravascular coagulation (DIC; see box on Causes of Red Blood Cell Fragmentation Hemolysis).

Pathophysiology

Fragmentation hemolysis occurs when mechanical forces disrupt the physical integrity of the RBC membrane. Brain et al.[2] observed a possible relationship between vascular lesions and RBC fragmentation. They postulated that lesions produced shearing forces sufficiently strong to fragment RBCs or incited inflammation of small vessel walls, which generated fibrin strands that cut the passing RBCs into irregular pieces. Subsequent studies documented that in vitro shear stresses in excess of 3000 dynes/cm^2 cause RBC fragmentation. In vivo studies in patients with mitral prosthetic regurgitation and hemolysis show high peak shear stresses of 4500 dynes/cm^2, very rapid acceleration or deceleration, or both.[3]

Research suggests alternative mechanisms of producing microangiopathic hemolysis that involve platelets and small-vessel thrombi. Taylor et al.[4] described a baboon model in which injection of C4b-binding proteins and *Escherichia coli* produced a picture of DIC with microangiopathic hemolysis and thrombocytopenia. Treatment with the F(ab)′$_2$ monoclonal antibody against platelet glycoprotein (GP) IIb/IIIa complex reduced the microangiopathic hemolysis and renal disease. The platelet-rich, fibrin-poor microvascular thrombi found in many patients with thrombotic thrombocytopenic purpura (TTP) now are thought to be caused by abnormally decreased ADAMTS-13 activity. This metalloprotease is responsible for converting the highly thrombogenic large multimers of von Willebrand factor made by platelets and endothelial cells into the smaller forms normally found in circulation. Mutations in or antibodies against ADAMTS-13 result in unusually large multimers of von Willebrand factor attached to endothelial cell surfaces, where platelets may excessively aggregate, leading to formation of microvascular thrombi even in the absence of endothelial damage.

Whatever the mechanism of mechanical trauma, the RBC membrane is viscoelastic and has self-sealing properties (see Chapter 46) so that little hemoglobin leaks out as the cell is being cut. However, prolonged distortion of the membrane produces a plastic change; therefore, the smaller RBC fragments usually do not become microspheres or microdisks but continue to display evidence of the shearing event or distortion in the form of typical irregular shapes. These irregular shapes and the rigidity that they reflect subsequently interfere with the ability of RBCs to fold, elongate, and deform sufficiently to pass through 3-μm capillaries and even smaller slits in the walls of the sinusoids of the reticuloendothelial system. This sequence leads to their destruction.

Differential Diagnosis

Generally, the differential diagnosis of fragmentation hemolysis can be deduced from the clinical findings. The presence of a prosthetic heart valve or a regurgitant jet that fragments or accelerates[5] (i.e.,

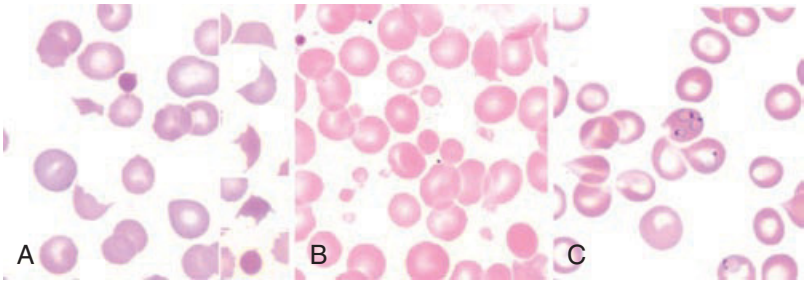

Figure 48–1 Peripheral blood smears from examples of extrinsic nonimmune hemolytic anemia. **A**, Microangiopathic hemolytic anemia. Note the schistocyte, fragmented cells, spherocyte, and polychromasia. More examples of damages red cells, including classic "helmet cell" (*top*), are seen to the immediate *right*. **B**, Thermal injury from burn. Thermally damaged red blood cells from numerous microspherocytes and tiny red cell fragments. **C**, Malaria infestation. Red cells contain *Plasmodium falciparum* malaria. Note the high rate of infestation, the presence of only ringed forms, and the multiply infested red cell (*center*).

Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias

There is no simple approach to the differential diagnosis of hemolysis caused by extrinsic nonimmune hemolytic anemia. The physician must pay close attention to the clinical finding. Useful clues come from a determination of whether RBC breakdown is predominantly extravascular or intravascular, but most important in the analysis is the observation of RBC morphology, which can focus the differential diagnosis. Unhelpful terms such as *aniso* and *poik* should be discarded. RBCs are spherocytic, stomatocytic, fragmented, echinocytic, acanthocytic, spurred, or bite cells or can be mixtures of these types.

Causes of Red Blood Cell Fragmentation Hemolysis

Damaged microvasculature
Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS)
Associated with pregnancy: Preeclampsia or eclampsia; hemolysis plus elevated liver enzymes plus low platelets (HELLP syndrome)
Associated with malignancy, with or without mitomycin C treatment
Vasculitis: Polyarteritis, Wegener granulomatosis, acute glomerulonephritis, or *Rickettsia*-like infections
Abnormalities of renal vasculature: Malignant hypertension, acute glomerulonephritis, scleroderma, or allograft rejection, with or without cyclosporine treatment
Disseminated intravascular coagulation
Malignant hypertension
Catastrophic antiphospholipid antibody syndrome
Atrioventricular malformations
Kasabach–Merritt syndrome
Hemangioendotheliomas
Atrioventricular shunts for congenital and acquired conditions (e.g., stents, coils, transjugular intrahepatic portosystemic shunt, Levine shunts)
Cardiac abnormalities
  Replaced valve, prosthesis, graft, or patch
  Aortic stenosis or regurgitant jets (e.g., in ruptured sinus of Valsalva)
Drugs: Cyclosporine, mitomycin, ticlopidine, tacrolimus, or cocaine

Waring blender syndrome) can be readily discerned. The clinical picture of thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS) is generally dramatic and acute (see Chapter 139). Atrioventricular malformations may be associated with DIC and platelet removal; the diagnosis requires a high index of suspicion and imaging studies. The presence of preeclampsia in a pregnant woman with microangiopathic hemolysis usually is obvious, but the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome is a serious complication of pregnancy that can occur without other signs of preeclampsia or hypertension.[6] This syndrome can produce hepatic rupture, visual failure, DIC, seizures, and congestive heart failure and requires treatment by prompt delivery of the fetus (see Chapters 140 and 161). Cancer can be an underlying cause of microangiopathy. Vessels supplying malignant tumors are thought to be structurally abnormal. They exhibit the same sort of fibrin stranding that produces fragmentation hemolysis in DIC and TTP–HUS.

Continued use of invasive diagnostic and therapeutic procedures with insertion of foreign bodies into the circulation has been complicated by microangiopathic hemolysis. A transjugular intrahepatic portosystemic shunt can cause the syndrome in approximately 10% of patients.[7] The hemolysis usually disappears after 12 to 15 weeks. Similarly, use of coil embolization to seal off a patent ductus arteriosus produced a fall in hemoglobin from 11.6 to 6 g in one patient.[8] Vasculitis also has been implicated as a cause.[9]

Several drugs are associated with microangiopathic hemolysis. Cyclosporine, tacrolimus, and mitomycin C have been implicated as causing an HUS picture that typically develops within weeks to months of exposure. Total body irradiation, combination chemotherapy, and bone marrow transplantation also are associated with microangiopathic hemolysis.[10] The antiplatelet agents ticlopidine and clopidogrel are capable of producing a TTP-like syndrome.[11] Quinine attaches to platelet glycoproteins and may induce antibodies against the altered glycoprotein epitopes. In one series, quinine exposure was implicated in 11% of 132 patients presenting with TTP–HUS.[12] Other reported exposures associated with TTP include use of cocaine,[13] the herb echinacea,[14] imatinib,[15] and gemcitabine.[16] The mechanisms of drug-induced TTP are not well understood but likely include direct toxicity to the endothelium.[16]

Therapy

Management is primarily directed toward the underlying disease or event. Compensation of RBC production should be optimized by replacing iron or folic acid if the patient is deficient in these nutrients. Occasionally removal or repair of a damaged native or prosthetic heart valve is necessary when the hemolysis produces a disabling transfusion requirement. Treatment of TTP–HUS with plasma exchange has been found to be superior to plasma infusions, with fresh frozen plasma and cryo-free plasma appearing to have equal efficacy.[17] The HUS of mitomycin C use in adenocarcinoma has been

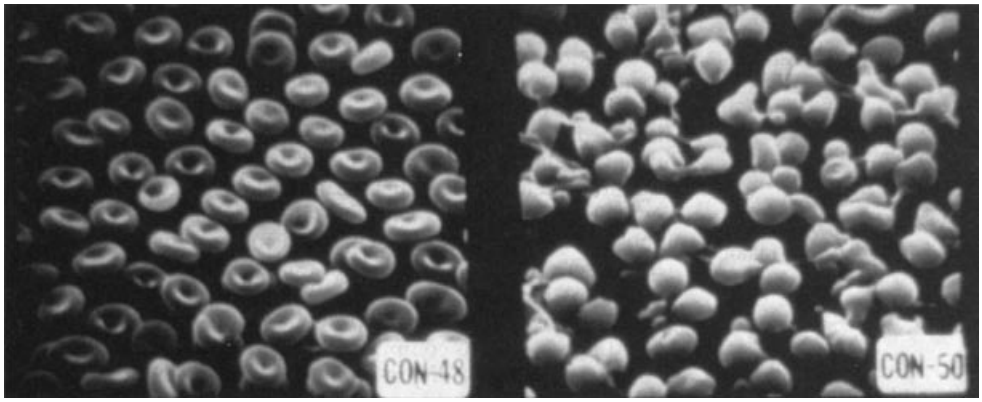

Figure 48–2 Morphologic changes are produced by heating normal red blood cells at the indicated temperatures. Budding begins abruptly at 50°C (122°F)and eventually leads to spherocytosis.

reported to respond reasonably well to use of the staphylococcal protein A immunoperfusion column[18] or to vincristine,[19] but apheresis with fresh frozen plasma replacement still may be needed. Thrombotic microangiopathy associated with cyclosporine often is reversible with cessation of cyclosporine.[20]

OTHER FORMS OF MECHANICAL DAMAGE TO RED BLOOD CELLS

Heat Denaturation

Normal RBCs undergo budding and fragmentation when exposed to a temperature of 49°C (120°F) in vitro (Fig. 48–1B). In some of the hereditary hemolytic anemias, this process occurs at temperatures as low as 46°C (115°F; see Chapter 46). Under some clinical circumstances, temperatures sufficient to cause heat denaturation of RBCs have been generated. Occasionally, cell warmers used with transfusions in cold agglutinin disease have malfunctioned and cooked the RBCs about to be transfused. In one case, a patient's mother warmed the RBCs with a hot water bottle, reasoning that such cells would cause less vein irritation to her child. Such transfusion was followed by evidence of intravascular and extravascular hemolysis, and the peripheral smear showed RBC budding and fragmentation (Fig. 48–2). Presumably, similar events can lead to hemolysis in patients who have sustained very extensive burns. In patients suffering from heat stroke, the temperature usually is below 42°C (108°F), a temperature at which little RBC denaturation occurs.

Mechanical Trauma

The classic example of RBC damage due to mechanical trauma is march hemoglobinuria, which occurs in soldiers after a long march, in joggers after running on a hard road, or in karate or conga drumming enthusiasts after practice. Anemia is rare, and reticulocytosis is uncommon. Evidence of typical intravascular RBC destruction is present and is thought to be caused by direct trauma to RBCs in the vessels of the feet or hands. Switching jogging paths or using better footwear often relieves the problem. Some cases show evidence of an underlying RBC membrane abnormality.[21] Strenuous exercise may induce oxidant stress, as evidenced by increased levels of malonyldialdehyde, a marker of lipid peroxidation, in marathon runners after a race.[22] Occasionally, malfunction of the cell savers used during abdominal or thoracic surgery mechanically injures RBCs.

Cardiopulmonary Bypass

Postperfusion syndrome occurs in some patients after cardiopulmonary bypass. The syndrome includes acute intravascular hemolysis and leukopenia as part of a febrile, inflammatory clinical picture. Affected patients may develop pulmonary distress and even adult/acute respiratory distress syndrome. Visible hemoglobinemia occurs, with rising plasma hemoglobin levels, and is associated with an increase in lysed RBC ghosts seen in the whole blood and plasma. These ghosts are coated with the complement complex C5bC9 (see Chapter 49). Presumably, the complement pathway is activated as the blood passes through the oxygenator. The reason why complement activation results in lytic attack on RBCs (and granulocytes) is unknown. Treatment involves knowledge of the process and requisite support[23] until the situation corrects itself.

Osmotic Attack

Abrupt changes in osmolality can cause hemolysis. Freshwater drowning may be associated with so much water in the lungs that the RBCs swell as they undergo an in vivo osmotic fragility test in the pulmonary vasculature. Conversely, saltwater drowning can cause profound dehydration of RBCs, producing a situation analogous to xerocytosis (see Chapter 46). Rarely, acute hemolysis occurs from mistaken infusion of, or exposure to, concentrated hypertonic solutions such as those used in hemodialysis. To manage such an event, the physician must recognize its cause, appreciate the shrunken RBCs on a peripheral smear, and restore isotonicity as quickly as possible. In this case, use of a hemodialysis device, if available, may be helpful.[24]

Hypersplenism

In all organs of the monocyte–macrophage system (i.e., reticuloendothelial system), blood cells leaving the arterial bed are generally unloaded into channels such that the RBCs must pass through the wall of the sinus to reenter the circulation. The sinusoidal wall has slits 2 to 3 μm long and usually is endothelialized on one side and has a macrophagic lining on the other side. The normal human adult RBC is a discocyte with a surface area 40% larger than a sphere of that volume (see Chapter 33). This excess surface area allows an RBC with a diameter of approximately 8 μm to twist, elongate, and deform sufficiently to squeeze through these 2- to 3-μm slits. The excess surface area, occasionally referred to as the *ratio of surface area to volume* (SA:V), is critical and normally is approximately 1.4. Any condition that reduces SA:V reduces the ability of RBCs to traverse these sinusoidal slits because plump spheres cannot deform sufficiently.

Factors that interfere with interaction of the cytosol and the membrane also impair the ability of the RBC to deform. Oxidant attack may produce Heinz bodies that come to lie adjacent to the membrane. They interfere with the smooth movement of the membrane over the cytosol, a process called *tank treading*. Such cells are selectively blocked from leaving the splenic cords and entering the sinuses.[25] Inflammation or infection may enhance the ability of splenic macrophages to attack and ingest RBCs. Although not strictly a mechanism of hypersplenism, Kupffer cell erythrophagocytosis is a prominent finding in patients undergoing graft-versus-host hemolysis seen after liver transplantation.[26]

Table 48–1 Causes of Splenomegaly

Cause	Example
Neoplasia	Lymphoma, hairy cell leukemia
Infection	Bacterial endocarditis, malaria, schistosomiasis, tuberculosis
Portal bed obstruction	Alcoholic cirrhosis, splenic vein thrombosis
Collagen vascular disease	Systemic lupus erythematosus, malignant phase of rheumatoid arthritis
Chronic inflammatory disease	Rheumatoid arthritis
Chronic hereditary or acquired hemolytic anemia	Severe β-thalassemia, autoimmune hemolytic anemia
Lipoidosis	Gaucher disease
Amyloidosis	AL and AA types
Tropical splenomegaly syndrome	Hyperreactive malarial splenomegaly syndrome

Therapy for Lead-Related Hemolysis

In an acute situation with multiple organ malfunctions and hemolysis, lead ingestion is stopped immediately, and therapy is begun inadults with edetate calcium disodium 30 to 50 mg/kg/day by either deep IM or slow intravenous infusion divided twice daily for up to 5 consecutive days. The chelator–lead complex is nephrotoxic, and urine output must be monitored. Dimercaprol is also started at least 4 hours prior to starting edetate calcium disodium in order to prevent worsening CNS toxicity with increased blood lead levels. Dimercaprol is given intramuscularly for a total of 11 days. It is dosed initially at 4 mg/kg every 4 hours for the first 48 hours, then at 6-hour intervals for the next 48 hours, and finally every 6 to 12 hours for 7 days.[36] If symptoms improve and urine lead levels fall satisfactorily, the patient can be started on a regimen of oral penicillamine, given at a dose of 1 to 1.5 grams/day for 1 to 2 months given 2 hours before or 3 hours after meals. If symptoms do not improve satisfactorily, another course of edetate calcium disodium is given. Dimercaprol is pregnancy category C, and penicillamine is pregnancy category D.

The spleen is more complicated than other reticuloendothelial organs in that the afferent arterioles pass through lymphoid nodules (i.e., white pulp) and then terminate in the cords of Billroth (i.e., red pulp), into which blood cells are discharged. In the slow flow of the cords of Billroth, blood cells are selectively attacked by macrophages and are in direct contact with several classes of lymphocytes. The blood cells then must pass through the cordal walls before they can approach the sinus wall, which they must pass through to reenter the circulation. The spleen provides a double filter, and the blood cells must be remarkably deformable to pass through it. This slow passage permits highly selective action by macrophages, which have receptors that can detect several sorts of alterations in these blood cells. These receptors include the Fc receptor for the appropriate portion of the immunoglobulin molecule, receptors for complement components such as C3b, and perhaps receptors that detect alterations in the outer portion of the phospholipid bilayer or in the externally oriented glycopeptides. The macrophage then holds, retards, modifies (i.e., pitting function), or removes (i.e., culling function) the blood cells identified. Normally, the pitting function of the spleen allows it to remove Howell-Jolly bodies and normally occurring endocytic vacuoles (called *pocks* because of their appearance on phase interference or Nomarski microscopy). The normal culling function of the spleen is exemplified by its removal of senescent RBCs.[27]

All the activities of the spleen presumably are markedly accentuated in a large spleen, and if the increased activity is sufficiently extensive, hypersplenism ensues. It is the size of the spleen, not the portal pressure, that is important in determining the degree of RBC sequestration.[28] Other factors that may play a role are the state of activation of the splenic macrophages and the size of the small slits between the splenic cords and sinuses. The macrophages and slits seem to be under a degree of control, as evidenced by variations in splenic removal of RBCs in patients with malaria.[29]

The clinical picture of hypersplenic hemolysis is dominated by the specific cause of the splenomegaly. Although the causes of splenomegaly are legion, there are several general mechanisms (Table 48–1). Usually some degree of anemia is seen, with evidence of a compensatory increase in RBC production. Because stasis and trapping in the spleen are associated with macrophagic attack and remodeling of the RBC surface, the reduction in SA:V leads to spherocytosis. If the RBCs undergo a prolonged period of distortion when traversing the cordal–sinus barrier, tailed RBCs will be present as the RBC membranes undergo a plastic change (see Chapter 46 and box on Therapy for Lead-Related Hemolysis). Because the enlarged spleen can trap and remove platelets and white blood cells, variable thrombocytopenia and leukopenia may occur. The bone marrow may show normal to increased cellularity with erythroid hyperplasia.

Management depends on the cause of splenic enlargement. The anemia or pancytopenia usually is not profound; however, splenectomy may be contemplated if the anemia is severe. In most situations, recognition of the possibility of hypersplenism is most important in guiding the approach to diagnosis of an unexplained anemia. Massive splenomegaly frequently is associated with expansion of the plasma compartment, and measurement of hemoglobin, hematocrit, or RBC levels may give a falsely low value of the RBC mass present. In that circumstance, the true RBC mass can be determined by ^{51}Cr assay.

A good example of massive splenomegaly causing plasma volume expansion is tropical splenomegaly syndrome, which has been renamed *hyperreactive malarial splenomegaly syndrome*. Diagnostic criteria include massive splenomegaly more than 10 cm below the costal margin, with no other cause identified; immunity to malaria; elevated serum IgM levels; and clinical response to treatment with antimalarial drugs such as chloroquine, proguanil, or pyrimethamine and folic acid.[30] The pathophysiology of the splenomegaly seems to be poorly controlled B-lymphocytic production of antibodies, and IgM stimulation may be a response to malarial antigens or an unidentified mitogen. Malarial parasites are almost never found. The apparent anemia is in large part caused by plasma volume expansion, although RBC survival is reported to be slightly attenuated. Antimalarial therapy for several months reduces spleen size, so splenectomy is unnecessary.

Infection

Infection can cause hemolytic anemia via several pathophysiologic mechanisms (Table 48–2).

Parasite Infections

The classic example of direct parasitization is infection by *Plasmodium falciparum* (Fig. 48–1C), *Plasmodium vivax,* or *Plasmodium malariae*. Infection with malaria, primarily *P. falciparum*, is a major health problem in the developing world, causing an estimated 300 to 500 million infections and one to three million deaths annually.[31,32] The burden of disease rests most heavily on young children and pregnant women. Falciparum malaria can cause a life-threatening anemia, with severe anemia defined as hemoglobin less than 5 g/dL.[31] Although malaria is primarily a disease of the tropical developing world, since the 1950s sixty-three outbreaks due to locally acquired mosquito-borne transmission have occurred in the United States.[33]

Table 48–2 Mechanisms by Which Infection Can Cause Hemolysis

Mechanism	Example
Direct parasitization of red cells	Malaria, babesiosis
Immune mechanisms	Cold agglutinin hemolysis after infectious mononucleosis or mycoplasmal pneumonia (see Chapter 47)
Induction of hypersplenism	Malaria, schistosomiasis
Altered red cell surface topology	*Haemophilus influenzae* infection
Release of toxins and enzymes	Clostridial infection causing thrombotic thrombocytopenic purpura–hemolytic uremic syndrome, *Escherichia coli* 0197, human immunodeficiency virus infection (?)

In each of the malarias, sporozoites injected by the mosquito in its saliva make their way to liver cells. After 1 to 2 weeks, they become merozoites, which burst out of the liver cells and into the bloodstream. Then, in a remarkable process, the parasite, by means of its apical end and related organelles called *rhoptries*, attaches to a specific receptor on the RBC surface. For *P. vivax,* the Duffy blood group antigen appears to be involved, making it a promising target for vaccine-based prevention.[34]

Plasmodium falciparum binds to sialic acid residues on the RBC surface that are on glycophorin A. After specific attachment, a convulsive movement occurs during which the RBC engulfs the parasite by a process resembling receptor-mediated endocytosis. The parasite then immediately recruits the RBC's metabolic machinery, degrades and ingests hemoglobin, and grows, eventually bursting out of the RBC, and the cycle begins again. The RBCs are lysed intravascularly as a consequence of direct parasitic destruction, extravascularly as a consequence of changes in the splenic microvasculature, and in the activation state of the monocyte–macrophage system. Treatment consists of the use of appropriate antimalarials and the support of erythropoiesis, including the use of RBC transfusion and/or exchange when indicated.[35]

The anemia of malarial infections also involves mechanisms distinct from lysis of parasitized RBCs. Erythropoiesis is suppressed, leading to suppression of erythroid precursors[37] and inadequate reticulocytosis during acute infection.[38] Bone marrow suppression may continue with persistent infection that is no longer demonstrable microscopically.[39] This inadequate hematopoietic response may be exacerbated by underlying iron deficiency, hemoglobinopathies, or concomitant infection (e.g., HIV), all potential contributors to the severity of anemia.[31] In addition, loss of uninfected erythrocytes plays a major role in the development of anemia, with an eight-fold to 10-fold greater loss of unparasitized red cells compared to parasitized cells.[40,41] Uninfected red cells have reduced deformability, and the degree of reduced deformability correlates with the severity of infection.[42,43] Poorly deformable red cells likely are cleared by the spleen. Evidence of in vivo removal of immature malarial forms prompts the question of whether "uninfected" cells that are lost represent previously infected cells that nevertheless remain abnormal. Insertion of a merozoite rhoptry protein, ring surface protein 2, on red cells in which infection was aborted has been implicated in the clearance of unparasitized erythrocytes and erythroid progenitors.[44] In addition, uninfected RBCs demonstrate increased binding of immunoglobulins that probably are nonspecific immune complexes.[45] Acute malarial infection, particularly with *P. falciparum*, also leads to alteration in splenic function that incites premature destruction of uninfected red cells.[29] Children with severe malarial anemia have low levels of complement regulatory proteins CR1 and CD55 in comparison to children with uncomplicated malaria or asymptomatic children,[46] suggesting a contribution of complement-mediated destruction of red cells. Oxidative stress may occur, as indicated by decreased α-tocopherol in RBC membranes of infected patients.[47]

The lifespan of transfused RBCs is likewise decreased. ^{51}Cr-Labeled normal RBCs infused into patients infected with malaria demonstrate a shorter lifespan than in normal controls; this effect may persist after clearance of the parasitemia.[48]

Alternatively, parasites can be removed from red cells along with red cell membrane by the process of pitting, producing parasite-free spherocytes.[49] This mechanism potentially explains the observed disparity between anemia and parasitemia.

Other infections that have somewhat similar pathophysiologies include Carrión disease (i.e., bartonellosis), in which a bite from the sandfly injects *Bartonella bacilliformis,* which attaches to the RBC surface of up to 80% of erythrocytes and causes lysis, leading to the massive hemolysis that characterizes acute infection. It appears that invasion of RBCs partly depends on the flagella of *Bartonella*. Incubation with antiflagellin antiserum reduces invasion of RBCs.[50] The bacteria also secrete deformin, a factor that leads to deep pitting on the surface of RBCs,[51] presumably providing a portal of entry into the erythrocyte. There also may be a role for splenic clearance of infected cells, and prior splenectomy appeared to protect a patient from hemolysis during acute infection.[52]

Babesia organisms also directly invade RBCs, producing fever and hemolytic anemia. The parasite is transmitted by ticks and transfusions of infected blood products[53] and can be transmitted vertically.[54] Most tick-borne cases occur on the West Coast, particularly in Washington and California, and in the northern portion of the Midwest; cases occurring on the East Coast are concentrated in Massachusetts and Nantucket Island.[55] The organisms can be seen invading RBCs on smear examination, somewhat like *P. falciparum* malaria, but these organisms produce no pigment. The highest risk of death from babesiosis occurs in individuals who are older than 50 years or are immunocompromised due to acquired immunodeficiency syndrome (AIDS), drugs, or asplenism. Sporadic reports indicate that acquired chronic toxoplasmosis occasionally is associated with hemolytic anemia.[56]

Alteration of the Red Blood Cell Surface by Bacterial Products

Infection can produce hemolysis by altering the RBC surface. An example is the hemolysis caused by *Haemophilus influenzae* type b.[57] Severely affected patients, particularly those with meningitis, have developed hemolytic anemias requiring RBC transfusions. The capsular polysaccharide of the bacterium, composed of polyribosyl ribitol phosphate (PRP), is released during infection and binds to the RBC surface. Infected patients develop antibodies to PRP. When the balance between PRP-coated RBCs and anti-PRP antibodies is correct, an immune-type hemolysis occurs and requires complement. RBC destruction is thought to be both intravascular and extravascular.

Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells

The most dramatic example of hemolysis due to bacterial action is clostridial infection, during which the organism releases enzymes that acutely degrade the phospholipids of the membrane bilayer and the structural membrane proteins. The resulting spherocytes are extremely sensitive to osmotic lysis. In one case, the serum phospholipase C level increased fivefold over 4 hours and the patient died.[58] The setting can be any infection, but my experience is limited to acute cholecystitis, surgery of the biliary tree, and infections surrounding an obstetric event, including criminal or self-induced abortion or other infection of the gravid uterus. Patients may also have an underlying malignancy, such as a gastrointestinal, genitourinary, neuroendocrine, or hematologic malignancy.[59] The signs of infections may be obvious, but fever may be unimpressive. Signs of collapse appear

acutely, and the clue is profound intravascular hemolysis, with a spherocytic anemia developing with shocking suddenness. The blood smear characteristically has numerous spherocytes with little evidence of microangiopathy, may be tinged red due to marked hemoglobinemia, and may have ghost cells.[59,60] A clue to the severity of the process may be the inability of the laboratory to perform chemical determinations or to type and cross-match the blood because the sample is hemolyzed. With even the slightest suspicion of hemolysis due to bacterial action, the physician immediately starts full doses of penicillin and clindamycin, evaluates the patient for DIC (see Chapter 132), and prepares to support the patient for shock, DIC, acute renal failure, and hemolytic anemia. Whether hysterectomy is lifesaving in the case of septic abortion is unclear.[61]

Hemolysis Caused by Less Well Understood Infections

HIV infection can cause Coombs-positive autoimmune hemolytic anemia, a TTP-like syndrome, and microangiopathic hemolysis. Cytomegalovirus infection was reported to cause hemolysis associated with thrombocytopenia by unknown mechanisms in an immunocompetent woman.[62] Case reports of autoimmune hemolytic anemia and HUS associated with cytomegalovirus infection have emerged. The hemolytic anemia in visceral leishmaniasis may be caused in part by generation of oxidative metabolic products.[63] Severe microangiopathic hemolytic anemia has been described for two cases of cutaneous anthrax.[64]

Hemolysis Associated with Liver Disease

Hemolysis in liver disease by itself usually is not of overwhelming clinical importance, but it may contribute to the severity of anemia when coupled with defects in RBC production and the type of gastrointestinal blood loss that occurs in several forms of liver disease. Hemolysis in patients with liver disease has several causes. The spleen may be enlarged as a consequence of portal hypertension and produce a hypersplenic picture, a phenomenon seen commonly in hepatic cirrhosis.

The literature on RBC shape change in liver disease is considerable. The target cell in cirrhosis has an increased SA:V that appears to be a consequence of increased cholesterol and phospholipid content of the membrane bilayer. The cholesterol increase usually is proportionately greater, resulting in an increased cholesterol-to-phospholipid ratio. This increase in lipid probably accounts for the increased RBC surface area, such that more membrane than usual is present in relation to cellular contents. These RBCs probably circulate as bell-shaped RBCs called *codocytes.* However, on dried blood films, they assume the appearance of target cells. Target cells do not have a shortened survival. The RBCs of patients with liver disease frequently are echinocytes when wet preparations are examined, but these echinocytes are not easily apparent on dried blood smears. The echinocytes seem to be produced by a material in the patient's plasma that causes normal RBCs to become echinocytic; this material is an abnormal echinocytogenic high-density lipoprotein. Echinocytes do not necessarily have a shortened survival. Some forms of echinocytic RBCs are normally deformable when studied in the ektacytometer or rheoscope.[65]

A brisk, clinically important hemolysis can occur in some patients with severe liver disease. The peripheral smear in these individuals usually shows acanthocytes (i.e., distorted RBCs). Extreme forms are called *spur cells,* which probably are acanthocytes additionally remodeled by an enlarged spleen (see box on Reduction of Dangerous Methemoglobin Levels) and are considerably enriched in cholesterol.[66] They are rapidly removed in the spleen, which usually is enlarged.

Increased RBC membrane proteolytic activity may be a partial explanation for the differences between acanthocytosis and spur cells,[67] and additional pathophysiologic mechanisms may be involved. Although the adult RBC cannot synthesize phospholipids de novo, it can identify and remove peroxidized fatty acid chains that interfere with normal membrane lipid fluidity.[66] When the fatty acid is removed, a lytic lysoderivative remains; therefore, the missing fatty acid chain must be replaced. A store of acyl groups in the form of acylcarnitine exists in RBC membranes. When needed, the fatty acid (i.e., acyl group) is transferred to acyl-coenzyme A and then inserted into the potentially lytic lysophospholipid by the enzyme lysophosphocholine acyltransferase. Lysophosphocholine acyltransferase is inhibited in spur RBCs, and the same inhibition can be produced by heavily loading RBCs with cholesterol in vitro.[66]

In spur cell anemia, the RBCs have an abnormal membrane SA:V ratio, their membrane fluidity is impaired, and they are unable to remove and repair peroxidatively damaged fatty acids. Occasionally, spur cell hemolytic anemia is severe enough to necessitate consideration of splenectomy. Operative morbidity in such cases is considerable because the underlying liver disease usually produces problems with thrombocytopenia and leukopenia as well as with procoagulants and intolerance to anesthesia.

Acute alcoholism can be associated with hypophosphatemia, defined as levels less than 0.2 mg/dL. Such hypophosphatemia presumably interferes with RBC intermediary metabolism (see Chapters 33 and 45), and RBC ATP levels fall. Very low ATP levels are associated with RBC rigidity, which leads to fragmentation, loss of surface area, and spheroidicity. The RBCs then are further trapped in the spleen. This hypophosphatemia syndrome can also cause neuromuscular disorders, including weakness, paresthesias, tremors, and seizures. It should be treated aggressively with orally and intravenously administered phosphate supplements. Hypophosphatemia also occurs in cirrhotic patients, patients receiving total parenteral nutrition whose phosphate intake is not carefully monitored, and patients taking large amounts of phosphate-binding antacids.[69–71]

Stomatocytosis can occur in severe liver disease and is thought to be a sign of acute alcoholic intoxication. The change in RBC shape can also be seen in acute pancreatitis. The stomatocyte is a cell well on its way to becoming a spherocyte. The reduction in SA:V leads to trapping in the microvasculature of the spleen and other organs of the monocyte–macrophage system, producing various degrees of hemolysis.

Reduction of Dangerous Methemoglobin Levels

Levels of methemoglobin in excess of 20% to 30% can be dangerous, but they can be easily treated with methylene blue (1–2 mg/kg) infused intravenously over 5 minutes as 0.1 to 0.2 mL/kg of a 1% solution. In the presence of a functioning, intact NADPH-methemoglobin reductase system, methylene blue is reduced to leukomethylene blue, which reduces methemoglobin to hemoglobin.

In a case of almost fatal oxidative hemolysis, hydrogen peroxide was injected directly into the Hickman catheter of a patient with AIDS because some persons infected with HIV had circulated a pamphlet suggesting that hydrogen peroxide could be used therapeutically to control HIV infection. We now are seeing AIDS patients with dapsone-induced methemoglobinemia and hemolytic anemia (see Chapters 44 and 45). Methemoglobinemia, if severe, is treated as described in the preceeding paragraph and in Chapter 44. One study suggests that the severity of the oxidative attack can be partially ameliorated by administration of 800 units per day of vitamin E, an antioxidant agent.[68]

Renal Disease

The anemia in renal disease is multifactorial. A major component is impaired RBC production, which can be well controlled with erythropoietin. Renal disease also impairs platelet function, which may lead to occult blood loss. However, hemolysis also can occur and is multifactorial. Disease of the small renal arterioles can produce frag-

mentation hemolysis of the sort seen in TTP–HUS, preeclampsia, and malignant hypertension (see box on Causes of Red Blood Cell Fragmentation Hemolysis). In the past, some patients undergoing chronic hemodialysis were exposed to unusual concentrations of chloramine in tap water and underwent acute oxidative hemolysis.[72] This occurrence has become rare or nonexistent. Otherwise, whether uremia produces significant shortening of RBC survival is not clear. Patients with chronic renal failure who are undergoing hemodialysis may be particularly susceptible to oxidative damage to their RBCs. RBC glutathione (GSH) is reduced in some patients, and the activity of the enzymes G6PD and glutathione peroxidase is relatively low. The ability of these RBCs to deal with generation of peroxides probably is impaired.[73]

Venoms, Bites, Stings, and Toxins

The best-known example of toxin-caused hemolysis was discussed in the earlier section on Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells.

Insect, Spider, and Snake Bites

Hemolysis occurs after bee and wasp stings, snake bites, and spider bites. Isolated cases of acute intravascular hemolysis after bee and wasp stings have been reported. Two kinds of dangerous spiders live in the United States: the southern black widow and the brown recluse spider. Both sexes of the black widow produce the venom, but only the female has fangs capable of penetrating human skin. Black widow spider bites produce generalized muscle pain and muscular rigidity. Hemolysis is not common. Brown recluse spider bites cause a considerable local reaction, called the *volcano lesion*. DIC and hemolysis may occur after a lag of 24 to 48 hours. Envenomation results in cleavage of RBC glycophorins, presumably making the RBCs more susceptible.[74] Corticosteroids may be beneficial. The hemolysis appears to be self-limiting, but RBC transfusion support may be needed.

In some parts of the world, cobra bites can cause intravascular hemolysis because the venom contains phospholipases. In the United States, the two classes of venomous snakes are pit vipers (e.g., rattlesnakes, cottonmouths, moccasins, and copperheads) and coral snakes. Pit viper venom affects hemostasis and may produce DIC with bleeding but rarely hemolysis. Coral snake venom produces severe neurologic impairment. Therapy consists of support and use of the appropriate antivenin and prophylactic antimicrobials and tetanus injections.

Drugs and Chemicals Exclusive of Those Producing Oxidative Hemolysis

Potassium Chlorate

Potassium chlorate ingestion is listed as a cause of hemolysis, but this compound is no longer available in hospital pharmacies and has no currently recognized medical use. Arsine gas (AsH_3) is generated in industrial plants that engage in lead plating, galvanizing, etching, and soldering. Inhalation of a toxic amount produces a severe intravascular hemolysis[75] of unknown pathogenesis and may require urgent RBC and plasma exchange.[76]

Copper

The idea that copper can produce human hemolytic disease is best supported by observations of episodes of severe hemolysis in patients with Wilson disease. The patient usually is a child, adolescent, or young adult for whom the diagnosis of Wilson disease has not yet been made.[77,78] The initial clinical presentation usually is dominated by the hemolytic anemia, accompanied by weakness and dark urine. The RBC morphology has not been well described, but reticulocytosis is present, with an increased serum bilirubin level partly attributable to the underlying liver disease. A clue to the underlying diagnosis is the presence of liver failure with low alkaline phosphate levels. Because of the hereditary deficiency in the copper-binding protein ceruloplasmin, urine and serum non–ceruloplasmin-bound copper levels in patients with hemolysis are very high. Curiously, in one report hemoglobin A_2 levels also were elevated.[77]

Free copper can interfere with glucose metabolism by hexokinase inhibition and alternatively can generate oxidative hemolysis, perhaps by acting as a Fenton reagent. It is important to establish the diagnosis promptly. When this condition is suspected, look for Kayser–Fleischer rings on physical examination and measure serum and urine copper and ceruloplasmin levels. Treatment with penicillamine reduces the serum copper level and stops the hemolysis. Plasmapheresis and hemofiltration may be beneficial in reducing the copper level and can serve as a bridge to transplant.[79–81] Other forms of copper poisoning may cause hemolysis in patients who do not have underlying Wilson disease. The amount of copper ingested would have to exceed the copper-binding capacity of normal ceruloplasmin levels.

Lead

There are at least two general forms of lead intoxication. One type is *chronic, slow cumulative poisoning* (i.e., saturnism). An example is occupational exposure. Symptoms are predominantly neurologic and nephrologic, with variable degrees of anemia, which may be caused by a production defect combined with hemolysis. *Relatively acute poisoning* occurs when lead inadvertently finds its way into a food source[82] or is consumed as part of an exotic medication. Subacute lead poisoning leads to central nervous system symptoms, hepatitis, nephrotoxicity, hypertension, and abdominal colic, along with seizures and severe hemolytic anemia. Physical examination may reveal the lead line on the gums. Peripheral smear shows extensive coarse basophilic stippling and reticulocytosis; however, RBC morphology is not otherwise characteristic. Some researchers state that intravascular destruction occurs, but no proof has been provided. Bilirubin levels are not significantly elevated.

The diagnosis of lead-related hemolysis can be made from the history and findings on physical examination finding: lead line on the gingiva and coarse basophilic stippling on RBCs, which reflects the pathologic aggregation of ribosomes. The diagnosis is confirmed by measuring blood and urine lead levels. The level of acuity determines the therapy.

The cause of the anemia is complex. Lead interferes with several steps in heme synthesis, particularly those involving heme synthetase and δ-aminolevulinic acid dehydratase (see Chapter 39). The inhibition of heme synthetase probably accounts for the elevation in free erythrocyte protoporphyrin, which provides a useful corroborative diagnostic test for lead toxicity. Inhibition of heme synthesis also probably accounts for the elevated urinary levels of δ-aminolevulinic acid and coproporphyrin. Lead poisoning mimics the basophilic stippling and accumulation of pyrimidines seen in hereditary deficiency of the enzyme pyrimidine 5′-nucleotidase, probably because lead attacks the enzyme (see Chapter 45).[83,84]

Ribavirin

Current treatment of chronic hepatitis C virus (HCV) infection consists of combination therapy with pegylated interferon and ribavirin, a nucleoside analogue. Ribavirin's activity against HCV includes inhibition of inosine monophosphate dehydrogenase, a key step in de novo guanine synthesis. Treatment with ribavirin may produce a dose-dependent hemolytic anemia, which typically is reversible 1 to 2 months after discontinuing treatment.[85] The hemoglobin drops by an average of 2 to 3 g/dL and may fall below 11 g/dL in one third or more of patients.[86] Although the anemia may necessitate a dose reduction in a substantial number of patients, decreases in hemoglobin can be treated with recombinant erythropoietin at 40,000 units

weekly.[87] Ribavirin is transported into the erythrocytes and accumulates as ribavirin monophosphates, diphosphates, and triphosphates.[85] The steady-state concentration of ribavirin in erythrocytes is approximately 100-fold higher than that of plasma, and higher erythrocyte ribavirin levels correlate with worsened anemia during therapy.[88] Accumulation of phosphates leads to a decrease in ATP levels in comparison to control erythrocytes.[89] Because ATP is required to generate the glucose-6-phosphate needed for glycolysis and the hexose monophosphate shunt, reduced levels of ATP may lead to oxidative damage, as evidenced by increased aggregates of band 3, which bind anti-band 3 IgG and complement.[89] Newer inosine monophosphate dehydrogenase inhibitors, which spare the erythrocyte, include the drug viramidine, which currently is in clinical trials.[90] The anemia in patients treated with ribavirin may be exacerbated by concomitant treatment with pegylated interferon, which suppresses hematopoiesis. In addition, treatment with pegylated interferon has been associated with autoimmune hemolytic anemia.[91]

DRUG-INDUCED OXIDATIVE HEMOLYSIS

General Concepts

The potential for normal RBCs to undergo auto-oxidative destruction is great because the cell is loaded with 20 mM hemoglobin, most of which is bonded to oxygen at the iron(II) atom in heme. The bond that allows the reversible association and dissociation of oxygen from the heme moiety of hemoglobin involves partial transfer of an electron from iron(II) to oxygen. That oxygen then has an extra electron, which makes it a superoxide radical. Ordinarily, when oxygen leaves hemoglobin, it returns the electron. If it does not, a highly reactive superoxide ion is released, leaving behind it an iron(III) moiety called *methemoglobin*.

$$Hb\ Fe^{2+}\ O_2 \rightarrow Hb\ Fe^{3+} + O_2^{-1}$$

Methemoglobin cannot reversibly bind oxygen. Methemoglobin in itself is not harmful to RBCs, but if the oxidative assault persists, methemoglobin is converted to hemichromes, which are variably denatured hemoglobin intermediates in which the distal histidine unit binds to the oxidized heme. This step is associated with conversion from a high to a low spin state, as measured by electron spin resonance. Continued oxidation leads to irreversibility of hemichrome oxidation, precipitation, and eventually formation of Heinz bodies. Hemichromes and Heinz bodies can destroy membrane function directly or by causing oxidation of membrane proteins and lipids.[92] Approximately 3% of hemoglobin is converted to methemoglobin each day, but the finding that only 1% of hemoglobin normally is in the form of methemoglobin indicates that a mechanism preventing oxidation in RBCs is in effect. These mechanisms are limited, as RBCs lack the ability to either efficiently generate ATP or synthesize enzymes. The primary means for preventing or addressing oxidant injury are the generation of the reduced form of nicotinamide adenine dinucleotide (NADH) via the Embden-Meyerhof glycolytic pathway and the generation of nicotinamide adenine dinucleotide phosphate (NADPH) via the hexose monophosphate shunt. NADH is used to reduce methemoglobin by cytochrome b5 reductase, and NADPH is used to reduce glutathione and for catalase activity.[93] Defects in this defense system against oxidation lead to an enhanced tendency to oxidative hemolysis. Examples are G6PD deficiency states. G6PD catalyzes the initial rate-limiting step in the hexose monophosphate shunt. Deficiencies lead to a reduced ability to generate NADPH in response to oxidant stress. Any agent or event that interferes with the smooth offloading of oxygen enhances the generation of O_2^{-1} and methemoglobin, as indicated in the equation. If the reducing power of the RBC is inadequate, hemichromes and Heinz bodies are generated. Many agents appear to cause oxidative hemolysis by interfering with the smooth functioning of the heme cleft.

Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia

Although large granular lymphocytic leukemia usually manifests as neutropenia and a rheumatoid-like picture, several patients with a severe Coombs-negative hemolytic anemia in the absence of splenomegaly have been described. Large granular lymphocytic leukemia has occurred in a splenectomized subject. The mechanism is unknown, but one report identified direct cytotoxicity against RBCs by the large granular lymphocytic cell lines.[102]

There are no formal studies on therapy for large granular lymphocytic leukemia-related hemolysis. One patient had a partial response to therapy with 60 mg/day of prednisone, and two patients responded well to weekly doses of methotrexate started at 5 mg/week.[103]

Pathophysiology

After the oxidative attack has been initiated, the sequence proceeds along a recognizable track. The oxidative attack is directed at hemoglobin and the RBC membrane. However, these structures are not clearly separable because the precipitated hemichrome and Heinz bodies come to lie against the cytosolic face of the membrane. Methemoglobin may be detectably elevated, with levels as high as 50% to 60% of total hemoglobin. The hemichromes, by themselves or with their iron portions acting as a Fenton reagent, mediate the generation of hydroxyl free radicals, which add their effect to that of superoxide and hydrogen peroxide. Lipid peroxidation may take place, leading to membrane blebbing and cell lysis as well as loss of asymmetry of the phospholipid membrane bilayer. Movement of phosphatidylserine and phosphatidylethanolamine to the outer bilayer of the membrane[94] results in increased recognition by macrophages in the reticuloendothelial system.[95] Membrane proteins may be cross-linked, with binding of denatured, oxidized hemoglobin to the membrane cytoskeleton,[96,97] which may increase splenic macrophage recognition.[98] In addition, the RBCs are rigid and susceptible to trapping in sinusoidal structures, whether or not they have Heinz bodies lying against the membrane. In vitro evidence suggests that oxidized RBCs are increasingly susceptible to phagocytosis by macrophages. These features may account for extravascular destruction. The oxidative lesions can be severe enough to cause intravascular destruction as well, producing hemoglobinemia and hemoglobinuria.

The smear may show bite cells, which look as if a macrophage had taken a bite, removing a Heinz body-containing segment of membrane. RBC rigidity may result in irregularly shaped cells because these undeformable cells are unable to undergo elastic recoil after fighting their way through the sinus wall. Recurrent loss of membrane material may produce spherocytes. Severe hemolysis may produce the kind of circulating ghost or hemighost called a *blister cell* or *bite cell*. These RBCs have an empty veil of membrane on one side and puddled hemoglobin on the other.[99,100] A Heinz body preparation may be positive. However, the absence of bite cells does not rule out the diagnosis.

The clinical picture is determined by the specific agent used. Screening for G6PD deficiency or a related disorder using an enzyme assay or the ascorbate cyanide test may be useful. Although any defect in the antioxidant defense mechanisms, such as G6PD deficiency, considerably increases the susceptibility to hemolysis, many agents can produce oxidant hemolysis even in persons with normal defense mechanisms (see box on Agents That Cause Oxidative Hemolysis). Paraquat ingestion has occurred inadvertently and in suicide attempts.[101] Profound cyanosis with methemoglobinemia can occur within hours, with levels of 120% or higher. The condition may be succeeded by hemolysis, with Heinz bodies seen in appropriate preparations of RBCs.

Toxic ingestion or inhalation of nitrites may occur in suicide attempts,[104] from industrial exposures, via diets high in pickled or smoked foods,[105] through intentional recreational use,[104] or, in

Agents That Cause Oxidative Hemolysis

- Therapeutic agents
  - Nitrofurantoin (Furadantin)
  - Sulfasalazine (Azulfidine)
  - *p*-Aminosalicylic acid
  - Phenazopyridine (Pyridium)
  - Phenacetin
  - Dapsone and other sulfones
  - Primaquine
- Recreational drugs
  - Isobutyl nitrate
  - Amyl nitrite
- Miscellaneous agents
  - Naphthalene mothballs
  - Paraquat
  - Hydrogen peroxide

infants, from formulas prepared using well water high in nitrates, which are reduced to nitrites in the infant gut.[106] The nitrite may be sold in sex shops under the names *locker room*, *sweat*, or *rush*. Nitrites bind to hemoglobin, producing methemoglobinemia, which may be so profound as to produce coma. If methylene blue infusion does not quickly turn the chocolate color of blood back to normal, the physician must consider the possibility that the patient is G6PD deficient and therefore unable to generate adequate amounts of NADPH (discussed earlier under Drug-Induced Oxidative Hemolysis; General Concepts). In that case, exchange transfusion may be lifesaving.[107,108] Benzocaine topical anesthesia in the form of a spray or cream can cause methemoglobin levels of 23% or more, with cyanosis and dyspnea requiring methylene blue treatment.[109,110]

Pyridium (phenazopyridine) can cause oxidative hemolysis,[111] even in the absence of renal disease.[112] This agent is commonly used for treatment of bladder irritation. The *Physician's Desk Reference* recommends maximum therapy of 2 days. However, patients not uncommonly are given a prescription for 1 to 4 weeks of therapy.

It has been recognized for more than 130 years that therapy with dapsone causes oxidative hemolysis.[113] In the past, dapsone was used primarily to treat leprosy and dermatitis herpetiformis and was not often encountered as a cause of oxidative hemolysis. Dapsone has come into more widespread use in some communities as a very effective prophylactic agent against *Pneumocystis carinii* pneumonia in patients with AIDS. The reduced levels of GSH reported in patients with AIDS may enhance dapsone toxicity. Some clinics screen potential recipients for G6PD deficiency (see Chapter 45) and, if negative, proceed with dapsone therapy. However, dapsone can cause oxidative attack on normal RBCs, leading sequentially to methemoglobinemia, Heinz bodies, and hemolysis, all occurring at generally accepted standard doses.[114] Dapsone is metabolized to a hydroxylamine derivative that is directly toxic to RBCs.[115]

MISCELLANEOUS, POORLY CHARACTERIZED CAUSES OF EXTRINSIC HEMOLYTIC ANEMIAS

Interferon-α as a Cause of Hemolytic Anemia

Both microangiopathic and autoimmune hemolysis have been reported with interferon-α use. Zuber et al.[116] reported eight patients with chronic myeloid leukemia who developed thrombotic microangiopathy confirmed by renal biopsy. Seven of these patients had identifiable hemolysis, and three had thrombocytopenia. They also reviewed 13 other cases of microangiopathy associated with interferon–α reported in the literature and observed that most cases occurred in the setting of prolonged therapy in chronic myeloid leukemia. Two cases of chronic hepatitis with microangiopathy were notable for having received unusually high doses of interferon for this indication. Cases of autoimmune hemolysis have been reported with interferon-α therapy in the setting of chronic myeloid leukemia or chronic hepatitis C.

Hemolysis With Intravenous Immunoglobulin G

Strictly speaking, hemolysis with intravenous immunoglobulin G (IgG) is a form of immune hemolysis. However, preparations of IgG contain anti-A and anti-B antibodies and rarely cause an alloimmune hemolytic anemia, as described in two young women undergoing treatment for idiopathic thrombocytopenic purpura. If this situation occurs and more intravenous IgG is needed, performing a minor cross-match and choosing a preparation of intravenous IgG that gives no reaction is recommended.[117] In addition to isoantibody production, anemia has been reported with intravenous IgG because of immune complex-mediated complement activation.[118]

For hemolytic anemia with large granular lymphocyte leukemia, see box on Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia.

CHAPTER 49

COMPLEMENT AND IMMUNOGLOBULIN BIOLOGY

Robert Mandle, Robert A. Barrington, and Michael C. Carroll

This chapter is divided into two parts. The first part details the current understanding of the activation and biology of the complement system and how it links innate and adaptive immunity. The second part focuses on immunoglobulins and their importance in protecting against disease. The goal of this chapter is to impart to the reader the underlying role of the complement system and antibody in protecting the host from microbial insult and disease.

THE COMPLEMENT SYSTEM: AN OVERVIEW

Complement refers to a family of distinct proteins that play a pivotal role in host defense against infection. In the 1880s, the serum factors involved in host response to pathogens were placed into two categories based on sensitivity to heat. The *heat-stable* component, antibody, was recognized as being specific for the invading pathogen and arose after immunization, whereas the *heat-labile* (>56°C [133°F]) fraction displayed nonspecific killing activity. The heat-labile fraction acted to *complement* the antibody-mediated killing of targeted organisms.[1–3]

In addition to its role in the effector arm of the antibody response, the complement system serves several other functions. First, components of the complement system are involved in clearance of targeted microorganisms by the process of opsonization. *Opsonization* is coating of a particle with proteins that facilitate phagocytosis of the particle by tissue macrophages and activated follicular dendritic cells (FDCs) as well as binding by receptors on peripheral blood cells.[4,5] Second, complement promotes inflammation by releasing small peptide fragments from complement proteins. These peptides cause mast cell degranulation, smooth muscle contraction, and directed migration (chemotaxis) of motile cells to sites of inflammation.[6,7]

Complement can be activated via three distinct pathways: classical, mannan-binding lectin, and alternative. Although all depend on different molecules for their initiation, eventually they converge to generate the same set of effector molecules. Each of these pathways is described here (Fig. 49–1).

Classical Pathway

The classical pathway (CP), so called because it was the earliest studied arm of the complement system, directly links the innate and acquired immune systems. There are nine proteins in the CP. As a matter of terminology, each CP component protein is designated with an uppercase C followed by a number. Fragments of these proteins generated by cleavage during the complement cascade are designated with a lower case letter suffix (e.g., C3a, C3b).

C1, the first component of the CP, binds and is activated by the Fc portion of the antibody molecule. C1q is a macromolecule complex composed of three individual protein subunits: C1q, C1r, and C1s.[8–12] The largest of these subunits, C1q, is a 18-chain molecule with six copies each of three chains: A, B, and C. Structurally C1q consists of a central core with six radiating arms. Each arm possesses a triple helical structure similar to collagen, capped at the end with a globular domain. C1q is responsible for forming an ionic bond that links the C1 complex to the antibody molecule. In addition to its capacity for binding to antibody molecules, C1q possesses the capability to bind directly to the surfaces of some microorganisms and apoptotic cells, not unlike mannan-binding lectin (see Mannan-Binding Lectin below).

Associated with C1q are two molecules each of C1r and C1s. In unactivated C1, C1r and C1s are proenzyme serine esterases. Upon binding of C1q with Fc or pathogen, a conformational change occurs that leads to activation of an C1r. The active form of C1r then cleaves its associated C1s to generate an active serine protease.

Activated C1s is responsible for cleaving C4 and C2, the next two proteins in the complement pathway. Cleavage of C4 yields two fragments: C4a and C4b. C4b possesses a highly reactive thioester group that allows it to bind covalently to molecules in the immediate vicinity of its active site. Only a small proportion of the C4b produced binds to proteins or carbohydrates on the targeted surface; the rest is inactivated by reaction with water in the surrounding milieu. This helps to prevent inadvertent C4b binding to surrounding host cells.

C2, the next substrate in the CP cascade, is susceptible to cleavage by C1s only when it is bound by C4b. This helps to prevent serum-phase activation of C2. Upon association with C4b, C2 is cleaved by activated C1s into two fragments: C2a and C2b. C2a remains bound to C4b, thereby confining C2a to the targeted surface. C4bC2a is termed the *C3 convertase*, an enzymatic complex that is responsible for binding and cleaving C3, the next component in the cascade. The function of the C3 convertase is to cleave large numbers of C3 molecules to produce C3b, which coats the targeted surface (opsonization of the target) and marks it for phagocytosis, and C3a, which initiates a local inflammatory response.

An Ig-independent mechanism for activation of C1q has been identified.[13] The lectin protein Sign R1, which is expressed on a subset of macrophages within the outer marginal zone sinus of the spleen and upon uptake of bacteria, binds C1q and activates the CP. This novel pathway provides an alternative innate recognition of pathogens leading to activation of the CP of complement.

Mannan-Binding Lectin

Before continuing with the discussion of the complement cascade at the point of C3 cleavage by convertase, we turn our attention to the other two complement-activating pathways: the mannan-binding lectin (MBL) pathway and the alternative pathway. What will become evident is that all of these pathways converge at C3.

The MBL pathway is a recently described pathway for complement activation.[14,15] MBL, like C1q, is a triple helical structure with six collagen-like arms coupled to globular domains, which form carbohydrate recognition domains that bind repeating polysaccharides present on the surfaces of many microorganisms. MBL attaches to the terminus of polymeric carbohydrate chains in the following order: mannose > GlcNAc > fucose > glucose. The greatest avidity appears to be for repeating mannose-based structural patterns typical of microbial surfaces. On vertebrate cells, these sugars often are covered by sialic acid residues, thus limiting recognition by MBL. Upon binding to polysaccharides on a pathogen surface, MBL activates the serine proteases MBL-associated serine protease (MASP)-1 and MASP-2. MASP-2 acts similar to C1s, cleaving C4 and C2 and

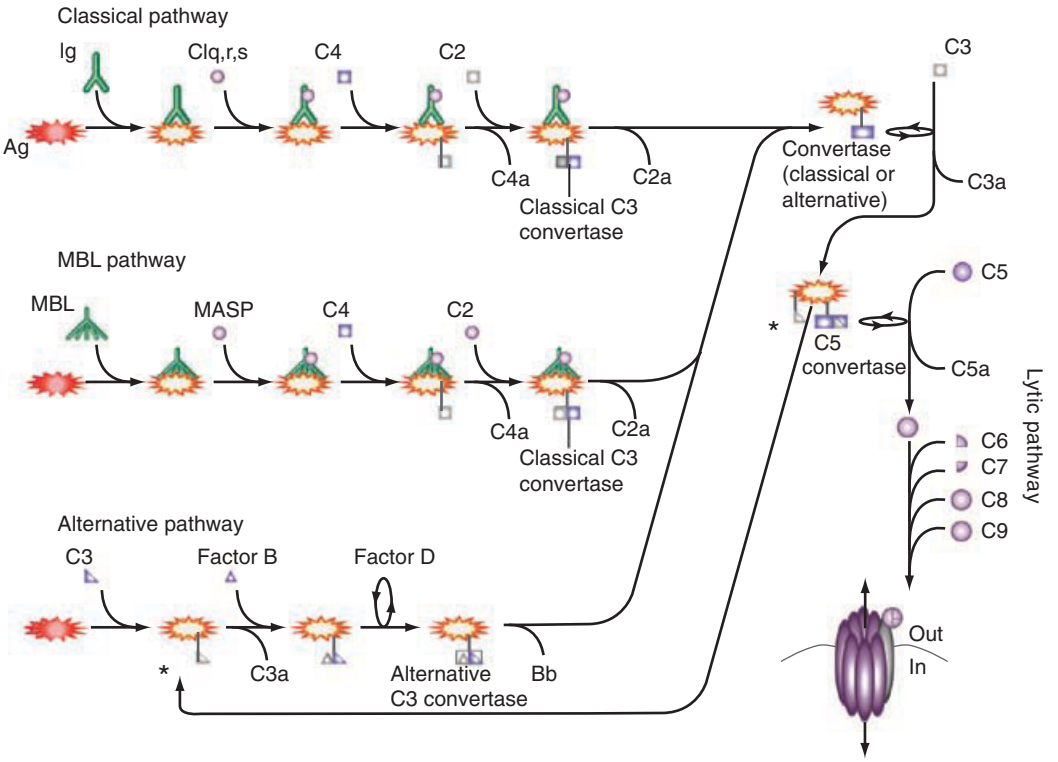

Figure 49–1 Schematic overview of the complement cascade. Classical, mannan-binding lectin, and alternative pathways commence from the left side of the figure, leading to the converging point of C3 activation (top right). In every subsequent proteolytic step, the position of the new addition to the antigen complex is shown in black for clarity. From the central C3 activation step downward, the C3 amplification loop through the alternative pathway is indicated by asterisks. The lytic pathway is initiated with the formation of C5 convertase and leads to the assembly of the C5,C6,C7,C8,(n)9 membrane attack complex, which interferes with the target's structural integrity by penetrating the cellular membrane (bottom right).

thereby forming a C3 convertase with C4bC2a, as found in the CP.[16]

MBL serum concentration can differ by up to 1000-fold among individuals, with those having low circulating MBL apparently more vulnerable to infections. MBL insufficiency appears to be a particular risk factor for infections in infants or individuals undergoing chemotherapy or immunosuppression treatment.[17]

Given the relatively recent discovery of the MBL pathway in the 1990s, progress into fully understanding this pathway is now just beginning. Gene-targeted knock-out mouse models deficient in MBL components have been described. Interestingly, mice rendered deficient for MBL appear to have resistance to infection compared to sufficient cohorts when challenged with microbial pathogens such as *Candida albicans* and *Plasmodium yoelii*.[18] Further study is needed to determine the role of MBL in host protection.

Alternative Pathway

The alternative pathway (AP) may represent the earliest form of innate immunity. Unlike the CP or MBL pathway, the AP can be fully activated in the absence of specific pathogen binding.[19] In fact, the AP is always "on" at a low level. In addition, the AP forms and uses the distinct C3 convertase C3bBb.[20]

Complement C3 is a two-chain protein with an apparent molecular weight of approximately 200 kd. The crystal structure of native C3 identified 12 distinct domains, including the thioester domain (TED).[21–23] Most recently, solution of the atomic structure of the activated form of C3 (i.e., Cb) demonstrated a dramatic shift in the location of the TED. Proteolytic cleavage releases the C3a anaphylatoxin peptide and the TED becomes fully exposed to engage potential targets. Thus, the dramatic shift in structure also exposes potential binding sites for factor B of the AP and competing sites for regulators of C3b, such as factor H (FH), membrane cofactor protein (MCP), complement receptor type 1 (CR1), and decay accelerating factor (DAF; all described later in this section). At a low level, the thioester bond undergoes spontaneous hydrolysis, forming C3(H_2O). This conformationally altered form of C3 allows for binding to factor B, a plasma protein. Factor B is a serine protease that is approximately 30% homologous to C2. The binding of factor B by C3(H_2O) allows factor D, another protease, to cleave factor B to form Ba and Bb. Bb remains associated with C3(H_2O) to form the C3(H_2O)Bb complex. Factor D appears to function as a serine protease in its native state but can cleave factor B only when bound to C3.

C3(H_2O)Bb is an enzymatic complex capable of cleaving native C3. This complex is a fluid-phase C3 convertase. Although it is formed only in small amounts, it can cleave many molecules of C3. Much of the C3b produced in this process is inactivated by hydrolysis, but some attaches covalently to the surface of host cells or pathogens. C3b bound in this way is able to bind factor B, allowing its cleavage by factor D to yield Ba and Bb. The result is the formation of C3bBb, a C3 convertase akin to C4bC2a found in the classical and MBL pathways, with the capability of initiating an amplification cascade.

In light of the nonspecific nature of C3b binding in the AP, it is not surprising that a number of complement regulators exist both in the plasma and on host cell membranes to prevent complement activation on self tissues. Some of these regulatory components are mentioned now for the sake of clarity; more detailed attention is provided later in this chapter (Table 49–1). CR1 and DAF (CD55) compete with factor B for binding to C3b on the cell surface and can displace Bb from a convertase that has already formed.[24] Factor I, a serum protease, in concert with CR1 or MCP (CD46) can prevent convertase formation by converting C3b into its inactive derivative, iC3b.[25] Another complement regulatory protein found in the plasma is FH. FH binds C3b and is able to compete with factor B and displace Bb from the convertase. In addition, FH acts as a cofactor for factor I to convert C3b to iC3b.

Table 49–1 Control Proteins of the Classical and Alternative Pathways

Name	Role in Regulation of Complement Activation
C1 inhibitor (C1INH)	Binds to activated C1r, C1s, removing it from C1q
C4-binding protein (C4BP)	Binds C4b, displacing C2b; cofactor for C4b cleavage by factor I
Complement receptor 1 (CR1)	Binds C4b, displacing C2b, or C3b displacing Bb; cofactor for factor I
Factor H (H)	Binds C3b, displacing Bb; cofactor for factor I
Factor I (I)	Serine protease that cleaves C3b and C4b; aided by factor H, MCP, C4BP, or CR1
Decay-accelerating factor (DAF)	Membrane protein that displaces Bb from C3b and C2b from C4b
Membrane cofactor protein (MCP)	Membrane protein that promotes C3b and C4b inactivation by factor I
CD59	Prevents formation of membrane attack complex on autologous cells; widely expressed on membranes

Pathogen surfaces normally are not afforded the protection offered by these regulators. Persistence of the C3bBb convertase on microbial surfaces may, in fact, be favored by the positive regulator properdin (factor P). Individuals with deficiencies in factor P have a heightened susceptibility to infection with *Neisseria* species.[26] Once formed, the C3bBb convertase rapidly cleaves more C3 to C3b, which can participate in the formation of more molecules of C3bBb convertase. The AP thereby activates an amplification loop that can proceed on the surface of a pathogen but not on a host cell.

Although specific antibody is not required for AP activation, many classes of immunoglobulin can facilitate AP activation.[27] The mechanism by which this occurs remains elusive. However, in contrast to CP activation, which requires Fc, AP activation can occur with F(ab)′2 fragments.

An instructive demonstration for the role of antibody in continuing the AP cascade, with possible ramifications for human disease, comes from a murine model of rheumatoid arthritis. Mice do not spontaneously develop rheumatoid arthritis.[28] However, a murine model has been developed in which expression of antibodies specific for the ubiquitously expressed cytoplasmic protein glucose-6-phosphate can cause joint destruction reminiscent of human rheumatoid arthritis. Interestingly, the disease state, through complement-mediated joint destruction, can occur even if the specific antibodies are of isotypes incapable of fixing complement through the CP. The response may be localized to the joints because of the absence of complement cascade regulators on cartilage.

C3, C5, and the Membrane Attack Complex

The formation of the C3 convertase, C4bC2a (CP and MBL) and C3bBb (AP), is the point at which the three pathways converge (Fig. 49–1). The function of these complexes is to convert C3 to C3a and C3b. C3 is the most abundant complement protein in plasma, occurring at a concentration of 1.2 mg/ml, and up to 1000 molecules of C3b can bind in the vicinity of a single C3 convertase.[29]

The attachment of C3b to either C4bC2a or C3bBb converts this enzyme into a trimeric complex (C5 convertase) capable of binding and cleaving C5 into C5a and C5b. C5b is the initiating component of the membrane attack complex (MAC). The MAC is a multiprotein complex whose components are C5b, C6, C7, C8 and multiple C9s.[30,31] The constituent components of the MAC associate in the numerical order C5b-C6-C7-C8-C9.

The MAC, when viewed by electron microscopy, resembles a cylinder that possesses a hydrophobic outer face and a hydrophilic central core. If assembled near a lipid bilayer, such as a cell or bacterial membrane, the MAC can associate with and insert into the lipid bilayer. Such insertion can be thought as "punching holes" into the membrane, allowing for passage of water and small ions into the cell. Osmotic equilibrium is thereby lost, leading to eventual lysis of the targeted cell or bacterium. C5b678 are sufficient to form small pores in the target membrane. The role of C9 appears to be to enlarge the channel, through multiple C9 polymerization, thereby causing more rapid loss of membrane function and lysis. Deficiencies in complement components C5–C9 have been associated with only increased susceptibility to *Neisseria* species–based infections such as gonorrhea and bacterial meningitis. It can be concluded from this observation that the requirement for MAC is limited in host protection.

Complement Receptors and Their Role in Immune Complex Clearance and Activation

As described in the previous section, complement can act by the direct lysis of targeted cells. Another important function of complement in host protection is facilitating the uptake and destruction of pathogens by phagocytic cells. This occurs by the specific recognition of C3b/C4b–coated (opsonized) particles by complement receptors.[32,33]

The best characterized complement receptor for the uptake of C4-coated immune complexes is CR1 (CD35). CR1 binds C4b/C3b–bearing immune complexes. CR1, like most proteins that bind activation products of C4 and C3 molecules, shares a structural motif known as the short consensus repeat. Each short consensus repeat consists of approximately 60 amino acids. CR1 in humans is composed of 30 linked short consensus repeats. CR1 possesses three binding sites for C4b and two for C3b.

CR1 is expressed on a wide variety of cell types in humans, including erythrocytes, macrophages, polymorphonuclear leukocytes, B cells, monocytes, and FDCs. The role of CR1 expression on B cells and FDCs in activating and maintaining the adaptive immune response is detailed below. For now, the focus is on the other cell types that express CR1.

Binding of C3b by CR1 expressed on phagocytic cells is not, in itself, capable of inducing endocytosis. A secondary signal is required to induce phagocytosis. This second signal can be provided by IgG binding to the phagocyte's Fc receptor, by carbohydrates commonly found on bacterial surfaces, or by exposure of the phagocytic cell to the appropriate cytokines. In addition, some phagocytic cells, such as macrophages, are activated by binding of C5a through C5a receptor (CD84; see following section).

The largest pool of CR1-expressing cells is erythrocytes.[34] Erythrocytes bearing opsonized material are removed from the circulation presumably to prevent deposition in tissue sites such as the renal glomerulus. Erythrocytes bearing opsonized material traverse the sinusoids of the liver and spleen, where they come into close contact with fixed phagocytic cells. These phagocytic cells effect the transfer of opsonized material from the erythrocyte onto their own membrane. The transfer is enhanced by cleavage of C4b/C3b to iC4b/iC3b by factor I and complexes taken up by complement receptor of the Ig superfamily (CRIg; see below).

CR2 (CD21) recognizes targets that have been coated with breakdown products of C3b/iC3b/C3dg/C3d. Given its central position in the complement cascade, the presence of C3b is tightly regulated. This regulation is brought about by cleaving C3b into inactive derivatives that cannot participate in forming an active convertase. One of the inactive derivatives of C3b, iC3b, can act as an opsonin in its own right. In addition to iC3b, CR2 binds C3dg and C3d, which are additional breakdown products of C3b. CR2 is the only complement receptor that recognizes C3dg. Likewise, CR3 (CD11b/CD18) binds iC3b and plays a major

role in inducing phagocytosis but probably not activation in the absence of a second signal (i.e., Fc receptor or pattern recognition receptor). CR4 (CD11c/CD18) also binds iC3b opsonized particles, resulting in direct endocytosis. Although its role as a phagocytic receptor is not well characterized, CD11c is the major marker for dendritic cells (DCs). It will be important to understand the functional importance of this complement receptor on DC and how it participates in uptake of antigen for presentation to T lymphocytes.

CR2 expressed on B cells augments cognate antibody receptor signaling (see section below). Activation of complement plays a contributing role in producing a strong antibody response. An interesting aside is that CR2 is the cell surface receptor on human B cells that is recognized by the Epstein-Barr virus.[35]

CrIg is a recently described complement receptor that plays an important role in the clearance of C3b opsonized complexes by phagocytic cells of the liver.[36] It is also expressed on subsets of macrophages, but less is known about this role. The recent cocrystallization of C3b and CrIg revealed binding to the C3b β chain, which is in contrast to all other known complement receptors in which binding to the activated C3 occurs via the α chain.

Biologic Activity of C3a, C4a, and C5a

The role of the complement fragments C3a, C4a, and C5a in the immune response is to produce localized inflammation.[37] C3a, C4a, and C5a are anaphylotoxins and are structurally similar to chemokines. When produced in large amounts or injected systemically, they induce a generalized circulatory collapse and shock-like syndrome similar to that seen in a systemic allergic reaction involving IgE antibodies.[38]

Of the three fragments, C5a is the most stable and possesses the best characterized and possibly highest specific biologic activity. All three induce smooth muscle contraction and increased vascular permeability. C5a and C3a also act on endothelial cells lining blood vessels to induce adhesion molecule expression.[39,40] Additionally, C3a and C5a can activate the mast cells that populate submucosal tissues and line vessels throughout the body to release histamine, tumor necrosis factor α, and protease.[41] The changes induced by C3a and C5a recruit antibody, complement, and phagocytic cells to the site of infection, thereby hastening the adaptive immune response. C5a also induces the upregulation of CR1 and CR3 on the surfaces of these cells.

Regulation of Complement Activation

Activation of the complement system must be tightly regulated in order to prevent autologous tissue damage (Table 49–1).[42] Some of the proteins involved in regulating complement action have been described (see Alternative Pathway above). In addition to these regulators, a number of other checkpoints limit the scope and target of complement activation.

As a result of binding to antibody or pathogen, conformational changes to C1q induce the enzymatic activity of C1r and C1s. Both of these enzymes are regulated by the C1 inhibitor (C1-INH). C1-INH is a member of a family of *ser*ine *p*rotease *in*hibitors termed serpins.[43] Serpins provide a bait sequence that mimics the active site of the substrate. When C1r or C1s cleaves this sequence, a new functional site on C1-INH is revealed that covalently binds to C1r or C1s, thereby destroying their proteolytic activity. C1-INH is responsible for preventing fluid-phase activation and degradation of C1 after complement activation has occurred, but it can be overridden by immune complexes.

Although C1 is capable of cleaving multiple C4 molecules, only approximately 10% of the produced C4b clusters about the targeted antigen.[44] The rest is released into the fluid phase. C4b in the fluid phase is rapidly bound by C4 binding protein (C4bp), which is a cofactor for factor I. Factor I cleaves C4b into two fragments, C4c and C4d, which are quickly cleared from the circulation.

In addition to its role in cleaving C4b, factor I is responsible, in combination with specific cofactors, for regulating C3b by cleavage. Factor I in association with FH in the serum or with CR1 and MCP on the cell surface cleaves C3b into iC3b and C3dg. Both of these products are incapable of participating in the formation of the C3 convertase.

CR1 also regulates the complement cascade by promoting the dissociation of C3 convertases (C4bC2b and C3bBb). DAF is involved in regulating the complement cascade in a similar manner. The importance of CR1 or CR1-like molecules in curbing the complement response can be witnessed in a rather unexpected condition. Complement receptor 1–related gene (Crry) is a murine homologue of the human CR1 gene.[45,46] Mice lacking Crry are unable to properly regulate C3. Crry mice spontaneously abort due to C3-dependent injury to the fetus. This presumably is the result of uncontrolled C3 deposition on the placenta. This observation in mice sheds light on the possibility that CR1 plays a role in recurrent fetal loss manifest in patients suffering from antiphospholipid syndrome.

Biologic Consequences of Complement Cascade Deficiencies

The important role of the complement system in preventing disease is witnessed in cases where components of the system are absent either due to random mutation in the human population or by design in gene-targeted "knock-out" mice. Some complement cascade deficiencies have been described. This section focuses on the biologic consequences of deficiencies in complement cascade activation that have profound biologic consequences and completeness, followed by a discussion on deficiencies in complement regulatory proteins.

Homozygous deficiencies in C1q, the most common form of C1 deficiency in humans, is a powerful susceptibility factor for the development of systemic lupus erythematosus (SLE).[47,48] Patients lacking C1q nearly always present with SLE. They have increased susceptibility to viral and bacterial infections, but it is not nearly as pronounced as in C3 deficiency (see below). C1q knock-out mice show increased mortality, with up to 25% of mice having histologic evidence of glomerulonephritis.

C4 in humans is encoded by two separate loci giving rise to two distinct protein products: C4A and C4B.[49] In certain populations, the absence of C4A is associated with greatly elevated risk for development of autoimmune diseases such as SLE or other lupus-like autoimmune disease. Moreover, as with C1q, mice deficient in C4 are predisposed to SLE-like disease.

C2 deficiency appears to be relatively benign.[50] Humans lacking C2 appear to have a normally functioning immune system, although autoimmune disorders and, less commonly, infections are observed with increased frequency.

In light of the central role of C3 in the complement cascade, it is not surprising that C3 deficiency has dire consequences for the host organism. Of all known cases of C3 deficiency among humans, no patients have been reported as disease-free. Infectious complications, predominately pyogenic in nature, occur frequently and recurrently. *Streptococcus pneumoniae* and *Neisseria meningitidis* are the major pathogens reported. In addition, SLE, vasculitic syndromes, and glomerulonephritis have been documented in up to 21% of C3-deficient patients. Mice deficient in C3 show, not unlike humans, greatly increased susceptibility to streptococcal infection and death.[51] The 50% lethal dose (LD_{50}) is 50-fold less for C3-deficient mice than for C3-sufficient controls. This may be due in large part to the inability of mice deficient in C3 to effectively opsonize the bacteria. Moreover, the deficient mice have an impaired humoral response (see section below).

Biologic Consequences of Complement Regulatory Protein Deficiencies

Deficiencies in C1-INH have been observed in the human population.[52] C1-INH deficiency can be inherited as an autosomal dominant trait or can result from autoantibodies that recognize C1-INH, blocking its function.[53] The inherited form of this deficiency is the cause of hereditary angioedema. Patients with hereditary angioedema experience chronic spontaneous complement activation leading to the production of excess cleaved fragments of C4 and C2. The biochemical cause of angioedema in these patients is not definitively elucidated. One line of reasoning points to excess production of C2 kinin and bradykinin. The peptide C2 kinin is a breakdown product of C2a after cleavage of C2. This peptide causes extensive swelling; the most dangerous is local swelling in the trachea, which can lead to suffocation. Bradykinin, which has similar actions to C2 kinin, also is produced in an uncontrolled fashion in this disease as a result of the lack of inhibition of another plasma protease, kallikrein, which is activated by tissue damage and is regulated by C1-INH. Although C1 is unregulated in patients with hereditary angioedema, large-scale cleavage of C3 is prevented by C4 and C2 control mechanisms and by regulation of C3 convertase formation on host cells. Increased risk of infection is not associated with C1-INH deficiency. This disease can be fully corrected by infusion of purified C1-INH.

Acquired C1-INH deficiency may be associated with lymphoproliferative disorders and in most cases represents development of an autoantibody that binds to and neutralizes C1-INH. In two examined cases, autoantibodies abrogate C1-INH activity by preventing formation of the C1s–C1-INH complex. However, once the complex formed, the autoreactive antibodies had no effect on C1-INH function. To date there is no uniform, fully effective therapy for these patients.

The role of factor I in complement cascade regulation can be witnessed in patients who suffer from factor I deficiency.[54] In the presence of a cofactor protein, Factor I cleaves C3b, producing iC3b, the inactive form of C3b. iC3b is incapable of reacting with factor B to form the AP C3 convertase, thereby preventing uncontrolled AP activation. In the absence of factor I, unrestrained C3 consumption occurs secondary to accelerated spontaneous AP turnover. Patients with factor I deficiency suffer from recurrent infections caused by pyogenic organisms, including meningococcal meningitis.

Likewise, mice deficient in the central protein FH exhibit unrestrained C3 activation via AP, leading to near depletion of serum C3. An important outcome of the failure to regulate C3 activation is glomerulonephritis. Strikingly, mice deficient in FH develop a disease resembling the human disorder membrane glomerulonephritis. The phenotype of the mice confirms the general notion that the AP is always "on" and that failure to regulate activated C3 results in consumption of circulating C3 and tissue injury.

The MAC is one mechanism used by the host to rid itself of certain microorganisms. Host cells are protected from MAC-mediated lysis by CD59 (protectin), a membrane-bound protein. CD59 performs its function by inhibiting the binding of C9 to the C5b-C6-C7-C8-C9 complex. CD59 as well as DAF are linked to the cell surface by a phosphoinositol glycolipid (PIG) tail. One of the enzymes involved in the synthesis of PIG tails is encoded on chromosome X. Mutation of this gene leads to a failure to synthesize PIG tails and with it an inability to express CD59 or DAF on the cell surface.[55–57] Lack of CD59 and DAF expression on host cell surfaces is the cause of paroxysmal nocturnal hemoglobinuria. This disease is characterized by episodes of chronic intravascular hemolysis and propensity to thrombosis.

Another example of the importance of FH regulation are reports of genetic association between variant alleles of FH and age-related macular degeneration. More functional studies are required, but it appears that even minor reductions in the efficiency of this important serum regulator lead to dramatic disease susceptibility.

Autoimmunity and Complement Deficiencies

There exists a strong correlative relationship between the lack of certain components of complement system (i.e., C1 and C4) and autoimmune disease, particularly SLE. Two general nonmutually exclusive hypotheses have been put forward to explain the increased incidence of SLE among complement deficient individuals: the clearance hypothesis and the tolerance hypothesis.[58–60] The clearance hypothesis is based on the known role of the CP of complement in binding to foreign antigens and transporting them to the liver and spleen for degradation and removal from the circulation. Thus, defects in clearance of apoptotic cells or debris would lead to inappropriate accumulation of self-antigen and overstimulation of self-reactive lymphocytes.

The tolerance model proposes that innate immunity protects against SLE by delivering lupus autoantigens to sites where immature B lymphocytes are tolerized, thereby eliminating a source of autoreactive antibody molecules. SLE is characterized by high-affinity antibodies specific for autoantigens such as double-stranded DNA (dsDNA), ribonuclear proteins, and histones. Validation of the model comes in part from studies with human B cells demonstrating that self-reactive B cells are eliminated or anergized at two major checkpoints: bone marrow and spleen. Thus, counterselection of potentially pathogenic B cells is an active process and most likely involves components of innate immunity.

The first part of this section familiarized the reader with the general aspects of the complement system. The remainder of this section focuses on the role of the complement system in the initiation and propagation of the adaptive immune response and begins with a description of natural antibody.

Natural Antibody

Natural antibody, in contrast to antibody secreted in response to active immunization, is continuously released, mostly by the B1 subpopulation of lymphocytes. Predominantly IgM but also IgA and IgG3 (in mice), natural antibodies tend to be polyreactive, with low-affinity binding for antigens such as nuclear proteins, DNA, and phosphatidylcholine, which are common structures among both pathogens and host tissue. These antibodies rarely show evidence of somatic mutation. It has been speculated that the variable region genes that predominate among natural antibodies have been selected evolutionarily for their ability to recognize pathogens and act as a rapid response to infection, thereby acting as a stop gap to provide sufficient time for the adaptive immune response to form. Natural antibody mediates its protective effects via the CP of complement.

Certain antibody specificities direct B cells into the B1 subset. An example comes from work using transgenic mice that express an immunoglobulin heavy chain originally derived from a B1 cell. In these mice, the vast majority of observed B cells are phenotypically B1-like.

IgM natural antibody is important in initiating CP leading to enhanced humoral immunity. In addition to its role in protecting against pathogens, natural antibody protects against lupus-like disease based on studies in mice. Thus, like C1q and C4, deficiency in IgM predisposes to an SLE-like phenotype.

Complement Links Innate and Adaptive Immune Responses

One of the critical functions of CP complement is providing a bridge between innate and acquired immune systems. The process is achieved through attachment of complement products to the antigen/pathogen, either directly to the surface or via antibody (see section above). This complement "tag" consists of breakdown products of C3 (i.e.,

C3b, C3dg, and C3d) that facilitate recognition of pathogens by the immune system. The recognition phase is mediated principally through complement receptors CD21 and CD35. This section details complement-dependent mechanisms of immune detection and humoral responses to thymus (T)-dependent antigens.

Soluble Complement Mediators of Antibody Responses

The first clue that complement is important in regulating B lymphocyte responses came from the observation that B lymphocytes bind activated C3 fragments.[61] Soon thereafter, it was noted that mice depleted of serum C3 by treatment with cobra venom factor had diminished responses to T-dependent antigens.[62] The discovery of naturally occurring genetic deficiencies in C3, C4, and C2 in species as diverse as guinea pigs,[63–65] dogs,[66] and humans[67,68] allowed description of impaired antibody responses as well. Because the impaired responsiveness is comparable among animals deficient in CP activators (C4, C2) and C3-deficient or C3-depleted animals, a model emerged suggesting that the effect is mediated through the CP of the complement system. That the impaired responsiveness is comparable among diverse animal species indicated the importance of CP complement in regulating antibody responses to T-dependent antigens.

The advance of gene targeting technology in the murine system led to development of engineered strains devoid of various components of CP complement. C1q-, C4-, and C3-deficient mouse strains generate reduced antibody responses to T-dependent antigens.[69–72] Furthermore, these strains fail to switch immunoglobulin isotypes normally, suggesting that germinal center responses are impaired.[70] Germinal centers are microanatomic structures whose purpose is to provide for increasing affinity of serum antibody for antigens (affinity maturation), isotype switching, and development and differentiation of memory B lymphocytes and plasma cells.[73] Consistent with this theory, immunized complement-deficient mice produce fewer and smaller germinal centers compared with immunized wild-type mice.[70] Importantly, humoral responses in each of the C1q-, C4-, and C3-deficient strains can be rescued by transplantation of wild-type bone marrow.[74–76] Therefore, bone marrow–derived cells can produce sufficient complement to reconstitute antibody responses to T-dependent antigens administered intravenously.

It is suggested that CP potentiates antibody responses through involvement of immune complex formation. The implication is that natural antibodies or specific IgM released early in the response by B cells responding to antigen recognize and bind pathogens, thereby activating the CP. Alternatively, binding of antigen by B cells through the B-cell receptor (BCR) is sufficient to activate CP on the B-cell surface. Several lines of evidence support this model. For example, genetically engineered mice producing only membrane IgM (i.e., with gene-targeted deletion of secretory signals) produce significantly reduced antibody responses to T-dependent antigens.[77] Although immune complex formation likely is important for stimulating antibody responses, it is not necessary. Antigens directly conjugated to C3b or C3d fragments are more potent immunogens compared to unconjugated antigen.[78,79] Furthermore, the magnitude of the immune response is directly influenced by the number of C3d fragments conjugated to the antigen.[78] Therefore, activated products of complement component C3 act as a natural adjuvant in driving efficient antibody responses.

Complement Receptors and Antibody Responses

B Lymphocyte Coreceptors

The effects of complement-coated antigens on antibody responses are mediated primarily through complement receptors CD21 and CD35 (Fig. 49–2). CD21 and CD35 are expressed predominantly on B lymphocytes and FDCs (Fig. 49–3).[80,81] CD35 is also found on polymorphonuclear cells, macrophages, mast cells, and DCs.[80] CD21 and CD35 are encoded for by separate, yet closely linked genes in human.[82] In mice, CD21 and CD35 originate from the same locus (Cr2) and are generated by alternative splicing events at the RNA level.[83,84]

Two novel sets of experiments demonstrated that CD21 and CD35 are important in regulating B-lymphocyte responses to T-dependent antigens. In the first set of experiments, antibodies specific for both CD21 and CD35 or CD35 alone were administered to immunized mice.[85–88] In the second set of experiments, a soluble form of CD21 was administered to immunized mice, thereby competing for C3d-coupled antigen interactions.[89] In both sets of experiments, treatment impaired antibody responses. In the first approach, blocking both CD21 and CD35 was more effective at blocking antibody responses compared to anti-CD35 antibody treatment, suggesting that, although both receptors contribute, CD21 is more important in regulating antibody responses.[85]

Because CD21 and CD35 are found on B lymphocytes and FDCs, two important cell types for humoral responses, two nonmutually exclusive models are proposed for their function. In the first model, CD21 augments antibody responses through activity as a coreceptor on B lymphocytes.[90] The second model proposes that CD21/CD35 on FDCs trap and focus antigen such that B lymphocytes can efficiently cross-link their antigen receptor to become activated.[91] As a coreceptor, engagement of CD21 by complement-coupled antigen on the surface of a B lymphocyte, in combination with membrane immunoglobulin (BCR) cross-linking, would lower the strength of signal through the BCR to activate the cell.[90] Accordingly, naive B lymphocytes bear low-affinity receptors for antigen; therefore, additional signaling by the CD21 coreceptor is required for efficient activation. This was demonstrated in vitro by culturing B lymphocytes with cognate antigen, either uncoupled or coupled to C3d. By measuring Ca^{2+}, it was estimated that 100 to 1000 less C3d-conjugated antigen was required to activate B lymphocytes compared to unconjugated antigen.[78]

The opportunity to test the importance of CD21 and CD35 as B-lymphocyte coreceptors in vivo came from studies using mice with targeted disruption in the Cr2 locus. Importantly, Cr2-deficient mice have impaired humoral responses similar to C1q-, C4- and C3-deficient mice (Fig. 49–3).[92–94] Using embryonic stem cells with a disrupted Cr2 locus, Croix et al.[95] used blastocyst complementation of $Rag2^{-/-}$ mice, such that chimeric mice expressed CD21/CD35 on FDCs but not on B lymphocytes. These chimeric mice displayed impaired antibody responses to the T-dependent antigen NP-KLH compared with controls. Therefore, CD21/CD35 on B lymphocytes is important for normal antibody responses.

Complement's covalent attachment to antigen engages CD21 as a complex with CD19/CD81 and BCR on the cell surface.[90,96,97] Dual binding of CD21/CD19/CD81 with BCR generates a stronger signal compared to BCR engagement alone.[90] If the combined signal is sufficient, the B lymphocyte is activated. If insufficient, then the B lymphocyte likely is eliminated by apoptosis.[98–101] The major ligand-binding receptor within the CD21/CD19/CD81 complex is CD21. CD19 appears more important in initiating a signaling cascade within the cell.[102] CD81 is a tetra-spanning molecule that stabilizes the complex within the membrane. Absence of any of the CD21/CD19/CD81 components adversely affects antibody responses to T-dependent antigens, although the degree of impairment varies.[92,103–105]

Focusing Antigen on Follicular Dendritic Cells

The second role of complement receptors CD21 and CD35 in regulating humoral responses is that they permit FDCs to trap antigen (Fig. 49–4).[91,106] FDCs concentrate in regions of ongoing immune responses, such as germinal centers, and they appear necessary for antibody responses. Germinal centers (see section above) promote somatic hypermutation within immunoglobulin heavy- and light-chain genes, along with isotype switching and production of memory

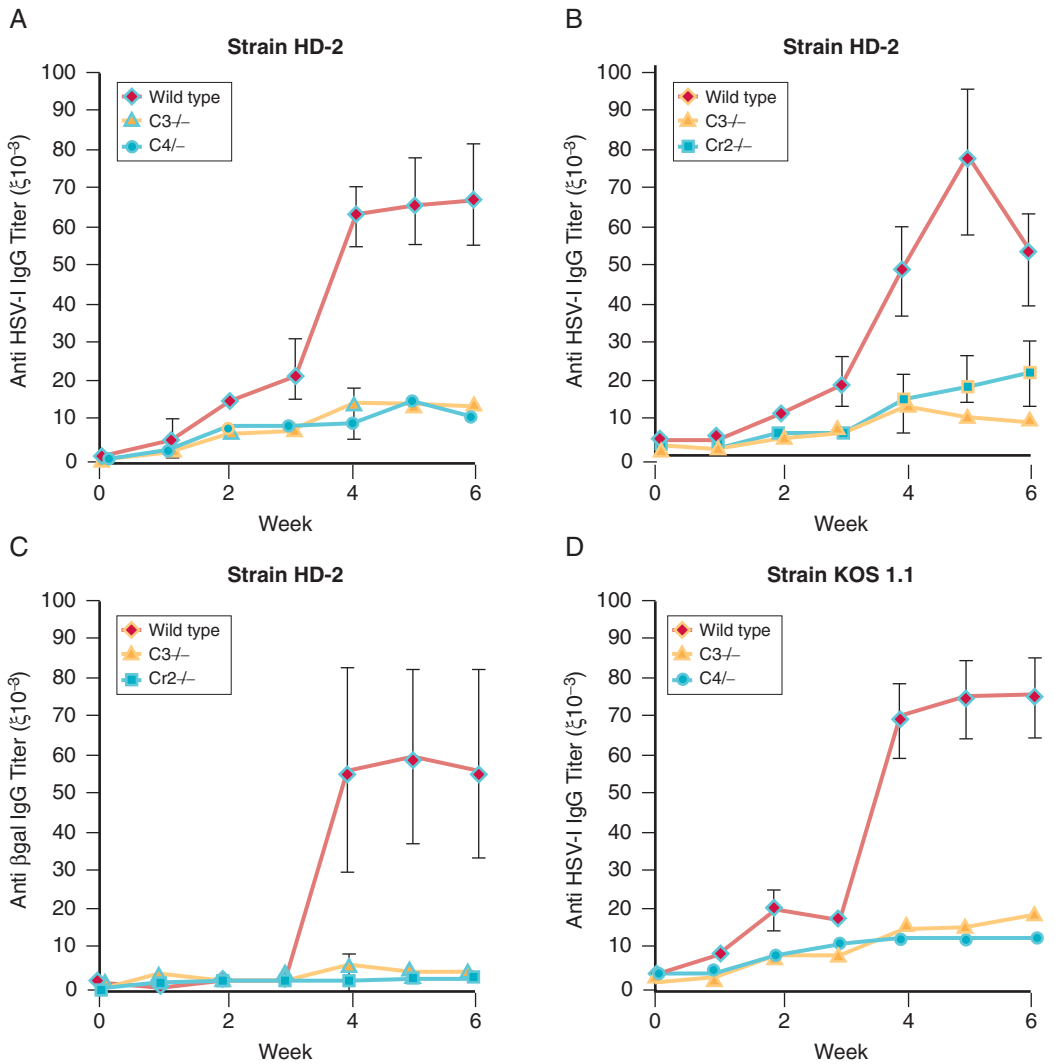

Figure 49–2 Classical pathway complement and complement receptors CD21/CD35 are required for the humoral response to replication-defective HD-2 virus or replication-sufficient KOS1.1 wild-type (WT) virus. Mice were injected at days 0 and 21 with 2×10^6 plaque forming units of replication-defective (**A–C**) or replication-sufficient (**D**) virus, HD-2, and KOS1.1, respectively. Antibody titers were determined by enzyme-linked immunosorbent assay. Mean titer ± SD represents at least five mice analyzed in two separate experiments. **A**, Deficiency in either C3 or C4 results in an impaired secondary humoral response to infectious HSV. **B**, Cr2–/– mice have an impaired secondary response similar to mice deficient in C3. **C**, Humoral response to recombinant virus-expressed heterologous protein (β-galactosidase) is also impaired in mice deficient in C3 or CD21/CD35. **D**, Secondary humoral response to replication-sufficient HSV-1 (strain KOS1.1) depends on complement C3 and C4. *(From Da Costa XJ, Brockman MA, Alicot E, et al: Humoral response to herpes simplex virus is complement-dependent. Proc Natl Acad Sci U S A 96:12708, 1999.)*

B lymphocytes and plasma cells. They can be divided into two regions: dark zone and light zone. To gain entry into the dark zone, B lymphocytes are activated by receiving above threshold signals from the CD21/CD19/CD81 and BCR, in combination with costimulation from helper T lymphocytes.[107] Within the dark zone, activated B lymphocytes divide and mutate their immunoglobulin receptor genes.[108–111] After several rounds of proliferation in the dark zone, B lymphocytes enter the light zone, where they are subjected to selection on antigen deposited on FDCs (i.e., clonal selection).[112,113] The selection of high-affinity B lymphocyte clones into memory B-lymphocyte and plasma cell pools ensures future protection against repeat antigen exposure.

How antigen is retained on FDCs, both for primary B lymphocyte responses and for long-term memory responses, is subject to intense research. However, supporting evidence indicates that complement receptors on FDCs are important in both short- and long-term B-lymphocyte responses. Papamichail et al.[91] demonstrated that retention of antigen–IgG immune complexes on FDCs was reduced upon depletion of C3 using cobra venom factor. Therefore, it appears that immune complex deposition on FDCs is complement dependent. In addition, antibody production in vitro using FDCs demonstrates that antibody production is dependent on CD21/CD35.[114]

Availability of Cr2-deficient mice has shed light on the importance of FDC-derived CD21/CD35 on humoral responses. Because FDCs, the other major cell type expressing CD21/CD35, are radioresistant, it was possible to generate chimeric mice that restricted CD21/CD35 expression to B lymphocytes by bone marrow transplantation. Ahearn et al.[92] made chimeric mice with Cr2-deficient FDCs by transplanting wild-type bone marrow (B-lymphocyte $Cr2^{+/+}$) into lethally irradiated Cr2-deficient recipient mice (FDC-$Cr2^{-/-}$).[115] After secondary challenge with antigen, the chimeric mice failed to sustain high-level antibody production, suggesting that CD21/CD35 on FDCs is important for recall or memory responses.

CD21/CD35 do appear important for persistence of antibody titers, normal frequencies of memory B lymphocytes and plasma cells, and affinity maturation. Adoptively transferring memory B lymphocytes into recipient mice lacking FDC-derived CD21/CD35

demonstrated that complement receptors on recipient mice stroma were required for each of these elements of memory.[116] Importantly, chimeric mice lacking CD21/CD35-bearing FDCs had severely impaired recall responses several months after transfer of memory B lymphocytes compared with wild-type recipients.[116] These studies suggest that CD21/CD35 on FDCs have an important role in long-term storage of antigen, thereby facilitating B-lymphocyte memory.

Complement and T-cell Immunity

The complement system is important not only in humoral immunity; it enhances responses by both CD4 and CD8 T cells.[117] Studies with influenza in C3-deficient mice first identified an important role for C3 in both the CD8 and CD4 response to infectious virus.[118] Although the mechanism is not clear, given the importance of DC in uptake and presentation of antigen, one likely role is C3 opsonization of virus. Moreover, the anaphylatoxins C3a and C5a released during C' (complement) activation stimulate cytokine releases by mast cells via their respective complement receptor. Studies of mice deficient in C3a receptor identified reduced responsiveness of a subset on CD4 T cells.[119] Likewise, C5a receptor appears to play an important role in the lung in T-cell–dependent allergic responses.

T-cell responses are also "tuned down" via complement receptor. Interestingly, cross-linking of the CD46 complement receptor via C3b on activated CD4 T cells induces differentiation to a T-regulatory phenotype.[120] Further investigation on this topic will reveal additional examples whereby the C' (complement) system participates in activation and regulation of T cells.

Conclusion

Over the past decade, a new appreciation for the complement system has come to light. Not only is the complement system required for host protection and innate immunity, but it plays a critical role in "directing" the humoral response to thymus-dependent and thymus-independent antigens. Covalent attachment of split products of C3 (i.e., C3d) alters the fate of antigen and targets it to FDC within the lymphoid compartment. Other studies are uncovering additional roles for complement in the regulation of self-reactive B cells. The next decade likely will witness a similar revolution as our understanding of how complement participates in protection against autoimmune diseases such as SLE.

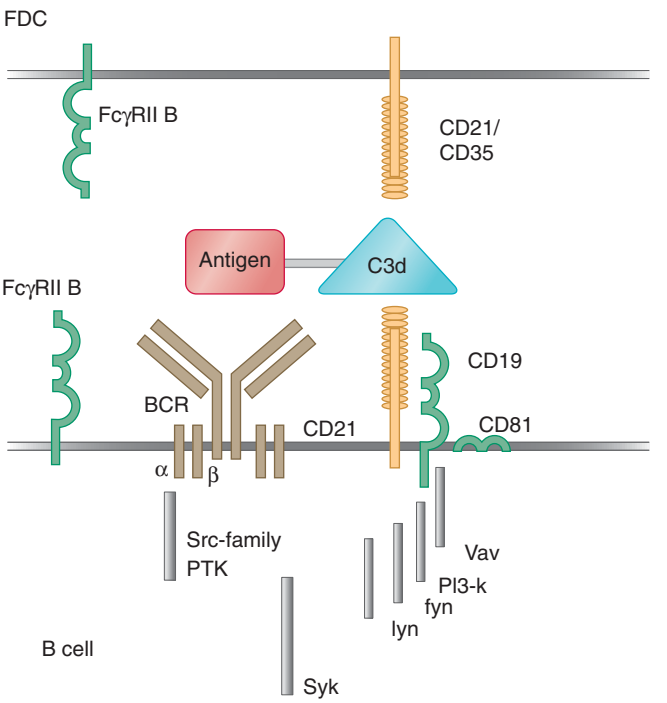

Figure 49–3 Coupling of C3d to antigen alters its fate in B-cell response. **A**, Coligation of the B-cell receptor (BCR) with CD19/CD21 by antigen coated with C3d regulates essential functions for B-cell activation. **B**, C3d-coated antigens are also captured on the surface of the follicular dendritic cells by CD21/CD35, allowing for efficient B-cell stimulation.

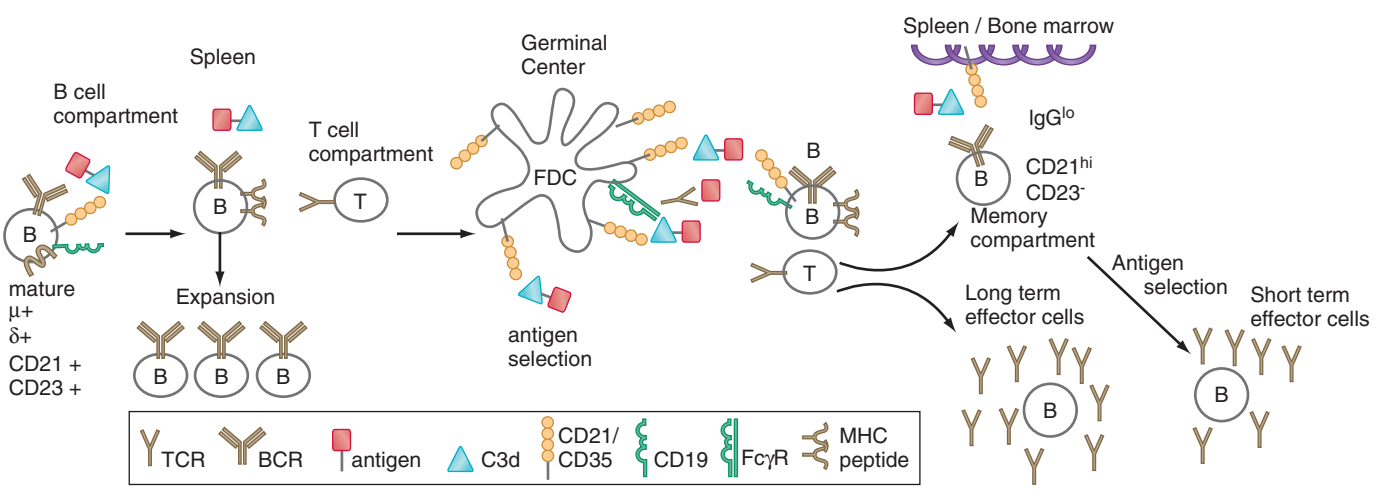

Figure 49–4 Role of complement-tagged antigen in directing B-lymphocyte activation and formation of memory B lymphocytes. Mature B lymphocytes survey secondary lymphoid tissues in search of antigen. Survival of mature B lymphocytes following antigen contact and T-cell help within splenic follicles depends on coreceptor signals through CD21/CD35. Lymphocytes receiving requisite signals expand and continue to differentiate within germinal centers, where CD21/CD35 is again important. B lymphocytes not receiving complement–ligand interactions in germinal centers die. In addition, complement-mediated deposition may localize antigen to follicular dendritic cells (FDCs), thereby providing the substrate for B-lymphocyte selection. Selection and differentiation in germinal centers lead to production of long-lived memory B lymphocytes and effector cells. The lifespan of memory B lymphocytes may also depend on continued interaction of antigen deposited on FDCs with CD21/CD35 in spleen and in bone marrow.

IMMUNOGLOBULINS

Properties and Structure

The mammalian immune system responds to the almost unlimited array of antigens by producing antibodies that react specifically with the molecules that induced their production. During the immune response, the structure of the inducing antigen is imprinted on the immune system, and subsequent challenges with the same or structurally related molecule(s) causes a more rapid rise in antibody levels to much greater concentrations than were achieved after the primary antigenic challenge. Thus, the hallmarks of the humoral immune system include induction, specific protein interaction, and memory.

Antibodies belong to the family of proteins called the *immunoglobulins*. The basic structure of all immunoglobulins consists of a monomer that contains four polypeptide chains: two identical heavy (H) chains and two identical light (L) chains covalently linked by disulfide bonds (Fig. 49–5).[121] A model of the monomeric form of immunoglobulin has been prepared based on x-ray crystallographic data obtained on the IgG myeloma protein Dob (Fig. 49–6).[122] The immunoglobulin monomer consists of a Y- or T-like structure. The size of the arms, called the Fab (fragment-antigen binding) domain of the Y or T, is 80 × 50 × 40 nm, and the size of base, called the Fc (fragment crystallizable) region, is approximately 70 × 45 × 40 nm according to models based on x-ray diffraction data. The immunoglobulin molecule exhibits considerable flexibility. In electron microscopic, low-angle x-ray scattering, transient electric birefringence, and resonance energy transfer studies, the angle between the Fab domains has been observed to vary from 0° to 180°. All antibodies have two identical combining sites for each antigen located at the ends of the Fab domains.

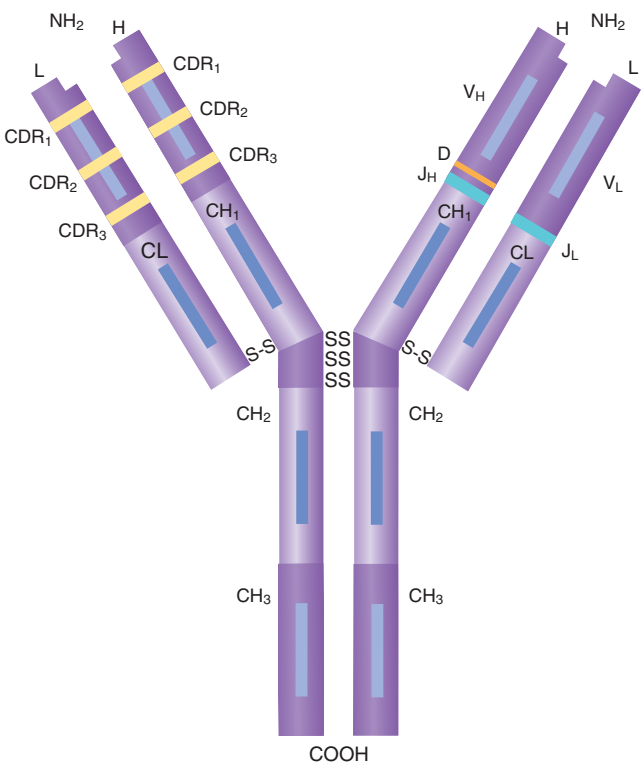

Figure 49–5 Diagrammatic representation of the structural features of an IgG molecule. NH_2 indicates the NH_2-terminus and COOH the C-terminus. V_H, C_{H1}, V_L, and C_L homology domains are shown as boxes. Only the disulfide linkages that join H and L chains are shown. **Left**, Approximate boundaries of the complementarity-determining region (CDR) regions in the V_L and V_H regions. **Right**, Sequences encoded by V_H, D, J_H, V_L, and J_L segments in the V_H and V_L regions.

Fab and Fc represent functional domains in immunoglobulins. They were discovered by performing limited proteolytic digestion of the molecule. Both the H and L chains contribute amino acids that constitute the antigen-binding site in Fab. The Fab will bind to, but will not precipitate, multivalent antigens, in contrast to native IgG. A fragment can be prepared, called $F(ab')_2$, which is devoid of Fc but still precipitates antigen. This form of immunoglobulin consists of two Fabs disulfide bonded at a part of the molecule called the *hinge region*. The hinge region is the part of the immunoglobulin molecule that is responsible for the molecular flexibility exhibited by all immunoglobulins. The other major function of immunoglobulins, binding to specific receptors on cells and certain effector proteins such as protein A and C1q, is associated with binding site(s) also found in Fc.

The chain structure of immunoglobulins explains neither antibody structural diversity nor antibody binding to antigen. The discovery of variable and constant regions of amino acid sequence formed the basis for understanding both phenomena. Thus, in the L chain, the 100 or so amino acids in the amino-terminal half of the protein (variable region [V_L]) vary between antibody molecules, but in the second half (constant region [C_L]) there is virtual complete correspondence in amino acids, position for position, to the carboxy-terminus. The H chains exhibit a similar pattern and can be divided likewise into V_H and C_H1, C_H2, and C_H3. Comparison of the amino acid sequence of many V_Ls has revealed that certain parts of the variable region exhibit excess variability, whereas others are less variable. The former regions are called *hypervariable* or *complementarity-determining regions* (CDRs). The latter framework regions function as a structural scaffold to support the CDRs. Antigen binding is mediated by six CDRs, three in each of the V_H and V_L domains. The combining site for antigen is a trough or cavity composed of parts of the hypervariable regions of both the H and L chains. It is a small region, representing only 25% of the antibody V region. The region that interacts directly with the epitope on the antigen is even smaller and is formed by the association of the CDR regions, each of which consists of approximately 20 amino acids. Thus, the variation in a few amino acids accounts for the specificity and diversity of antibodies with respect to antigen binding.[123]

Immunoglobulins exhibit additional physical heterogeneity, which imparts to each immunoglobulin a special effector function that is reflected in unique biologic properties independent of antigen-binding activity. Heterologous and autologous antisera raised against

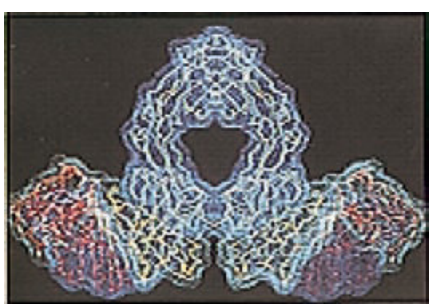

Figure 49–6 α-Carbon backbone and overall surface shape of the intact Dob IgG structure. The antigen-combining sites are located at the ends of the two horizontal Fab arms formed by the association of the light chains (α-carbon backbone as red lines and surface as light blue dots) and heavy chains (α-carbon backbone as yellow lines and surface as blue dots). On the basis of amino acid sequence studies, Dob has a substantial deletion in the hinge region, which probably limits its segmental flexibility. The molecular surface represents the area accessible to a probe sphere the size of a water molecule (1.4-Å radius). In this representation, the surface of the IgG is composed of convex regions, formed by the solvent-accessible van der Waals surface of individual atoms and concave regions. Small gaps and crevices inaccessible to the probe sphere are smoothed over. *(From Getzoff ED, Tamer JA, Lerner RA, et al: The chemistry and mechanism of antibody binding to protein antigens. Adv Immunol 43:1, 1988.)*

immunoglobulins have been used to classify three types of physical heterogeneity. The first kind is based on the antigenic heterogeneity exhibited by immunoglobulin when it is used as an immunogen in other species. This is called *class* or *isotypic variation*. In humans, five isotypes can be distinguished based on unique antigenic (isotypic) determinants found on the H chain. These are designated by capital Roman letters as IgG, IgM, IgA, IgD, and IgE. The H chain of each class is designated by the lower case Greek letter corresponding to the Roman letter of the class. Thus, the H chain for IgG is γ, for IgM is μ, for IgA is α, for IgD is δ, and for IgE is ε. Some of the immunoglobulin classes are composed of polymers of the basic monomer. In humans the two antigenic varieties of the L chain are kappa (κ) and lambda (λ). Each immunoglobulin has two identical L chains; the κ and λ are shared by all classes. The monomeric form of any immunoglobulin is described by its chain structure. The molecular mass of the immunoglobulins can vary from 150 to 1000 kd. This variation is due to polymerization of the basic monomer form. None of the immunoglobulins are polymeric forms of another class. IgG is the most prevalent, constituting 75% of the total immunoglobulin in blood. It is present in normal adults at concentrations of 600 to 1500 mg/dL. IgG is designated γ2κ2 or γ2λ2. It is the only class of immunoglobulin that crosses the placenta (Table 49–2).[124]

The isotype IgM is a pentamer consisting of five monomeric units disulfide linked at the C-terminus of the H chain. Each monomer of IgM is 180 kd due to the presence of an additional C_H domain. The complete protein has a sedimentation coefficient of 19 S, which corresponds to a molecular mass of 850 kd. IgM is designated $(\mu 2\kappa 2)_5$ or $(\mu 2\lambda_2)_5$. IgM also contains a 15-kd protein called the *J chain*. In the current structural model of IgM, the J chain forms a disulfide-bonded clasp at the C-terminus of two H chains (Fig. 49–7).[121]

The structure of the other isotypes of immunoglobulins are summarized as follows. The isotype IgA has a variable number of monomeric units and is designated $(\alpha 2\kappa_2)_n$ or $(\alpha 2\lambda_2)_n$, where n = 2 to 5. Serum IgA constitutes 20% of the total serum immunoglobulin, and 80% of this is monomeric. The remainder exists as polymers, where n = 2 to 5. The other form of IgA is found in external secretions such as saliva, tracheobronchial secretions, colostrum, milk, and genitourinary secretions. Secretory IgA consists of four components: a dimer of two monomeric molecules, a 70-kd secretory component that binds noncovalently to the IgA dimer, and the 15-kd J chain that is believed to form a disulfide-bonded clasp at the C-terminus of the H chains (Fig. 49–7). The isotype IgD has a molecular mass of 180 kd. Its serum concentration is very low, approximately 3 mg/dL. IgD apparently functions as a membrane molecule, being associated on mature but unstimulated B cells in association with IgM. IgE is the homocytotropic or reaginic immunoglobulin and mediates immediate hypersensitivity. It has a molecular mass of 180 kd and, like IgM, has four C domains. The Fc portion of IgE binds strongly to a receptor on mast cells, and this is how this immunoglobulin exerts its particular activity. The overall properties of the immunoglobulins are summarized in Table 49–2.[124,125]

Subclasses of isotypes IgG, IgA, and IgM have been identified. The structural basis for this heterogeneity is antigenic variation (e.g., amino acid sequence differences) in the Fc portion of the H chain of a given class. The subclasses of IgG, called IgG1, IgG2, IgG3, and IgG4, are the best characterized. Each has a slightly different structure, with the most notable difference being the interchain disulfide-bonding pattern (Fig. 49–7 and Table 49–2). IgG1 constitutes 70% of the total IgG and IgG2 20%. IgG3 and IgG4 constitute 8% and 2%, respectively, of the total IgG. The subclasses of IgG exhibit different catabolic rates and bind differentially to cell-associated Fc receptors. IgG2 crosses the placenta slightly more slowly than the other three subclasses. The other known subclasses of immunoglobulin isotypes are associated with IgM (IgM1 and IgM2) and IgA (IgA1 and IgA2). The properties and function of these subclasses are less well known.

The second type of variation is called *allotypic variation*. It is due to genetically controlled antigenic determinants found on both the H and L chains. Although each human has all immunoglobulin isotypes, an individual has only one form of each allotype on his or her immunoglobulin molecules. Allotypes are codominantly expressed, but an individual B lymphocyte secretes only one of the parental forms. This phenomenon is called *allelic exclusion*.

Table 49–2 Properties and Function of Human Immunoglobulins

	IgG1	IgG2	IgG3	IgG4	IgM	IgA1	IgA2	IgD	IgE
H chain	γ1	γ2	γ3	γ4	μ	α1	α2	δ	ε
Molecular weight (kd)	146	146	170	146	970	160	160	194	199
Molecular weight of H chain (kd)	51	51	60	51	65	56	52	70	73
No. of H-chain domains	4	4	4	4	5	4	4	6	5

Data primarily from Golub1[24] and Glynn and Steward.[125]

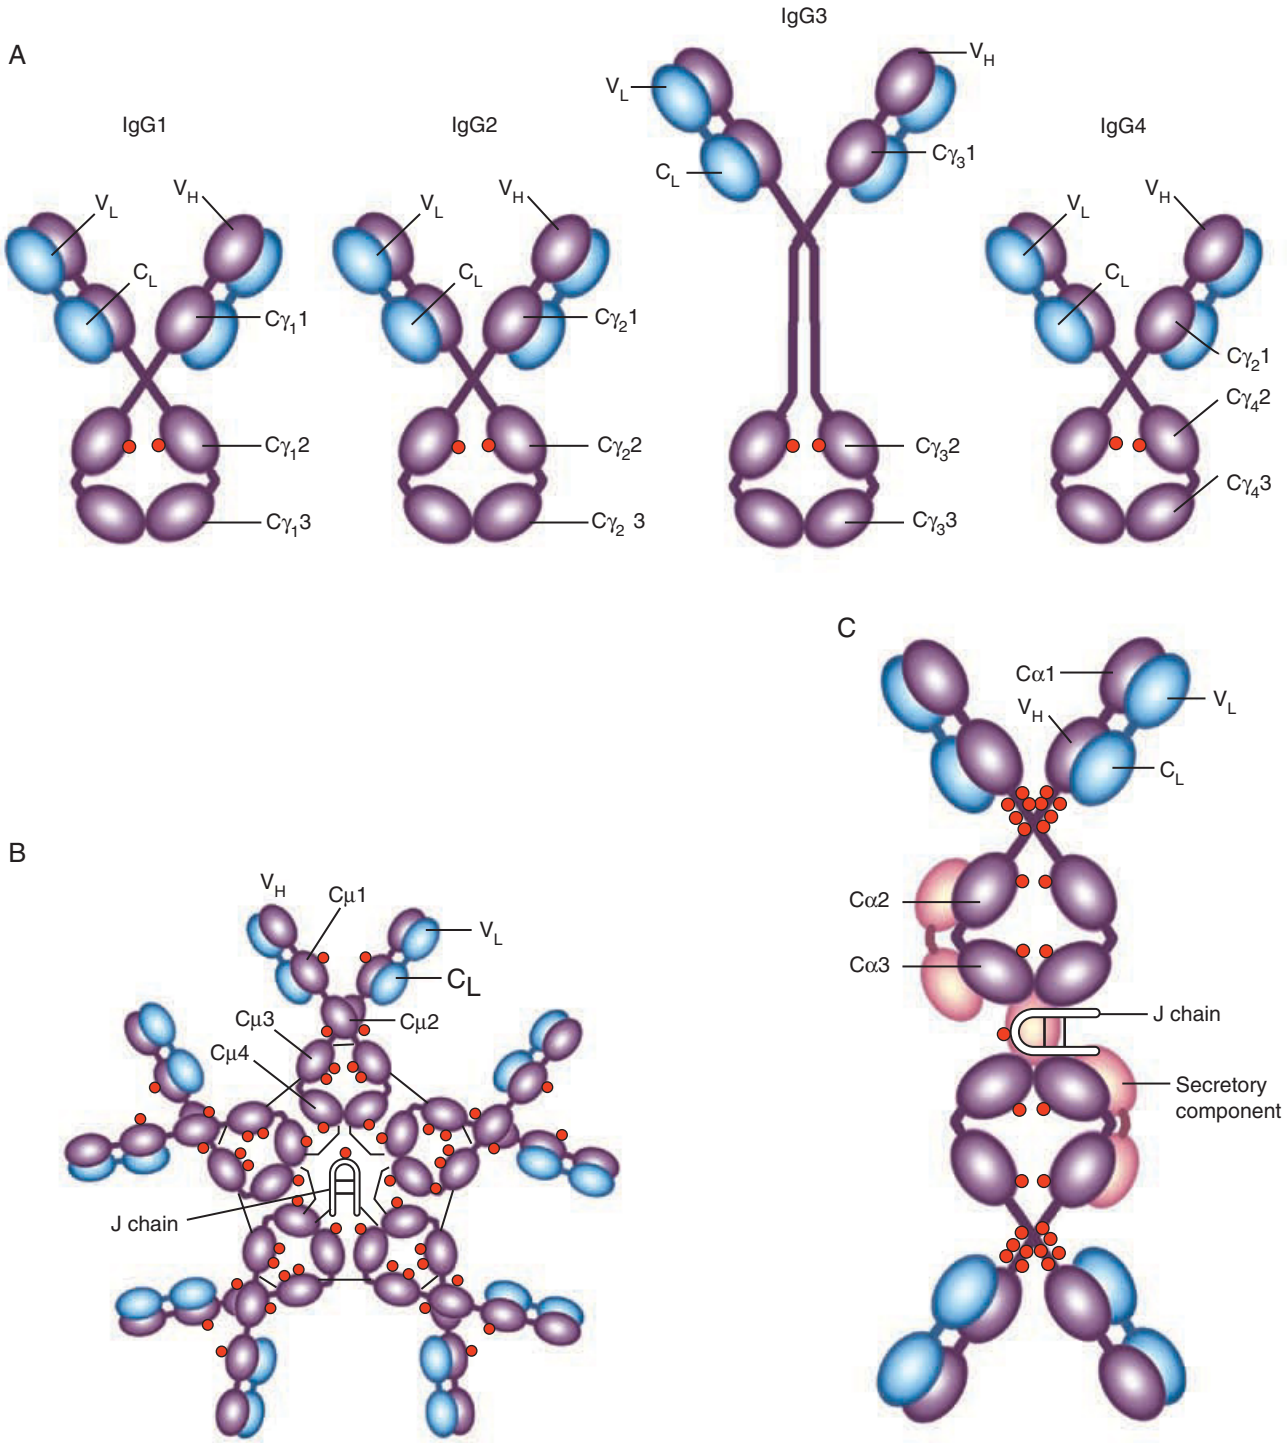

Figure 49–7 **A**, Structure of the four subclasses of human IgG. Constant region domains are indicated by C_nN, where n is the subclass and N is the domain. **B**, Structure of human IgM. The J chain is shown in the model as disulfide linked to two μ-chains. Other models have been proposed. Filled circles indicate carbohydrate. **C**, Structure of human secretory IgA. This model shows the possible arrangement of the two IgA monomers in relation to the secretory component and J chain. As the IgA molecule passes through the epithelial cells, the secretory components are synthesized and attached covalently to the Fc domain of the α-chains that have previously been joined to the J chain with disulfide links. Light chain are shown in pink, heavy chain in red, disulfide bonds as black lines, and carbohydrates as black circles. *(From Turner MW: Mannose-binding lectin: The pluripotent molecule of the innate immune system. Immunol Today 17:532, 1996.)*

The third type of variation is due to antigenic determinants that are unique to each particular antibody molecule produced by an individual. These markers are called *idiotypic determinants,* and they are associated with a single species of antibody. The antiidiotypic antibodies that recognize a particular idiotype will not react with any other immunoglobulins in the donor other than the purified antibody that was used to raise the antiidiotype antibody. In most cases, the immune response to an antigen results in a mixture of several antibodies, each of which has identical binding specificity but distinct idiotypic determinants. Thus, there can be many idiotypes for a given antigenic specificity, which has been interpreted as being a reflection of physical heterogeneity in or near the antibody combining site, for example, in the variable region domains. In some species (notably certain strains of mice), the response to antigen results in a predominant idiotype on all antibodies of a given specificity. Because this quality is inherited, the idiotypes are called major, cross-reactive, or public. Some public idiotypes have been found in certain species (again most notably mice) to be genetically linked to allotypes. Three kinds of antiidiotype antibodies have been described: those that function as an internal image of the original antigen by mimicking the antigen structure, those that recognize antibody combining site-associated idiotypes, and those that are specific for framework-associated determinants. The internal image antiidiotypic antibodies are of clinical interest.

Every immunoglobulin is a glycoprotein, and the critical glycan is attached to the H chain in the Fc domain at the conserved asparagine at position 297 (Asn297). This single, N-linked glycan is essential for maintaining an open conformation of the two H chains. The core structure of the N-linked glycan is a biantennary heptapolysaccharide containing *N*-acetylglucosamine plus additional sugars (fucose, galactose), with bisecting *N*-acetylglucosamine and sialic acid variably present. Effector functions depend on the Asn297-linked glycan and are influenced by its structure.[126] Deglycosylated IgG does not interact effectively with Fcγ receptors (FCγRs) and cannot support in vivo effector responses, including antibody-dependent cell-mediated cytotoxicity or complement-dependent cytotoxicity.[127] Individual glycoforms contribute to modulating inflammatory responses and have disease association. For example, glycosylation differs in patients with rheumatoid arthritis[128] or vasculitis[129] compared to the normal population. Addition of sialic acid to the N-linked glycan reduces binding of IgG to FcγRs and reduces in vivo cytotoxicity. Regulation of sialylation of IgG contributes to the anti-inflammatory homeostasis of serum IgG. Upon antigen challenge, reduced sialic acid–IgG can mediate immune clearance and protective immunity through interaction with subclass specific FcγRs. Ravetch et al. have proposed that the protective effect of intravenous immunoglobulin (IVIg) therapy is due to the minor fraction of sialylated IgG species in the total IVIg preparation and that the high doses required (1–3 g/kg body weight) for antiinflammatory activity could be significantly reduced by increasing the percentage of sialylated IgG.[130]

Therapeutic Use

Immunoglobulin G was one of the first plasma proteins prepared in a purified state as a therapeutic drug for treatment of clinical disorders. It remains, along with albumin and alpha-proteinase inhibitor, the most widely used therapeutic plasma derivative, and is currently the major plasma product on the global market. Polyvalent human immunoglobulin preparations have been used to reconstitute humoral immunity in agammaglobulinemic patients for more than three decades. Until 25 years ago, intramuscular treatment was the mode of administration. Intramuscular preparations caused severe adverse reactions when injected intravenously.[131–133] The most serious were anaphylactoid reactions, and were probably complement mediated. Efforts to reduce anticomplementary activity (ACA) and the prekallikrein activator activity (PKA) were initiated in the early 1980s and safer IVIg preparations became available.

Intravenous immunoglobulin is prepared from pooled human plasma pools of 3000 to 50,000 L. The World Health Organization (WHO) requires more than 1000 donors per lot. The majority of IVIg is produced by cold ethanol fractionation procedures,[134,135] with filtration and polishing chromatography steps added to increase yield and decrease pathogen transmission.[136,137] Gamunex (Talecris Biotherapeutics) is produced from cold ethanol fractionation followed by caprylate precipitation and chromatograpy.[136,138] This is the first significant change in commercial IVIg production in 20 years. Intravenous immunoglobulin contains concentrated IgG with normal plasma ratios of IgG1 and IgG2, lower percentages of IgG3 and IgG4, and only trace amounts of IgA and IgM. It retains the antibody repertoire, reflecting the combined immunologic experience of the donors.[139] Hyperimmune IGIV is purified from donor plasma selected for high titer toward a specific pathogen. Prophylaxis for cytomegalovirus and respiratory syncytial virus are two approved clinical applications.[140,141]

The availability of safe IVIg preparations and the fortuitous observation that IgG treatment of a patient with thrombocytopenia and IgG deficiency increased the patient's platelet count began an intense period of clinical use of IVIg for indications other than primary immune deficiency. In 1990, the National Institutes of Health sponsored a Consensus Development Conference, which produced the first consensus statement on IVIg clinical indications.[142] As a result, six disease indications—primary immunodeficiency, Kawasaki syndrome, chronic lymphocytic leukemia, human immunodeficiency virus (HIV) infections during childhood to prevent infections, bone marrow transplantation to prevent graft-versus-host disease or bacterial infections in adults, and idiopathic purpura—were approved by the Food and Drug Administration (FDA) for labeling and marketing. The licensed indications remain unchanged, but off-label uses include more than 100 conditions.[143,144]

Off-label uses include a variety of immune-mediated, presumed immune-mediated, and idiopathic diseases. Consensus recommendations for 53 off-label uses were developed by a University Hospital Consortium Expert Panel and published in 1995.[145] In addition to the indications listed above, chronic demyelinating polyneuropathy has been added as a clear indication for treatment with IVIg. Additional autoimmune and inflammatory diseases in which clinical benefit has been established in controlled clinical trials include Guillain-Barré syndrome, myasthenia gravis, multifocal motor neuropathy, corticosteroid-resistant dermatomyositis, antineutrophil cytoplasmic-autoantibody–positive vasculitis, autoimmune uveitis, multiple sclerosis, cancer, and solid organ transplant.[146–153] Currently, more than half of the available IVIg is given for off-label treatment.[144,154] Although the shortage of product experienced a decade ago is no longer an issue, the treatment remains expensive at $50 to $80 per gram. Treatment of chronic neuropathy, including chronic inflammatory demyelinating polyneuropathy and multifocal motor neuropathy, exceed annual costs of $50,000 per patient.[144]

The experience with IVIg clinical development has been largely empirical and anecdotal. The mechanisms for patient benefit or harm are poorly understood, especially for high-dose immune modulation therapy. Various known and some yet undiscovered functions of immunoglobulins in immune homeostasis may contribute, including modulation of the function and expression of Fc receptors, interaction with complement and cytokine systems, antiidiotypic antibodies, and regulation of T-cell and B-cell function.[155–157]

Many effects of IVIg are explained by mechanisms beyond antigenic recognition of pathogens. Intravenous immunoglobulin preparations contain up to 30% dimers composed of idiotype–antiidiotype antibody pairs. These dimers appear to be very effective as a sink for activated complement and can inhibit complement activation.[158] Benefit for treatment of immune thrombocytopenia purpura seem to be mediated by Fc-receptor blockade of reticuloendothelial cell salvage receptor (FcRn) combined with an antiidiotypic neutralization of antiplatelet antibody that together eliminate antiplatelet antibody from the blood. Other indications of antibody neutralization can be seen in IVIg treatment of myasthenia gravis. The dramatic success of IVIg in treating Kawasaki syndrome may be due to several

mechanisms, including antiidiotypic neutralization of antiendothelial antibodies, inhibition of cytokine production and function, and elimination of causative superantigens.[159,160] Intravenous immunoglobulin inhibits B-cell activation and autoantibody production by enhancing $CD8^+$ suppressor T-cell function. Cell-mediated immunity also is affected.[155]

Adverse Events Related to Intravenous Immunoglobulin Infusion

Adverse events associated with IVIg can be characterized as (a) early systemic events, (b) infectious disease transfer, and (c) high-dose treatment related adverse effects.[133]

Early Systemic Events

Common transfusion-related early events are listed in Table 49–3. Most early events are self-limiting and infusion rate dependent. Premedication with steroids, aspirin, or other nonsteroidal antiinflammatory drugs often decreases symptoms. Prophylaxis propanolol can be effective for induced migraine. Aseptic meningitis is a rare early event, is observed 1 to 2 days postinfusion, is unrelated to infusion rate, and can be treated with IV steroids and analgesics.[133,161]

The frequency of reported adverse events varies considerably, ranging from 10% to 85%.[133,142,162–164] There are many reason for this high variability in reporting: (a) differences in product,[137,152,162] (b) infusion rate, (c) dose and frequency of dosing, (d) patient population, and (e) relative experience of patient and physician. Both patients and physicians become steeled to the adverse events, and because incidents are not life threatening and often respond to prophylaxis medication, they are ignored as "normal." Nonetheless, these events are common and affect health and quality of life of patients.[144,162]

Infectious Disease Transfer

A few early preparations of IVIg transmitted hepatitis C virus. Manufacturers have added viral inactivation and partitioning steps, and current licensed products are safe with respect to HIV, hepatitis C virus, hepatitis B virus, and other blood-born pathogens.[165] The industry has responded to the threat of prions with process validation,[163,166] donor screening, donor testing, inventory management (look back), and plasma pool testing.

Table 49–3 Early Systemic Adverse Events Associated with Intravenous Immunoglobulin Infusion

Fever	Rash/urticaria
Chills	Chest tightness
Sore throat	Dyspnea
Face flush	Wheezing
Tachycardia	Low/high blood pressure
Palpitations	Shock
Lumbar pain	Anxiety
Abdominal pain	Nervousness
Nausea	Headache
Vomiting	Migraine
Shaking	Anaphylaxis
Fatigue	Malaise
Myalgia	Leukopenia

High-Dose Treatment-Related Adverse Events

Intravenous immunoglobulin treatment for immune modulation of neurologic diseases requires doses of 1 to 2 kg per kilogram of body weight, or two to five times the dose recommended for replacement therapy. Adverse events with high-dose administration include those listed in Table 49–3 and occasionally thromboembolic events, renal complications, and anemia.[133,164,167–170] Thromboembolic events include deep vein thrombosis, pulmonary embolism, myocardial infarction, and stroke. Thromboembolic events and renal failure seem to be independent of infusion rate. The cause of thromboembolic events is not known. Dalakas[171] has suggested that increased serum viscosity plays a role. Factor XIa has also been identified in IVIg preparations.[172] Factor XIa could directly lead to shortening of coagulation time and risk of thrombosis. Renal complications are rare but result in high morbidity and mortality. Whether IgG, contaminants, or excipients are responsible is not clear. Of the 88 renal adverse events reported to the FDA, 90% were stabilized with sucrose.[133,161] Whether the adverse events observed with IVIg treatment of neurologic diseases are related to a preexisting medical condition or the high doses required for treatment is not clear.

Monoclonal Antibody Therapy

Monoclonal antibody (mAb) technology as described in 1975 by Kohler and Milstein[173] is now well established for the production of diagnostic and therapeutic mAbs. Despite early enthusiasm and much research and development effort, the development of clinical mAb was frustrated for 20 years by reports of severe toxicity and poor clinical efficacy. Only one mAb, OKT3, an anti-CD3, was licensed for clinical use before 1994. Over the last decade the situation has changed. Monoclonal antibody products constitute as much as 25% of new biologicals in clinical development, with a first in humans to regulatory approval success rate of 27%, which compares very favorably to the 11% rate for small-molecule drugs.[174,175] Table 49–4 lists the 18 mAbs that have received FDA approval; 17 are marketed and one has been withdrawn.[176]

The list includes antibodies for diverse clinical conditions, including oncology, chronic inflammatory conditions, solid organ transplantation, infectious disease, and cardiovascular medicine. Approved antibody therapy includes unmodified mAb, radio-immunoconjugates, immuno-drug conjugates, and antibody fragments. More than 150 mAbs are in clinical development, with at least 33 in clinical trials for conditions including colorectal cancer, melanoma, postmenopausal osteoporosis, cutaneous T-cell lymphoma, rheumatoid arthritis, and respiratory syncytial virus infection.[174] Part of the progress is due to the advent of genetic engineering, which has allowed the production of "humanized" mAbs. Human–mouse chimerized Ab with limited mouse determinants or fully human mAb now are produced by DNA technology or with transgenic mice. The humanization of mAbs provides some protection from the patient's immune system, prolonging the circulation half-life from less than 24 hours for murine mAbs in humans and approaching the 21-day half-life of native IgG. Increased circulation time is due in part to the reduction in immune reactivity and subsequent opsonization of mAbs but also because human but not murine IgG is recycled by receptors (FcRn) on human epithelial cells.[177,178]

ReoPro (abciximab) is a chimeric Fab fragment directed to glycoprotein IIb/IIIa and is one of the early successful clinical mAbs (approved for marketing in 1994). ReoPro prevents thrombus formation in patients undergoing procedures such as percutaneous coronary intervention.[179] Another example of a chimeric mAb (IgG1) is Remicade (infliximab), which is an anti–tumor necrosis factor α. Remicade was approved in 1998 for treatment of Crohn disease and in 1999 for treatment of rheumatoid arthritis.[180,181]

Monoclonal antibodies for cancer therapy are divided into two stratagems. "Naked" mAbs target specific tumor-related antigens or

Table 49–4 Monoclonal Antibody Products Approved by the Food and Drug Administration

Product Name, Antibody Name (Company)	Antibody Format	Antigen	K_d (nM)	Proposed Mechanisms of Action	Approved Indications
Orthoclone OKT3, muromonab-CD3 Ortho Biotech Products, LP)	Mouse IgG2a	CD3	0.83	Blocking of function of T-cell expressed CD3; reversal of graft rejection	Prophylaxis of acute kidney transplant rejection
ReoPro, abciximab (Centocor, Inc.)	Chimeric Fab	GpIIb/IIIa and $\alpha_1\beta_3$-integrin	5	Receptor binding and antagonism; inhibition of platelet aggregation	Prevention of platelet-mediated clots in coronary angioplasty
Rituxan, rituximab (Genentech, Inc., and Biogen Idec Inc.); Mab Thera (F. Hoffmann-La Roche Ltd.)	Chimeric IgG1	CD20	8.0	Sensitization of cells to chemotherapy; induction of apoptosis, ADCC and CDC	Non-Hodgkin lymphoma and rheumatoid arthritis
Zenapax, daclizumab (F. Hoffmann-La Roche Ltd.)	Humanized IgG1	CD25	0.3	Receptor binding and antagonism	Prophylaxis of acute kidney transplant rejection
Simulect, basiliximab (Novartis AG)	Chimeric IgG1	CD25	0.1	Receptor binding and antagonism	Prophylaxis of acute kidney transplant rejection
Synagis, palivizumab (MedImmune Inc., and Abbott Laboratories)	Humanized IgG1	RSV gpF	0.96	Binding neutralization of RSV; inhibition of viral fusion and replication	Prophylaxis against RSV infection in children at high risk
Remicade, infliximab (Johnson & Johnson, and Schering-Plough Corporation)	Chimeric IgG1	TNF	0.1	Ligand binding and receptor antagonism	Crohn disease, rheumatoid and psoriatic arthritis, ulcerative colitis, ankylosing spondylitis
Herceptin, trastuzumab (Genentech, Inc., and F. Hoffmann-La Roche Ltd.)	Humanized IgG1	ErbB2	5	Sensitization of cells to chemotherapy; inhibition of angiogenesis and proliferation; induction of ADCC	Metastatic breast cancer that overexpresses ERBB2
Mylotarg, gemtuzumab ozogamicin (Wyeth)	Humanized IgG4, calicheamicin conjugated	CD33	0.08	Induction of double-stranded DNA breaks and cell death (caused by calicheamicin)	Acute myeloid leukemia that expresses CD33
Campath, alemtuzumab (Genzyme Corp. and Schering AG)	Humanized IgG1	CD52	10–32	Induction of ADCC and CDC	B-cell chronic lymphocytic leukemia
Zevalin, ibritumomab tiuxetan (Biogen Idec, Inc.)	Mouse IgG1, Y-labelled	CD20	14–18	Induction of cell death by radiation; induction of apoptosis	Non-Hodgkin lymphoma
Humira, adalimumab (Abbott Laboratories)	Human IgG1	TNF	0.1	Ligand binding and receptor antagonism; induction of CDC	Rheumatoid and psoriatic arthritis
Xolair, omalizumab (Genentech, Inc., and Novartis AG)	Humanized IgG1	IgE	0.17	Ligand binding and receptor antagonism; reduction release of allergic-response mediators from mast cells and basophils	Persistent asthma
Bexxar, I-tositumomab (GlaxoSmithKline)	Mouse IgG2a, I-labelled	CD20	1.4	Induction of cell death by radiation; induction of apoptosis, ADCC, and CDC	Non-Hodgkin lymphoma

Product Name, Antibody Name (Company)	Antibody Format	Antigen	K_d (nM)	Proposed Mechanisms of Action	Approved Indications
Raptiva, efalizumab (Genentech, Inc., and Serono S.A.)	Humanized IgG1	CD11a	3	Receptor binding and antagonism; inhibition of leukocyte adhesion to other cells	Plaque psoriasis
Erbitux, cetuximab (ImClone Systems, Inc., and Bristol-Myers Squibb Company)	Chimeric IgG1	EGFR	0.2	Receptor binding and antagonism; inhibition of cell proliferation; induction of apoptosis; sensitization of cells to chemotherapy and radiotherapy; inhibition of angiogenesis, invasion, and metastasis; induction of ADCC	Metastatic colorectal cancer
Avastin, bevacizumab (Genentech, Inc., and F. Hoffmann-La Roche Ltd.)	Humanized IgG1	VEGF	1.1	Ligand binding and receptor antagonism; inhibition of angiogenesis and metastatic disease progression	Metastatic colorectal cancer, head and neck cancer
Tysabri, natalizumab (Biogen Idec, Inc., and Eland Corporation, PLC)	Humanized IgG4	α_4-Subunit of $\alpha_4\beta_1$-integrin and $\alpha_4\beta_3$-integrin	0.3	Receptor binding and antagonism; inhibition of leukocyte adhesion to their counterreceptors	Multiple sclerosis

Sources include drug prescribing information, company Web sites.[174] Products are listed in order of first regulatory approval, from Orthoclone OKT3 (1986) to Tysabri (2004).

ADCC, antibody-dependent cell-mediated cytotoxicity; CDC, complement-dependent cytotoxicity; EGFR, epidermal growth factor receptor; ErbB2, Her-2/neu, CD340, erythroblastic leukemia viral oncogene homolog 2 neurolglioblastoma derived oncogene homolog (avian); RSV gpF, Human respiratory syncytial virus glycoprotein F; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

cell receptors to recruit the immune system or to modify the growth of tumor cells. Examples of approved naked mAbs are Rituxan (rituximab),[182] an anti-CD20 approved for non-Hodgkin lymphoma, and Herceptin (trastuzumab),[183] an anti-HER2 approved for advanced breast cancer. To date most naked mAb candidates have been disappointing, and the most efficacious are used as adjuvant therapy. The most promising naked mAbs may not directly affect the tumor cell but instead may modify the patient's immune response to the tumor. An example of immune-modulating mAbs in development is anti-CD152,[184] which may modulate the way T cells respond to cancer cells.

The second strategy is to attach or conjugate an antitumor agent to an antitumor mAb. The mAbs deliver the toxic agent to the tumor or tumor cells in an attempt to obliterate the cancer cells. Both radioactive and chemical toxins have been conjugated to a variety of tumor-specific mAbs. Two mAbs that deliver radioactivity directly to the tumor are Zevalin (ibritumomab tiuxetan) and Bexxar (tositumomab), which were approved in 2002 and 2003, respectively, for B-cell non-Hodgkin lymphoma.[185,186] Many immunotoxins have been developed, but without much clinical success. Mylotarg (gemtuzumab ozogamicin), an anti-CD33 mAb, is approved for myelogenous leukemia when chemotherapy is not effective or appropriate.[187]

A listing of approved mAb therapy for cancer can be found online on the American Cancer Society web page (at www.cancer.org) under Monoclonal Antibody Therapy (Passive Immunotherapy). For a review of therapeutic MAbs, see Carter.[176]

CHAPTER 50

DISORDERS OF PHAGOCYTE FUNCTION AND NUMBER

Mary C. Dinauer and Thomas D. Coates

INTRODUCTION

Phagocytic leukocytes are an essential component of the innate immune system that has evolved to rapidly respond to the presence of invading bacteria, fungi, and parasites. This first line of host defense also includes natural killer lymphocytes, complement, and other plasma proteins. As reviewed in Chapters 10 and 26, phagocytes are responsible for ingesting, killing, and digesting pathogens. Granulocytic phagocytes (neutrophils and eosinophils) circulate in the bloodstream until they sense chemotactic signals from infected tissues, which result in adhesion to the vascular endothelium and subsequent migration into the site of infection. Mononuclear phagocytes (macrophages and their circulating precursor, the monocyte), on the other hand, function primarily as resident cells in a variety of tissues such as lung, liver, peritoneal cavity, and spleen, where they perform a surveillance role and also interact closely with lymphocytes to promote specific immune responses. Microbial killing is accomplished by two types of mechanisms: (a) de novo synthesis of highly toxic and often unstable derivatives of molecular oxygen by an enzyme known as the respiratory burst oxidase and (b) preformed polypeptide "antibiotics" and proteases stored within several types of lysosomal granules that are delivered into phagocytic vacuoles containing the ingested microbes.

This chapter reviews the major congenital and acquired disorders of phagocyte function and number, which from the clinical standpoint largely involve neutrophils. As would be predicted, these disorders are manifested clinically by recurrent bacterial and fungal infections, often with atypical pathogens or unusual presentations. Interestingly, the converse of this is only rarely observed. Most patients with recurrent infections do not have any identifiable abnormality in their phagocytes. There are at least two explanations for the clinical rarity of phagocyte disorders. First, given their critical role in host defense, nature may be quite intolerant of major abnormalities in phagocytes. Prior to the modern antibiotic era, patients afflicted with severe disorders probably did not survive into their childbearing years. Second, there is a remarkable redundancy in the antimicrobial machinery of the phagocytes that permits one system to compensate for a defect in another. For example, the host does not rely on a single chemotactic signal or neutrophil membrane receptor to ensure that phagocytes accumulate at sites of infection. Instead, multiple chemotactic signals and receptors are employed. A similar phenomenon is seen in the reactions that kill microbes as both oxidative and nonoxidative systems are employed.

This chapter is divided into two sections. The first is focused on functional abnormalities and is organized according to the cellular functions outlined above: disorders of the respiratory burst microbicidal pathway, abnormalities of phagocyte adhesion and chemotaxis, and defects in the structure and function of lysosomal granules. The second section outlines the quantitative abnormalities—leukocytosis and leukopenia—with a particular emphasis on neutropenia. The chapter is not meant to be an encyclopedic review of the numerous papers published on phagocyte abnormalities. It is important to note that many of these reports describe marginal in vitro defects, with little evidence that they are responsible for a clinical problem. Many comprehensive reviews offering additional information on phagocyte disorders are available.[1–8]

DISORDERS OF PHAGOCYTE FUNCTION

Inherited and acquired clinical disorders of phagocyte function result from defects in one or more of the major steps leading to microbial killing—adhesion, chemotaxis, ingestion, degranulation, and production of microbicidal oxidants (Fig. 50–1). Patients with inherited disorders typically present in infancy or childhood with recurrent, unusual, or recalcitrant bacterial and fungal infections, and it is usually not difficult to determine that these are outside the range of normal. The presentation of these different inherited disorders can overlap, so that a specific diagnosis cannot be made on clinical grounds alone. Infections commonly seen include those of the skin or mucosa, lung, lymph node, deep tissue abscesses, or childhood periodontitis. These can often have an indolent presentation with only low-grade fevers. Bacterial sepsis is an unusual initial symptom, and usually reflects dissemination from an infected site. Inherited defects in phagocyte function are rare, and represent only approximately 20% of the primary immunodeficiencies.[1] Thus, children with suspected disorders of host defense should be also screened for defects in humoral, cellular, and complement-mediated immunity. An approach to evaluating the patient with significant recurrent infections is shown (Fig. 50–2). If a defect is identified, it is recommended that the patient be referred to a center specialized in care of such patients.

In clinical practice, although nearly all patients with well-characterized phagocyte abnormalities have recurrent or unusual infections, the majority of those individuals with histories of persistent or recurrent infections do not have identifiable phagocyte disorders or other immune defects. In some cases, these reflect another underlying medical condition or nonimmunologic problem related to an anatomic or obstructive defect. This chapter will focus largely on those disorders in which a good correlation exists between the clinical condition and an identifiable defect in phagocyte function.

DISORDERS OF THE RESPIRATORY BURST PATHWAY

Reactive oxygen species generated by the phagocyte respiratory burst are critical for microbial killing. The enzyme responsible for the initial reaction in this pathway is a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase found in plasma and phagolysosomal membranes. Upon activation by inflammatory stimuli, the NADPH oxidase catalyzes the transfer of an electron from NADPH to molecular oxygen, thereby forming superoxide (as the O_2^- ion) (Fig. 50–2, reaction 1).[9–11] This NADPH oxidase, along with the enzymes and reactions that are directly involved in the production or metabolism of O_2^-, constitute the respiratory burst pathway as depicted in Fig. 50–2. Superoxide is the precursor to numerous microbicidal oxidants, including hydrogen peroxide and hypochlorous acid. Five clinically significant defects have been identified in the respiratory burst, involving the following enzymes: NADPH oxidase (reaction 1), leukocyte glucose-6-phosphate dehydrogenase (G6PD) (reaction 8), myeloperoxidase (reaction 4), glutathione reductase, and glutathione synthetase (reaction 9).[2,12–14] These reactions are involved in the production of O_2^- (reactions 8 and 1), in the conversion of O_2^- and hydrogen peroxide to other toxic derivatives (reaction 4), or in the

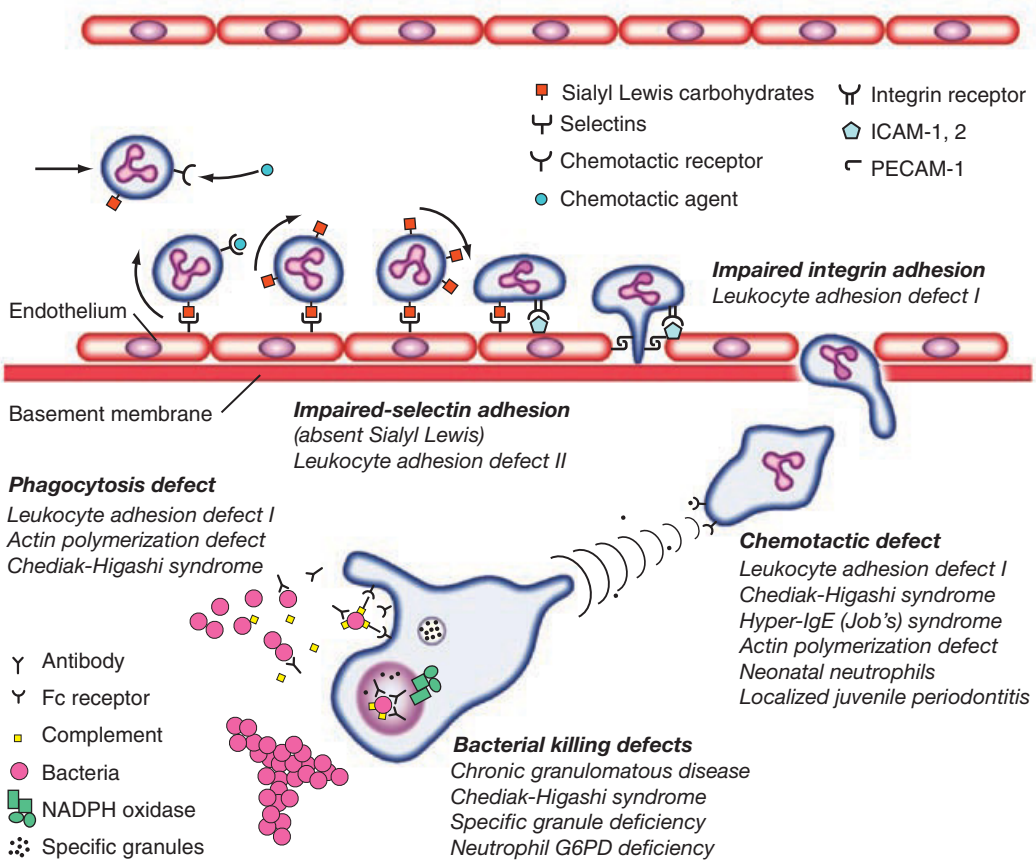

Figure 50–1 Steps in the response of circulating neutrophils to infection or inflammation in tissues. The adhesion molecule E-selectin is upregulated on endothelial cells in response to inflammatory mediators (IL-1, endotoxin, and TNF-α) resulting in the rolling attachment and margination of neutrophils through interactions with sialyl Lewis carbohydrates on its surface. Chemoattractants, such as IL-8, released by endothelial cells cause upregulation of neutrophil β2 integrins, which, in turn, mediate tight adhesion to ICAM-1 and PECAM-1 on endothelial cells. Activated neutrophils can detect as little as a 2% change in the chemoattractant gradient and move toward the site of infection. Neutrophils phagocytose bacteria opsonized by antibody and complement. Both oxidative and nonoxidative antimicrobial mechanisms are then used to kill bacteria. Disorders of phagocyte function associated with each of these steps are listed. *(Modified from Kyono W, Coates TD: A practical approach to neutrophil disorders. Pediatr Clin North Am 49:929, 2002, with permission.)*

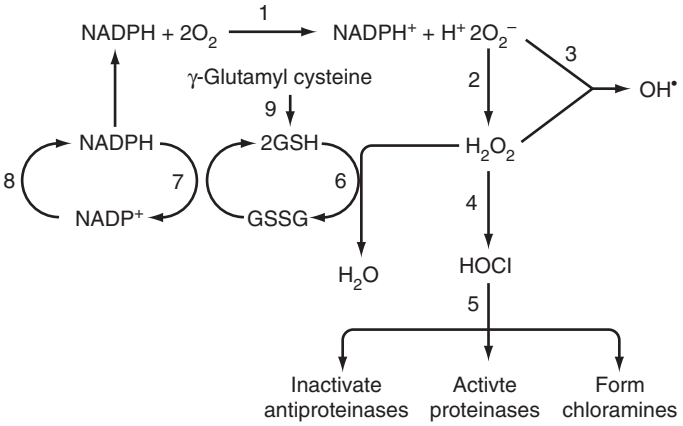

Figure 50–2 Reactions of the respiratory burst pathway. The enzymes responsible for reactions 1 to 9 are as follows: (1) The respiratory burst oxidase (NADPH oxidase); (2) superoxide dismutase or spontaneous; (3) nonenzymatic, Fe^{2+}-catalyzed; (4) myeloperoxidase; (5) spontaneous; (6) glutathione peroxidase; (7) glutathione reductase; (8) glucose-6-phosphate dehydrogenase; (9) glutathione synthetase.

detoxification of excess hydrogen peroxide needed to protect the phagocyte during the respiratory burst (reactions 7 and 9). Of note, homologues to the oxidase NADPH oxidase have recently been discovered in the gut, vascular cells, and other tissues, which may generate oxidants for local host defense or for regulation of other cellular functions.[15,16]

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is a genetically heterogeneous group of defects that share in common the failure of neutrophils, monocytes, macrophages, and eosinophils to undergo a respiratory burst and generate O_2^-.[2,9,12,17–20] CGD is relatively rare, having an estimated incidence of between 1/200,000 and 1/250,000 live births based on data from the United States CGD Registry.[17] The absence of respiratory burst-derived oxidants results in recurrent, often life-threatening, bacterial and fungal infections and is also associated with formation of inflammatory granulomas. The disease was first described in 1957 in two independent reports by Good and colleagues[21] and Landing and Shirkey,[22] both of which describe severe recurrent infections in boys associated with visceral granulomas containing pigmented histiocytes. The disease was termed fatal granulomatous disease owing to this distinguishing histologic feature and the grim clinical course in most patients. It was not until the late 1960s and early 1970s that the defect in oxygen consumption and O_2^- produc-

tion was identified and a convenient diagnostic assay, the nitroblue tetrazolium (NBT) test, was developed.[23,24] In the 1980s, a combination of biochemical and molecular genetic approaches led to the identification of four critical subunits of the NADPH oxidase, and the recognition that mutations in the corresponding genes are responsible for four different genetic subgroups of CGD (Fig. 50–3).[2,9,12,18,25]

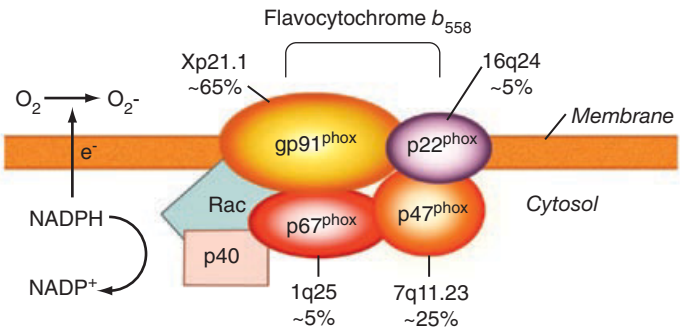

Figure 50–3 NADPH oxidase and molecular genetics of chronic granulomatous disease. Shown is the assembled form of the enzymatically active NADPH oxidase, along with subunits affected in the four different genetic subgroups of chronic granulomatous disease (CGD), the approximate incidence, and the chromosomal location of the corresponding gene. Flavocytochrome b_{558} is the redox center of the enzyme, and is located in plasma, specific granule, and phagolysosomal membranes. This heterodimer is composed of the gp91^{phox} and p22^{phox} subunits of the NADPH oxidase, which are affected in X-linked and an autosomal recessive form of CGD, respectively. The soluble regulatory proteins p47^{phox}, p67^{phox}, and p40^{phox} are found in the cytosol until phagocyte activation by soluble or particulate inflammatory stimuli, on which they move to the membrane where p47^{phox} and p67^{phox} bind flavocytochrome b_{558}. Mutations in the genes encoding p47^{phox} and p67^{phox} account for two autosomal recessive forms of CGD. Another essential regulatory component of the NADPH oxidase is the small GTPase, Rac, which in its active GTP-bound state, becomes membrane-bound and associates with the oxidase. By a mechanism that is not fully understood, binding of these multiple regulatory subunits activates the flavocytochrome to catalyze the transfer of electrons from cytosolic NADPH across the membrane via the FAD and heme redox centers to molecular oxygen, thereby forming superoxide in the extracellular or intraphagosomal compartment. No cases of CGD have been described owing to mutations in p40^{phox} or Rac.

Molecular Genetics of Chronic Granulomatous Disease

CGD results from mutations in any of the four genes encoding essential subunits of the NADPH oxidase, which forms the basis of a modern classification scheme (Table 50–1). In turn, the biochemical and genetic analysis of CGD has been instrumental in characterizing this complex enzyme.[2,9,12,18,20] The oxidase subunits are referred to by their apparent molecular mass (kd), and have been given the designation *phox*, for *ph*agocyte *ox*idase. A b-type cytochrome known as flavocytochrome b_{558}, a membrane-bound heterodimer composed of gp91^{phox} and p22^{phox}, is the redox center of the oxidase. Approximately two-thirds of CGD cases result from defects in the X-linked gene encoding the gp91^{phox} subunit of flavocytochrome b_{558},[26–29] which contains both the flavoprotein and heme-binding domains responsible for electron transport. A rare autosomal recessive form of CGD is caused by mutations in the gene encoding p22^{phox},[30] the smaller subunit of flavocytochrome b_{558}, which provides a critical docking site for p47^{phox}, a regulatory subunit of the oxidase. The remaining cases of autosomal recessive CGD involve genetic defects in either p47^{phox} or p67^{phox}, two regulatory proteins that are associated with each other in the cytosol of unstimulated cells but rapidly move to the membrane to activate flavocytochrome b_{558} and superoxide formation when neutrophils are exposed to inflammatory or phagocytic stimuli. Computerized databases for all four genetic subgroups of CGD have been developed that are accessible through the Web site bioinf.uta.fi/idr.[31]

A fifth *phox* protein, p40^{phox}, is also associated with p67^{phox} and, indirectly, p47^{phox}.[32] Although p40^{phox} is not essential for enzymatic activity, this subunit is important for high-level superoxide production in response to certain stimuli, including immunoglobulin-opsonized particles and *Staphylococcus aureus*.[33,34] Formation of the active NADPH oxidase complex also involves the activation of the small GTP-binding protein Rac2, which then binds to the plasma membrane and p67^{phox}.[35,36] No cases of CGD have been identified resulting from genetic defects in either p40^{phox} or Rac2, although a mutation in the latter was found in an infant with recurrent infections and abnormal neutrophil adhesion, motility, and partial NADPH oxidase defects.[37,38]

The gene for gp91^{phox}, termed CYBB (MIM306400), spans approximately 30 kb in the Xp21.1 region of the X chromosome and contains 13 exons.[39–41] More than 300 distinct mutations have been identified in the gp91^{phox} gene in X-linked CGD, which include deletions, frameshifts, splice site, nonsense, and missense mutations that are distributed throughout the gene (Table 50–2).[18,42,43] Approxi-

Table 50–1 Classification of Chronic Granulomatous Disease

Component Affected	Gene Symbol	Gene Locus	Inheritance	Subtype[a]	NBT Score (% Positive)	O_2^- Production (% Normal)	Flavocytochrome *b* Spectrum (% Normal)	Defect in Cell-Free NADPH Oxidase Assay	Frequency (% of Cases)[b]

X, X-linked inheritance; AR (or A), autosomal recessive inheritance; NBT, nitroblue tetrazolium; N, normal.

[a]In this nomenclature, the first letter represents the mode of inheritance (X-linked [X] or autosomal recessive [A]) and the number indicates the *phox* component that is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (°), diminished (–), or normal (+) as measured by immunoblot analysis.

[b]Combined data from 209 kindreds evaluated at the Scripps Research Institute/Stanford University CGD Clinic and a cooperative European study[1] representing 57 kindreds and 63 patients (Modified from Casimir C, Chetty M, Bohler MC, et al: Identification of the defective NADPH-oxidase component in chronic granulomatous disease: A study of 57 European families. Eur J Clin Invest 22:403, 1992; and Curnutte JT: Chronic granulomatous disease: The solving of a clinical riddle at the molecular level. Clin Immunol Immunopathol 67:S2, 1993.).

Table 50–2 Summary of Mutations in the CYBB Gene Encoding gp91^{phox} in 261 Kindreds with X-linked Chronic Granulomatous Disease

Type of Mutation	Number of Kindreds	Frequency (%)	Phenotype
Deletions	63	24.2	X91^0
Insertions	27	10.3	X91^0
Splice-site mutations	42	16.1	X91^0
Missense mutations	59	22.6	X91^0, X91$^-$, X91$^+$
Nonsense mutations	70	26.8	X91^0

Data are from Roos D, Curnutte J, Hossle JP, et al: X-CGDbase: A database of X-CGD-causing mutations. Immunol Today 17:517, 1996.

mately 10% to 15% of X-linked CGD is caused by new germline mutations. In most X-linked CGD, gp91^{phox} is completely absent and there is no measurable cytochrome *b*, NBT reduction, or intact cell superoxide production (the X91° subtype). In about 5% of X-linked cases, gp91^{phox} can be present in normal levels but be nonfunctional (X91+), mutated in such a way that gp91^{phox} is poorly functional (X91−), or expressed in only a small fraction of phagocytes (X91+).[18,43] The first two "variant" forms of X-linked CGD result from coding sequence mutations whereas the latter are due to mutations in the regulatory portion of the gp91^{phox} gene. Some X-linked CGD patients have large deletions that affect not only the gene encoding gp91^{phox} but also portions of or all the flanking gene loci for the McLeod hemolytic anemia syndrome (absence of the Kell erythrocyte antigen, Kx), Duchenne muscular dystrophy, and X-linked retinitis pigmentosa.

Autosomal recessive CGD involving p22^{phox} occurs in approximately 5% of CGD patients and usually involves the complete absence of cytochrome *b* (A22°). The p22^{phox} gene, termed CYBA (MIM 233690), resides at chromosome 16q24 and contains six exons that span 8.5 kb.[30] Mutations in A22 CGD are heterogeneous and range from large interstitial gene deletions to point mutations associated with missense, frameshift, or RNA-splicing defects.[18,44] Because the full expression of flavocytochrome *b* in the membrane requires the production of both subunits, a primary deficiency of either component leads to a secondary loss of the other. Thus, neither subunit can be detected on immunoblot analysis in either X91° or A22° CGD. A single patient with A22$^+$ CGD has been described, who has a missense mutation disrupting the binding site for p47^{phox}.[45]

Autosomal recessive patients with p47^{phox})-deficient CGD account for approximately one-fourth of cases in the United States and Europe, but only about 7% of cases in Japan.[2,9,25] The gene for p47^{phox}, termed NCF1 (MIM 233700), resides on chromosome 7 at q11.23[46] and contains nine exons spanning 18 kb.[47] A limited number of mutations have been identified in the p47^{phox} gene. Virtually all patients are either homozygotes or compound heterozygotes for a mutant allele with a GT deletion at the beginning of exon 2 that predicts a premature stop codon and results in absence of the p47^{phox} protein.[18,48,49] The high frequency of the p47^{phox} GT deletion mutation appears to reflect the existence of at least one closely linked highly conserved p47^{phox} pseudogene(s) that contains this GT deletion. This close physical proximity leads to recombination events between the wild-type gene and pseudogene(s).[48]

Finally, a heterogenous group of mutations in the p67^{phox} gene are responsible for A67 CGD, a rare autosomal recessive form of CGD accounting for approximately 5% of cases overall.[2,50] This gene, referred to as NCF2 (MIM233710), is located on the long arm of chromosome 1 at position q25[46] and contains 16 exons that span 40 kb.[51] Almost all of the mutations identified to date in A67 CGD lead to absent expression of the p67^{phox} protein. However, one A67$^+$ patient has been reported in which a nonfunctional form of p67^{phox} with an amino acid deletion is expressed, but is unable to translocate to the membrane or bind to Rac.[52]

Despite the fact that more than 90% of patients with CGD have respiratory burst defects that result in undetectable levels of O_2^- production, there is a surprising heterogeneity in the clinical manifestations of the disease.[17,25] At one end of the spectrum are the patients who begin to suffer from severe bacterial and fungal infections during infancy, and who rarely have more than 4 to 12 months between such serious infections. At the other end of the spectrum are patients who are well for many years and then unexpectedly develop a serious infection typical of CGD, such as a staphylococcal hepatic abscess or Aspergillus pneumonia. After their first major infection, some of these patients may be relatively healthy again for another 3 to 10 years before the next severe infection occurs. As a group, patients with X-CGD, A22 CGD, and A67 CGD seem to have a more severe clinical course compared to patients with A47 CGD.[17,25,53] Those individuals with partial respiratory burst activity less than 10% of normal (most X91− patients; see Table 50–1) also tend to have disease of intermediate severity. Polymorphisms in oxygen-independent antimicrobial systems or other components regulating the innate immune response are also likely to play an important role in modifying disease severity. Specific polymorphisms in the myeloperoxidase, mannose-binding lectin, and FcγRIIa genes are associated with a higher risk for granulomatous or autoimmune/rheumatologic complications.[54] Because of this heterogeneity, the diagnosis of CGD should be entertained not only in young children with recurrent severe infections but also in adolescents and young adults who experience exceptionally severe or unusual infections.

Clinical Manifestations

In approximately two-thirds of patients, the first symptoms of CGD appear during the first year of life with the onset of recurrent, purulent bacterial and fungal infections.[17] Table 50–3 summarizes the types of infections and infecting organisms most frequently encountered in CGD. The most common types of infections are those that involve sites in contact with the outside world—consistent with the role of neutrophils as the first line of defense against infection. *S aureus*, enteric gram-negatives, *Serratia marcescens*, *Burkholderia cepacia*, and *Aspergillus* species represent the most frequently encountered pathogens. Although *S aureus* is the most frequently isolated organism overall, the most common causes of death reported in a recent series were pneumonia and/or sepsis due to *Aspergillus* and *B cepacia*.[17]

Most CGD pathogens share the property of being catalase-negative and as such, inadvertently "lend" H_2O_2 secreted from the pathogen to the peroxide-starved CGD phagocyte that in turn uses it (once converted to HOCl by myeloperoxidase; see Fig. 50–2) to kill the microbe. It also appears that at least some of the CGD pathogens are resistant to the nonoxidative killing mechanisms of the phagocyte.[55] It is somewhat surprising how often one fails to identify the infecting organism in CGD—perhaps greater than half the time despite aggressive culturing. In this situation, one treats empirically with the antibiotic that ought to work and if it fails, one then aggressively pursues more invasive diagnostic procedures looking for one (or more) of the less commonly seen microbes such as *Nocardia* species, *Candida*, atypical mycobacteria, and a host of other bacteria and fungi (see Table 50–3). Other unusual organisms that cause infection in CGD include other members of the Burkholderia family,[56,57] including *B. cenocepacia*, *B. gladioli*, and *B. Mallei* (the causative agent in melioidosis, a septic illness common in East Asia) and *Chromobacterium violaceum*, found in brackish fresh water and which can cause a febrile illness with bacteremia in CGD.[58] A previously unknown gram-negative bacteria, *Granulobacter bethesdensis*, was recently identified in a CGD patient with recurrent fevers associated with chronic necrotizing deep lymphatic infection.[59] This organism appears to be a member of the Acetobacteraceae family, which has previously not been linked to invasive human disease.

Pneumonia is the most common type of infection seen in CGD with *S aureus*, *Aspergillus* species, *B cepacia*, and enteric gram negatives as the major pathogens. It is noteworthy that *B cepacia* has

Table 50–3 Infections in Chronic Granulomatous Disease

Infections	% of Infections	Infecting Organisms
Pneumonia	70–80	*Aspergillus, Staphylococcus, B cepacia, Pseudomonas, Nocardia, Mycobacterium* (including atypical), *Serratia, Candida, Klebsiella, Paecilomyces*
Lymphadenitis	50–60	*Staphylococcus, Serratia, Candida, Klebsiella, Nocardia*
Cutaneous infections/impetigo	50–60	*Staphylococcus, Serratia, Aspergillus, Klebsiella, Candida*
Hepatic/perihepatic abscesses	20–30	*Staphylococcus, Serratia, Streptococcus viridans, Nocardia, Aspergillus*
Osteomyelitis	20–30	*Serratia, Aspergillus, Paecilomyces, Staphylococcus, B cepacia, Pseudomonas, Nocardia*
Perirectal abscesses/fistulae	15–30	Enteric gram-negative organisms, *Staphylococcus*
Septicemia	10–20	*B cepacia, Pseudomonas, Salmonella, Staphylococcus, Serratia, Klebsiella*
Urinary tract infections/pyelonephritis	5–15	Enteric gram negatives
Brain abscesses	<5	*Aspergillus, Staphylococcus*
Meningitis	<5	*Candida lusitaniae, Hemophilus influenzae, B cepacia*

The relative frequencies of different types of infections in CGD are estimated from data pooled from several large series of patients in the United States, Europe, and Japan: (a) Mouy R, Fischer A, Vilmer E, Seger R, Griscelli C: Incidence, severity, and prevention of infections in chronic granulomatous disease. J Pediatr 114:555, 1989; (b) Bemiller LS, Roberts DH, Starko KM, Curnutte JT: Safety and effectiveness of long-term interferon gamma therapy in patients with chronic granulomatous disease. Blood Cells Mol Dis 21:239, 1995; (c) Forrest CB, Forehand JR, Axtell RA, Roberts RL, Johnston RB Jr: Clinical features and current management of chronic granulomatous disease. Hematol Oncol Clin North Am 2:253, 1988; (d) Hitzig WH, Seger RA: Chronic granulomatous disease, a heterogeneous syndrome. Hum Genet 64:207, 1983; (e) Tauber AI, Borregaard N, Simons E, Wright J: Chronic granulomatous disease: A syndrome of phagocyte oxidase deficiencies. Medicine (Baltimore) 62:286, 1983; (f) Cohen MS, Isturiz RE, Malech HL, et al: Fungal infection in chronic granulomatous disease. The importance of the phagocyte in defense against fungi. Am J Med 71:59, 1981; (g) Hayakawa H, Kobayashi N, Yata J: Chronic granulomatous disease in Japan: A summary of the clinical features of 84 registered patients. Acta Paediatr Jpn 27:501, 1985; (h) Johnston RB, Newman SL. Chronic granulomatous disease. Pediatr Clin North Am 24:365, 1977. These series encompass approximately 550 patients with CGD after accounting for overlap between reports. Unpublished data from the United States CGD Registry encompassing 368 patients was also used to estimate the relative frequencies of infections and the responsible organisms. The infecting organisms are arranged in approximate order of frequency for each type of infection. Note: *Burkholderia cepacia (B cepacia)* was previously classified as *Pseudomonas cepacia.*

emerged as a particularly lethal organism in CGD.[17,60] This organism often is not covered with the first line of antibiotics used for *S aureus* and most gram negatives, and can quietly proliferate (with persistent fevers) to the point of quick, explosive collapse due to endotoxic shock. Intravenous trimethoprim-sulfamethoxazole has been most effective in treating patients if given before widespread dissemination of the infection. An open lung biopsy is often needed to establish the diagnosis. *Aspergillus* pneumonia is also difficult to treat, but usually responds to 3 to 6 months of daily (then thrice weekly) amphotericin B therapy (with interferon gamma). Surgery has generally not been needed except for biopsy or resection of large cavitary lesions.

Lymphadenitis is the second most common infection and is usually caused by gram negatives, *S aureus*, or *Serratia marcescens*. Incision and drainage should not be delayed if the lesion fails to respond to parenteral antibiotics. Cutaneous abscesses should be similarly managed. Recurrent perinatal impetigo is almost a signature infection in CGD and often requires months of therapy (mostly oral antibiotics) to clear. Hepatic (and perihepatic) abscesses are also common in CGD and are usually, but not always, caused by *S aureus*.[61,62] Most lesions require drainage (needle or surgical) to permit efficient healing to occur. Bone infections, most commonly due to *Serratia* species or *Aspergillus*, are particularly problematic in CGD and arise from either hematogenous or contiguous spread (as often is the case with *Aspergillus* infections in the lung invading ribs, vertebral bodies, or the diaphragm).[17,63] Perirectal abscesses are difficult to treat even with months of therapy and can lead to fistula formations.

Chronic inflammation with granuloma formation is a distinctive hallmark of CGD and contributes to some of its more problematic complications. In some cases, this results from imperfectly controlled infections in which stalemates develop between the pathogen and the patients' leukocytes. These lesions become granulomas as the host employs lymphocytes and activated macrophages to assist in containing the pathogens. However, this complication is not always clearly linked to persistent infection, and in these cases has been speculated to involve a dysregulated inflammatory response and/or inefficient degradation of debris.[64–66] In the absence of oxidant production, excessive production of cytokines and delayed neutrophil apoptosis at inflammatory sites appear to contribute as underlying mechanisms.[66–68]

As a result of persistent inflammatory stimulation, CGD patients can suffer from a variety of more chronic complications (Table 50–4). Lymphadenopathy, hepatosplenomegaly, eczematoid dermatitis and anemia of chronic disease (hemoglobin levels usually 8–10 g/dL) are common manifestations of this process and are most prominent in the first 5 to 10 years of life in CGD. Throughout the body, granuloma formation can lead to dysfunction and obstruction in the esophagus,[69] intestine,[70] and urinary bladder and kidneys.[71–74] In the stomach, the gastric antral narrowing can be severe enough in infants and children to resemble pyloric stenosis. Inflammatory involvement of the gastrointestinal tract can be seen in up to one-third of CGD patients, typically in association with the X-linked form.[75] A chronic ileocolitis resembling Crohn disease occurs in about 10% of patients and can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can necessitate a colectomy.[17,61,75,76] Other types of chronic inflammation include gingivitis, chorioretinitis, destructive white matter lesions in the brain,[77] and glomerulonephritis.[17,78] Occasional patients may develop either discoid or systemic lupus erythematosus, sarcoidosis, or rheumatoid arthritis.[17,19,79] The underlying mechanisms are poorly defined although recent studies suggest that these manifestations may be in part related to subtle defects in the absence of the NADPH oxidase in memory B cells[80] or T cells.[81]

Carriers of CGD, whether the X-linked form or any one of the autosomal recessive forms, are usually asymptomatic, with two important exceptions. First, about one-fourth of X-linked carriers are at risk of developing mild to moderately severe discoid lupus erythematosus characterized by discoid skin lesions and photosensitivity.[82–84] The onset is usually in the second decade of life. The disease does not progress to systemic lupus nor does one find serologic evidence of even subclinical disease. Severe discoid lupus can be treated with hydroxychloroquine (Plaquenil). Recurrent stomatitis or significant gingivitis, or both, have also been noted in as many as half of X-CGD carriers.[25] A few will also suffer from arthralgias, polyarthritis, and Raynaud phenomenon. The second important complication of the X-linked CGD carrier state is serious infection in those women who

Table 50–4 Chronic Conditions Associated With Chronic Granulomatous Disease

Condition	Relative Frequency (%)
Lymphadenopathy	98
Hypergammaglobulinemia	60–90
Hepatomegaly	50–90
Splenomegaly	60–80
Anemia of chronic disease	Common*
Underweight	70
Chronic diarrhea	20–60
Short stature	50
Gingivitis	50
Dermatitis	35
Hydronephrosis	10–25
Granulomatous ileocolitis	10–15
Gastric antral narrowing	10–15
Ulcerative stomatitis	5–15
Granulomatous cystitis	5–10*
Pulmonary fibrosis	<10*
Esophagitis	<10*
Granulomatous cystitis	<10
Chorioretinitis	<10
Glomerulonephritis	<10
Discoid lupus erythematosus	<10

The relative frequencies of chronic conditions associated with CGD were estimated from the series of reports listed in Table 50–3. In some instances (asterisks), the incidence is estimated from the 50 cases of CGD followed at Scripps Research Institute and Stanford University (unpublished data).

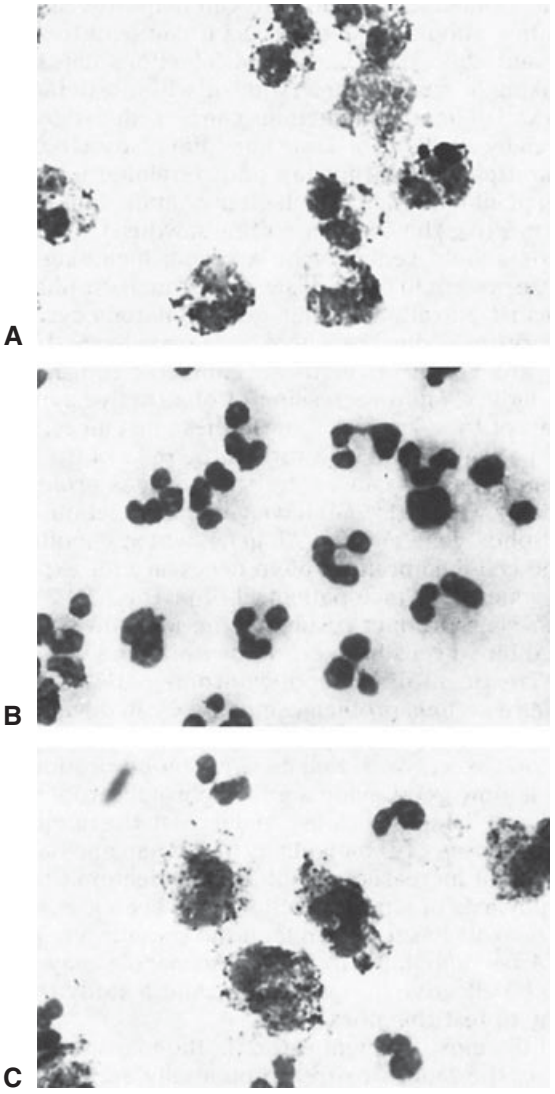

Figure 50–4 Nitroblue tetrazolium (NBT) slide test. Peripheral blood neutrophils and monocytes from a drop of fresh whole blood were made adherent to glass slides and stimulated with phorbol myristate acetate. **A**, Normal neutrophils and monocytes, all of which are NBT-positive. **B**, Neutrophils and monocytes from an X-linked CGD patient, which are all NBT-negative. **C**, A mixture of NBT-positive and NBT-negative neutrophils from the X-linked carrier mother of the patient in part **B**. CGD, chronic granulomatous disease.

have a usually high degree of inactivation of the normal X chromosome in their myeloid cells. If the circulating neutrophil population is skewed to the point that fewer than 10% to 15% of the cells function, then the carrier has an increased risk of bacterial infections that in some cases have been severe.[85–87] Those with fewer than 5% oxidase positive cells have full-blown CGD.

Diagnosis

The diagnosis of CGD is usually suggested by the unusual clinical histories outlined above or by a family history of CGD. The nitroblue tetrazolium (NBT) slide test on fresh blood is the classic diagnostic test.[24] A typical result is shown in Fig. 50–4. Figure 50–4A shows the normal positive staining of a group of seven neutrophils and one monocyte. Figure 50–4B shows the complete absence of NBT staining in a patient with X91° CGD, the classic X-linked form of the disease. Figure 50–4C shows the mixed population of NBT-positive and NBT-negative cells observed in that patient's mother, reflecting random X-chromosome inactivation. Because in this test nearly 100% of the normal cells are positive, the carrier state in X-linked CGD can be detected when as few as 5% of the cells are NBT-negative. This test also permits detection of diffuse populations of weakly positive cells such as those seen in X91$^-$ CGD, which are characterized by a partial deficiency of flavocytochrome *b*. Because X-linked CGD can arise by new mutations in the maternal germ line, one does not always see NBT-negative cells in the mother. Flow cytometric assays of oxidase activity, such as those based on the conversion of dihydroxyrhodamine 123 (DHR) to rhodamine 123,[88,89] can also provide both quantitative measurements of oxidant generation and the cell-by-cell distribution of activity. The DHR 123 assay for oxidase activity is now available in many referral centers and through reference laboratories. In addition to X91$^-$ CGD neutrophils, weak staining in the NBT test or a small but measurable level of DHR fluorescence can be seen in A47° cells because of a small amount of residual oxidant production. Regardless of diagnostic assay employed, it is important to have these tests performed on appropriately handled blood samples and by experienced laboratories to avoid inconclusive or false normal results.

Genetic classification is useful primarily for purposes of genetic counseling and prenatal diagnosis. With the exception of classic X-linked disease in a male whose mother is a carrier, determining the specific oxidase gene affected in a given CGD patient (Table 50–1) requires additional laboratory studies. Genetic testing for all four genetic subgroups is now commercially available. Prenatal diagnosis can be performed using fetal DNA from the chorionic villus or amniocytes, or by in utero fetal blood sampling and NBT slide test

Table 50–5 Efficacy of Interferon (IFN)-γ in Preventing Serious Infections in Chronic Granulomatous Disease

	Clinical Study				
Variable	Phase III Placebo[a]	Phase III IFN-γ[a]	Phase IV (U.S.) IFN-γ[b]	Phase IV (Europe) IFN-γ[c]	Phase IV IFN-γ[d]

analysis of fetal neutrophils.[2,17] Laboratories specializing in neutrophil biochemistry can also perform immunoblot analysis of neutrophil extracts, flavocytochrome *b* spectroscopy, and/or functional analysis of membrane and cytosol fractions in the cell free oxidase assay. In a male with absent flavocytochrome *b* without clear evidence for a maternal carrier, it is necessary to search for the mutation in both the gp91^{phox} and p22^{phox} genes by DNA sequencing or another method of analysis.

Prognosis and Treatment

The cornerstones of therapy in CGD are currently (a) prevention and early treatment of infections; (b) aggressive use of parenteral antibiotics for most infections; (c) use of prophylactic trimethoprim/sulfamethoxazole (5 mg/kg/day of trimethoprim) or dicloxacillin (25–50 mg/kg/day) for sulfa-allergic patients; (d) prophylactic itraconazole (200 mg daily if 13 years of age or older or if weighing at least 50 kg, or 100 mg daily if less than 13 years of age or weighing less than 50 kg), and (e) use of prophylactic recombinant human gamma-interferon (rIFN-γ) (0.05 mg/m^2 or 0.0015 mg/kg if <0.5 m^2 three times per week). Using these guidelines, the prognosis for patients afflicted with CGD has improved dramatically since the disorder was first described in the 1950s, at which time almost all patients died in childhood.[21,22] In a large study based on data collected by a CGD registry in the United States in the 1990s, the overall mortality was estimated to be 5% per year for X-CGD and 2% per year for autosomal recessive CGD.[17] A more recent single-institution study on seventy-six patients reported an overall mortality rate of 1.5% per year.[90] There is a general consensus that a large majority of newly diagnosed children should survive well into their adult years with aggressive and careful management. As already noted, patients with deficiency of p47^{phox} have a tendency for milder disease compared to those with flavocytochrome-negative CGD. On the other hand, there are some patients (usually X-linked) that prove to have more frequent serious infections and/or inflammatory complications, likely due to the effects of modifier genes, who may warrant more aggressive treatment such as bone marrow transplantation (see below).

Several approaches can be used to prevent infections. Patients with CGD should receive all their routine immunizations on schedule (including live virus vaccines), with influenza vaccine administered each year as well. Cuts and skin abrasions should be cleansed promptly with soap and water and a topical antiseptic applied (2% hydrogen peroxide and/or povidone-iodine ointment). Frequent brushing, flossing, and professional cleaning of teeth can help prevent gingivitis. Constipation should be avoided as it can lead to rectal/anal fissures and abscesses. Early anal infections can be treated with soaking in soapy water (with or without Betadine). The frequency of pulmonary infections can be reduced by not using commercially available bedside humidifiers, by avoiding smoking (cigarettes and marijuana), and refraining from handling decaying plant materials, which often contain numerous *Aspergillus* spores (eg, hay, mulch, rotting sawdust).[91]

There is clear evidence that chronic prophylactic trimethoprim/sulfamethoxazole can decrease the number of bacterial infections in CGD patients by more than half without a concomitant increased risk of fungal infection.[92,93] In addition, itraconazole has recently been shown to be an effective agent for prophylaxis for fungal infections in CGD, as studied in a randomized, double-blind, placebo-controlled study.[94] Liver function tests should be monitored on patients receiving itraconazole.

Prophylactic rIFN-γ is another mainstay of current management of CGD. The clinical benefit of rIFN-γ is probably related to generally enhanced phagocyte function and killing by nonoxidative mechanisms, because its use is not accompanied by any measurable improvement in NADPH oxidase activity in the vast majority of CGD patients.[95] In a multicenter trial, patients were randomized in a double-blind fashion to receive either placebo or rIFN-γ (0.05 mg/m^2 three times per week).[96] As summarized in Table 50–5, there was a substantial decrease in the number of serious infections in the rIFN-γ arm. Side effects were observed in some of the patients, but typically restricted mild fever and flu-like symptoms. No additional adverse reactions, including any increased incidence of chronic inflammatory complications, have been noted with more prolonged courses of prophylactic rIFN-γ (more than 10 years) and the patients continue to have a substantial benefit with fivefold fewer serious infections compared to the placebo group in the Phase III study in Table 50–5.[90,97,98] On average, this group of patients is averaging one serious infection per patient every 4 to 5 years.

One of the most frequent errors in the management of CGD patients is the failure to treat potentially serious infections promptly and aggressively with appropriate parenteral antibiotics. Even the best antibiotics can be rendered ineffective if given too late in the course of an infection in CGD. Therefore, early intervention is advisable. Although many of the minor infections and low-grade fevers in CGD patients can be managed on an outpatient basis, episodes of consistently high fever over a 24-hour period or clearly established infections (such as pneumonia or lymphadenitis) should be treated with parenteral antibiotics that cover, at least initially, *S aureus* and enteric gram negatives. Reasonable attempts to define the source of the infection and the responsible microbe should also begin promptly. Monitoring the erythrocyte sedimentation rate (ESR) can be very useful, both as a clue to the presence of a significant infection as well

as following the patient's response to therapy. If the patient fails to respond, then more aggressive diagnostic procedures should be instituted (CT, bone, and gallium scans; open biopsies if indicated) and empirical changes in the antibiotics used to broaden coverage to *Pseudomonas cepacia*. If fungus is identified or strongly suspected, amphotericin B has been the drug of choice in the past, although newer azole antifungal agents such as voriconazole are supplanting its use.[99–101] Even with appropriate antibiotics, certain types of infections respond slowly and may require months of therapy, particularly *Aspergillus* infections. In this instance, 4 to 12 months of parenteral antifungal therapy followed by a 1- to 3-year course of daily oral itraconazole has been effective in clearing most infections and preventing their recurrence. Surgical drainage or resection can sometimes play a key role in accelerating healing of certain types of infection such as lymphadenitis, osteomyelitis, and abscesses of visceral organs such as the liver or lung. Finally, granulocyte transfusions may be of benefit in the treatment of stubborn or life-threatening infections.[17,102,103]

Use of corticosteroids should generally be avoided, including extensive topical use, except in cases of severe asthma, esophageal strictures, gastric antral narrowing, granulomatous cystitis, or inflammatory bowel disease. There is clear evidence that corticosteroids are beneficial in these clinical settings as the steroids induce rapid regression of obstructive symptoms at low oral doses (eg, 1 mg/kg/day of prednisone).[75,104] In these cases the physician and patient should be aware of the risks of the additional immunosuppression caused by the corticosteroids.

Rare patients with X91° CGD have genomic deletions that span the gp91^{phox} gene and the Xk gene, which encodes a membrane protein necessary for expression of the Kell genes.[105] Absence of the Xk gene product results in the McLeod syndrome, in which red blood cells have weak Kell antigens and variable acanthocytosis, along with nerve and muscle disorders related to its expression in nonerythroid tissues.[105,106] Transfusion of McLeod syndrome patients poses a serious problem, because they can develop alloantibodies of wide specificity that can preclude any further transfusions except with Kell-negative blood products.

Allogeneic bone marrow transplantation can be used to treat CGD and has been successfully employed.[107–111] However, because of the risks associated with this procedure, marrow transplantation is generally considered only for those patients who have a fully HLA-matched sibling and frequent and severe infections despite aggressive medical management. Reduced-intensity conditioning regimens for allogeneic transplantations have recently been used for bone marrow transplantation in CGD, including several cases with ongoing fungal infections.[108,111,112] Cord blood transplants have also been reported.[113,114] Graft-versus-host disease can be a significant problem for adult patients.[108] Finally, genetic therapies aimed at correcting the defective gene in bone marrow stem cells hold promise for the future, if obstacles can be solved to achieve effective and safe gene delivery with prolonged expression of delivered genes.[19,115,116] Observations on female carriers of X-linked CGD with skewed X-inactivation and preclinical studies in murine CGD models suggest that complete correction of NADPH oxidase activity in 10% of circulating neutrophils will lead to clinically relevant improvements in host defense.[20]

Neutrophil Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH, the primary substrate for the respiratory burst oxidase, is generated by the first two reactions of the hexose monophosphate shunt pathway, which are catalyzed by glucose-6-phosphate dehydrogenase (G6PD) (Fig. 50–2, reaction 8) and 6-phosphogluconate dehydrogenase (6PGD).[14] The leukocyte and erythrocyte G6PD are encoded by the same gene. Thus, a severe deficiency of G6PD in neutrophils can result in a greatly attenuated respiratory burst because of low levels of NADPH. However, the vast majority of individuals with inherited G6PD deficiency do not have problems with a decreased respiratory burst or recurrent infections. A CGD-like syndrome has very rarely been observed in G6PD-deficient patients who have congenital nonspherocytic hemolytic anemia (CNSHA), where hemolysis occurs in the absence of redox stress.[14,117–120] Even in CNSHA, most G6PD mutations cause the enzyme to decay over a period of days and weeks, so that levels in the short-lived neutrophil usually do not become critically low, even in some of the most unstable G6PD variants. A few rare and poorly understood G6PD mutations that cause CNSHA are associated with extremely low (less than 5% of normal) levels of G6PD in the neutrophil, resulting in a deficient respiratory burst and CGD-like symptoms. The combination of chronic, severe hemolytic anemia, recurrent infections, and the laboratory demonstration of extremely low G6PD levels in neutrophils and erythrocytes serves to distinguish this disease from CGD. The treatment for neutrophil G6PD deficiency is the same as for CGD except that the efficacy of rIFN-γ has not been demonstrated in the former. The chronic hemolytic anemia is treated by supportive means, including transfusions.

Disorders of Glutathione Metabolism

As depicted in Fig. 50–2 (reaction 6), the reduced form of glutathione (GSH) serves to protect the neutrophil from the harmful effects of hydrogen peroxide on NADPH oxidase and other neutrophil proteins such as microtubules.[121,122] Adequate intracellular levels of reduced glutathione are maintained by recycling oxidized glutathione (GSSG) to GSH by glutathione reductase (Fig. 50–2, reaction 7) as well as by de novo synthesis of glutathione by glutathione synthetase (Fig. 50–2, reaction 9). Severe deficiencies in either of these enzymes are extremely rare and are apparently inherited in an autosomal recessive manner. In the case of glutathione reductase deficiency, the respiratory burst terminates prematurely, presumably owing to the toxic effects of accumulating hydrogen peroxide on NADPH oxidase.[123] This brief burst of O_2^-, however, appears to be sufficient for adequate microbial killing, because the few patients reported have not had problems with recurrent infections.[124] However, they do have a congenital hemolytic anemia during periods of oxidant stress owing to diminished levels of glutathione reductase in erythrocytes.[124] In glutathione synthetase deficiency, the respiratory burst proceeds normally.[122] Patients have a severe metabolic acidosis as a result of elevated levels of 5-oxoproline, which is the product of the first step in glutathione synthesis and is present in increased levels because of a lack of feedback of GSH on the synthetic pathway. Patients with glutathione synthetase deficiency also have intermittent neutropenia[125] (perhaps caused by the acidosis) as well as oxidant-induced hemolysis.[122] There are mild problems with recurrent infections. Therapy with vitamin E (400 IU/day) has been found to be beneficial in patients with severe glutathione synthetase deficiency suffering from hemolysis and infections.[125]

Myeloperoxidase Deficiency

Myeloperoxidase (MPO) deficiency is the most common inherited disorder of phagocytes, but is almost always asymptomatic.[126,127] MPO is present in azurophilic granules of neutrophils and monocytes, and catalyzes the production of a potent antimicrobial agent, hypochlorous acid (HOCl) from chloride and hydrogen peroxide (Fig. 50–2, reaction 4).[13] HOCl in turn reacts with a variety of primary and secondary amines to form chloramines, some of which can be toxic. Moreover, HOCl is capable of activating latent metalloproteinases (eg, collagenase) and inactivating antiproteinases.

Complete MPO deficiency is seen in approximately 1 in 4000 individuals, and partial deficiency is even more common (1 in 2000 persons).[126,127] The key features of MPO deficiency are summarized in Table 50–6. The disorder is inherited in an autosomal recessive manner. In the few cases reported, several different mutations have been identified, which generally appear to affect the posttranslational processing of a precursor polypeptide for MPO.[126,128,129] Acquired

Table 50–6 Summary of Myeloperoxidase (MPO) Deficiency

Incidence	1 in 2000 (partial deficiency) 1 in 4000 (total deficiency)
Inheritance	Autosomal recessive with variable expression; MPO gene on chromosome 17 at q22–q23
Molecular defect	Defective posttranslational processing of an abnormal MPO precursor polypeptide; eosinophil peroxidase encoded by different gene and levels normal
Pathogenesis	Partial or complete MPO deficiency leads to diminished production of HOCl and HOCl-derived chloramines; MPO products are necessary for rapid killing of microbes (especially *Candida*) but not absolutely required
Clinical manifestations	Usually clinically silent Disseminated candidiasis/fungal disease (rare; usually in conjunction with diabetes mellitus) Acquired deficiency in M2, M3, and M4 acute myeloid leukemias (AMLs) and myelodysplasia
Laboratory evaluation	Deficiency of neutrophil/monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal, killing of bacteria in vitro Failure to kill *Candida albicans* and hyphal forms of *Aspergillus fumigatus* in vitro
Differential diagnosis	Acquired partial MPO deficiency seen in M2, M3, and M4 AML, myelodysplastic syndromes, and Batten disease
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetics
Prognosis	Usually excellent

forms of MPO deficiency are also seen. The gene that encodes for MPO is located on chromosome 17 at q22–q23 near the breakpoint for the 15–17 translocation of promyelocytic leukemia. Subpopulations of MPO-deficient cells can be seen not only in the M3 (promyelocytic) form of acute myeloid leukemia but also in the M2 and M4 forms.[126,114] MPO-deficient cells are also seen in approximately 25% of patients with chronic myeloid leukemia and myelodysplastic syndromes.[130–132]

One of the most curious features of MPO deficiency is the remarkable lack of clinical symptoms in affected persons, given the prediction that severe MPO deficiency would cripple important antimicrobial reactions catalyzed by HOCl. In vitro, an impressive defect in killing *Candida albicans* and hyphal forms of *Aspergillus fumigatus* is observed.[127,133,134] Bacterial killing in vitro is also abnormal in being somewhat slower than normal, but eventually it is complete. MPO-deficient mice also exhibit abnormalities in host defense against Candida and Klebsiella.[135,136] Excessive or unusual infections in MPO-deficient patients, however, are uncommon, except for rare individuals who also suffer from diabetes mellitus.[126,127] In these individuals, disseminated fungal infections (usually candidiasis) are seen.

The discrepancy between the in vitro and in vivo manifestations of MPO deficiency in most patients can be explained in several ways. First, the respiratory burst in MPO-deficient neutrophils is substantially augmented, presumably from the absence of HOCl-mediated toxic effects on the NADPH oxidase.[126] Second, other products of the respiratory burst, together with the oxygen-independent antibacterial proteins, appear to have sufficient potency to compensate for the loss of MPO-dependent reactions. Finally, residual amounts of MPO coupled with the normal levels of eosinophil peroxidase may provide at least some degree of peroxidative activity at the sites of infection.

Treatment is usually not required for MPO deficiency except in those individuals suffering from fungal infections. In these patients aggressive use of antifungal antibiotics is indicated. The prognosis is excellent in the majority of patients with MPO deficiency.

DISORDERS OF PHAGOCYTE ADHESION AND CHEMOTAXIS

Since 1970 numerous investigators have found in vitro chemotactic abnormalities in neutrophils from patients suffering from a wide variety of clinical disorders associated with increased susceptibility to bacterial and fungal infections.[131,132,137–139] In most circumstances the chemotactic abnormality identified was only marginal and not always clearly related to the clinical status of the patient. In other instances, clear and major defects were identified in vitro that correlated with the in vivo propensity for infection. Extensive classification systems have been devised to categorize the numerous acquired defects in chemotaxis,[140] and several reviews are available on this subject.[4,140,141] The problem in many of these reports is that it is unclear whether the infections were caused by the in vitro chemotactic abnormality or by the medical complications of the underlying disorder (eg, acidosis, malnutrition, or exposure to nosocomial infections). A further complicating factor is that there are inherent limitations in the in vitro chemotaxis assay, which is subject to laboratory artifacts both as a result of neutrophil purification procedures as well as the assay itself. Furthermore, the extent to which these in vitro chemotactic assay systems faithfully reflect prevailing in vivo conditions is not known. Our understanding of chemotactic disorders has been hampered by the limitations of these assays, just as the elucidation of respiratory burst defects was obscured when the major available assay was in vitro bacterial killing. In this section the most important and best characterized of the chemotactic disorders, leukocyte adhesion deficiency, will be discussed in detail. A brief discussion of several other clinically significant chemotactic disorders will also be provided.

Leukocyte Adhesion Deficiency Type I

Leukocyte adhesion deficiency type I (LAD I) is a rare autosomal recessive disorder of leukocyte adhesion, chemotaxis, and ingestion of C3bi-opsonized microbes as a result of decreased or absent expression of the leukocyte β_2 integrins (Table 50–7).[142–145] The hallmark of LAD I is the occurrence of repeated, often-severe bacterial and fungal infections without the accumulation of pus despite persistent granulocytosis (Table 50–7). The molecular basis for LAD was first suggested by Crowley and colleagues, who found that neutrophils from a patient with this clinical syndrome lacked a high-molecular-weight membrane glycoprotein.[146] The patient's neutrophils could not be made to adhere to plastic surfaces or to respond to serum-opsonized particles in terms of ingestion and respiratory burst activity.[146] Several other reports quickly followed, which described other patients in whom a similar glycoprotein was missing.[147,148] In 1984, it was found that the missing glycoprotein was actually a group of three closely related glycoproteins with molecular weights ranging from 95 kd (the β2 subunit) to 150 to 180 kd (three distinct α subunits) that form three types of α–β heterodimers.

The molecular basis of LAD I is now known to result from mutations in the gene for the common CD18 β2 subunit for these three leukocyte glycoproteins, now termed β2 integrins, that belong to the integrin superfamily of adhesion molecules.[133,134,149,150] Integrins are noncovalently linked heterodimeric glycoproteins consisting of an α and a β subunit. Within each of the eight known integrin subfamilies the β subunit is identical (and defines the subfamily) whereas the α

Table 50–7 Summary of Leukocyte Adhesion Deficiency Type I (LAD 1)

Incidence	Approximately 60 patients described in literature
Inheritance	Autosomal recessive
Molecular defect	An absent, diminished, or structurally abnormal β subunit (CD18) caused by one of several types of mutations in the β gene; in the absence of a normal β subunit, the three types of α chains in the β_2 integrin subfamily (CD11a, b, c) cannot assemble into normal α-β heterodimers
Pathogenesis	All three β_2 integrins (CD11a/CD18, CD11b/CD18, and CD11c/CD18) are deficient on all leukocytes, causing multiple abnormalities in cell function: adherence, chemotaxis, and C3bi-mediated ingestion/degranulation/respiratory burst
Clinical manifestation	Persistent granulocytosis (neutrophil count of 12,000–100,000/mm^3) Severe or moderate phenotypes depending on severity of deficiency Recurrent pyogenic infections with absent neutrophil infiltration Delayed umbilical cord separation Severe gingivitis/periodontitis
Laboratory evaluation	Flow cytometric measurement of surface CD11b in stimulated neutrophils with monoclonal anti-CD11b
Differential diagnosis	Chronic Granulomatous Disease May be associated with severe neutrophil actin dysfunction
Therapy	Bone marrow transplant in clinically severe patients (CD11b <0.3% of normal) Aggressive use of parenteral antibiotics Possible benefit of prophylactic trimethoprim/sulfamethoxazole
Prognosis	Severe: high incidence of death before 2 years Moderate: Can survive into twenties and thirties but with recurrent infections

subunit varies and confers the functional specificity on the integrin. The molecular defect in LAD involves all members of the β2 integrin subfamily: αL β2 (CD11a/CD18), αm β2 (CD11b/CD18), and αx β2 (CD11c/CD18).[142,143,151] CD11a/CD18 is often referred to as LFA-1 whereas CD11b/CD18 is also called Mac-1, Mo1, or CR3. In the dozens of patients with LAD who have been studied thus far at the molecular level, an absent, diminished, or structurally abnormal β2 subunit (CD18) has been identified.[152] In the absence of a normal β subunit, the three types of α chains in the β2 integrin subfamily cannot assemble into normal α–β heterodimers. Thus, all three β2 integrins are moderately to severely deficient on all leukocytes in LAD.

The β2 integrins serve as receptors for the opsonic complement fragment C3bi, the intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2) that are expressed on endothelial cells and leukocytes, and fibrinogen.[142] The diminished or absent expression of β2 integrins in LAD I leukocytes results in the failure of phagocytes to emigrate from the bloodstream to sites of infection.[153] The early interactions with the endothelium, termed *rolling*, are normal in LAD I, as these are mediated by a different family of adhesion molecules known as selectins.[153] However, β2 integrins are responsible for the subsequent tight binding of neutrophils and monocytes to cytokine-activated endothelium, and this step is therefore severely defective in LAD I. Transendothelial migration is also impaired. A second major functional defect in LAD is the failure of phagocytes to bind C3bi opsonized microbes. Because CD11b/CD18 is the predominant phagocyte receptor for this complement fragment, C3bi-mediated ingestion, degranulation, and respiratory burst activity are severely affected in LAD.[142] Finally, β2 integrin-dependent signals play a key role in activating neutrophils for enhanced migration, phagocytosis of antibody-opsonized microbes, and degranulation.[154,155]

Despite in vitro defects in lymphocyte responses dependent on LFA-1 (CD11a/CD18), patients with LAD I rarely have clinical manifestations related to impaired lymphocyte function.[143,149,151] It is believed that the role CD11a/CD18 plays in lymphoid cell function can be compensated by other adhesion proteins (CD2, CD4, CD8, etc).[142]

Molecular Genetics of Leukocyte Adhesion Deficiency Type I

The fact that LAD I involves a deficiency of all leukocyte β2 integrins focused attention on the common β2 chain (CD18), and mutations in the corresponding gene have been identified in all LAD I patients who have been analyzed at the molecular level to date. Although expression of the leukocyte integrin α subunits is normal in LAD I, these are not transported to the cell surface because the β2 chain is absent or contains mutations that disrupt its structure or its interaction with the α subunit. Mutations in the α subunits have not been found thus far in patients with LAD I. The gene encoding CD18 is located on the long arm of chromosome 21 at position q22.3 (the genes for β2 integrin α subunits are clustered on chromosome 16p11.1-p13).[142,156] The CD18 glycoprotein has a large extracellular domain at the N terminus, a single transmembrane domain, and a 46-residue cytoplasmic tail. As with X-linked CGD, CD18 mutations in LAD I are heterogeneous in nature, family-specific, and can lead to either undetectable or low (9%–20% of normal) levels of α–β dimer expression that correlates with the clinical severity of the disease. More than 30 different mutations have now been characterized in more than 35 patients.[2,133,143,152] These include missense mutations, mRNA splicing defects, small deletions, and a premature termination signal. Many patients are compound heterozygotes, and have two different mutant alleles for CD18. About one-half of patients with LAD I in whom the genetic defect has been identified have point mutations in a stretch of 250 amino acids in the extracellular domain of CD18. This region is highly conserved among all β subunits, and appears to be important for interaction with the α subunit.

Clinical Features

The key features of LAD I are summarized in Table 50–7. The clinical presentation of LAD is heterogeneous and is related to the severity of the deficiency of the β2 integrins. The severe clinical phenotype is associated with less than 0.3% of the normal amount of these glycoproteins on the leukocyte surface, whereas the moderate phenotype has 2.5% to 6% of normal levels.[157] In both the severe and moderate forms of the disease, persistent granulocytosis (neutrophil count of 12,000–100,000/mm^3) is a constant finding, as are recurrent cutaneous abscesses and aggressive periodontitis and/or gingivitis.[143,149,151,158,159] Additional clinical features seen more often in the severe clinical phenotype include delayed umbilical cord separation, omphalitis, perirectal cellulitis, severe ulcerative stomatitis, and bacterial sepsis. A striking finding in LAD I is that abscesses and other sites of infections are devoid of pus despite the marked neutrophilia, because neutrophils are unable to emigrate to tissues. *S aureus* and gram-negative enteric bacteria cause the majority of infections in LAD I. Fungal infections can also occur, in particular from *Candida albicans* and *Aspergillus* species.

Note that infants with delayed separation of the umbilical cord who are healthy and have normal blood counts are very unlikely to

have LAD I. Although the mean age of cord separation ranges from 7 to 15 days, 10% of healthy infants can have cord separation at 3 weeks of age or later.[160,161]

Diagnosis

The diagnosis of LAD I is made by flow cytometric measurement of surface CD11b (Mac1) (or the shared CD18 subunit) in unstimulated and stimulated neutrophils using commercially available monoclonal antibodies directed against CD11b or CD18.[142,162] Neutrophils contain an intracellular pool of CD11b/CD18 in their secondary (specific) and tertiary granules, which can be mobilized to the cell surface during stimulation.[142,163] Therefore, the deficiency of CD11b can be more dramatically demonstrated by using stimulated neutrophils. Carriers of LAD I can be identified by this method, because they have been found to express approximately 50% of normal levels of CD11b on the surface of their stimulated neutrophils.[157,163]

Prognosis and Treatment

Treatment for LAD I depends on the clinical severity of the disorder. In those patients with the moderate clinical phenotype, cutaneous and oral infections can be managed as they occur. The use of prophylactic antibiotics such as trimethoprim/sulfamethoxazole appears to be beneficial, as does aggressive prophylactic treatment of periodontal disease. It is important to note that even patients with the moderate phenotype can die of overwhelming infection.[142,157,162] In patients with severe LAD I, aggressive management is indicated because of the high incidence of death before the age of 2 years, and bone marrow transplantation is recommended.[19,109,142,164–167] Graft versus host disease can be problematic.[164,167,168] LAD I should also be amenable to gene replacement therapy in the future, and studies in canine LAD suggest that restoring CD18 expression to even approximately 10% of leukocytes will improve the clinical symptoms.[19,169]

Leukocyte Adhesion Deficiency Types II and III

LAD II is a very rare clinical syndrome closely related to LAD I, but caused by a defect in selectin-mediated adhesion events due to a deficiency in leukocyte sialyl Lewis X ligands. It was first reported by Etzioni and colleagues in two unrelated boys of Moslem Arab origin, and since described in a total of five individuals (four Arab and one Turkish).[170–174] The disease is inherited in an autosomal recessive manner. Patients presented with neutrophilia, recurrent bacterial infections, and periodontitis, similar to LAD I although these symptoms were generally not as severe. In addition, LAD II is associated with dysmorphic features and psychomotor retardation. LAD II neutrophils express normal levels of CD18. A clue as to the molecular cause of LAD II came from the observation that LAD II red cells were Lewis antigen negative and also had the rare Bombay (hh) erythrocyte phenotype, in which red cells express a nonfucosylated variant of the H antigen. These antigenic defects share in common the failure to form certain fucose carbohydrate linkage. The defect in fucose metabolism in LAD II has now been shown to result from mutations in the Golgi GDP-fucose membrane transporter.[172,173] This leads to a generalized loss of expression of fucosylated glycans on the surface of cells, in particular, the sialylated and fucosylated tetrasaccharide, SleX (CD15a), on the neutrophil surface. As a result, LAD II neutrophils are unable to bind to E- and P-selectin receptors on endothelium and therefore have an impairment in the early steps of rolling and loose binding to blood vessel walls prior to tight adhesion and emigration into infected tissues. Fucose supplementation has been partially successful in increasing expression of SLeX and decreasing clinical problems.[175,176]

LAD III has recently been described in a handful of patients with severe, recurrent infections similar to LAD I as well as a bleeding tendency.[177–181] The inheritance appears to be autosomal recessive and is associated with functional defects in the activation of multiple classes of integrins in response to G protein-coupled receptor stimulation. In one patient, activation of the Rap1 GTPase, known to be involved in the regulation of integrin signaling, was defective,[182] and a mouse genetically engineered to lack a blood cell-specific enzyme catalyzing the formation of Rap1 GTP had manifestations similar to LAD III. Because the clinical manifestations are typically severe, early bone marrow transplantation may be indicated for patients with LAD III.[180,181]

Hyperimmunoglobulin E Syndrome

The hyperimmunoglobulin E syndrome (HIES) is a complex disorder characterized by markedly elevated serum IgE levels, serious recurrent staphylococcal infections, chronic dermatitis, and skeletal and dental abnormalities.[183–188] Although not a primary phagocyte defect, neutrophils from patients with this syndrome exhibit a variable and at times profound chemotactic defect.[184,185,189,190] HIES was first described in 1966 and was called Job syndrome, in reference to the biblical description of Job as being afflicted with "sore boils from the soles of his feet unto his crown."[184] The skin abscesses in patients with HIES lack the erythema that is typical of such lesions and are referred to as cold abscesses. The key features of the hyperimmunoglobulin E syndrome are described in Table 50–8.

Although many cases of HIES are sporadic, autosomal dominant inheritance and, rarely, autosomal recessive inheritance are also described.[186,191] HIES has been described in all racial and ethnic groups. The molecular basis for the syndrome is also not known. The

Table 50–8 Summary of Hyper-IgE Syndrome (HIES)

Incidence	More than 200 patients reviewed in the literature
Inheritance	Sporadic is most common; also autosomal dominant with variable penetrance and autosomal recessive forms
Molecular defect	Unknown
Clinical manifestations	Staphylococcal pneumonia Pneumatoceles Fungal superinfection of lung cysts "Cold" cutaneous skin abscesses and furuncles Chronic eczematoid dermatitis Mucocutaneous candidiasis Coarse facies, growth retardation Osteopenia, recurrent fractures Sinusitis, keratoconjunctivitis Scoliosis Hyperextensible joints Delayed shedding of primary teeth Severe viral infections (autosomal recessive) Neurologic problems (autosomal recessive)
Laboratory evaluation	Serum IgE >2500 IU/mL Peripheral blood eosinophilia
Differential diagnosis	Atopic dermatitis Wiskott–Aldrich syndrome, DiGeorge syndrome Hypergammaglobulinemia Chronic granulomatous disease
Therapy	Prophylactic anti-*S aureus* antibiotics Aggressive treatment of acute infections with parenteral antibiotics Surgical drainage of deep infections and resection of lung cysts Monitor for scoliosis, fractures
Prognosis	Generally good if managed aggressively Some patients develop lymphoid malignancies

extremely high serum IgE level is believed to reflect a T-lymphocyte imbalance, leading to abnormal regulation of IgE production as well as decreased production of IFN-γ and tumor necrosis factor.[192,193] Further evidence for a more broad-based immune disorder is the finding that HIES patients mount abnormal antibody responses to vaccines.[194] The recurrent bacterial infections are thought to arise by two mechanisms: (a) excessive production of IgE directed against *S aureus* that occurs at the expense of protective antistaphylococcal IgG[195] and (b) a variable neutrophil chemotactic defect that occurs independently of fluctuations in the serum IgE level.[196,197] The underlying T-cell defect may be responsible for this chemotactic defect, as it may cause the release of chemotactic inhibitors from mononuclear cells. How the immunologic abnormalities relate to the dental and skeletal defects that are the other hallmarks of this disorder (see Table 50–8 and below) is not known.

Clinical Manifestations

The clinical manifestations of HIES are at times dramatic.[186–188] Onset is generally in the first 2 months of life and is manifested by chronic dermatitis. By 5 years of age patients have a history of recurrent skin abscesses, pneumonias, chronic otitis media, and sinusitis. As patients grow older, recurrent staphylococcal pneumonia is a common problem and can be complicated by the formation of pneumatoceles. Septic arthritis, cellulitis, and osteomyelitis are also observed, and are usually caused by *S aureus*, although other bacterial pathogens have also been found. Patients can have chronic mucocutaneous candidiasis and occasionally exhibit keratoconjunctivitis, sometimes complicated by corneal scarring. One feature noted in the majority of patients by the time they reach the teenage years is the presence of coarse facial features (broad nasal bridge, prominent nose). Dental and bone abnormalities are also common features of HIES. Delayed or failure to shed primary teeth occur in the majority. Hyperextensible joints and scoliosis are frequent. Osteopenia of unknown etiology is observed in most patients, and there is an increased risk of fractures to the long bones and vertebral bodies even in the absence of osteopenia.[186]

Diagnosis

The diagnosis of HIES should be entertained in any child or young adult who has the above-described clinical picture or simply a history of recurrent infections. The hallmark laboratory finding is a marked elevation of serum IgE, almost always greater than 2500 IU/mL.[187,188] Levels can be as high as 150,000 IU/mL. Most patients also have peripheral eosinophilia. However, there is no correlation of clinical disease activity with the level of either IgE or peripheral eosinophilia.[3,187,188] Atopic dermatitis is the major differential diagnosis, as comparably high serum levels of IgE can be seen in patients in this disorder, as well as superficial skin infections. The severe and recurrent nature of the staphylococcal furuncles and pneumonias usually seen in HIES can help distinguish these patients from those with atopic dermatitis. Patients with other primary immunodeficiency syndromes may also manifest elevated IgE levels.

Therapy

The therapy for HIES is largely supportive.[187,188] Prophylactic antibiotics (eg, dicloxacillin or trimethoprim/sulfamethoxazole) can be effective in preventing *S aureus* infections. Dermatitis can be treated with topical steroids. Intravenous antibiotics are used for deep-seated infections or for resistant cutaneous infections. Surgical resection of persistent pneumatoceles is sometimes indicated to prevent superinfection by fungal and gram-negative organisms. Plasmapheresis has been reported to be effective in treating patients who have not responded to the above-mentioned therapies. Recombinant IFN-γ has been used with inconsistent results.[188] Recently, either cyclosporin A or intravenous Ig infusions have shown some success in the management of HIES.[188]

Miscellaneous Chemotactic Disorders

It is extremely rare to have primary defects in neutrophil actin polymerization as a cause of abnormal chemotaxis and recurrent infections. In one case, neutrophils had diminished actin polymerization, chemotaxis, and phagocytosis of serum opsonized particles.[198] Family members had decreased CD11b/CD18 expression and a partial decrease in actin polymerization, which suggested that this disorder might be a variant of LAD I; however, no similar cases have otherwise been described. An apparent autosomal recessive disorder of actin polymerization has been described in a male infant of Tongan descent who presented with severe skin infections, recurrent pulmonary infiltrates, thrombocytopenia, and invasive *Candida tropicalis* infection.[199] Neutrophil actin polymerization was markedly abnormal, and associated with increased expression of an actin-binding protein.[200] Finally, a heterozygous point mutation in β-actin affecting binding to actin-regulatory proteins was discovered in a female patient with recurrent infections, photosensitivity, and mental retardation.[201] Neutrophils had a marked impairment in chemotaxis and in the formyl peptide-induced respiratory burst.

A new syndrome of severe neutrophil dysfunction due to a dominant-negative mutation in Rac2, a small GTPase expressed in blood cells that acts in many signal transduction pathways, was recently described in an infant boy born to unrelated parents.[37,38] This baby presented with rapidly progressive and deep-seated soft tissue infections, along with neutrophilia and poor formation of pus but normal expression of β2 integrins and fucosylated proteins. Neutrophils had marked defects in actin polymerization, chemotaxis, degranulation, and the respiratory burst in response to chemoattractants. Neutrophil responses to other agonists were normal, suggesting that the dominant negative Rac2 mutation produces a selective intracellular signaling defect.

Localized juvenile periodontitis (LJP) is a heterogeneous disorder of unknown etiology characterized by chronic and recurrent periodontal infections and severe alveolar bone loss with onset at the time of puberty.[202–205] Nearly three-quarters of patients with LJP have been reported to have defective neutrophil chemotaxis in vitro.[202,206–209] At present it appears that LJP is an acquired disorder in some patients and a genetic disorder in others. It may also be a combination of both in certain patients as they may inherit an unusual sensitivity to the chemotactic inhibitors released by certain periodontal microorganisms. The diagnosis of the disorder is made on the basis of severe periodontal disease and destructive alveolar bone loss involving the first molars and incisors developing during adolescence. It is important to note that many qualitative and quantitative neutrophil disorders are also associated with severe periodontal disease.[210] Therefore, the differential diagnosis should include neutropenia (both chronic and cyclic), LAD, CGD, and Chediak–Higashi syndrome.

One of the most consistently observed chemotactic abnormalities is seen in neonatal neutrophils.[141,211–214] These cells exhibit impaired chemotaxis in vitro in response to a wide variety of chemotactic factors.[143] It appears as though this abnormality is due, at least in part, to defects in cellular adhesion as a result of diminished mobilization of intracellular adhesion-promoting molecules to the cell surface.[211] Defective neutrophil chemotaxis can be seen in normal neonates between birth and 5 days of age. In severely ill infants, the defect may persist for a longer time.

DEFECTS IN THE STRUCTURE AND FUNCTION OF LYSOSOMAL GRANULES

Two major disorders of neutrophil granules have been described: Chediak–Higashi syndrome and specific granule deficiency. A great deal has been learned about the structural and functional abnormalities of neutrophils from patients with these conditions. Although

rare, these disorders are also obligatory components in the differential diagnosis for any patient with recurrent bacterial/fungal infections.

Chediak–Higashi Syndrome

The Chediak–Higashi syndrome is a rare autosomal recessive, multisystem disease resulting from widespread defects in granule morphogenesis, with giant lysosomes in leukocytes and other cells throughout the body.[215–221] The disorder is characterized by partial oculocutaneous albinism, frequent (and sometimes fatal) bacterial infections, a mild bleeding diathesis, and peripheral as well as cranial neuropathies associated with defects at the optic chiasm. Those who survive the recurrent infections develop an "accelerated phase" of the disease—a progressive lymphoproliferative syndrome that is eventually fatal owing to a profound pancytopenia that develops.

The most dramatic granule defects are manifested in the various blood cells. Neutrophils contain a highly inhomogeneous population of huge granules derived from coalescence of azurophilic (primary) and specific (secondary) granules.[222–224] The giant granules are often more prominent in the bone marrow than in the peripheral blood,[225] because many of the abnormal myeloid precursors are apparently destroyed before they leave the marrow, resulting in moderate neutropenia with absolute neutrophil counts ranging from 500 to 2000 cells per cubic millimeter. Granules are also markedly deficient in antimicrobial granule enzymes such as cathepsin G and elastase, consistent with a defect in granule morphogenesis.[226] Degranulation is delayed and incomplete in Chediak–Higashi neutrophils, resulting in impaired bacterial killing.[140,216] Chemotaxis is also defective, perhaps related to poor deformability due to the presence of the large granules.[217] Monocytes and macrophages exhibit similar giant cytoplasmic granules, with resultant abnormalities in their phagocytic functions.[216] Giant granules are also seen in lymphocytes and are associated with defects in cytotoxic T lymphocyte and natural-killer cell function.[227–229] Eosinophils contain large granules, the functional significance of which is not known.[230] Platelets in this disorder have a storage pool deficiency of ADP and serotonin, presumably because of the abnormal granule morphogenesis in megakaryocytes, leading to a defect in platelet aggregation.[218,221]

Abnormal giant granules are also present in other cell types. These include melanocytes, which contain abnormal melanosomes that cannot transfer their contents to adjacent keratinocytes, Schwann cells, astrocytes, and certain cells in the liver, spleen, pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.[219,221,231]

Table 50–9 Summary of Chediak–Higashi Syndrome (CHS)

Incidence	Approximately 200 cases described
Inheritance	Autosomal recessive
Molecular defect	A defect in granule morphogenesis in multiple tissues resulting from mutations in the CHS1 (LYST) gene encoding a lysosomal trafficking regulator protein
Pathogenesis	Giant coalesced azurophil/specific granules in neutrophils resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis
Clinical manifestations	Partial oculocutaneous albinism Recurrent severe bacterial infections (usually *S aureus*) Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss) Hepatosplenomegaly and complications of pancytopenia in the accelerated phase
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in bone marrow myeloid progenitor cells Widespread lymphohistiocytic infiltrates in accelerated phase
Differential diagnosis	Other genetic forms of partial albinism Giant granules can be seen in acute and chronic myelogenous leukemias
Therapy	Prophylactic trimethoprim/sulfamethoxazole Parenteral antibiotics for acute infections Ascorbic acid (200 mg/day for infants; 6 g/day for adults) Bone marrow transplant at beginning of accelerated phase
Prognosis	Most patients die from infection or complications of the accelerated phase during the first or second decade of life. A few patients have survived into their thirties

Molecular Genetics

A gene termed CHS1 or LYST (for its presumed function as a lysosomal trafficking regulatory protein) affected in the majority of Chediak–Higashi syndrome (CHS) cases has recently been identified, and is on the long arm of chromosome 1.[218–220,232,233] The encoded protein is very large (3801 amino acids); its specific function is unknown but recent studies suggest that it may inhibit lysosome fusion with other intracellular membrane vesicles.[234] A variety of frameshift and nonsense mutations that predict synthesis of truncated forms of the protein have been identified in most, but not all, CHS patients studied to date.[218,220,232,233,235] There is no correlation between the length of the truncated CHS1 protein and the severity of the disease. Disorders similar to human CHS have also been described in many mammalian species, including Aleutian mink, *beige* mice, blue foxes, cats, killer whales, and Hereford cattle.[219] Identification of the human CHS1 gene was aided by positional cloning of the mouse *lyst* homolog affected in *beige* mice.[232,236]

Clinical Manifestations

The key features of Chediak–Higashi syndrome are summarized in Table 50–9. The disease usually presents in infancy or early childhood, with infections involving the lungs, skin, and mucous membranes being most commonly encountered.[215] Dental caries and periodontal disease are also common. The most frequent offending organism is *S aureus*.[216] Gram-negative bacteria, *Aspergillus* spp and *Candida* spp also are responsible for many infections. Platelet granule defects result in easy bruising and epistaxis. There is partial oculocutaneous albinism and photosensitivity. Patients can have a white forelock or an ashen or grayish silver sheen to the hair, which can vary from blond to dark brown. In younger patients, there may be a cartwheel distribution of pigment in the iris and an abnormal red reflex. Neurologic manifestations include peripheral or cranial neuropathies, gait abnormalities, muscle weakness, sensory loss, seizures, or spinocerebellar degeneration.[221] Neurologic symptoms worsen with age.

Approximately 85% of children surviving into the second decade of life develop an accelerated phase of the disease, with fever, lymphadenopathy, and progressive pancytopenia. A reactive-appearing lymphohistiocytic proliferation occurs in the liver, spleen, lymph nodes, and bone marrow.[215,237,238] Occasionally, younger children with Chediak–Higashi syndrome present in the accelerated phase. The cellular infiltration is not neoplastic by histopathologic criteria, although the prognosis is uniformly fatal unless patients undergo bone marrow transplantation. The accelerated phase resembles the virus-associated hemophagocytic syndrome because the invading histiocytes often exhibit hemophagocytosis.[237] The bone marrow infiltration and progressive hepatosplenomegaly lead to pancytopenia and death due to infection and bleeding. The accelerated phase is thought

to be precipitated by Epstein–Barr virus (EBV) infection, and may become fulminant because of a lack of NK cell function.[238,239]

Diagnosis

The diagnosis of Chediak–Higashi syndrome is made on the basis of the giant peroxidase-positive lysosomal granules in the peripheral blood granulocytes or in bone marrow myeloid cells. Identification of large, acid phosphatase-positive lysosomes in amniocytes and chorionic villus cells has been used to diagnose CHS prenatally.[240,241] Other clinical features characteristic of CHS can support the diagnosis, including mild oculocutaneous albinism, silvery hair, and a bleeding diathesis. The accelerated phase of the disease is characterized by diffuse infiltrates of lymphohistiocytic cells seen on biopsy and by pancytopenia.[237] Occasionally, giant granules that resemble those of Chediak–Higashi syndrome can be seen in both acute and chronic myelogenous leukemias.[242]

Therapy

The treatment for the stable phase of Chediak–Higashi syndrome is similar to that for other neutrophil disorders. Prophylactic antibiotics such as trimethoprim/sulfamethoxazole appear to be beneficial. Parenteral antibiotics are indicated for acute infections and responses are often slow. Treatment with high-dose ascorbic acid (200 mg/day for infants, 6 g/day for adults) has been found to improve the clinical status of some patients in the stable phase.[243,244] Although there is some controversy regarding the efficacy of ascorbic acid,[245] given the safety of this medication it seems prudent to administer it to all patients.

The treatment of the accelerated phase is extremely difficult. The lymphohistiocytic infiltrates respond poorly, if at all, to vincristine and corticosteroids.[215,228,237] The only curative therapy appears to be bone marrow transplantation,[246,247] which is ideally performed prior to or at the beginning of the accelerated phase. If transplantation is successful, the accelerated phase of the disease does not recur, and NK cell activity is improved. However, transplantation does not prevent the progressive neuropathy of CHS.

Specific Granule Deficiency

Neutrophil specific granule deficiency (SGD) is an extremely rare congenital disorder characterized by recurrent bacterial and fungal infections, primarily involving the skin, ears, and lungs.[216,248–250] Infections are often indolent and smoldering, and *S aureus*, *Pseudomonas aeruginosa*, enteric gram-negative bacteria, and *C albicans* are the major pathogens. Inheritance appears to be autosomal recessive,[248,251,252] suggesting that it is inherited in an autosomal recessive manner. Neutrophils from patients with SGD have atypical bilobed nuclei, absent specific granules, and multiple deficiencies of secondary and tertiary granule mRNAs and proteins, including lactoferrin, vitamin B_{12}-binding protein and gelatinase B.[248–251] Although azurophil granules in this disorder are present and contain myeloperoxidase and lysozyme, they are markedly deficient in defensins.[226] Monocytes display cell surface and functional defects,[253] eosinophils lack eosinophil-specific granule proteins such as eosinophil cationic protein,[254] and platelets have abnormal α granules,[255] suggesting that the underlying defect may be related to regulation of the synthesis of certain granule and membrane proteins. This defect in synthesis is confined to bone marrow-derived cells, as lactoferrin secretion is normal in the glandular epithelia of SGD patients despite the severe deficiency in the neutrophils.[256]

The recurrent skin and pulmonary infections characteristic of SGD appear to be caused by two fundamental defects in the neutrophils. One defect is the marked deficiency of at least two important microbicidal granule proteins, lactoferrin[251] and defensins.[226] The other defect is a relatively severe chemotactic abnormality presumably caused by the absence of the intracellular pool of leukocyte adhesion molecules that normally reside in the specific granules. As discussed above, these $\beta 2$ integrins play a key role in phagocyte chemotaxis.

The molecular defect responsible for most cases of SGD has recently been shown to involve a myeloid transcription factor known as C/EBPε that regulates expression of certain genes activated during granulocyte differentiation. This came about serendipitously when it was recognized that mice with a targeted deletion in the C/EBPε gene had similar characteristics to SGD patients, including neutrophils with bilobed nuclei, absent secondary granules and impaired chemotaxis, along with increased susceptibility to bacterial infections.[257–259] To date, mutations in the C/EBPε gene have been identified in two SGD patients that encode truncated, nonfunctional proteins.[250,260,261] However, DNA sequencing of the C/EBPε gene of several other SGD patients has not revealed abnormalities, suggesting that SGD is a genetically heterogeneous disorder.[262] The diagnosis of SGD can be readily made by microscopic examination. Wright-stained neutrophils are devoid of specific granules but contain normal numbers of azurophilic granules.[216] Electron microscopy reveals small peroxidase-negative vesicles, which presumably represent empty specific granules.[216] The diagnosis of SGD can also be established by demonstrating a severe deficiency in either lactoferrin or vitamin B_{12}-binding protein. An acquired form of SGD can be seen in burn patients[216] or in individuals with various myeloproliferative disorders.[263] The treatment for SGD is similar to that for other neutrophil disorders. If medical management is aggressive, the prognosis appears quite good, with patients surviving into their adult years.

MISCELLANEOUS INHERITED AND ACQUIRED DISORDERS OF PHAGOCYTE FUNCTION

Defects in phagocyte production of inflammatory cytokines or their intracellular signaling pathways are now being identified, in parallel with our improved understanding of the molecular basis of these important regulatory networks.[264,265] All of these disorders are rare. Inherited defects in macrophage IL-12 production or expression of the IFNγ receptor have been described that present with recurrent and severe atypical mycobacterial infections.[255,256,264,266] Another patient with deficient mononuclear cell production of IL-12 presented with recurrent episodes of pneumococcal pneumonia with the unusual absence of fevers.[267] A variety of genetic defects in a scaffolding protein known as IKK-gamma or NEMO that is important for activation of the NF-κB signaling pathway have been reported in patients with anhydrotic ectodermal dysplasia and immunodeficiency; affected children have recurrent pyogenic infections with a minimal systemic inflammatory response, and can also develop opportunistic infections with atypical mycobacteria or *Pneumocystis carinii*.[265,268–271] Several other kindreds have been described with genetic deficiency of another protein, IRAK-4, important for NF-κB activation by pyogenic bacteria via the Toll-like receptor/Il-I receptor superfamily.[265,271,272] Affected children also had recurrent infections with *S pneumonia* and *S aureus* and a poor inflammatory response but no dysmorphic features or opportunistic infections. A similar patient with endotoxin and IL-1 hyporesponsiveness has also been reported,[273] which may involve a similar genetic defect.

There are a variety of noncongenital defects in phagocyte function that can be associated with an increased risk of bacterial or fungal infection. Several have already been mentioned above, including neonatal neutrophil dysfunction manifested as poor adhesion and chemotaxis. Patients with myelodysplastic syndromes and acute nonlymphoblastic lymphoma can have subpopulations of neutrophils variably defective in adhesion, migration, production of reactive oxidants, and microbicidal activity that can be correlated with an increased risk of infection.[4] Similar defects have been described in diabetes mellitus, Gaucher disease, and renal failure. Severe bacterial infections, surgical trauma, and severe burns can also result in transient depression of a variety of neutrophil functions.[2–4] The underly-

ing mechanism(s) are incompletely defined, and may be related to effects of high levels of inflammatory mediators produced in response to infection or trauma, or to products released by bacteria.

Leukocytosis and Leukopenia

Leukocytosis or leukopenia is defined according to the respective age and population-based means of neutrophils, lymphocytes, monocytes, or eosinophils as the distribution of leukocytes or "differential" undergoes specific developmental changes as well as changes reflecting disease states (Chapter 164). Changes in the number of circulating leukocytes may represent a primary disorder of leukocyte production or reflect a secondary response to some disease process or toxin. This chapter focuses on abnormal elevation or depression of mature neutrophils.

Definitions of Leukocytosis and Neutropenia

Leukocytosis refers to an elevation of the white blood cell count greater than 2 standard deviations above the mean value of circulating white cells. Neutrophilia refers specifically to elevation of the absolute neutrophil count. The latter is calculated by multiplying the percentage of neutrophilic granulocytes by the total white cell count. The usual explanation for leukocytosis is neutrophilia. Abnormal elevations of eosinophils and lymphocytes are considered elsewhere in this text.

Neutrophil counts show considerable variability during the neonatal period with a mean of 11,000/mm^3 and a range of 6000 to 26,000/mm^3. Total white cell counts may be as high as 38,000/mm^3 at 12 hours of age.[274] The white cell count drops after 12 hours, reaching a mean neutrophil count of 5500/mm^3 (1500–10,000) at 1 week. The differential in the first week of life resembles that of the adult, with approximately 60% neutrophils. From 1 week until 5 to 6 years, however, there is a predominance of lymphocytes. Thereafter, neutrophils increase to about 60%. The mean adult total leukocyte count is 7500/mm^3 (4500–11,000) and the mean neutrophil count is 4400/mm^3 (1800–7700).[274] Total neutrophil counts of premature infants are about 30% lower than those of term infants. The sequential changes noted after birth also occur in premature infants but with wider variability.[275]

Neutropenia is defined as a neutrophilic granulocyte count of less than 1500/mm^3. This definition can be used for all ages and races, though, strictly speaking, separate standards should be used for particular groups. For example, newborn infants have elevated granulocyte counts in the first few days of life[274,275] and certain populations of Africans and Yemenite Jews normally have lower granulocyte counts.[276,277]

The absolute neutrophil count (ANC) is calculated by multiplying the total white blood cell count (WBC) by the percentage of bands and mature neutrophils:

$$\text{Absolute neutrophil count} = \text{WBC} \times (\%\ \text{bands} + \%\ \text{mature neutrophils}) \times 0.01$$

Granulocytes less mature than bands are not included in the calculation.

Regulation of Granulocyte Counts

The peripheral neutrophil count reflects the equilibrium between intra and extramedullary compartments. The bone marrow contains a mitotic pool, a maturation pool, and a storage pool. Outside the marrow, there is a circulating pool, a marginated pool of neutrophils adherent to vascular endothelium, and a tissue pool. A complex interplay of factors regulates the production of granulocytes and their movement from one pool to another.[278–282] The clinical assay reporting the number of neutrophils, that is, the white blood cell count (WBC) and the differential, only monitors neutrophils that are in the circulating pool during a brief 3- to 6-hour period of transit from marrow to tissue and thus does not provide definitive information regarding the cause of neutrophilia or neutropenia.

Granulocytes are derived from a common progenitor that also gives rise to erythrocytes, megakaryocytes, eosinophils, basophils and monocytes. The biology of hematopoiesis is quite complex and is regulated by a number of cytokines with overlapping activities. The hematopoietic stem cells normally reside in the bone marrow in a state of quiescence/dormancy. Cytokines that lead to proliferation (or exit from dormancy) of the early progenitor/stem cells are stem cell factor (SCF), thrombopoietin (TPO), FLT3 ligand, interleukin-11 (IL11), granulocyte stimulating factor (G-CSF), and interleukin-6 (IL6). Interleukin-3 (IL3) and GM-CSF act on the later progenitor cells, whereas cytokines supporting differentiation along specific lineages are G-CSF, monocyte colony stimulating factor (M-CSF), and erythropoietin (Epo), leading to granulocytic, monocytic, and erythroid differentiation, respectively.[283–288] Some of these cytokines along with components of complement[289–292] release granulocytes from the marrow storage pool into the circulation. This can result in a two- to threefold increase in the granulocyte count within 4 to 5 hours.[289,293]

It is now clear that neutrophils not only move from the marrow to the circulation, but also reenter the marrow pool from the periphery.[280,294–296] This process involves complex and regulated interactions between hematopoietic growth factors, proinflammatory cytokines, and marrow adhesion receptors. Stromal cell-derived factor-1α (SDF-1α/CXCL12), the ligand for the chemokine receptor, CXCR4, is important in the regulation of B-cell lymphopoiesis and myelopoiesis during embryonic life and of CD34$^+$ cell and lymphocyte trafficking postnatally.[297] This receptor is also responsible for retention of neutrophils in the bone marrow and for homing of peripheral neutrophils back into the marrow.[298] The CXCR4/SDF-1α pathway plays an important role in homing of CD34$^+$ progenitors to the marrow through regulation of α4-integrin and α4-integrin/VCAM-1 engagement, though cooperation of CXCR4 is not an absolute requirement.[280] The bone marrow is important in the release of neutrophils that have reached maturity and in the accelerated release of less mature cells in response to inflammation. However, it also plays an important role in regulating circulating neutrophil counts and in controlling their reentry into the marrow from the periphery. In animal models at least, infused peripheral neutrophils redistribute equally between the marrow and the liver whereas activated neutrophils, such as those found in exudates, home to the liver and marrow-derived neutrophils return primarily to the marrow.[296] This suggests that the marrow recaptures circulating neutrophils and can re-release them. This is supported in humans by the fact that radiolabeled neutrophils infused into humans can be detected in the bone marrow.[299] Retention of neutrophils in the marrow is increased by activation of CXCR4 and blocking neutrophil CXCR4 reduces neutrophil retention and mobilizes neutrophils from the marrow into circulation in animal models[298] and in humans.[300,301] In fact, myelokathexis, a rare congenital disorder where CXCR4 activity is increased, is characterized by neutropenia and marked retention of neutrophils in the marrow, supporting a role for this mechanism in humans.[297,302–304] Similarly, infusion of AMD3100, a CXCR4 antagonist, results in marked increase in the neutrophil count as well as release of CD34+ cells into the periphery.[305,306] Furthermore, inflammatory mediators cause much greater release of neutrophils when CXCR4 is blocked,[298] providing additional support for the role of CXCR4 in regulation of neutrophil counts. Surface expression of CXCR4 on neutrophils decreases with maturation and with activation. This would favor the retention of immature cells in the marrow and cause mature and stimulated neutrophils to remain in the circulation. Although surface levels of CXCR4 are low on freshly isolated human neutrophils, intracellular stores are high, suggesting a high level of spontaneous endocytosis.[307] CXCR4 surface expression increases as neutrophils become senescent, resulting in clearance from circulation and return to the marrow. Furthermore, activation of CXCR4 reduces the chemotactic response of neutrophils to CXCR2 agonists,[307] perhaps explaining the chemotactic defects reported in some patients with myelokathexis.[294,308] The adhesion of hematopoietic cells in the bone

marrow is mediated through the interaction of α4β1 integrin (VLA-4) with marrow fibronectin and VCAM-1 in the stroma and is regulated in part by CXCL12/SDF-1α activation of CXCR4.[298,307,309]

During acute inflammation, elevated levels of CXC cytokines stimulate mobilization of neutrophils from the bone marrow and this response is enhanced by inhibition of marrow retention by blockade of CXCR4.[307] It has been suggested that inactivation of SDF-1α by serine proteases such as neutrophil elastase or cathepsin-G released from neutrophils upon activation by cytokines may promote egress by decreasing CXCR4 stimulation.[307,310–312] These studies suggest that the CXCR4/SDF-1α axis is critical in maintenance of neutrophil homeostasis.

More than half of the granulocytes in the peripheral circulation at any given time are attached to the vascular endothelium.[313] These "marginated" neutrophils can be released almost immediately at times of stress, an effect mediated in part by epinephrine.[314] Margination is regulated by specific receptors called selectins that mediate rolling adhesion of leukocytes to the endothelium.[278]

Normally, 1.5×10^9 granulocytes/kg body weight are produced per day, of which approximately 20% are in the myeloid precursor pool, 75% in the marrow storage pool, 3% in the marginated pool, and 2% in the circulating blood.[313,315] Granulocytes spend about 9 days in the marrow, 3 to 6 hours in the blood, and 1 to 4 days in the tissues.[313] Thus, the total granulocyte count as measured from peripheral blood represents a sample of only 2% of the total population.

Movement of neutrophils from one compartment to another as well as changes in production contribute to states of neutrophilia and neutropenia. Thus, neutrophilia can be due to increased production as in infection or myeloproliferative disorders or inhibition of egress from the blood as in certain chemotactic disorders or steroid therapy.[293] Neutropenia may be due to decreased production, to increased margination and egress as in systemic complement activation or burns,[316,317] to destruction as in immune neutropenia, or to increased apoptosis of neutrophils.[318–325]

Practically, evaluation of these processes is limited to examination of the peripheral blood and of the bone marrow. Although sophisticated radiotracer techniques exist, they are not clinically useful. Similarly, clinical tests such as hydrocortisone challenge and epinephrine stimulation, which reflect a releasable marrow storage pool or marginated pool, have limited differentiating power.

Secondary Causes of Neutrophilia

Most leukocytosis occurs as a reaction to some inflammatory process. Infection was documented in 207 of 400 patients (53%) in a prospective study of 400 inpatients with white cell counts greater than 15,000 cells/mm^3. Of these 207 patients, 47% had pneumonia, 29% had urinary tract infection, 16% had soft-tissue infection, and 16% had *C difficile* infection. *C difficile* infection was present in 25% of patients with WBC counts greater than 30,000 cells/mm^3. Other causes of leukocytosis included physiological stress (38%), medications or drugs (11%), hematologic disease (6%), and necrosis or inflammation (6%).[326]

Leukemoid Reaction

Leukocytosis exceeding 50,000/mm^3 is referred to as "leukemoid reaction"[327] and is characterized by a significant increase in early neutrophil precursors in the peripheral blood. The differential count has a marked "left shift," evidenced by presence of myelocyte, metamyelocyte, and band forms. Progranulocytes and myeloblasts may be observed in severe reactions. In contrast to acute leukemia, proliferation and orderly maturation of all normal myeloid elements is observed in the bone marrow and the morphology of the myeloid elements is normal. Presence of the Philadelphia chromosome on karyotypic analysis of the bone marrow distinguishes adult chronic myeloid leukemia from a leukemoid reaction. Leukemoid reactions due to infections may be accompanied by toxic granulation, Doehle bodies, and cytoplasmic vacuoles in the neutrophils.[327]

Newborns have unique responses to stress and infection. The relative number of band forms and less mature granulocyte precursors in the differential of newborn infants has been correlated with sepsis and with depletion of the marrow neutrophil storage pool.[328,329] In the normal infant, the band to neutrophil ratio is less than 0.14 to 0.11 in the first 48 hours, irrespective of birth weight or gestational age.[329] An immature/total neutrophil ratio exceeding 0.8 in the peripheral blood indicates that the marrow reserves are depleted and the risk for death in septic infants is significantly increased.[328] Some infants have extreme responses to stress and as many as 15% of extremely low birth weight infants (<1000 g) presented with leukemoid reactions with no identifiable cause.[330,331] Transient leukemoid reactions have also been seen in phenotypically normal infants who had trisomy 21 limited to their hematopoietic cells.[332,333]

When the marrow is directly invaded by tumor, or in cases of marrow fibrosis or granulomatous reactions, neutrophilia associated with immature granulocytes, nucleated red cells, "stubby elliptocytes,"[334] and teardrop-shaped erythrocytes may be seen, often accompanied by thrombocytosis.[335] Vasculitis and marrow infarction can also cause this picture.[336,337] This is called a leukoerythroblastic response. Essentially, presence of leukoerythroblastosis suggests the presence of an irritative or inflammatory process in the marrow itself. A bone marrow aspirate and biopsy should be performed in these cases to look for granuloma, tumor, or marrow fibrosis. Cultures of the marrow for fungus and tuberculosis[338] should be obtained. Leukoerythroblastic reaction may also be seen during recovery from marrow suppression after chemotherapy. Interestingly, transient erythroblastopenia of childhood has been reported to present with leukoerythroblastosis.[339]

Pelger–Huet Anomaly

Although technically not leukocytosis, the Pelger–Huet anomaly can raise the question of serious infection because of an apparent high band count. The Pelger–Huet anomaly is a benign, dominantly inherited defect of terminal neutrophil differentiation with a frequency at birth of 1:6000. Most of the neutrophils have bilobate nuclei and excessively coarse clumping of nuclear chromatin. The two lobes are joined by a thin, hair-like bridge, which is much thinner than that seen in a normal band. This gives the characteristic "pince-nez" spectacle appearance to the nucleus. Nevertheless, the function of these cells is normal.[340] Interestingly, Pelger–Huet cells can develop multiple lobes during vitamin B_{12} or folate deficiency but return to their bilobate state when the vitamin deficiency is corrected.[341] Colchicine, sulfonamides, ibuprofen, taxoids,[342] and valproate induce the anomaly reversibly.[343–347] This so-called pseudo Pelger cell has also been reported to transiently appear during certain acute infections, acute myelogenous leukemia and in myelofibrosis. In particular, the defect has been associated with cytogenetic abnormalities of chromosome 17 in leukemias.[348–350] Most cases of genetic Pelger–Huet anomaly are due to mutations in the lamin-B receptor, LBR, which is located on chromosome 1q41–43. LBR is a sterol reductase integral to the inner nuclear membrane and targets heterochromatin and lamin to the nuclear membrane.[351–353] Neutrophils of homozygotes have ovoid nuclei with clumped chromatin and varying degrees of developmental delay, epilepsy, and skeletal anomalies.[351,352] Eosinophils and basophils may also be involved. An unusual case of Pelger–Huet anomaly has been reported in association with four generations of one family with late-onset progressive proximal muscular dystrophy.[354] Neutrophilia and a differential "left shift" can be indicative of disease or may be totally benign. An outline of the major primary and acquired causes of neutrophilia is presented in Table 50–10. We have divided the causes of neutrophilia into two groups, those that seem to be due to intrinsic problems with the neutrophil or with the regulation of neutrophil production, and those that are secondary to some other disease process.

Table 50–10 Classification of Neutrophilia

Primary (no other evident associated disease)
Hereditary neutrophilia
Chronic idiopathic neutrophilia
Chronic myelogenous leukemia (CML) and other myeloproliferative diseases
Familial myeloproliferative disease
Congenital anomalies and leukemoid reaction
Leukocyte adhesion factor deficiency (LAD)
Familial cold urticaria and leukocytosis
Secondary
Infection
Stress neutrophilia
Chronic Inflammation
Drug induced
Nonhematologic malignancy
Generalized marrow stimulation as in hemolysis
Asplenia and hyposplenism

Chronic Myelogenous Leukemia

The major differential diagnosis of leukemoid reaction is chronic myelocytic leukemia (CML). This topic is considered in detail in Chapter 69. Leukemoid reactions and CML can be difficult to distinguish. The classic differentiating features are the presence of a low leukocyte alkaline phosphatase (LAP) score and Philadelphia chromosome in CML. The LAP score is also low in familial myeloproliferative disease[355] and paroxysmal nocturnal hemoglobinuria.[356] However, the LAP score can be normal in CML and thus is of little diagnostic value. Juvenile CML (see Chapter 74) can be distinguished from the usual adult form by the ability of circulating stem cells to form monocyte colonies in vitro[357] and the absence of Philadelphia chromosome. Leukocyte counts in CML can be extremely high, occasionally exceeding 500,000/mm^3. Patients with granulocyte counts above 200,000/mm^3 to 300,000/mm^3 require emergent intervention to prevent the vasoocclusive complications of hyperviscosity related to the markedly elevated white blood cells.

Acute Infection

Modest leukocytosis with a left shift is commonly seen in association with many acute bacterial infections. Certain bacterial agents such as *pneumococcus* or *staphylococcus* may cause particularly high leukocyte counts. Leukocytosis is seen in association with acute otitis media, with 9% of patients having greater than 20,000 WBC/mm^3, whereas 27% of culture-proven positive acute otitis media cases have WBC below the mean for age.[358] The predictive value of leukocytosis and increased band forms (WBC >15 × 10^9/L; immature/total >0.2) in detecting bacterial disease was increased from 32% to 71% when associated with depressed fibronectin levels (1 SD < Mean for age). This is of particular interest in view of the role of fibronectin in promoting phagocytosis by PMN and monocytes.[359] The risk of positive blood cultures in children between 3 and 36 months of age with fever >39.5°C (103°F) directly related to white cell count. If the temperature is >39.5°C (103°F) and the WBC is >15,000/mm^3, 16% have a positive culture, whereas 43% of cultures from children with a WBC >30,000/mm^3 are positive. In contrast, only 3.7% of children with counts less than 15,000/mm^3 and none with counts <10,000/mm^3 had positive blood cultures.[360] In hospitalized adults, *C difficile* infection was present in 25% of patients with WBC counts of >30,000 cells/mm^3,[326] and a poor outcome is predicted in elderly inpatients[361] by a WBC >20,000 cells/mm^3. Neutrophilic leukocytosis can also be associated with severe viral disease. Patients with Hantavirus infection, for example, have WBC as high as 65,000/mm^3 (median 26,000/mm^3) with 67% bands (median 27%).[362]

Stress Neutrophilia

Modest elevation in the neutrophil count has been associated with many types of "stress." Neutrophilia can occur within minutes of exercise[363] or stress[364] or epinephrine injection[314] and is presumed to be related to movement of neutrophils from the marginated pool into the circulating pool. The neutrophilia secondary to catecholamine injection has been related to reduced neutrophil adherence to endothelium. The neutrophilia and the adherence-inhibiting ability of plasma can be blocked by pretreatment of the subject with propranolol[365] or by treatment of neutrophils in the in vitro adherence assay system with an antibody to cyclic AMP.[314]

Propanolol does not block exercise-induced neutrophilia, despite measurable increases in plasma epinephrine.[366] The neutrophilia was directly related to the workload and cardiac output during exercise, suggesting a larger role for mechanical- and flow-related effects on dislodgment of the leukocytes sequestered in the lung than for a possible direct effect of catecholamines upon the neutrophils. Other studies show no effect of exercise upon circulating CFU-GM or CFU-GEMM,[363] although it has been suggested that the delayed leukocytosis (up to 235% increase at 5 hours postexercise) may be related to marrow release of leukocytes.[367]

Mild neutrophilia and lymphopenia have been associated with unipolar depression[368] but may be related to the use of antidepressant medications.[369]

Neutrophilia is also seen in the postoperative period. There is a doubling of the leukocyte count approximately 3 hours after surgery. This does not seem to be related to the type of anesthesia.[370,371]

Leukocytosis in the 12,000 to 20,000/mm^3 range has been reported in the postictal state. This can be associated with fever or pulmonary edema and resolves in a few hours to days.[372]

There is an interesting association between leukocyte count and myocardial infarction. Subjects with a leukocyte count greater than 9000 had a 4.5-fold higher incidence of myocardial infarction than those with a leukocyte count less than 6000.[373] It is also not clear whether the leukocyte count is a risk factor or merely an indicator of chronic stress.[374] However, WBC has been shown to be an independent indicator of atherosclerotic cardiovascular disease.[375]

Drug-Induced Neutrophilia

Leukocytosis has been seen in association with a number of drugs and drug reactions. Steroids are well known to induce release of neutrophils from the bone marrow[293] and result in a chronic low-grade neutrophilia. Leukocytosis as high as 200,000/mm^3 in neonates has been associated with maternal steroid administration.[331,376,377] Beta agonists produce an acute neutrophilia by releasing neutrophils from the marginated pool[378] and phenytoin and other anticonvulsants have been associated with leukocytosis.[379–383] Lithium is well-known to produce leukocytosis by increasing production of the colony-stimulating factor and has been used with varying success to treat several neutropenic states.[384] Tetracycline has also been associated with leukemoid reaction with a white cell count greater that 80,000/mm^3.[385] Granulocyte colony stimulating factor is now in common clinical use and can cause significant neutrophilia if its use is not closely monitored.

Nonhematologic Malignancy

Leukocytosis is frequently seen in large-cell lung cancer.[386] Usually, the leukocytosis seen with solid tumors is modest, in the 12,000 to 30,000/mm^3 range,[386–390] although it can be as high as 106,000/mm^3 in the absence of marrow metastasis.[391] Leukemoid reactions have been seen in patients with marrow involvement with tumors from lung, stomach, and breast or with neuroblastoma in children.[391] In some cases, solid tumors of lung, tongue, and kidney have been shown to secrete colony-stimulating activity.[392–394]

Marrow Stimulation

Significant leukocytosis can be seen in states of chronic stimulation of the bone marrow, such as hemolytic anemia or immune thrombocytopenia.[395] For example, patients with sickle cell anemia commonly have leukocyte counts in the 12,000 to 15,000/mm^3 range and have an exaggerated elevation in leukocyte counts with infection. The mechanism of leukocytosis may be related to production of placenta-derived growth factor by erythroid progenitors that stimulates production of inflammatory cytokines by monocytes.[396] This response may be further augmented by functional asplenia seen in sickle cell disease. Likewise, significant rebound leukocytosis can occur in the recovery phase of marrow suppression.[397,398] These reactions can last several weeks. In one instance, there were 90% myeloblasts in the marrow and as many as 20% myeloblasts in the peripheral blood.[399]

Primary Causes of Neutrophilia

Hereditary Neutrophilia

A family of four was described in 1974[400] with leukocyte counts chronically in the 20,000 to 70,000/mm^3 range, splenomegaly and widened diploe of the skull. There was no apparent propensity to bacterial infections. The defect seemed to be dominantly inherited. Subsequent follow-up (W. Herring, personal communication, 1989) revealed that two more children had been born to the same mother and both had chronic leukocytosis. The LAP scores were high in all affected subjects. None of the family members have had any serious medical problems other than a bleeding diathesis related to platelet dysfunction.[400] We have studied one of the members of this family and found normal neutrophil function and normal expression of surface CD18/CD11b (W. Herring, T. D. Coates, unpublished data), indicating that it is not a variant of leukocyte adhesion deficiency. We have seen a second family with this syndrome (D. Powars, personal communication). In this case, the father had marked leukocytosis and splenomegaly and eventually had his spleen removed. His son had similar problems with neutrophil counts at times in the 100,000/mm^3 range and with massive splenomegaly. The neutrophil function and CD18/CD11b expression in the affected father and son were also normal (D. Powars and T. D. Coates, unpublished data).

Chronic Idiopathic Neutrophilia

Chronic leukocytosis can occur in patients who are otherwise well. A series of thirty-four patients with leukocyte counts between 11,000 and 40,000/mm^3 were followed for up to 20 years without occurrence of clinical problems. Bone marrow aspirations were generally normal as were the LAP scores. The remainder of the blood counts were normal, except for occasional thrombocytosis.[401] These data point out that certain normal subjects fall outside of the 95th percentile with respect to WBC. This entity is obviously a diagnosis of exclusion.

Familial Myeloproliferative Disease

A syndrome encompassing growth retardation, hepatosplenomegaly, anemia, and leukocytosis has been described.[355] Some of the affected children died in early life whereas others remained stable or improved. All of the affected subjects had low LAP scores. Several other members of the family in four generations had low LAP scores but no other findings. Chromosomal analysis showed no significant consistent abnormalities and no subject had a Philadelphia chromosome. Other families have been reported with familial occurrence of polycythemia vera, CML, and myelofibrosis.[402–404] Furthermore, there is evidence that some myeloproliferative syndromes associated with monosomy 7 may have familial features.[405,406] Subsequent studies of families with familial myeloproliferative syndromes suggest that there is an inherited predisposition to the acquisition of JAK2 (V617F) mutations that are involved in the final pathway in the development of the myeloproliferative disorder.[407] This acquired mutation is found in some children[408] and in two-thirds of adults with familial myeloproliferative syndrome. Homozygosity is associated with disease progression.[409]

Congenital Anomalies and Leukemoid Reaction

Leukemoid reactions have been associated with amegakaryocytic thrombocytopenia and congenital deformities, such as Tetralogy of Fallot, dextrocardia and absent radii, and rudimentary little toes.[410,411] Transient leukemoid reactions and myelodysplastic syndrome have also been associated with the Noonan Syndrome.[412–414]

Down Syndrome

Infants with Down syndrome may have a transient leukemoid reaction that resembles congenital leukemia.[415] These children can also have an exaggerated leukemoid response to stress.[416] A transient leukemoid reaction has been seen in a phenotypically normal child who expressed trisomy 21 mosaicism in myeloid cells but not in skin fibroblasts. The chromosomal abnormality disappeared after the leukemoid reaction resolved.[333,417] The transient leukemoid reaction in Down syndrome has been associated with several mutations in important regulatory genes, which provide important insights into the control of myelopoiesis.[418,419]

Leukocyte Adhesion Deficiency

Since the 1970s, several patients have been described with persistent leukocytosis, delayed separation of the umbilical cord, recurrent infections, and a stimulus-dependent activation defect of the neutrophil. The laboratory hallmark of these disorders is leukocytosis. White blood cell counts may be only mildly elevated (10,000–12,000/mm^3) but often are in the 18,000/mm^3 to 30,000/mm^3 range and may be as high as 150,000/mm^3 during infection.[420,421] There are no specific morphologic abnormalities seen in the granulocytes. The diagnosis is established by demonstration of marked reduction (<10% of control) or absence in the CR3 receptor (CD11b/CD18) on granulocytes. These patients have severe functional defects as well and are described in detail earlier in this chapter.

Familial Cold Urticaria and Leukocytosis

A very interesting syndrome of leukocytosis, fever, urticaria, rash, and muscle and skin tenderness upon exposure to cold has been reported. This syndrome appears to be dominantly inherited. The onset of symptoms is in infancy and symptoms have been provoked by exposure to cold in the delivery room. Urticaria followed by fever starts about 7 hours after cold exposure. Leukocytosis, sometimes up to 34,000/mm^3, starts approximately 10 hours after cold exposure and begins to subside 12 to 14 hours later.[422,423] In contrast to other causes of urticaria, the skin rash in these patients is characterized histologically by a marked infiltration by neutrophils. The leukocytosis and urticaria were blocked when the patients were infused with endotoxin prior to cold exposure. This has been related to "cold activation of clotting system," as it is associated with a transient decrease in levels of C1 esterase inhibitor.[424,425] The gene has been mapped to a 10-cM region on chromosome 1q44, and the gene (CIAS1) responsible was subsequently identified.[426]

Approach to the Evaluation of Neutrophilia

Laboratory error must always be considered in the differential diagnosis of unexplained, isolated neutrophilia or neutropenia. With current technology, much of the human error has been removed,[427] although some clinicians continue to believe that manual counts are more accurate. Blood counts that do not fit the context of the clinical findings should be repeated before extensive evaluation is undertaken.[428]

Factitious leukocytosis can occur because of blood sampling problems or certain primary disease states. Inadequate anticoagulation of the specimen can result in platelet clumps that are being counted as leukocytes by automated cell counters. The WBC is rarely increased more than 10% and is usually associated with spurious thrombocytopenia.[429,430] In cryoglobulinemia, a temperature-dependent increase in leukocyte and platelet counts occurs at about 30°C and can result in white cell counts as high as 50,000/mm^3 and in a doubling of the platelet count, presumably because of various sizes of precipitated cryoglobulin particles.[431,432] This effect is increased if the sample is allowed to cool to lower temperatures.

The general approach to the evaluation of the patient with neutrophilia will depend on the degree of neutrophilia and the signs and symptoms of the associated diseases. Neutrophilia is most commonly seen secondarily to some acute or chronic inflammatory processes and the diagnosis and treatment are dictated by the nature of the primary illness. In the absence of clear history or physical examination findings, we find the sedimentation rate to be very helpful. An elevated sedimentation rate suggests that a more extensive evaluation for collagen vascular disease or other occult inflammatory disease is warranted whereas a normal value suggests that watchful waiting may be the best course. Examination of the bone marrow is of little help in cases of mild leukocytosis. In leukemoid reactions or leukoerythroblastosis, direct invasion of the marrow and myelodysplasia must be excluded. Bone marrow biopsy, marrow cytogenetics, and fungal, tubercular, and collagen vascular disease evaluation should be assessed. The marrow biopsy may reveal granulomata, which may intensify the search for fungus, or may reveal metastatic tumor that is often missed in marrow aspirate. Marrow cytogenetics may reveal mosaic trisomy 21[332,333] and monosomy 7,[405] Philadelphia chromosome, or other markers of dysplastic states. Much has been written about the leukocyte alkaline phosphatase score, which classically is high in infection and low in CML; however, this test is not diagnostic and is of limited utility.

Many factors contribute to the wide variability in granulocyte counts in normal populations. Particularly in the asymptomatic patient with persistent mild neutrophilia, one must remember that, by definition, the white blood cell count in 2.5% of the normal population must be greater than two standard deviations above the mean. Because regulation of granulocyte production is genetically controlled (W. Herring, personal communication, 1989),[276,277,401] examination of the parents' or siblings' blood counts may be of help in these few cases.

Leukopenia

Neutropenia is usually discovered when a blood cell count is performed as part of an evaluation for fever or as an incidental finding on a blood count done for some unrelated reason. In one study of adults with incidentally discovered neutropenia the causes were chronic idiopathic (34%), exposure to chemical agents (16.5%), infection (9.3%), autoimmune (9.3%), hematologic disorders (9.3%), thyroid disease (8.2%), ethnic neutropenia (7.5%), drug induced (2.1%), and others (4.2%).[433] The biggest concern in the neutropenic patient is the propensity to infection. In this case, the ability to deliver neutrophils to the tissue is the most important parameter, not the absolute neutrophil count.[434]

Table 50–11 Clinically Significant Neutrophil Counts

Absolute Neutrophil Count	Clinical Significance
>1500/mm^3	Normal
1000–1500	No significant propensity to infection. Fevers can be managed as an outpatient.
500–1000	Some propensity to infection. Occasionally fever can be managed as an outpatient.
<500	Significant propensity to infection. Always should be managed as inpatient with parenteral antibiotics. Few clinical signs of infection.

These rules apply strictly for neutropenia with hypoplastic marrow, early myeloid arrests and decreased granulocyte reserve pools. There is more latitude for clinical judgment in neutropenias with normocellular marrow. The only regular exception to these rules is documented chronic benign neutropenia of childhood.

Relation of Absolute Neutrophil Count to Propensity to Infection

Adequacy of the marrow reserve pool of neutrophils is the most important determinant of propensity to infection, and bone marrow aspiration is the single most helpful way to assess neutrophil reserve pool adequacy. When the reserve pool is significantly depleted, the propensity to infection is directly related to the absolute neutrophil count (see Table 50–11). In contrast, there is no good correlation between degree of neutropenia and propensity to infection in patients with good bone marrow reserve. If the marrow cellularity is good and there is no early myeloid arrest, it is unlikely that a patient's propensity to infection is due solely to the neutropenia.

Patients with neutropenia secondary to chemotherapy, marrow failure, or marrow exhaustion are at great risk for overwhelming bacterial infection.[328,329,435] In contrast, children with chronic benign neutropenia of infancy and childhood may have neutrophil counts less than 200/mm^3 for months or years but do not have any serious infectious problems.[435] Similarly, some adults with immune neutropenia may have severe depression of their neutrophil counts and suffer no serious episodes of infection. Changes in the number of circulating leukocytes may represent a primary disorder of leukocyte production or reflect a secondary response to some disease process or toxin. Both of these entities are characterized by neutropenia and cellular marrow. The marrow differential usually shows normal early granulocyte precursors but may have maturation arrest at the metamyelocyte or band stage.

Many patients with chronic neutropenia have normal or increased monocytes. These cells are functioning phagocytes, which may explain the lack of correlation between neutrophil count and propensity to infection in certain patients.[436,437] Tissue delivery of neutrophils in chronic immune-mediated neutropenia has been shown to be greater than in chemotherapy-induced neutropenia of equal degree, suggesting that the peripheral blood count may not accurately reflect neutrophil availability.[434] Although adequacy of the marrow reserve pool of granulocytes is a very important determinant of propensity to infection in neutropenic patients, the clinical setting in which the neutropenia occurs is also of great importance. For example, patients with severe congenital neutropenia have a markedly reduced marrow myeloid reserve but do not develop fulminant sepsis as rapidly as a chemotherapy patient would when mucosal barriers have been broken and both lymphocyte-mediated and phagocytic immunity have been destroyed.[1,438]

The types of infections encountered in neutropenic patients depend on the degree and chronicity of the neutropenia as well as the nature of the associated diseases causing the neutropenia. Patients in good clinical condition with severe neutropenia secondary to decreased production may have prolonged periods without serious infection, although pyogenic infection is inevitable. If the patient is

debilitated or receiving suppressive chemotherapy, the frequency of infection is greater. *S aureus*, *P aeruginosa*, *Escherichia coli*, and *Klebsiella* spp are common causes of infection in these patients.[436,437,439] Patients with less severe chronic neutropenia (ANC >300) may have recurrent sinusitis, stomatitis, perirectal infection and gingivitis,[436,437,440] but usually do not become septic.

Patients with significant chronic inability to produce neutrophils almost always have some evidence of gingival disease. However, the converse is not always true, particularly in the case of autoimmune disease. Autoimmune disorders can independently cause neutropenia and oral vasculitis associated with significant oral ulcerations and gingival disease. In this case, the oral lesions may not be secondary to the neutropenia at all. Although it is tempting to attribute the oral symptoms to the neutropenia, they can get worse with administration of G-CSF and resolve with immunosuppressive treatment of the vasculitis, despite persistence of severe neutropenia.

Classification of Neutropenia

It is simplest to classify neutropenia as primary or acquired (Table 50–12). From a mechanistic standpoint, neutropenia can be due to decreased production of neutrophils, shift of granulocytes from the circulating pool to marginated or tissue pools, peripheral destruction, apoptosis,[321,323–325,441,442] or a combination of these causes.[324,325] Regardless, the clinical implications for the patient depend on the effectiveness of delivery of neutrophils to the tissue and the nature of the primary disorder responsible for the neutropenia. These depend on marrow reserve and comorbidities such as collagen vascular disease, T or B cell abnormalities, or cytogenetic abnormalities. We have listed the various neutropenic disorders based on adequacy of the marrow reserve pool and mechanisms in Tables 50–13A and 50–13B.

The laboratory characteristics of many of the neutropenia syndromes overlap; thus, the differential diagnosis can be very difficult. Classification of some of the neutropenia syndromes depends on the clinical course. If there is no family history of neutropenia and the bone marrow is normocellular or hypercellular, there is no certain way to differentiate the various neutropenia syndromes other than to follow the patient clinically. In fact, the syndromes called "chronic benign neutropenia," "chronic idiopathic neutropenia," "chronic benign neutropenia of infancy," and "autoimmune neutropenia" are all very similar, differing only in age of onset, or association with recognizable immune disease. Chronic idiopathic neutropenia (CIN) with mildly hypocellular marrow is associated with mild to moderate neutropenia (1000–1500) and is due to increased apoptosis at the early myeloid progenitor stage.[441] The clinical course is also benign. Differentiating these syndromes is probably not important. It may be better to lump them into a category of "neutropenia with adequate marrow neutrophil reserve" as this better predicts the clinical behavior. The algorithm in Fig. 50–5 outlines an approach to these disorders that is based largely on the patients' symptoms and physical examination (see also Table 50–14).

Table 50–12 Classification of Neutropenia

Acquired neutropenia
Postinfectious
Drug induced
Chronic benign neutropenia
Chronic benign neutropenia of childhood
Autoimmune neutropenia
Isoimmune neonatal neutropenia
Pure white cell aplasia
Neutropenia associated with immunologic abnormalities
Neutropenia and lymphoproliferation of granular lymphocytes
Neutropenia associated with metabolic diseases
Neutropenia due to increased margination
Hypersplenism
Nutritional deficiency
Intrinsic defects
Ethnic neutropenia
Nonimmune chronic idiopathic neutropenia
Severe congenital neutropenia (SCN; Kostmann's syndrome)
Cyclic neutropenia
Myelokathexis (WHIM Syndrome)
Schwachman–Diamond–Oski syndrome
Barth syndrome
Chediak–Higashi syndrome
Griscelli syndrome
Hermansky–Pudlak II
Reticular dysgenesis
Dyskeratosis congenita

Acquired Neutropenia

Many acquired neutropenia have decreased survival of neutrophils in the peripheral circulation. Bone marrow examination reveals normal or increased cellularity with a late maturation arrest, usually at the metamyelocyte or band stage. Elevation of serum lysozyme or lactoferrin helps demonstrate destruction of circulating neutrophils but does not help with clinical management.[316,443] Bone marrow examination is the most helpful test in the evaluation of neutropenia. However, this can be delayed or omitted in the absence of other clinical findings (Fig. 50–5).

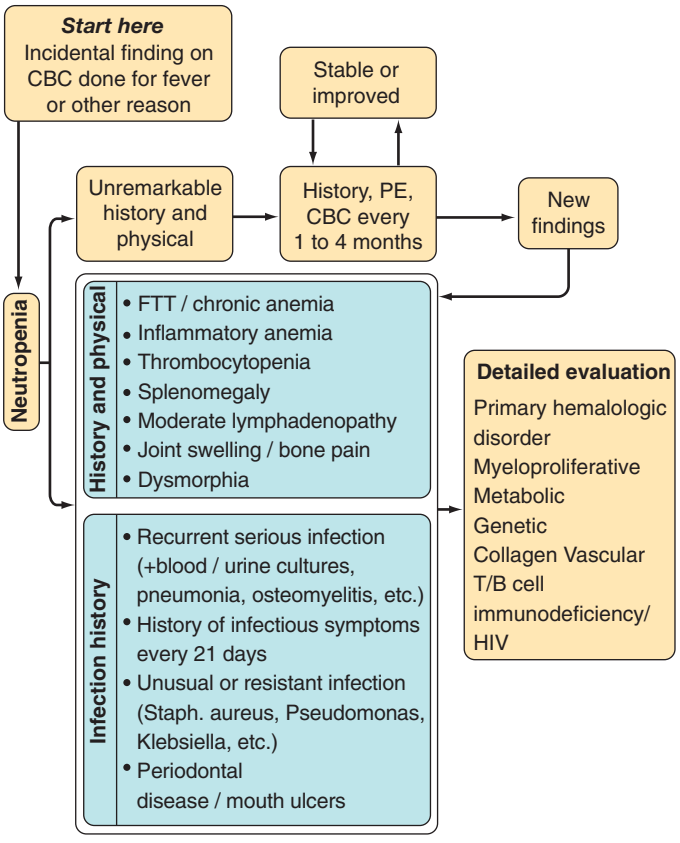

Figure 50–5 Algorithm for evaluation of neutropenia. Patients with neutropenia who are otherwise normal are followed clinically unless one of the noted danger signs or events occurs. Presence of one of the noted physical findings or infectious events should trigger an immediate detailed evaluation as outlined in Table 50–14. CBC, Complete blood count; FTT, failure to thrive; PE, physical examination.

Table 50–13A Neutropenia With Decreased Marrow Reserve

	Disorder	Mechanism	Inheritance/ Frequency	Clinical Characteristics	Diagnosis	Treatment
Primary	Severe congenital neutropenia	Apoptosis of precursor cells; *ELA2* gene mutations	AR, AD, S 1–2/million	Severe neutropenia in newborn; 2% a year progress to MDS or AML	Promyelocyte-myelocyte arrest on BMA, *ELA2* mutation analysis	G-CSF at 6–100 μg/kg/day to maintain ANC 500–1500/mm^3; and keep ESR low
	Shwachman–Diamond syndrome	Abnormal bone marrow stroma; Fas-mediated PMN precursor apoptosis	AR, S Extremely rare	Infections and steatorrhea; exocrine pancreatic deficiency; metaphyseal dysplasia; physical anomalies; 50% survival; 1/3 progress to MDS and AML; ANC <500/mm^3; thrombocytopenia; macrocytic anemia; chemotactic defect	Hypoplastic bone marrow; normal sweat chloride, increased 72-hour fecal fat, short stature. SBDS mutation analysis	G-CSF in selected cases; pancreatic enzyme replacement; CBC 2–3×/year. BMA + cytogenetics if marrow failure develops
	Cyclic neutropenia	Precursor apoptosis; also linked to *ELA2* mutations	AD, S 1–2/million	Regularly recurring fever every 21 days with associated oropharyngeal and skin infections	CBC 2–3 times per week for 8 weeks. Marrow aspirate not helpful. *ELA2* mutation	G-CSF at 2–3 μg/kg qd-qod; G-CSF dosage adjusted to maintain ANC >500/m^3 and keep ESR low
Secondary	Lymphoproliferative disorder of granular lymphocytes	Increased apoptosis due to circulating FAS ligand	Uncommon	Recurrent infection, fever, mouth ulcers, splenomegaly, arthritis. Primarily adults.	Clonal proliferation of granular lymphocytes. CD3$^{+/-}$ and CD8$^+$, or CD16$^+$ or CD56$^+$ or CD57$^+$	Cyclosporin or methotrexate primary treatment. Treat sepsis. Careful use of G-CSF
	Chemotherapy	Direct toxicity to neutrophil precursors	Common	Severity of neutropenia dependent on treatment intensity and cytotoxic agents used; poor marrow reserve = high risk of infection	Appropriate clinical history; BMA done when neutropenia is unusually prolonged or severe	Supportive; prophylactic TMP/SMX at 5 mg/kg divided BID on 3 consecutive days is often used; G-CSF in selected cases
	Drug-induced (nonimmune)	Direct suppression of myelopoiesis	Not uncommon	Medications account for 72% of all cases of neutropenia; mortality rates as high as 12%–25% (chloramphenicol, etc.)	Appropriate clinical history; often empiric discontinuation of drug will assist in diagnosis	Stop unnecessary medications; G-CSF can be used
	Nutritional	Ineffective myelopoiesis	Uncommon	Protein-calorie malnutrition; folate, B_{12}, copper deficiency. Unusual cause of isolated neutropenia	Appropriate clinical history. BMA	Supportive care; correct nutrition/deficiency
	Viral Infection (varicella, EBV, measles, CMV, hepatitis, HIV)	Direct effect; immune-mediated	Uncommon	General—neutropenia can be mild to severe HIV—aspergillosis; pyomyositis		G-CSF sometimes used in severe neutropenia with infection

AML, acute myeloid leukemia; ANC, absolute neutrophil count; BMA, bone marrow aspirate; CBC, complete blood count; CMV, cytomegalovirus; EBV, Epstein–Barr virus; ESR, erythrocyte sedimentation rate; G-CSF, granulocyte colony stimulating factor; MDS, myelodysplasia; TMP/SMX, trimethoprim-sulfamethoxazole.

Postinfectious Neutropenia

Neutropenia can be commonly seen after viral infections, particularly in children. The neutropenia can start within a few days of the onset of infection and last several weeks. Neutrophil counts usually return to normal as the viremia resolves. Viral diseases that have been implicated include varicella, measles, rubella, hepatitis A and B, infectious mononucleosis, influenza, parvovirus, cytomegalovirus,[444–446] and Kawasaki disease. The mechanisms of the neutropenia are multiple and can involve decreased production, redistribution, and destruction of neutrophils.[447–450] In addition, virus-induced antibody can result in protracted immune neutropenia. Parvovirus B19 is commonly associated with transient neutropenia and can cause protracted leukopenia in immunosuppressed patients.[451,452]

Leukopenia is seen in more than 70% of patients with AIDS and can be associated with hypersplenism and with the presence of antineutrophil antibodies[453–455] and disordered T-cell function.[457]

Infection with *S. aureus*, brucellosis, tularemia, rickettsia, mycobacterium tuberculosis, ehrlichiosis, and leishmaniasis[447,458,459] can cause moderate neutropenia. Marked neutropenia can occur in any patient with overwhelming sepsis. This is more likely to occur in debilitated adults or in the newborn. The mechanism is probably due to exhaustion of the marrow reserve pool, and is particularly well documented in newborn sepsis.[328,329,460] Furthermore, systemic activation of complement during sepsis with production of C5a, a neutrophil activator, can result in increased adherence of neutrophils to the vascular endothelium and margination of activated cells, resulting in neutropenia.[461]

Table 50–13B Neutropenia With Normal Marrow Reserve

Neutropenia	Mechanism	Inheritance/ Frequency	Clinical History	Diagnosis	Treatment
Chronic benign neutropenia of infancy and childhood	Anti-PMN antibody most likely	Common	Median age of detection 8 months; 90% detected before 14 months of age; ANC generally <500/mm^3; no significant predisposition to infection	Normal to increased myeloid precursors. See text for details of diagnosis	Supportive, risk of infection is not high; treatment specifically to raise ANC is not indicated
Nonimmune chronic benign neutropenia	Increased apoptosis	Not uncommon	Described mainly in adults. Incidental finding on CBC. Mild neutropenia; ANC >800–1000. No evidence of rheumatic disease	Selective hypoplasia of myeloid series. Serology negative for collagen-vascular disease	Supportive, risk of infection is minimal
Ethnic or benign familial neutropenia	Unknown	Not uncommon AD	Mild neutropenia in the 800–1400 range. No increased infections. American and South African blacks, Yemenite, Black Beduin, and Falasah Jews	Diagnosis of exclusion. Low ANC in family member	None required
Autoimmune neutropenia	Antibody mediated destruction; sequestration can also occur	Not uncommon	Associated with idiopathic thrombocytopenic purpura, immune hemolytic anemia, systemic lupus erythematosus, and Felty syndrome	Increased marrow cellularity and a late maturational arrest. Some have early arrest	Treat primary autoimmune disorder; G-CSF only if marrow reserve decreased
Alloimmune neutropenia	Maternal allo-immunization	Not uncommon	Moderate to severe neutropenia in newborn period; may have increased cutaneous infections	Resolves by 3 to 4 months of age. See Fig. 50–2	G-CSF if appears septic, otherwise supportive care and observation
Drug-induced neutropenia	Antibody or complement mediated	3.4/million	Fever, sore throat, sepsis, stomatitis, pneumonia; 12%–25% mortality; 80% recover	Medication history; BMA when done demonstrates late maturation arrest	Stop unnecessary medications; can observe if normal marrow cellularity and ANC >500/mm^3
Infection-related neutropenia	Virus-induced antibody	Common	Infection specific clinical history. If bacterial sepsis, patient may have decreased marrow reserve.	Parvovirus B19 and HIV screen. See Fig. 50–2	None required to raise ANC unless early arrest
Hypersplenism	Sequestration; possible PMN destruction	Not uncommon	Usually mild neutropenia; associated with a variety of diseases: infection (malaria, TB), neoplasm, collagen-vascular diseases, hemolytic anemia	Clinical examination; blood smear with spherocytes and tailed cells	Treatment of underlying disorder; splenectomy in rare cases (usually done for anemia or thrombocytopenia)

AD, autosomal dominant; AML, acute myelogenous leukemia; ANC, absolute neutrophil count; AR, autosomal recessive; BMA, bone marrow aspirate; G-CSF, granulocyte colony stimulating factor; MDS, myelodysplastic syndrome; S, sporadic; TMP/SMX, trimethoprim-sulfamethoxazole.

Table 50–14 Screening Evaluation for Patients With Symptomatic Isolated Neutropenia

Screening Tests	SCN SDS	CN	LDGL	SLE RA	CVID	ID	MDS	Comments
Bone marrow aspirate/biopsy	↓ PA[1]		↑ ↓ →		↑	↑ ↓	↓ ABN	Arrows refer to cellularity
Marrow cytogenetics	ABN[3]						ABN	
CBC 2–3 ×/week for 8 weeks	(CY[2])	CY	(CY[2])			(CY[2])		Only done it there is suggestive history
ANA, RF, anti-DNA, immune complexes			+	+				
Quantitative immunoglobulins			↑	↑	↓ →	↓		CVID and ID require at least one deficiency
T + B cell quantitation					↓ →	→ ↓		
Clonal granular lymphocytes (FACS)[4] CD3$^{+/-}$ and CD8$^+$ or CD16$^+$ or CD56$^+$ or CD57$^+$			+	±				Cytotoxic clone >5%–20%[5]
HIV screen	Should be done for most cases of neutropenia							

→ normal, ↓ decreased, ↑ increased; ABN, abnormal; CN, cyclic neutropenia; CVID, common variable immunodeficiency; ID, immunodeficiency; LDGL, lymphoproliferative disorder of granular lymphocytes; MDS, myelodysplastic syndrome; PA, progranulocyte arrest; RA, rheumatoid arthritis; SCN, severe congenital neutropenia; SDS, Shwachman–Diamond syndrome; SLE, systemic lupus.

[1]Progranulocyte arrest (PA) is classic for SCN; SDS marrow findings are variable.
[2]Seen rarely with these syndromes.
[3]May show chromosome 7 abnormality in SDS. This is not a diagnostic criteria for SDS.
[4]Double stain CD3 with other markers. A clone with 5% to 20% of lymphocytes is highly suggestive.
[5]Polyclonal patterns may evolve into a monoclonal pattern over 4 to 6 months.

Drug-Induced Neutropenia

Many therapeutic agents cause neutropenia.[462] Common agents associated with neutropenia are listed in Table 50–15.[463] The mechanism can involve direct bone marrow suppression as seen with many antineoplastic agents, antibody and complement-mediated damage to precursor cells,[464,465] or peripheral destruction and clearance of neutrophils.[363,466–468] The rapid increase in our ability to look for genetically determined drug sensitivities will likely increase our understanding of the mechanisms of many episodes of neutropenia previously thought to be idiosyncratic. The relation of clozapine-induced agranulocytosis to TNF and HLA polymorphisms is an excellent example.[458,469]

The most common presenting symptoms are fever, sore throat, pharyngitis, sepsis, stomatitis, or pneumonia.[463] Mortality rates as high as 12% to 25% have been reported, though full recovery can be expected in more than 80% of patients.[463,470] An overall annual risk of agranulocytosis of 3.4 cases per million has been reported in an ambulatory population from Israel, Europe, and northeast United States. Approximately 72% of all cases of agranulocytosis in the United States are attributed to medications, with procainamide, antithyroid drugs, and sulfasalazine being the most commonly implicated.[471] Most episodes of drug-related neutropenia are due to dose-dependent marrow suppression. Phenothiazine, semisynthetic penicillins, nonsteroidal antiinflammatory agents, aminopyrine derivatives, benzodiazepines, barbiturates, gold compounds, sulfonamides and antithyroid medications are the most common causes.[471,472] The cardiac drugs, propanolol (relative risk 2.5), dipyridamole (3.8), digoxin (2.5), and acetyldigoxin (9.9) are significantly associated with agranulocytosis. The excess risk from these drugs ranges from 1 to 3 cases per 10 million persons exposed for up to 1 week.[473] A more extensive list can be seen in Table 50–14.[463] Usually, the neutropenia becomes evident within 1 to 2 weeks of exposure to drug.[472] Recovery typically starts within a few days of stopping the drug and is preceded by the appearance of monocytes and immature neutrophils in the peripheral blood.[467] Changes in the number of circulating leukocytes may represent a primary disorder of leukocyte production or reflect a secondary response to some disease process or toxin. Early recovery occurs more frequently in patients with normal or increased marrow cellularity. In patients with pancytopenia, the median leukocyte recovery time was 14 days for patients with marrow hypoplasia and 10 days for those without marrow hypoplasia.[474] Rebound leukocytosis with marrow and peripheral blasts has been reported, simulating a leukemic state.[398,399]

Although it is always best to stop the drug if neutropenia occurs, clinical circumstances often make it difficult to do so. With certain medications, such as sulfamethoxazole, the neutropenia depends on the dose and duration of therapy. It is often possible to continue the medication with careful observation. Neutropenia secondary to anticonvulsants often places the clinician in the difficult situation of having to balance the risk of neutropenia with losing control of the seizures by stopping the medication. As long as the ANC remains above 500 to 700 cells/mm^3 and there is no infection, it may be safe to continue the medication, albeit with careful follow-up. A bone marrow aspiration can be helpful under these circumstances. A cellular, late-arrested marrow suggests the neutropenia is immune-mediated. In this case, the neutropenia is less likely to be associated with infectious risk.

Chronic Benign Neutropenia

Chronic benign neutropenia is a syndrome occurring in older children and adults. Onset can occur from childhood to late adulthood. The clinical findings and presentation are quite variable.[436,437] Neutrophil counts are commonly between 200 and 500/mm^3 and the bone marrow examination usually reveals normal to increased numbers of myeloid precursors with an arrest at metamyelocyte or band stage. Often, peripheral monocytosis is also present. Hepatosplenomegaly is not seen and no other infectious, inflammatory, or malignant diseases can account for the neutropenia. Frequently, these patients have a benign course despite the degree of neutropenia. They are able to mobilize more neutrophils to the tissue better than patients with acute drug-induced suppression of equal degree.[434] Antineutrophil antibodies, as well as other immunologic abnormalities have been seen in some patients, although these studies are usually normal.[437,475–477] Bone marrow cytogenetic studies are normal.[437,478]

Corticosteroids, splenectomy, and cytotoxic agents have been used successfully to increase neutrophil counts in these patients.[437] A patient with idiopathic neutropenia was effectively treated with human G-CSF.[479] This patient's course was benign for several years until his marrow became hypocellular, whereupon he developed multiple infections. This particular case underscores the relation between marrow reserve and propensity to infection. G-CSF has been shown to decrease the rate of infection in patients with chronic idiopathic neutropenia.[480] Because the clinical course of this disease is usually benign, treatment intended to increase the neutrophil count should be reserved for those patients with significant recurrent infectious complications.[438,458] In such cases, if the patient's marrow is cellular, other causes of immune deficiency should be explored.

Chronic Benign Neutropenia of Infancy and Childhood

Chronic benign neutropenia of infancy and childhood[481–483] is a chronic state of mature neutrophil depletion with a compensatory increase in immature granulocytes in the bone marrow.[483] This interesting subset of chronic benign neutropenia also highlights the relation between marrow reserve pool and propensity to infection. Even though these patients have severe neutropenia, they have no significant propensity to infection. They may have purulent otitis despite a neutrophil count less than 200/mm^3, emphasizing the fact that neutrophils can go to sites of infection, even though they are not seen in the peripheral blood. It is common for these patients to go several months with neutrophil counts less than 200/mm^3 and have no febrile episodes.

The median age of detection is 8 months. Though it can present any time in the first 3 years of life, 90% of patients are detected before 14 months of age. There is a slight female predominance (3:2) and no correlation with birth order. Neutrophil counts are usually normal at birth but very low at presentation. There is no family history of neutropenia.[435,481–483] Antineutrophil antibodies have been detected in 98% of patients by both immunofluorescent and agglutination assays.[435,482,484,485] Although the exact mechanism of the neutropenia is unclear, the fact that antineutrophil antibodies are frequently no longer detectable late in the course of the disease[435] and that antiimmune therapy is effective in raising the neutrophil counts[435,486,487] suggests an immune mechanism.[435] In spite of the immune nature of this disorder, measuring antineutrophil antibodies is of little or no practical help in diagnosis or management of the patient. There is a significant false negative rate depending on the type and number of assays used and antibodies can be found in many subjects who are not neutropenic.

Some children and adults with benign neutropenia have mucosal infections in spite of normal marrow reserve. Although the children do not become septic, the ulcers can be very bothersome. These cases are difficult to explain. However, we speculate that an antibody-induced neutrophil functional defect may contribute to the symptoms. Some of these patients have measurable defects in neutrophil movement and have been described as having the so-called lazy leukocyte syndrome.[488,489] Antibodies against functional epitopes have been seen in subjects with benign neutropenia[490] and can induce neutrophil dysfunction.[491,492] Alternatively, the mouth ulcers may be a direct effect of a vasculitis-like syndrome that is also producing the neutropenia.

Table 50–15 Causes of Agranulocytosis/Neutropenia (206 Patients, More Than One Cause Per Patient Possible)[420]

	Agranulocytosis/Neutropenia Probable[h]		Agranulocytosis/Neutropenia Possible[i]

Agranulocytosis: nadir of neutrophil count ≤0.5 × 109/L . Neutropenia: nadir of neutrophil count >0.5 × 109/L but ≤1.5 × 109/L.

A = causal relation certain or probable: Drug taken within 10 days of onset of neutropenia, recovery when drug stopped, no other likely cause of the agranulocytosis or neutropenia. **B** = causal relationship possible: Same as **A**, but more than one possible cause of neutropenia present.

[a]Procainamide (2), ajmaline (I). tocainide (I), aprindine (5), and amiodarone (I)

[b]Amoxicillin (I), azlocillin (I), benzylpenicillin (3), phenethicillin (I), cloxacillin and penicillin (2)

[c]Methylthiouracil (I) and propylthiouracil (7).

[d]Captopril (5) and enalapril (I).

[e]Cephalexin (I), cephazolin (I), cefuroxime (I), cefotaxime (I), and cephradine (I).

[f]Glibenclamide (I) and tolbutamide (3).

[g]Phenytoin (2), chlorthalidone (2), sulfamethizole (2), norfloxacin (2), naproxen (2), clomipramine (2), Trazodone (2), omeprazole (2), alimemazine (2), pirenzepine. ticlopidine, ibopamine, hydralazine, nifedipine, spironolactone, nalidixic acid, doxycycline, clindamycin, gentamicin, fusidic-acid, dapsone, azapropazone, combination preparations with aminophenazone, respectively, prophenazone, sulindac, piroxicam, pirprofen, niflumic acid, allopurinol, glaphenine, valproate, levodopa with carbidopa, chlorpromazine, haloperidol, zuclopenthixol, zopiclone, cinnarizine, metronidazole, combination preparations with pyrimethamine, and theophylline.

[h]Isolated agranulocytosis or neutropenia: marrow results and complete blood count information available.

[i]Agranulocytosis or neutropenia present but results of hemoglobin, platelet count, or bone marrow aspiration not available.

Autoimmune Neutropenia

Autoimmune neutropenia has been seen as an isolated phenomenon,[466,493] secondary to other known autoimmune diseases,[466,493,494] related to infections,[448] or related to administration of drugs.[466] There is overlap with the chronic benign neutropenia syndromes mentioned previously. The term *autoimmune neutropenia* is probably more appropriately used when there is evidence for other associated immune phenomena. Immunologic mechanisms are found in cases of neutropenia that have been classified as "idiopathic."[435,466,477,480,494] Immune neutropenia can be seen in association with immune thrombocytopenia and immune hemolytic anemia.[466] In the neutropenia associated with Rh hemolytic disease, there is evidence of downregulation in neutrophil production associated with increase in erythropoiesis.[495]

Patients with autoimmune neutropenia have moderate to severe neutropenia, usually accompanied by monocytosis. Marrow cellularity is increased with a late maturation arrest. The propensity to infection is poorly correlated to the degree of neutropenia.[466,494,496] Hepatosplenomegaly has been seen in about half of the patients. The age of presentation is wide, ranging from early childhood to old age.

Neutrophil-specific antibodies to the neutrophil antigens NA1, NA2, ND1, ND2, NB1 as well as to antigens shared by erythrocytes and to HLA antigens have been detected.[485] They are detected by a variety of assays, including leukoagglutination,[485,497] opsonization,[378,494] immunochemical assays,[466] direct antibody binding,[493] complement activation[466,498] and various modifications of these techniques.[499] The antibodies are usually of the IgG and IgM type. Because of the lack of a good, readily available panel of known neutrophil antigens, most assays detect only the presence of neutrophil-associated antibody. Antibodies to CD13 have been detected in some neutropenic patients with cytomegalovirus.[500] Detection of antineutrophil antibodies is rarely helpful in establishing the diagnosis of immune neutropenia. Many people have antineutrophil antibodies and do not have neutropenia. Conversely, a negative assay does not exclude the diagnosis.[466,485] This may be due to antibody specificity for neutrophil progenitors rather than mature neutrophils.[464,465,477] When antineutrophil antibodies have been measured, the degree of neutropenia has been related to the specificity of the antibody as well as the titer.[466,493,494] In addition to neutrophil-associated antibodies, circulating immune complexes have been detected in about one-third of patients with immune neutropenia[494] and in patients with chronic idiopathic neutropenia.[476]

Antineutrophil antibodies of the IgG type have been reported in systemic lupus. These antibodies have been seen both before and after correction of neutropenia by therapy of the lupus.[466,501] Neutropenia in lupus has been attributed to neutrophil-reactive IgG, increased neutrophil apoptosis, and marrow dysfunction.[320,501–504] The mechanism of the increased neutrophil apoptosis seen in lupus may be linked to increased levels of TNF-related apoptosis-inducing ligand (TRAIL) and relative decrease in the TRAIL receptor 3, and anti-apoptotic receptor.[505] Although approximately 50% of patients with lupus are neutropenic, recurrent infection due to neutropenia is rare.[325,501]

Treatment of autoimmune neutropenia depends on the severity of the neutropenia-related symptoms and the nature of the underlying disease. Because many of these patients have a benign course, therapy solely to increase the neutrophil count is not indicated. If the patient has significant neutropenia (ANC <500/mm^3) and recurrent or severe infections, high-dose gamma globulin[486,487,506] or steroids may be used. Splenectomy provides only transient correction of the neutropenia, and results in a subsequent propensity to infection. Other cytotoxic therapy may be considered, particularly in lupus or rheumatoid arthritis.[501,507]

G-CSF has been used successfully in patients with immune neutropenia and may be considered if the patient is having problems with infection.[480] However, G-CSF must be used at the lowest dose needed to raise the neutrophil count in patients with rheumatic disease as it has been associated with flaring of lupus-associated symptoms and general worsening of the patient's condition.[508,509]

Isoimmune Neonatal Neutropenia

Moderate to severe neutropenia can occur in newborn infants secondary to IgG antibodies transferred from mother to infant. The pathogenesis of this disorder is identical to that of Rh hemolytic disease with prenatal sensitization to neutrophil antigens resulting in production of antibodies to FcRγIIIb that then cross the placenta.[458,485,510] The incidence has been estimated at 2 per 1000 live births.[458,510] If the infant is clearly septic or if subsequent episodes of bacterial infection occur, then marrow aspiration should be considered to rule out primary neutropenia. If there is early arrest or storage pool depletion, treatment with granulocyte transfusion or colony-stimulating factor should be considered.

Neutropenia in Infants of Hypertensive Mothers

Neutrophil counts as low as 500/mm^3 have been reported in infants of hypertensive mothers.[511] Forty-nine percent of infants of hypertensive mothers had neutropenia that lasted from 1 hour to 30 days.[512] Neutropenia was more common in infants who had growth retardation or whose mothers had severe hypertension. Thrombocytopenia to 90,000/mm^3 was also seen.[512] The neutropenia seems to be due to marrow suppression and may be associated with a slightly increased incidence of infection.[511–513]

Pure White Cell Aplasia

Pure white cell aplasia (PWCA) is a rare syndrome characterized by severe pyogenic infections and neutropenia. Many (70%) of these patients have an associated thymoma. In some cases, PWCA occurred years after thymoma removal. Bone marrow examination shows almost complete absence of myeloid precursors with normal erythroid precursors and megakaryocytes. This is in contrast to T-gamma neutropenia or Kostmann syndrome, where early myeloid precursors are seen. Marrow inhibitory activity is found in both IgG and IgM fractions of patient's serum and goes away as the marrow recovers.[464,465,514–516] In some cases, the inhibitory activity is in the lymphocyte fractions and not in the serum. PWCA has been associated with ibuprofen therapy. In vitro serum inhibitory activity required the presence of the drug and of complement. The clinical syndrome resolved when ibuprofen was discontinued.[465] PWCA has also been associated with chlorpropamide[517] and certain natural remedies.[518] In cases associated with thymomas, removal of the mass is indicated but may not result in resolution of the neutropenia. Cytoxan, steroids, as well as cyclosporin A have been effective in treatment of PWCA, as has IV IgG.[519,520]

Neutropenia Associated with Immunologic Abnormalities

Neutropenia has been seen in association with a number of immunologic abnormalities. The patients usually present in childhood with frequent bacterial infections, hepatosplenomegaly, and failure to thrive. Some of these children die in the first few years of life. Hypergammaglobulinemia or hypogammaglobulinemia,[521–524] T-cell defects,[525,526] NK cell abnormalities,[475] and autoimmune phenomena[526,527] have been seen. Many of the reported patients had a positive family history of neutropenia.[521–523] Neutropenia is seen in 26% of patients with X-linked agammaglobulinemia and 40% to 50% of patients with X-linked hyper-IgM syndrome and has been associated with decreased marrow production of neutrophils.[524,528] The neutropenia can be chronic, episodic, or cyclic. The most common

form of hyper-IgM syndrome is due to mutations in CD40, resulting in marked depression of IgG and IgA with elevation of IgM.[529] Chronic diarrhea, skin rashes, recurrent viral infection may also be seen in these children. The treatment in these disorders depends on the constellation of immunologic abnormalities present. Some of these patients have been treated with bone marrow transplantation.[525]

Neutropenia is also associated with a number of other rare primary immunodeficiency syndromes.[529] Common variable immunodeficiency (CVID) is the most frequent primary immunodeficiency. Its frequency has been estimated at 0.0092 and is associated with certain HLA haplotypes.[530] These patients usually present in the second decade, although they may present in childhood. They have a variety of immunologic abnormalities and usually present with recurrent infection. They are prone to autoimmune disorders, including autoimmune neutropenia.[529] This syndrome should be considered in patients who present as benign neutropenia and subsequently develop significant recurrent infection. In contrast to benign neutropenia, children with global immune defects associated with neutropenia have manifestations of recurrent or unusual infections.

The majority of patients with AIDS have neutropenia as well as anemia. About 30% have thrombocytopenia.[531] Neutropenia has been seen in up to 8% of asymptomatic HIV carriers. The bone marrow is usually hypercellular and has lymphoid aggregates and plasmacytosis. There are commonly dysplastic changes in the granulocytes. The neutropenia is felt to be due to ineffective hematopoiesis. The immunoglobulin fraction of HIV-positive serum inhibits CFU-GM and BFU-E in vitro and thus may contain antibodies to progenitors.

Neutropenia and Lymphoproliferative Disorders of Granular Lymphocytes

A number of somewhat heterogeneous disorders can be grouped under the general name of lymphoproliferative disorders of granular lymphocytes (LDGL) and have been variously called large granular lymphocyte (LGL) leukemia, Felty syndrome, T-gamma lymphocytosis, and T- and natural killer (NK) cell-LGL leukemia.[325,532,533] Approximately 80% of patients with LDGL present with neutropenia during the course of evaluation for recurrent infections.[534] The median age of onset is 55 to 65 years, although it has also been seen in children. There may also be a history of rheumatoid arthritis. Splenomegaly occurs in many of the patients but enlarged liver or lymphadenopathy is not common. The peripheral blood usually, but not always, shows lymphocytosis, with prominent large granular lymphocytes. The bone marrow in these disorders is normocellular to somewhat hypocellular and may have an early myeloid arrest. Most patients follow a benign course for many years. However, some patients die of progressive lymphoproliferation or of sepsis related to neutropenia. Although the course may be relatively protracted and benign, the lymphocytosis does represent a clonal proliferation and is felt by some to be malignant.[527,535]

More than 50% of LDGL patients have other associated disorders such as lupus or rheumatoid arthritis. The most common clinical features are recurrent infection (>50%), splenomegaly (>45%), severe neutropenia (>30%), lymphocytic marrow infiltration (>57%), recurrent infection (>50%), anemia (>45%), positive ANA (>30%), positive rheumatoid factor (>40%), hypergammaglobulinemia (>40%), and immune complexes (>40%).[533] Interestingly, these findings overlap with those of rheumatoid arthritis and Felty syndrome. About one-third of patients with rheumatoid arthritis and neutropenia have LGL proliferation. Felty syndrome (rheumatoid arthritis, splenomegaly, and neutropenia) is associated with decreased granulocyte survival as well as decreased production.[536–538] Infection is the major cause of death in Felty syndrome. Nearly all patients with Felty syndrome are HLA-DR4 positive, whether LGL clones are present or not, whereas patients with LGL proliferation not associated with arthritis have a normal prevalence of HLA-DR4. These findings suggest that rheumatoid arthritis, Felty syndrome, and LDGL may be part of the same general disease process.[539–541]

Lymphoproliferative disorders of granular lymphocytes are associated with a chronic clonal proliferation of $CD3^+$ or $CD3^-$ lymphocytes that are also $CD8^+$, $CD16^+$, $CD56^+$, or $CD57^+$. The disorder was initially associated with lymphocytosis and has been defined as a granular lymphocytosis greater than 2000/μL of more than 6 months' duration.[542] However, it is now recognized that patients can have increased populations of LGL without absolute lymphocytosis. These lymphocytes can be either $CD3^+$ or $CD3^-$, reflecting a T-LGL or NK-LGL phenotype, respectively. Most $CD3^+$ granular lymphocytes (GL) are $CD16^+$. Because the $CD3^+CD16^+$ subset represents less than 5% of lymphocytes in healthy subjects, an increase in this population is very suggestive of LDGL. Approximately 75% to 80% of LDGL patients have $CD3^+CD8^+$ clones and 90% to 100% have $CD57^+$ clones. Approximately 30% have $CD3^-CD16^+CD56^+$ clones. Most cases show a single clone, although polyclonal cases have been seen. In the latter case, repeat study over a 6-month period is recommended to see if a single clone evolves. Although a homogeneous pattern of monoclonal antibody reactivity strongly suggests LDGL, confirmation by studying T-cell receptor rearrangement is optimal.[325,533] Cytotoxic T-cell clones have also been seen in association with other immunologically mediated hematologic disorders including pure red cell aplasia, aplastic anemia,[543] autoimmune hemolytic anemia,[544] post organ transplant,[545] and in other hematologic disorders not associated with neutropenia.[545]

The neutropenia in LDGL has been associated with increase in the rate of apoptosis of granulocytes likely mediated through FAS. In fact, these patients have increased circulating levels of FAS ligand, which drop substantially or disappear after treatment with methotrexate.[323]

Neutropenia and associated infection is the most common reason that LDGL patients require treatment. Methotrexate or cyclosporin A is the treatment of choice for the neutropenia associated with LDGL.[325] In a series of 29 patients, the overall response rate to methotrexate was 85.7% with doses in the 10 mg/M^2 per week range. The overall response rate to cyclosporine A, 1 to 6.7 mg/kg/day, was 78.2%, with a median time to response of about 1 month. The median time to recurrence was 4.5 years. Therapy can be stopped with no recurrence in some patients. Deoxycoformycin and cyclophosphamide have also been used.[546] Improvement in neutropenia and decrease in antineutrophil antibody levels with methotrexate treatment or with cyclosporin A has been reported in patients with Felty syndrome,[507,547] even though the LGL clone persists after treatment.[548] About half of patients do not experience any infections in spite of continued neutropenia.[549]

Treatment with G-CSF has been reported to be successful in management of complications of neutropenia due to Felty syndrome.[549] Although G-CSF can be a useful adjunct to therapy in selected cases, it should always be used with caution as exacerbation of vasculitis has been reported with its use. The dose should start low (3 μg/kg/day) and be increased gradually, usually with concomitant low- to medium-dose prednisone.[325] A high dose of GCSF may be required initially to overcome the effects of the T-cell clone. However, as cyclosporin becomes effective, the dose of GCSF may have to be reduced dramatically to prevent significant neutrophilia.

Neutropenia Associated with Metabolic Diseases

Neutropenia can be associated with ketoacidosis in patients with hyperglycemia, hyperglycinuria, orotic aciduria, and methylmalonic aciduria.[550–553]

Glycogen-storage disease type 1a is due to mutations in glucose-6-phosphatase (GSDase) and type 1b is due to mutation in the glucose-6-phosphate transporter. Both type 1a and 1b are associated with hypoglycemia, dyslipidemia, hyperuricemia, elevated lactic acid, and hepatosplenomegaly. Although not seen with glycogen storage disease type Ia, neutropenia is commonly observed in association with glycogen storage disease type Ib. Recurrent infections are a major

source of morbidity in these patients. In particular, gastrointestinal inflammation leads to an inflammatory bowel disease-like picture.[554] The degree of neutropenia is variable but absolute neutrophil counts commonly are less than 500/mm^3. The bone marrow is normocellular or hypercellular. Variable functional defects have been seen in the neutrophils from these patients, including motility and oxidative metabolism defects.[555–558] The gene for the glucose-6-phosphate transporter that is defective in glycogen storage disease type Ib has been mapped to chromosome 11q23[559,560] and there are now at least sixteen known mutations of the gene encoding glucose-6-phosphate translocase (G6PT1). Some of these mutations abolish transport activity whereas others result in up to 23% residual activity. There seems to be no correlation between the mutation or level of residual enzyme activity and presence or degree of neutropenia. Overall, mutations have been seen in 94% of 284 independent alleles, with the 400X mutation being most common and present in 23.6 of the alleles.[561] Inhibition of G6PT1 found in neutrophil microsomes results in increased apoptosis[562] and is consistent with the finding of apoptosis of circulating neutrophils of patients with GCS1b.[322] Furthermore, transfer of G6PT$^{-/-}$ marrow into to wild type mice produced chimeric (BM-Gls-6-PT$^{-/-}$) mice that have impaired neutrophil function and neutropenia, suggesting that G6PT is necessary for neutrophil function and may play a role in the neutropenia of GSC1b.[563] Patients with glycogen storage disease Ib have been treated with G-CSF and GM-CSF.[554] Two patients with severe Crohn-like symptoms were greatly helped by treatment with GM-CSF.[554,564] Interestingly, both of these patients had hypercellular marrows with no evidence of arrest. Neutrophil counts went up within hours of injection of G-CSF and twice daily dosing was required to maintain granulocyte counts, suggesting a clear role in promoting release of granulocytes from the marrow storage pool.[554]

Neutropenia Due to Increased Margination

Both acute and chronic neutropenia can occur because of complement activation.[443,461,565–568] This mechanism was first recognized in patients undergoing hemodialysis and is associated with pulmonary dysfunction.[566,567] The C5a generated during activation stimulates neutrophils, resulting in increased adherence and aggregation and subsequent entrapment in the pulmonary vasculature.[461,568] Similar activation of complement and neutropenia has been seen with the use of membrane oxygenators.[569] Complement-mediated neutropenia due to shifts in the neutrophil pools has also been seen with burns[316] and transfusion reactions.[443] Because lung dysfunction and pulmonary infiltrates have been seen in some of these processes, the neutrophil has been implicated in the pathophysiology of adult respiratory distress syndrome (ARDS).[316,443,568] However, the occurrence of ARDS and severe neutropenia without neutrophilic infiltration of the lungs suggests that mechanisms other than direct damage to the lungs by neutrophils are possible.[570] Neutropenia may be related to complement-mediated destruction of neutrophils as seen in PNH[571,572] or due to similar destruction of granulocyte precursors.[464,465,498]

Neutropenia Associated with Hypersplenism

Neutropenia can be seen in association with hypersplenism. Usually, the neutropenia is not severe enough to cause symptoms, unless there is an antibody present. Anemia and thrombocytopenia are usually also present. Improvement in the hypersplenism-induced neutropenia in a patient with AIDS was obtained by splenic embolization.[573]

Neutropenia Associated with Nutritional Deficiency

Neutropenia has been seen in association with anemia in nutritional deficiency of vitamin B_{12}, folate, and copper.[574–576] All of these neutropenia syndromes are characterized by ineffective myelopoiesis and megaloblastic changes in the bone marrow. Similar findings have been seen in the inherited deficiency of transcobalamin II.[577] Neutropenia and megaloblastic changes have also been seen in association with sideroblastic anemia in the DIDMOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, deafness). The hematologic abnormalities were responsive to thiamine.[577]

Primary Causes of Neutropenia

There have been significant advances in our understanding of the mechanisms of primary neutropenia that have come in large part from the study of very rare primary neutropenia syndromes or hereditary bone marrow failure states. It is very likely that many of these disorders will eventually be diagnosed by molecular diagnostic approaches in the near future. The primary neutropenia syndromes with known genetic mechanisms are noted in Table 50–16, many of which have commercially available mutational analysis.

Ethnic or Benign Familial Neutropenia

Neutropenia has been seen in several ethnic groups and has been referred to as ethnic, pseudo-, or benign familial neutropenia. The level of neutropenia is usually mild and is not associated with any increased propensity to serious infection. Benign familial neutropenia is characterized by neutrophil counts in the 800 to 1400/mm^3 range and no propensity to infection.[578] The disorder has dominant inheritance. The bone marrow is normocellular.[579,580] Ethnic neutropenia has been seen in American Blacks,[276] South African Blacks,[276,581] Yemenite Jews,[277,581] Black Beduin, and Falasah Jews.[581] Although this entity is generally benign,[578,580,582] periodontal problems have been described in some of these patients.[583–585]

Nonimmune Chronic Idiopathic Neutropenia

Nonimmune chronic idiopathic neutropenia is described mainly in adults and is characterized by a mild neutropenia below the normal range for a given ethnic population and a benign course. It differs from what we have called chronic benign neutropenia in that the neutropenia is generally milder and marrow shows selective hypoplasia of the granulocyte lineage with increased immature-to-mature cell ratio. The patients are asymptomatic, have no concomitant rheumatic disease or other systemic disease and no detectable antineutrophil antibodies. Although there is no significant splenomegaly, some enlargement can be detected by ultrasound.[586] They have few infections and the outcome of the infections is favorable. There is a female predominance and an HLA class II genetic predisposition.[587–589] We list it separately because the neutropenia is now believed to be secondary to apoptosis of early myeloid precursors at the CD34$^+$/CD33$^-$ stage. This is associated with increased expression of Fas in CD34$^+$/CD33$^-$ cells but not in later myeloid cells. Decreased clonogenic potential and increased production of TNF-α, IFN-gamma, and FasL have also been reported in stromal cells from chronic idiopathic neutropenia subjects.[441] There is some evidence that mutations in GFL-1 may be responsible for some cases of nonimmune chronic neutropenia.[590]

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) was described by Kostmann in 1956.[591] It presents in early infancy with severe, recurrent infections and neutropenia. There is a significant monocytosis associated with the neutropenia, as is also seen in cyclic neutropenia, suggesting a reciprocal relation between these two cell types that are derived from the same progenitor.[592] Most cases of SCN arise sporadically, consistent with the transmission as an often lethal autosomal dominant disorder.[570,592,593] In the original cohort, transmission appeared

Table 50–16 Neutropenia Syndromes With Known Gene Defects
Neutropenia due to genetic mutations

Syndrome	Incidence	Genetics	Gene	Chromosome	% with a mutation	Comments	References[b]
Severe congenital neutropenia[a]	1–2 : 10^6	Sporadic AD	ELA2	19p13.3	≈60%	ELA2 mutations more common in severe forms. Progranulocyte arrest in bone marrow. Preleukemic	1, 2
		AR	HAX1	1q	≈10%	"Classic Kostmann syndrome." HAX1 deficiency: Increased threshold for apoptosis. Preleukemic	3
		AD	GFI-1	1p22	<5%	Neutropenia and T/B cell deficiency. Regulates ELA2 leading to increased elastase. Other mutations may give milder phenotypes	4, 5
Cyclic neutropenia*	1–2 : 10^6	AD	ELA2	19p13.3	60%–80%	Diagnose by getting a CBC 2 to 3 times/ week for 8 weeks with ANC nadir <200/mm^3	1, 4
Shwachman–Diamond*	Estimate carrier 1 : 277, disease 1 : 76,563	AR	SBDS	7p10–7q11	90%	Neutropenia, short stature, pancreatic dysfunction, may have anemia or thrombocytopenia as well. G-CSF helps, not always needed. Preleukemic	6, 8
Wiskott–Aldrich*	4 : 10^6	X	WASP	Xp11.23		Rare cause of SCN. Decreased lymphocyte/ NK numbers	6, 26
Myelokathexis (WHIM syndrome)	40 cases	AD	CXCR4	2q21		Hypersegmented PMN, more prominent in BMA. CXCR4 mediates homing of stem cells to marrow and retention of mature neutrophils. G-CSF may help	6, 7
Dyskeratosis congenita*	1 : 10^6	X, AD, AR	DKC1 TERC	Xq28 3q21–28	36%	Integument disorder, marrow failure in 80% by third decade, marrow failure can precede skin changes. Disordered telomerase function. Median survival 16 years. Preleukemic	9, 10
Cartilage hair hypoplasia	1 : 23,000	AR	RMRP	9p13		Impaired cellular immunity, 27% have neutropenia, the marrow shows a myelocyte arrest in some. G-CSF may be of benefit	11, 12
Chédiak–Higashi	1 : 10^6	AR	LYST	1q42		Hypopigmentation, large inclusions in myeloid, lymphoid, and other cells. Develop HLH picture that can be fatal	13–15
Griscelli syndrome		AR	Rab27a	15q21		Hypopigmentation of skin and hair, abnormal immune regulation. Develop HLH picture	6, 16
Hermansky–Pudlak II	4 cases	AR	AP3B1	5q14.1		Hypopigmentation, T-cell defects, bleeding, neutropenia	17
P14 deficiency	1 family	AR	P14	1q21		Albinism, neutropenia, cellular marrow with maturation, T- and B-cell defects. Short stature. Reason for neutropenia not clear	18
Cohen syndrome	136 cases	AR	COH1	8q22–q23	94%	Typical facies, developmental delay, retinal dystrophy, intermittent neutropenia with normal marrow	19–23
Barth syndrome*	1 : 400,000	X	TAZ1	Xq28		3-Methylgluconic aciduria, short stature, myocardiopathy, skeletal myopathy. Severe cardiolipin deficiency; 25% have neutropenia, which may be cyclic	24, 25
Glycogen storage disease 1b*	1 : 100,000	AR	G6PT1	11q23	97%	IBD like picture, hypoglycemia, hepatosplenomegaly, neutrophil and platelet dysfunction. Hypoglycemia, Responds to G-CSF, marrow hypercellular. Mutations do not correlate with clinical phenotype	4, 30

Table 50–16 Neutropenia Syndromes With Known Gene Defects—cont'd

Syndrome	Incidence	Genetics	Gene	Chromosome	% with a mutation	Comments	References[b]
Hyper-IgM*	1:10^6	X AR	CD40-LG	Xq26–28 12p13	91%	IgG, IgA, IgE deficient. 60% present with neutropenia. Neutropenia is due to immune dysfunction	27–29
Chronic nonimmune neutropenia in adults	1:60 overall in Crete	AD	GFI-1	1p22		One CIN patient identified with this mutation which not the same mutation seen in SCN	5, 31

IBD, inflammatory bowl disease, AP, apoptosis; X, X-linked; AD, autosomal dominant, AR, autosomal recessive; ELA2, Elastase; AP3b1, adapter-related protein 3 beta-1; Rab27a, RAS associated protein 27a; G6PT1, glucose-6-phosphate translocase, TAZ, taffazin; GFI-1, growth factor independent-1;WASP, Wiskott–Aldrich protein; LYST, Lysosomal trafficking regulator; P14, mitogen activated protein kinase binding partner interacting protein; DKC1, Dyskerin-1; TERC, telomerase RNA component; HAX1, HS1 associated protein X1; SBDS, Shwachman–Bodian–Diamond syndrome; RMRP, RNA component of mitochondrial RNA processing endoribonuclease; WHIM, Warts hypogammaglobulinemia immune deficiency myelokathexis.

to be as a recessive trait.[591,594] Rare cases of X-linked inheritance have also been described that are now recognized as mutations of the Wiskott–Aldrich syndrome gene. The mutations resulting in neutropenia differ from other WASP mutations in that they do not result in complete loss of the WASP protein.[595,596] Bone marrow examination reveals myeloid hypoplasia with an arrest at the promyelocyte stage and ultrastructural examination shows abnormalities in granule production in some patients.[570] Bone marrow culture studies generally show colony growth[478,597] when exogenous colony-stimulating factors are provided.

Mutations in the neutrophil elastase gene (*ELA2*) have been found in patients with SCN.[319,590,598–603] At least 45 different heterozygous constitutional mutations of ELA2 have been seen in patients with SCN, with frequencies ranging from 38%[604] to 78%.[592] ELA2 mutations are also seen in patients with cyclic neutropenia. There are no clear relationships between the specific mutations and the type of neutropenia. There seems to be a set of mutations that are seen in SCN but not in cyclic neutropenia and a group that are seen in both disorders.[592] In addition to direct mutations in *ELA2*, mutations in GFI-1, a transcriptional oncoprotein, have been found in a kindred with SCN. The severity of the neutropenia associated with this dominant mutation was variable within the family. Mutations in GFI-1 cause overexpression of *ELA2*, suggesting that they may be involved in the mechanism of the neutropenia. Interestingly, other mutations in GFI-1 have been seen in patients with chromic nonimmune neutropenia.[590] In contrast to the dominant inheritance of the *ELA2* mutations, the original kindred described by Kostmann seemed to be autosomal recessive in inheritance.[591] Evaluations of patients with recessive inheritance including members of the original kindred revealed mutations in HAX1, which participates in B-cell receptor–mediated signal transduction and may be involved in control of apoptosis.[605] This suggests that HAX1 is responsible for the recessively inherited or "classical" form of Kostmann syndrome. Although there are some theories regarding common pathways in these disorders, there is no clear genetic mechanism for the neutropenia.[592,601] Moreover, although the exact pathways remain unclear, the neutropenia is ultimately due in part to increased apoptosis of marrow myeloid cells.[606]

The G-CSF receptor seemed like a logical choice in the search for the cause of SCN. Although mutations have been found, they are a very rare cause of SCN and can be associated with hyporesponsiveness to G-CSF.[607,608] Mutations in the G-CSF receptor (CSF3R) have been detected in patients who developed leukemia.[609] However, it is not clear how much these contribute to malignant transformation in SCN patients.[602] Such mutations have not been detected at birth but they seem to arise spontaneously, including in SCN subjects who do

not have malignancy.[592] This suggests that they are not responsible for the neutropenia and are acquired postnatally.[610] Approximately 78% of SCN patients with evidence of malignant transformation have a CSF3R mutation. However, when patients with CSF3R mutation and no evidence of malignancy were followed, rapid progression to leukemia did not ensue in spite of evidence for highly clonal hematopoiesis.[609]

Approximately 90% of SCN patients respond to G-CSF with increased cell counts or total correction of their neutropenia.[610–614] Treatment may require doses of G-CSF of 5 to 20 μg/kg/day up to as much as 100 μg/kg/day.[610–612,615] Prior to the availability of G-CSF, most of these patients died of infection at an early age. Some patients also develop myelodysplastic syndrome or myeloid leukemia, regardless of their response to treatment. Although there have been some concerns that G-CSF may provoke malignant transformation, there is no clear evidence that this is the case.[612] According to data from the Severe Congenital Neutropenia International Registry (SCNIR), the likelihood of malignant transformation is dependent on responsiveness to G-CSF. Those patients who required more than 8 μg/kg/day and still were not able to maintain an absolute neutrophil count greater than 2188/μL had a cumulative risk for myelodysplasia (MDS) or acute myeloid leukemia (AML) of 40% at 10 years and a 14% risk of death from sepsis. Patients who required less than 8 μg/kg/day and had neutrophil counts more than 2188/μL had a cumulative incidence for MDS/AML of 15% at 10 years and 3% for death from sepsis.[616] In one study, SCN patients could also be classified as high or low risk based on presence of the ELA2 mutation. Presence of this mutation correlated with a younger age at diagnosis (median 2.8 months vs 16.8 months), lower absolute neutrophil counts (0.13 × 109/L vs 0.38 × 109/L), higher monocyte counts (1.33 × 109/L vs 0.96 × 109/L), higher incidence of infection, and a higher incidence of malignant transformation.[604]

More than 90% of patients with this previously fatal disorder respond well to G-CSF. The usual starting dose is 5 μg/kg/day subcutaneously. However, as mentioned earlier, a higher dose is often required. Blood counts in patients with SCN cycle as seen in cyclic neutropenia in response to treatment with GCSF.[603] This can make monitoring of the counts and dose adjustment difficult, especially if the cycle of the neutrophil count is poorly synchronized with the frequency of clinic visits. We find the routine monitoring of the sedimentation rate and C-reactive protein to be useful in following these patients. If the neutrophil counts on average are in an acceptable range, the sedimentation rate and CRP will be in a normal range. Elevation in these parameters or inflammatory anemia should evoke a search for occult infection, particularly in the sinuses and lung. Because the neutrophil counts can vary significantly with administration of the same dose of G-CSF, the G-CSF dose should not be increased on the basis of a single low neutrophil count, especially if the patient is otherwise doing well and the sedimentation rates have been low. The possibility that the neutrophil counts are cycling should be considered before increasing the G-CSF dose. Because of the chance of malignant transformation, progressive anemia, thrombocytopenia, or macrocytosis warrants reexamination of the marrow and evaluation of marrow cytogenetics.

Although G-CSF is the primary treatment for SCN, bone marrow transplantation should be considered, if there is a sibling donor. This is particularly true if the patient is in a high-risk group by virtue of high G-CSF requirement or presence of the ELA2 gene.[604,616] In small uncontrolled series, 9 of 11 patients had a favorable outcome with marrow transplantation.[617] Transplantation is also an important option in SCN patients who develop progressive myelodysplastic changes or frank leukemia, although the outcome is very poor for patients transplanted under these circumstances.[618]

Cyclic Neutropenia

Cyclic neutropenia is a rare, dominantly inherited disorder with variable expression and is characterized by neutropenia that recurs every 14 to 35 days, although more than 90% of the patients exhibit a cycle period of 21 days.[321] Associated recurrent fever, pharyngitis, gingivitis, stomatitis, and bacterial infections are observed in most patients. The severity of the infections parallels the severity of the neutropenia, and can vary from patient to patient. Although the disease tends to be benign, several patients have died of infection.[619] Most of the patients present in the first year of life; however, there is also an adult-onset form. The disorder can persist for many years but tends to decrease in severity with time. Cyclic fever due to cyclic neutropenia must be differentiated from cyclic fevers associated with TNF-receptor mutations or hyper-IgD,[620–623] which are not associated with neutropenia.

Cyclic neutropenia can be cured by bone marrow transplantation in an animal model[619] and has been transferred from an affected human donor to a recipient during bone marrow transplantation.[624] The bone marrow during times of neutropenia is usually hypoplastic with a myelocyte arrest.[619,625,626] At the onset of the neutropenia, postmitotic cells are absent from the marrow but earlier precursors are present. Microscopic studies during all phases of the cycle show cellular blebbing and nuclear condensation, typical of apoptosis. Furthermore, flow cytometric studies show increased numbers of annexin-V labeled myeloid precursors, indicating selective apoptotic death resulting in removal of neutrophil precursors.[627] Consistent with these observations, early mathematical models of hematopoiesis predicted that oscillations would occur if there were an increased rate of irreversible cell loss in the stem cell pool.[606,628–630]

Cyclic neutropenia has been attributed to mutations in the elastase gene (ELA2) on chromosome 19p13.3.[600,601,603,631] The mutations occur in exon 4 or 5 or at the junction of exon 4 and intron 4. Mutations occur in only one allele of the ELA gene, suggesting a gain of function or aberrant function mutation.[321,600,603] Unlike in SCN, presence of the ELA2 mutation does not have a significant effect on disease severity and does not predict a worse outcome.[604] Also, unlike SCD, cyclic neutropenia is not associated with malignant transformation.[616]

The diagnosis of cyclic neutropenia is established by documentation of periodic neutropenia. This requires monitoring of the neutrophil counts at least twice and preferably three times a week for 8 weeks. Bone marrow aspiration is not helpful. The nadir of the neutropenia usually lasts 3 to 5 days and can be missed if the patient is monitored less frequently than two to three times per week. To establish the diagnosis, there must be regular cyclic fluctuations in neutrophil count with a nadir of less than 200/mm^3 at a period of approximately 21 days. Interestingly, patients may report an increased sense of well-being as their counts recover to greater than 500/mm^3.[472] Note that the cycling phenomenon can occur intermittently throughout the course of cyclic neutropenia.[603] It is not uncommon to see patients whose neutrophil counts cycle with nadirs in the 500 to 1000/mm^3 range. These patients usually do not have any symptoms nor do they have the signs of chronic gingival infection characteristic of patients with chronic severe neutropenia. The diagnosis of cyclic neutropenia is reserved for patients with neutrophil counts that periodically fall below 200 to 300/mm^3.

Patients with cyclic neutropenia as defined above almost always have or will soon develop severe dental, gingival, and mucosal infection and therefore should be treated with G-CSF. Most patients respond at doses in the range of 2 to 3 μg/kg every 1 to 2 days and do not usually require the higher doses often needed in SCN.[592] Treatment should also include regular and aggressive dental care. The antibacterial mouthwash chlorhexidine (Peridex), is useful in decreasing gingivitis.[472,611,632] Shwachman syndrome, neutropenia with LDGL, and neutropenia with primary immunodeficiencies can also present with a cyclic pattern.

Myelokathexis

Myelokathexis is a rare syndrome associated with neutropenia and characterized by a cellular marrow with retained mature neutrophils (*kathexis* = retained) and abnormal nuclear morphology of the myeloid series. Since the initial descriptions,[633,634] several patients

with the constellation of warts, hypogammaglobulinemia, infections, and myelokathexis have been described,[308,570,635,636] leading to the acronym WHIM syndrome.[637] The inheritance appears to be dominant and considerable heterogeneity in clinical characteristics exists among these patients.[119,297,303,635,637]

Neutrophil counts are in the 100 to 450/mm^3 range. The bone marrow cellularity is usually increased. In some cases, mature neutrophils, some bands, and metamyelocytes have bi- or tetraploid nuclei whereas early precursors are normal. Only rare abnormal neutrophils are found in the peripheral blood.[308,635,636] Myelokathexis is associated with an increased rate of apoptosis and decreased expression of bcl-x pro-survival gene in myeloid precursors, which explains in part the abnormal nuclear morphology.[318,606,638] In addition to neutropenia, these patients also have marked T-cell lymphopenia. The onset of verrucae may not be until the second decade and is absent in some patients, as is the case for hypogammaglobulinemia.[297,303,637,639]

Most of the cases of WHIM syndrome have been linked to autosomal dominant mutations in the CXC chemokine receptor 4 (CXCR4), all of which cause mutations in the carboxy-terminus of CXCR4.[297,304,639] Mutations of CXCR4 in WHIM syndrome cause failure of receptor downregulation and internalization, resulting in prolonged activation.[281,640] Activation of CXCR4 leads to increased retention and homing of neutrophils to bone marrow.[297,298] It is the decreased ability of mutant CXCR4 to downregulate that causes increased retention and apoptosis of neutrophils,[640] likely explaining the neutropenia, hypercellular marrow, and apoptosis seen in patients with myelokathexis.[282,302,318]

Patients with this syndrome respond to treatment with GCSF.[641,642]

Shwachman–Diamond–Oski Syndrome

The combination of neutropenia, metaphyseal dysplasia, and pancreatic insufficiency is known as Shwachman–Diamond–Oski syndrome.[643–646] These patients present in the first 10 years of life with steatorrhea, growth failure, and infections. Severe or fatal infections occur in more than half of the patients whereas many have relatively few problems with infection in spite of the neutropenia.[647] A 72-hour fecal fat measurement is useful to demonstrate fat malabsorption. Although pancreatic insufficiency is detectable by fecal fat determination, trypsin or lipase measurements, some patients have minimal problems with steatorrhea. Half of patients show moderate improvement in fat malabsorption by 5 to 8 years of age.[644] Thus, absence of a clear history of bowel problems does not rule out this diagnosis. Physical examination reveals short stature and a variety of other physical anomalies including strabismus, cleft palate, syndactyly, and microcephaly. Twenty-five percent have metaphyseal dysplasia. The pancreas is normal or enlarged and has a characteristic fatty appearance by magnetic resonance imaging.[648] The liver may be enlarged and liver enzymes may be elevated two- to threefold in patients under 2 to 3 years and normalizes with age.[644,649] Determination of characteristic polymorphisms is now very helpful in making the diagnosis. Note that there is great variability in the clinical phenotype, including absence of neutropenia or fat malabsorption. Thus, DNA analysis has become an essential part of the evaluation.

The neutrophil counts are usually less than 500/mm^3. Thrombocytopenia is present in 24% to 60% of the patients and a mildly megaloblastic, prednisone-responsive anemia is seen in 10% of patients.[643] Pancytopenia develops in 10% to 44% of patients and can progress to full aplastic anemia.[643,644] Although rare, patients can present in the newborn period with severe pancytopenia[650] and diabetes.[651]

The bone marrow is usually hypoplastic but can also be normal. In addition to neutropenia, a neutrophil capping and chemotactic defect is present. A partial chemotactic defect may be seen in the parents,[652] consistent with the presumed recessive inheritance. The reported functional defects have been corrected by injection with thiamine in some patients.[653,654] The mechanism for this response is unknown. Sweat chloride determination is normal.

The disorder has been mapped to the centromeric portion of chromosome 7[655] and has not been associated with mutations in elastase.[603] Detailed studies have identified various mutations in this region of the chromosome that may be related to the pathophysiology of the disorder.[656–659] Between 75% and 90% of patients have mutations in the *SBDS* gene (Shwachman–Bodian–Diamond syndrome), which may regulate ribosomal RNA maturation, that maps to the 7q11 centromeric region of chromosome 7.[649] There seems to be no relation between the polymorphisms seen and the clinical phenotype.[660] Mutational analysis is available commercially from several laboratories and is helpful in establishing the diagnosis as well as for genetic counseling. Most of the mutations found to date result in decreases in production of the SBDS protein.

The most common clonal cytogenetic abnormalities seen with malignant transformation or development of myelodysplasia in SDS are associated with chromosome 7.[661–663] About 44% of mutations are associated with i(7q), and other mutations involving chromosome 7 in combination with i(7q) accounted for another 35%.[649] It is important to note that these chromosomal abnormalities in SDS may be present without development of marrow failure and may be transient,[659,664,665] making it unclear whether patients should be transplanted simply because of presence of a chromosome 7-related clone.[666] In one small prospective study, none of four patients with del(20q) or i(7q) developed marrow failure.[664] The rate of MDS/AML seems to be about the same as for SCN at about 2% per year and does not seem to be related to treatment with G-CSF.[616] The marrow dysfunction and propensity to malignant transformation has been associated with shortened telomere length,[667] increased p53 expression,[657,668] and increased apoptosis of myeloid cells.[664,669]

The steatorrhea responds to pancreatic enzyme replacement and resolves by 5 or 10 years of age in about 50% of the patients, although the pancreatic insufficiency remains.[645] Treatment consists of management of infections and supplementation with pancreatic enzymes. The anemia may respond to treatment with prednisone. However, chronic inflammatory anemia can also occur and warrants a thorough search for the source of chronic inflammation and aggressive treatment. The neutropenia responds to G-CSF and in general the required dose is lower than for SCN.[616] Some patients have neutrophil counts in the 600/mm^3 or higher range and do not have problems with infection. Thus, it is not necessary to treat all patients with G-CSF. However, if the patient develops any serious infection related to the neutropenia or any evidence of chronic infection, G-CSF should be started. Furthermore, patients must be monitored closely for evidence of chronic inflammation, particularly chronic sinopulmonary infection.

The overall expected survival is approximately 50%. As with other constitutional marrow failure syndromes, there is an increased incidence of malignancy. Both lymphocytic and nonlymphocytic leukemias have been seen,[670,671] accounting for some of the mortality associated with this syndrome. Blood counts should be routinely monitored three to four times per year and bone marrow examination and cytogenetics be done in case of any evidence of deterioration of the hematologic status.

Barth Syndrome

Barth syndrome (BTHS) is an X-linked disorder characterized by neutropenia, cardiomyopathy, skeletal myopathy, and growth delay. Cognitive function is usually, but not always, normal. It is caused by mutations in the taffazin (*TAZ*) gene at Xq28 that result in cardiolipin deficiency and abnormal mitochondria. The patients also have 3-methylgluconic aciduria, though this is not specific to BTHS. Clinically, the patients present at an early age with heart failure, arrhythmia, gross motor delay, and may have a positive Gower sign. Half of the patients have height less than the 5th percentile but the BMI and growth velocity seem to be normal. The neutropenia, which may be present at birth, is often cyclic. The clinical findings are quite

variable, with about 20% having leukopenia and 25% having neutropenia. There is no correlation between neutropenia and cardiac findings or genotype.[672,673]

Chediak–Higashi Syndrome

The Chediak–Higashi syndrome (CHS) is a rare inherited disorder characterized by oculocutaneous albinism, progressive neurologic impairment, and giant granules in many cells, including neutrophils (see also Table 50–9). The patients also develop severe neutropenia, felt to be due to ineffective granulopoiesis.[674] Chediak–Higashi syndrome results from mutations in the lysosomal trafficking regulator (*LYST*) gene on chromosome 1q42 that code for an adapter protein related to intercellular membrane fusion reactions.[675] The neutropenia and neurologic symptoms are not present at birth, although the abnormal neutrophil granules, diagnostic of the syndrome, are. Patients have defects in neutrophil chemotaxis, natural killer cell activity, T-cell cytotoxicity, and bactericidal function of neutrophils and monocytes.[221,676] Death ensues from a lymphoproliferative syndrome called the "accelerated phase." The accelerated phase of CHS is indistinguishable from hemophagocytic lymphohistiocytosis (HLH). In fact, CHS has been classified as one of the genetic forms of primary HLH.[677] The accelerated phase can be successfully treated using etoposide-containing regimens.[677] However, cure can only be achieved by marrow transplantation.[677,678] Bone marrow transplant is successful in eliminating the immunologic defects with an overall survival of 62%, although only 4 of 11 patients transplanted in accelerated phase survived.[676] Although bone marrow transplant may help the hematologic problems, it does not correct the neurologic abnormalities. In fact, neurologic dysfunction can develop years after successful marrow transplant.[679]

Griscelli Syndrome

Griscelli syndrome is an autosomal recessive disorder characterized by hypopigmentation of the skin and hair and abnormal regulation of the immune system. Neutropenia occurs in association with pancytopenia.[680] In spite of the apparent immunodeficiency, these patients, like CHS patients, develop a progressive HLH syndrome, which is fatal if not treated.[680–682] Mutations in *RAB27A*, *MYO5A*, and *MLPH* have been reported, with Rab27a being associated with immunologic impairment.[681]

Hermansky–Pudlak Syndrome Type II

The seven genetically defined Hermansky–Pudlak syndromes present primarily as bleeding disorders and oculocutaneous albinism. Like Chédiak–Higashi, Griscelli syndrome, and familial hemophagocytic lymphohistiocytosis (HLH), HPS is associated with abnormalities in lysosomal trafficking. All reported cases have nystagmus and bleeding, and some have pulmonary fibrosis. HPSII, like diseases that predispose to HLH, has disordered secretion of lytic granule by cytotoxic T cells and NK cells. The bleeding is due to abnormal platelet granules. HPS-II is consists of oculocutaneous albinism, bleeding, recurrent infection, and neutropenia and is caused by mutations in AP3B1, the cytosolic adaptor protein AP-3, which is involved in lysosomal trafficking. The neutrophil counts are less than 1000/uL and the bone marrow has an early myeloid arrest at the progranulocyte and myelocyte stage, reminiscent of SCN. GCSF is effective in raising the neutrophil counts.[683–685]

Cohen Syndrome

Cohen syndrome is an autosomal recessive condition associated with developmental delay, facial dysmorphism, pigmentary retinopathy, and neutropenia.[686–688] Of the 136 reported cases,[687] 35 are from Finland and are the most clinically homogeneous.[688] The subjects do have oral mucosal infections and can have chronic gingivitis. The neutropenia is isolated, mild to moderate, and intermittent but not cyclic and starts as soon as 2 days of life. The bone marrow cellularity is normal, with no characteristic changes. It is left-shifted in some cases. G-CSF was effective in the patients in whom it was tried.[689]

The disorder is associated with mutations in *COH1* whose function is unknown. It is homologous to the VPS13 protein in yeast, suggesting a role in vesicle-mediated sorting and intracellular protein trafficking.[686,690–692] Ninety-four percent of patients who meet five of eight clinical criteria have mutations in *COH1*.[686]

Reticular Dysgenesis

A syndrome of agranulocytosis, lymphoid hypoplasia, and thymic dysplasia with normal megakaryocyte and erythroid precursors has been called reticular dysgenesis.[693,694] These patients have low IgM and IgA and abnormal T cells.[694] The marrow is hypoplastic, with very few neutrophilic or lymphocytic precursors. The few early myeloid cells present have decreased granule formation.[694] These patients die in infancy. Immediate bone marrow transplantation should be considered.

Dyskeratosis Congenita

Dyskeratosis congenita is an inherited disorder involving abnormalities of integument and usually mild neutropenia,[695] though some patients have pancytopenia.[696,697] Although it is usually X-linked, autosomal dominant, and recessive, inheritance is also seen.[642] It is characterized by nail dystrophy, oral leukoplakia, and reticular pigmentation of the skin. Bone marrow failure develops in more than 80% of cases by the third decade and is the primary cause of death. About 10% of patients develop malignancy and 20% have pulmonary complications that can prove fatal. Now that the genes associated with DC have been identified, it is clear that patients may not present with typical physical findings. In fact, the diagnosis of marrow failure can precede the mucocutaneous manifestations.[698]

The gene for the x-linked form of DC was assigned to band Xq28 and is a mutation in the gene *DKC1* with codes for dyskerin, a protein expressed in all tissues of the body. Mutations in *DKC1* are seen in most x-linked DC patients.[698] Mutations have also been seen in the telomerase RNA component (TERC) as well as telomerase reverse transcriptase (TERT), which are part of the complex that is responsible for maintaining the telomeric ends of chromosomes. These have most commonly been seen in dominant forms of DC. Both DKC1 and TERC are part of the telomerase complex leading in part to the hypothesis that DC is primarily a disorder of telomere maintenance. Interestingly, mutations in TERC and TERT have been reported in other marrow failure syndromes, including aplastic anemia, myelodysplastic syndrome, paroxysmal nocturnal hemoglobinuria, and essential thrombocythemia. Thus, it may be that the pathophysiology of neutropenia and marrow failure in DC is related to stem cell failure due to the role of dyskerin in processing of ribosomal RNA as well as maintenance of the telomere by participation of TERC, TERT, and dyskerin in the telomerase complex.[698,699]

MANAGEMENT OF NEUTROPENIA

The clinical management of neutropenic states depends on the cause and degree of the neutropenia and on associated disease states. The major problem is management of infectious complications. Patients with severe neutropenia and little marrow reserve have acute severe pyogenic infection, whereas patients with hypercellular marrows tend to have chronic infection or no infection problems at all.

The approach is greatly influenced by the clinical context. The clinical approach for patients who are known to be on cytotoxic chemotherapy and present with fever and neutropenia has been well

studied and reviewed.[700–702] The approach is largely dictated by the risk level, which is in turn dependent on the intensity of chemotherapy and the nature of the underlying malignancy. In this setting, patients on conventional chemotherapy who are hemodynamically stable and have a predicted short duration of neutropenia may be treated as an outpatient.[700,701,703] However, in the absence of a history of cytotoxic chemotherapy, the situation is less clear. Patients with ANC lower than 500 and fever require prompt evaluation and the rapid initiation of broad-spectrum parenteral antibiotics, regardless of the ultimate cause for the neutropenia. It usually takes days or weeks to establish the specific diagnosis. Until a diagnosis of a benign form of neutropenia is firmly established, the risk associated with not treating a patient with fever and markedly decreased marrow reserve is too grave. Thus, empiric parenteral antibiotic therapy that covers the most common infecting organisms in individuals with severe neutropenia (*S aureus*, *P aeruginosa*, *E coli*, and *Klebsiella* spp) should be started immediately. If the patient is nontoxic, the follow-up is reliable, and the patient has none of the signs of more serious neutropenia syndromes, management can proceed as an outpatient with parenteral ceftriaxone 50 to 75 mg/kg/day. The patient should be seen within 24 hours to follow up on the cultures, to check the patient status, and to give a second dose of antibiotic. This approach can avoid hospitalization in many patients. However, admission is recommended if there is any question that the patient may be toxic. Any possible causative drugs should be stopped and the blood counts followed weekly. As many acquired neutropenia episodes resolve spontaneously, this approach often avoids the need for marrow aspiration and expensive laboratory evaluation.

Table 50–11 gives the relation of the absolute neutrophil count to propensity to infection. These guidelines should be used in patients with chemotherapy-induced neutropenia and in neutropenia associated with granulocyte hypoplasia, such as aplastic anemia, SCN, or familial severe neutropenia. These patients have no marrow reserve and tend to have decreased marrow cellularity with an early myeloid arrest. Because these patients cannot respond to infection, many of the inflammatory signs of infection may be absent. For example, radiographs may not reveal pneumonias or there may be no abdominal tenderness with an early-ruptured viscus. The organisms causing infection come from the gastrointestinal tract or skin and can result in overwhelming sepsis very quickly. Thus, febrile patients with neutropenia related to marrow suppression should be treated immediately with broad-spectrum parenteral antibiotics. Antibiotics should be continued for several days, past the end of fever. If fever and neutropenia persist more than a week, consideration should be given to the empiric use of an antifungal agent. Granulocyte transfusions are effective in certain instances of culture-proven gram-negative sepsis. They should be used in patients with severe neutropenia with culture proven gram-negative sepsis and who have not shown a clinical response to antibiotics within 24 to 48 hours. Enthusiasm for the use of granulocyte transfusion has waned in recent years, in part due to difficulties in procurement and in part due to better antibiotics. There is some recent increase in interest with the availability to increase yields by treating the donor with G-CSF.[704,705] Routine reverse isolation procedures are of no benefit[706,707] and serve to decrease contact with medical personnel. Whereas empiric antibiotics are clearly indicated in case of fever, prophylactic antibiotics should not be routinely used.

Patients with late marrow arrest and normocellular marrow may be able to handle infections reasonably well. Children in whom the diagnosis of chronic benign neutropenia of infancy has been confirmed can be treated like normal children. In older patients with evidence of marrow reserve and a several-month history of severe neutropenia without serious infections, less aggressive therapy may be reasonable as well. When these patients are first encountered, however, they should be treated like other patients with more severe forms of neutropenia.

All patients with chronic neutropenia should receive regular dental care. Chronic gingivitis and recurrent stomatitis can be major sources of morbidity. Antibiotic mouthwash such as Peridex can be very helpful in preventing gingivitis.

Recombinant G-CSF has been effective in correcting neutropenia in cyclic neutropenia and severe congenital neutropenia and is recommended for these patients.[480,611,613,614,632] Bone marrow transplantation has been used successfully in certain cases of severe neutropenia and should be considered if an appropriate donor is available.

MONOCYTOPENIA AND MONOCYTOSIS

Alterations in the number of circulating monocytes are seen in a number of clinical situations (Table 50–17), although generally the disorders are less well defined than those of neutrophils. Production of monocytes is regulated by IL-3 and GM-CSF produced by T-lymphocytes and M-CSF produced by endothelial cells and by monocytes themselves. IL-3 and GM-CSF selectively induce M-CSF production by monocytes, suggesting one mechanism for production of the monocytosis associated with certain chronic infections and enhanced T-lymphocyte activity.[708] Monocytes comprise 1% to 9% of peripheral leukocytes, except during the first 2 weeks of life where the total monocyte count is higher.[709,710]

The blood monocyte and tissue monocyte–macrophages undoubtedly play an important role in defense against bacteria and fungal invasion; however, there is no clear association between circulating numbers of monocytes and propensity to infection as is clearly documented with neutrophils. Decrease in the number of monocytes has been seen with endotoxemia and with glucocorticoid administration.[711] Noncirculating monocytes seem to be relatively resistant to radiation and cytotoxic chemotherapy.[712]

Monocytosis is generally observed in association with chronic inflammatory processes, whether infectious or immune in nature. Monocytosis has been seen with tuberculosis,[713] subacute bacterial endocarditis, syphilis, and fever of unknown origin.[713,714] Collagen vascular diseases such as rheumatoid arthritis, systemic lupus erythematosus, myositis, periarteritis, and temporal arteritis have been associated with monocytosis as well as granulomatous diseases such as sarcoid, regional enteritis, and ulcerative colitis.[713,715]

Monocytosis has been seen with several primary neutropenic syndromes, including cyclic neutropenia, chronic idiopathic neutrope-

Chronic neutropenia
Post splenectomy

nia, and Kostmann syndrome.[483,579,591,619] An increase in monocytes usually heralds recovery from agranulocytosis.

Monocytosis is commonly seen in a number of primary hematologic malignancies. Patients with chronic and acute nonlymphocytic leukemias as well as in preleukemic states have increased promonocytes and monocytes.[716–718] In many of these cases, the monocytes may be malignant but are indistinguishable from normal by light microscopy.[718] In addition to leukemia, monocytosis has been seen in both Hodgkin's and non-Hodgkin lymphomas, histiocytoses, as well as nonhematologic malignancies.[719–721] Monocytic leukemoid reactions have been seen in association with corticosteroids in myelodysplastic syndrome.[722]

CHAPTER 51

DISORDERS OF LYMPHOCYTE FUNCTION

David B. Lewis, Kari C. Nadeau, and Aileen C. Cohen

Disorders of lymphocyte function can be categorized as either primary defects or secondary defects, such as those due to malnutrition, human immunodeficiency virus infection, or treatment with immunosuppressive or cytotoxic agents. This chapter emphasizes primary lymphocyte defects (Table 51–1)[1–4] involving the three major lineages of lymphocytes: T cells, B cells, and natural killer (NK) cells. Genetic immunodeficiencies that are mainly associated with the hemophagocytic syndromes (e.g., deficiency of perforin or MUNC 14–3) are discussed in Chapter 52. Immunodeficiency secondary to Epstein–Barr virus (EBV; e.g., X-linked lymphoproliferative syndrome) are discussed in Chapters 54 and 90. The autoimmune lymphoproliferative syndrome secondary to defects in Fas-mediated apoptosis in lymphocytes is discussed in Chapter 90. Treatment of primary immunodeficiency and other inherited disorders by transplantation of hematopoietic cell precursors contained in bone marrow, peripheral blood, or cord blood is discussed in detail in Chapter 100.

Primary immunodeficiencies of lymphocytes arise from abnormalities in development, maturation, or function. They can be divided into those giving rise to immunodeficiency diseases primarily involving antibody production and those characterized by combined defects in both antibody production and T-cell function (see Table 51–1). A few of these disorders, particularly certain forms of severe combined immunodeficiency (SCID), also have NK-cell deficiency as a prominent feature. Excluding selective immunoglobulin (Ig) A deficiency, which affects approximately 1:600 persons, primary immunodeficiency disorders due to inherited gene defects occur in approximately 1:10,000 live births and often but not invariably manifest in the first 6 years of life.[5] The immunodeficiency diseases are characterized by an increased frequency or severity of infections and by infections with unusual, relatively avirulent organisms, such as opportunistic pathogens or attenuated viruses used in vaccination (see box on Evaluation for Suspected Immunodeficiency). Antibody deficiency diseases, which are more common than T-cell disorders, are most frequently characterized by recurrent pyogenic infections, particularly with encapsulated bacteria involving the sinopulmonary tract. T-cell deficiency directly results in difficulty handling intracellular infections with viral and certain fungal (e.g., *Candida*, *Aspergillus*, *Pneumocystis*), parasitic (e.g., *Toxoplasma*), and bacterial (e.g., *Mycobacteria*, *Salmonella*, *Listeria*) pathogens. T-cell deficiency often includes infections with pyogenic bacteria, secondary to impaired production of opsonizing or neutralizing antibody by B cells from the lack of $CD4^+$ T-cell help as well as invasive infection with aerobic gram-negative bacteria (e.g., *Pseudomonas*, *Enterobacter*), most likely because of a lack of interleukin (IL)-17–producing helper T (T_H)17 $CD4^+$ cells. Diarrhea and malabsorption often manifest as failure to thrive in early infancy, autoimmune disorders, especially autoimmune cytopenias, and malignancies frequently occur in primary immunodeficiency diseases. The majority of malignancies are observed in patients with ataxia-telangiectasia, Wiskott–Aldrich syndrome (WAS), common variable immunodeficiency (CVID), and the hyper-IgM syndrome.

Immunodeficiency diseases may reflect discrete defects of lymphocyte development along a maturational pathway, as detailed in Chapters 11 and 12 and summarized in Figure 51–1, or in the function and cooperative interaction of mature lymphoid cells with each other, as shown in Figure 51–2 for interactions of T cells and B cells (see Chapter 14), or of T cells with dendritic cells and mononuclear phagocytes, as shown in Fig. 51–2. Primary defects of lymphocyte function usually are inherited, but whether this is true for some disorders, such as CVID, is uncertain in most cases. Autoantibodies can cause acquired immunodeficiency (see IFN-γ/T_H1 Pathway Deficiencies later). The gene defects for many primary immunodeficiencies have been described, often in great molecular detail, and have provided important insights into the immunobiologic role of the affected genes as well as the nature of clinically important genetic mutations in humans.

ANTIBODY DEFICIENCIES

X-Linked Agammaglobulinemia

Etiology and Pathophysiology

Primary immunodeficiencies in which B-cell development is blocked are characterized by early postnatal hypogammaglobulinemia and markedly depressed numbers of peripheral B cells. These disorders have an incidence of approximately 5:1,000,000; approximately 85% of these cases are due to X-linked agammaglobulinemia (XLA).[6] In XLA, mature B cells are absent or markedly decreased in the peripheral blood, plasma cells are absent in lymphoid tissue and bone marrow, and functional antibody is not produced or is present in low amounts.[6–8] Pre-B cells, $CD19^+CD34^-$ cells that express intracytoplasmic IgM heavy chain (Cμ) but not light chain or surface Ig, are present in low to normal numbers or are absent in the bone marrow.[6] When pre-B cells are present in XLA, a smaller proportion is proliferating. In contrast, pro-B cells, defined by a $C\mu^-$, $CD10^+CD19^+CD34^+$, terminal deoxytransferase-positive (TdT^+) phenotype, are present in normal numbers, suggesting a block at the $C\mu^+$ pre–B-cell stage of B-cell development (see Fig. 51–2). Rare B cells can be detected in the circulation of patients and, when present, have an immature surface phenotype with a high ratio of surface IgM to IgD and low levels of human leukocyte antigen (HLA) class II surface proteins.[9] Occasionally, circulating mature B cells and serum IgG levels higher than those observed in typical XLA are detected in patients, but deficiency of antibody production usually persists. At least one adult patient with normal levels of IgG but with B-cell lymphopenia and an apparently selective inability to mount antibody responses to unconjugated polysaccharide vaccines has been reported.[10]

The defective gene in XLA is intrinsic to the B cell, maps to Xq21.3-q22, and encodes the B-cell–specific, 77-kd, cytoplasmic Bruton tyrosine kinase (btk), named after the discoverer of human agammaglobulinemia.[6,7,11] This Tec family tyrosine kinase is expressed in all hematopoietic lines except T cells and plasma cells and is involved in signal transduction from surface Ig. More than 600 unique *btk* mutations involving all five domains of the protein have been shown to give rise to XLA,[11] with the kinase domain the most frequent target. In most patients, a direct correlation between clinical phenotype and specific *btk* mutations has not been demonstrated. In fact, phenotypical differences can be observed even among males in a single kindred,[12] indicating the importance of modifying genes or the environment in influencing the immunologic phenotype. The role of btk in signal transduction from a pre–B-cell receptor (pre-

Table 51–1 Primary Lymphocyte Defects

Disorder	Inheritance	Locus	Gene Defect/Pathogenesis	Associated Features
Predominantly Antibody Deficiencies				
X-linked agammaglobulinemia	XL	Xq21.3–22	Defective pre–B-cell maturation secondary to abnormality of Btk, a B-cell–lineage cytoplasm tyrosine kinase	
BLNK deficiency	AR	10q23.2	Lack of the BLNK protein signal transduction molecule compromises B-cell development at the pre–B-cell stage	
Igα (CD79a) deficiency	AR	19q13.2	Defect in Igα, which associates with BCR and pre-BCR, blocks pre–B-cell maturation	
Ig μ heavy-chain deficiency	AR	14q32.3	Mutations of Ig heavy chain gene locus prevents pre-BCR expression and blocks pre–B-cell maturation	
λ5/14.1 deficiency	AR	22q11.21	Absence of λ5/14.1, surrogate light-chain component of the pre-BCR arrests development at pre–B-cell stage	
LRRC8 deficiency	AD, chromosomal translocation	9q34.13	Truncation of C-terminal coding region of LRRC8 gene resulting in a dominant negative impact on B-cell development	Mild facial dysmorphism
κ-chain deficiency	AR	2p11	Point mutation at κ light-chain gene locus	Clinically significant(?)
Hyper-IgM syndrome due to AID (HIGM2) or UNG (HIGM5) defect	AR	12p13 (AID) 12q23–q24.1 (UNG)	B-cell isotype switching defect due to AID or UNG deficiency; decreased IgG and IgA and normal to elevated IgM; T-cell function presumably normal	
Hyper-IgM syndrome due to IKK-γ/NEMO deficiency	XL	Xq28	Defective activation of NF-κB signaling after engagement of CD40 resulting in defective B-cell isotype switching (in most patients); poor innate immune response to gram-positive bacteria due to impaired Toll-like receptor signaling	Hypoplastic/conical teeth, absence of sweat glands, sparse hair
CVID			Defect of B-cell maturation/differentiation, often with defective T-helper function or augmented suppression by T cells; autoimmunity in 10%–15%	
ICOS deficiency	AR	2q33	CVID phenotype: Defect of B-cell maturation/differentiation due to defective costimulation of B cells by T cells	
TACI deficiency	AD or AR	17p11.2	CVID phenotype: Intrinsic defect of B-cell maturation/differentiation	
CD19 deficiency	AR	16p11.2	CVID phenotype: Intrinsic defect of B-cell maturation/differentiation	
Antibody deficiency with normal Ig	?	?	Impaired responses to unconjugated polysaccharide antigens may be prominent; forme fruste of CVID(?)	
IgA deficiency	AR(?)	6p21.3(?)	Failure of deletional isotype switching to and terminal differentiation of IgA-secreting B cells or function may overlap with CVID or TACI deficiency	Autoimmunity, allergy
Selective IgG subclass deficiency	AR(?)	14q32.3(?)	Selective defects of isotype differentiation associated with poor antibody responses to antigens such as polysaccharides, often with IgA deficiency; very rare AR form due to deletion of IgG subclass switch regions	
Hypoimmunoglobulin M syndrome	?	?	Selective decrease in IgM, which usually is depressed but not undetectable; often associated with poor antibody responses to polysaccharide vaccines	
Combined Immunodeficiencies				
SCID				
T^-B^+ SCID				
X-linked (γ_c deficiency)	XL	Xq13.1–13.3	Defect of T-cell and NK-cell development secondary to mutation of common γ chain (γ_c) of IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 receptors	
Jak3 deficiency	AR	19p13.1	Mutations in Jak3, signaling molecule for γ_c; phenotype identical to X-linked SCID phenotype	
IL-7 receptor deficiency	AR	5p13	Defect of T-cell but not NK-cell development due to block in IL-7 and possibly TSLP signaling	
PNP autoimmunity deficiency	AR	14q13.1	Defect of T-cell development and function secondary to toxic metabolites due to deficiency of PNP	Anemia, neurologic symptoms
CD3δ, CD3ε, CD3ζ deficiencies	AR	11q23 (CD3δ and CD3ε), 1q22–q23 (CD3ζ)	Defect in intrathymic signaling via the pre-TCR or TCR resulting in thymocyte maturational arrest	
CD45 deficiency	AR	1q31–32	Defect in intrathymic signaling leads to perturbed thymocyte development and maturational arrest	
WHN/FOXN1 (nude) deficiency	AR	17q11–q12	Defective thymic microenvironment with impaired thymocyte maturation	Alopecia

Table 51–1 Primary Lymphocyte Defects—cont'd

Disorder	Inheritance	Locus	Gene Defect/Pathogenesis	Associated Features
T^-B^- SCID				
RAG1/RAG2 deficiency	AR	11p12–13	Maturation defect of T-cell and B-cell development secondary to absence of antigen receptor gene recombination from mutations of RAG1 or RAG2 recombinase proteins	
Artemis deficiency (includes Athabascan SCID)	AR	10p	Maturation defect of T-cell and B-cell development secondary to absence of Artemis protein required for TCR and Ig antigen receptor gene recombination	Radiation sensitivity
DNA ligase IV deficiency	AR	13q22–q34	Maturation defect of T-cell and B-cell development secondary to absence of DNA repair enzyme required for TCR and Ig gene recombination and lymphocyte survival	Radiation sensitivity, microcephaly
Cernunnos/XLF	AR	2q35	Maturation defect of T-cell and B-cell development secondary to absence of Cernunnos/XLF, which is required for nonhomologous DNA repair during TCR and Ig antigen receptor gene recombination	Radiation sensitivity
ADA deficiency	AR	20q13–ter	Defect of T-cell, B-cell, and NK-cell development secondary to toxic metabolites due to ADA deficiency	Cartilage and neurologic abnormalities in some patients; autoimmunity if partial defect; sensorineural hearing loss
Reticular dysgenesis	AR	?	Stem cell defect affecting maturation of lymphoid and myeloid cells, particularly T cells and neutrophils	Sensorineural hearing loss
T^+B^- SCID				
Omenn syndrome eosinophilia	AR	11p12–13 (RAG1/RAG2), 5p13 (IL-7Rα), 9p21–p12 (RMRP)	Hypomorphic mutations in *RAG1*/*RAG2*, *IL-7Rα*, or *RMRP* genes resulting in severe but partial block of T-cell and B-cell development with oligoclonal expansion of peripheral T cells with limited TCR repertoire; usually no peripheral B cells but elevated IgE	Erythroderma, hepatosplenomegaly, severe diarrhea, failure to thrive
Other Forms of SCID				
MHC class II deficiency	AR	16p13.1–2 (CIITA), 1q21, (RFX5), 13q (RFXAP)	Mutation of transcription factors (CIITA, RFX5, RFXAP, RFXANK) required for transcription of MHC class II, invariant chain, and HLA-DM molecules	Diarrhea, severe viral infections
ZAP-70 deficiency	AR	2q12	Mutations in ZAP-70 kinase gene required for TCR signaling resulting in decreased intrathymic development of $CD8^+$ T cells and peripheral $CD4^+$ T cells that are functionally defective	
CD25 (IL-2 receptor α chain) deficiency	AR	10p15–p14	Mutation in IL-2 receptor α gene resulting in abnormal T-cell compartment and defective T-cell activation; possible effect on regulatory $CD4^+$ T cells	Lymphadenopathy, hepatosplenomegaly
lck Deficiency	AR	10p15–p14	Mutations in $p56^{lck}$ associated with other T-cell defects	
Orai1 deficiency	AR	12q24	Ion channel defect resulting in decreased generation of an intracellular increase in calcium in T cells after engagement of T-cell receptor	
Hyper-IgM Syndromes with T-cell Immunodeficiency				
X-linked hyper-IgM syndrome (HIGM1; CD40-ligand deficiency)	XL	Xq26–27	Defective B-cell activation and T-cell function due to abnormal CD40-ligand (CD154) expression on activated T cells	Neutropenia, autoimmune cytopenias, rheumatoid arthritis
X-linked hyper-IgM with ectodermal dysplasia	XL	Xq28	Defect in NEMO gene resulting in defective signaling after engagement of CD40	Similar to HIGM1 plus ectodermal dysplasia and NK-cell dysfunction
CD40 Deficiency (HIGM3)	AR	20q12–q13.2	Lack of CD40 blocks CD40-ligand– dependent signaling of B cells, APC-mediated activation of T cells, and mononuclear phagocyte activation by CD40 ligand	Likely similar to CD40 deficiency (HIGM1)
Other Disorders Affecting T-cell Number or Function				
Cartilage-hair hypoplasia syndrome	AR	9p13	Mutation of RMRP gene encoding a nonmessenger RNA resulting in perturbed T-cell development and function; can present as T^-B^+ SCID in severe cases	Absence of hair, short-limbed dwarfism

Table 51–1 Primary Lymphocyte Defects—cont'd

Disorder	Inheritance	Locus	Gene Defect/Pathogenesis	Associated Features
Schimke immunoosseous dysplasia	AR	2q34–q36	Mutation of *SMARCAL1*, a gene likely involved in regulating chromatin configuration and gene expression; associated with decreases in peripheral T-cell compartment; thymic hypoplasia(?)	Spondyloepiphyseal dysplasia, focal segmental glomerulosclerosis, thyroid and ocular abnormalities, cerebral ischemia
DiGeorge/velocardial facial syndrome	Most commonly due to haploinsufficiency due to chromosomal deletions	22q11.2 10p14–p13	In 22q11.2 interstitial deletion, haploinsufficiency of *Tbx1* and *CrkL* genes may block development of third and fourth branchial arch derivatives; thymic hypoplasia with normal B-cell and NK-cell compartments; if hypoplasia is severe, can manifest clinically similar to other forms of T^-B^+ SCID syndromes	Abnormal facies, hyperparathyroidism, anomalies of cardiac outflow tract, velopharynx, lower airway, kidney; developmental delay autoimmunity
CD3γ or CD3ε deficiency	AR	11q23	Defective expression of the αβ TCR–CD3 complex on thymocytes and T cells and abnormal signal transduction capacity; either CD3γ or CD3ε can also present as SCID	
TAP1 and TAP2 deficiencies	AR	6p21.3	Defect in TAP function resulting in decreased MHC class I expression and intrathymic $CD8^+$ T-cell generation	Bronchiectasis (mechanism?)
CD8-α	AR	2p12	Absence of CD8 T cells with increased $CD4^-CD8^-$ T-cell population in periphery	Bronchiectasis (mechanism?)
IFN-γ/T_H1 pathway defects				
IL-12 p40 deficiency	AR	5q31.1–q35	Lack of IL-12 resulting in limited generation of T_H1 cells; IFN-γ responsiveness is normal	
IL-12 receptor β1 deficiency	AR	19p13.1	Lack of IL-12 receptor signaling resulting in limited generation of T_H1 cells; IFN-γ responsiveness is normal	
IFN-γ receptor deficiency	AR or AD	6q23–q24 (IFNGR1) 21q22.1–22.2 (IFNGR2)	Lack of responsiveness to IFN-γ	Can be mimicked by autoantibodies to IFN-γ
STAT1 deficiency	AR or AD	2q32.2–q32.3	Partial form: Blockade of IFN-γ–mediated STAT1 activation; severe form in which STAT1 responses to type I IFN and IFN-γ are ablated	
Other Immunodeficiencies				
Wiskott-Aldrich syndrome	XL	Xp11.22–11.3	Defect of cytoskeletal signaling secondary to *WASP* gene mutation affecting activation of T cells, B cells, and APCs	Thrombocytopenia, small platelets, eczema, malignancies, IgA-mediated autoimmunity
Ataxia-telangiectasia	AR	11q23.1	Disorder of cell-cycle checkpoint pathway and cellular responses to DNA damage secondary to mutation of *ATM* gene	Ataxia, telangiectasia, malignancies, radiation sensitivity
IPEX syndrome	AR	Xp11.23–q13.3	Deficiency of FOXP3 transcription factor resulting in decreased numbers of regulatory $CD25^+CD4^+$ T cells	Autoimmune enteritis, endocrinopathy
STAT5b deficiency	AR	17q11.2	Deficiency of cytokine-and hormone-driven STAT5b signal transduction resulting in T-cell lymphopenia and decreased regulatory $CD25^+CD4^+$ T cells	Laron dwarfism, autoimmune diathesis(?)

AD, autosomal dominant; ADA, adenosine deaminase; AID, activation-induced cytidine deaminase; APC, antigen-presenting cell; AR, autosomal recessive; ATM, ataxia-telangiectasia mutated; BCR, B-cell receptor; BLNK, B-cell linker protein; btk, Bruton tyrosine kinase; CVID, common variable immunodeficiency; HIGM, hyperimmunoglobulin M syndrome; HLA, human leukocyte antigen; ICOS, inducible T-cell costimulator; IFN, interferon; Ig, immunoglobulin; IKK, inhibitor of κB kinase; IL, interleukin; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance; Jak, Janus kinase; LRR8, leucine-rich-repeat-containing 8; MHC, major histocompatibility complex; NEMO, NF-κB essential modulator; NK, natural killer; PNP, purine nucleoside phosphorylase; RAG, recombination-activating gene product; RMRP, RHA component of the RHA-processing endo ribonucleave; SCID, severe combined immunodeficiency; SMARCAL1, SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily A-like protein 1; STAT, signal transducer and activator of transcription; TACI, transmembrane activator and CAML interactor; TAP, transporter associated with antigen processing; TCR, T-cell receptor; TH1, T helper-1; TSLP, thymic stromal lymphopoietin; UNG, uracil N-glycosylase; WASP, Wiskott-Aldrich syndrome protein; WHN, winged-helix nude; XL, X-linked, XLF, XRCC4-like factor.

BCR; IgM heavy chain with surrogate light chain) or other receptors, the substrates phosphorylated by btk, and the mechanism(s) of inhibition of pre–B-cell maturation with *btk* gene defects are only partially understood.[6,7] The btk appears to be involved in activation of phospholipase Cγ, which in turn acts to increase calcium fluxes in B-lineage cells. The btk-dependent activation of phospholipase Cγ involves interaction of btk with the B-cell linker (BLNK) adapter protein.[13] In female carriers of XLA, B cells in which the non-inactivated X chromosome encodes the normal btk allele predominate in the periphery. This is believed to be secondary to decreased proliferation or survival of developing B cells in which the non-inactivated X chromosome expresses the mutant *btk* allele.[14] As in other X-linked disorders, female carriers may have clinically evident agammaglobulinemia due to an extreme proportion of the normal *btk* allele being inactivated, although this is extremely rare in btk deficiency.[15]

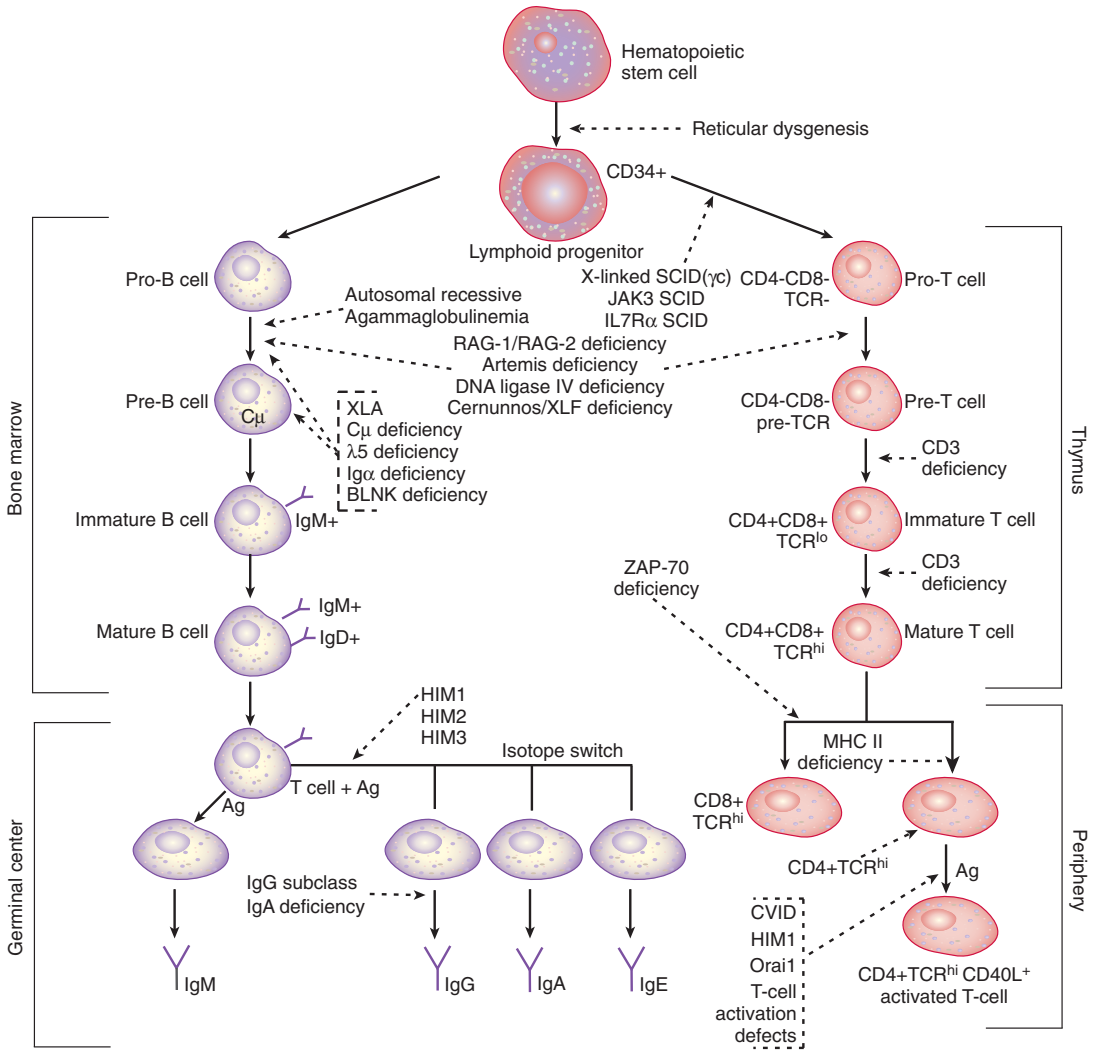

Figure 51–1 Select immunodeficiency diseases associated with maturation of T and B cells. Ag, antigen; Ig, immunoglobulin; BLNK, B-cell linker protein; CD40-L, CD40-ligand; CVID, common variable immunodeficiency; HIGM, hyper-IgM syndrome; ICOS, inducible T-cell co-stimulator; IL-7Rα, interleukin-7 receptor α; JAK, Janus kinase; MHC II, major histocompatibility complex class II; RAG, recombination activating gene; SCID severe combined immunodeficiency; TACI, transmembrane activator and CAML interactor; TCR, T-cell receptor; XLA, X-linked agammaglobulinemia; XLF, XRCC4-like factor.

Non–X-Linked Agammaglobulinemia

Rare disorders of absent B cells and panhypogammaglobulinemia that resemble XLA but are inherited in an autosomal recessive mode have been described. Patients with one form have defects of the μ heavy-chain constant region gene (Cμ deficiency) and defective expression of membrane μ heavy chain. Membrane μ heavy chain is an obligatory component of the pre-BCR and is required for normal B-cell development. Cμ deficiency results in failure of B-cell development at the pro–B-cell to pre–B-cell transition (see Fig. 51–1).[16] Compared with patients with btk deficiencies, persons with genetic defects of the Cμ region tend to have more severe disease, with an earlier clinical presentation and an increased frequency of complications.[17] Defects of other components of the pre-BCR complex, which include a surrogate light chain composed of λ5/14.1 and Vpre-B and the Ig-associated signal-transducing chains Igα (CD79a) and Igβ (CD79b), or of intracellular molecules required for pre-B-cell signaling, also give rise to a clinical picture similar to that of Cμ deficiency. Human mutations have been identified in λ5/14.1,[18] Igα,[19] and the B-cell signaling adaptor molecule BLNK.[20] Another non–X-linked, presumably autosomal recessive form of agammaglobulinemia is characterized by an arrest of B-cell development at the $CD10^+CD34^+$ pre–B-cell stage, with complete absence of pre-B cells in the bone marrow and mature B cells in the periphery.[21] The genetic cause is unknown. A single case of agammaglobulinemia in a girl with unusual facial features and a chromosomal translocation that truncates the leucine-rich-repeat-containing 8 (LRRC8) gene product of chromosome 9 has been reported; this condition appears to act in a dominant manner to somehow inhibit B-cell development.[22]

Clinical Manifestations

In affected boys with XLA, recurrent pyogenic infections begin during the latter half of the first year of life as maternal antibody titers wane. The clinical presentation may include chronic or recurrent otitis media, sinusitis, conjunctivitis, pneumonia, or pyoderma.[23,24] Infections occur at more than one anatomic site and usually are caused by pyogenic bacteria such as *Streptococcus pneumoniae*, *Streptococcus pyogenes*, or *Haemophilus influenzae*. There is a striking tendency for boys who present in the first year of life to have a more severe clinical presentation that may include pyoderma gangrenosum, perirectal abscess, cellulitis, or impetigo associated with sepsis due to gram-negative bacteria (e.g., *Pseudomonas*) or *Staphylococcus aureus* and neutropenia.[25,26] On physical examination, patients

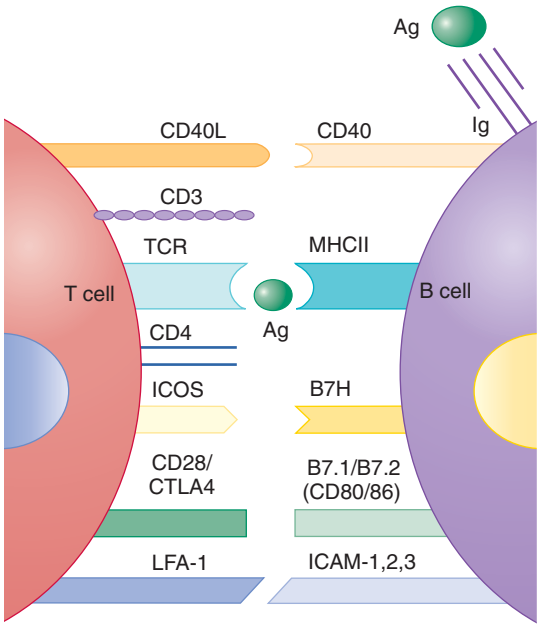

Figure 51–2 Receptor–ligand interactions of T and B cells. Ag, antigen; CD40L, CD40 ligand; CTLA, cytotoxic T-lymphocyte associated; ICAM, intercellular adhesion molecule; ICOS, inducible T-cell costimulator; Ig, immunoglobulin; LFA, leukocyte function-associated antigen; MHCII, major histocompatibility complex class II; TCR, T-cell receptor.

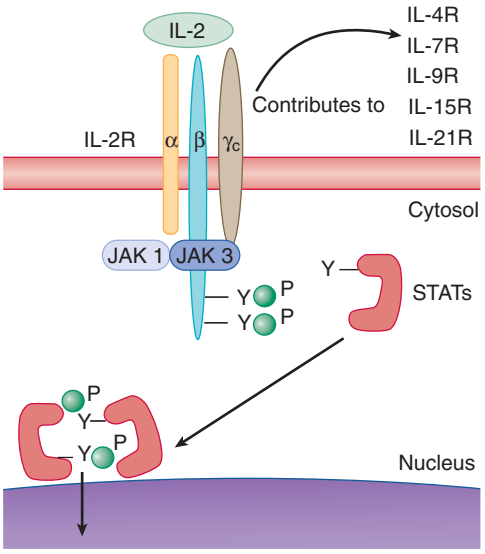

Figure 51–3 T-cell–derived cytokine receptor activation. Interleukin-2 (IL-2) binds to the multimeric IL-2 receptor (IL-2R), which is composed of three transmembrane proteins: CD25 (IL-2Rα), which confers on the receptor a high level of affinity for IL-2, and two other surface chains, IL-2Rβ and the common γ chain (γ_c), which are involved in intracellular signaling after engagement of the IL-2 receptor by IL-2. IL-2Rβ is constitutively associated with Jak1 (Janus kinase 1), and γ_c binds Jak3. The γ_c also is a component of the specific cytokine receptors for IL-4, IL-7, IL-9, IL-15, and IL-21. With IL-2 binding to the IL-2 receptor, Jak1 and Jak3 are activated, which in turn leads to tyrosine (Y) phosphorylation of various signal transducer and activator of transcription (STAT) proteins, including STAT1, STAT3, and STAT5. STAT5 includes two highly homologous proteins, STAT5a and STAT5b. Phosphorylation of STATs leads to their dimerization through reciprocal phosphotyrosine–SH_2 domain interactions and subsequent translocation to the nucleus, where they mediate transcriptional activation. Severe combined immunodeficiency (SCID) with absence of T cells but normal B cells arises from mutation of the γ_c chain (X-linked SCID) or the *JAK3* gene (autosomal recessive SCID) and is due mainly to blockade of IL-7R signaling by developing thymocytes. A SCID-like immunodeficiency also occurs with mutations of CD25. STAT5b deficiency mainly impairs upregulation of CD25 that occurs in response to IL-2 and maintenance of $CD25^+CD4^+$ T cells that express the FOXP3 transcription factor and have regulatory activity (i.e., are capable of inhibiting the function of effector T cells).

with XLA are found to have a paucity of tonsils, adenoids, and peripheral lymph nodes. Monoarticular or oligoarticular arthritis of large joints with sterile effusions caused by infection with enterovirus or a nonpathogenic commensal Mycoplasma strains, such as *Ureaplasma urealyticum*, may be the presenting problem.[27] Diarrhea from infection with organisms such as *Giardia lamblia* or rotavirus commonly occurs. Vaccine-associated poliomyelitis is a potential complication caused by the persistence and mutation of the attenuated live poliovirus vaccine strain into a virulent neurotropic form.[28] Eradication of natural poliovirus infection in most of the world and phasing out of immunization with oral poliovirus vaccine should make this condition mainly an historic medical problem in developed countries. Before diagnosis and institution of therapy with Ig replacement therapy, neutropenia may occur in approximately 25% of affected patients.

Infectious diseases can cause significant morbidity. Chronic infections of the upper and lower respiratory tracts with otitis media, sinusitis, pneumonia, and even bronchiectasis may occur in spite of early institution of Ig replacement therapy.[29] In the past, chronic pulmonary disease was described in almost half of patients with XLA, and hearing loss, resulting from chronic otitis media or meningoencephalitis, occurred in approximately one third of patients.[23] Rarely, sensorineural hearing loss associated with btk deficiency is due to a contiguous gene defect involving deletion of *btk* and an adjacent deafness-dystonia protein gene.[30] Chronic, disseminated enteroviral infection, usually from echovirus, is a potentially fatal complication. It almost always involves the central nervous system (CNS) and may include hepatitis, pneumonia, vasculitis, and a dermatomyositis-like syndrome consisting of rash, brawny edema of the subcutaneous tissues and myositis with muscle weakness.[31–33] In the past, these complications as well as other serious infections accounted for a mortality rate of approximately 15% of patients by age 20 years.[23] In recent times, earlier diagnosis and more effective Ig replacement therapy using the intravenous or subcutaneous route rather than the intramuscular route have decreased the incidence of these complications. However, a recent series found that the majority of patients with XLA were not diagnosed until they had been hospitalized for infection, which suggests there is still room for earlier clinical recognition of the syndrome.[25]

Laboratory Evaluation

Absent antibody responses after immunization or natural antigenic exposure, low levels of serum Ig, and absence or very low levels of peripheral blood B cells are characteristic of the disease (see box on Laboratory Evaluation for Suspected Immunodeficiency). The B cells present usually have an increased surface density of IgM. The IgG level usually is less than 100 mg/dL, and all other Ig isotype levels usually are low or undetectable. However, approximately 10% to 20% of patients may have higher levels of serum Ig and detectable circulating levels of B cells. In rare cases, these can reach normal levels of Ig, although B-cell numbers still are markedly low. Patients with higher Ig levels often present later in life, which may indicate the impact of other modifying genes. T-cell numbers and antigen-specific function are intact, with a tendency for greater T_H1 responses (interferon [IFN]-γ predominant) than T_H2 responses (IL-4, IL-5, and IL-13 predominant).[34] Peripheral neutropenia accompanied by a maturation arrest in the bone marrow is a frequent presenting feature.[26,35] Possible mechanisms of neutropenia include consump-

tion of neutrophils and their immediate precursors after cell activation by endotoxin or other bacteria-derived products during severe bacterial infections. Alternatively, there might be a requirement for btk in stressed myeloid lineage cells. Lymph nodes show an absence of plasma cells, lymphoid follicles, and germinal centers. Definitive diagnosis, prenatal diagnosis, and diagnosis of the carrier state can be performed by genetic analysis. Screening for btk protein expression using either flow cytometry after intracellular staining[36] or Western blotting will rapidly identify most patients with the deficiency, but confirmatory gene sequencing is important, particularly in cases where result of flow cytometry are normal or equivocal and the clinical presentation is strongly suggestive of XLA.

Therapy

Ig replacement therapy is the mainstay of treatment and should be started once the diagnosis is made (see box on Immunoglobulin Replacement Therapy), preferably before repetitive infections have caused irreversible pulmonary damage.[37] Although subcutaneous replacement with Ig can be used to maintain adequate IgG levels in most patients, initial replacement with intravenous immunoglobulin (IVIG) should be used to rapidly achieve normal levels. Maintaining adequate levels of IgG can prevent chronic pulmonary disease and chronic enteroviral meningoencephalitis. Although the latter has been reported even with IVIG therapy, most patients received relatively low doses of Ig compared with current recommendations.[33] The subcutaneous route for rapid Ig administration is an alternative means of antibody replacement,[38] although it requires more frequent dosing than does the intravenous route.

Pyogenic infections should be treated with antibiotics promptly and vigorously to prevent organ damage. Chronic or recurrent infections of the upper and lower respiratory tracts may require the addition of continuous prophylactic antibiotic therapy.

Persistent enteroviral infections have been treated successfully with Ig preparations containing high titers of antibody specific for the infecting enterovirus.[32,39] For treatment of enteroviral meningoencephalitis, these high-titer antibodies specific for the infecting virus may require administration directly into the ventricles of the brain to obtain sufficiently high levels at that site.[40] However, even with this therapeutic approach, infections have not always been cleared.[33] Pleconaril, a drug with activity against enteroviruses, may be useful for this complication in patients with XLA or other primary immunodeficiencies, including hypogammaglobulinemia. However, the development of pleconaril resistance has been reported in this setting.[41] Single positron emission computed tomographic scanning may be a useful noninvasive method for following patients with chronic enteroviral meningitis.[42]

Common Variable Immunodeficiency

Etiology and Pathophysiology

CVID is the most common symptomatic primary antibody deficiency syndrome. It includes a group of heterogeneous disorders associated with recurrent infections, poor antibody responses, and hypogammaglobulinemia.[43,44] Both genders are affected. Onset often is insidious and usually occurs during the second or third decade of life. In approximately 10% to 20% of cases, the disorder is familial, with predominance of an autosomal dominant over an autosomal recessive inheritance pattern.[45] Offspring and first-degree relatives may have selective IgA deficiencies or autoimmune diseases, such as systemic lupus erythematosus (SLE), hemolytic anemia, or immune thrombocytopenic purpura.[45–47] In some instances, SLE may evolve into CVID.[48] Viral infections, including congenital rubella and EBV, have been suspected in the etiology of CVID. In contrast, human immunodeficiency virus and hepatitis virus infections have been reported to restore IgG and antibody production in some patients.[49,50]

Evaluation for Suspected Immunodeficiency

Laboratory studies should be used to confirm a diagnosis of an immunodeficiency disease after a thorough history and physical examination have been performed to exclude a localized anatomic or physiologic defect that may predispose to recurrent infections. An immunodeficiency should be suspected with the occurrence of infections of unusual frequency, location, type, or severity. Recurrent infections may occur at multiple sites, and infections may be caused by unusual or opportunistic organisms, such as *Pneumocystis, Candida, Mycobacterium avium, Pseudomonas, Serratia,* or Cytomegalovirus (CMV). Often the patient lacks a history of exposure. Excessive severity or complications of infections and poor response to treatment are common. With immunodeficiency diseases, organisms may disseminate more widely, multiply in greater numbers, or remain alive in phagocytes. Patients with immunodeficiency diseases often fail to recover to normal health between infections and may experience weight loss or poor weight gain. Autoimmune diseases may accompany antibody deficiency states and other disorders in which T-cell tolerance is compromised.

Recurrent infections such as otitis media, sinusitis, pneumonia, meningitis, arthritis, and osteomyelitis from encapsulated bacteria (e.g., *S. pneumoniae, H. influenzae* type b, *Neisseria meningitidis, Staphylococcus aureus*) suggest a deficiency of antibody or, less commonly, an abnormality of phagocytes or serum complement. Low numbers or poor function of polymorphonuclear leukocytes also is commonly associated with abscesses and infections with unencapsulated nonpathogenic bacteria that reside in the skin or mucosal surfaces. Recurrent infections from viruses, fungi, or intracellular bacteria, such as *Mycobacteria, Listeria*, or *Salmonella*, suggest a defect in T-cell function. Intracellular bacterial infection also is characteristic of defects in the T_H1 pathway involving the generation of IFN-γ–producing T cells or the responsiveness of cells to IFN-γ. Infection with *Pneumocystis* strongly suggests T-cell deficiency. CD40-ligand deficiency is strongly suggested if T cells are present in normal numbers in a male with documented *Pneumocystis* pneumonia. Combined deficiencies of T-cell and B-cell function are characterized by infections with bacteria or viruses. Recurrent systemic *Neisseria* infections suggest deficiency of a terminal complement component or, in male patients, of properdin, a component of the alternative complement pathway encoded in the X chromosome. Antibody deficiency in young children usually does not predispose the patient to infections until the latter half of the first year of life due to the passive protection provided by maternal antibody. However, T-cell immunity is not transplacentally transmitted and is not present at birth.

Laboratory evaluation initially should be directed to the type of deficiency suspected on the basis of the history and results of physical examination. Studies should begin with less expensive and more readily available tests. Results must be compared with age-related normal values. Examinations of the complete blood count and peripheral blood smear may suggest the diagnosis. In patients with suspected T-cell deficiency, live viral immunization should be withheld. Blood products should be obtained from donors who are CMV-antibody seronegative and should be irradiated before administration to prevent graft-versus-host disease.

Although the exact nature of the defects giving rise to CVID are unknown in approximately 85% of cases, many immunologic abnormalities have been described.[51,52] Most patients with CVID have normal numbers of mature B cells that fail to differentiate into antibody-secreting cells. Failure of in vivo B-cell maturation and differentiation usually is believed to be due, at least in part, to defective interactions between T and B cells and possibly between dendritic

cells and T cells or B cells. Intrinsic B-cell defects include a failure to proliferate and to secrete one or more Ig isotypes, most often IgG or IgA, with appropriate stimuli. This failure may be explained in part by the observation that many patients with CVID have markedly decreased circulating levels of $CD27^+$ memory B cells, including those of the IgM^+IgD^+ cell subset that have not undergone isotype switching.[53,54] This unswitched B-cell population is also absent in patients who have undergone splenectomy and may be enriched in B cells originating from the marginal zone of the spleen, which has a natural antibody repertoire for the immune control of encapsulated bacteria.[54] Consistent with this idea, CVID patients who have low levels of $CD27^+IgM^+IgD^+$ memory B cells appear to be at particularly high risk for infections with *S. pneumoniae* and marked impairment of the production of antibodies against the capsules of *S. pneumoniae* after vaccination.[55] CVID patients can be divided into those with detectable numbers of switched memory B cells ($CD27^+IgM^-IgD^-$) and those lacking such cells.[56] The latter group tends to have lower levels of IgG, poorer responses to vaccination with polysaccharides, and higher incidences of autoimmune and granulomatous disease and bronchiectasis.[55,56] Many patients also have a dramatic reduction in the degree to which expressed Ig genes have undergone somatic hypermutation,[57,58] a finding that has been suggested to be a better predictor of severe respiratory tract infection than decreases in peripheral blood memory B-cell numbers.[59] As isotype switching, somatic hypermutation, and memory B-cell generation typically require help from $CD4^+$ T cells, particularly in response to protein antigens, these observations are consistent with a defect in interactions between T cells and B cells. Intrinsic limitations in T-cell function may contribute to CVID immunopathology, as T cells from CVID patients may have abnormalities in signal transduction and the ability to express CD40 ligand and cytokines that are important for B-cell help.[51,60] CVID B cells also may not effectively increase expression of B7–2 (CD86), a molecule that is important in providing costimulation to T cells through engagement of CD28.[61] Several studies have focused on potential intrinsic defects or dysregulation in innate immune mechanisms mediated by antigen-presenting cells (APCs) and B cells that might account for poor specific antibody production. A subset of patients with decreased numbers of peripheral $CD4^+$ T cells and splenomegaly have evidence of persistent activation of mononuclear phagocytes, apparently as a result of chronic production of tumor necrosis factor (TNF)-α.[62] Results have been conflicting as to whether CVID patients have increased or decreased production by APCs of IL-12,[63,64] a potent cytokine for T_H1 differentiation. Defects in the ability of CVID dendritic cells to activate T cells also have been reported,[64,65] although these studies used dendritic cells generated in vitro from monocytes using high doses of cytokines and may not be accurate predictors of the function of circulating and tissue-associated myeloid dendritic cells. CVID B cells and plasmacytoid dendritic cells may be impaired for Toll-like receptor (TLR)-9 signaling.[66] TLR-9–dependent activation of plasmacytoid dendritic cells (i.e., by viral or bacterial DNA) normally results in high levels of production of type I IFN, which is a potent stimulus for B-cell activation that synergizes with B-cell TLR-9 signaling. Thus, it is plausible that defects in both plasmacytoid dendritic cell and B-cell TLR-9 signaling are major mechanisms for limiting antibody responses in CVID.

Monogenetic defects in transmembrane activator and calcium modulator ligand interactor (TACI, TNF receptor superfamily member 13B), inducible costimulatory (ICOS) receptor, or CD19 can present as CVID, particularly in kindreds in which multiple family members are affected (see Table 51–1).[52,67,68] TACI, which binds to the secreted ligands BAFF and APRIL, may be particularly important for isotype switch recombination by B cells. ICOS, which is expressed by activated and memory T cells, appears to provide important B-cell activation and differentiation signals, such as for memory cell generation and isotype switching, by binding to ICOS ligand on B cells. CD19 is a B-cell surface protein that is essential for signal transduction after engagement of surface Ig by antigen; it also is important in memory B-cell generation. These gene defects clearly show that both intrinsic T-cell and B-cell genetic defects can present as CVID in humans.[69] TACI mutations, which usually act in a dominant negative manner, may involve 5% to 10% of patients with CVID.[52,67] TACI defects are also found at an increased rate in relatives of patients with CVID who have IgA deficiency.[52,67] The other monogenetic defects act in an autosomal recessive manner and probably account in aggregate for less than 1% of CVID patients in most countries.

Clinical Manifestations

CVID occurs in both genders, Age at onset varies from early childhood to late adulthood. Recurrent pyogenic infections with otitis media, sinusitis, bronchitis, and pneumonia, often from pneumococci, staphylococci, *H. influenzae*, *Moraxella*, or *Mycoplasma pneumoniae*, are typical.[43] Bronchiectasis is a frequent complication and may be the presenting abnormality. Cor pulmonale and respiratory failure associated with chronic lung disease are common causes of death. Patients who are not receiving adequate Ig replacement are at increased risk for disseminated enteroviral infections, although this complication is less common than in patients with XLA.[33] In contrast to XLA, lymphoid tissue is normal or enlarged as a result of B-cell proliferation and prominent germinal center formation. Nodular lymphoid hyperplasia of the gastrointestinal tract is common. Splenomegaly, secondary to reactive follicular hyperplasia, occurs in approximately 25% of patients and may be associated with neutropenia and thrombocytopenia from hypersplenism and with expansion of B cells that are $CD19^{high}CD21^{low/negative}$.[70] Noncaseating granulomas that resemble those found in sarcoidosis may occur in the spleen, liver, lung, bone, and other tissues. Arthritis and arthralgia are common. Gastrointestinal abnormalities with chronic gastritis and achlorhydria, diarrhea, and a sprue-like syndrome with malabsorption, lactose deficiency, and protein-losing enteropathy may complicate the clinical course.[71] Pernicious anemia develops in some patients because of atrophic gastritis and absence of intrinsic factor due to autoantibodies. Reactivation of varicella-zoster virus and recurrent herpes simplex virus infection can occur, suggesting a diminution of T-cell–specific responses to these viruses.

Autoimmune disorders, including autoimmune hemolytic anemia, thrombocytopenia or neutropenia, rheumatoid arthritis, SLE, chronic active hepatitis, and thyroiditis, are frequently seen (see box on Peripheral Blood Abnormalities in Immunodeficiency).[43,72] There is an overall fivefold increase in the incidence of cancer, with a 51-fold increase in gastric cancer and at least a 30-fold increase in lymphoma.[73–77] This increased incidence of gastric cancer may be related to the high frequency of achlorhydria and atrophic gastritis in patients with CVID.[78] A nonmalignant lymphoproliferative disorder with follicular hyperplasia of lymph nodes or nodular lymphoid hyperplasia of the intestine and splenomegaly also may occur and must be distinguished from a malignancy.[79]

Laboratory Evaluation

Serum Igs, especially IgG and IgA, are moderately to markedly decreased, and antigen-specific antibody responses are impaired. The peripheral blood B-cell number is normal in approximately 75% of patients, but the surface phenotype may be immature, and the cells of some patients fail to differentiate to antibody-secreting cells after appropriate stimuli. Decreased numbers of memory ($CD27^+$) B cells is a frequent finding. Atypical XLA must be excluded when a low number of B cells is detected in a male with a presumed diagnosis of CVID. T-cell numbers may be decreased, and a reversal of the ratio of T_H/cytotoxic ($CD4^+/CD8^+$) T-cell ratio may be noted, usually secondary to an increase in $CD8^+$ T cells. Some patients have an expanded number of activated $CD57^+CD25^+$, $HLA\text{-}DR^+$ circulating $CD8^+$ T cells,[80] which also are commonly found in chronic viral infection. Depressed T-cell function and absent delayed-type hypersensitivity skin test reactivity may occur, especially in patients who are older or have lymphopenia. As described above, in the Etiology

and Pathophysiology section, CD40-ligand expression and the elaboration of soluble cytokines by T cells activated in vitro may be decreased. In males with CVID that manifests during childhood, care should be taken to exclude two X-linked genetic disorders, btk deficiency (XLA) and SLAM-associated protein (SAP) deficiency (the cause of X-linked lymphoproliferative syndrome), which in the past have been misdiagnosed as CVID. Mutation of the lck protein tyrosine kinase gene has presented as CVID in one instance.[80a]

Therapy

Ig replacement and aggressive antibiotic therapy are indicated (see box on Immunoglobulin Replacement Therapy).[37] After Ig replacement therapy is instituted, pulmonary radiographic and functional changes may stabilize. Serial pulmonary function tests are important for clinical assessment. However, acute infections still may occur with Ig replacement therapy, necessitating prolonged use of antibiotics to prevent deterioration of lung function. In the face of chronic lung disease and bronchitis, some patients require higher doses of Ig replacement (e.g., 600 mg/kg IV every 3–4 weeks or 150 mg/kg subcutaneously every week) than are commonly used to prevent acute lung exacerbations.[81] Therapy with IL-2 has been used experimentally in a limited number of patients, with some improvement of in vitro T-cell function and the ability to mount antibody responses to a neoantigen.[82] Whether such IL-2 therapy has long-term clinical benefits for patients with CVID is unknown. CVID-related granulomatous disease has been responsive to therapy with glucocorticoids or TNF-α inhibitors in some patients. The addition of hydroxychloroquine, a relatively mild immunosuppressive agent, may reduce the need for glucocorticoid therapy in some cases of lymphoid interstitial pneumonitis associated with CVID.

Selective Immunoglobulin A Deficiency

Etiology and Pathophysiology

Deficiency of serum IgA, defined as serum IgA concentration less than 5 mg/dL, is found in approximately 1:600 persons in Europe and North America but occurs in only 1:18,000 in Japan and 1:4000 in China.[83] Most affected persons are asymptomatic, but some IgA-deficient persons suffer from recurrent sinopulmonary infections, autoimmunity, or allergies.[47,83,84] Autoimmunity or allergies may occur in some patients as a consequence of increased absorption of environmental and dietary antigens into the systemic circulation due to the lack of secretory IgA at mucosal surfaces or, alternatively, reflect a broader underlying immunologic defect with poor regulation of autoantibody production.

IgA deficiency may be primary or secondary. It can occur in a sporadic form or with an autosomal dominant or autosomal recessive pattern of inheritance.[85,86] IgA deficiency or CVID may be found in extended families with evidence of linkage or no linkage to the major histocompatibility complex (MHC) locus. A CVID susceptibility locus, designated *IGAD1*, has been fine mapped to the HLA-DQ/HLA-DR region of chromosome 6.[87] This finding suggests an autoimmune pathogenesis in CVID/IgA deficiency that may involve $CD4^+$ T-lineage cells, as these cells mainly recognize antigenic peptides that are associated with MHC class II molecules.

IgA deficiency can be transitory in children, especially when the serum IgA level is only moderately decreased, but in adults the deficiency usually is permanent.[88,89] Congenital infections with rubella virus, cytomegalovirus (CMV), or *Toxoplasma gondii* and acquired EBV infection have been associated with IgA deficiency. In addition, IgA deficiency may occur after use of drugs such as penicillamine, phenytoin, sodium aurothiomalate, captopril, sulfasalazine, or antimalarial agents.

The susceptibility to infection in IgA deficiency may be secondary not to IgA deficiency per se but to concomitant deficiencies of IgG2 and IgG4 subclasses of Igs,[90–92] although this is a highly controversial issue. In some patients, IgA deficiency is a manifestation of a more widely based immunologic defect with similarities to CVID, which also is, at least in part, an arrest in B-cell differentiation. As noted previously, CVID also occurs in family members and shares MHC haplotypes with IgA deficiency. IgA deficiency may evolve into CVID and is frequently found in ataxia-telangiectasia, which also is associated with IgG subclass deficiency.

IgA deficiency usually is associated with an intact structural IgA heavy-chain gene segment (Cα switch region of the Ig heavy-chain gene). Surface IgA-bearing B cells are present in normal or reduced numbers, and the cells may display an immature phenotype with coexpression of surface IgM in some patients.[93] The primary defect appears to be failure of B cells to differentiate to mature isotype-switched surface IgA-positive B cells and IgA-secreting plasma cells with appropriate stimuli.[83] The basis for the defect is not known.

Clinical Manifestations

The majority of persons with IgA deficiency are healthy, but many have various clinical symptoms. Patients with IgA deficiency who were asymptomatic when young may develop symptoms in later life. The frequencies of upper and lower respiratory tract infections are increased. Infections occur more commonly when IgA levels are low with a deficiency in IgG subclasses and with decreased levels of antipneumococcal polysaccharide antibodies.[83,90–92] Some patients have recurrent bacterial infections with recurrent sinusitis, otitis media, or bronchitis and may develop bronchiectasis. The incidence of autoimmune diseases, especially rheumatoid arthritis and SLE, is increased.[72] Other autoimmune diseases may occur, although autoantibodies may be present without symptoms. Allergic diseases, including rhinitis, urticaria, eczema, and asthma, occur with increased frequency. Gastrointestinal and hepatic complications associated with IgA deficiency include malabsorption, celiac disease, giardiasis, nodular lymphoid hyperplasia, pernicious anemia, atrophic gastritis, primary biliary cirrhosis, and chronic active hepatitis. Gastric and colon carcinomas are found with increased frequency. Production of antibodies to food antigens, such as cow's milk, may cause immune complexes that may be pathogenic.

Laboratory Evaluation

The serum concentration of IgA is less than 5 mg/dL, and the levels of IgG and IgM are normal. Secretory IgA is decreased. Approximately 25% of patients have decreased levels of IgE. Some patients, especially those with recurrent sinopulmonary infections, have a concomitant deficiency of IgG2 and IgG4 subclasses and defective antibody responses to polysaccharides, such as those contained in the 23-valent pneumococcal polysaccharide vaccine. Determination of IgA and IgG levels should be repeated at a later date to determine if the deficiency of IgA is persistent and, if so, whether the immunologic disorder has evolved to resemble CVID. IgA-deficient patients have an increased incidence of autoantibodies directed against nuclear proteins, Igs, thyroglobulin, or adrenal, parietal, smooth muscle, or pancreatic cells, or of antibodies to food antigens, such as cow's milk protein. Serum antibodies to IgA occur in greater than 20% of patients with IgA deficiency, especially if IgA is completely undetectable. However, the presence of these antibodies is not highly predictive of adverse reactions to blood products containing IgA. Exposure to blood products with IgA may, however, induce IgE anti-IgA antibodies that can cause anaphylactic reactions.[94]

Therapy

Treatment should be directed at the associated infections and allergic, autoimmune, and gastrointestinal diseases. Precipitating drugs should be discontinued. Antibiotic therapy is indicated for bacterial infections. If infections are severe or cause significant sequelae, prophylac-

tic antibiotics should be considered. Ig replacement therapy is not usually indicated for IgA deficiency unless a defect in specific antibody production to antigens, such as pneumococcal polysaccharides, is documented. Severe or fatal anaphylactic reactions can occur with intravenous administration of IgA-containing blood products to IgA-deficient patients.[94] This may be caused by anti-IgA antibody of the IgE isotype, which may increase after Ig replacement therapy. Treatment with IVIG preparations containing low levels of IgA may be helpful for IgA-deficient patients for whom IVIG therapy is indicated but who have anaphylactic reactions to IgA-containing products.[95] Blood products should be washed prior to transfusing IgA-deficient individuals or if obtained from IgA-deficient donors, including the recipient, before surgery. Plasma for transfusion also should be collected from IgA-deficient persons. Oral administration of γ-globulin has led to improvement in some patients with chronic diarrhea.

Immunoglobulin Deficiency with Normal or Increased Immunoglobulin M (Hyper-IgM Syndrome)

Etiology and Pathophysiology

The hyper-IgM syndrome is so named because of the frequent and characteristic finding of an elevated level of serum IgM and low levels of other Ig isotypes, particularly IgG.[96,97] Two forms of the disease are inherited in a X-linked manner: hyper-IgM syndrome type 1 (HIGM1), which is due to CD40-ligand deficiency, and X-linked hyper-IgM ectodermal dysplasia (XHM-ED), which is due to deficiency of the NF-κB essential modulator (NEMO) protein. Other forms are inherited in an autosomal recessive manner, including hyper-IgM syndrome type 2 (HIGM2), which is due to deficiency of activation-induced cytidine deaminase (AID), and hyper-IgM syndrome type 3 (HIGM3), which is due to CD40 deficiency.

HIGM1, which maps to Xq26, is due to failure of activated T cells, particularly those of the $CD4^+$ subset, to express functional CD40 ligand (CD154).[98,99] CD40 ligand is a type II transmembrane glycoprotein and a member of the TNF ligand family that binds to CD40 on B cells. The interaction between CD40 ligand on the CD4 T cell and the CD40 molecule on APCs, mononuclear phagocytes, and B cells is essential for many adaptive immune responses, but it is not required for normal T- and B-cell development. Because the number of T and B cells and the absolute lymphocyte count is normal, diagnosis requires assaying for functional CD40-ligand surface expression on activated $CD4^+$ T cells by flow cytometry.[97] The engagement of CD40 by CD40 ligand activates NF-κB–dependent transcription by a kinase complex that includes the inhibitor of κB kinase γ (IKK-γ) protein, also known as NEMO. CD40 engagement by CD40 ligand signals the B cell to proliferate and undergo deletional isotype switching (also referred to as *switch recombination*).[96,98,99] CD40-ligand/CD40 interactions are also required for induction of germinal center formation in lymphoid follicles and generation of memory B cells, which occurs in germinal centers. As a result, the main isotypes expressed on B cells in HIGM1 usually are IgM and IgD. When these B cells are immortalized with EBV, they mainly secrete IgM and not other isotypes. Cross-linking of CD40 on B cells from patients with HIGM1 with anti-CD40 antibody or functional CD40 ligand and stimulation with appropriate cytokines (e.g., IL-4, IL-10) can bypass the defect and activate normal isotype switching and Ig secretion. The engagement of CD40 by CD40 ligand also results in increased expression or upregulation of costimulatory molecules (e.g., B7–1 [CD80] and B7–2 [CD86]) on APCs, such as dendritic cells and mononuclear phagocytes. These costimulatory molecules are required for effective activation of T cells by APCs. CD40 engagement also induces secretion of cytokines, such as IL-12, from APCs, which promotes differentiation of naive $CD4^+$ T cells into T_H1 immune effector ($CD4^+$ T cells that produce high levels of IFN-γ). Defective CD40-ligand expression may lead to impaired generation of memory T cells, including T_H1 cells. CD40-ligand/CD40 interaction is essential for control of certain opportunistic infections, such as *Pneumocystis*. Another frequent abnormality in HIGM1 is neutropenia, whose underlying mechanism is elusive.[26]

XHM-ED, which maps to Xq28, is due to mutations in NEMO that result in a primary immunodeficiency characterized by hypoplasia of hair, teeth, and sweat glands (hypohidrotic ectodermal dysplasia) in combination with some features of the hyper-IgM syndrome. The ectodermal abnormalities observed are due to the NEMO mutation, which compromises signaling through ectodysplasin 1 anhidrotic receptor, which, like CD40, is a member of the TNF receptor superfamily. Susceptibility to infections, particularly encapsulated gram-positive and gram-negative bacteria,[96,98,100,101] is characteristic and appears to mainly reflect limitations in NF-κB–mediated immunity. In contrast to HIGM1, opportunistic infections characteristic of T-cell immunodeficiency are less common in XHM-ED, suggesting substantial signaling via CD40 engagement in the absence of NEMO.

HIGM2 is a form of hyper-IgM syndrome maps to 12p13 and arises from defects in AID.[102] It is inherited in an autosomal recessive manner. AID is a member of the RNA-editing deaminase family that contains proteins able to create new functional products from messenger RNA (mRNA) by base substitution. AID expression is limited to germinal center B cells, suggesting a role of AID in terminal B-cell differentiation. AID is directly involved in the isotype switching process. Because T-cell development and function are unaffected in patients with HIGM2, patients experience increased bacterial infections due to antibody deficiency but are not at increased risk for the opportunistic infections seen in HIGM1 and other T-cell disorders. An autosomal recessive form of hyper-IgM syndrome, also known as HIGM5, results from mutations of the enzyme uracil *N*-glycosylase (UNG).[102,103] It is phenotypically almost indistinguishable from AID deficiency.

An autosomal recessive form of hyper-IgM syndrome, termed HIGM3, due to mutations in CD40 has been described.[104] HIGM3 is similar to HIGM1 (CD40-ligand deficiency), resulting in the combination of increased risk of pyogenic and T-cell deficiency opportunistic infections. This phenotype fits with CD40 being the only major receptor for CD40 ligand.

Clinical Manifestations

HIGM1 and HIGM3 result in severe qualitative defects in B-cell function and recurrent sinopulmonary infections, such as otitis media, upper respiratory tract infections, and pneumonia, with encapsulated bacteria. Rarely, the humoral immunodeficiency results in chronic parvovirus-induced anemia or enteroviral meningoencephalitis. A partial but important qualitative defect in T-cell function has been demonstrated by the extreme susceptibility of these patients during infancy to *Pneumocystis jiroveci* pneumonia. This finding highlights the importance of CD40 ligand produced by $CD4^+$ T cells in the normal control of this fungus, perhaps by activating alveolar macrophages of the lung. Other infections indicative of T-cell immunodeficiency have been reported, including hepatobiliary infection with *Cryptosporidium*, cryptococcal meningitis, disseminated histoplasmosis, oral candidiasis, disseminated toxoplasmosis, severe CMV disease, enteroviral pneumonia, and progressive multifocal leukoencephalopathy due to JC virus.[105] The susceptibility of CD40-ligand or CD40 deficiency also may be due to failure of CD40 ligand on activated T cells to activate CD40-expressing macrophages or to induce dendritic cells to secrete IL-12, which is required for memory T_H1-type immune responses. Diarrhea and sclerosing cholangitis occur secondary to *Cryptosporidium* infection, which is a major risk factor for the development of tumors of the hepatobiliary system.[106] Lymphoid hyperplasia with lymphadenopathy, tonsillar enlargement, and hepatosplenomegaly are common. In contrast, hyper-IgM syndrome due to AID and UNG deficiencies are not associated with increased susceptibility to T-cell opportunistic infections but only pyogenic bacterial infections.

Chronic neutropenia occurs in about half of patients with HIGM1 and usually appears after the first year of life. Although the precise mechanism is unclear, neutropenia appears to arise from defective myeloid differentiation at the promyelocyte or myelocyte stage and probably is not due to autoantibodies. The neutropenia may be cyclic or episodic and associated with infection. Stomatitis and chronic recurrent oral or rectal ulcers may complicate the neutropenia but can occur independently. Autoimmune manifestations include arthritis or arthralgia, nephritis, and hemolytic anemia. Surface IgM-positive non-Hodgkin and Hodgkin lymphomas with gastrointestinal tract involvement may occur.

Laboratory Evaluation

Serum levels of IgM and, at times, IgD are markedly elevated. Other Ig isotypes, particularly IgG and IgA, are present in low levels or are absent. However, the IgM level may be normal at an early age. In one study, only half of the patients with HIGM1 had increased serum IgM levels at the time of diagnosis, and one third of patients failed to develop increased levels of IgM during follow-up.[105] IgM is polyclonal, and antibody responses, when they occur, are restricted to the IgM isotype. Peripheral blood B cells are normal in number and express IgM and IgD, but cells with surface IgG or IgA usually are absent. In vitro stimulation of peripheral blood B cells with anti-CD40 antibody or CD40-ligand–expressing cells in the presence of IL-10 or IL-4 will activate isotype switching and secretion of IgG or IgE, respectively, in HIGM1. Definitive diagnosis of HIGM1 is made by demonstrating lack of surface expression of CD40 ligand on activated T cells and failure of soluble forms of CD40 to bind such cells. Lymph nodes lack secondary follicles within germinal centers and show severe depletion of follicular dendritic cells. Female carriers of HIGM1 can be diagnosed by demonstrating expression of functional CD40 ligand on approximately half of their activated T cells. Rarely, female carriers are symptomatic as a result of excessive expression of the cells bearing the X chromosome encoding the abnormal CD40-ligand allele.[107] CD40 deficiency should be suspected in male or female patients who have the clinical features of HIGM1 but have normal expression of functional CD40 ligand (i.e., able to bind to recombinant CD40). XHM-ED should be suspected in patients with clinical findings similar to HIGM1, particularly with recurrent severe infections with encapsulated bacteria, but that is accompanied by hypoplasia of the hair, teeth, and sweat glands. Patients with normal CD40 and CD40-ligand expression should be examined for mutations in AID and UNG, particularly if no evidence of T-cell opportunistic infections is seen.

Therapy

Hematopoietic cell transplantation (HCT) with hematopoietic precursor cells contained in bone marrow, peripheral blood, or cord blood should be strongly considered because of the high morbidity and mortality rates associated with the HIGM1.[105] Even in cases of preexisting cholangiopathy, a nonmyeloablative approach to HCT has been successful in some patients.[108] With Ig replacement therapy, increased IgM levels fall to normal in about half of patients, presumably as a result of feedback inhibition and prevention of infection. Lymphoid hyperplasia and neutropenia also may be reversed with Ig replacement therapy. The neutropenia may respond to therapy with granulocyte colony-stimulating factor. Prophylaxis against *Pneumocystis* pneumonia should be initiated immediately after diagnosis and maintained indefinitely for all forms of the disorder, except possibly in patients with AID or UNG deficiency. Identification of the genetic causes of hyper-IgM syndrome has improved diagnosis, prenatal detection, and counseling and may allow for development of gene therapy.

Selective Deficiencies of Immunoglobulin G Subclasses and Immunoglobulin Isotypes other than Immunoglobulin A

Patients evaluated for recurrent infections may have selective IgG subclass deficiency, such as abnormally low levels of IgG2 and IgG4 or selectively decreased IgG3 levels. Such subclass deficiencies usually are not associated with structural gene abnormalities of the heavy-chain gene locus, and the mechanism for these decreases is unknown. Caution is indicated in the diagnosis of IgG4 subclass deficiency in young children because this subclass has the most delayed appearance after birth of the four IgG subclasses. As in the case of IgA deficiency, IgG subclass deficiencies may be more common in CVID and certain other primary immunodeficiencies, such as ataxia-telangiectasia. Treatment of these IgG subclass deficiencies with Ig replacement usually is not indicated unless reduced antibody-specific responses to vaccines, such as the 23-valent pneumococcal polysaccharide vaccine, is documented. Rare deletions of the heavy-chain gene involve several or single constant region IgG subclass segments.[109,110] Most patients with these partial deletions usually are healthy, potentially as a result of the increased generation of protective IgG3 antibacterial antibodies.[110]

Selective IgM deficiency is a rare immunodeficiency disorder characterized by a low level of serum IgM and severe or life-threatening recurrent infections.[111] Pneumococcal and meningococcal sepsis or meningitis may occur. IgM antibodies are not produced, and IgG antibody responses usually are decreased, although the IgG level is normal. Defects of T_H and excessive suppressor T-cell activity have been described. Some of these patients subsequently develop a CVID-like syndrome.

Absence of either κ or λ light chains associated with hypogammaglobulinemia or IgA deficiency and recurrent respiratory tract infections, pernicious anemia, diarrhea, or malabsorption have rarely been reported. One individual with κ light-chain deficiency had a point mutation in the Cκ gene segment involving amino acid residues required for formation of intrachain disulfide bonds and protein folding, but no clinical immunodeficiency was apparent.[112]

SEVERE COMBINED IMMUNODEFICIENCIES

Etiology and Pathophysiology

SCID is an inherited severe immunodeficiency of T-cell and B-cell function[113] that occurs in approximately 1:50,000 live births. The term *combined* reflects the fact that severe T-cell deficiency usually compromises B-cell function because of a lack of T-cell help, even if B cells are present in normal numbers and have the potential for intrinsically normal function. About 80% of affected patients are boys, and only approximately one third of patients with SCID have a positive family history. SCID may result from single X-linked or autosomal recessive gene defects or, less commonly, from chromosome abnormalities. Peripheral T-cell dysfunction in all forms of SCID is mainly or entirely due to perturbed intrathymic maturation of αβ T cells (i.e., T cells that express αβ T-cell receptors [TCRs]) resulting in thymic hypoplasia.[113]

The most common causes of SCID are defects in expression of cytokine receptors or associated kinases by immature thymocytes. X-linked SCID, which accounts for approximately 45% of SCID cases in most series, is characterized by an absence of mature T and NK cells and normal to increased numbers of peripheral B cells.[113] X-linked SCID is due to abnormalities of the gene encoding the common γ chain (γ_c, or CD132), which is an obligate component of the IL-7 receptor (IL-7R) as well as other cytokine receptors. Deficiencies of other components of IL-7R, such as the IL-7R α chain, or of proteins required for IL-7R signal transduction, such as Janus kinase 3 (Jak3), which is intracellularly associated with the cytoplas-

Immunoglobulin Replacement Therapy

Replacement therapy with Ig is indicated for patients with recurrent infections who have defects in antibody production. Such therapy can be lifesaving and prevent recurrent infections and progressive lung damage. However, the cost of Ig replacement therapy is high, so it should not be used indiscriminately. Antibody titers before and after immunization with protein and polysaccharide antigens should be evaluated to assess the need for replacement therapy whenever possible (see Table 51–1). Usual indications include X-linked agammaglobulinemia, common variable immunodeficiency, severe combined immunodeficiency disease, hyper-IgM syndrome, and Wiskott-Aldrich syndrome.

Replacement therapy should not be given to patients with isolated IgG subclass deficiency or low IgM levels unless they have a documented deficiency of specific antibody production and have not benefited from antibiotic prophylaxis. IgG replacement therapy usually is not indicated for isolated IgA deficiency, but some patients with IgA deficiency and concomitant deficiency of IgG antibody production and severe, recurrent infections have improved with replacement therapy. Patients with IgA deficiency may develop anti-IgA antibodies of the IgE isotype that can cause severe or fatal anaphylactic reactions with intravenous administration of IgA-containing blood products. Ig replacement therapy with Ig preparations containing low levels of IgA that are administered by the intravenous or subcutaneous route has been used successfully in these patients.

Development of safe IVIG formulations allows administration of high doses without the pain, side effects, and tissue loss experienced with intramuscular γ-globulin replacement. Multiple IVIG preparations have been approved by the Food and Drug Administration (FDA). All preparations are safe, contain predominantly IgG1 and IgG2, have approximately comparable and consistent IgG antibody titers, and generally are therapeutically equivalent. The FDA-licensed Ig preparations do not carry a risk of transmitting the human immunodeficiency virus. IVIG formulations in the 10% concentration can be used for subcutaneous administration, and a higher concentration product (16%) has been licensed specifically for subcutaneous administration.

The half-life of administered IgG varies among patients. The optimal amount and frequency of infusion of Ig and the serum level of IgG to be achieved must be individualized to render the patient asymptomatic from recurrent infections. In general, with IV administration a trough serum level that is at least 200 to 400 mg/dL higher than the pretherapy level (or >500 mg/dL) should be attained before the next injection. In cases of severe hypogammaglobulinemia, an initial IgG dose of 400 mg/kg usually is given, followed by a similar dose 3 to 7 days later and then every 3 to 4 weeks thereafter. Trough levels should be checked bimonthly for the first 8 months and then every 6 months thereafter. This dosage regimen will result in a steady-state level after 4 to 8 months, with trough levels greater than 500 mg/dL. In general, an IVIG dose of 100 mg/kg will increase the IgG peak by 200 to 300 mg/dL and trough levels by 100 mg/dL (28 days postinfusion). Higher doses (≥600 mg/kg) of IVIG may be required to prevent infections in some patients and may prove better at preventing acute infections or exacerbations in patients with chronic pulmonary disease. If patients complain of fatigue, upper respiratory infections, or conjunctivitis during the week before the next infusion or if intercurrent infections occur, the frequency of infusion or the dose should be increased to raise the trough serum level to greater than 500 mg/dL. During infections, extra infusions may be required because of increases in the catabolic rate of the passively provided Ig. Home infusion therapy is now being practiced widely.

Subcutaneous infusion of Ig is an alternative to intravenous infusions, with a low frequency of systemic adverse reactions. For example, postinfusion headaches are extremely rare. Moreover, the serum level of IgG varies much less between doses because of slow absorption of the product, avoiding breakthrough infections that can occur as IgG levels decline following IVIG administration. The main disadvantage of the subcutaneous route is that less Ig can be administered in a single dose than can be given by the intravenous route. Typically, patients receive approximately 100 to 150 mg/kg every 7 to 10 days using multiple sites for infusion of each dose. This method can be technically challenging in patients with limited subcutaneous tissue.

Adverse reactions to IVIG administration include flushing, chest tightness, flank or abdominal pain, nausea and vomiting, chills, fever, headache, myalgias, dyspnea, diaphoresis, and hypotension. These reactions usually can be controlled by decreasing the infusion rate. In general, reactions are more common with the first infused dose and in the presence of an intercurrent infection. In these situations, infusions should be slower. Repeated severe reactions that do not respond to a decrease in the rate or volume of the infusion may be averted in some patients by pretreatment 1 hour before IVIG with aspirin, ibuprofen or acetaminophen, antihistamines, or steroids. Aseptic meningitis, usually manifesting as a severe headache, may occur after IVIG infusion but apparently not after subcutaneous administration of Ig. Rarely, anaphylactic reactions to IVIG occur. Anaphylactic reactions require stopping the infusion and immediate administration of epinephrine, steroids, and antihistamines, together with respiratory and circulatory support. Anaphylactic reactions rarely are caused by production of IgE antibodies to IgA in patients with IgA deficiency or those with common variable immunodeficiencies with absent IgA. Anti-IgA antibodies should be quantitated following an anaphylactic reaction. If anti-IgA antibodies are present, IVIG preparations with low levels of IgA should be used and the subcutaneous route strongly considered. Anaphylaxis after Ig administered subcutaneously can occur but is rare.

mic domain of γ_c, also results in SCID. The phenotype is similar to that in γ_c deficiency, except that these types of SCID have an autosomal recessive rather than an X-linked inheritance pattern and NK cells are present in IL-7R α-chain deficiency.[113] CD25 deficiency, which is a component of the high-affinity IL-2 receptor, is another example of a cytokine receptor deficiency resulting in SCID. SCID with an autosomal recessive inheritance pattern also may be due to any of the following conditions:

- Increased thymocyte death from toxic effects of accumulated purine metabolites, as in deficiency of adenosine deaminase (ADA) or purine nucleoside phosphorylase (PNP) (which accounts for approximately 20% of cases of autosomal recessive SCID)
- Defective thymocyte rearrangement of TCR genes, including defects of recombination-activating gene 1 (RAG1) or RAG2 proteins (which accounts for approximately 10% of cases of autosomal recessive SCID), partial RAG deficiency (major cause of Omenn syndrome), and nonhomologous end-joining DNA repair (deficiency of Artemis, Cernunnos-XLF (XRCC4-like factor), and DNA ligase IV)
- Defects in the ability of developing thymocytes to transmit intracellular signals through the αβ TCR–CD3 complex (deficiency of CD3δ, CD3ε, CD3ζ, CD3ζ-associated protein [CD3-zeta-associated protein of 70 kilodaltons (ZAP-70)] kinase, lck tyrosine kinase, and CD45 protein tyrosine phosphatase)
- Failure of development of bone marrow precursors that normally colonize the thymus and give rise to thymocytes (reticular dysgenesis)
- Deficiencies in expression of class II MHC molecules, which are required for intrathymic development (positive selection) of

Laboratory Evaluation for Suspected Immunodeficiency

General
- Complete blood cell count
- Chest radiograph
- Serology, culture, and polymerase chain reaction or antigen detection for human immunodeficiency virus

Antibody Deficiency
- *Initial*
  - Quantitative Ig levels: IgG, IgM, IgA, IgE
  - Antibody titers before and after immunization: Tetanus toxoid, diphtheria toxoid, *Haemophilus influenzae* type b, pneumococcal capsular polysaccharides
  - Isohemagglutinin titer
- *Later*
  - Quantitation of B cells
  - IgG subclasses
  - In vitro Ig isotype switching and synthesis (generally only available as a research test) btk or other suspected gene mutations: DNA sequencing
  - T-cell CD40-ligand expression by flow cytometry using monoclonal antibodies or CD40 fusion protein

T-Cell Deficiency
- *Initial*
  - Absolute lymphocyte count
  - Quantitation of T cells and T-cell subsets
  - Lymphocyte proliferative response to mitogens and vaccine antigens (e.g., tetanus)
- *Later*
  - Proliferative responses to other antigens and allogeneic cells
  - Flow cytometric analyses for intracellular cytokines and MHC/tetramer binding
  - Quantitation of enzyme activity: Adenosine deaminase, nucleoside phosphorylase
  - Protein and mutation analyses for SCID: γ_c, Jak3, interleukin-7 receptor α chain (IL-7Rα), RAG1, RAG2, ZAP-70, Ick, Artemis, DNA ligase IV, Cernunnos/XLF, Orai1, winged helix nude (WHN), CD3γ, CD3δ, CD3ε, CD3ζ, CD25, CD45
  - MHC class I and II expression and mutation analysis for RFXANK, RFX5, RFXAP, and CIITA if MHC class II mRNA is low or undetectable
  - In vitro T-cell activation studies

Complement Deficiency
- *Initial*
  - Total hemolytic complement (determination of 50% hemolyzing dose [CH_{50}])
  - Properdin (in males with *Neisseria* infections)
- *Later*
  - Quantitation and functional analysis of individual components

Polymorphonuclear Leukocyte and Macrophage Deficiency
- *Initial*
  - Polymorphonuclear leukocyte count and morphology
  - Howell-Jolly bodies
  - IgE level
  - Dihydrorhodamine (DHR) flow cytometric respiratory burst assay (preferable to nitroblue tetrazolium [NBT] reduction test)
- *Later*
  - Rebuck skin window test
  - Assays for chemotaxis, chemokinesis, random migration, phagocytosis, phagocyte killing, oxidative metabolism, enzyme activity
  - CD11/CD18 expression
  - Spleen/liver scan (^{35}S colloid uptake)

Ig, immunoglobulin; MHC, major histocompatibility complex; SCID, severe combined immunodeficiency.

$CD4^+$ T cells from $CD4^+CD8^+$ thymocytes as well as antigen presentation to mature peripheral $CD4^+$ T cells (RFXANK, RFX5, RFXAP, CIITA deficiency)
- Mutations in the sequence for an RNA (RNA polymerase II subunit 5 [RPB5]-mediating protein [RMP]), which is involved in mitochondrial RNA processing
- Abnormalities in calcium channel function due to mutations in Orai1, which affects T-lineage cell signaling
- Mutations in winged helix nude (WHN), a transcription factor important for normal development of the thymic microenvironment necessary or thymocyte differentiation

T^-B^+ Severe Combined Immunodeficiency

X-Linked Severe Combined Immunodeficiency

X-linked SCID maps to the chromosome Xq13.1 region. It results from abnormalities of the gene encoding γ_c, which is an obligate component of a specific surface receptor for IL-7 as well as the IL-2, IL-4, IL-9, IL-15, and IL-21 receptors (see Fig. 51–3).[114] A lack of functional γ_c interferes with T-cell development in the thymus, mainly because of a lack of IL-7 signaling by thymocytes. B cells are present in the periphery in normal or increased numbers but usually are not functionally competent. The lack of competence probably is due to an intrinsic impairment in B-cell responsiveness to cytokines[115] such as IL-4 and IL-21. In most instances, memory B cells are absent, and the B cells present have an immature phenotype. NK cells are absent because of their impaired development, probably secondary to a lack of IL-15 signaling. Mutations of γ_c that retain some expression of normal protein (e.g., splice-site mutations) suggest that NK-cell development and IL-15 receptor signaling is retained as the amount of cell surface γ_c becomes limiting for T-lineage cell development. In female carriers of X-linked SCID, there is nonrandom inactivation of the X chromosome bearing the X-linked SCID mutation in T cells, mature differentiated B cells, and NK cells. More than 151 different mutations of the human γ_c gene have been identified, with missense mutations of exon 5 among the most common and gene segment deletions the least common.[116] Up to one third of mutations that result in SCID may allow γ_c protein expression on the surface of leukocytes. Milder forms of the disease due to missense mutations that preserve some intracellular signaling have been described.[117] In one extreme example, a missense mutation resulted in clinical SCID with opportunistic infections despite apparently normal peripheral T-cell, NK-cell, and B-cell development.[118] In up to one third of affected children, the disorder arises spontaneously; therefore, a family history is lacking.

Jak3 Deficiency

Jak3 deficiency is another form of B-cell–positive SCID that is clinically indistinguishable from X-linked SCID except for its autosomal recessive inheritance pattern.[113,119,120] Jak3 is a tyrosine kinase that associates with the cytoplasmic domain of γ_c and is activated on cytokine binding at the cell surface.[121] Activated Jak3 tyrosine phosphorylates STAT (signal transducer and activator of transcription) proteins, which then dimerize and translocate to the nucleus to activate gene transcription. The STAT5 proteins STAT5a and STAT5b appear to be critical for the Jak3-dependent effects of IL-7 on thymocyte development. The immunologic phenotype of low T-cell numbers, absence of NK cells, and defective B-cell signaling in Jak3 deficiency is typically identical to that in X-linked SCID.

IL-7 Receptor α-Chain Deficiency

IL-7R α-chain deficiency is another autosomal recessive cause of SCID that is phenotypically similar to γ_c or Jak3 deficiency in that peripheral T cells are markedly decreased and normal numbers of B

Peripheral Blood Abnormalities in Immunodeficiency

- Anemia
  - Hemolytic: Antibody deficiency (especially CVID); 22q11.2 syndrome
  - Hypoplastic: PNP deficiency, thymoma, X-linked lymphoproliferative syndrome
  - Megaloblastic: Transcobalamin II deficiency, PNP deficiency, antibody-mediated pernicious anemia associated with APECED, CVID, IgA deficiency, cartilage-hair hypoplasia syndrome
  - Blood loss: Wiskott-Aldrich syndrome, malabsorption and diarrhea associated with antibody deficiency
- Lymphopenia
  - Combined T-cell and B-cell deficiency: SCID due to deficiencies of ADA, RAG1/RAG2, Artemis, Cernunnos-XLF, DNA ligase IV
  - T-cell lymphopenia with relatively preserved or increased B-cell numbers: X-linked SCID, Jak3 deficiency, ZAP-70 deficiency (greater decrease in $CD8^+$ relative to $CD4^+$ T cells), MHC class II deficiency, CD25 deficiency, $p56^{lck}$ deficiency (all three disorders with greater decrease in $CD4^+$ relative to $CD8^+$ T cells), PNP deficiency, CD45 deficiency, 22q11.2 deletion syndromes ($CD8^+$ often more depressed than $CD4^+$ T cells), WHN deficiency, cartilage-hair hypoplasia syndrome, reticular dysgenesis
- White Blood Cell Deficiency
  - Neutropenia: Antibody deficiency (e.g., XLA before IVIG treatment), hyper-IgM syndromes (CD40-ligand and CD40 deficiencies), cartilage-hair hypoplasia syndrome
- Neutrophilia
  - Qualitative white blood cell disorders (e.g., LAD due to CD18 deficiency)
- Eosinophilia

ADA, adenosine deaminase; APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; CVID, common variable immunodeficiency; GVHD, graft-versus-host disease; IgM, immunoglobulin M; IVIG, intravenous immunoglobulin; LAD, leukocyte adhesion deficiency; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase; SCID, severe combined immunodeficiency; XLA, X-linked agammaglobulinemia; WHN, winged helix nude.

cells are present.[122] The lack of a functional IL-7R α chain results in a loss of signaling by IL-7 as well as a related cytokine thymic stromal lymphopoietin (TSLP),[123] which, based on murine studies, appears to also play a role in $CD4^+$ T-cell development.[124] Thus, absent or reduced IL-7 and thymic stromal lymphopoietin–mediated signaling both may contribute to T-cell immunodeficiency. In contrast with X-linked SCID or SCID due to Jak3 deficiency, the number of NK cells is normal, indicating that NK-cell development is not IL-7 dependent.[122] Other cytokines, such as IL-15, likely are critical for NK-cell development, accounting for the absence of NK cells in γ_c or Jak3 deficiency.

CD3δ, CD3ε, and CD3ζ deficiency

The CD3 cell surface complex of proteins consists of CD3δ, CD3ε, CD3γ, and CD3ζ. These proteins are associated with and are required for surface expression of and signal transduction function by the αβ TCR or γδ TCR of the mature T cell.[125] The CD3 complex proteins are expressed beginning during early thymocyte development and are involved in the transduction of signals from the pre-TCR that contains a functionally rearranged TCR β protein. Genetic deficiency of either CD3δ[126,127] or CD3ε[127] can result in an autosomal recessive form of T^-B^+ SCID in which NK cells are also present in normal numbers. In contrast to many forms of SCID, thymic tissue may be radiologically detected in CD3δ deficiency, possibly because thymocytes may develop to a $CD4^+CD8^+$ intermediate stage of development. Two cases of CD3ζ deficiency due to a homozygous nonsense mutation were identified as a cause of SCID in which B cells and NK cells were present in normal numbers, but the number and function of T cells were reduced.[128,129] Interestingly, one of these patients had a subpopulation of clonally diverse $CD4^+$ T cells in the circulation in which one of the mutated alleles had undergone reversion to three different missense mutations, allowing increased expression of CD3ζ expression and improved T-cell function.[128] In the absence of such reversion, the phenotype appears to be a $T^-B^+NK^+$ form of SCID,[129] and murine studies suggest that a lack of CD3ζ results in an intrathymic maturational arrest just after TCR β-gene rearrangement at the $CD4^-CD8^-$ stage of thymocyte development.

CD45 Deficiency

An autosomal recessive form of T^-B^+ SCID also may result from a deficiency of CD45.[130,131] CD45 is a transmembrane protein tyrosine phosphatase that functions to regulate Src family kinases required for TCR and BCR signal transduction. In this form of SCID, αβ T cells, particularly those of the $CD4^+$ T-cell subset, are markedly decreased in number, whereas the percentage of γδ T cells is unaffected. Peripheral blood mononuclear cells have reduced responses to mitogens, consistent with a severe quantitative deficiency of αβ T cells. Although B-cell numbers are normal, serum Ig levels decrease with age, consistent with a chronic lack of $CD4^+$ T-cell help. Diagnosis is made by demonstrating a lack of surface CD45 and confirming that the lack is due to a genetic defect of the CD45 gene.

WHN (FOXN1) Deficiency

Two cases of an autosomal recessive form of T^-B^+ SCID that likely result from homozygous mutations of the WHN/FOXN1 gene have been reported.[132–134] The human WHN gene encodes a transcription factor that is required for thymic, hair follicle, and nail development and is the ortholog of the murine WHN gene, which is the cause of the mouse nude phenotype. Nude mice lack most peripheral T cells as a result of thymic hypoplasia. WHN mutation is expressed by nonhematopoietic cells, including those of the thymic epithelium, and its mutation results in a perturbed thymic microenvironment for T-cell differentiation. B-cell and NK-cell development and numbers are normal. The two patients that in retrospect were identified as having WHN nonsense mutations presented with generalized alopecia, hypomorphic nails, and severe T-cell lymphopenia. HCT is unlikely to permanently cure the disease given that the genetic defect is located in nonhematopoietic cells. Thymic transplantation might be considered for future cases that are identified.

DiGeorge Syndrome

DiGeorge syndrome (DGS) may result in a $T^-B^+NK^+$ form SCID in less than 5% of cases [see DiGeorge/Velocardiofacial Anomalies (Third and Fourth Pharyngeal Pouch Syndrome) later]. This severe form of the disorder is referred to as *complete DGS*. Complete DGS may be more common with deletion of the chromosome 10p14–13

region than with interstitial deletions of chromosome 22q11.2, which by far are the more common cause of DGS. Genetic screening for DGS by fluorescent in situ hybridization is advisable in cases of $T^-B^+NK^+$ SCID because not all of these patients have other nonimmunologic characteristic features of the syndrome, such as cardiac disease or neonatal-onset hypoparathyroidism.[135] This is particularly important because patients with complete DGS may have a more sustained clinical response to thymic transplantation than to conventional HCT. Complete DGS may be associated with a severe dermatitis with T-cell infiltration and lymphadenopathy and high circulating levels of T cells.[136] These circulating T cells result from extreme oligoclonal expansion and lack signal-joint TCR excision circles (TRECS) and surface expression of CD45RA and CD62-L, indicating that they are not naive T cells. These patients have essentially no detectable antigen-specific T-cell immune responses.

T^-B^- Severe Combined Immunodeficiency

Adenosine Deaminase Deficiency and Purine Nucleoside Phosphorylase Deficiency

Approximately 15% of patients with SCID and 30% to 40% of patients with autosomal recessive SCID have deficiencies of ADA, an enzyme of the purine salvage pathway that deaminates adenosine and deoxyadenosine to inosine and deoxyinosine, respectively.[113,137] Although ADA is expressed by all cell types, ADA deficiency is particularly deleterious to the lymphoid system and interferes with lymphoid development in the thymus, which normally contains the highest level of ADA activity in the body. In the absence of ADA, accumulation of adenosine and deoxyadenosine increases the tendency of immature thymocytes to undergo apoptosis. The accumulation of deoxyadenosine triphosphate (dATP) in particular may inhibit survival signals mediated by signaling from the pre-TCR and the αβ TCR of the thymocyte. B-cell and NK-cell numbers are severely depressed in early-onset ADA deficiency manifesting as SCID,[138] and murine experiments indicate that ADA-deficient B cells are intrinsically sensitive to the accumulation of dATP.[139] ADA genetic deficiency may be complete or partial and usually is due to point mutations giving rise to a nonfunctional protein because of alterations in enzyme activity, stability, or structure. Rarer splicing defects and chromosome deletions of the ADA gene have been described. The immunodeficiency is progressive. Age at presentation is variable, depending on the amount of residual normal ADA activity that results from the particular ADA genotype; it can even first manifest in adulthood.[140] In contrast to most other forms of SCID, ADA deficiency may be associated with thymus development and production of Hassall corpuscles. ADA deficiency can rarely present with neonatal cholestatic jaundice or liver failure during infancy.

PNP deficiency is a rare, autosomal recessive disease of the purine metabolic pathway.[141,142] Although PNP deficiency differs from ADA deficiency in that B cells usually are present in normal numbers, it is discussed here with ADA because its pathogenesis and presentation are similar to that of SCID. PNP immunodeficiency is progressive. Symptoms commonly begin in early infancy as part of an SCID syndrome with enhanced susceptibility to opportunistic viral and fungal infections and failure to thrive. Death may result from overwhelming opportunistic infections, such as CMV or varicella-zoster virus.[143] The immunodeficiency is believed to be due to failure of conversion of deoxyguanosine to guanine and its consequent phosphorylation to deoxyguanylic acid (deoxyguanosine monophosphate [dGMP]) in lymphoid tissue. The toxic metabolite deoxyguanosine triphosphate (dGTP) accumulates in cells and inhibits ribonucleotide reductase, which is required for DNA synthesis and normal proliferation of thymocytes. T-cell numbers are markedly decreased. In vitro T-cell responses are abnormal, with absent delayed-type cutaneous hypersensitivity. B-cell numbers typically are normal, and circulating Ig is detectable. However, cases of complete PNP deficiency with severe depression of T cells usually lack an antibody-specific response to T-cell-dependent antigens, such as proteins. In contrast, autoantibodies, including rheumatoid factor, antinuclear antibodies, and antibodies to blood cells, may be produced, and autoimmune hemolytic anemia, immune thrombocytopenic purpura, and SLE may ensue. These autoimmune phenomena are particularly common with partial PNP deficiency, which can present in adulthood. Other possible features include megaloblastic anemia, neurologic abnormalities with spastic paresis of the trunk and extremities, cerebrovascular disease, developmental delay, and mental retardation. Diagnosis is made by assaying PNP activity in erythrocytes, lymphocytes, or fibroblasts and levels of deoxyguanosine and dGTP in blood. A low serum uric acid level is a useful screening assay for this enzyme deficiency. Prenatal diagnosis is feasible. Attempts at enzyme replacement therapy have not altered the clinical course, but improved methods for in vivo delivery are under development and appear promising.[144] HCT currently is the preferred form of therapy.

Lymphocyte Receptor Gene Rearrangement Defects—RAG1 and RAG2

The generation of a diverse repertoire of TCR and antibody requires VDJ recombination of the TCR α-, β-, γ-, and δ-chain genes and the heavy and light (κ and λ) Ig chain genes, respectively. This rearrangement process requires RAG1 and RAG2, which are expressed only by immature T- and B-lineage lymphocytes and act as DNA endonucleases, as well as widely expressed proteins that are involved in the process of nonhomologous end-joining (NHEJ) DNA repair.[145] SCID due to defects in this rearrangement process was first suggested by the finding of aberrant DJH joining in bone marrow pre-B cells from patients with SCID. In this form of the disease, ADA activity is normal, with failure of maturation of T and B cells resulting in lymphopenia and a complete absence of adaptive immune responses. NK cells are present and functional. About half of patients with the autosomal recessive forms of B^-ADA^+ SCID have nonsense, missense, or deletion mutations in *RAG1* and/or *RAG2*, resulting in loss of functional VDJ recombinase activity and an inability to generate antigen receptors in both T and B cells.[145,146] Hypomorphic mutations of RAG can result in other immune phenotypes, including a form of SCID in which γδ T cells are present in normal or increased numbers, possibly because of CMV infection,[147] and some specific B-cell immune responses are preserved.[148] Another RAG hypomorphic mutation was identified in a 6-month-old girl who demonstrated normal circulating levels of $CD4^+$ and $CD8^+$ αβ T cells but absent B cells; however, the $CD4^+$ and $CD8^+$ T cells were the product of just a few clones, so the patient was severely T-cell immunodeficient.[149]

Omenn Syndrome—Hypomorphic Gene Mutations of RAG and Other Proteins as Causes of Severe Combined Immunodeficiency

Omenn syndrome (originally called reticuloendotheliosis with eosinophilia by its discoverer, Gilbert Omenn) is an autosomal recessive form of SCID that includes scaly erythroderma, generalized lymphadenopathy, hepatosplenomegaly, intractable diarrhea, failure to thrive, eosinophilia, and increased IgE levels. In most cases, IgE levels are elevated despite an absence of peripheral B cells and decreases in other Ig isotypes.[150] This syndrome can result from RAG deficiency due to hypomorphic mutations,[151] but it also has been associated with other genetic causes of SCID, such as mutations of the IL-7Rα chain,[152] Artemis,[153] or the RNA component of the mitochondrial RNA-processing endoribonuclease (RMRP).[154] Omenn syndrome clinically resembles (GVHD) but the T cells infiltrating the skin and organs and in the circulation are autologous, activated ($HLA\text{-}DR^+CD45R0^+CD25^+$), self-reactive cells with a severely restricted αβ TCR repertoire and a skewing toward the production of T_H2 cytokines, such as IL-4 and IL-5. This cytokine profile explains the eosinophilia and increased IgE levels. Normal or increased numbers

of peripheral lymphocytes may be observed as a result of the marked peripheral T-cell expansion. The source of the B-lineage cells for production of IgE is unexplained. A study of several Omenn syndrome patients with hypomorphic RAG deficiencies suggests that these patients also have reduced expression of the *AIRE* gene,[155] which is required for expression of a variety of self-antigens in the thymic medulla. This secondary AIRE deficiency may result in impaired negative selection of the small number of thymocytes that are generated in Omenn syndrome, allowing them to enter the periphery and undergo clonal expansion to self-antigens and attack tissues, such as the skin and gut. Failure of these SCID patients to also produce regulatory T cells within the thymus may compound the autoimmune disease. Families in which one offspring had Omenn syndrome and another had typical lymphopenic SCID have been described, suggesting that the presentation may be strongly influenced by modifying genes or possibly by environmental factors, such as infection. Prompt HCT, often with adjunctive immunosuppressive therapy to control the autoimmune disease, is required to correct the syndrome permanently and prevent death. The correct diagnosis is important; Omenn syndrome can be mimicked by other diseases, such as Netherton syndrome (mutation of the *SPINK5* gene), in which neonatal-onset severe erythroderma and elevated IgE levels are common.[156]

Lymphocyte Receptor Gene Rearrangement Defects—DNA Repair Defects

Other patients with ADA$^+$ T$^-$B$^+$NK$^+$ SCID inherited in an autosomal recessive manner may demonstrate impaired VDJ recombination but normal RAG1 and RAG2 activity. This condition results from mutations in proteins involved in the general process of NHEJ DNA repair, including Artemis, which performs nucleolytic processing of the DNA ends generated by the RAG proteins so that they can be properly ligated,[157] and Cernunnos-XLF (XRCC4-like factor)[158] and DNA ligase IV (*LIG4* gene),[159,160] which are involved in the later DNA ligation step.[161] NHEJ is important not only for resolution of RAG-induced breaks in the TCR and Ig genes in developing lymphocytes but in all cell types for repair of double-stranded DNA breaks that can occur from radiation and other noxious stimuli. Therefore, a characteristic feature of SCID patients with Artemis, Cernunnos-XLF, or DNA ligase IV mutations is marked sensitivity to ionizing radiation, a feature that is not observed with RAG deficiencies. T$^-$B$^+$NK$^+$ SCID in Athabascan-speaking Native Americans occurs at a very high incidence (1 : 2000 live births) and is due to the high gene frequency of a particular Artemis mutant allele from a founder effect.[162] NHEJ also appears to be important for central nervous system development, as developmental delay and microcephaly are frequent findings in some of these patients, such as those with DNA ligase IV mutations.[159,160,163]

Reticular Dysgenesis

This rare autosomal recessive form of SCID is characterized by the absence of T cells and granulocytes in the peripheral blood and bone marrow.[164–166] B cells and monocyte numbers are normal in at least some patients.[167] Maturation of both lymphoid and myeloid lineage cells in the bone marrow is defective, and sensorineural deafness is a frequent complication.[168] Megakaryocyte and monocyte lineage development in the bone marrow usually is normal. The genetic cause of reticular dysgenesis is unknown. Overwhelming infections ensue unless the defect is corrected by HCT.[169]

Severe Combined Immunodeficiency with Preservation of αβ T-Cell Populations

A number of T-cell defects that impair T-cell activation through the αβ TCR–CD3 complex, including gene defects of the CD3γ component of the CD3 complex, CD25, the tyrosine kinases ZAP-70 and p56^{lck}, and Orai1, a protein required for generation of activation-induced intracellular calcium signal, can result in a form of immunodeficiency that clinically resembles other forms of SCID, except that substantial numbers of αβ T cells with a diverse αβ TCR repertoire may be preserved.[113] Increased incidences of infections, autoimmune hemolytic anemia, neutropenia or thrombocytopenia, allergies, cancer, and chronic diarrhea are typical.

CD3γ and CD3ε Deficiency

An autosomal recessive clinical SCID syndrome in which T cells are present in substantial numbers can result from CD3γ deficiency.[125] CD3γ, along with CD3δ, CD3ε, and CD3ζ, is a component of the CD3 complex required for intracellular signal transduction after the TCR is engaged by antigen. However, in contrast to complete CD3δ or CD3ε deficiency, in which a T$^-$B$^+$ form of SCID is typical (see section on CD3δ, CD3ε, and CD3γ deficiency, above), CD3γ does not appear to be essential for thymocyte development. CD3γ deficiency allows for generation of substantial numbers of CD4$^+$ and CD8$^+$ T cells. However, the T cells have reduced surface levels of the αβ TCR–CD3 complex and impaired signaling properties, as indicated by decreased in vitro T-cell responses to mitogens and specific protein antigens. B-cell and NK-cell numbers are normal.[170] The clinical phenotype is highly variable even for a particular genotype. For example, family members bearing the same CD3γ mutation as that of a severely affected patient may have only mild evidence of clinical immunodeficiency. A single patient with compound heterozygote CD3ε deficiency who presented with a relatively mild immunodeficiency characterized mainly by sinopulmonary infections with pyogenic bacteria rather than infections characteristic of T-cell immunodeficiency has been identified.[171] This mild phenotype may be possible because one of the CD3ε alleles is hypomorphic as well as the possible impact other modifying genes.

CD25 Deficiency

A truncation mutation of the IL-2 receptor α chain (CD25), which is an obligatory component of high-affinity IL-2 receptors, results in a clinical presentation of SCID. In contrast with most forms of SCID, there is a moderate level of circulating T lymphocytes, with relative preservation of the CD8$^+$ compared with the CD4$^+$ T-cell subset.[172] Thymic development appears to be perturbed, with a failure of thymocytes to express CD1 and downregulate the Bcl-2 antiapoptotic protein.[172] B-cell numbers are normal. Lymphocytic infiltration of multiple tissues, including the lung, liver, gut, and bone, is prominent. The lymphocytic infiltration may be due, at least in part, to decreased activity of regulatory T cells, which require high-affinity IL-2 receptor signaling for their generation and peripheral maintenance and play an important in peripheral control of potentially autoreactive T cells (see Immune Dysregulation, Polyendocrinopathy, Enteropathy, and X-Linked Inheritance Syndrome below).

ZAP-70 and lck Deficiencies

SCID can arise from mutations of two tyrosine kinases: ZAP-70 and lck. Deficiency of ZAP-70, which encodes a non-Src protein tyrosine kinase of the Syk family, is characterized by decreased CD8$^+$ T cells, with normal to increased numbers of CD4$^+$ T cells.[173,174] ZAP-70 kinase associates with the TCR after T-cell activation to transduce signals from the TCR. The paucity of CD8$^+$ T cells is due to failure of maturation and positive selection in the thymus. Although double-positive thymocytes accumulate in the thymus in this disorder, only single-positive CD4$^+$ thymocytes and not CD8$^+$ thymocytes develop and immigrate to the periphery, that is, peripheral CD8$^+$ T cells are absent. The peripheral CD4$^+$ T cells fail to proliferate in response to mitogens or to antigens that activate through the TCR but normally

are activated by stimulation with phorbol esters and calcium ionophore, which bypass the requirement for TCR-associated protein tyrosine kinases. Thus, there is a complete lack of a functional T-cell compartment. B cells and NK cells are normal in number and intrinsic function. A single case of SCID due to defective expression of lck, a Src family tyrosine kinase expressed by lymphocytes of T-cell and NK-cell lineages, has been reported.[175] lck Deficiency results in selective $CD4^+$ T-cell lymphopenia, with the predominant $CD8^+$ T-cell population lacking CD28 expression. T cells have reduced responsiveness to mitogenic stimuli and IL-2, which becomes more severe with aging. B-cell and NK-cell numbers are in the low to low–normal range, and hypogammaglobulinemia is present.

CRAC Channel Function Defects

Ca^{2+}-release activated Ca^{2+} (CRAC) channels are a principal pathway for calcium influx into T cells from the extracellular space after engagement of the TCR by antigen. Activation-induced increases in intracellular Ca^{2+} concentration activate the calcium-dependent enzyme calcineurin, which in turn dephosphorylates serine residues of target proteins, including proteins of the nuclear factor of activated T cells (NFAT) transcription factor family. NFAT proteins then translocate from the cytoplasm to the nucleus, where they are involved in transcription of cytokines and CD40 ligand. T cells from two patients with SCID who had a T-cell defect in generating NFAT-binding activity to cytokine gene promoters[176] were shown to have a defect in the Orai1 gene.[177] Orai1 is an essential component of the CRAC channel,[178] which highlights its importance for lymphocyte activation and normal T-cell–mediated host defense.

Major Histocompatibility Complex and CD8α Deficiencies

MHC class II deficiency (also known as *bare lymphocyte syndrome type 2*) is a disorder of autosomal recessive inheritance characterized by failure of expression of MHC or HLA class II surface molecules on B cells, monocytes, activated T cells, dendritic cells, Langerhans cells in the skin, and epithelial cells in the thymus and intestine.[179] The most typical presentation is clinical SCID with a selective decrease in $CD4^+$ T cells but not $CD8^+$ T cells and normal numbers of B cells. The immunodeficiency arises from mutations of regulatory factors essential for MHC class II gene transcription that are not linked to the *MHC* locus. MHC class II recognition is required for the normal positive selection of $CD4^+$ T-lineage cells in the thymus. MHC class II expression by APCs also engages the αβ TCR of peripheral $CD4^+$ T cells to provide survival signals in the context of bound self-peptides and to activate these cells for immune responses in the context of bound foreign peptide antigens. In addition to decreased MHC gene transcription, expression of other genes involved in MHC class II antigen presentation, including invariant chain and HLA-DM molecules, is reduced. There is heterogeneity in the gene defects in MHC class II deficiency, with four distinct genetic complementation groups (A, B, C, and D) of *trans*-activating factors that regulate MHC class II gene expression. In most patients, there are mutations of the multimeric protein *trans*-activating regulatory factor X (RFX) complex, including RFXANK (complementation group B), RFX5 (complementation group C), and RFXAP (complementation group D), which cause a loss of transcription factor activity or binding to the X box segment of 5′ promoter region common to HLA class II genes. This results in complete loss of MHC class II gene transcription. Another form of the disease (complementation group A) is caused by a defect of the MHC class II *trans*-activator (CIITA), a master coactivator that forms a complex with the other transcription factors and is essential for activating RNA polymerase II at the promoter. These four proteins are also required for upregulation of MHC class II transcription by IFN-γ. In MHC class II deficiency, moderate reductions in HLA class I expression is also observed in some patients, but these decreases are relatively modest and of uncertain clinical significance.

Frequent clinical manifestations of MHC class II deficiency include primarily septicemia and recurrent gastrointestinal, upper and lower respiratory, and urinary tract infections. Patients are prone to bacterial, fungal, viral, and protozoal infections that start within the first year of life[180] and usually are progressively severe. Diagnosis is made by demonstrating absence of MHC class II expression on B cells, monocytes, or activated T cells. Few children reach puberty; the majority die between the ages of 6 months and 5 years. Rarely, patients have hypomorphic mutations resulting in a mild clinical course and a delay in diagnosis until adulthood.

MHC class II deficiency contrasts with a human disorder of MHC class I antigen presentation (also referred to as *bare lymphocyte syndrome type 1*). This condition results from mutations of the *TAP1* and *TAP2* genes.[181] TAP1 and TAP2 form the heterodimeric TAP peptide transporter that is required for transport of cytoplasmic peptides into the endoplasmic reticulum for binding to nascent HLA class I molecules. Because peptide is an obligatory component of the stable HLA class I molecules, these peptide-free molecules are degraded and fail to reach the cell surface. TAP deficiency is associated with reduced $CD8^+$ T-cell numbers, which most likely is the result of decreased positive selection of immature double-positive thymocytes for the single-positive $CD8^+$ T-cell lineage. A SCID phenotype has not been reported. More surprising is the apparent lack of severe viral infections in view of the well-documented importance of $CD8^+$ T cells in viral clearance in animal models and immunodeficient patients, such as HCT recipients. Instead, human TAP deficiency is associated with bronchiectasis, suggestive of chronic bacterial lung inflammation, but the precise pathogenesis of this complication is unclear. It is possible that TAP-independent HLA class I-restricted viral antigen recognition and preserved NK-cell activity may provide substantial antiviral host immunity in humans. A single family with homozygous CD8-α gene deficiency in which surface CD8 expression on peripheral T cells is completely absent has been identified.[182] CD8-α deficiency is associated with an increased percentage of $CD4^-CD8^-$ T cells expressing αβ TCRs, but whether these cells are MHC class I–restricted cells, as are most conventional $CD8^+$ T cells in normal individuals, is unclear. In this family, the clinical presentation of CD8-α deficiency ranged from asymptomatic to recurrent bronchitis and chronic lung disease, similar to TAP deficiency.

Clinical Manifestations of Severe Combined Immunodeficiency

Infections related to severe T-cell deficiency, which is shared by all forms of SCID, constitute the predominant feature of the disease. Thus, the different forms of SCID in general are clinically indistinguishable.[113] SCID usually manifests in early infancy with recurrent severe infections or persistent infections with low-virulence, opportunistic organisms, such as *Candida* or *Pneumocystis*, giving rise to chronic thrush or interstitial pneumonitis with severe hypoxemia, respectively. Chronic diarrhea and failure to thrive are usual features. Recurrent otitis media, skin infections, and chronic severe viral infections are frequently present. Invasive infections with gram-negative aerobic bacteria, such as *Pseudomonas* and *Enterobacter*, may occur, possibly because of a lack of IL-17–producing $CD4^+$ T cells. Fungal ulcers of the pharynx and nasal mucosa (Noma) are particularly frequent in patients with the Athabascan form of Artemis deficiency.[162] The diagnosis of SCID should be considered a pediatric emergency because correction of the defect becomes more difficult if serious infection ensues before HCT.

In partial ADA deficiency or hypomorphic mutations in other types of SCID that allow some development of the adaptive immune system, onset of symptoms may be delayed until the latter half of the first or second year of life, or even later (3–8 years).[140] With partial ADA deficiency, progression of the deterioration of immunity is

slower because of the time required to accumulate the toxic metabolites. About half of children with ADA deficiencies have anomalies involving the ribs (flared costochondral junctions), scapula, or other parts of the skeleton, but these abnormalities are not specific for ADA deficiency. Neurologic and hepatic abnormalities also have been observed with ADA deficiency.

Patients with MHC class II deficiency present in the first year of life with a clinical picture typical of SCID, with recurrent severe bacterial, viral, or fungal infections causing recurrent bronchopulmonary disease, chronic protracted diarrhea, malabsorption, liver disease, or failure to thrive. Death often is caused by severe viral infections, particularly those of the herpesvirus group, that occur in the first years of life.

GVHD may arise from transfusion of unirradiated blood products or from maternal–fetal transfer of T lymphocytes in utero or at delivery. It may be associated with fever, eczematoid rash, diarrhea, hepatosplenomegaly, and eosinophilia and may be difficult to distinguish from Omenn syndrome. Although engraftment with maternal T lymphocytes occurs in up to 40% to 50% of patients with SCID, symptomatic GVHD often does not ensue, probably because maternal T cells represent a limited repertoire and/or may have suboptimal responses to activation.

Infection in SCID prior to HCT can induce hemophagocytosis in which secondary impairment of production of multiple hematopoietic cell lineages, including neutrophils and megakaryocytes, occurs.[183] Thus, in potential cases of reticular dysgenesis, consideration must be given to the possibility of a different etiology of SCID, such as γ_c or PNP deficiency,[183] in which the neutropenia may be secondary to hemophagocytosis. Hemophagocytosis of any etiology frequently is associated with secondary decreases in the numbers of circulating B cells,[184] which can complicate the clinical interpretation of the pattern of lymphocyte subsets in SCID. Rarely, hemophagocytosis can be the result of maternally engrafted T cells rather than severe infection.

Laboratory Evaluation of Severe Combined Immunodeficiency

Diagnosis of SCID should be established at the earliest age possible so that optimal therapy can be offered.[113] The total lymphocyte count may be markedly low for age in the T^-B^- forms of SCID, but normal counts do not exclude the diagnosis. T-cell numbers, especially $CD4^+$ T cells, usually are markedly decreased, and the T cells that are present may display an immature phenotype. If substantial numbers of T cells are present, they may be derived from engraftment of maternal lymphocytes or result from a marked oligoclonal expansion of a small number of the infant's T cells with a limited $\alpha\beta$ TCR repertoire. Omenn syndrome due to partial RAG1 or RAG2 deficiency or other genetic etiologies of SCID is a classic example of such an oligoclonal expansion. A typical sign of Omenn syndrome is the absence of peripheral B cells with markedly elevated IgE levels. Marked expansion of $\gamma\delta$ T cells with severe $\alpha\beta$ T-cell lymphopenia can occur in some cases of hypomorphic RAG deficiency. In addition, some forms of SCID may affect only certain subsets of T cells or have only a modest impact on T-cell numbers while having a more severe effect on T-cell function (see section on Severe Combined Immunodeficiery with Prevervation of $\alpha\beta$ T-cell populations). For example, with MHC class II deficiency, there may be an increase in $CD8^+$ T-cell numbers and normal numbers of B cells, which conceals the absence of $CD4^+$ T cells. ZAP-70 deficiency is associated with a normal number of dysfunctional $CD4^+$ T cells with a paucity of $CD8^+$ T cells. In X-linked SCID, Jak3 deficiency, and CD45 deficiency, T cells are markedly depressed; B cells are normal or increased in number, but they fail to mature and function. PNP deficiency tends to selectively decrease T cells but leaves B cells unaffected. Deficiencies of ADA, RAG1, RAG2, Artemis, Cernunnos-XLF, and DNA ligase IV are associated with decreases in T and B cells.

In vitro T-cell responses to mitogens and allogeneic cells are absent or very limited, and responses to antigens, such as cell proliferation of peripheral blood mononuclear cells, are absent in SCID. Cutaneous delayed-type hypersensitivity reactions are absent. Ig levels usually are decreased, and specific antibody responses usually are absent, except in some patients with partial ADA deficiency. NK cells are decreased in γ_c-deficient, Jak3-deficient, and ADA-deficient SCID, although any NK cells found in ADA-deficient SCID may display normal function. The thymus in SCID typically is hypoplastic and fat filled, with markedly reduced thymocyte cellularity. Some mutations may permit sufficient thymic development to allow radiographic detection (e.g., CD3δ deficiency). Hassall corpuscles typically are absent, except with ADA or PNP deficiency.

Special studies that may be necessary for diagnosis include assays of the γ_c chain, Jak3, CD3 complex proteins, CD25, CD45, ADA and PNP enzyme activity, dATP, deoxyadenosine, dGTP, deoxyguanosine, ZAP-70 and lck tyrosine kinases, Orai1, and WHN. Analysis of signal transduction in T cells, $\alpha\beta$ TCR repertoire, thymic output based on polymerase chain reaction for signal-joint TCR excision circles, MHC class I and class II MHC surface expression, and evaluation of peripheral T cells for maternal genetic markers (e.g., HLA type) as well as skin biopsies of rashes may be useful for establishing the diagnosis of SCID and GVHD.

For many of these diseases, diagnoses by genetic analysis or immunologic evaluation of fetal blood can be performed. For example, in ADA-deficient SCID, prenatal diagnosis is performed by assaying ADA activity or dATP levels in cultured amniotic cells, fetal blood obtained by fetoscopy, or chorionic villus samples. However, some children have small amounts of residual ADA activity, which may make diagnosis difficult. Prenatal diagnosis of SCID can be performed by molecular approaches once the specific gene defect in family members has been identified. Strategies are being developed for population-wide neonatal screening for SCID using polymerase chain reaction to measure the levels of TRECs in DNA isolated from Guthrie card blood spots.[185]

Therapy for Severe Combined Immunodeficiency

The optimal preparative regimen for HCT is a complex and controversial issue and must consider the risk of peritransplantation complications, including death, with the immunologic outcome (see Chapter 100). Although HCT with omission of such preparation usually results in T-cell engraftment and reconstitution of T-cell immunity in recipients with X-linked SCID, these patients usually do not have engraftment of donor B cells and have poor antibody-specific responses to antigen, requiring chronic Ig replacement. NK-cell engraftment may also not occur.

If the immunodeficiency is not corrected, SCID is invariably fatal. Transplantation of hematopoietic cells from HLA genotypically identical family donors completely restores the immunologic function of patients with various forms of T^-B^- and T^-B^+ SCID and also is successful in correcting MHC class II deficiency and PNP deficiency.[113] Pretransplantation preparative cytoablation is not required; mortality with this approach has been minimal. T-cell–depleted haploidentical parental transplantation without cytoablative therapy has been successful in cases where HLA-matched relatives were not available. The frequency of GVHD with this approach has been relatively low, but the procedure may carry the risk of a late decline in T-cell immune function, particularly after the first decade following transplant.[186] However, to the best of our knowledge, no study has directly compared long-term immune reconstitution for different cell lineages with cytoablative versus noncytoablative preparative regimens. HCT using matched unrelated donors from cord blood, peripheral blood, or bone marrow may achieve more complete immune reconstitution of both donor T cells and B cells but also may carry a higher risk of posttransplantation mortality than approaches in which pretransplant cytoablation is avoided.[187] Lymphoid and hematopoietic stem cell engraftment is required to correct SCID from reticular dysgenesis

and MHC class II deficiency. The presence of preexisting infection or GVHD hinders the success rate for transplantation. Although in utero transplantation of parenteral CD34+ hematopoietic progenitor cells has corrected X-linked SCID diagnosed in the fetus, HCT performed during the neonatal period appears to provide the best results in terms of outcome and is technically less challenging.

All blood products should be irradiated before transfusion of patients with SCID to prevent GVHD. Ig replacement therapy, nutritional support, and prophylaxis against *Pneumocystis* infection usually are required before HCT. Family members should be immunized with a killed rather than live vaccines (e.g., for influenza) to prevent infection in patients.

In the absence of an HLA-identical bone marrow donor, gene therapy has been used in infants with X-linked SCID or ADA deficiency (see Chapter 109).[188] Gene therapy has involved retroviral transduction of a normal cDNA for γ_c or ADA under the control of constitutive promoters into autologous CD34+ hematopoietic precursor cells that have the gene defect. This is followed by infusion of the transfected cell cultures into SCID patients. The initial results of treatment in 10 patients with γ_c deficiency were promising, with evidence of acquisition of normal T-cell and T-cell–dependent B-cell immunity and transduction of multiple lineages, including hematopoietic stem cells. However, several patients developed γδ T-cell leukemia that was related, at least in part, to retroviral integration of the gene therapy vector into the *LMO2* gene, with subsequent dysregulated LMO2 expression, an event that has been implicated in leukemogenesis. A similar retroviral transduction approach also resulted in substantial reconstitution of immunity in ADA deficiency, which appears to be stable. In contrast, leukemias have not been observed as yet in these ADA-deficient patients, perhaps because of technical differences in the retroviral transduction protocol or transgene (see Chapter 109).

Patients with ADA deficiency may be given ADA enzyme replacement therapy by intramuscular injection of polyethylene glycol (PEG)-modified bovine ADA.[189] Modification of ADA with PEG prolongs the circulating half-life of the enzyme and decreases its immunogenicity. PEG-ADA can improve the immunologic and clinical status of patients with ADA deficiency. The exogenous ADA lowers the level of the toxic metabolites in ADA-deficient lymphocytes by deaminating adenosine and 2′-deoxyadenosine. However, immune reconstitution provided by PEG-ADA can result in antibodies to ADA with a loss of secondary loss of immune function. In the absence of an HLA-identical donor, an HLA-haploidentical or matched-unrelated donor HCT is an alternative to ADA replacement therapy. However, use of PEG-ADA before HCT may restore host immunologic function and predispose to graft rejection. Similarly, ADA activity in the transplanted marrow may stimulate immunologic function of the recipient's residual T cells, preventing engraftment. This can be avoided by use of pretransplantation cytotoxic agents.

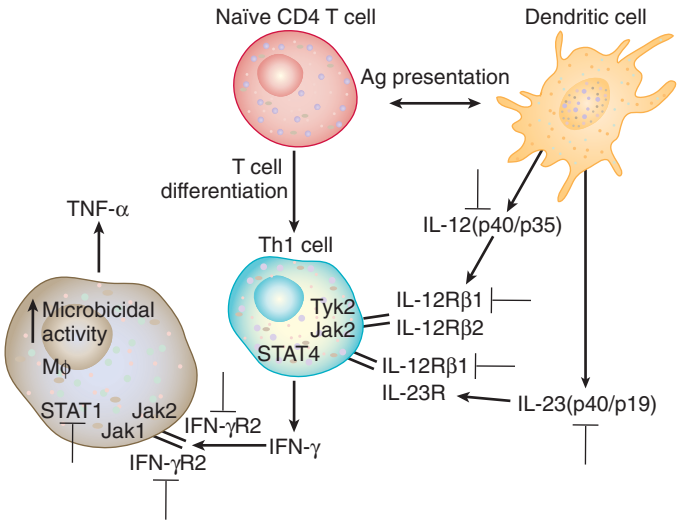

Figure 51–4 Interferon-γ/T helper-1 cell subset 1 (T_H1) pathway deficiencies. T_H1 differentiation is initiated when dendritic cells or mononuclear phagocytes are activated by foreign antigen (Ag) to produce interleukin-12 (IL-12), a heterodimer composed of p40 and p35 subunits. IL-23 is composed of the IL-12 p40 subunit and a unique p19 subunit. IL-12 and IL-23 bind to their specific receptors, IL-12Rβ1 and IL-12Rβ2 and IL-12Rβ1 and IL-23R subunits, respectively, on activated T cells and natural killer cells. IL-23 is less potent than IL-12 at T_H1 differentiation and, although not indicated in the figure, may be an important cytokine for the generation and/or maintenance of CD4 T cells that produce IL-17 (T_H17 cells). IL-12 binding to its receptor activates the Jak/STAT4 pathway of signal transduction and the release of the signature T_H1 cytokine interferon-γ (IFN-γ). IL-23 binding to its receptor may preferentially activate STAT3 than STAT4, accounting for its different effect from IL-12 on CD4 T-cell differentiation. The IFN-γ receptor (IFN-γR) consists of IFN-γR1 and IFN-γR2 subunits and is widely expressed. Upon IFN-γ binding to IFN-γ receptors to cells, such as macrophages, and natural killer cells, Jak1 and Jak2 are activated and phosphorylate STAT1, leading to induction of many proteins that enhance microbicidal activity, including the production of tumor necrosis factor α (TNF-α). Abnormalities in the T_H1 pathway result from mutations in five distinct genes that encode IL-12p40, IL-12Rβ1, IFN-γR1, IFN-γR2, and STAT1. Blocks in these genes are indicated in the figure (by ⊥ in various orientations). Spontaneously arising autoantibodies to IFN-γ that interfere with its biologic activity have been described. Jak, Janus kinase; STAT, signal transducer and activator of transcription.

Interferon-γ/T Helper-1 Pathway Deficiencies

Etiology and Pathophysiology

Defects in the T_H1 pathway (Fig. 51–4) result in markedly increased susceptibility to infections with intracellular bacterial organisms, such as *Mycobacteria* and *Salmonella*. Mutations in five different genes (those encoding IL-12p40, IL-12Rβ1, IFN-γR1, IFN-γR2, and STAT1) result in disorders whose common pathogenesis is impaired IFN-γ–mediated immunity.[190] The T_H1 pathway of T-cell differentiation is initiated by APCs producing IL-12 in response to certain microbial and inflammatory stimuli. IL-12 is a heterodimer composed of p40 and p35 subunits. IL-23 is a close relative of IL-12. It consists of the IL-12 p40 subunit in association with a novel p19 subunit that is homologous to p35. IL-23 may be particularly important in the generation or maintenance of CD4 T cells that produce IL-17 (T_H17 cells), which have a role in host defense distinct from that of T_H1 cells (one at the period control of infections with gram-negative bacteria).[191] IL-12 and IL-23 mediate their effects by binding to specific receptors that are highly expressed by T cells and NK cells. The IL-12 receptor is composed of IL-12Rβ1 and the IL-12Rβ2 subunit. The IL-23 receptor consists of an IL-12Rβ1 subunit that associates with an IL-23R subunit. Many of the effects of IL-12 are mediated by STAT4. In response to IL-12 receptor engagement, STAT4 undergoes tyrosine phosphorylation by Jak2 and Tyk2, homodimerizes, and then moves to the nucleus, where it influences gene expression. IL-12 signaling results in the synthesis and secretion of IFN-γ by T cells and NK cells and in other effects, such as enhanced lymphocyte proliferation and induction of an antiapoptotic state. The IFN-γ receptor consists of two surface proteins, IFN-γR1 and IFN-γR2, both of which are required for receptor function. IFN-γ receptor signaling activates Jak2, resulting in translocation of STAT1 homodimers to the nucleus, where they increase transcription of IFN-γ response genes. STAT1 also is a component of a heterotrimeric complex consisting of STAT1/STAT2/IRF9 that mediates signaling by the type I IFN receptor, which specifically binds IFN-α or IFN-β proteins. In addition to these genetic deficiencies, the acquisition of autoantibodies against IFN-γ may mimic the phenotype due to genetic defects of the IFN-γ receptor.[192–194]

Clinical Manifestations

Partial IFN-γR1 or IFN-γR2 deficiency due to missense mutations, partial STAT1 deficiency (in which a STAT1 protein is expressed that cannot signal in response to IFN-γ but is able to signal in response to IFN-α or IFN-β), and complete deficiency of IL-12p40 or IL-12Rβ1 all result in a similar clinical picture, manifested by usually curable infections with intracellular bacterial infections, particularly *Mycobacteria*. Complete IFN-γR1 or IFN-γR2 deficiency predisposes the patient to overwhelming intracellular bacterial in-fections during infancy and early childhood.[190,195,196] In the case of IFN-γR2 deficiency, the severe phenotype can result from gain of glycosylation mutants in which amino acid substitutions from missense mutations create de novo glycosylation sites.[196] A partial dominant form of IFN-γR1 deficiency has been reported in which T_H1 immunity appears to be less impaired than for persons with complete IFN-γR deficiency but with greater vulnerability to infection than for those with partial deficiencies.[197] The IFN-γR1 mutant allele with this partial dominant phenotype encodes a protein that has a truncated cytoplasmic domain and is defective in signaling. This truncation also removes a domain involved in receptor recycling from the cell surface, resulting in accumulation of abnormally high levels of the mutant IFN-γR1 on the cell surface. Because IFN-γ receptors require two normal IFN-R1 molecules for normal function, only a small number of surface IFN-γ receptors in patients with this partial dominant mutation effectively signal.[197] Complete STAT1 deficiency is similar to complete IFN-γR deficiencies, except that patients also are highly susceptible to viral pathogens, such as herpes simplex virus,[198] as a result of the absence of type I IFN receptor signaling.

Patients with complete or partial IFN-γR deficiency usually have disseminated infections caused by bacille Calmette-Guérin (BCG) vaccine and environmental nontuberculous *Mycobacteria*, including organisms not usually pathogenic in an immunocompetent host, such as *Mycobacterium smegmatis*. Infected tissue lacks well-defined granulomas, demonstrating the importance of the T_H1 pathway in this form of tissue reaction. Disseminated infections with *Salmonella* are seen in approximately 50% of patients, and *Listeria* infection occurs occasionally. Severe oral or respiratory tract infections with CMV, herpes simplex virus, varicella-zoster virus, respiratory syncytial virus, and parainfluenza virus may occur. In some of these patients, prior lung infection with *Mycobacteri*a may contribute to the severity of viral infections. Patients with partial dominant IFN-γR1 deficiency appear to be particularly prone to develop mycobacterial osteomyelitis.[190,197] Deficiency of IL-12p40 or IL-12Rβ1 predisposes affected patients to intracellular bacterial infections that are similar to those seen with the IFN-γR deficiencies but often are less severe. Extraintestinal infections with nontyphoidal *Salmonella* is much more frequent than mycobacterial infections in IL-12p40 or IL-12Rβ1 deficiency.[199] This striking vulnerability to *Salmonella* infection may reflect a greater role of IL-23 as well as IL-12 in the control of these pathogens.

Several cases of adults with an acquired T_H1 immunodeficiency due to autoantibodies to IFN-γ have been reported. Most patients presented with persistent infection with atypical *Mycobacteria* of low virulence and did not have underlying diseases that would predispose to production of autoantibodies, such as frank SLE or CVID.[191–193] In one series, all six reported cases were Asian women.[193] Both IgG and IgM antibodies have been isolated with anti–IFN-γ activity.[193] The mechanism underlying the production of IFN-γ autoantibodies is unknown.

Laboratory Evaluation

Most patients with complete IFN-γR deficiency will not express the receptor on the surface of mononuclear phagocytes and do not secrete TNF-α in response to IFN-γ. Cells from patients with partial IFN-γR deficiencies may respond weakly to IFN-γ, and deficient responses may be overcome with increasing doses of IFN-γ. The partial dominant phenotype of IFN-γR1 deficiency is distinguished from other forms of the deficiency by increased rather than decreased expression on the cell surface, as the mutation impairs receptor internalization after ligand binding. As with other primary immunodeficiencies, gene sequencing, guided by functional or biochemical assays, often is essential for a definitive diagnosis. An accurate molecular diagnosis is crucial to determine the optimal treatment strategy for individual patients and family members. A useful set of screening assays for these deficiencies evaluates IFN-γ responsiveness by determining the ability of IFN-γ to induce TNF-α production by lipopolysaccharide-primed peripheral blood mononuclear cells IL-12 production; the ability of lipopolysaccharide (LPS) to induce IL-12p70 secretion by IFN-γ primed peripheral blood mononuclear cells; and IL-12 responsiveness by the ability of IL-12 and IL-23 to induce IFN-γ by peripheral blood mononuclear cells (T cells are the main producers in this assay), screening for high circulating levels if IFN-γ may also help identify IFN-γ receptor defects.[200]

Therapy

Treatment of all IFN-γ pathway deficiencies requires prompt administration of antimicrobials to treat infection. Mycobacterial infections in patients with complete IFN receptor deficiency or complete STAT1 deficiency should be treated aggressively with at least four different drugs. Surgery to remove a refractory infectious site may be effective. For patients with complete IFN-γR deficiency, prophylactic administration of antibiotics is recommended. Because of the poor outcomes in these patients, definitive correction of the defect by HCT is the treatment of choice. For patients with the partial dominant form of IFN-γ deficiency, prophylactic antibiotics may be useful, but HCT is not indicated. Patients with partial IFN-γR deficiency or partial dominant deficiency of STAT1, in which type I IFN receptor signaling (mediated by binding of IFN-α or IFN-β) is preserved, have good outcomes; therefore, neither prophylactic antibiotic therapy nor HCT is indicated. Patients with IL-12p40 deficiency and IL-12Rβ1 deficiency also appear to have generally good outcomes, and recalcitrant infections in these individuals often are responsive to IFN-γ treatment.

Wiskott-Aldrich Syndrome

Etiology and Pathophysiology

WAS is an X-linked recessive syndrome characterized by the triad of eczema, thrombocytopenia, and immunodeficiency.[201] Lymphoid as well as other hematopoietic cell types, such as APCs, are affected. The Wiskott-Aldrich gene maps to chromosome position Xp11.22–11.3 and encodes a 502-amino-acid protein termed WASP (WAS protein).[202] More than 160 different *WASP* mutations spanning all 12 exons of the gene have been identified. WASP couples TCR engagement with transcriptional activation and actin polymerization.[201] Defects in signal transduction and actin polymerization of APCs and B cells may contribute to the immunodeficiency.

Abnormal thrombocytopoiesis makes a major contribution to thrombocytopenia. This may be explained by a tyrosine kinase signaling pathway that signals through WASP and controls the assembly of actin, which is essential for megakaryocyte differentiation. Increased platelet destruction due to an intrinsic platelet defect also contributes to thrombocytopenia. Mean platelet volume is reduced, but there is a broad overlap with the normal range. The platelets in WAS express decreased surface glycoproteins IIb, IIIa, and IV and display defective thrombin-induced expression of CD62P (P-selectin) and CD63 and a decreased actin content. After splenectomy, the platelet count usually increases, and the mean distribution of the platelet volume returns to normal, indicating that platelet circulation through the splenic microarchitecture leads to reduced platelet size. Platelet-associated IgG frequently is present but disappears after splenectomy.

Female carriers are asymptomatic because of selection against cells that have the X chromosome carrying the mutant *WASP* gene as their

active X chromosome. Nonrandom X chromosome inactivation patterns are observed in obligate carriers in T and B cells, monocytes, polymorphonuclear leukocytes, and platelets but not in fibroblasts. However, affected carriers with symptomatic WAS most likely due to skewed X chromosome activation have been discovered. Hereditary X-linked thrombocytopenia is characterized by thrombocytopenia and small platelets, similar to findings in WAS, without the immunodeficiency or eczema. This disorder is an allelic variant of WAS arising from mutations of the *WASP* gene that often result from missense or splice-site mutations that permit residual detectable WASP expression by cells rather than null mutations, such as frameshifts, deletions, and insertions, which usually ablate all protein expression.[203]

Clinical Manifestations

The initial manifestations usually are petechiae or bleeding in the skin, mouth, nose, or gastrointestinal or urinary tract, or from the umbilical cord, beginning in the first several months of life. Thrombocytopenia is present at birth. A life-threatening bleeding episode (gastrointestinal, intracranial, or severe oral) occurs before a diagnosis is made in up to one third of patients. Early in life, an eczematoid rash usually appears, although it can be quite subtle in some patients. Typically, the rash is prominent in the antecubital and popliteal fossae and tends to become petechial. At the time of diagnosis, only approximately 25% of patients with WAS have the classic triad of thrombocytopenia, eczema, and recurrent otitis media. Infections with bacteria cause recurrent otitis media with chronic purulent drainage and perforated tympanic membranes, recurrent pneumonia, sinusitis, and bacteremia. Viral infections may include recurrent and severe disease due to herpes simplex virus or varicella-zoster virus. Patients lacking all cellular WASP expression may be at particular risk for more severe opportunistic infections, such as *Pneumocystis* pneumonia or invasive fungal infections.[203] The thrombocytopenia and bleeding tendency often are worsened with infection. Autoimmune disorders develop in up to 40% of patients and include arthritis, vasculitis, uveitis, inflammatory bowel disease, and autoimmune hemolytic anemia. Certain instances of autoimmune disease, such as that involving the gastrointestinal tract and kidney, appear to be due to IgA deposition.

The median survival time in untreated WAS patients is 6.5 years. The cause of death is infection, usually from pneumonia or sepsis, in 59% of patients, bleeding in 27%, and malignancy in 5%. The risk of malignancy in patients with WAS is 100-fold higher than normal. A high incidence of lymphoreticular tumors that initially manifest at extranodal sites, especially non-Hodgkin lymphomas with B-cell immunoblastic sarcomas, is observed in patients who survive to later childhood.

Laboratory Evaluation

Immune abnormalities in WAS include a reduced antibody response to unconjugated polysaccharide antigens (severely depressed), protein antigens (moderately depressed), low serum IgM levels, and often elevated serum IgA and IgE levels.[201,203] Moderate T-cell lymphopenia, particularly of $CD8^+$ T cells, is observed in some cases, and T-cell function in vitro usually is depressed after stimulation with allogeneic cells or CD3 monoclonal antibody. The capacity of T cells activated in vitro to differentiate into effector cells producing IFN-γ is impaired.[204] The platelet count is decreased, ranging from 5000/mm^3 to 100,000/mm^3, and the platelet size is characteristically small, a feature that is highly specific for WAS or X-linked thrombocytopenia. The platelet count may vary considerably in an individual patient, with a decrease occurring with acute infections, such as with viruses. The number and morphology of megakaryocytes in the bone marrow are normal. The bleeding time is more prolonged than predicted from the platelet count, indicating platelet dysfunction. Rare cases of constitutively activating *WASP* mutations resulting in severe congenital neutropenia have been reported.[205] The carrier state can be diagnosed by demonstrating nonrandom X-chromosome inactivation patterns in leukocytes, although this technique has largely been supplanted by molecular diagnosis. Prenatal diagnosis can be made by detecting polymorphisms flanking the *WASP* gene or its mutations and by decreased fetal platelet count and size. The diagnosis after birth is suggested by the distinct clinical features of the syndrome and can be screened for by flow cytometry following cellular permeabilization and intracellular staining for WASP protein. Confirmation of the diagnosis requires molecular analysis of the *WASP* gene sequence. Determination of WASP expression by cells using Western blotting may be particular helpful in determining prognosis,[203] with detectable protein associated with a milder clinical course.

Therapy

Ig replacement therapy is indicated to decrease the risk of infections. This modality also may decrease the severity of autoimmune disease. HCT can correct all of the defects of this otherwise fatal disorder, including the susceptibility to malignancy and autoimmune disease.[206] Successful engraftment requires preparative ablation or cytoreduction of the recipient's bone marrow. The success rate with HLA-identical HCT is high. Matched unrelated donor HCT for WAS has resulted in some success, especially when performed at an early age. Unfortunately, the success rate of haploidentical parental HCT has been disappointing, and outcomes include a relatively high incidence of severe viral infections, lymphomas, EBV-induced B-cell lymphoproliferative disease, or chronic GVHD in the posttransplantation period.

Splenectomy combined with regularly administered prophylactic antibiotics has been used to manage some patients with severe bleeding problems who could not undergo transplantation.[207] Splenectomy increases the platelet count and decreases the bleeding tendency, but it also may increase the susceptibility to overwhelming sepsis, even with use of prophylactic antibiotics. A majority of splenectomized patients have a sustained increase of platelet counts by at least 20,000/mm^3, and over half of these patients have a sustained increase by at least 100,000/mm^3. Recurrences of thrombocytopenia with an acute immune thrombocytopenic purpura–like episode can occur after splenectomy; therapy with corticosteroids and IVIG may be useful in such cases.

Ataxia-Telangiectasia

Etiology and Pathophysiology

Ataxia-telangiectasia is an autosomal recessive disorder caused by mutations of the ataxia-telangiectasia mutated (*ATM*) gene. The disease is characterized by progressive cerebellar ataxia, telangiectasia, recurrent sinopulmonary infections, combined immunodeficiency, increased incidence of malignancies, and premature aging.[208] The frequency of ataxia-telangiectasia is estimated to be between 1 : 40,000 to 1 : 100,000 live births. The *ATM* gene encodes a 350-kd protein kinase with a phosphatidylinositol-3-kinase domain involved in multiple signaling pathways of cellular responses to DNA damage and in control of the cell cycle and DNA replication, recombination, and repair.[208,209] Mutations have included nonsense, splice-site variants, small insertions or deletions causing frameshifts with premature stop codons, missense mutations, and, rarely, large genomic deletions.[210] Ataxia-telangiectasia cells display chromosomal instability and hypersensitivity to agents that cause DNA strand breaks, including γ-rays and x-rays, ionizing radiation, and radiomimetic chemicals such as bleomycin. Ataxia-telangiectasia cells have an increased number of spontaneous and radiation-induced chromosome breaks, which are not rejoined as efficiently as in normal cells. Cells of heterozygous carriers have a sensitivity that is intermediate between those of cells from normal persons and homozygotes. These carriers may be at increased risk for cancer compared to the general population.

Ataxia-telangiectasia cells do not reduce their rate of DNA synthesis after irradiation, as do normal cells, because of dysfunction or absence of the ATM protein. In normal cells, irradiation-induced double-strand breaks in DNA lead to an arrest at the G_1–S transition, S, or G_2–M transition phase of the cell cycle. These cell-cycle checkpoints ensure that damaged DNA is not replicated and cell division does not occur until DNA strand breaks have been repaired. The ataxia-telangiectasia gene product functions in several irradiation-induced signal transduction pathways that recognize DNA damage and transduce a signal from damaged DNA to arrest the cell cycle and repair damaged DNA.[209,210]

The ATM protein is also required for maintaining immature B cells and thymocytes undergoing VDJ recombination from dividing during this process, which also requires double-stranded breaks, in this case by the endonuclease activity of the RAG genes acting on the Ig and TCR gene loci. Failure to prevent cell cycle entry in these developing lymphocytes in ataxia-telangiectasia accounts for the high frequency of lymphocytes with chromosome translocations and aberrant interlocus TCR and Ig gene rearrangements,[211] which also is important in the genesis of lymphoid tumors.[212] Aberrant TCR gene rearrangement may contribute to the relatively low number of peripheral αβ T cells, although these numbers usually are not severely depressed. This is paralleled by thymic hypoplasia and a lack of Hassall corpuscles. Isotype switching by ataxia-telangiectasia B cells may be impaired by a similar mechanism. Double-stranded DNA breaks in the Ig heavy chain switch region are part of normal isotype switching, and failure of the ATM protein to prevent entry of these B cells into the cell cycle may perturb this process.[209] Ataxia-telangiectasia may result in a persistence expression of proteins characteristic of early development, including elevated levels of serum α-fetoprotein and carcinoembryonic antigen. Ovarian agenesis and hypogonadism are frequent. In the absence of cell cycle arrest with *ATM* gene dysfunction, even low levels of DNA damage in ataxia-telangiectasia cells may activate an apoptotic cell death in various tissues, which in normal cells would be activated only by irreparable DNA damage. The increased apoptosis may explain organ atrophy in ataxia-telangiectasia.

Clinical Manifestations

The most common initial presentation of ataxia-telangiectasia is a progressive cerebellar ataxia that typically has onset in the second year of life.[208] Other neurologic symptoms occurring later are choreoathetosis, nystagmus, strabismus, dysarthric speech, and decreased deep tendon reflexes. Telangiectasias appear later in childhood and are most prominent on the bulbar conjunctivae, exposed areas of the skin, external ear, eyelids, face, flexor folds of the neck, extremities, and dorsa of the hands and feet. Recurrent sinopulmonary infections occur in a majority of patients and may become chronic, resulting in bronchiectasis and respiratory insufficiency. The overall risk of cancer is 60 to 180 times normal, with development of malignancies in up to 10% of patients.[73–75,208,213] Black patients with ataxia-telangiectasia have even higher risks of malignancy, especially lymphomas and leukemia. Most neoplasms occur before age 15 years, with a predominance of non-Hodgkin lymphomas having histologic subtypes that are observed with chromosome 14 translocations, Hodgkin lymphoma (mostly of the lymphocytic depletion type), T-cell leukemia, and epithelial carcinomas. Heterozygotes for the *ATM* gene have an approximately threefold to fourfold increased risk of malignancy. It is suggested that heterozygous females, who have an approximately fivefold increased risk of breast cancer, account for up to 8% of all patients with breast cancer in the United States. Caution must be exercised in the treatment of neoplasms because of the increased sensitivity of patients with ataxia-telangiectasia to radiation therapy. Endocrinologic abnormalities occur commonly and include delayed somatic growth, insulin resistance, delayed development of secondary sexual characteristics in females (secondary to absent or hypoplastic ovaries), hirsutism in females, and hypogonadism in males. Premature aging of the skin and diffuse graying of the hair usually occur. Venoocclusive disease of the liver has occurred in association with ataxia-telangiectasia.

Laboratory Evaluation

Absence or deficiency of serum and secretory IgA and of serum IgE are found in approximately 75% of patients. This finding may reflect impaired isotype switch recombination. Low levels of IgG2 and IgG4 and decreased antibody responses to immunization, particularly to purified polysaccharides, also are found. Anergy to delayed-type hypersensitivity skin testing, decreased T-cell numbers, and abnormal in vitro lymphocyte proliferative have been reported. In the mouse knockout model of ATM, thymocyte differentiation is perturbed because of frequent biallelic disruption of the TCRα gene locus. Production of T_H1 and T_H2 cytokines by T cells from patients with ataxia-telangiectasia after polyclonal stimulation in vitro is normal,[214] consistent with the relative rarity of infections characteristic of T_H1 deficiency (e.g., infection with *Mycobacteria*, *Salmonella*, and *Listeria*), in this disorder. Serum levels of α-fetoprotein are increased in greater than 95% of patients, and levels of carcinoembryonic antigen may be elevated. Nonrandom chromosome breaks and chromosome 14 translocations are frequently detected. Early diagnosis can be facilitated by demonstrating the radiosensitivity of EBV-transformed B-cell lines.[215] Genetic confirmation of the diagnosis is difficult because of the large size of the *ATM* gene (66 exons) and the diverse mutations that have been reported. Specialized assays, such as DOVAM-S (detection of virtually all mutations-SSCP),[216] may help with genetic confirmation.

Therapy

There is no established therapy for halting the disease. For ataxia-telangiectasia due to single nucleotide changes resulting in premature stop codons, treatment consisting of in vitro incubation of cells with aminoglycosides may allow increased read-through and expression of full-length protein.[217] Whether aminoglycoside treatment of patients with these mutations has clinical benefits is unclear. Antibiotics are indicated for recurrent pulmonary infections, and IVIG replacement therapy may be indicated. Exposure to excessive sunlight should be minimized to prevent skin changes. Treatment of malignancies in patients with ataxia-telangiectasia may require use of lower doses of radiotherapy and chemotherapy. Radiologic investigations using ionizing radiation, such as computed tomography scans, should be minimized whenever possible in favor of other modalities.

Digeorge/Velocardiofacial Anomalies (Third and Fourth Pharyngeal Pouch Syndrome)

Etiology and Pathophysiology

The DiGeorge or velocardiofacial syndromes most frequently result from a monosomic deletion of genes contained in the chromosome 22q11.2 region.[218] The 22q11.2 interstitial deletions of one chromosome may occur at a frequency of 1:3000 live births, with approximately 90% of cases due to deletion of a three-megabase segment flanked by low-copy repetitive sequences.[219] Most cases are sporadic, but the deletion can be either maternally or paternally inherited. In rare cases, a phenotypically similar syndrome results from monosomy for the chromosome 10p13 region. However, this is a relatively rare disorder and is not discussed further here.

This hemizygous genetic defect results in abnormal development of tissues derived from the third and fourth pharyngeal pouches. These pouch derivatives normally develop during the fourth to seventh weeks of fetal development and contribute to thymus, parathyroid glands, and conotruncal components of the heart, ear, and facial structures.[218,220] Possible clinical consequences of the 22q11.2

deletion include severe congenital heart disease, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia. Haploinsufficiency for the *TBX1* gene, possibly in combination with other genes, such as *CrkL*, which is involved in intracellular signal transduction, as part of the 22q11.2 deletion may affect the migration of cephalic neural crest mesenchymal cells into the pharyngeal pouches, thereby disrupting tissue differentiation.[221] Haploinsufficiency of *TBX1* and *CrkL* appears to increase local retinoic acid signaling. It is intriguing that the DiGeorge anomaly also may arise from an environmental insult, including retinoid exposure as well as maternal alcoholism and diabetes. The observation that monozygotic twins with the 22q11.2 deletion can have markedly different phenotypes suggests that environmental or postzygotic events have important influences on the clinical expression of the syndrome.[222,223]

The thymus may be completely absent in the most severe form of this developmental field defect. However, more frequently the thymus is small, hypoplastic, and ectopic in location as a result of the lack of descent into the mediastinum. Most patients have a relatively clinically mild partial T-cell deficiency (i.e., without frank opportunistic infections), with decreased numbers of $CD4^+$ and $CD8^+$ $\alpha\beta$ T cells that may improve with time. The $CD8^+$ T-cell compartment tends to be more affected than the number of $CD4^+$ T cells.[224] Rarely, complete thymic aplasia results in profound T-cell deficiency accompanied by a marked susceptibility to infections with intracellular pathogens typical of SCID. These severe cases usually do not improve with time.

Clinical Manifestations

A broad and variable spectrum of malformations is possible.[218,225] Affected infants often present with hypocalcemic tetany in the newborn period. Cardiac malformations include interrupted, right-sided, or double aortic arch; truncus arteriosus; pulmonary atresia; aberrant subclavian artery; ventricular septal defect; tetralogy of Fallot; and patent ductus arteriosus. These defects may give rise to cyanosis and cardiac murmurs. Type B interrupted aortic arch or truncus arteriosus are particularly suggestive of the diagnosis. Facial dysmorphic features include hypertelorism, antimongoloid slant of the eyes, midline facial clefts, micrognathia, shortened philtrum of the lip, cleft palate, choanal atresia, low-set posteriorly rotated ears, and notched ear pinnae. If the T-cell deficiency is severe, which occurs in less than 5% of patients, the infant may present with a SCID-type syndrome, with development of chronic or recurrent rhinitis, pneumonia, candidal infections, diarrhea, and failure to thrive. Moderate–to-severe developmental delays, renal anomalies, and dysphagia are common, and hearing loss may be present. Autoimmune disease, including autoantibody-mediated cytopenias, thyroid disease, and juvenile rheumatoid arthritis, are present in approximately 10% of patients with 22q11.2 hemizygous deletions.[218]

Laboratory Evaluation

In the approximately 70% of patients with thymic hypoplasia, total numbers of T cells are low, and B-cell numbers may be normal or increased, resulting in a normal total lymphocyte count. In vitro T-cell responses to nonspecific mitogens or allogeneic lymphocytes may range from normal to absent but in general are directly related to the numbers of T cells present. T-cell signal transduction through the TCR and the TCR repertoire appear to be normal in most patients.[226] Thus, most studies suggest that T-cell deficiency of the DiGeorge or velocardiofacial syndrome is mainly a quantitative rather than a qualitative disorder. The increased incidence of autoimmunity indicates that the 22q11.2 hemizygosity may have a relatively greater impact on mechanisms involved with tolerance, such as the production of regulatory T cells.[227] Unless the T-cell defect is severe, Ig levels of IgG, IgA, and IgM are normal or sometimes increased. Selective IgA deficiency may occur at an increased incidence compared with the general population.[228] Patients with partial T-cell immunodeficiency typically have normal specific antibody responses to T-dependent antigens.[229] A subset of patients with an increased susceptibility to sinopulmonary infections also may demonstrate a decreased antibody response to T-independent antigens, such as polysaccharide antigens.[230] Infants with $CD4^+$ T-cell counts less than 400/μL and decreased in vitro T-cell responses to mitogens are likely to be highly susceptible to infections and to have a persistent immunodeficiency. Profound T-cell deficiency is accompanied by defective antibody responses due to a lack of $CD4^+$ T-cell help. Decreased serum calcium, increased phosphorus, and decreased parathyroid hormone levels are typical with parathyroid hypoplasia. Cytogenetic studies with fluorescent in situ hybridization are used to identify chromosome 22q11.2 abnormalities in the patient and the parents.

Therapy

Hypocalcemia should be treated with intravenous calcium replacement, but the condition may prove difficult to control. Long-term treatment with oral calcium replacement, vitamin D, and a low-phosphate formula usually is required. Cardiac abnormalities, which may be severe, must be evaluated completely. Therapy usually is not required for partial T-cell deficiency because of frequent spontaneous improvement in T-cell function with increasing age and the usually mild clinical phenotype. For patients who present early life with severe, persistent T-cell deficiency and marked susceptibility to infections and failure to thrive, transplantation therapy is indicated because improvement from the immunodeficient state is much less likely. Treatment using transplantation of the thymus of fetal or postnatal origin has been successful.[231] Some severe cases of immunodeficiency also have received HCT,[232,233] but the durability of immune reconstitution after HCT is not known. Blood products from CMV-negative donors should be used and should be irradiated before administration to prevent GVHD. Antibiotic prophylaxis to prevent *Pneumocystis* pneumonia also is indicated in the face of severe T-cell deficiency. Prenatal diagnosis is possible and may be indicated if molecular evaluation is informative in a parent of an affected child.

Cartilage-Hair Hypoplasia Syndrome

Etiology and Pathophysiology

Cartilage-hair hypoplasia syndrome is a rare disorder of autosomal recessive inheritance that includes short stature due to metaphyseal chondrodysplasia, thin and sparse scalp and eyebrow hair, and immunodeficiency. This disorder is particularly common in Finland and among the Amish in the United States. The gene for cartilage-hair hypoplasia, *RMRP*, was identified by positional cloning and encodes an untranslated 267-basepair RNA that is part of a ribonucleoprotein complex.[234] This complex may be involved in multiple cellular processes, including nuclear and mitochondrial functions. Based on studies in yeast,[235] it is believed to include a role in normal cell cycle progression. Presumably, certain cell types, such as chondrocytes and lymphocytes, are more dependent on the function of RMRP-containing ribonucleoprotein than others. The immunodeficiency of cartilage-hair hypoplasia syndrome usually involves decreased numbers of $CD4^+$ and $CD8^+$ T cells, with relative sparing of B-cell numbers. The gene defect may result in thymic hypoplasia, perhaps by resulting in increased apoptosis, which has been documented for peripheral T cells.[236] Although B cells are present in normal numbers, IgA and IgG subclass deficiency is common, as is macrocytic anemia and neutropenia.

Clinical Manifestations

Although the best characterized immune defects of patients with cartilage-hair hypoplasia involve T cells and neutropenia, recurrent

sinopulmonary infections are the most frequent problems.[237] In cases with severe T-cell deficiency, the presentation may be similar to that in T^-B^+ SCID, with characteristic opportunistic infections, such as *Pneumocystis* pneumonia. The chondrodysplastic skeletal manifestations are invariably part of the syndrome and can be present in the absence of immunodeficiency. In addition to skeletal, hair, and immunologic defects, the syndrome may include many other manifestations, such as hypoplastic anemia, ligamentous laxity, increased risk for malignancy (especially for non-Hodgkin lymphoma), Hirschsprung disease, and impaired spermatogenesis.

Laboratory Evaluation

Patients with cartilage-hair hypoplasia syndrome typically have modest T lymphopenia, predominantly of $CD4^+$ T cells, neutropenia, and hypoplastic anemia. Proliferation of peripheral blood mononuclear cells to mitogens may be reduced, and this effect probably is a result of a combination of $CD4^+$ T-cell lymphopenia as well as intrinsic defects in T-cell proliferation, such as reduced production of IL-2 and increased apoptotic tendency. Diagnosis requires identification of mutations in the *RMRP* gene. Insertional mutations involving the 5′ flanking region have been described, and the region encoding RMRP also displays a number of single-nucleotide polymorphisms, both of which can make the proper genetic diagnosis challenging.

Therapy

IVIG replacement therapy may be helpful in cases of recurrent sinopulmonary infections, particularly if specific defects in antibody production are documented. Prophylaxis for *Pneumocystis* infection with trimethoprim-sulfamethoxazole (TMP-SMX) is indicated in patients in whom $CD4^+$ T-cell numbers are substantially depressed. Treatment with IL-2 may improve T-cell function in vitro, but the clinical significance is less clear. In patients with severe infections whose immunodeficiency mimics T^-B^+ SCID or Omenn syndrome, prompt HCT is indicated. HCT also corrects neutropenia and the predilection to develop lymphoma but not other features of the disorder.

Schimke Immunoosseous Dysplasia

Etiology and Pathophysiology

Schimke immunoosseous dysplasia is a very rare autosomal recessive disorder due to mutations in the SWI/SNF2-related matrix-associated, actin-dependent regulator of chromatin subfamily A-like 1 (SMARCAL1) gene.[238] SMARCAL1 appears to regulate gene expression by its impact on the configuration of DNA, but why SMARCAL1 deficiency has particularly deleterious effects on certain organs is unclear. Characteristic pathology includes spondyloepiphyseal dysplasia with short stature and unusual facies, focal glomerulosclerosis, cerebral ischemia, thyroid dysfunction, and T-cell lymphopenia.[239] Whether the T-cell lymphopenia is mainly due to thymic hypoplasia or decrease survival of peripheral T cells is unclear. T-cell proliferative responses to cytokines, such as IL-2, are reduced.

Clinical Manifestations

Patients are at increased risk for opportunistic infections characteristic of T-cell immunodeficiency, such as *Pneumocystis* pneumonia, particularly if they are also receiving immunosuppressive drugs. Anemia, neutropenia, thrombocytopenia, and pancytopenia are frequent. Progressive renal failure and hypothyroidism are common.

Laboratory Evaluation

Patients with Schimke immunoosseous dysplasia frequently have decreased numbers of both $CD4^+$ and $CD8^+$ T cells, poor responses, even with addition of IL-2, to mitogenic stimuli, and reduced responses to delayed-type hypersensitivity skin tests. Ig levels may be reduced. Specific diagnosis can be made by evaluating the *SMARCAL1* gene for mutations.

Therapy

HCT has been reported to improve the outcome of T-cell immunodeficiency and bone marrow abnormalities, suggesting that these abnormalities are due to an effect that is cell autonomous for hematopoietic cells.[240] Renal transplantation has been performed for treatment of chronic renal failure, although these patients are at relatively high risk for opportunistic infection because of chronic lymphopenia.

Immune Dysregulation, Polyendocrinopathy, Enteropathy, and X-Linked Inheritance Syndrome

Etiology and Pathophysiology

The immune dysregulation, polyendocrinopathy, enteropathy, and X-linked inheritance (IPEX) syndrome is a rare primary immunodeficiency syndrome in which profound early autoimmune disease involving the gut and endocrine tissues is characteristic.[241,242] IPEX is the first example in humans of a single-gene deficiency that results in a selective defect of regulatory T cells rather effector T cells. The syndrome maps to the chromosome Xq11.23-Xq13.3 region and is caused by defects in the gene encoding Forkhead P3 (FOXP3), a member of the Forkhead protein family of transcription factors. FOXP3 is expressed by $CD4^+$ T cells, with particularly high levels contained in the $CD4^+CD25^+$ subset of T cells, which include cells with potent regulatory (immunosuppressive) function. Based on studies in mice lacking FOXP3, this transcription factor appears to be required for the generation and survival of regulatory $CD4^+$ T cells. Intrathymic generation of $FOXP3^+$ regulatory $CD4^+$ T cells is well characterized. More controversial is the importance of the generation of regulatory $CD4^+$ T cells from nonregulatory $CD4^+$ T cells in the periphery. Transfection of FOX3P into naive murine $CD4^+$ T cells confers a regulatory phenotype, suggesting that this transcription factor acts as the key factor for regulatory $CD4^+$ T-cell function, perhaps by inhibiting effector function genes, such as those encoding cytokines. Adoptive transfer studies in mice indicate that $CD4^+CD25^+$ T cells potently suppress immune responses that otherwise may lead to autoimmune disease. For example, these regulatory $CD4^+$ T-cell populations are critical in preventing autoimmune gastrointestinal disease from endogenous bacterial flora.

Clinical Manifestations

An enteropathy present in all patients results in watery or mucoid/bloody diarrhea.[241,242] Small-bowel biopsies may reveal villus atrophy and mucosal erosions with lymphocytic infiltration of the lamina propria or submucosa. The most frequently observed endocrinopathies include insulin-dependent diabetes mellitus and Hashimoto-type thyroiditis, often accompanied by lymphocytic infiltration of these organs. Skin involvement most commonly consists of eczema but can include erythroderma, exfoliative dermatitis, and pemphigoid nodularis. Virtually all children manifest severe failure to thrive, which is due to the enteritis as well as other features of the chronic illness, such as diabetes. Autoimmune hemolytic anemia, immune thrombocytopenic purpura, or both are frequent. Lymphadenopathy,

hepatosplenomegaly, arthritis, and glomerulonephritis have been reported less frequently. Viral infections or immunizations may trigger severe clinical symptoms, most likely as a result of T-cell activation. Female carriers with one affected allele are healthy despite the random occurrence of X-inactivation.

Laboratory Evaluation

Absolute lymphocyte and T- and B-cell numbers usually are normal, although increases in $CD4^+$ T cells have been reported. In patients with FOXP3 null mutations, flow cytometry can be used to detect a lack of FOXP3 protein expression after intracellular staining of $CD4^+$ T cells with FOXP3 monoclonal antibodies. The development of better markers for regulatory T-cell populations in humans, which would be expected to be markedly decreased or absent in these patients, should improve laboratory diagnosis in the future. Responses to in vitro lymphocyte stimulation to mitogens or antigens have ranged from normal to slightly decreased. These and other immune abnormalities often are difficult to interpret because most patients require immunosuppression to control enteritis. Increased responses, with enhanced IL-2 production, have been observed only infrequently. Complement and serum levels of total IgM, IgG, and IgA usually are normal. Total IgE levels may be elevated. Specific antibody responses may be decreased, but this is variable. Even within a single family, only some affected members may have decreased antibody responses to protein or unconjugated polysaccharide antigens. Antiislet cell, anti-GAD65, antinuclear antibodies, and other autoantibodies may occur in addition to those reactive with red blood cells and platelets.

Therapy

Immunosuppression with cyclosporine A or FK506, often combined with glucocorticoids, has been the mainstay of therapy but usually is not able to control autoimmune symptoms for prolonged periods. HCT is curative and demonstrates that the genetic defect is caused by autonomous effects on hematopoietic cells. In one patient, beneficial effects included resolution of insulin-dependent diabetes mellitus, which started with the conditioning regimen; partial donor chimerism was sufficient for control of autoimmunity.[243] Based on the handful of patients who have undergone transplantation, the mortality rate associated with this procedure may be relatively high. With the identification of the FOXP3 genetic defect, it now is possible to identify female carriers as well as perform prenatal diagnoses in affected families.

STAT5b Deficiency

Two patients with Laron dwarfism resistant to human growth hormone therapy and lymphopenia have been identified as homozygous defects in the STAT5b gene.[244,245] Both patients had moderate CD4 and CD8 T-cell lymphopenia, most likely reflecting a role for STAT5b in conjunction with STAT5a in signal transduction by T-cell growth-promoting cytokines, such as IL-7 and thymic stromal lymphopoietin. However, peripheral T-cell function appears to be relatively normal. In contrast, the T cells of these patients have substantial defects in expression of CD25 in response to IL-2 and in the generation of regulatory $CD4^+$ T cells that express FOXP3. Hypergammaglobulinemia and idiopathic lymphoid interstitial pneumonia also occurred in one of the patients, consistent with an autoimmune diathesis secondary to decreased regulatory T cells. Opportunistic infections have been observed only in conjunction with immunosuppressive therapy.

CHAPTER 52

HISTIOCYTIC DISORDERS

Jeffrey M. Lipton and Robert J. Arceci

The histiocytic disorders comprise a broad grouping of hematologic diseases united by the observation that a dendritic cell or monocyte/macrophage appears to be the principal pathologic protagonist. The ubiquitous nature of these histiocytes, their varied metabolic capabilities and lineage plasticity, their role as regulators of hematopoiesis, their prominence in immune and inflammatory responses, and the uncertainty regarding dendritic cell and monocyte/macrophage ontogeny all have contributed to the confusion regarding the nosology of these disorders. To help clarify the nomenclature, Favara et al.[1] refer to "histiocytes" as ". . . a group of immune cells . . . that include macrophages and dendritic cells." Thus, the term *histiocyte* is ". . . analogous to 'lymphocyte' in that both denote groups of immune cells that are phenotypically and functionally diverse." Based upon this definition, a classification system derived from information on cell lineage and biologic behavior has been developed[1] and has replaced earlier classification systems.[2] In so doing, the World Health Organization's Committee on Histiocytic/Reticulum Cell Proliferations and the Reclassification Working Group of the Histiocyte Society have created a paradigm for continued reassessment of the classification of these disorders as new laboratory and clinical data come to light.

Currently, two broad categories of disease, "disorders of varied biological behavior" and "malignant disorders," are each subdivided into dendritic (antigen-presenting) cell or macrophage/monocyte (antigen-processing cell) related disorders. Other disorders in which histiocytes are implicated include ". . . storage diseases, hyperlipidemic xanthomas, well-defined chronic infections such as tuberculosis and leprosy and granulomatous reactions to foreign materials, are excluded."[1]

This chapter focuses on Langerhans cell histiocytosis (LCH), previously known as histiocytosis X, as the primary dendritic cell-related disorder.[3,4] Juvenile xanthogranulomatosis disease and related disorders, such as Erdheim-Chester disease, derived from dermal dendrocytes, are briefly considered. Macrophage-related histiocytoses include primary or secondary hemophagocytic lymphohistiocytosis (HLH), previously referred to as familial erythrophagocytic lymphohistiocytosis, and infection-associated hemophagocytic lymphohistiocytosis or malignancy-associated hemophagocytic lymphohistiocytosis, in addition to sinus histiocytosis with massive lymphadenopathy, also referred to as Rosai-Dorfman disease. Malignant histiocytic disorders (which include malignant proliferations of the monocyte/macrophage lineage), such as acute monocytic leukemia (FAB-M5), acute myelomonocytic leukemia (FAB-M4), chronic myelomonocytic leukemia, macrophage-related histiocytic sarcoma, and dendritic cell-related neoplasms, are more appropriately discussed in Chapters 59, 62, and 74. Table 52–1 lists a currently accepted classification of the histiocytic syndromes.

DENDRITIC CELL DISORDERS

Langerhans Cell Histiocytosis

Etiology and Epidemiology

The etiology of LCH remains unclear, although arguments and data support both neoplastic and primary immune dysfunction etiologies. Spontaneous remissions have been reported occasionally in patients with LCH, even with multiple sites of involvement.[5,6] In addition, variable morbidity and mortality have been reported in untreated patients with LCH, depending on the extent of disease. Pathologically, the lesions of LCH are characterized by a mixed cellular infiltrate. The hallmark is proliferation and accumulation of immature Langerhans cells, which do not show the cellular atypia characteristic of most malignancies. Using flow cytometry, most investigators have found no evidence of DNA aneuploidy.[7–9]

Studies by Willman et al.[10,11] and Yu et al.[12] demonstrated that LCH is characterized by clonal proliferation of $CD1a^+$ cells, based on differences in repetitive sequences between paternal and maternal X chromosomes. Clonality was observed in both localized and multisystem LCH.[10,13] The identification of clonality does not, however, necessarily indicate malignancy. However, additional data now have demonstrated specific chromosomal regions in lesional cells that display loss of heterozygosity and microsatellite instability.[14,15] In addition, a chromosome t(7;12) translocation has been reported in a single case.[16] Telomere shortening, found in many pre-neoplastic and neoplastic disorders, has also been reported.[16a,16b] A significant concordance of LCH has been observed in twins.[17] Furthermore, aberrant expression of proteins that both promote and block cell cycle progression has been reported in LCH.[18–21] The lesional Langerhans cell is also characterized by its immunophenotypic and functional immature phenotype that can be matured in vitro after exposure to CD40 ligand.[22] No abnormalities inherent to other cells that characterized LCH lesions have been observed.

These data demonstrate that LCH is a clonal proliferative disorder of immature Langerhans cells with variable clinical behavior. Therefore, it is possible that certain forms of LCH that show spontaneous remission represent a disorder similar to that observed in infants with Down syndrome and transient myeloproliferative disease. While the great majority of these cases spontaneously remit, approximately 20% may progress to acute megakaryoblastic leukemia. Interestingly, both transient myeloproliferative disease and acute megakaryoblastic leukemia in patients with Down syndrome are characterized by mutations in the *GATA1* gene, which may contribute to abnormal expansion of megakaryoblasts, facilitating the chance of a subsequent genetic event leading to acute megakaryoblastic leukemia. More data, particularly information documenting specific genetic mutations, may help clarify the etiology and nature of LCH. Although one could conclude that understanding the true etiology of LCH is only an academic issue, this determination has immense implications on the development of future approaches to treatment.[23–27]

Historically, the classic LCH syndromes comprise monostotic i.e. solitary, or multifocal eosinophilic granuloma localized lesion(s) confined to bone[28,29]; Hand-Schüller-Christian disease, which is characterized by protracted multisite and multisystem involvement with the classic but relatively rare triad of skull defects, diabetes insipidus, and exophthalmos[30–33]; and Abt-Letterer-Siwe disease, which is characterized by extensive involvement of the skin, liver, lungs, bone marrow, lymph nodes, spleen, and other organs.[34,35] The prevalence of these disorders has been estimated to be approximately 1:50,000, with an incidence of approximately 5 to 10 cases per million per year in children younger than 15 years.[36] An approximately 2:1 male predominance has been reported.[37–41] Although infants and children are predominantly affected, adults with LCH, including the

elderly,[27,42] have been described; however, well-defined incidence figures have not been reported for adults.

Biologic Characteristics

In order to understand the histiocytic disorders, particularly LCH, it is important to review monocyte/macrophage and dendritic cell differentiation, which is characterized by the developmental sequence shown in Fig. 52–1.[43–48] In the bone marrow, this process begins with the pluripotent hematopoietic stem cell, which may give rise either to a lymphoid progenitor capable of T- or B-lymphocyte lineage commitment or to a multipotent myeloid progenitor capable of differentiation to the erythroid, megakaryocytic, eosinophil, basophil/mast cell, or granulocyte/macrophage cell line. The granulocyte and macrophage share a progenitor, the colony-forming unit granulocyte-macrophage (CFU-GM). CFU-GM, which is capable of granulocyte or monocyte differentiation, gives rise to the monocyte/macrophage progenitor (colony-forming unit-macrophage [CFU-M]). CFU-M gives rise to the monoblast, then to the bone marrow promonocyte (the first morphologically identifiable macrophage precursor), and finally to the monocyte, a process that takes approximately 6 days.[49] The promonocyte ranges from 10 to 18 μm in diameter and has a well-developed Golgi apparatus as well as peroxidase-positive granules. The typical monocyte has a folded nucleus, lightly basophilic cytoplasm, and faint azurophilic granules.

Bone marrow monocytes enter the circulation and can migrate into tissues where they transform into tissue-specific macrophages under the influence of the local environment and become the cells of the mononuclear phagocyte system.[49] Dendritic cells likewise have their origin in the bone marrow[50] and can be cultured from progenitors residing in both the bone marrow and peripheral blood.[45] A $CD34^+$ progenitor can, in single cell culture, give rise to either dendritic cells or macrophages, confirming that dendritic cells and macrophages share a progenitor. Proliferative precursors of the dendritic cell enter the circulation from the bone marrow in a fashion similar to the monocyte. They then enter the tissues[51,52] in which proliferation and differentiation lead to functional, antigen-presenting dendritic cells. The morphology of the dendritic cell may vary depending upon its functional (veiled vs dendritic) state. The dendritic cell is a large cell, essentially devoid of phagolysosomes and other cytoplasmic organelles, with multiple cytoplasmic extensions. The cytoplasm of this mobile cell is rich with mitochondria. The nucleus is eccentric with small nucleoli. Langerhans cells are characterized by Birbeck granules, which appear ultrastructurally as "tennis-racquet shaped pentalaminar structures."[43]

Functionally the mononuclear phagocyte system, also known as the reticuloendothelial system, consists of a multitude of ordinary tissue histiocytes (fixed macrophages) that provide host defense by

Table 52–1 Classification of Histiocytic Disorders

Disorders of varied biologic behavior
Dendritic cell-related
Langerhans cell histiocytosis
Secondary dendritic cell processes
Juvenile xanthogranuloma and related disorders
Solitary histiocytomas of various dendritic cell phenotypes
Macrophage-related
Hemophagocytic syndromes
Primary hemophagocytic lymphohistiocytosis
Secondary hemophagocytic syndromes
Infection-associated
Malignancy-associated
Other
Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy)
Solitary histiocytoma with macrophage phenotype
Malignant disorders[a]
Monocyte-related
Leukemias (FAB and revised FAB classifications)
Monocytic leukemia M5A and B
Acute myelomonocytic leukemia M4
Chronic myelomonocytic leukemia
Dendritic cell–related histiocyte sarcoma (localized or disseminated)
Macrophage-related histiocytic sarcoma (localized or disseminated)

Data from Wright-Browne V, McClain KL, Talpaz M, Ordonez N, Estrov Z: Physiology and pathophysiology of dendritic cells. Hum Pathol 28:563, 1997.

disposing of senescent or damaged blood cells, ingesting invading organisms, processing antigens for the immune system, and stimulating the inflammatory process through production of cytokines,[44,49,53,54] such as interleukin (IL)-1 and tumor necrosis factor (TNF), which activate T lymphocytes as well as other macrophages. Tissue-specific cells of the mononuclear phagocyte system include splenic sinusoidal macrophages, hepatic Kupffer cells,[55] pulmonary alveolar macrophages,[56] bone osteoclasts,[57] pleural, peritoneal, and synovial macrophages, and microglial cells of the brain.[58,59]

Ordinary tissue histiocytes have strong IgG Fc receptors, whereas tissue-based dendritic cells, which comprise the dendritic cell system, have less phagocytic capacity, peroxidase, esterase, or Fc receptor expression, but they are potent antigen-presenting cells.[43,60] Found in virtually all tissues,[43] the Langerhans cell is the major immunologic cellular component of the integument and mucosa. Normal Langerhans cells reside within the epidermis, regional lymph nodes, thymic epithelium, and bronchial mucosa.[61] Functionally, cells of the dendritic cell system process antigen then migrate to lymphoid organs, where they participate as effector cells stimulating primary T-cell responses, thus generating a cellular and, indirectly, a humoral immune response.[43] The types of dendritic cells are summarized in Table 52–2. As with the cells of the mononuclear phagocyte system, dendritic cells are capable of elaborating a wide array of cytokines, including IL-1 and TNF.[62]

Hematopoietic differentiation is regulated by a family of glycoproteins termed colony-stimulating factors and interleukins (see Chapter 16). A large family of these growth factors has been purified, cloned, and functionally characterized. Colony-stimulating factor granulocyte-macrophage (CSF-GM), IL-3 or multi-CSF, CSF-M, and CSF-G[63,64] exert a major influence on monocyte/macrophage and dendritic cell differentiation.[65–67] CSF-GM and IL-3 have a broader range of activity, influencing differentiation of primitive as well as committed progenitors.[68,69] In addition, CSF-GM increases functional activity of mature granulocytes, eosinophils, and monocytes.[70–72] CSF-M and CSF-G are more restricted in their activity and modulate monocyte/macrophage and granulocyte differentiation and function.[73] Early work implicated T cells as a source of stimulating activity.[74] Since then, the monocyte/macrophage, the fibroblast, and other cells have also been shown to be involved in factor production.[75–77] The production of these factors by cells outside the bone marrow supports the finding that some factors have the dual functions of stimulating marrow progenitor differentiation and proliferation and enhancing the activity of mature myeloid cells.[78]

Dendritic cells can be generated from progenitors in vitro using CSF-GM plus IL-4 or TNF.[51] CSF-GM appears to serve as a survival rather than a differentiation factor, whereas TNF induces maturation of these cells.[79,80] Thus, a complex regulatory network with activation by a wide variety of stimuli controls the proliferation and function of macrophages and dendritic cells along with other inflammation-associated cells. The ability of dendritic cells and macrophages to produce cytokines and activate T lymphocytes and other inflammatory cells likely contributes to the varied and sometimes protean clinical manifestations encountered in the histiocytic disorders. In particular, since Nezelof et al.[81] first concluded that histiocytosis X was characterized by proliferation of Langerhans cells, a better understanding of the pathobiology of what is now called LCH has resulted from more focused investigations.

Clinical Manifestations

The signs and symptoms of LCH vary considerably depending on which organs are infiltrated by the Langerhans cells and accompanying immunoreactive cells. Bone, skin, teeth, gingival tissue, ear, endocrine organs, lung, liver, spleen, lymph nodes, and bone marrow all can become involved and exhibit dysfunction secondary to cellular infiltration.[82] Although patients rarely fall into discrete categories defined by the classic designations of eosinophilic granuloma, Hand-Schüller-Christian disease, and Abt-Letterer-Siwe disease, this nomenclature remains valuable if only to catalog the clinical manifestations of LCH and preserve the important historic perspective of these disorders.

Solitary or multifocal eosinophilic granuloma is found predominantly in older children and young adults, usually within the first three decades of life. The incidence peaks between 5 and 10 years of age.[83] Solitary or multifocal eosinophilic granuloma represents approximately 60% to 80% of all instances of LCH.[83] Patients with systemic involvement frequently have similar bone lesions in addition to other manifestations of disease.[82] Patients often cannot bear weight and have tender swelling due to tissue infiltrates overlying the bone lesions.[82,84] Radiographically, the lesions are sharply marginated, round or oval, and usually have a beveled edge that gives the appearance of depth.[82]

Hand-Schüller-Christian disease (multisystem disease) is most commonly described in younger children aged 2 to 5 years. It represents 15% to 40% of these patients, although this type of involvement can be observed in patients of all ages.[26] Signs and symptoms include bony defects, with exophthalmos due to tumor mass in the orbital cavity being characteristic. This condition usually occurs from involvement of the roof and lateral wall of the orbital bones (although skeletal involvement is not necessary).[85] In addition, teeth are often lost due to gum infiltration and/or mandibular involvement (Fig.

52–2). The most frequent sites of skeletal involvement include the flat bones of the skull, ribs, pelvis, and scapula. There may be extensive involvement of the skull, with irregularly shaped, lucent lesions giving rise to the so-called geographic skull.[86] Long bones and lumbosacral vertebrae, usually the anterior portion of the vertebral body, are involved less frequently. In one series, the majority of children with vertebral involvement had only a single affected vertebra, but nine of the 15 patients had other skeletal lesions. Two patients had visceral involvement.[87] In long bones, growth of lesions in the medullary cavity leads to pressure that may result in erosion through the cortex, stimulating the formation of periosteal new bone accompanied by soft-tissue extension.[88] Differential diagnosis includes Ewing and osteogenic sarcoma, bone lymphoma, benign bone tumor and cyst, and infection. Involvement of the wrists, hands, knees, feet, or cervical vertebrae is less common.[82] Orbital involvement may result in vision loss or strabismus due to optic nerve or orbital muscle involvement, respectively. Oral involvement commonly affects the gums and/or palate. Erosion of the lamina dura gives rise to the characteristic "floating tooth" seen on dental radiographs.[89] The entire mandible may be involved (Fig. 52–2), with loss of bone leading to diminished height of the mandibular rami. Erosion of gingival tissue causes premature eruption, decay, and tooth loss.[90] Parents of affected children, particularly infants, frequently report precocious eruption of teeth, when, in fact, the gums are receding leading to exposure of immature dentition. Chronic otitis media, due to involvement of the mastoid and petrous portion of the temporal bone, and otitis externa are not uncommon.

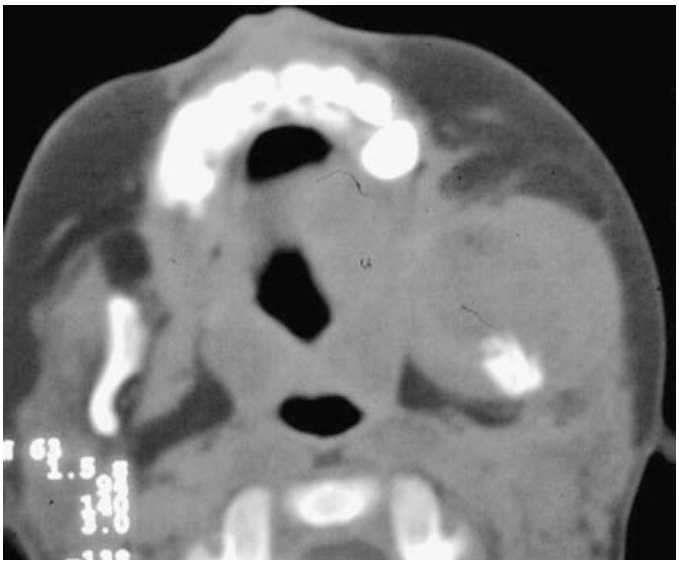

Figure 52–2 Computed tomographic scan of a destructive Langerhans cell histiocytosis mandibular lesion in a child.

Diabetes insipidus (DI) affects 5% to 40% of patients with LCH, depending upon the report.[91–94] Most instances of DI occur in children who present with systemic disease and involvement of the orbit and skull.[95] Fewer than one third of children who ultimately develop DI have polydipsia and polyuria as presenting symptoms of LCH.[95,96] Most children present within 4 years of diagnosis. DI is due to infiltration by Langerhans cells and macrophages into the hypothalamus with or without involvement of the posterior pituitary gland (Fig. 52–3).[97] DI may occur at any time during the course of LCH.[96,98,99] Patients should be instructed to report signs of DI as soon as they develop because dehydration and electrolyte imbalance may be quite serious. In addition, definitive documentation of DI with measurement of serum and urine electrolytes and osmolality before and after a several-hour water deprivation period should be performed. Vasopressin levels can be measured to document a deficiency. Infants who are being tested should be carefully monitored in the clinic or hospital setting to ensure that they do not become severely dehydrated. Once the definitive studies are obtained, a test dose of desmopressin acetate (DDAVP) can be used to determine whether the concentration of urine is increased. Treatment of new-onset DI is controversial.

Short stature has been found in up to 40% of children with systemic LCH.[94,97,100] Chronic illness and steroid therapy play an important role in this phenomenon. However, short stature also may be a consequence of anterior pituitary involvement and growth hormone deficiency,[94,97,100] which can occur in at least half of patients with initial anterior pituitary dysfunction. Other endocrine manifestations include hyperprolactinemia and hypogonadism due to hypothalamic infiltration.[101,102] Pancreatic and thyroid involvement have been reported.[101–103]

Gastrointestinal tract disease has been identified.[104–106] In one retrospective series, only 2% of 348 children had biopsy-proven gastrointestinal involvement.[107] However, in the prospective DAL HX-83 trial, 13% of 78 patients had digestive tract symptoms.[108]

Abt-Letterer-Siwe disease is the rarest (10% of cases) and most severe form of LCH.[83] Typically, patients are younger than 2 years and present with a scaly seborrheic, eczematoid, sometimes purpuric rash involving the scalp, ear canals, abdomen, and intertriginous areas of the neck and face (Fig. 52–4). The diagnosis of LCH in neonates often is delayed beyond the neonatal period and may be unpredictable in terms of outcome when skin only is involved. However, when multisystem disease is evident, outcome is significantly worse.[109] The rash may be maculopapular or nodulopapular. Ulceration may result, especially in intertriginous areas. Ulcerated and denuded skin may serve as a portal of entry for microorganisms, leading to sepsis. Draining ears, lymphadenopathy, hepatosplenomegaly, and, in severe cases, hepatic dysfunction with hypoproteinemia and diminished synthesis of clotting factors can occur. Anorexia, irritability, failure to thrive, and significant pulmonary symptoms, such as cough, tachypnea, and pneumothorax, may occur. One of the most significant areas of

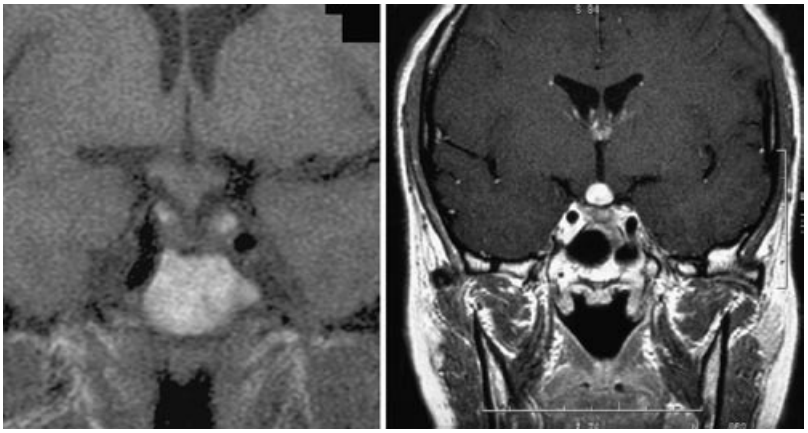

Figure 52–3 Magnetic resonance imaging contrast coronal views showing two patients with diabetes insipidus and pituitary involvement due to Langerhans cell histiocytosis.

involvement is the hematopoietic system, with the potential for pancytopenia. The pathophysiology of hematopoietic dysfunction can be hypersplenism as well as direct involvement by Langerhans cells and/or reactive macrophages. Thrombocytopenia frequently portends a fatal outcome.[37]

A severe manifestation of LCH is nonhypothalamic–pituitary involvement of the central nervous system (CNS).[110,111] Bernert et al.[112] reviewed the course of 38 children with LCH and CNS involvement. The majority of patients with CNS involvement had associated skull, orbit, or mastoid disease. Magnetic resonance imaging with contrast is the best method for identifying lesions of the CNS. As expected, the hypothalamic–pituitary region, characterized by DI, was the most common site of involvement, followed by the cerebellum, pons, and cerebral hemispheres. Lesions of the basal ganglia, spinal cord, and optic nerves also were seen. Involvement of the CNS was frequently observed years after the initial diagnosis. Extraaxial lesions of the dura, meninges, or choroid plexus can be treated effectively with surgery, radiotherapy, or systemic treatment. However, infiltrative and atrophic lesions of the cerebellum or pons frequently result in severe, even fatal, sequelae and have been characterized as primarily neurodegenerative.[98] Rare biopsy material of such involvement has shown a primarily inflammatory, lymphocyte infiltrate associated with gliosis, demyelination, and neuronal death.[113] The etiology of this neurodegenerative process is unknown but is believed to be an immune-mediated paraneoplastic response.[26,110,113,114]

LCH can have a strictly nodal presentation, not to be confused with sinus histiocytosis with massive lymphadenopathy, also known as Rosai-Dorfman disease. This presentation is characterized by significant enlargement of multiple lymph node groups, with little or no other signs of disease. Isolated pulmonary involvement usually is seen in young adults in their third or fourth decade of life and occasionally in adolescents. It may follow a severe and often chronic debilitating course; patients may present with pneumothorax.[115] Cigarette smoking has been strongly implicated in primary pulmonary histiocytosis.[115] In contrast, pulmonary involvement in younger patients with systemic disease frequently is mild, although fulminant pulmonary disease may occur in this age group.[116,117] Findings on chest radiograph vary, from a diffuse infiltrate consistent with bilateral interstitial pneumonia to a "honeycomb lung" appearance (Fig. 52–5).[117,118] Cutaneous disease with no evidence of dissemination has been described in children and adults.[119] Rarely, patients present with deep subcutaneous skin nodules only (formerly described as Hashimoto–Pritzker syndrome).[120]

With such a vast spectrum of disease, adherence to strict labels such as eosinophilic granuloma, Hand–Schüller–Christian disease, or Abt–Letterer–Siwe disease cannot adequately describe a particular patient. Thus, the development of a classification scheme predictive of prognosis becomes particularly useful.

Natural History and Prognosis

As originally proposed by Lahey,[121] the prognosis for patients with LCH depend on three factors: age at onset, number of organs involved, and degree of dysfunction of specific organs (Tables 52–3 and 52–4). An adolescent or adult who presents with solitary bone eosinophilic granuloma has the best prognosis, and an infant with multiple affected organs has the worst prognosis.[37–40,121,122] Prognosis-based classification allows one to discard the labels of eosinophilic granuloma, Hand–Schüller–Christian disease, Abt-Letterer-Siwe disease, and other presentations to group patients according to optimizing treatments. One system grouped patients according to age at onset, disease site and severity. Specifically, patients older than 2 years had a good prognosis, whereas patients younger than 2 years did more poorly.[121] Involvement of fewer than four organ systems was a relatively good prognostic sign, whereas involvement of four or more organ systems predicted a less favorable outcome. Dysfunction of three specific organ systems (hepatic, pulmonary, and hematopoietic)

Table 52–6. Risk Groups According to the Histiocyte Society LCH-III Trial

Group 1—Multisystem "Risk" Patients
Multisystem patients with involvement of one or more "risk" organs (i.e., hematopoietic system, liver, spleen, or lungs). Patients with single-system lung involvement are not eligible for randomization.
Treatment includes vinblastine plus steroids, with randomization to receive intermediate-dose methotrexate during first course of therapy followed by lower-dose maintenance methotrexate versus no methotrexate. Duration of therapy is 12 months.
Group 2—Multisystem "Low Risk" Patients
Multisystem patients with multiple organs involved but without involvement of "risk" organs.
Treatment includes vinblastine plus steroids, with randomization to receive 6 versus 12 months of therapy.
Group 3—Single-System "Multifocal Bone Disease" and Localized "Special Site" Involvement
Patients with multifocal bone disease (i.e., lesions in two or more different bones). Patients with localized special site involvement, such as "CNS-RISK" lesions with intracranial soft-tissue extension or vertebral lesions with intraspinal soft-tissue extension.
Treatment includes 6 months of vinblastine plus steroid therapy.

CNS, central nervous system; LCH, Langerhans cell histiocytosis.

was an extremely important adverse predictor of outcome (Table 52–5).[121] In a review covering a 25-year experience at a single institution, seven of 28 patients with multisystem disease died; among these patients, five of 14 had single and nine of 14 had multiple disease recurrences.[123] When LCH presents after age 65 years, regardless of site and extent of disease, the prognosis often is poor.[124]

Organ dysfunction must be distinguished from involvement (e.g., hypoproteinemia hyperbilirubinemia vs hepatomegaly), because involvement alone is not as adverse a prognostic sign as is dysfunction. Such a classification is a reliable prognostic tool and helps to indicate which patients may benefit most from systemic therapy. A review of 62 patients aged birth to 14 years (median age 18 months) confirmed these observations, stressing the importance of the two factors age and localized disease. All but one of the 15 patients who died were younger than 2 years at diagnosis. With regard to local involvement, the presence of skeletal involvement was a good prognostic sign, and skin involvement that was localized to the scalp predicted a considerably better outcome than generalized cutaneous involvement.[125]

The international Histiocyte Society initiated clinical trials that identified the response after the initial 6 weeks of therapy with weekly vinblastine and daily prednisolone as the single most important factor in predicting outcome, especially mortality.[126] Of the approximately 79% of patients who responded to initial therapy, 94% were alive at 5 years, whereas only 11% of the 14% of nonresponders survived. These important data suggest that alternative therapies should be tested early during the course of therapy for patients with poor early responses.[126] From these clinical trials, a staging system has been developed for the LCH-III trial (Table 52–6).

Pathologic Diagnosis

The typical histologic appearance of LCH varies with the age of the lesion examined (Fig. 52–6). The Langerhans cell is the prominent diagnostic feature in the histology of LCH.[127,128] Early lesions often are locally destructive, with proliferation and accumulation of phenotypically and functionally immature Langerhans cells.[61,124] Mitoses usually are not present in great numbers but when found are of no known prognostic significance.[129] Multinucleated giant cells are

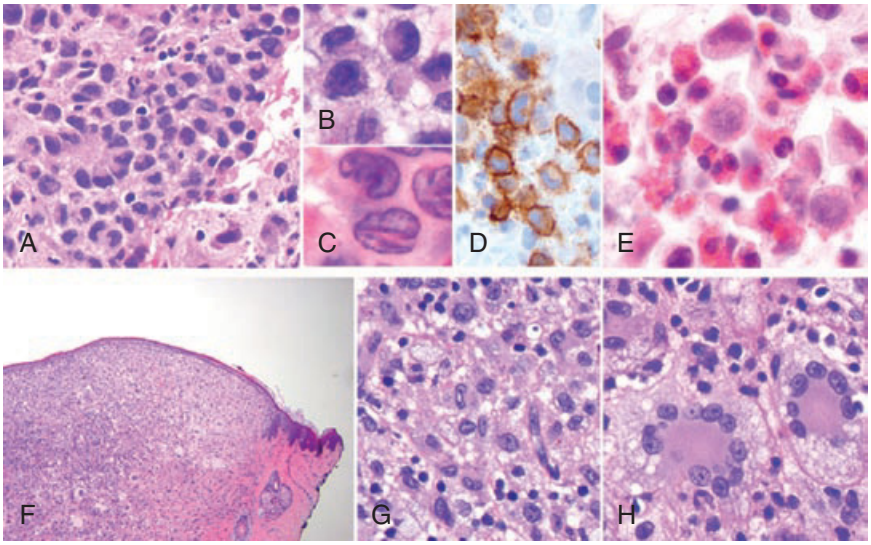

Figure 52–6 A-E, Langerhans cell histiocytosis. (**A**, **B**) Biopsy sample shows sheets of histiocytes with abundant pink cytoplasm and folded nuclei with prominent nuclear grooves. **C**, Cell with a central longitudinal nuclear groove gives the cell a coffee-bean appearance. **D**, Immunohistochemical stain for CD1A shows the histiocytic cells are positive. **E.** Some cases of Langerhans histiocytosis are associated with prominent eosinophilia. Another term for such cases is *eosinophilic granuloma*. **F–H**, Juvenile histiocytosis. Histologic features of juvenile xanthogranuloma vary. **F**, In this case, low-power magnification shows a dome-shaped lesion with an attenuated epidermis. **G**, At higher power, the bulk of the lesion is composed of a proliferation of histiocytes with abundant pink cytoplasm. Sometimes these histiocytes show more vacuolization or xanthomatization. **H**, Scattered Touton-type giant cells are present.

often present.[130] Other inflammatory cells, such as granulocytes, eosinophils, macrophages and lymphocytes, are present. Giant cells and macrophages may be phagocytic[129] and, over time, may accumulate cholesterol. As lesions mature or show signs of regression, fewer Langerhans cells are present and development of fibrotic reaction is less.

Pathologically, a "presumptive diagnosis" of LCH can be made on the basis of a biopsy demonstrating the characteristic histopathology.[124,127,129,131,132] The Langerhans cell is 15 to 25 μm in diameter, with a ". . . central to slightly eccentric ovoid to uniform-shaped nucleus with a delicate chromatin network and inconspicuous nucleoli. An indentation or groove across the face of the nucleus is a feature of many cells."[132] Additional diagnostic criteria beyond standard histopathology, such as immunochemical staining with ATPase, S100 protein, α-mannosidase, peanut lectin, vimentin, and other markers,[129,133,134] are necessary for a "diagnosis." An extensive immunophenotype of normal and LCH Langerhans cells has been reviewed (Table 52–7).[43] A "definitive diagnosis" of LCH relies upon the immunohistochemical identification of the presence of Langerhans cells by cell surface CD1a or by the presence of Birbeck granules by electron microscopy.[81] Thus, pathologic criteria for the diagnosis of LCH have been established and were formalized by the Histiocyte Society in 1987.[135] With the availability of antibodies to CD1a for use in routinely processed paraffin-embedded specimens, electron microscopy is rarely needed.

Differential diagnosis of LCH is limited and depends on the clinical presentation. It includes immunodeficiency syndromes with graft-versus-host disease, viral infection, infiltrative malignant disease such as leukemia, lymphoma or metastatic solid tumor, reticuloendothelial storage disease, congenital infection, benign and malignant bone tumor and cyst, and papular xanthoma.

Careful evaluation of biopsy material generally results in a diagnosis. However, one of the historic dilemmas in the evaluation of LCH is that the histopathology of lesions from patients with single-site eosinophilic granuloma is similar, if not identical, to that of multisystem disease.[82,131] This is consistent with the finding that tissue in lesions from patients with localized or systemic disease cannot be distinguished on the basis of clonality.[10,11,13] As expected on the basis of these observations, efforts to distinguish "favorable" from "unfavorable" histology[136] have not been shown to be prognostically useful.[137] Although patients are grouped in large part based upon their extent of disease, untreated patients generally do not progress to a higher stage.[82] Within a few months after presentation, it will become apparent that the lesions seen initially are limited to the skeleton or were the "heralding lesion(s)" of diffuse systemic involvement. When cutaneous involvement is the only obvious presenting sign, several months may be required to determine the ultimate extent of disease.[6,82,109]

These observations enforce the need for a complete clinical and laboratory evaluation with proper imaging studies once a definitive diagnosis of LCH is made. In general, baseline evaluation of a newly diagnosed patient requires a reasonable search for all sites of disease. The laboratory and imaging evaluation must be guided by a complete history and thorough physical examination, including a dental examination. All patients should be evaluated with a complete blood count, chemistries including liver function tests, coagulation workup, urine osmolality, chest radiograph, and complete skeletal survey. In a series of children with LCH for whom both radiographic and radionucleo-

Therapy for Langerhans Cell Histiocytosis

Approach

The optimal management, yet to be determined, for the patient with LCH balances the most effective therapy with the desire to minimize both short-term and long-term disease-related morbidities. Currently almost all patients who respond to therapy will be able to discontinue treatment completely, although recurrences are common. Another goal is finding effective therapy for patients whose disease does not respond to therapy. These patients should undergo HLA typing early after diagnosis and their initial response to therapy has been determined, and they should be considered for bone marrow transplantation or other experimental therapies.

Prognostic Grouping

When patients are grouped using three prognostic variables (age, extent of disease, and presence of organ dysfunction(, the prognosis and extent of treatment can be evaluated. The grouping or staging of patients currently is best evaluated according to the Histiocyte Society LCH-III clinical trial, which stratifies treatment arms based on measurement of the initial extent and sites of disease (Table 52–6).

Supportive Care

Severely ill patients are hospitalized. They are given antibiotic, ventilatory, nutritional (including hyperalimentation), blood product, skin care, physical therapy, and medical and nursing support as required in addition to definitive treatment. Scrupulous hygiene is helpful in limiting auditory canal, cutaneous, and dental lesions. Débridement, and even resection of severely affected gingival tissue, is used to limit oral involvement. The seborrhea-like dermatitis of the scalp may improve with use of a selenium- or phenolic-based shampoo twice per week. Topical steroids occasionally are effective but should be used sparingly and only for short-term control of small affected areas. Topical tacrolimus also can be considered. DI may occur at any time during the course of LCH. Patients should be instructed to report signs of DI as soon as they develop because dehydration and electrolyte imbalance may be quite serious. The results of hypothalamic and pituitary radiotherapy instituted early in the course of DI have been poor, and use of this modality is not recommended. Some evidence indicates that a short course of systemic chemotherapy given early after onset of DI may be helpful in reversing the signs and symptoms of DI.

Local Therapy (Surgery and Radiotherapy)

After complete evaluation, patients with disease involving a single bone and (in some cases) patients with disease involving multiple lesions and multiple bones are managed with local therapy. This involves surgical curettage for patients whose lesions are in easily accessible, noncritical locations. Complete "cancer operation" resections usually are not indicated. Surgical restraint must be exercised to avoid drastic cosmetic and orthopedic deformities and loss of function. Local soft-tissue disease (e.g., scalp, thymus, lymph nodes) generally recurs despite surgery; thus, systemic treatment or low-dose radiation in emergent situations is recommended for these types of lesions. Localized radiotherapy (usually 600–1200 cGy) in 200-cGy fractions, utilizing only megavoltage equipment, is currently used. Older patients may require slightly higher doses (1500–2000 cGy), although this idea has not been definitively studied. Patients at risk for skeletal deformity, visual loss secondary to exophthalmos, pathologic fractures, vertebral collapse, and spinal cord injury should receive radiotherapy. Patients suffering from severe pain or symptomatic adenopathy, even when multiple lesions exist, may also warrant low-dose radiotherapy to affected areas if systemic therapy is not rapidly effective. Lesions in poorly accessible sites, such as the orbit, or lesions recurring after curettage also should be irradiated if chemotherapy is not rapidly effective.

Chemotherapy

If symptomatic lesions or failure to thrive is evident, treatment should be pursued. The LCH-III international clinical trial is pursuing risk-stratified therapy depending on the extent and sites of disease involvement as well as the response to initial therapy (Table 52–5). Experimental modalities, such as bone marrow transplantation, are being pursued at specialized centers for group IV patients who are nonresponsive to conventional chemotherapy.

The persistent philosophy for treatment of LCH has been use of an appropriate amount of the least toxic therapy to effectively treat the disease. In patients with potentially morbid or life-threatening disease at presentation or in those who develop morbid or life-threatening disease during the course of treatment, alternative therapy, including bone marrow transplantation, should be implemented. This approach emphasizes the need for treatment protocols based upon careful prognosis-based risk stratification. Whether more intense upfront therapy in lower-risk patients with systemic disease can reduce disease sequelae such as DI, CNS degeneration, sclerosing cholangitis, or disease recurrence and whether a reduction in these problems outweighs the risk of more intense therapy is under evaluation. Patients with this rare disease are best served by treatment according to collaborative protocols such as those of the Histiocyte Society. *Pneumocystis carinii* and fungal prophylaxis in patients for whom long-term immunosuppressive therapy is anticipated should be used.

Long-Term Followup

All patients with LCH should undergo long-term followup. In addition to late malignancies, patients should be monitored for signs of long-term disabilities, including cosmetic and functional orthopedic and cutaneous deformities that may lead to loss of function and severe emotional disorders, loss of permanent dentition, endocrinologic disorders and growth failure, hearing impairment, CNS abnormalities, psychosocial problems, sclerosing cholangitis, pulmonary fibrosis, and cor pulmonale. Patients with chronic disabilities, such as sequelae of LCH, should be followed by appropriate subspecialists.

tide skeletal evaluations were performed, radiologic evaluation detected virtually all significant skeletal lesions.[138] Other tests such as panoramic dental radiographs, pulmonary function tests, imaging of the brain and middle ear, and bone marrow aspirates/biopsies and biopsies of other tissue should be performed based on the findings of initial evaluation. However, an increasing awareness of CNS involvement in LCH has led some clinicians and investigators to obtain magnetic resonance imaging scan with contrast of the brain to evaluate radiographically evident but clinically silent disease or to serve as a baseline comparison for future studies.

Therapy

A generally accepted standard for initial treatment of patients with LCH is use of an appropriate amount of the least toxic therapy to treat the disease (see box on Therapy for Langerhans Cell Histiocytosis). In patients with potentially morbid or life-threatening disease at presentation or in those who develop morbid or life-threatening disease during the course of treatment, alternative and sometimes more aggressive treatment should be implemented. This approach emphasizes the need for treatment protocols based upon careful prog-

Table 52–8 Treatment[a] Versus No Treatment[b]

nosis-based risk stratification. Whether more intense up-front therapy in lower-risk patients with systemic disease can reduce disease sequelae such as diabetes insipidus, CNS degeneration, sclerosing cholangitis, or disease recurrence and whether a reduction in these problems outweighs the risk of more intense therapy is under evaluation.

For the majority of patients with localized or limited systemic disease, the goal of therapy should be minimizing loss of function and preventing cosmetic deformity. Severely ill patients often are hospitalized and given intensive supportive care in addition to definitive treatment. Scrupulous hygiene plays an important role in limiting auditory canal, cutaneous, and dental lesions. Débridement, and even resection of severely affected gingival tissue, is sometimes used to limit oral involvement. Seborrhea-like dermatitis of the scalp may improve with use of a selenium- or phenol-based shampoo. Topical steroids can be effective, but prolonged exposure or use on the face should be avoided. Topical tacrolimus (FK506) has become available and can be used for skin involvement. Topical nitrogen mustard has been used for problematic focal skin lesions.[139] In patients with particularly refractory and extensive skin involvement, Psaraler Ultraviolet-A (PUVA) can be effective.[140–142] These topical therapies have not been studied in clinical trials.

Surgery and Radiotherapy

Patients with disease involving a single bone usually can be managed with local therapy. This most often involves surgical curettage for patients whose lesions are in easily accessible, noncritical locations. Complete "cancer operation"‘ resections are not considered necessary and should be avoided in order to reduce cosmetic or orthopedic deformities as well as loss of function. Local soft-tissue disease (e.g., scalp, thymus, lymph nodes) generally recurs despite surgery; thus, additional treatment usually is required. Because of concerns about the development of secondary malignancies, systemic therapy usually is favored over radiation. However, local radiotherapy is indicated under certain circumstances, for example, when patients are at risk for visual or hearing loss, skeletal deformity, spinal cord injury, or severe pain when systemic therapy is not rapidly effective. Localized radiotherapy (usually 600–1500 cGy) in 200-cGy fractions is currently recommended.[143,144] Lesions in poorly accessible sites, such as the orbit or lesions recurring after curettage, can be effectively treated with radiotherapy. A review of 40 patients who received radiotherapy between 1970 and 1984 indicated that patients with unifocal disease have a higher rate of response for individual lesions than do patients with multifocal disease (two or more soft-tissue sites).[145] In this review, the complete plus partial response rate for bone lesions was 100%, with 35 patients evaluated and 24 complete responses. Soft-tissue lesions adjacent to involved bone healed better than did isolated soft-tissue lesions. No patients responded to irradiation applied for liver, spleen, or lung lesions, and none of eight patients with DI responded.[145] The results of hypothalamic and pituitary radiotherapy instituted early in the course of DI have been poor overall, but with anecdotal successes; use of this modality is not recommended.[91,100,109–111] Use of chemotherapy has been reported in anecdotal cases.[146]

Chemotherapy

Historically, drugs used in therapy for classic malignant diseases have been used systemically for treatment of LCH. Nitrogen mustard, vincristine, vinblastine, cyclophosphamide, procarbazine, chlorambucil, etoposide, methotrexate, corticosteroids and 6-mercaptopurine have been used, alone or in combination, with variable success. Response to chemotherapy varies from 25% to 90%. Lahey[37] showed that treatment improves survival in patients younger than 2 years (Table 52–8). Table 52–9 summarizes selected and mostly early single-arm chemotherapeutic trials.[147–156]

A reasonable therapeutic approach to systemic therapy is to observe patients with limited disease who respond to local (i.e., surgery, radiation) or nonsystemic (i.e., topical steroids) therapy and look for signs of continuing disease resolution. If symptomatic lesions or evidence of progressive disease is seen, systemic treatment should be pursued. Patients in groups II and III with multisystem or systemic disease usually will benefit from chemotherapy, although significant numbers of patients with systemic disease and risk-organ involvement still show poor responses and mortality. Because of the rarity of LCH and the large number of therapeutic questions for which answers

must be sought, all patients with disseminated disease should be placed in well-designed studies whenever possible. Based on data from several small studies demonstrating the efficacy of etoposide in previously untreated patients[155,157] and those with resistant disease,[158] in 1991 the Histiocyte Society sponsored its first international randomized study, LCH-I, for patients younger than 18 years. The purpose of the study was to compare the efficacy of vinblastine to that of etoposide in patients with previously untreated multisystem or disseminated LCH.[159] Treatment in each arm consisted of a single pulse of high-dose methylprednisolone for "induction" followed by weekly vinblastine (6 mg/m^2 intravenous bolus) versus every-3-week etoposide (150 mg/m^2 intravenous over 2 hours per day for 3 days). The total treatment period was 24 weeks. LCH-I showed that the rapidity of the initial response correlated with prognosis and that patients with a poor initial response to either arm tended not to benefit from crossover to the alternative arm.[126,159,160] No difference in outcome measures with use of vinblastine compared to etoposide was observed.

Comparison of the results from the DAL HX-83/90 study to those of the LCH-I trial suggested that the more aggressive DAL HX-83/90 might be responsible for a lower recurrence rate and a lower incidence of diabetes insipidus.[161] Therefore, the subsequent LCH-II trial was designed to test this suggestion in a randomized fashion for high-risk patients with multisystem disease. The LCH-II trial used part of the framework of the DAL HX-83 study,[160] in which all patients receive a 6-week "induction" with prednisone, vinblastine, and etoposide. The subsequent treatment period for 1 year and consisted of only oral 6-mercaptopurine, vinblastine, and prednisone (treatment a) or 6-mercaptopurine, vinblastine, and prednisone plus either etoposide (treatment b) or etoposide and methotrexate (treatment c) for patients with multifocal bone involvement (treatment a), soft-tissue involvement without organ dysfunction (treatment b), and organ dysfunction (treatment c), respectively.[160] In the LCH-II trial, patients were stratified into "low risk" (patients older than 2 years with no involvement of the hematopoietic system, liver, lungs, or spleen) or "at risk" (patients younger than 2 years with involvement of the hematopoietic system, liver, lungs, or spleen). Patients with multisystem disease in the "low-risk" group received initial treatment consisting of a 6-week course of prednisone and weekly vinblastine, followed by continuation treatment with oral 6-mercaptopurine, prednisone pulses, and weekly vinblastine for 24 weeks. Patients in the "at-risk" group were randomized to the low-risk treatment arm versus that same treatment but with the addition of etoposide to both initial and continuation treatment. Results from the LCH-II trial show no significant advantage to adding etoposide in terms of survival or frequency of disease recurrence in the overall patient group. However, patients with risk organ involvement had a between 5 years survival when treated with the more intensive Arm B.[160,106a,162] In an attempt to improve the response rate and possibly reduce the frequency of recurring disease, the LCH-III trial currently is addressing whether the initial response rate is improved by the addition of intermediate-dose methotrexate to prednisone and vinblastine and whether overall outcome is improved using 6 or 12 months of continuation therapy.

Alternative treatment has not been standardized for patients with recurrent and/or refractory disease. Patients with recurrent disease (i.e., disease that reappears after a period of remission) often respond well to the drugs with which they initially were treated. A variety of experimental modalities, such as hemibody irradiation,[163] thymic hormone therapy,[164,165] and α-interferon[166] have been explored for treatment of advanced or refractory disease, but these approaches have been largely abandoned. A number of chemotherapeutic approaches have had limited success and require evaluation in prospective studies.[167–169] Alternatively, several studies, including an international phase II trial, have demonstrated significant activity of 2-chlorodeoxyadenosine (2-CdA) against recurrent and refractory LCH.[106,146,169–181] In addition, the combination of 2-CdA and high-dose cytarabine has been used in refractory patients.[106,182] An anecdotal experience using TNF-inhibitors has been reported,[183] as has pamidronate for bone lesions.[184–187] Thalidomide has shown activity in treating skin disease.[188–191] Bone marrow transplantation for high-risk or refractory patients warrants further evaluation in the context of a controlled clinical trial.[192–198]

Table 52–10 Late Malignancy After Treatment of Langerhans Cell Histiocytosis

Patients	Treatment	Malignancy	Interval Between Histiocytosis and Malignancy (years)
1	CMB	Hepatocellular carcinoma	14
2	CMB + RT	Thyroid carcinoma	16
3	CMB (CT) + RT	Acute leukemia	2
4	CMB, NM (CT) + RT	Acute leukemia	6.5
5	CMB, NM (CT) + RT	Acute leukemia	5
6	RT	Thyroid carcinoma	28

CMB, chlorambucil; CT, combination therapy; NM, nitrogen mustard; RT, radiotherapy.

Data from Greenberger JS, Crocker AC, Vawter G, Jaffe N, Cassady JR: Results of treatment of 127 patients with systemic histiocytosis. Medicine (Baltimore) 60:311, 1981.

Long-Term Follow-up

A retrospective analysis by Willis et al.[123] of 71 patients from a single institution followed for a median of 8.1 years from diagnosis revealed the presence of significant late sequelae in 64% of patients followed for more than 3 years despite a relatively good survival rate of 88%, 88%, and 77% at 5, 15, and 20 years, respectively. Skeletal defects were found in 42%, dental problems in 30%, DI in 25%, growth failure in 20%, sex hormone deficiency in 16%, hypothyroidism in 14%, hearing loss in 16%, and CNS dysfunction in 14%. These data emphasize the importance of appropriate therapeutic choices, as sequelae such as bone malformations, including scoliosis, appeared to be a consequence of treatment with radiation. Although Gadner et al.[108,160] found a lower incidence of DI and fewer recurrences in their study that used aggressive initial chemotherapy, including etoposide and methotrexate, for patients with multifocal bone and disseminated disease, the study by Willis et al. included 28 patients with multisystem disease, many of whom received aggressive chemotherapy and still had recurrences and late sequelae.[108,123]

This risk of malignancy in patients with LCH undergoing radiation and chemotherapy is well documented. In the study by Willis et al.,[123] three of 51 patients followed beyond 3 years developed a malignancy. All three patients were younger than 3 years at the time of diagnosis. Two tumors were in a radiation field, but one was a leukemia in a patient treated with an etoposide-containing chemotherapy regimen. Of 127 patients with LCH reported by Greenberger et al.,[40] 84 received chemotherapy, and six developed late malignancies (Table 52–10). Two patients who received radiotherapy developed an in-field tumor, and one of these patients received no chemotherapy. Late malignancy developed in five of 54 patients who received chlorambucil as a single agent or in combination with other chemotherapeutic agents. Two of 29 patients received nitrogen mustard as part of combination therapy, including chlorambucil, vincristine, procarbazine, and prednisone. The risk of malignancy is similar to that reported after chlorambucil given for treatment of polycythemia vera. Thus, judicious use of radiotherapy, avoidance of potentially carcinogenic chemotherapeutic agents, and good supportive care are recommended. Although patients with LCH could have an inherently increased risk of malignancy,[199] the experience cited strongly suggests an excess of malignancy was associated with chlorambucil use. Leukemia in LCH patients treated with etoposide

as a single agent[156,200,201] and in combination with other agents[202,203] has been reported. Because etoposide was not shown to be any more effective than vinblastine in both the LCH-I and LCH-II trials for patients without risk organ involvement, there does not appear to be reason to include this leukemogenic agent in the treatment of these patients with newly diagnosed LCH.

Another serious late effect of LCH is sclerosing cholangitis, which may lead to secondary biliary cirrhosis and liver failure.[204–213] The only successful treatment of sclerosing cholangitis has been liver transplantation. Another late complication of LCH is pulmonary cyst formation, fibrosis, and chronic pneumothoraces.[92,214–218] No effective treatment is available, and progression to cor pulmonale and respiratory failure are not uncommon.[219,220] Lung transplantation has been used for treatment of such patients.[221–224] Thus, all patients with LCH require long-term followup. In addition to late malignancies, patients should be monitored for signs of long-term disabilities, including cosmetic, orthopedic, and cutaneous deformities that may lead to loss of function and emotional disorders, loss of permanent dentition, endocrinologic disorders and growth failure, hearing impairment, CNS abnormalities and neurocognitive function, sclerosing cholangitis with biliary cirrhosis, and pulmonary fibrosis and cor pulmonale. More effective treatments that reduce the incidence of these sequelae are needed.

Juvenile Xanthogranulomatous Disease and Erdheim-Chester Disease

Juvenile xanthogranulomatous disease (JXG) is particularly common in infants and young children. The cell of origin and classification of the type of disease represented by JXG have been debated for more than 50 years, but current information demonstrates several important insights. The immunophenotype of JXG cells shows that they are positive in expression for CD14, CD68, CD163, factor XIIIa, and often fascin.[225] The cells usually are negative for CD1a, S100, and the plasmacytoid monocyte antigen CD123. These data support that JXG lesions originate from dermal dendrocytes.[226,227]

JXG most commonly presents as a single skin lesion in infants and young children (see Fig. 52–6). The lesions are nodular and usually yellowish to reddish purple. Lesions may vary significantly in size and number but often are several millimeters to 1 cm in size and solitary. However, in some patients, the lesions become widespread and quite disfiguring (Fig. 52–7). Furthermore, JXG may become systemic, involving multiple organs including the liver, lungs, heart, and CNS. CNS involvement can present with seizures, hemiplegia, and increased intracranial pressure.[228]

Cutaneous JXG lesions usually resolve over several months and require no treatment.[229,230] Benign cephalic histiocytosis is a closely related disorder that presents during infancy. It is characterized by multiple, small reddish-brown, palpable macular lesions primarily involving the head and upper extremities.[231–235] This disorder usually slowly regresses spontaneously over several weeks to months. With both JXG and benign cephalic histiocytosis, residual pigmented regions may persist even after lesions have regressed. In patients in whom JXG becomes systemic and involves multiple organs, systemic chemotherapy similar to that for patients with LCH has been used. In patients who do not respond to initial treatment with vinblastine and steroids, use of other agents, such as methotrexate, steroids, and 2-CdA, has led to responses according to anecdotal reports.[236]

Erdheim-Chester disease is seen most commonly in patients 50 years or older. It usually presents with xanthoma-like skin nodules and bilateral lower limb bone pain. Patients with more disseminated disease may have cardiopulmonary insufficiency, renal failure due to characteristic perinephric constrictive changes, and CNS involvement manifested by ataxia, diabetes insipidus, and altered mental status.[237–240] Periorbital involvement with exophthalmos and impingement on the optic nerves.[225] The disease may be progressive and fatal. Successful effective treatment has been limited, although responses have been observed with steroids, vinblastine plus steroids, methotrexate, 2-CdA, bisphosphonates, and interferon-α.[241–247] Autologous hematopoietic bone marrow transplantation has been reported.[248]

Figure 52–7 Extensive juvenile xanthogranulomatous disease in an infant.

HEMOPHAGOCYTIC SYNDROMES

Hemophagocytic Lymphohistiocytosis

Familial HLH was formerly known as familial erythrophagocytic lymphohistiocytosis. Familial HLH usually is a rapidly fatal, inherited disorder characterized by either persistent or intermittent fevers with hepatosplenomegaly (often presenting initially as isolated splenomegaly), thrombocytopenia and anemia, pancytopenia, coagulation abnormalities with hypofibrinogenemia, and hepatic dysfunction.[249–253] The Histiocyte Society has developed five "diagnostic criteria" for HLH, specifying the clinical criteria of (a) fever and (b) splenomegaly in the presence of the laboratory criteria of (c) cytopenias involving at least two lineages accompanied by (d) hypofibrinogenemia and/or hypertriglyceridemia and (e) hemophagocytosis, in the absence of malignancy, in the bone marrow, spleen, or lymph nodes.[249–253] In addition, three additional criteria have been included: (f) low or absent natural killer (NK) lymphocyte activity, (g) hyperferritinemia, and (h) high levels of soluble IL-2 receptor.[254] Five of the eight criteria must be fulfilled unless a patient has a molecular diagnosis consistent with HLH.

Most affected children are infants (age 2 weeks to 7 years), and two thirds of affected children present within the first 3 months of life.[251,255] Patients usually present with pallor, irritability, anorexia, diarrhea, and failure to thrive. Occasionally, a nonspecific, maculopapular skin rash is seen. Pulmonary effusions are present in one third of patients. The clinical course usually is progressive, resulting in death within approximately 6 weeks without effective treatment.[251,256,257] Most patients die of sepsis, bleeding, or a lymphohistiocytic-mediated meningitis accompanied by refractory seizures. Approximately 75% of patients have CNS involvement at diagnosis.[255] Disease essentially confined to the CNS, leading to seizures, has been reported.[255,258,259] There is no gender predilection, and the presence of the disorder in siblings and in cousins as well as the presence of parental consanguinity supports an autosomal recessive mode of inheritance.

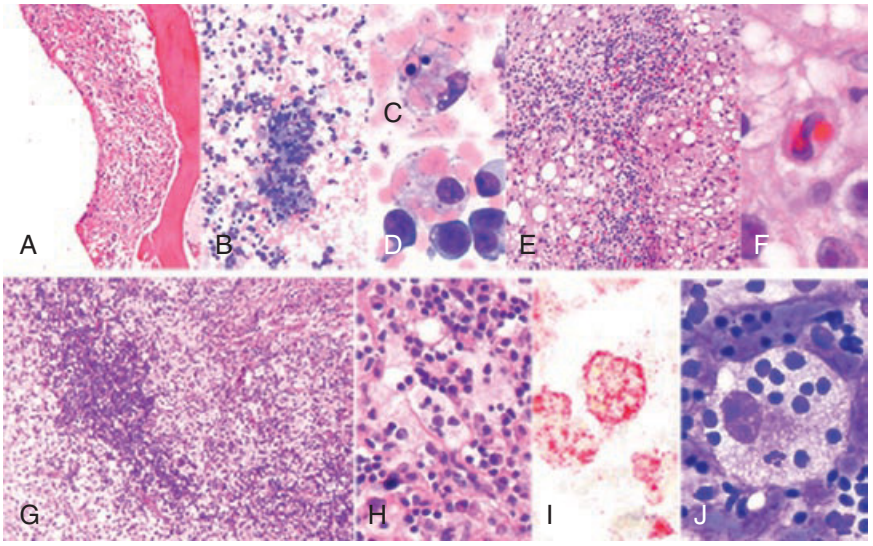

Figure 52–8 A–F, Familial hemophagocytic lymphohistiocytosis. Illustrations from a 3-month-old girl who presented with diarrhea, pancytopenia, hepatomegaly, and liver failure. bone marrow (**A**, **B**) showed left-shifted granulopoiesis and increased histiocytes, which at high power (**C**, **D**) were undergoing prominent phagocytosis of erythrocytes, platelets, and other cells. Liver biopsy sample (**E**) showed a lymphohistiocytic infiltrate also associated with hemophagocytosis (**F**). The patient was shown to harbor a mutation of the perforin gene in exon 2. **G–J**, Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease). Low-power magnification of the biopsy sample (**G**) shows a mottled appearance of the lesion due to dark areas containing small lymphocytes and lighter areas containing histiocytes. At higher magnification (**H**), the histiocytes have abundant pale cytoplasm with scattered cells within. This is emperipolesis, or a process of cells traveling through the cytoplasm but not becoming phagocytized or degraded. Note plasma cells in the background. The emperipolesis can be better visualized with a CD68 stain for histiocytes (**I**). This process delineates the cell boundary and the cells within the histiocyte cytoplasm. The emperipolesis can also be seen on a Wright-stained touch preparation (**J**).

Pathology of the liver shows focal fatty changes, necrosis, and infiltration by lymphocytes and histiocytes. The infiltrate is periportal but can extend into adjacent lobules. Typical hemophagocytosis may be evident only at presentation in as few as one third of patients with verified HLH.[251,260] Thus, convincing evidence of hemophagocytosis should be pursued with serial bone marrow examinations when there is clinical suspicion of HLH. The spleen demonstrates similar focal necrosis along with lymphohistiocytic infiltrates associated with hemophagocytosis. Involvement of the thymus and lymph nodes is similar; however, lymph nodes show significant lymphocytic depletion later in the course of disease. Hemophagocytosis may be present. The lungs are infiltrated with lymphocytes and histiocytes, again with some hemophagocytosis. The bone marrow usually is hyperplastic, with increased numbers of hemophagocytic histiocytes (Fig. 52–8).[260,261] The cellular infiltrate lacks features of malignant cells. The characteristic pathology and clinical presentation clearly distinguishes HLH from LCH and other histiocytic disorders.

Advances in immunology and molecular biology have allowed clinicians to increasingly refine the diagnostic category of HLH. Initial clinical observations had permitted a somewhat crude distinction of the familial syndrome known as familial erythrophagocytic lymphohistiocytosis from viral-associated or infection-associated hemophagocytic syndrome or malignancy-associated HLH.[262–264] In addition, rheumatologists and immunologists have been able to identify a clinically similar "macrophage activation syndrome" in a subset of patients with juvenile rheumatoid arthritis or certain immunodeficiency states.[265]

Aricò et al.[266] have proposed a "diagnostic algorithm" incorporating the current understanding of HLH. The path to a correct diagnosis begins with a patient who meets the described diagnostic criteria. A search for infectious agents, such as Epstein-Barr virus, cytomegalovirus, parvovirus B19, and a number of bacteria, fungi, mycobacteria, and parasites, should be undertaken. A detailed history, physical examination, and laboratory screening usually eliminates from consideration the macrophage activation syndrome associated with juvenile rheumatoid arthritis. Hypoparathyroidism, thymic dysfunction, and orofacial and cardiac anomalies resulting from abnormal development of the third and forth pharyngeal pouches characterize DiGeorge syndrome, which can be associated with secondary HLH.[266,267] The presence of hyperammonemia is characteristic of the metabolic disorder lysinuric protein intolerance that may result in an immunodeficiency state and HLH.[268]

Other rare immunodeficiency syndromes in addition to DiGeorge syndrome and lysinuric protein intolerance can be associated with HLH. The accelerated phase of Chédiak-Higashi and Griscelli syndromes are indistinguishable from other forms of HLH.[266,269–272] Both syndromes are characterized by albinism. Classic granules found in the neutrophils of patients with Chédiak-Higashi syndrome and melanin inclusions in the hair of patients with Griscelli syndrome support the diagnosis. The presence of mutations in *LYST*[273] or *RAB27A*,[270] respectively, confirms the diagnosis.

In males, a diagnosis of X-linked lymphoproliferative disease should be ruled out. In this disorder, a mutation in the *SH2D1A* gene leads to an inhibitory mutation in the lymphocyte 2B4 receptor, resulting in the inability of NK cells to kill cells infected with Epstein–Barr virus.[274–278] This, in turn, results in the sustained proliferation of ineffective cytolytic effector cells and the syndrome of HLH.[279]

Familial HLH is an autosomal recessive disorder whose underlying pathophysiology is impaired NK and cytotoxic T-lymphocyte activity.[257,269] In 1999, the two chromosomal loci 9q21.3–22 and 10q21–22 were linked to the disease, defining HLH type 1 and type 2, respectively.[280–282] Shortly thereafter, mutations in the gene on chromosome 10q22, coding for perforin (PRF1), were identified.[283–285] Perforin functions by creating holes in target cell membrane that in turn allow for entry of granzymes that initiate apoptotic cell death. The pathways leading to perforin synthesis, subcellular compartmentalization, and directional targeting and release of cytolytic granules all represent potential points that could be mutated and contribute to different genetic causes of inherited HLH syndromes. An example of this is the description of mutations in the *Munc13–4* gene, located at chromosome 17q25, which is essential for cytolytic granule fusion.[286] Inactivating mutations in this gene now have been shown to cause familial HLH, termed *FHL3* subtype.[286] Similarly, mutations in syntaxin, another product involved in assembly and trans-port of cytolytic granules in lymphocytes, have been linked to HLH.[287,288]

In the absence of perforin activity, the resulting inability to kill infected target cells results in sustained NK and cytolytic T-lymphocyte activity. This, in turn, results in overexpression of inflammatory cytokines (soluble IL-2 receptor, IL-6, TNF-α, IL10, and IL-12), leading to excessive macrophage activation, dissemination, and organ infiltration along with the signs, symptoms, and laboratory abnormalities that characterize HLH.[256,269,289]

Impaired NK cell activity and number are important keys to the diagnosis. The absence of intracytoplasmic perforin can be used as a reliable marker in the 20% to 40% of patients with familial HLH type 2 (NLH1) associated with the 10q21–22 locus and perforin gene mutations.[266,290,291] The remaining familial cases may be recognized by impaired NK cell function not associated with the absence of perforin expression. HLH type 1 linked to the 9q21.3 locus represents approximately 10% of the cases.[266] However, a substantial proportion of familial cases of HLH remains genetically uncategorized. Patients with absent perforin expression should undergo PRF1, MUNC 13–4, and syntaxin mutation analysis. In the absence of a positive mutation analysis, reevaluation of NK function after successful treatment should be undertaken.

Etoposide has induced clinical remissions accompanied by resolution of clinical, hematologic, and biochemical abnormalities.[292] Although all patients relapse with familial disease, etoposide, usually in combination with prednisone and intrathecal methotrexate,[255] has resulted in complete to very good responses in patients with familial HLH and has been used prior to more definitive therapy with bone marrow transplantation in patients with this otherwise lethal disorder.[293,294] Thus, based on our understanding of the pathophysiology of these disorders, the initial strategy for HLH therapy consists of initial use of etoposide, dexamethasone, and cyclosporine A according the International HLH-2004 clinical trial.[254] Even when an associated infection or malignancy can be identified and treated, therapy directed toward the HLH also may be necessary. Patients with known familial disease or severe or persistent acquired disease should go on to hematopoietic stem cell transplantation (see Chapters 59, 62, and 74). The 3-year actuarial survival using this approach in patients with familial HLH has been reported as 51% ± 20%.[254,256,295]

Sinus Histiocytosis With Massive Lymphadenopathy

First described in 1969, sinus histiocytosis with massive lymphadenopathy, or Rosai-Dorfman disease, is clinically characterized as a benign, frequently chronic, painless massive lymphadenopathy usually involving cervical lymph nodes and, less frequently axillary, hilar, peritracheal, and inguinal nodes.[296] Extranodal disease is present in approximately 28% of patients.[297–299] The upper respiratory mucosa is involved in 20% of patients,[300] bone in 25%,[301,302] and orbit or eyelid in 10%.[303,304] Occasionally there is involvement of skin,[305] CNS, lung, liver, and kidney.[306–308] Ocular manifestations, such as uveitis, have been observed.[309]

Although sinus histiocytosis with massive lymphadenopathy is a histologically reactive and molecularly polyclonal disorder,[310] significant morbidity and death have been associated with massive tissue invasion of the liver, kidney, lung, brain, and other critical structures.[306,311] In these instances, the disease may have a rapid downhill course. Respiratory distress due to tracheal obstruction[312] as well as paraplegia secondary to epidural involvement have been described.[313] Death from sinus histiocytosis with massive lymphadenopathy has occurred as a consequence of severe hemolytic anemia.[311]

Eighty percent of patients are diagnosed in the first or second decade of life; however, the disorder also can affect the elderly.[314] Typically, patients are of African descent.[315] Males and females are equally affected. The incidence of sinus histiocytosis with massive lymphadenopathy is greatest in Africa and the West Indies.[315]

Laboratory evaluation frequently reveals an elevated erythrocyte sedimentation rate, moderate polyclonal hypergammaglobulinemia, anemia, and granulocytosis.[305,312] Involved lymph nodes (see Fig. 52–8) show marked sinusoidal dilation with proliferation of foamy histiocytes within the sinuses. Eosinophils usually are low in number, but plasma cells are abundant.[296,297,300,301] A characteristic finding, referred to as emperipolesis, demonstrates lymphocytes surrounded by the membranes of histiocytes as observed best by electron microscopy.[312] The proliferating histiocytes share properties of macrophages and interdigitating cells. These large pale cells show variable expression of S100. They can be distinguished from Langerhans cells found in the lymph nodes of patients with classic LCH by the absence of Birbeck granules, the presence of α_1-antichymotrypsin, and the absence of CD1a expression.[312]

The etiology of Rosai-Dorfman disease is unknown, but disordered immune regulation has been proposed as a significant contributor. It was originally thought that Rosai-Dorfman disease represented an unusual response to a *Klebsiella* antigen or Epstein-Barr virus,[314] but this has not been confirmed.[305] There has also been an association of the disease with herpesvirus 6.[316] Although patients frequently are febrile, infectious agents are not commonly implicated, and the fever is presumed to be a manifestation of systemic disease.

Disease manifestations can subside over several months to years. Of 215 cases in a patient registry, 21% had complete resolution of disease. However, 14 patients died. Five died of "immunologic" causes, such as severe hemolysis, three died of infections and six probably died as a direct consequence of disease infiltration.[317] As the disease resolves, extranodal disease regresses prior to nodal disease. Corticosteroids, vinblastine, and low-dose cyclophosphamide are sometimes effective; however, the results with these agents have been inconsistent.[297,313,318,319] Thalidomide has been used in some cases, with anecdotal responses.[320] Similarly, 2-CdA has been reported to have activity in Rosai–Dorfman disease.[321] Attempts at treatment should be reserved for special circumstances, such as tracheal or epidural compression or invasion of other vital structures, as well as for significant cosmetic disfigurement. Local excision may be useful in selected patients.[301]

CHAPTER 53

LYSOSOMAL STORAGE DISEASES: PERSPECTIVES AND PRINCIPLES

Gregory A. Grabowski and Nancy D., Leslie

THE CONCEPT OF THE LYSOSOME

The lysosome was first described by deDuve as an acid phosphatase-containing, unit membrane-bound organelle within the cytoplasm of eukaryotic cells.[1] As their name implies, lysosomes participate in the lysis or breakdown of cellular material, functioning as a digestive tract within the cell. An array of more than 50 hydrolytic enzymes is contained within the organelles to prevent autodigestion of cellular contents. Since the original description, the role of the lysosome has expanded to that of a dynamic and heterogeneous subcellular organelle with functions tailored to specific cell types and tissues. For example, the specialized lysosomes of neutrophils and osteoclasts extrude hydrolytic enzymes into the extracellular microenvironment, providing a critical component of host defense and bone remodeling, respectively.

The concepts of lysosomes as hydrolytic sacs and the need for specific targeting of enzymes to the lysosome have provided a fertile milieu for research during the past three decades. deDuve was the first to delineate engorged lysosomes in patients with α-glucosidase deficiency (Pompe disease)[2] and, in concert with Van Hoof, in patients with other lysosomal storage diseases.[3] The initial descriptions of lysosomal storage diseases focused on a pathophysiologic view relating morbidity and cellular dysfunction to architectural distortion produced by lysosomal storage. More recently, a more active role for the accumulating catabolic intermediates (eg, lysosphingolipids) has been suggested because of their toxic effects on cells.[4] Further investigation of lysosomal function and derangements has delineated additional categories of disease, including defects of lysosomal membrane proteins, transport, and defects of enzyme processing and uptake.

An important element in understanding the biology and pathobiology of the lysosome is the concept of receptor-mediated endocytosis. The Goldstein and Brown model of receptor-mediated endocytosis for the low-density lipoprotein (LDL) particle[5] and its general implications for the uptake and targeting of proteins to cells were expanded by Neufeld[6] and others. Fratantoni described the phenomenon of cross-correction of lysosomal storage diseases during coculture of skin fibroblasts from patients with two different types of mucopolysaccharidoses (MPSs).[6] Specific "corrective factors" secreted by one MPS cell type could be internalized by the other cell type,[6] resulting in depletion of accumulated substrate. These corrective factors were later identified as enzymes, reinforcing the notion that a single lysosomal hydrolase usually is defective in each MPS variant. However, cross-correction requires the secretion of a functional enzyme containing a signal for receptor-mediated endocytosis by other cells. This signaling system, subsequently characterized by the groups of Sly,[7] Kornfeld,[8,9] von Figura,[10] and others, involves modification of the secreted enzyme to include a mannose-6-phosphate (M6P) recognition signal and its interaction with a specific receptor, allowing reuptake of the tagged enzyme back into the cell or similarly equipped neighbors. This ligand-mediated targeting system is central to selective sorting of most soluble lysosomal proteins within many cells,[9] and to their uptake into cells and delivery to the lysosome. By comparison, membrane-bound lysosomal proteins use different, incompletely defined, amino acid-based targeting systems.[11] These concepts of storage, cross-correction, and targeting have provided the foundation for the development of therapeutic interventions for lysosomal storage diseases, including enzyme reconstitution by transplanted tissue or direct replacement. Both approaches may stabilize or reverse the pathophysiologic process in select lysosomal storage diseases. These findings imply a dynamic and interactive communication of the lysosome with intra- and extracellular compartments. Comprehensive reviews of individual lysosomal diseases are presented in Tables 53–1 and 53–2.

PHYSIOLOGY OF LYSOSOMES

Lysosomal biogenesis is a continuous process that requires synthesis of lysosomal hydrolases, membrane constitutive proteins and membranes, as well as establishment of the acidic milieu required for hydrolytic function. Unlike mitochondria, lysosomes do not contain DNA and therefore cannot self-replicate. Thus, biogenesis includes the fusion of vesicles from the *trans*-Golgi network (TGN) with late endosomes (multivesicular bodies [MVBs]) (Fig. 53–1).[12,13] The TGN vesicles contain lysosomal hydrolases. The maturation of TGN vesicular bodies to lysosomes and of endosomes from early to late compartments accompanies progressive intravesicular acidification. A gradient is established, so that early endosomes have an internal pH of approximately 6.0 to 6.2, whereas late endosomes and lysosomes have pH values of approximately 5.5 to 6.0 and less than 5, respectively. This acidification is needed for the pH-dependent dissociation of receptors and ligands (eg, the M6P receptor and M6P-containing oligosaccharides) and the optimal functioning of lysosomal hydrolases.[14] Dissociation occurs in a virtual compartment termed CURL (*c*ompartment of *u*ncoupling of *r*eceptors and *l*igands). Formation and segregation of lysosomes with their constitutive integral and associated membrane proteins are less well understood.[15] These proteins are essential for lysosomal integrity and function. In particular, the lysosomal membrane contains a proton pump needed for developing and maintaining the acidic internal environment required for lysosomal hydrolase function. The signals for the fusion of TGN vesicles with endosomal vesicles (PL-EN) require the interaction of several membrane components, the sorting of proteins destined for the lysosome, the loss of the M6P receptors, the recycling of these receptors to the *mid-* (*medial-*) Golgi bodies and plasma membrane,[14] and segregation of endosomal membrane and contents. Consequently, the view of the lysosome as an end-stage compartment has been replaced by one of a dynamic communicating organelle with continuously changing contents that, at least in part, exchanges material with other lysosomes in the cell. This leads to a lysosomal compartment that is composed of heterogeneous populations of similar organelles whose individual contents differ greatly in time and space.

Posttranslational modifications of lysosomal hydrolases are important both for specific sorting and targeting of enzymes and for their enzymatic activity. Lysosomal enzymes are glycoproteins that are synthesized on ribosomes of the rough endoplasmic reticulum (ER). As with all secretory proteins, lysosomal hydrolases are synthesized with an amino-terminal (N-terminal) hydrophobic leader or signal peptide that is required for penetration through the ER membrane and into the lumen of the ER. During penetration through the ER membrane, the lysosomal proteins are cotranslationally glycosylated on select N-glycosylation consensus sequences (asparagine–X–serine or -threonine). This occurs by the en bloc transfer of a core mannosyl

Table 53–1 Select Lysosomal Storage Diseases (See Box on Perspective on Diagnosis of Lysosomal Storage Diseases)

Disease*	Common Name	Enzyme Defect	Major Organs Involved; Phenotype Variation	Stored Substrate(s)
MUCOPOLYSACCHARIDOSES (MPSs)[137]				
MPS IH	Hurler syndrome	α-L-Iduronidase	Liver, spleen, brain, heart, cornea, bone; mild and severe variants	Dermatan and heparan sulfate
MPS II	Hunter syndrome	Iduronidate sulfatase	Liver, spleen, brain, heart, bone	Dermatan and heparan sulfate
MPS III[138,139]	Sanfilippo syndrome type A	Heparan *N*-sulfatase	Brain, liver, spleen, heart, bone	Heparan sulfate
	Sanfilippo syndrome type B	*N*-Acetyl-glucosaminidase	Brain, liver, spleen, heart, bone	Heparan sulfate
MPS IV[138]	Morquio syndrome type A	*N*-Acetyl-galactosamine 6-sulfatase	Bone, cornea	Keratan sulfate, chondroitin 6-sulfate
	Morquio syndrome type B	β-Galactosidase	Bone, cornea	Keratan sulfate
MPS VI	Maroteaux–Lamy syndrome	*N*-Acetyl-galactosamine 4-sulfatase	Bone, cornea, liver, spleen, heart; moderate and severe variants	Dermatan sulfate
MPS VII	Sly syndrome	β-Glucuronidase	Brain, liver, spleen, bone, coronary arteries	Dermatan sulfate, heparan sulfate, chondroitin 4- and 6-sulfate
GLYCOPROTEINOSES[56]				
Mannosidosis		Lysosomal α-mannosidase	Brain, liver, spleen and bone; several variants	α-Mannose-rich oligosaccharides
Fucosidosis		Glycoprotein α-fucosidase	Brain, liver, spleen, heart, skin; several variants	Fucose-containing oligosaccharides
Aspartylglucosaminuria[140]		Aspartyl-glucosaminidase	Brain, liver, spleen, bone, heart	Aspartylglucosamine-containing peptides
Sialidosis		Glycoprotein α-neuraminidase	Brain, liver, spleen, bone, retina; several variants	Sialylated glycopeptides
Galactosialidosis[141]		Protector protein-combined α-neuraminidase/β-galactosidase deficiency	Brain, liver, spleen, bone; several variants	Ganglioside G_{M1} and sialylated glycopepetides
Mucolipidosis II[142]	I-Cell disease	*N*-Acetylglucosamine-1-phosphotransferase	Brain, bone, connective tissue	Glycoproteins, glycolipids
Mucolipidosis III[142]	Pseudo-Hurler (syndrome) polydystrophy	*N*-Acetylglucosamine-1-phosphotransferase	Brain, bone, connective tissue	Glycoproteins, glycolipids
SPHINGOLIPIDOSES				
Gaucher disease[52]	Gaucher disease Type 1 (nonneuronopathic)	Acid β-glucosidase; glucocerebrosidase	Liver, spleen, bone, bone marrow; highly variable phenotype	Glucosylceramide
	Gaucher disease type 2 (acute neuronopathic)	Acid β-glucosidase; glucocerebrosidase	Brain, brainstem, liver, spleen, bone marrow, lungs	Glucosylceramide; glucosylsphingosine
	Gaucher disease type 3 (subacute neuronopathic)	Acid β-glucosidase; glucocerebrosidase	Brain, liver, spleen, bone marrow, lungs; variable phenotype	Glucosylceramide; glucosylsphingosine
Metachromatic leukodystrophy (MLD)[143]	Infantile MLD	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
	Juvenile MLD	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
	Adult MLD	Arylsulfatase A	Brain, peripheral nerves	Sulfatide
		Saposin B deficiency	Brain, peripheral nerves normal	Sulfatide
	Pseudo deficiency	Partial arylsulfatase A deficiency		None
Fabry disease[35,144]		α-Galactosidase A	Kidney, vascular endothelial system, heart, CNS vessels	Globotriaosylceramide
Schindler disease[145]		β-*N*-acetyl-galactosami dase	Brain; probably several variants	*N*-Acetylgalactose linked oligosaccharides; ? other
Krabbe disease[146]		Galactocerebrosidase	Brain	Galactocerebroside
Niemann–Pick disease[147,148]	Niemann–Pick disease type A (infantile)	Sphingomyelinase	Brain, liver, spleen, lungs	Sphingomyelin
Multiple sulfatase deficiency[61]		Cysteine modification enzyme	Brain, liver, spleen, bone	Sulfatide, dermatan, and heparan sulfate
GANGLIOSIDOSES				
G_{M2} gangliosidoses[68]	Infantile Tay–Sachs disease (TSD)	β-Hexosaminidase A (α-chain)	Brain	Ganglioside G_{M2}
	Juvenile TSD	β-Hexosaminidase A (α-chain)	Brain	Ganglioside G_{M2}
	Adult TSD	β-Hexosaminidase A (α-chain)	Brain	Ganglioside G_{M2}
	Activator deficiency	G_{M2}-activator	Brain	Ganglioside G_{M2}
	Sandhoff disease	β-Hexosaminidase B, A (β-chain)	Brain, liver, spleen, bone	Ganglioside G_{M2}, globoside

Table 53–1 Select Lysosomal Storage Diseases (See Box on Perspective on Diagnosis of Lysosomal Storage Diseases)—cont'd

Disease*	Common Name	Enzyme Defect	Major Organs Involved; Phenotype Variation	Stored Substrate(s)
G_{M1} gangliosidoses[55]	Landing disease	α-Galactosidase	Brain, liver, spleen, bone	Ganglioside G_{M1}, keratan sulfate
NEUTRAL LIPID STORAGE DISEASES				
Wolman disease[36]		Lysosomal acid lipase	Liver, spleen, adrenal glands, bone marrow	Cholesteryl esters, triglycerides
Cholesterol ester storage disease (CESD)[36]		Lysosomal acid lipase	Liver, spleen, blood vessels	Cholesteryl esters
Farber disease[149]		Ceramidase	Brain, joints, tendons, skin, liver	Ceramide

CNS, central nervous system.
*Reference numbers refer to major reviews.

Table 53–2 Non-Hydrolase-Mediated Lysosomal Diseases

Protein	Function	Mouse Model[150]	Human Disease	Pathology
LAMP-1	Not defined			
LAMP-2	Lysosomal biogenesis, chaperone-mediated autophagy[152]	Vacuoles in liver, pancreas, muscle, heart[153]	Danon disease[151]	Cardiomyopathy, skeletal myopathy
LIMP-2	Endosomal transport, lysosomal biogenesis	Demyelinating neuropathy, deafness, ureteropelvic junction obstruction[154]	Not defined	
Cystinosis	Lysosomal cystine transport	Cystine storage in eye and bone, but NO renal disease[155]	Cystinosis	Cystine storage in renal tubules and cornea
Sialin[156]	Free sialic acid transport		Salla disease, infantile sialic acid storage disease	
Mucolipin-1[157]	Calcium-permeable channel, abnormal sorting of lysosomal proteins		Mucolipidosis IV	Mental retardation, cloudy corneas
Cathepsin K[158]	Osteoclast degradation of bone protein matrix (collagen)		Pyknodystostosis	Skeletal dysplasia
Niemann–Pick type C[73]	Lysosomal accumulation of cholesterol	Yes	Niemann–Pick disease type C	Neurodegeneration, liver disease
Tripeptidyl peptidase I[159]	Protein trafficking/degradation		Late infantile neuronal ceroid lipofucsinosis (LINCL)	Neurodegeneration, seizures, visual and motor disturbances

LAMP, lysosomal-associated membrane protein; LIMP, lysosomal-integral membrane protein.

Perspective on Diagnosis of Lysosomal Storage Diseases

The increasing elucidation of the molecular lesions underlying the lysosomal storage diseases has provided insight into the great heterogeneity within each of these diseases. In addition, the proliferation of tests for the specific genetic lesions has led many practitioners to substitute molecular testing for enzyme-based diagnosis. The great specificity of molecular testing is its downfall, whereas the more generic nature of enzyme testing is a major strength. For any of the disease categories listed in Table 53–1, the diagnosis is established by detection of the specific enzyme defect. In experienced laboratories, many of these activities are accurately determined and will establish the specific diagnosis. Once the diagnosis is established, additional molecular testing can provide supplementary information and, in some cases, prognostic insight. In some lysosomal diseases, the frequency of pseudodeficiency alleles mandates the use of molecular testing, and other adjunct investigations (eg, sulfatide loading studies in metachromatic leukodystrophy) are necessary to fully establish a phenotype and prognosis, particularly in presymptomatic siblings or in prenatal testing. As the therapeutic armamentarium expands, there will be a push to establish diagnoses earlier, perhaps before the onset of clinical symptoms. Population-based screening for lysosomal storage disorders is more complicated than newborn screening for small metabolites, but a number of analytic techniques are being explored. Regardless of the method and timing of ascertainment, every effort should be made to thoroughly and completely characterize these patients at the clinical, biochemical, and molecular levels. Periodic detailed neurologic and physical assessments by imaging and clinical examinations are indicated in all patients to evaluate the effects of intervention or relationship of specific mutations to phenotype. As clinical trials for therapeutic approaches to an increasing number of conditions evolve, it is expected that surrogate markers for disease control will be developed and validated. These markers are likely to add to the armamentarium of modalities for the management of lysosomal disease. The development of registries for several of these conditions will foster the collection of valuable data as new approaches become available.[17]

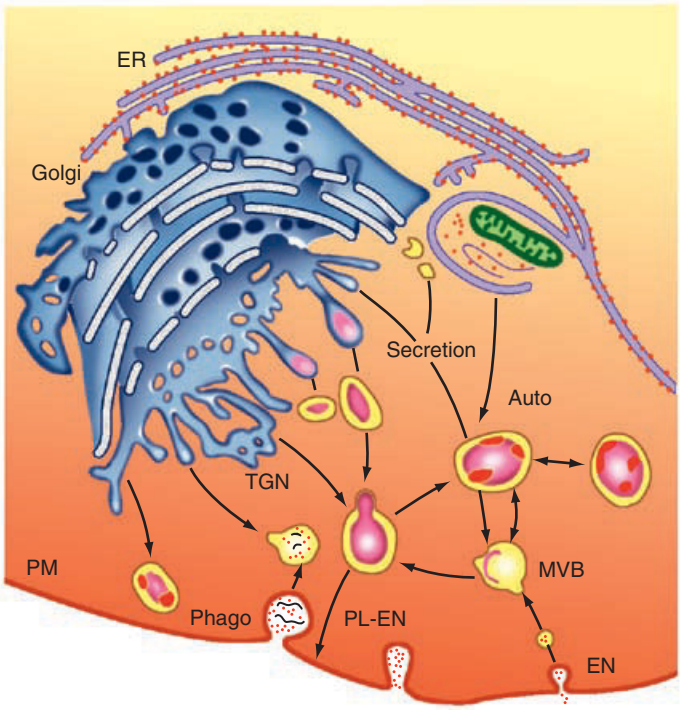

Figure 53–1 Schematic diagram of lysosomal development from the endoplasmic reticulum (ER), through the Golgi apparatus (GOLGI), and the endosomal compartments (EN). EN is shown to develop from the plasma membrane (PM) coated pits. The EN and TGN pathways converge in vesicles containing material from newly synthesized lysosomal proteins, and ER and/or MVB (multivesicular body) contents. Between the MVB, PL-EN, and return to the PM exists the CURL, a virtual compartment for the uncoupling of receptors and ligands. The various EN and lysosomal compartments are distinguished by the progressive acidification of the vesicles from early to late endosomes and the loss of the mannose-6-phosphate (M6P) receptors in the CURL. The MVB is an ultrastructural compartment that contains internal small vesicles derived from the PM. Vesicles that bud from the TGN fuse with late EN or MVB to form the lysosomal compartment. M6P receptors are recycled to the PM and to the mid-Golgi. Secretion indicates a direct route from the TGN to EN for delivery outside of the cell. Auto and Phago refer to autophagy and phagocytosis, respectively, by which internal and external materials are delivered to preexisting lysosomes. *Larger arrows* indicate a major common pathway through the maturing lysosomes. The *double-headed arrows* depict a necessary interaction between various types of lysosomes to account for the major similarities of lysosomes in cells. Lysosomes are inherently heterogeneous. This indicates a dynamic compartment that communicates, probably bidirectionally, with other components of the endosomal/lysosomal system. In addition to what is shown, vesicular transport is needed between the ER and GOLGI.

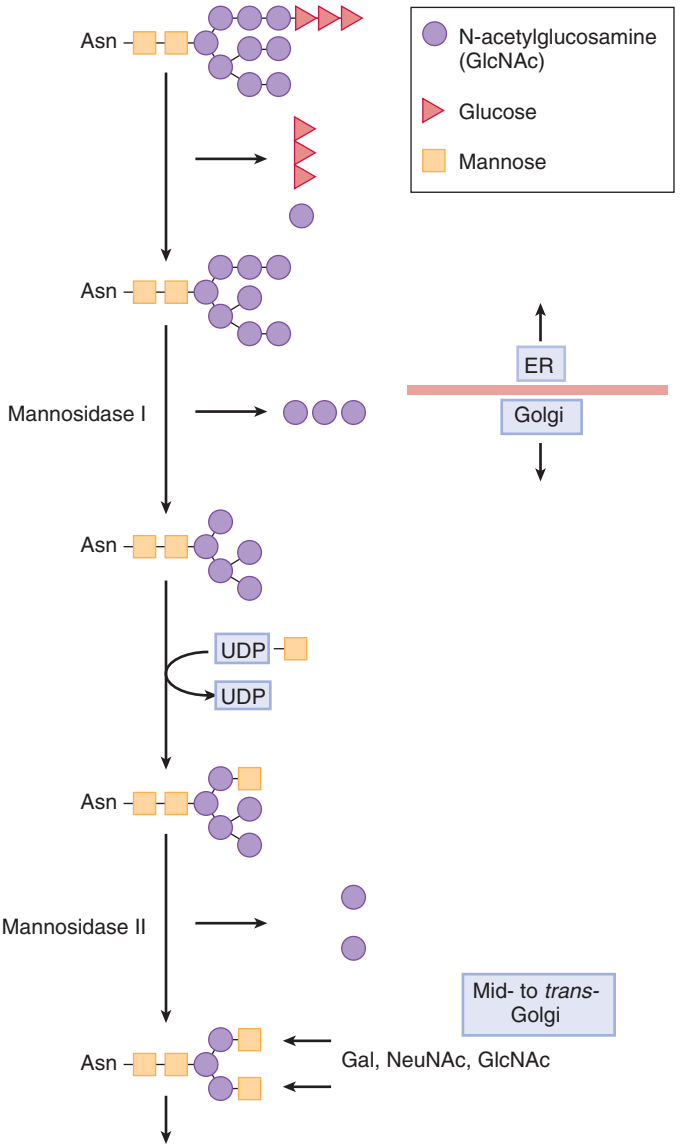

Figure 53–2 Compartmentalized N-linked oligosaccharide modifications of lysosomal proteins. Attachment of the core mannosyl-glucose to select Asn-X-Ser/Thr consensus sequences occurs cotranslationally in the endoplasmic reticulum (ER) lumen through en bloc transfer of the illustrated core oligosaccharide structure from a dolichophosphate. Initial removal of terminal glucosyl residues and a mannosyl residue are removed before exit from the ER to the Golgi. Additional α-mannosyl residues are removed by specific mannosidases in the *cis*-Golgi to a pentamannosyl core. *N*-acetyl-glucosamine-1-phosphate is transferred by glucoaminylphosphotransferases for the creation of a mannose-6-phosphate (M6P). In the *medial-* (*mid-*) and *trans*-Golgi, β-galactosyl and sialyl (NeuNAc) residues are added by transferases localized to those compartments. The final oligosaccharide structures can contain mostly mannose (high mannose), short mannose cores, *N*-acetyl-glucosamines, β-galactosyl and sialyl residues on the core structure (complex), or several combinations of these on different branches of the structure.

oligosaccharide chain from a long-chain lipid phosphate, terminal dolichophosphate (Fig. 53–2). It is unclear how N-glycosylation sequences are selected for occupancy,[16] except that asparagine–proline–serine or–threonine sites are not used and the surrounding protein sequences appear important for transfer of the dolichophosphate oligosaccharide.

Following complete synthesis and glycosylation, the lysosomal enzymes may undergo additional proteolytic processing or assembly and are incorporated into transport vesicles for delivery to and further processing in the *cis*-Golgi apparatus. At this stage, all proteins destined for the lysosomes contain only branched mannosyl chains that terminate with short-chain α-glucosyl moieties. Most enzymes destined for the lysosome acquire complex oligosaccharide modifications during transport through the Golgi apparatus (see Fig. 53–2). A series of glycosylhydrolases and glycosyltransferases within specific regions of the *cis*-, *mid*-, or *trans*-Golgi participate in these sequential modifications. In the *cis*-Golgi network, α-glucosidases and α-mannosidases remove terminal glucose and mannose residues to produce mannose-terminated core oligosaccharides. For each branch point of the mannosyl chain, there are specific α-mannosidases for cleavage.

Following mannosyl trimming, additional sugars including β-*N*-acetylglucosamine and β-galactoside are added to the short mannosyl core by the *mid*-Golgi system. The addition of terminal sialic acid

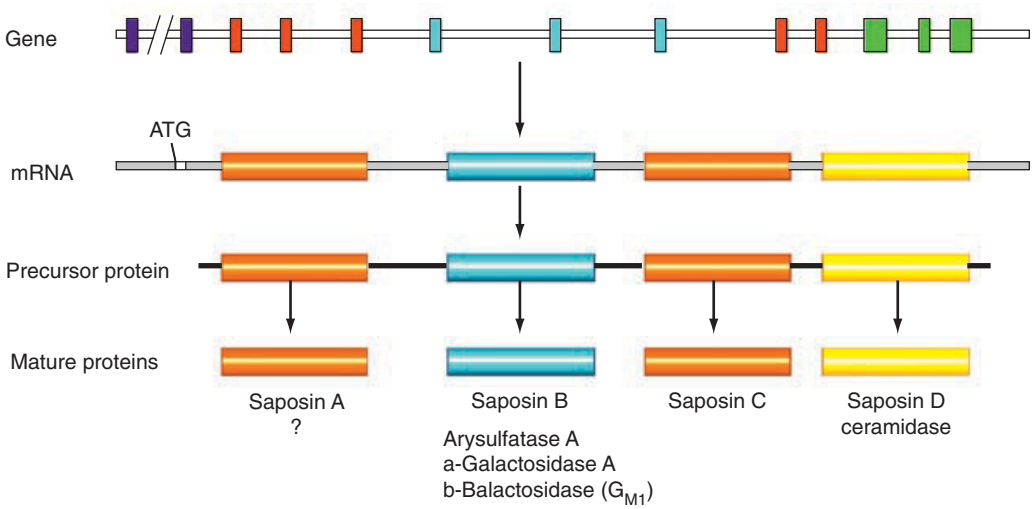

Figure 53–3 Diagram of the processing of prosaposin from the chromosomal gene to messenger RNA (mRNA) to mature saposin proteins that interact with lysosomal enzymes. The chromosomal gene is more than 30 kb in length; the first intron is longer than 20 kb and is located on chromosome 10p. Introns are shown as the *white rectangles*, and exons are filled and matched to the domains for each saposin. The mRNA contains four highly homologous, but not identical, domains that code for the saposins A, B, C, and D. The mature mRNA encodes the saposins and intersaposin peptide links in the same reading frame. The intersaposin peptides are removed by proteolysis. The individual saposins are produced by proteolytic cleavage mostly within the lysosomes, where they interact with their respective lysosomal hydrolases.

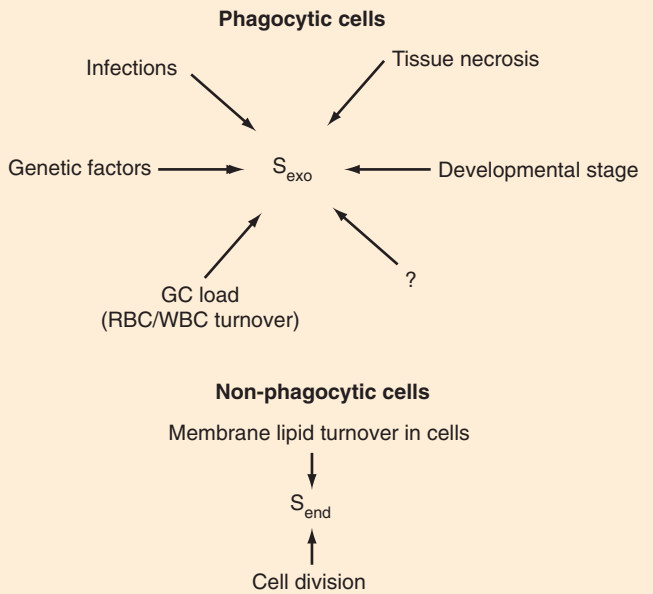
residues occurs in the *trans*-Golgi. Each of these sugars is added by glycosyl transferases that have been retained in their respective Golgi compartments by specific signals. Thus, the carbohydrate composition of the lysosomal proteins is indicative of its passage through regions of the Golgi during the synthetic process. Before, or coincident with, ER or *cis*-Golgi modifications is the attachment of an *N*-acetylglucosamine-1-phosphate to the sixth position on mannosyl residues of the mannosyl core oligosaccharide. This modification can be uni- or multivalent and is selective for various branches of the oligosaccharides on a specific lysosomal protein. An *N*-acetylglucosylaminyl-1-phosphotransferase[8,10] is essential for this process, and its deficiency leads to a severe condition, I-cell disease, in which many soluble lysosomal enzymes are lost by default secretion out of the cell.[8]

Shortly after the attachment of the phospho-sugar group, a specific hydrolase cleaves the protecting *N*-acetylglucosamine from the phosphate to expose the M6P residue, the targeting signal for soluble lysosomal proteins. These modification processes culminate in most lysosomal enzymes having several oligosaccharide chains with nonidentical antennerary modifications. As a result, the lysosomal enzymes can have portions of the attached oligosaccharide tree having only mannose residues (high-mannose modification), mannosyl-, *N*-acetyl-glucosylaminyl-, β-galactosyl-, and sialyl-containing oligosaccharides (mixed type modification), or only terminal sialyl acid residues (complex-type modification).[18,19] Of importance, many soluble enzymes employ ill-defined M6P-independent intracellular trafficking signals alone or in combination with the M6P system.

Defective M6P targeting of soluble lysosomal proteins, as occurs in I-cell disease, has no effect on the integrity of the lysosome per se or its membrane. Lysosomal integral or associated membrane proteins (LIMPs or LAMPs) are sorted to the lysosomal membrane or to the interior of the lysosome through M6P-independent trafficking systems. Signals for such trafficking have been identified as strategically located tyrosine residues near the carboxyl-terminal (C-terminal) end of some LIMPs and LAMPs.[15] Additional signals are required for targeting of other lysosomal membrane components. Of importance, for the diseases involving LIMPs and LAMPs, cross-correction of cocultured cells would not occur; this has significance in considering therapeutic strategies of such diseases.



In addition to glycosylation, some lysosomal proteins require proteolytic clipping, phosphorylation, or macromolecular assembly for the development of full function within the lysosomal environment. Proteolytic processing can occur at the N or C termini or by clipping of single-peptide precursors into mature subunits or active peptides. For example, prosaposin is cleaved into four biologically active saposins—A, B, C, and D—that are functional in the lysosomal compartment (Fig. 53–3).[20–22] A "protector protein" precursor is involved in galactosialidosis and is clipped from its zymogen form into two disulfide-linked subunits within the Golgi apparatus before its achieving proteolytic activity.[22,23] Some proteins also may acquire phosphorylation of serines or threonines or sulfation of tyrosines. Macromolecular assembly is required for several heteromeric lysosomal proteins. The association of the β-hexosaminidase α- and β-chains in the mid-Golgi is necessary for synthesis of active hexosaminidase A (α- and β-heteromers) or hexosaminidase B (β-homomers). Macroassembly of the β-galactosidase/neuraminidase/protector protein complex probably occurs within the Golgi apparatus coincident with other processing required for the assembly of the active catalytic complex.[23]

Although the control of tissue expression of many lysosomal proteins has not been characterized, tissue- and cell-specific expression have been described for prosaposin and lysosomal acid lipase[24,25] and probably exist for other lysosomal proteins. These expression patterns may have importance in explaining the variability of the phenotypes of these diseases. Most tissues contain similar lysosomal hydrolases for degradation of macromolecules, such as mucopolysaccharides, glycoproteins, and glycosphingolipids, because these are essential to cell function. Thus, excessive lysosomal storage can be demonstrated in most tissues using histological or biochemical tools. However, concordant levels of lysosomal hydrolase activities are not found in all tissues. The specialized lysosomes of neutrophils contain myeloperoxidases that are not in fibroblast lysosomes.[26] This variation may play an important role in diagnostic assays, because some of the lysosomal proteins are found at measurable levels in plasma, but others require isolation of circulating leukocytes. The activity of α-L-iduronidase, the enzyme deficient in MPS I, is easily detected in amniocytes and placental tissue, but is nearly absent in early chorionic villi. Acid β-glucosidase (deficient in Gaucher disease) is present at nearly 10-fold lower levels in myeloid-derived cells compared with fibroblastic cells.[27]

A formal explanation for variability in both expression and cellular dysfunction is proposed in the Conzelmann and Sandhoff threshold hypothesis for the development of manifestations of specific lysosomal hydrolase deficiency diseases.[28,29] This working hypothesis

Factors Influencing Substrate Flux and Concentration

Factors influencing the substrate concentration (S) in phagocytic (S_{exo}) and nonphagocytic (S_{end}) cells. This reflects the major, but not exclusive, dependence of S on these pathways in these different cell types. GC = glucosylceramide.

implies that a set level of residual enzymatic activity, or substrate flux, is necessary to prevent lysosomal disease manifestations. Below this threshold, disease manifestations (in tissues or specific cell type) will be expressed, whereas above this threshold, there will be no phenotype. This formalizes the commonsense notion that less enzyme activity leads to more severe disease and that more enzyme activity results in less severe or delayed disease manifestations. The hypothesis also implies that each tissue or cellular type may require specific levels of activity. The therapeutic importance of threshold is clear, because the existence of attenuated disease variants demonstrate that 1% to 10% of normal lysosomal enzyme levels may be sufficient to correct metabolism in many tissues and prevent, reverse, or significantly delay localized disease manifestations. Similarly, very small incremental changes in enzyme activity or substrate flux could have profound effects on disease development and severity. However, expansion of this hypothesis also incorporates the caveat that threshold levels may vary during development. Failure to meet critical thresholds during these stages may result in irreversible changes not amenable to later therapeutic interventions. For example, after progression to a pathologic stage, dysostosis multiplex of bones, cardiac valvular involvement, or neurodegeneration in the MPSs may not be reversed by bone marrow transplantation (BMT) or enzyme replacement therapies.

The threshold hypothesis leads directly to a model for the pathogenesis of lysosomal disease phenotypes; that is, necessary and sufficient conditions can be identified for the occurrence of the disease state. The presence of deleterious mutations that lead to the deficiency of specific proteins is a necessary prelude to the phenotype. However, the relationships of the residual mutant activity to the level of substrate flux through the lysosome, to the temporal and spatial metabolic needs of a particular tissue, and to the phenotype, are poorly understood. Conzelmann and Sandhoff studied ganglioside G_{M2} and sulfatide degradation in fibroblasts from patients with Tay–Sachs disease and metachromatic leukodystrophy (MLD), respectively. Their data support the contention that the age at onset (and therefore disease severity) of a lysosomal disease phenotype correlates with a threshold level of residual activity within lysosomes of cells.[28,29] However, additional factors can dramatically impact substrate flux and must be defined to provide a larger conceptual background as a model for pathogenesis.

As shown below, the total body turnover of a particular substrate represents the total rate of change of substrate concentrations, $v_T = \Delta S_T/\Delta t$, in a variety of cell types. The flux of substrate in individual cells or organs, $v_i(t) = \Delta S_i/\Delta t$, varies substantially throughout the body and potentially with developmental stage. For the purposes of this discussion, the subscript i incorporates the organ- or cell-specific property at different developmental stages. Thus, the sum of all $v_i(t)$ values would represent the total body substrate flux. The quantity v_T also may depend on developmental stage and the level of substrate in the cell—that is, $v(S_i)$. Four major factors impinge on S_i attained in each cell at each developmental stage: S_{exo}, S_{end}, L_{ex}, and L_{en} (see upper diagram in box). These represent, respectively, the exogenous (exo) and endogenous (end) source(s) of substrate(s) that alter intracellular concentration (S_i). Also included are the pathways that lead to decreases in substrate levels (L) through excretion/secretion (ex) and enzymatic degradation (en) to end products within the lysosome. L_{en} represents decreases in substrate concentration due to the residual activity. Although such an equation is a heuristic device, it provides a means of examining, both qualitatively and quantitatively, each of the factors that influences intracellular substrate concentration. This could provide an overall conceptual framework for the dissection of the various phenotypes in lysosomal storage disease and potential targets for therapeutic intervention that may have the greatest impact on the phenotype.

$$v_T = \partial S_T/\partial t = \Sigma \partial S_i/\partial t = \Sigma[v_{xi}\,(S_i) + v_{ni}(S_i) + v_{Li}\,(S_i) + v_{eni}\,(S_i)]$$

The equation calculates the flux (v_T) of substrate (S_i) through various cell types. The sum of various rates of substrate change in n tissues ($\Delta S_i/\Delta t$) equals the total flux of substrate ($\Delta S_T/\Delta t$) through the body of an affected person. The term $v(S_i)$ represents the developmental stage-specific rate of substrate concentration changes in a particular cell type and its potential dependence on the concentration of substrate (S_i) in that tissue. The subscripts of v represent substrates from various sources (ie, x_i = exogenous, phagocytosis, n_i = endogenous sources from catabolism of more complex macromolecules, L_i = losses due to excretion/secretion, en_i = decreases due to enzymatic degradation).

As shown in the box on Factors Influencing Substrate Flux and Concentration (see diagram), the level of S_{exo} is influenced by genetic factors, that is, genetic determinants of cellular turnover or substrate delivery; by exogenous (environmental) agents that lead to increased substrate availability; and by the developmental stage, which could include increased cellular and substrate turnovers. This last aspect may be of importance for changes in the progression of various lysosomal diseases with age. Thus, different developmental stage-specific genes and substrate turnovers could affect an age-dependent threshold for the balance of $v_{in} \rightarrow v_{out}$. It is implicit in this discussion that disease progression is likely to be nonuniform, and exacerbations and remissions of symptoms may occur depending on exogenous factors and other genetic factors. Also, the balance of v_{Sex} and v_{Send} between cells and organs may differ substantially. This will depend greatly on the pathophysiology of various organs. Gaucher disease is a prime example. In many visceral tissues (hepatocytes, skin cells, lymphoid cells), v_{Sexo} for glucosylceramide is much less than v_{Sen}. The v_{Sen} value probably is very low, because even in the most severe variants, storage of glucosylceramide cannot be detected ultrastructurally in such cells. In comparison, in phagocytic cells of the viscera, $v_{Sexo} >> v_{Send}$. This implies that phagocytic cells will have a much greater variation in degree of involvement because of the inherent greater dependence on the exogenous supply of substrate (ie, greater variation in S_{exo} and v_{xi}) (see upper diagram in the box). In contrast, involved central nervous system (CNS) cells are dependent primarily on the S_{exo} for glucosylceramide and other substrates that accumulate in the brain. The contribution of S_{exo} is small. Detailed histologic examination of brains

from patients with Gaucher disease type 2 consistently shows significant regional variations in neuronal loss, neuronophagia, and gliosis. There is a rostral-to-caudal gradient of involvement, with greatest severity in the basal ganglia and the dentate nucleus.[30,31] Thus, in Gaucher disease, not only are the pathophysiologic findings in the viscera and the brain fundamentally different, but also within the CNS there are regional variations. The greater dependence of the visceral pathology on S_{cx} implies a potentially greater number of steps that could be altered to influence the rate and degree of disease progression.

These considerations indicate that a necessary condition for the development of disease is the *relative* enzymatic deficiency within the lysosome—that is, is there sufficient hydrolytic power in the lysosome to cleave the substrate presented at any given time? The enzyme deficiency reduces the ability of cells and, therefore, the individual, to adapt to changes in v_T. Thus, the variation in v_T, either endogenous or exogenous, determines to a great extent the eventual phenotypical severity. Because v_T can vary, the progressivity of the specific disease manifestations may be variable at different stages of the disease. The most maladaptive mutations (eg, a homozygous null mutation) frequently may be associated with the most severe phenotypes, but modifier factors (genes) could alter disease severity. The converse also applies. Currently, little is understood about the essential factors that influence substrate flux in the tissues of patients with lysosomal storage diseases.

Definition of these thresholds of activity also may provide clues to dose–response relationships for treatment of various storage diseases and the evaluation of exogenous enzyme replacement therapy. Once delivered to the tissue and cellular sites of pathology, exogenous enzymes will have finite life spans. Assuming appropriate stoichiometric relationships for components required for intracellular activity, the initially high hydrolytic rates will decrease to background levels over several half-lives of the supplied enzyme. Thus, large amounts of enzyme, potentially several-fold above threshold levels, may be needed to eliminate the extreme excess tissue burden of the substrate. Normal metabolism could then be maintained with pulses or intermittent dosing of lesser amounts of enzyme or other therapeutic agents, presumably at levels slightly above the disease threshold, because only catabolism of new substrate would be required.[29] This pulse model of therapy assumes that small amounts of reaccumulating substrates are not irreversibly toxic. Otherwise, a continuous supply of enzyme would be required to avoid such toxic effects. This model also assumes metabolic interaction between lysosomal compartments in cells and that the exogenous enzyme is delivered to the cells that are causal to the disease manifestations.

PATHOPHYSIOLOGY OF LYSOSOMAL STORAGE DISEASES

A majority of lysosomal enzyme deficiencies result from point mutations or genetic rearrangements at loci encoding a single protein required for the activity of the lysosomal hydrolase (see Table 53–1). Defects in lysosomal membrane proteins, transporters, and other nonhydrolytic enzymes also have been described (see Table 53–2), resulting in abnormalities in macromolecular association or trafficking (see later). The final common pathway for lysosomal storage diseases is the accumulation of macromolecules within tissues and cells that synthesize or ingest particular substrates or toxic metabolites in substantial amounts. For many lysosomal storage diseases, the clinical manifestations derive from the accumulation of substrates that are endogenously synthesized within particular tissue sites of pathology. The degree of involvement of any particular organ or organ system reflects the rate of endogenous synthesis or degradation, or both, of those specific compounds in particular tissues. The stored substrates are macromolecules—mucopolysaccharides, glycoproteins, or glycosphingolipids—that require degradation through a pathway with the sequential removal of single components of the substrate molecules at each step in a catabolic cascade (Fig. 53–4). Most of the enzymes are exo-hydrolases. Table 53–1 lists select lysosomal storage diseases categorized according to substrate groups and indicates some of the

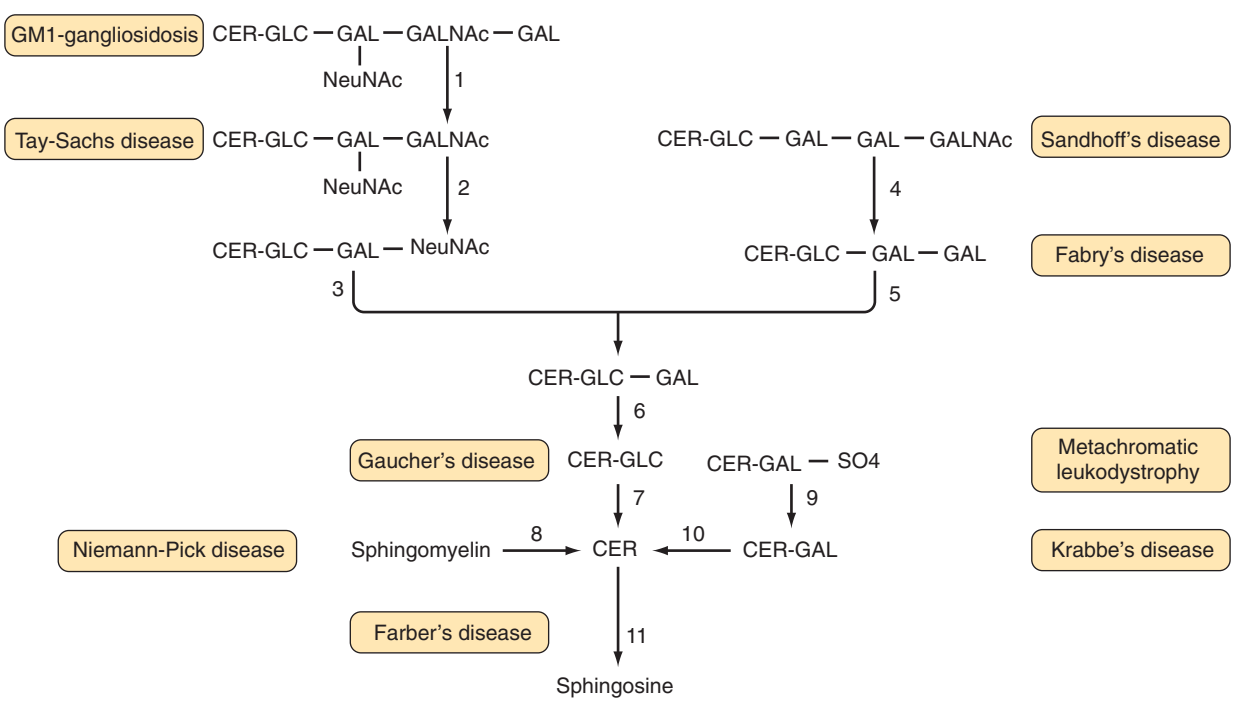


Figure 53–4 Pathway of glycosphingolipid degradation and the diseases that result from specific enzyme deficiencies. The numbers refer to the following lysosomal hydrolases: 1, β-galactosidase; 2, β-hexosaminidase A; 3, ganglioside neuraminidase; 4, β-hexosaminidase B; 5, α-galactosidase A; 6, β-galactosidase for lactosylceramide; 7, acid β-glucosidase (glucocerebrosidase); 8, sphingomyelinase; 9, arylsulfatase A; 10, β-galactocerebrosidase; 11, ceramidase. The deficiency of each of the respective enzymes leads to the accumulations of the substrate preceding the hydrolytic step. Diseases due to the deficiencies of either enzyme 3 or 6.

tissues involved by the various diseases. Specific organ systems are involved by particular diseases to a greater or lesser extent, reflecting the balance of endogenous and exogenous substrate presentations (see above). For example, in Hurler syndrome (comprising mucopolysaccharidoses IA), dermatan and heparan sulfate accumulate in connective tissue leading to joint contractures and abnormal skin consistency. Tissue-specific pathology also is present in several other diseases. Galactocerebroside is found in the greatest concentrations within the myelin sheaths of the CNS and peripheral nervous system (PNS). Although the deficiency of galactocerebrosidase in Krabbe disease occurs in all tissues, the synthesis of galactocerebroside is much greater in CNS and PNS.[32,33] Consequently, the manifestations of the disease are localized to the nervous system. Similarly in Tay–Sachs disease (TSD) or Sandhoff disease, the deficiencies of β-hexosaminidase A or of β-hexosaminidase A and B, respectively, result either in primarily CNS disease or in combined CNS and visceral diseases due to the different accumulated substrates.[34] β-Hexosaminidase A cleaves the specific substrate ganglioside G_{M2}, whereas β-hexosaminidase B cleaves primarily sialylgangliosides and globosides. Ganglioside G_{M2} is synthesized in large amounts only in brain or other nervous tissues, and globoside is synthesized primarily in visceral tissues.

Additional mechanisms, other than endogenous substrate synthesis, must be involved in pathologic substrate deposition in Fabry disease, Gaucher disease, and cholesterol ester storage disease (CESD). Fabry disease (α-galactosidase A deficiency)[35] and CESD (lysosomal acid lipase deficiency)[36] result from an inability to catabolize globotriaosylceramide and cholesterol esters, respectively. Both of these compounds are carried in the plasma associated with LDL particles. These LDL particles are internalized through receptor-mediated endocytosis and presented to the lysosome for degradation. In these two disorders, the major respective pathophysiologic features, endothelial cell and macrophage involvement, are due to the LDL uptake of these substrates and the inability to degrade them within the lysosomes. Endogenous synthesis of globotriaosylceramide and of cholesterol esters is relatively low within most tissues. Most accumulated substrate is derived from distant sources (ie, hepatocytes). The visceral manifestations of Gaucher disease (acid β-glucosidase deficiency) derive from the storage of glucosylceramide, primarily in cells of monocyte-macrophage origin (Figs. 53–5 and 53–6).[37] The vast majority of the viscerally stored substrate probably derives from white blood cell (WBC) and red blood cell (RBC) membrane turnovers through phagocytosis of aging blood-formed elements.[38] The inability to degrade all of the glucosylceramide from the membranes of these cells results in storage in macrophage lysosomes. Thus, the major pathophysiology of the visceral disease involves imported glycosphingolipid substrate rather than endogenously synthesized substrate within cells of the monocyte-macrophage system. By comparison, Gaucher disease type 2 is a severe neurodegenerative disorder of infancy. The visceromegaly, particularly of the spleen and liver, and bone marrow infiltration by Gaucher cells in this disease result from a defect in the phagocytic pathway. However, the severe neurodegenerative disease appears to be related to the presence of toxic by-products derived from degradation of endogenously synthesized glucosylceramide within CNS neurons of affected patients. These endogenous toxic metabolites and the importation into the brain of glucosylceramide from peripheral sources conjointly contribute to severe neurodegenerative disease. The contribution of transported and imported substrates to the pathophysiology of other diseases (ie, metachromatic leukodystrophy, the mucopolysaccharidoses, and the glycoproteinoses) is not fully understood and certainly would have an impact on therapeutic approaches. Thus, several mechanisms—thresholds of enzyme activity, tissue or developmental specificity, substrate localization, and substrate importation—play roles in the pathophysiology of specific lysosomal storage diseases. The relative importance of each process varies among diseases and may explain differential organ involvement within a specific disease category.

The direct distortion of the lysosomal architecture (ie, engorgement of lysosomes) probably has significant pathologic consequences, but the pharmacologic effects of the accumulated substrates or by-products are increasingly recognized as major components of the disease pathophysiology.[4,39] In the glycosphingolipidoses, the toxic metabolites of these complex lipids derive from their incomplete or improper degradation in the lysosome. The deacylated analogs of

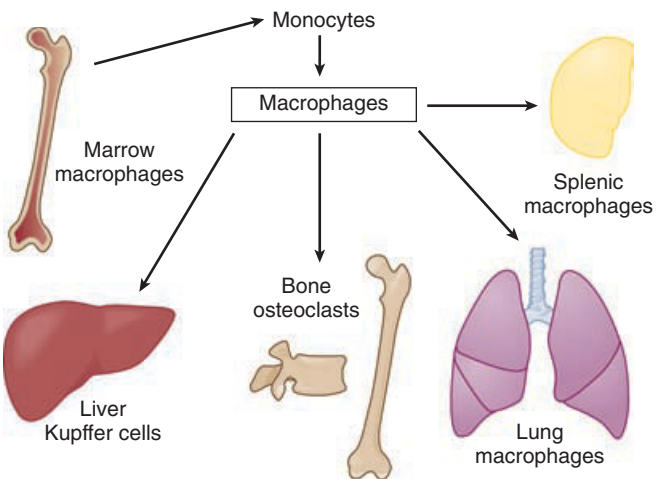

Figure 53–5 Diagram of the cellular pathophysiology of Gaucher disease. Monocytes are produced in the bone marrow and mature to macrophages in the marrow or in specific sites of distribution as liver Kupffer cells, bone osteoclasts, and lung and tissue macrophages. Once resident, they accumulate glucosylceramide by phagocytosis and become end-stage Gaucher cells. The resultant tissue fibrosis, ischemia, osteoporosis, and other pathologic features have not been adequately explained.

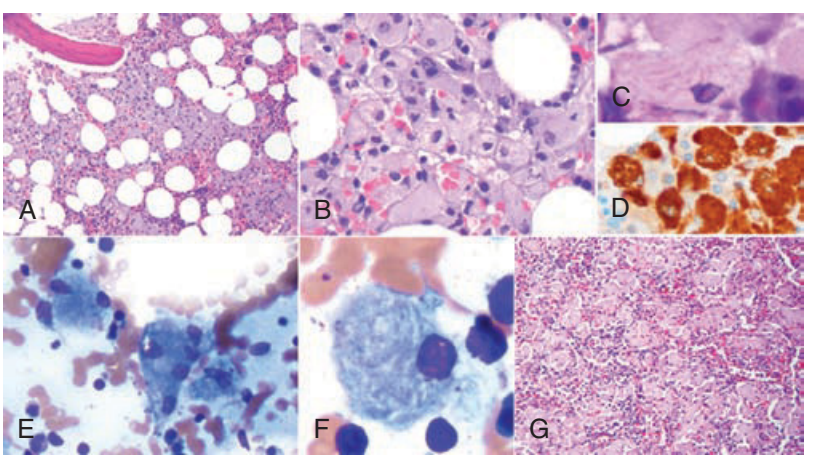

Figure 53–6 Gaucher disease: bone marrow biopsy, aspirate, and spleen: (**A**–**G**). The bone marrow space is filled with plump histiocytes (**A**, **B**) which at high power (**C**) show cytoplasmic fibrillary material producing striations. The cells are CD68 positive (**D**). The aspirated material shows clusters of similar histiocytes or macrophages (**E**), which at high power (**F**) illustrate the so-called crumpled tissue paper effect in the cytoplasm (Gaucher cell). The spleen, from a separate case (**G**), has pale clusters of similar histiocytes.

glycosphingolipids are known as sphingoid bases. These compounds are potent inhibitors of a variety of cellular enzymes including protein kinase C isozymes and other membrane proteins.[39,40] Sphingoid bases (lyso-glycosphingolipids) accumulate in Tay–Sachs disease, Sandhoff disease,[41] Krabbe disease,[42] and Gaucher disease type 2 and type 3.[43] The toxicity of sphingoid bases is the most clear-cut in Krabbe disease and Gaucher disease type 2. The excessive accumulation of galactosylsphingosine and glucosylsphingosine in these diseases, respectively, leads to the destruction of neurons within the brains of affected persons. Consequently, the CNS disease manifestations probably are the results of neuronal loss and death rather than the storage of galactosyl- or glucosylceramide per se. In Gaucher disease type 1, small amounts of glucosylsphingosine are known to accumulate in visceral organs and may be related directly or indirectly through cytokines[44,45] to the fibrosis in liver, spleen, and bone marrow of affected patients.[46] The increase in cytokines could provide a unifying pathophysiologic basis (ie, cell death and scarring) for the manifestations of Gaucher disease. In Tay–Sachs disease, ganglioside G_{M2} and lyso-ganglioside G_{M2} accumulate.[41] The formation of meganeurites in TSD indicates that at least one of these stored substrates may alter the growth and development of neurons, as well as accumulating in lysosomes.[47]

In some categories of lysosomal diseases, characteristic pathologic patterns are present. In MPSs I, II, and VI, a pattern of bone abnormalities known as *dysostosis multiplex* is observed, as well as short stature and degenerative joint disease. In cultured articular chondrocytes from rats and cats with MPS VI, increased nitric oxide release and tumor necrosis factor-α (TNF-α) secretion were observed; this phenomenon could be reproduced by exposing normal cells to dermatan sulfate, suggesting that the increased chondrocyte death observed in affected animals might be due to metabolite exposure or inflammatory cytokines.[48] Decreased formation of insoluble elastin can be demonstrated in both Hurler fibroblasts and those from certain forms of MPS IVb, suggesting mechanisms for coronary artery disease or joint disease in some of these conditions.[49] The enormous variation in clinical manifestations in each of these lysosomal storage diseases is of major clinical relevance. Each disease has very severe, rapidly progressive variants, and more attenuated variants that are late in onset, mildly symptomatic, and, in some cases, nearly normal phenotypes.[50,51]

MOLECULAR GENETIC MECHANISMS OF LYSOSOMAL STORAGE DISEASES

The molecular mechanisms that result in the lysosomal storage diseases are as varied as the diseases. The following mechanisms have been identified:

- Deficiency of a single hydrolase, predisposing to multiple phenotypes
- Deficiencies of multiple lysosomal proteins mediated by a single gene defect
- Specific in vivo substrate accumulation with intact in vitro hydrolase activity
- Absence of functional lysosomal hydrolysis with intact hydrolase activities
- Lysosomal membrane transporters of specific metabolites

Single Gene, Multiple Phenotypes

The vast majority of the lysosomal storage diseases result from mutations at single loci that involve a single gene product and are either point mutations or deletions/insertions in genes encoding subunits of particular proteins. Missense or nonsense mutations result in the production of proteins with abnormal catalytic function, stability, or processing. For many of these mutations, an abnormal protein with low enzyme activity is synthesized. For example, numerous mutations have been described at the respective loci for Gaucher disease, Fabry disease, or Tay–Sachs disease. These mutations have differential effects on enzyme stability, catalytic activity, and effector interactions (reviewed by Beutler et al[52]). Because Gaucher and Tay–Sachs diseases are found at high frequencies in the Ashkenazi Jewish population, a few common mutations would be expected as a result of either founder effect or selective pressures. The phenotypical variation in these two diseases represents a continuum of degrees of involvement or age at onset of symptoms. For Gaucher disease, this continuum extends to the asymptomatic population. Approximately 50% of affected Ashkenazi Jews with the *N370S/N370S* genotype are minimally symptomatic and never come to medical attention.[53,54]

By comparison, two completely different disease phenotypes appear to result from the same enzymatic deficiency due to mutations at the β-galactosidase locus: the G_{M1} gangliosidoses and Morquio syndrome type B (MPS IVB). In the former, ganglioside G_{M1} accumulates preferentially in the CNS and mucopolysaccharide metabolites in the visceral organs.[55] In Morquio syndrome type B, keratan sulfate accumulates in visceral organs, leading to skeletal dysplasia and abnormal connective tissue properties (eg, hypermobility). The CNS is not directly involved. These very different phenotypes result from mutations in structural loci for β-galactosidase, affecting different protein domains of β-galactosidase.[55,56] Thus, mutations in single lysosomal polypeptides can result in multiple disease variants that differ in molecular etiology. The severe infantile variant (G_{M2} gangliosidosis) can be associated with a protein that poorly interacts with its protector protein (see later) and is rapidly degraded. The later-onset variant has a protein peptide that can be improperly targeted, with little enzyme routed to the lysosome. The MPS IVB protein binds to protector protein, is properly routed to the lysosome, but exhibits little catalytic activity toward keratan sulfate.[57]

Single Gene, Multiple Enzymes

Several lysosomal hydrolases are multimeric or occur as multienzyme complexes. A mutation in a component of the multienzyme structure or a common subunit could result in selective deficiencies of individual enzyme components or in all of the components of the complex, respectively. Tay–Sachs disease and Sandhoff disease are typical examples of heteromeric proteins in which distinct phenotypes result from mutations in different subunits. β-Hexosaminidase A is composed of α- and β-chains, whereas β-hexosaminidase B is composed of only β-chains. Mutations at the α-chain locus result in Tay–Sachs disease (β-hexosaminidase A deficiency), whereas those in the β-chain result in Sandhoff disease (β-hexosaminidase A and B deficiencies).[58] Because the substrates for β-hexosaminidase B occur in the viscera and those for β-hexosaminidase A, that is, ganglioside G_{M2}, occur predominantly in the CNS, Sandhoff disease has manifestations in the CNS and in the viscera. The β-galactosidase–neuraminidase–protector protein complex is more complicated. Isolated deficiencies of each of these enzymatic components have been described.[55,59] Neuraminidase deficiency results in sialidosis, a glycoprotein storage disease, and protector protein defects result in deficiencies of both β-galactosidase and neuraminidase. The so-called protector protein is a protease that attaches to the neuraminidase–β-galactosidase complex at some time during synthesis and "protects" this complex from inactivation or degradation.[23] Thus, point mutations in the protector protein can lead to galactosialidosis, a triple enzymatic deficiency producing variable phenotypical effects.[60]

A unique and important example of a mutation in a nonlysosomal enzyme causing multiple enzyme deficiencies is multiple sulfatase deficiency (MSD). In this disease, hydrolysis of sulfated mucopolysaccharides and glycolipids is impaired, and a phenotype is produced that resembles a composite of metachromatic leuko-

dystrophy (arylsulfatase A deficiency), MPS II (iduronate sulfatase deficiency), and ichthyosis (microsomal steroid sulfatase deficiency). Because the structural genes for the sulfatases are not involved, a co- or posttranslational modification defect common to cellular sulfatases was suspected. By direct analyses of cellular sulfatases, von Figura and coworkers showed that active sulfatases require a specific posttranslational modification of a conserved cysteine. An enzyme is required to modify this cysteine to 2-amino-3-oxopropionic acid that acts as a carrier of the sulfite group at the active site of sulfatases. MSD cells are deficient in this posttranslational process.[61,62]

Normal In Vitro/Deficient In Vivo Substrate Cleavage

Mutations in protein activators or cofactors necessary for the catalytic activities of a variety of glycosphingolipid hydrolases result in diseases that are phenocopies of particular enzyme deficiencies. For glycosphingolipid hydrolysis, five such protein activators have been described. Four of these, termed saposins A, B, C, and D, are encoded by a single locus on chromosome 10 (see Fig. 53–3). The G_{M2} activator required for catabolism of ganglioside G_{M2} by β-hexosaminidase A is encoded by a locus on chromosome 5.[63] The hallmark of the saposin deficiencies is the accumulation of specific lipid substrates for a suspected deficient enzyme activity but normal in vitro activity of the associated enzyme. Gaucher-like diseases due to deficiencies of saposin C and prosaposin have been described.[64,65] Metachromatic leukodystrophy-like diseases result from saposin B deficiency,[66,67] and Tay–Sachs-like diseases are due to G_{M2} activator deficiencies.[68] Of these saposin deficiencies, the defects in the prosaposin locus are particularly interesting. Each of the saposins A, B, C, and D participates in the hydrolysis of a variety of glycosphingolipids (see Fig. 53–4). These saposins are believed to participate in specific interactions with the cognate enzyme in glycosphingolipid catalysis,[69] in ganglioside transport,[70] and in substrate presentation. As expected, the deficiency of prosaposin leads to a complex disorder mimicking the deficiency of several glycosphingolipid hydrolases.[71] Of importance, the in vitro activities of the corresponding enzymes are nearly normal in tissues from patients with the saposin defects. It is anticipated that several other activator or cofactor molecules, required for the assistance in hydrolysis of complex macromolecules, will be discovered in the future.

Intracellular Deficiencies/Extracellular Excess

I-cell disease exemplifies the impact on lysosomal enzymes of mutations at loci for nonlysosomal proteins. The enzyme, *N*-acetylglucosamine-1-phosphotransferase is required for the attachment to many lysosomal proteins of the M6P ligand-sorting signal.[8,10] Mutations at the loci for subunits encoding this enzyme result in the absence of the M6P ligand and the secretion into the media of most soluble lysosomal enzyme proteins. The lysosomes are nearly devoid of M6P receptor-targeted enzymes. Consequently, the phenotypes resemble a mixture of various mucopolysaccharide, glycoprotein, and glycosphingolipid degradation defects due to the loss of many enzymes and proteins involved in the respective catabolic pathways. Because some of the membrane-bound proteins of the lysosome are targeted through M6P-independent pathways, they are retained within the lysosomes. Their catalytic activity may be affected, however, by the loss of activator proteins and other lysosomal components, which require the M6P receptor-mediated sorting.

Lysosomal Membrane Transporters of Specific Metabolites

For recycling and use, metabolic products of the hydrolytic reactions within the lysosomes require movement out of the lysosome and into the cytoplasm. The defective transport of such metabolites has been discovered to lead to specific disease phenotypes. Of importance to the hematologist is Niemann–Pick disease type C1 (NPC). This disease is associated with a specific defect in the transport of free cholesterol across the lysosomal membrane and into the cytosol. The deficiency of this transporter leads to the accumulation of free cholesterol within the lysosomes in visceral tissues, lack of negative feedback of cholesterol synthesis within cells, and accumulation of sphingolipids, particularly within the brain and macrophages. The connection of this accumulation and CNS deterioration requires elucidation. Histologically, the bone marrow and other tissues contain numerous macrophage storage cells and "sea-blue histiocytes." The molecular description of NPC indicates that additional lipid storage diseases may be associated with transport deficiencies that will require characterization in the future.[72,73]

GENOTYPE–PHENOTYPE CORRELATIONS

Implicit in the threshold hypothesis is a relationship between the level of enzymatic activity in cells and the phenotype expressed in the tissues. Consequently, for lysosomal storage diseases and other inherited defects, investigators have attempted to relate genetic mutations to phenotypical manifestations. For three lysosomal storage diseases, good, albeit imperfect, correlations have been obtained: metachromatic leukodystrophy (MLD), Tay–Sachs disease, and Gaucher disease. In each of these disorders, major variants include rapid-onset to slowly progressive-onset types. In MLD, combinations of two mutant arylsulfatase A alleles account for a majority of infantile, juvenile, and adult-onset variants of this disease.[74–76] The presence of two copies of a null allele (splicing defect in intron 2) results in a severe infantile disease. By comparison, homozygotes for a P426L substitution develop an adult-onset disease. The combination of a null and P426L mutant alleles can lead to a juvenile-onset variant. These results correlate well with the measured in situ lysosomal cleavage of exogenously supplied sulfatide substrate.[8] It is noteworthy that a very common "pseudodeficiency allele" at the arylsulfatase A locus results in deficient activity toward artificial substrates as measured in vitro, whereas the in vivo flux of sulfatide is low-normal in these cells. This mutant allele contains an altered polyadenylation signal in the 3′ untranslated region leading to inefficient polyadenylation and a decrease in available messenger RNA (mRNA) for protein synthesis. In combination with the glycosylation or null alleles for MLD, persons with a pseudodeficiency allele appear to be deficient for arylsulfatase A activity and would be expected to develop MLD symptoms, but they are asymptomatic. Because this pseudoallele is present in 10% to 15% of the population, it is important to exclude its presence in suspected MLD families, particularly before the institution of therapies.[74] Disease-causing mutations can occur on the background of the pseudodeficiency allele. Thus, the detection of the pseudodeficiency mutation does not exclude a disease mutation on the same allele. In situ measurement of sulfatide cleavage is required to ensure proper diagnosis, and interpretation can be difficult.[77] The pseudodeficiency alleles for β-hexosaminidase A[78] and α-L-iduronidase[79] raise similar concerns.

In Tay–Sachs disease combinations of null and missense mutations produce varying levels of β-hexosaminidase A deficiency that lead to clinical forms with differing rates of progression. The most common allele in the Ashkenazi Jewish population is a 4–base–pair insertion that results in the production of a nonfunctional mRNA—that is, a null allele resulting in the total lack of α-chains for β-hexosaminidase A synthesis. By comparison, the missense mutation leading to a glycine 269 to serine (G269S) substitution produces residual β-hexosaminidase A activity and a more slowly progressive disease. The onset of neurodegeneration and dementia occurs between adolescence and adulthood.[80] As in MLD, the combinations of null mutations with those that lead to partially functional enzymes lead to the different ages at disease onset. In these disease variants, neuronopathic manifestations are progressive, and the rate of deteriora-

tion correlates inversely with the in situ level of enzyme activity from 0% to 5% of normal.

By comparison, all Gaucher disease types are associated with residual enzymatic activity within cells. Although good correlations have not been obtained between the level of in vitro enzymatic activity of acid β-glucosidase and the disease phenotype, improved correlations have been found when in situ lysosomal glucosylceramide cleavage is estimated.[81] Within this more physiologic environment, lower levels of residual activity were found in the more severe type 2 and type 3 variants than in the type 1 nonneuronopathic variants. Unlike in the Tay–Sachs and MLD variants, the genotype-phenotype correlations in Gaucher disease relate to the presence or absence of neuronopathic disease, not the delayed onset of CNS involvement (reviewed by Agmon and colleagues[81]).

Gaucher disease is the prototype for lysosomal storage diseases in which several thresholds of substrate flux are apparent. The first threshold is for the preservation of normal glucosylceramide metabolism. This threshold (approximately 50% of normal) is apparent in carriers, because they do not develop disease manifestations or have Gaucher cells in their tissues. The next level is that in affected homozygotes who are enzyme deficient (levels <20% of normal) and are relatively mild to asymptomatic. These patients have enzyme deficiency and Gaucher cells in their bone marrow, but minimal to no disease involvement. The next threshold is for children, adolescents, or young adults with significant to severe visceral manifestations and shortened life spans. Within this group of persons with type 1 disease, the presence of the N370S and other disease alleles modifies the disease expression. Although the degree of involvement is highly variable, it is less severe in homozygotes for N370S, some of whom are asymptomatic. Indeed, approximately 50% of N370S homozygotes in the Ashkenazi Jewish population are minimally symptomatic to asymptomatic.[53] By comparison, the N370S/null allele genotype usually leads to a very severe, but nonneuronopathic, disease course. The next threshold is for the development of neuronopathic disease. Within this group are patients with type 2 and type 3 disease; type 3 patients have later onset of neuronopathic manifestations. Among type 3 variants there is significant heterogeneity, with two different subtypes of neuronopathic disease designated 3a and 3b.[82] From studies of in situ glucosylceramide metabolism, as well as genotype analyses among homozygotes for the L444P mutation, the type 3 patients appear to have significantly greater flux of glucosylceramide through their fibroblasts than that in type 2 patients. The most severely affected type 2 patients may have one L444P mutation and an additional allele that is null, or two null alleles. The latter leads to an early lethal phenotype termed the collodion variant. These thresholds are relative, because even in normal persons, the massive substrate load presented by acute myelogenous leukemia (ie, leukocyte membranes) leads to the presence in bone marrow of Gaucher-type cells in patients with completely normal enzymatic activity. Thus, not unexpectedly, other factors or genes can modify the disease expression, even in patients with the same genotype. These factors or genes have yet to be identified, and the role of ethnic or racial background on disease expression requires definition.

From a practical view, the level of residual enzymatic activity could determine the eventual need for enzyme or gene therapy. In patients with substantial amounts of residual enzymatic activity, such as symptomatic N370S homozygotes, less total enzyme may be needed than in patients who have the genotype N370S/null or other severely compromised alleles. The former patients can supply significant amounts of endogenous enzymatic activity for the cleavage of glucosylceramide and may have lesser needs for exogenous enzyme. For other lysosomal diseases, calculations based on in situ activity of enzymes indicate that very small differences in the quantity of enzyme in cells have major impacts on the phenotype.[29,83] Exogenously supplied enzyme might also influence the onset of specific organ, tissue, or cellular disease manifestations. The findings in Tay–Sachs disease, MLD, and Gaucher disease variants anticipate those in other lysosomal storage diseases. Clearly, mutation analysis for the defective gene alone will not provide an accurate prognosis. Considerable intrafamilial variations exist among affected members with these diseases. This variability makes it difficult to counsel and prognosticate from historic family data.

THERAPEUTIC APPROACHES AND IMPLICATIONS

The threshold hypothesis implies that small amounts of enzymatic activity may be sufficient for prevention of various disease manifestations in the lysosomal diseases. During the past 2 decades, two major approaches have been exploited to reach these thresholds and correct the underlying metabolic defects: (a) direct enzyme therapy in which a specific, pure, lysosomal enzyme that is missing is delivered and (b) transplantation of normal organs or cells to supply the missing normal enzyme. For the latter strategy, bone marrow, liver, spleen, or skin cells, natural or gene enhanced, could act as metabolic or enzyme pumps for delivery of enzyme to the plasma for uptake at distant sites, to contiguous host cells, or for direct replacement and correction of specific cell types. Both of these approaches require receptor-mediated endocytosis effected through specific recognition in the target sites of pathology. This approach implies the need to correct only specific cell types, such as those using the specific receptor system or derived from bone marrow precursor cells. The normal enzyme could be supplied to deficient cells through partially corrected cell populations (chimerism) or by the administered enzyme. This therapeutic strategy applies to enzymes that are soluble or can be solubilized into plasma or interstitial spaces. For membrane-bound proteins, cell–cell contact (ie, metabolic cooperation) may be required for the direct transfer of the enzyme with subsequent targeting to the lysosome. This mechanism may constrain delivery of the enzyme only to cells in direct proximity to the nondeficient cell and could lead to nonuniform correction. In diseases in which the target sites of pathology may be distant from the sites of synthesis of a membrane-bound protein, delivery of enzymes through a secretory pathway will not work, and alternative strategies will be required for delivery of enzyme. Thus, the approach with enzyme therapy or cellular transplantation strategies is disease dependent and requires knowledge of enzyme distribution and intra- and intercellular transport.

Substantial amounts of accumulated substrates in various tissues may be of exogenous origin—that is, transported from distant sites and deposited in lysosomes within particular sites of pathology. Consequently, depletion of the plasma pool of these accumulating substrates may lead to a reequilibration of previously stored material from tissue sources into the plasma. Although this mechanism is hypothetic for most diseases, in Fabry disease, previously stored substrate can be mobilized from tissue storage sites. Such a depletion mechanism has obvious therapeutic implications and implies an interaction of several organs and cell types in phenotypical development. In the neuronopathic Gaucher disease phenotypes, some accumulating substrate in adventitial layers of CNS blood vessels is derived from visceral sources.[83] Depletion of substrate from these visceral sources might lead to a modified progression of the phenotype, depending on the impact of this pathologic process on CNS function. This depletion approach has not been exploited in many of the lysosomal storage diseases, because little is known about glycosphingolipid, mucopolysaccharide, and glycopeptide systemic trafficking. If such depletion and reequilibration can occur, the delivery of particular enzymes for specific diseases to the target sites of pathology may not be essential, and transport of soluble disease metabolites from tissues might prove efficacious alone or in combination with enzyme reconstitution.

The implications for genetic therapeutic approaches to the treatment of lysosomal storage diseases are clear. If the deficient enzyme must be delivered directly to the target site of pathology, transplantation of the appropriate stem cell containing the appropriate genes is attainable in select visceral tissues. The macrophages/monocytes of liver, spleen, bone marrow, lungs and other reticuloendothelial tissues can be replaced with normal cells using BMT. Thus, irrespective of the complex practical and theoretical issues surrounding gene therapy approaches, gene transfer into bone marrow progenitor stem cells of

the affected persons should prove efficacious. Of note, metabolites might not reequilibrate out of brain rapidly enough to prevent the manifestations of the disease in the CNS. In that case, the enzyme or cells would need to be delivered to the CNS or areas that are pathologically involved. The delivery of macromolecules, cells, and recombinant viruses to the brain has proved to be difficult and continues as a significant barrier to the development of gene delivery for neurologic diseases, as it has been for their enzyme therapy.

Animal models of human lysosomal storage diseases are essential to the continuing development of therapies and pathophysiology studies. Although numerous naturally occurring models have been identified in mice, rats, dogs, cats, cattle, and other species, targeted gene disruption techniques provide for the generation of null and missense mutations in any desired gene, particularly in mice. Although critical to applied and basic advancements, caution is needed in extrapolating data from such mice directly to humans. There are several examples of knockout mice[84] that have either no disease or lethal phenotypes and for which phenotypes do not correspond well to those in the humans. For the lysosomal storage diseases, the generated phenotypes have been similar to those in humans when similar mutations are compared, such as with Gaucher disease, Tay–Sachs disease, and Niemann–Pick disease type A. The presence or absence of alternative metabolic pathways in different species, however, can have a major impact on the phenotype or the efficacy of a therapeutic intervention.

RESULTS AND LESSONS FROM THERAPY

The principal objective of therapy is to reconstitute a balance between substrate accumulation and degradation, with the therapeutic set point below the threshold of pathology for all involved tissues. The accumulated experience of 20 years has focused on BMT for a number of disorders and enzyme replacement therapy (ERT) for Gaucher disease. In recent years, additional ERTs have become available (Fabry disease and MPS I) and therapeutic augmentation through substrate deprivation or enzyme enhancement has been explored in animal models and clinical trials (Table 53–3). These experiences are critically important to the development of future strategies for lysosomal storage disease. Based on the pluripotency of bone marrow stem cells, most transplantation studies have focused on these cells. The isolation and characterization of stem cells from other organs, including neuronal stem cells, have been encouraging and may provide pluripotent sources of enzyme in the future. The expanding plasticity of such stem cells or bone marrow mesenchymal stem cells[85,86] suggests an expanded potential for multicell reconstitution, particularly neurons. As indicated in Table 53–1, various lysosomal storage diseases have preferential sites of pathology. However, all cells in the body are involved with the enzyme deficiency and most tissues can manifest symptoms and signs of these diseases. For BMT or other organ transplantations to be effective, the cells containing enzymes must be able to catabolize the supplied substrate. This ultimately depends on the mass of cells transplanted because each cell can synthesize only limited amounts of enzyme for supply to the body. Such considerations are particularly relevant for organs such as the kidney or liver, where the donor cells do not migrate from the organ.

Transplantation Approaches

Most lysosomal storage diseases are pleiotropic, and solid organ transplantation is rarely effective as a sole strategy, although kidney or liver transplantation may be necessary to replace a failing organ. Because all cells are enzyme deficient, and most tissues have some evidence of disturbed function from this deficiency (see Table 53–1), BMT has been widely applied as a therapeutic approach, with a variety of outcomes. For any transplantation therapy to be effective, the cells containing the enzymes must be able to catabolize accumulated and newly supplied substrate. This ultimately depends on the mass of cells engrafted, because each cell can synthesize only limited quantities of enzyme.

Animal and human studies identified a critical limitation to BMT, that of engrafting sufficient bone marrow-derived cells into brain substance. Insufficient data are available from autopsy or clinical material of humans who have undergone BMT to show conclusively the extent of biochemical or clinical improvement in the CNS; thus, data obtained from animal models are important in the design of therapies.

The MPS I dog results from a point mutation in the α-L-iduronidase gene leading to a truncated protein.[87] The visceral phenotype is similar to the moderately severe MPS IHS in humans, although the CNS storage resembles the more severe MPS IH. BMT from unaffected litter mates leads to functional and pathologic improvements in bony deformities, cardiac abnormalities, corneal

†"Investigational" indicates that clinical trials are under way in humans.

clouding, and hepatosplenomegaly of affected dogs.[88] The host hepatocytes were cleared of storage material, consistent with uptake of α-L-iduronidase from donor Kupffer cells. Vertebral and joint pathologies continue to progress, although at slower rates than in untransplanted affected dogs. The CNS effects were difficult to evaluate functionally, but lysosomal distention was decreased in glial cells, and there were various improvements in neurons.

The efficacies of BMT, enzyme infusions, and gene therapy have been compared in the MPS VII mouse, a naturally occurring strain with a single base deletion in exon 10 of the *gus* gene encoding β-glucuronidase.[89] BMT using marrow from syngeneic unaffected mice transplanted into irradiated MPS VII-affected mice increased life span and cleared storage material from liver, spleen, kidney, and cornea. Early BMT resulted in greater improvement in the skeleton and in auditory function, but neurologic and behavioral improvements were not demonstrated. The pre-BMT irradiation regimen was shown to directly affect CNS development in young mice, producing CNS dysplasia in these animals. In comparison, infusion of recombinant β-glucuronidase had no effect on the cornea and limited ability to slow the skeletal disease when initiated at 6 weeks of age. The combination of neonatal enzyme infusion, followed by later BMT, showed synergistic effects even though brain enzyme levels were restored to only 0.75% of normal, compared with 20% in the spleen of treated mice. Clearly, poor entry of enzyme into the brain, either by infusion or BMT, is a barrier. More recent attempts to treat the brain of these mice with gene therapy have used a lentivirus vector. Such experiments were successful in reducing storage within the CNS, accompanied by evidence of improvement in cognitive function.[90] The results indicate that reconstitution toward normal substrate flux may require very small amounts of enzyme. However, the threshold amount probably will prove to be disease and tissue dependent.

Conclusive outcomes of BMT in human lysosomal storage disease accrue only over many years. For many conditions, only limited numbers of patients have undergone transplantation, and rigorous long-term evaluation and appropriate natural history controls have been difficult to compile. For MPS I, however, greater than 800 patients have undergone transplantation procedures, and considerable data are available on these patients, both in the United States[91] and in Europe.[92] Durable engraftment of MPS I (severe phenotype) results in prolonged life, improved cardiorespiratory disease, dramatic reduction in hepatosplenomegaly, and, if transplantation is performed early, some protection of the brain. Skeletal disease remains a considerable problem, resulting in significant functional disability and sometimes death (Fig. 53–7). The neurocognitive outcomes in these patients depend on the age at transplantation and the pretransplantation developmental quotient (DQ). The trajectory of development does improve, even with BMT from unrelated donors, but the absolute mean developmental index decreases in 50%. The residual impairment appears to be multifactorial.

In assessing the comparative therapeutic effects in animals and humans, the effects of different genotypes at the disease-producing locus may be considerably greater in humans, in whom the genetic background variation is large compared with that in inbred animals. Nevertheless, responses to transplantation vary within and between disease types. The effects of cytoreductive therapy and graft-versus-host disease, and their interactions with the underlying disease, make the analysis of effectiveness even more complicated in humans, in whom controlled trials are difficult. Also, the therapeutic goals should be carefully delineated. In humans, the natural evolution of tissue lesions in many of the lysosomal storage diseases and, particularly in the brain and bones, are poorly documented. However, with time, these lesions probably become irreversible in a tissue-dependent manner, and a window of opportunity may exist for achieving reversal of disease manifestations in each disease. Once this disease-specific developmental threshold is passed, the damage to the brain or other organs may progress in spite of therapy. Progressive CNS involvement in Krabbe disease (human and murine) and Sanfilippo syndrome, and the worsening skeletal disease of MPS IH following BMT support this notion. In addition, the various levels of reconstitution

Figure 53–7 Skeletal deformities in a patient with mucopolysaccharidosis (MPS) IH more than a decade after bone marrow transplantation. Central nervous system function was nearly normal, but the axial skeletal disease continued to progress. Additional deformities of the long bones also were present but did not constitute the typical dysostosis multiplex of MPS IH. *(Courtesy of J. E. Wraith.)*

of metabolic flux in each tissue may lead to differing results in patients. For example, variable reconstitution in the CNS following BMT may convert infantile to juvenile MLD—that is, from an earlier-onset, severe abnormality to a later-onset progressive disease. BMT will have its greatest potential beneficial effects in diseases that are pathophysiologically derived from a single cell line that can be replaced by BMT. Gaucher disease is the prime example in which BMT "cures" the visceral lesions if instituted before irreversible damage in liver, spleen, lung, or bone marrow.[93–95] The visceral components of this disease derive from monocyte/macrophage-lineage cells. Clearly, BMT effects on the resolution and/or progression of signs and symptoms have been disease variant and stage-specific. BMT is probably not warranted in patients with severe irreversible pathology. Careful baseline evaluation, selection, and follow-up evaluation of patients will be required to assess the therapeutic impact of BMT in the individual lysosomal storage diseases.

The results of transplantation of other organs in these diseases including the liver, kidney, and spleen have been limited. In those diseases that result from soluble enzyme defects, hepatic, splenic or other solid organ transplantation may be beneficial if sufficient amounts of enzyme can be synthesized and secreted for delivery to distant sources. In comparison, diseases such as Gaucher disease where the enzyme is not normally secreted, transplantation of liver into such patients has resulted in the reaccumulation of Gaucher cells and redevelopment of pathology in transplanted livers.[96] These results indicate that hepatic transplantation alone is insufficient for preventing redevelopment of symptoms in such severely involved patients. Blood chimerism may develop following hepatic transplantation, because the donor liver may supply small amounts of enzyme and bone marrow-derived cells to recipient organs. In the absence of concomitant enzyme replacement therapy, patients receiving hepatic transplantation and small amounts of donor bone marrow may become chimeric and develop two populations of bone marrow-derived cells in their bodies: those that are normal and those that are not. At a low level of chimerism, the storage cells would be expected to accumulate in tissues and, in the absence of cross-correction, eventually result in recurrence of disease manifestations. Greater degrees of monocyte/macrophage chimerism could lead to improvement if the normal cells can prevent accumulation of end-stage Gaucher cells in tissues.[97]

Enzyme Therapy Approaches

Enzyme replacement therapy (ERT) has been available for treatment of Gaucher disease for more than a decade, and has been recently approved for treatment of Fabry disease, MPS I,[50] MPS II,[98] MPS VI,[99] and GSD II[100] (see box Management of Gaucher Disease) Clinical trials are ongoing for Niemann–Pick disease type B. Animal model studies have been published for some of these conditions, as well as for several additional diseases of human relevance.[84,101] With rare exceptions, enzymes for replacement therapy are produced by recombinant methods of gene amplification, resulting in enhanced production of the desired protein product. In most human clinical trials or treatment protocols, the enzymes have been infused intravenously every 1 to 2 weeks.

A significant concern in enzyme therapy is the development of antibodies to the exogenous enzyme. This has been assessed in both animal and human studies. MPS I dogs given recombinant canine or human α-L-iduronidase developed antibodies. Similarly, in dogs implanted with retrovirally transduced myoblasts expressing canine α-L-iduronidase, anti-iduronidase antibodies were produced, with eventual loss of the transduced cells in these animals.[102] In clinical trials of ERT for MPS I,[103] MPS II,[98] MPS VI,[99] Fabry disease,[104] and GSD II,[100] most patients developed antibodies and many developed infusion-associated reactions. It would be expected that the presence or absence of endogenous enzyme protein would alter the cadence and clinical significance of antibody development. These difficulties cannot be ascribed only to the presence or absence of endogenous enzyme protein, however, because 15% of treated Gaucher disease patients develop antibodies to administered enzyme, and all have

Management of Gaucher Disease

The clinical management and enzyme replacement/replenishment therapy (ERT) for Gaucher disease type 1 are complicated by the marked variation in phenotype and in the rates of disease progression. In addition, significant ethnic variation exists in disease severity, and the involved organ systems involved and their progression rates. Much of the literature has focused on the description of the disease in the Ashkenazi Jewish population that is skewed to the adult population of less severely involved patients with slower progression rates.[1,2] Recent studies have clearly shown that within other ethnic groups, and even within the Ashkenazi Jewish population, subsets of affected patients exist with more progressive and severe disease even within specific genotypes.[3] Homozygosity for a common mutation, termed N370S, in the Ashkenazi population can be associated with minimal symptomatology in many patients (approximately 50%). However, a significant number (approximately 30%) of children (<20 years) with this genotype have severe progressive disease.[4] Lacking genetic or validated biomarkers to provide prediction for eventual outcome or track disease progression also complicates treatment programs.

Comprehensive treatment plans are significantly influenced by the clinical context of individual patients. Recently, therapeutic goals or guidelines and timelines to the achievement of therapeutic effects have been developed and can be used to provide a background of therapeutic assessments.[5,6] Increases in hemoglobin and platelet levels, and splenic and liver volumes within the first 6 to 24 months of ERT provide instructive approaches to facilitate dosing and/or goal achievement. However, until recently, dose response characteristics have been lacking for ERT. An extensive analysis using statistical methods (propensity scoring) to diminish significant phenotypic variations show significant incremental dose responses between 15 U (0.375 mg) and 60 U (1.5 mg/kg) [Cerezyme™, imiglucerase, Genzyme Corp., Cambridge, MA] every 2 weeks for the above clinical parameters, as well as bone mineral density.[7,8] In these matched populations over a period of approximately 8 years, greater rates and total responses to enzyme therapy were found at the higher doses. These dose responses can provide guidance for physicians to the attainment of therapeutic goals and the relevant timelines. Such data also provide guidance for dose adjustments in patients who have inadequate responses to initiating doses. For example, in patients with severe thrombocytopenia and very enlarged spleens with extensive bone marrow infiltration and significant losses of bone mineral density, higher doses of enzyme could be chosen to initiate therapy to alleviate potential devastating consequences of severe involvement. On the other hand, adults who have slowly progressing disease over a decade or more, whose platelet counts have slowly decreased, and whose bone mineral density is slowing decreasing may do well on lower doses of enzyme. Either case requires careful follow-up monitoring of responses to ERT. For example, in the high-dose case with severe thrombocytopenia, a patient may be monitored very intensively for platelet values and other parameters to ensure that responses are adequate to avoid complications. Similarly, a patient with very large liver and spleen and mechanical interference with eating or breathing should be monitored carefully to ensure that adequate doses are given. For the patients with less severe involvement on the lower-dose ERT, good responses to therapy after 6 or 8 months might suggest dosage adjustments are not needed. These judgments can be conducted in conjunction with physicians with extensive experience in the management of many patients with Gaucher disease, because hard-and-fast rules cannot be made for each patient.

Some general recommendations can be made on the basis of specific judgments of the physician and the individual patient. Adults with more slowly progressing disease without major complications of Gaucher disease, for example, severe hepatic or splenic involvement or rapidly progressing bone disease, usually are instituted on approximately 30 U/kg every 2 weeks and therapeutic response monitored initially at 6 months. During that period of time, if the therapeutic goals are met, judgments can be made as to whether or not dosage should be decreased, and whether the goals are maintained on that new dose. This author rarely uses less than 20 U/kg every 2 weeks. This is based on clinical observations of a significant number of patients redeveloping progressive disease and/or symptomatology on lower doses. However, lower doses could be appropriate in certain adult patients. In children, the disease is generally more rapidly progressing with more severe involvement (eg, larger livers, spleens and degrees of anemia and thrombocytopenia),[2,4] a higher dose (60 U/kg every 2 weeks) is used to initiate therapy. Also, the clinical impression that bony disease progresses more rapidly during puberty gives impetus to using higher doses in children until the skeleton has matured. This author adjusts to lower doses once puberty has been completed and a mature skeleton has developed, if other parameters have responded well. The objective is to facilitate entrance of children into adult life with adequate bone structure and as normal other parameters to support a normal adult life.

Approximately 13% of patients (close to 500/4000) receiving ERT for Gaucher disease type 1 develop antibodies to the drug; approximately 50% of these develop adverse infusion-related events within 6 to 12 months of initiation.[9] The majority of these antibodies and adverse events disappear within 24 months of regular ERT and create no major problems. Infusion-related adverse events are usually managed with NSAID and/or antihistamines. Rare (3 or 4) patients have developed neutralizing antibodies that inactivate the enzyme with consequent redevelopment of disease signs. These patients have been tolerized by using high dose (120–240 U/kg every 2 weeks) enzyme therapy in combination with cytotoxic drugs although rigorous evaluation and development of protocols has not been undertaken.[10] In addition, IgE mediated anaphylaxis has resulted from ERT in one

Management of Gaucher Disease—cont'd

or two cases. These patients would be candidates for alternative forms of therapy, such as substrate reduction or bone marrow transplantation.

Because of the expense of therapy, the use of this resource to move children and adults to more normal lives can be accomplished within the framework of the therapeutic guidelines and goals. The next series of studies should evaluate the effect of enzyme dose on the achievement of therapeutic goals using a consensus severity score to match patients.

residual enzyme activity. Similarly, antibodies developed in cross-reacting immunologic material-positive ($CRIM^+$) patients with Pompe disease who were infused with recombinant human acid α-glucosidase as well as in patients with MPS HS and IS treated with α-L-iduronidase. These antibodies can lead to direct neutralizing effects[105] and, potentially, to misdirection or redistribution of enzyme to "nontherapeutic" sites.[106] From a clinical standpoint, antibody therapies appear manageable in terms of both efficacy and infusion safety, but must remain under scrutiny as ERT for other lysosomal storage diseases becomes a reality.

Enzyme therapy has been studied extensively in human Gaucher disease for more than a decade.[107,108] This therapy exploits the receptor for α-mannosyl-terminated oligosaccharides on the surface of cells of monocyte/macrophage origin. The membrane-bound human acid β-glucosidase is extracted from media of overexpressing Chinese hamster ovary cells, purified to homogeneity, treated with exoglycosidases to expose α-mannosyl groups, and intravenously administered to affected patients. Several independent studies have demonstrated the usefulness of this approach, and many patients have demonstrated excellent responses.[108–113] The population of reported patients is varied, and insight can be gained into responses for individual patients during treatment. Response to therapy varies significantly, but by 1 year of enzyme therapy, responses can include (a) an approximately 20% to 30% decrease in liver volume if the liver is initially enlarged, (b) an approximately 30% to 50% decrease in splenic volume, (c) an increase in hemoglobin level by 1.5 g/dL if the patient initially is anemic, with approximately 33% to 50% of such patients achieving normal hemoglobin levels, and (d) an increase in platelet counts. In many patients with massive or heavily scarred spleens, thrombocytopenia may persist for several years. For liver and splenic volume decreases and hemoglobin increases, approximately 50% of patients met or exceeded these responses by 1 year. Patients on higher doses have somewhat better responses in terms of decreased splenic volume than those on smaller doses, but dose–response relationships are highly individualized. Patients with massive splenic enlargement (>20-fold greater) in general have poor hematologic responses until the splenic volume decreases by 50% to 70%. This correlation suggests that there may be a threshold size of spleen for adequate hematologic response as a result of intrasplenic hemolysis and platelet consumption. The variation in response to enzyme therapy is great among patients and at different times during therapy in one patient. Consequently, continued follow-up and monitoring are required to evaluate responses and to initiate treatment changes. Guidelines for monitoring therapy are available.[114]

Hepatic and splenic changes are more rapid than those in the bone and lungs. One cannot exclude the possibility of a different dose-response threshold for each tissue. This is particularly concerning in light of the inability to discern bone or pulmonary changes during a period of rapid dose reduction while hematologic, hepatic, and splenic improvement rates are maintained. Data on the tissue, cellular, and subcellular distribution, or on the half-lives of the administered enzyme, are scarce. Evidence obtained in mice suggests that the enzyme has relatively low uptake by monocyte/macrophage cells,[115] with very different and distinct uptake and survival patterns in the bone marrow, liver, and lung.[111,116] Also, the cellular distribution of exogenous enzyme in affected patients is unknown, but the slowness of response to enzyme suggests that the pre-Gaucher cell compartment may be the major target for enzyme uptake. These "corrected cells" would then ingest Gaucher cells and degrade the contained glucosylceramide. Such a mechanism has implications for enzyme therapy of other lysosomal diseases.

In view of the high cost of enzyme therapy with all current infusion protocols, the timing of the initiation of therapy must be carefully evaluated. Highly symptomatic patients should begin therapy immediately. In addition, other patients with major hematologic and visceral involvement should receive high priority for therapy. Although bone disease appears to be the slowest to respond,[117] patients with substantial bone involvement are candidates for treatment to recover bone integrity and to prevent irreversibility of some bone damage. (see box Management of Bone Crises in Gaucher Disease). A more difficult decision must be made in presymptomatic patients whose susceptibility to major disease manifestations can be anticipated by genotype analysis.[53] Clearly, the issue of the timing and use of an apparently universally effective therapy must be carefully considered and evaluated as a potential preventive intervention. The major inhibition to the use of BMT for Gaucher disease is the risk of the procedure compared with that associated with enzyme therapy, for which the major barrier is cost. If the risk of BMT could

Management of Bone Crises in Gaucher Disease

Bone crises are the most devastating and frightening clinical complications of Gaucher disease type 1. Although the etiology and exact pathogenesis of the bone crisis are not well delineated, the final common pathway appears to be bone infarction. Such infarction leads to localized intramedullary edema and swelling with increased pressure, and occasionally localized erythema and swelling. These crises are exceedingly painful, can be incapacitating, and necessitate the use of narcotic analgesics or even general anesthesia to alleviate the pain. The caricature of the clinical bone crises is a localized episode that begins with an undefined period of a dull aching pain in a specific bone region with increasing pain to excruciating levels over a period of 3 to 4 days. The excruciating pain plateaus for 4 to 7 days with a subsequent period of gradual resolution that can extend from weeks to a month or more. The bone crisis can occur in any bone and in any region of a bone, but most commonly presents as AVN of the head and/or neck of the femur. The shaft of the femur, the head of the humeri, vertebral bodies and the ischial tuberosities of the pelvis can be involved. The immediate consequences of a bone crises, other than pain, are relatively minor. On x-ray or MRI, little evidence is present for structural change in the bone, that is, lytic lesions at the site of infarction. However, a technicium sulfur colloid or pyrophosphate nuclear scans will show a localized area absent blood flow in the acute painful phase. Over a period of several weeks to months, the involved area may develop lytic lesions evident on plain radiographs. That can heal to become normal bone or remain as isolated lytic lesions. Involvement of the heads of the femurs and humeri, or the infarction of vertebral bodies, can lead to functional impairment, need for joint replacement, and/or chronic degenerative disease. Less intense bone crisis episodes probably occur frequently in some patients with intermittent bone pain, but these are difficult to document.

The accompanying localized swelling, pain, and elevation of sedimentation rate, leukocytosis, and fever can simulate an osteomyelitis. Osteomyelitis needs to be excluded, because its occurrence can be life threatening and can be caused by difficult-to-treat organisms within the bone marrow.

Approximately 10% of patients with Gaucher disease experience at least one bone crisis during their disease course.[1] They are more common in children than adults, although the hip involvement with AVN is relatively more common in adults. Recurrent infarctions and/or structural alterations can lead to destructive secondary bony lesions collapse of the hip and the need for hip replacement. Treatment of the acute episode includes the exclusion of osteomyelitis and analgesic treatment as needed. Hyperbaric oxygen and corticosteroids have been tried with variable success.[2] On a short-term basis, high-dose corticosteroids may be beneficial, after osteomyelitis has been excluded, and do not pose any significant threat or complication risk to the patient. Data are lacking on the use of hyperbaric oxygen. Core decompression to alleviate the secondary edema, and reestablish more normal blood flow to the bone marrow, may be an alternative for some patients. Although not critically evaluated, this approach has been accomplished on numerous occasions to alleviate pain and higher intramedullary pressures. Core decompression must be done early in the crisis course and under completely sterile conditions, preferably in an operating room, to avoid secondary contamination and the development of osteomyelitis. The results of early intervention with core decompression suggest utility in selected patients.

An evaluation of bone pain and bone crises in patients who had follow-up for ERT showed that bone crises diminished dramatically within the first year of enzyme therapy.[3] Bone pain also decreased significantly, but a residual level of bone pain could not be alleviated by ERT. This is probably secondary to complications of irreversible bone disease rather than Gaucher disease itself. Thus, ERT has been shown to have significant effects on bone mineral density[4] and on the alleviation and prevention of bone crises.[3] ERT has no role in the acute management of bone crises but rather a preventive role.

be decreased dramatically, possibly through autologous BMT of corrected cells, this may become the treatment of choice.

Several difficult issues need to be resolved to promote optimal use of therapeutic strategies in the lysosomal storage diseases. There is extensive interpatient variability in dose response. What are the determinants of this variability? Will the effects of more easily accessed tissues be preferentially evaluated rather than those in more difficult, potentially more relevant, tissues? Will certain tissues require specific doses of enzyme that will determine overall efficacy of therapy? Is there a concomitant diminution in the need for intense therapy for continued improvement as the tissues are healed? Is there a role for combined BMT/ERT, for example, in MPS I? Most important, what is the window of opportunity for effective therapy? Is it more efficacious to prevent the disease manifestations than to attempt to return a very sick person, with potentially irreversible tissue damage, to health? This issue is particularly relevant for those disorders that involve the CNS.

CNS disease represents a substantial challenge to effective therapy. Although BMT remains the recommended therapy for severe (neuropathic) MPS I, the window of opportunity for clinically significant effects on cognitive function is relatively short. For early-onset neurodegenerative diseases, including Krabbe and Tay–Sachs diseases, even stem cell transplantation in the first weeks of life may not produce the desired level of CNS protection. Enzyme therapy for MPS III is feasible, but as demonstrated in mouse models, little of conventionally infused enzyme penetrates the blood–brain barrier.[118] Clearly, different approaches must be taken in significant CNS disease. Animal experiments have demonstrated expression of TPP-I (the defective protein in late-infantile neuronal ceroid lipofuscinosis [LINCL]) after direct injection of adenovirus vectors in mouse brain.[119] Using a cell-based approach to treat murine Niemann–Pick disease, Jin and colleagues demonstrated prolonged cell survival and a protective effect on Purkinje cells, but limited spread of the effect beyond the injection site.[120]

Substrate Deprivation

Substrate deprivation approaches have demonstrated a potentially more viable approach to CNS disease compared with current technically limited approaches to enzyme-, cell-, or gene-based therapy. The theoretical basis for this approach is the "supply side" of the threshold hypothesis, limiting inflow rather than enhancing outflow. Proof of principle was provided in animal experiments in which Sandhoff

mice were crossed with a knockout line lacking the ability to synthesize ganglioside G_{M2} de novo.[121] These animals demonstrated significant delays in onset of neurologic symptoms and prolonged life span compared with controls, although little effect was seen in animals with heterozygote levels of G_{M2} synthesis. Further pharmacologic attempts at synthetic inhibition have shown efficacy in Sandhoff[122] and Fabry mice,[123] and human trials for late-onset Tay–Sachs disease are in the planning stages. The results in human trials of Gaucher disease showed minor effects, with significant adverse event profiles.[124] The appeal of substrate inhibition, beyond its potential ability to affect the CNS, is that these drugs tend to be small molecules that can be administered orally and may have a therapeutic effect on more than one disease, a significant factor in these orphan conditions. However, the generalized effect has drawbacks, including side effects due to the more general pharmacologic activity and distribution.

Gene Transfer

Lysosomal diseases that can be treated successfully by BMT should be amenable to permanent correction by gene therapy using hematopoietic stem cells carrying a copy of the normal gene. Following autologous transplantation with these corrected cells, somatic genetic reconstitution could be achieved by the repopulation of tissues with monocyte/macrophage-derived cells. For diseases due to defects of soluble enzymes, only a portion of stem cells would need to be corrected, because the corrected cells could supply enzymes to other tissues. For diseases that result from membrane-bound enzymes, such as Gaucher disease, all or most of the cells would need to be corrected, unless the transduced cells exhibited a selective advantage. For either of these types of enzyme defects, the amount of enzyme supplied to tissues directly or via cellular replacement would be mass dependent, and insufficient amounts of enzyme or cells would lead to the redevelopment or delay of onset of symptoms and signs. Also, stem cells that produce active lysosomal enzymes do not have any obvious proliferative advantage over those that do not. Thus, therapeutic effects would be expected only if the patient's untransformed cells were ablated by chemotherapy or irradiation. Rational strategy for the treatment of these diseases would include marrow ablation followed by autologous transplantation with transformed hematopoietic stem cells. Considerable effort has been expended to develop the required efficient gene transfer technology and hematopoietic stem cell culture systems. Significant long-term expression of transgene has been accomplished for several of these enzymes.[125–128] Protocols for somatic gene therapy of lysosomal diseases will continue to be evaluated during the next several years.

Gene therapy studies in animal analogs have attempted to exploit targeted enzyme delivery and cell transplantation strategies. The objective of the former is to implant a continuous source of enzyme for delivery to distant sites. The latter approach attempts to replace the primary cells of pathologic involvement with gene-corrected cells. The major motivation for cellular replacement approaches in gene therapy is to avoid the real and potential immunologic barriers to tissue transplantation using allogeneic transplants of corrected cells. Overexpression of β-glucuronidase or α-L-iduronidase from retrovirally transduced fibroblasts, implanted as neo-organs, results in secretion of sufficient enzyme for detection in distant organs. The levels achieved in these enzyme-deficient organs are modest, up to 2% of control levels in liver, compared with those achieved with enzyme infusion or BMT, approximately 5% to 18%.[129] Immunohistochemical studies show detectability of the secreted enzyme only in periadventitial macrophages in the brain and not in brain substance, even though in vitro studies showed enzyme uptake into neuronal and glial cells. Many enzyme deficiency states are being approached similarly. The use of neuronal stem cell transplantation appears to have promise for neuronopathic diseases. Ideally, these cells would be pluripotent neuronal cells that when transplanted into neonatal or adult mice would migrate to specific brain regions and differentiate into appropriate neurons. These cells, allogeneic or "immunotolerized," could then replace diseased neurons or supply enzymes to neighboring diseased cells for metabolic correction. Initial animal studies are promising, but clinical trials are in the future. The recent development of leukemia in SCID patients who received corrected autologous stem cells has raised significant safety concerns.[130]

Pharmacologic Chaperone Approaches

In theory, point mutations lead to expression of mutant proteins with altered stability, folding, targeting, or catalytic activity. Those in the first three groups can accumulate the mutant proteins in prelysosomal compartments, including the endoplasmic reticulum or Golgi (*cis*, mid or *trans*). These accumulations can evoke a cellular response, particularly the ER stress response, endoplasmic reticulum-associated degradation response, or unfolded protein response.[131] If sufficiently severe, these responses promote cellular apoptosis and inflammatory responses that can propagate disease manifestations. Use of chemicals that can promote more appropriate folding and/or stability have been termed pharmacologic chaperones.[132–135] For the lysosomal storage diseases, the counterintuitive use of potent competitive, active site-directed inhibitors has been proposed as potential chaperones to direct the refolding and, potentially, retargeting of mutant lysosomal enzymes to enhance their delivery and targeting to the lysosomes, as well as their stability within the lysosomes (Fan). Several studies in tissue culture[134,135] have indicated that such compounds can lead to enhanced mutant enzyme refolding, activity, and/or stability of selected Gaucher disease enzymes. Intravenous galactose in high doses was used in one Fabry disease cardiac variant patient to alter the mutant α-galactosidase A with some clinical effect.[136] To date, additional in vivo studies in animal models or humans are needed to assess the clinical effectiveness of this interesting and promising approach across a broad spectrum of mutations that produce enzymes with partial activity.

CHAPTER 54

INFECTIOUS MONONUCLEOSIS AND OTHER EPSTEIN–BARR VIRUS-ASSOCIATED DISEASES

Stephen Gottschalk, Cliona M. Rooney, and Helen E. Heslop

INTRODUCTION

The initial clinical descriptions of primary Epstein–Barr virus (EBV) infections are credited to Filatov and Pfeiffer at the end of the 19th century. Pfeiffer coined the term *glandular fever*, which described an illness consisting of fever, malaise, sore throat, and lymphadenopathy.[1] In 1920, Sprunt and Evans introduced the term *infectious mononucleosis* (IM) describing a series of patients with fatigue, fever, lymphadenopathy, and prominent mononuclear lymphocytosis (Fig. 54–1).[2] Serologic diagnosis of IM became available in the 1930s with the heterophile agglutination test developed by Paul and Bunnel and later modified by Davidson.[3,4]

The identification of EBV as the causative agent of IM was impeded for many years by the inability to transmit the disease to animals or to grow the virus ex vivo. In 1958 Burkitt described a lymphoma in African children and investigators suspected an infectious etiology because the lymphoma's geographic distribution pattern coincided with the African mosquito belt.[5] In 1964 Epstein, Achong, and Barr described herpesvirus-like particles in tumor biopsies from Burkitt lymphoma patients.[6,7] Werner and Gertrude Henle developed an indirect immunofluorescent antibody assay to this new virus, now called Epstein–Barr virus, and showed that Burkitt lymphoma patients as well as 90% of American adults had antibodies against EBV.[8] In 1965 the Henles documented seroconversion to EBV of an individual who presented with clinical symptoms of IM.[9] This initial observation was corroborated by larger studies confirming the association of EBV and IM.

Since then EBV has been linked to a heterogeneous group of diseases.[10–12] EBV was the first human virus implicated in oncogenesis and the biology of the virus has been studied extensively on a cellular and molecular level.[7,12,13] Because primary EBV infection is a self-limiting disease in almost all individuals, therapeutic strategies have focused on the treatment of rare, potentially fatal EBV-associated diseases. Over the last decade, successful immunotherapeutic approaches have been developed for EBV-associated lymphoproliferative disease using either monoclonal antibodies or the adoptive transfer of EBV-specific T cells.[14,15]

BIOLOGY OF EPSTEIN–BARR VIRUS

EBV belongs to the family of herpesviruses, which has almost 100 members.[16] Membership is based on the architecture of the viron that is 120 to 300 nm in size and contains (a) a core of linear, double-stranded DNA, (b) an icosadeltahedral capsid with 162 capsomers, (c) an amorphous material between the capsid and envelope designated tegument, and (d) an envelope containing viral glycoproteins. Besides EBV, designated human herpesvirus 4, seven other herpesviruses have been isolated from humans: herpes simplex viruses 1 and 2, cytomegalovirus, varicella-zoster virus, human herpesvirus 6, human herpesvirus 7, and the Kaposi's sarcoma-associated herpesvirus (KSHV, human herpesvirus 8). Herpesviruses are further divided into subfamilies to reflect evolutionary relatedness and similar biological properties. EBV and KSHV belong to the human gamma herpesvirus subgroup and have a limited tissue tropism to B and T lymphocytes and certain types of epithelial cells.

Several variants of EBV have been identified by genomic polymorphisms. Initially, two EBV types were distinguished by sequence changes in EBV nuclear antigens 2 and 3 (EBNA-2 and -3). However, using polymorphisms in the latent membrane protein 1 (LMP-1) further subtypes have been described.[17] EBV strains vary by geography and have not been linked to a particular EBV-associated disease.

EBV-ASSOCIATED CLINICAL SYNDROMES

- Infectious mononucleosis[36]
- Chronic active EBV infection[60,164]
- Hemophagocytic lymphohistiocytosis[165]
- X-linked lymphoproliferative disease[78]
- Oral hairy leukoplakia[83]

PRIMARY EBV INFECTION

Primary EBV infection usually occurs through the oropharynx, where mucosal epithelial cells and/or B cells become productively infected (see Fig. 54–1).[18] Infection of B cells by EBV is initiated by binding of the dominant viral glycoprotein gp350/220 to CD21, the C3d complement receptor, and subsequent cell entry is mediated by a complex of three viral glycoproteins, gH, gL, and gp42. Gp42 binds to HLA class II, which functions as a coreceptor, and gH is most likely involved in virus–cell fusion.[19] The entry of EBV into epithelial cells may occur through multiple mechanisms because the majority of epithelial cells are CD21 negative.[20–22] After viral entry, the capsid is dissolved and the EBV genome is transported into the nucleus, where it circularizes. Infection of epithelial cells results in lytic or

EBV-ASSOCIATED MALIGNANCIES[119]

Malignancy	*EBV Frequency*
Hodgkin disease[166]	~40%
Non-Hodgkin Lymphomas	
Burkitt Lymphoma[167]	20%–95%
Diffuse large B-cell lymphoma and CD30$^+$ Ki-1$^+$ anaplastic large cell lymphoma[124,126]	10%–35%
Lymphatoid granulomatosis[168]	80%–95%
T cell-rich B-cell lymphoma[125]	20%
Angioimmunoblastic lymphoma[169]	>80%
T-cell, NK-cell, and T/NK-cell lymphomas[132,170]	30%–90%
Nasopharyngeal carcinoma[154]	>95%
Gastric adenocarcinoma[171]	5%–10%
Pyothorax-associated lymphoma[172]	>95%
Leiomyosarcoma in immunocompromised patients[173]	>95%

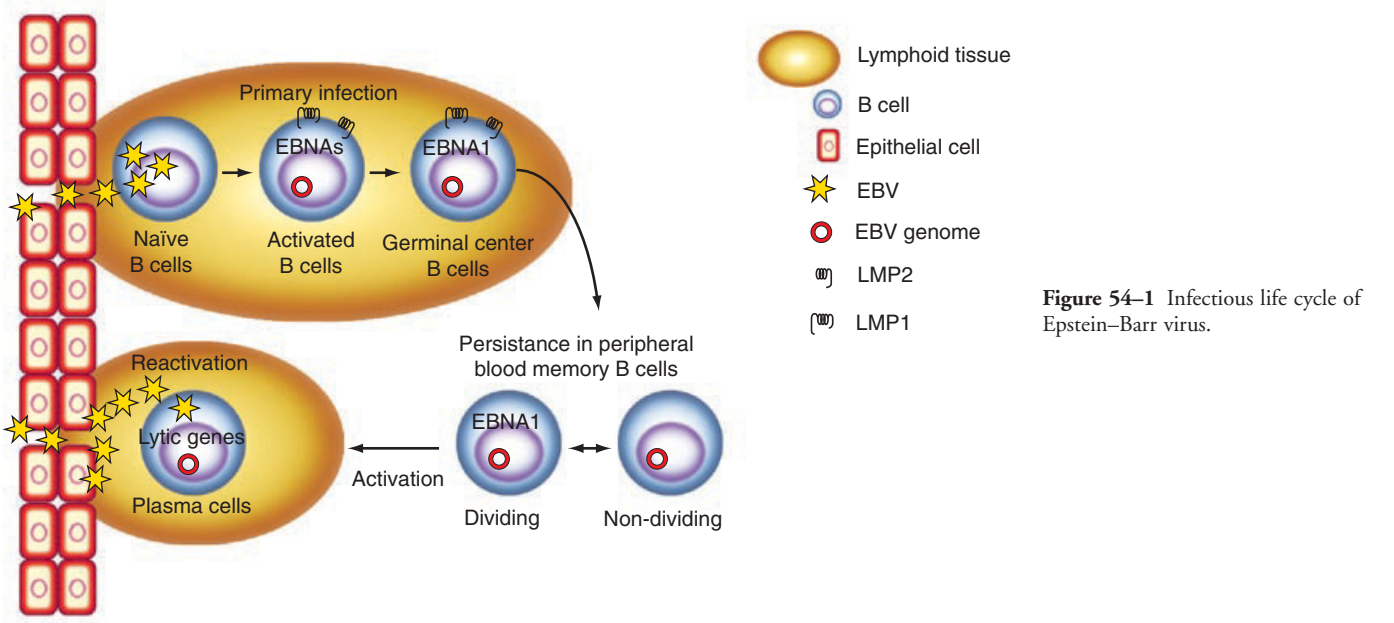

Figure 54–1 Infectious life cycle of Epstein–Barr virus.

abortive infection, and whereas B-cell infection results predominantly in latency, the lytic infection also occurs resulting in the release of infectious virus into the saliva and other secretions. During primary infection, EBV establishes lifelong latency in B cells and it is estimated that 1 to 50 cells per 1×10^6 B cells in the peripheral circulation are infected with EBV. The number of latently infected B cells within a person remains stable over years; however, intermittent reactivation of EBV in B cells into the lytic cycle at mucosal sites is probably responsible for the observed shedding of infectious virus into the saliva of asymptomatic carriers (Fig. 54–1).[12]

Although EBV can infect any B cell and express the full spectrum of latency proteins, extensive studies by the group of Thorley-Lawson have suggested that only infection of naïve B cells results in persistent infection (Fig. 54–1).[23,24] EBV infection pushes the naïve B cell into a memory state independent of an antigen-dependent germinal center reaction by upregulation of cytosine deaminase, which induces both class switching and somatic hypermutation. The former also requires the expression of EBV-encoded LMP1, a constitutively activated CD40 molecule, or CD40 ligation, most likely provided by germinal center Th3 cells that can provide T-cell help for B-cell differentiation by provision of CD40 ligand, IL-4, and IL-10 while preventing antigen-dependent effector T cell-mediated B-cell elimination by expression of TGF-β.[25] This reaction occurs within the lymph node and also involves downregulation of latency proteins and expression of latency type II. On exit from the lymph node, expression of latency proteins is completely inhibited. In this way infected B cells can evade immune elimination. By contrast, primarily infected memory B cells enter and remain in latency type III and are rapidly eliminated by effector T cells and therefore do not contribute to virus persistence.

LATENT EBV INFECTION

During latent infection, EBV persists episomally in resting memory B cells. Initially it was thought that EBNA-1 and LMP-2 is expressed in memory B cells; however more recent studies indicate that the majority of infected cells do not express viral proteins and that of the almost 100 viral proteins, only EBNA-1 is expressed during memory B cell division (see Fig. 54–1).[24,26] This extremely limited expression of viral proteins allows EBV to persist long term despite a robust cellular EBV-specific immune response.

Three other distinct types of EBV latency have been characterized in a heterogeneous group of malignancies (Fig. 54–2).[10–12] Latency type III, which can be readily produced by infecting B cells in vitro

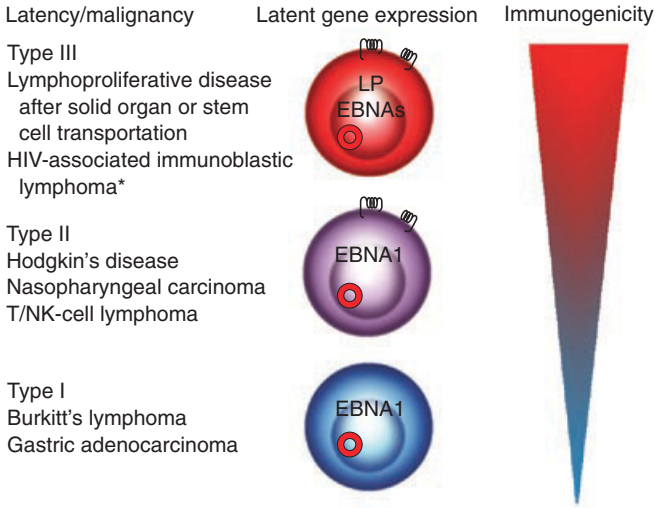

Figure 54–2 Epstein–Barr virus (EBV) latent gene expression and immunogenicity of common EBV-associated malignancies. EBNA: Epstein-Barr nuclear antigen, LP: leader protein. For explanation of symbols, see Fig. 54–1. *Not all lymphomas are latency type III.

with EBV, is expressed in lymphoblastoid cell lines (LCL). These cells express the entire array of nine EBV latency proteins: EBNAs-1, 2, 3A, 3B, 3C, EBNA leader protein (LP), and the two viral membrane proteins LMP-1 and LMP-2. This pattern of EBV gene expression characterizes the EBV-associated lymphoproliferative diseases (EBV-LPD) that occur in individuals severely immunocompromised by solid organ or hematopoietic stem cell transplantation, congenital immunodeficiency, or human immunodeficiency virus (HIV) infection. Latency type II is the hallmark of EBV-positive Hodgkin disease and non-Hodgkin lymphomas (NHL), and nasopharyngeal carcinomas.[11,12] EBV proteins expressed in these malignancies are EBNA-1, LMP-1 and LMP-2. In latency type I, found in EBV-positive Burkitt lymphoma and gastric adenocarcinomas, only EBNA-1 is expressed. However variants in which all EBNAs are expressed in the absence of LMP1 have also been desribed.[27]

The EBV proteins expressed during type III latency are involved in the transformation and growth of EBV-infected B cells. EBNA-1 binds to the origin of replication of the latent viral genome and is

Table 54–1 Frequently Determined EBV-Specific Antibodies

Antibody Specificity	Positive in IM (%)	Time of Appearance in IM	Persistence	Comments
Viral capsid antigen				
VCA-IgM	100	At clinical presentation	4–8 weeks	Highly sensitive and specific; of major diagnostic utility
VCA-IgG	100	At clinical presentation	Lifelong	Useful for documentation of past EBV infection
Early antigen				
Anti-D	70	Peaks 3–4 weeks after onset	3–6 months	Correlates with disease severity; seen in NPC patients
Anti-R	Low	2 weeks to several months after onset	2 months to >3 years	Occasionally seen with unusually severe cases; seen in African Burkitt lymphoma patients
EBNA	100	3–4 weeks after onset	Lifelong	Presence excludes primary EBV infection

EBNA, EBV nuclear antigen; EBV, Epstein–Barr virus; IM, infectious mononucleosis; NPC, nasopharyngeal carcinoma; VCA, viral capsid antigen.

responsible for the maintenance of the EBV episome in host B cells.[28] EBNA-2 upregulates the expression of the viral proteins LMP-1 and LMP-2 and cellular proteins that contribute to transformation. EBNAs-3A and -3C are essential for EBV-induced B-cell transformation, and although EBNA-3B is not essential for transformation it is highly conserved and therefore must provide a survival function in vivo.[29] EBNA-LP cooperates with EBNA-2 in the induction of viral and cellular genes. LMP-1, a viral oncogene, behaves like a constitutively activated CD40 molecule and is essential for EBV mediated B-cell transformation.[30] LMP-2 mimics an activated B-cell receptor (BCR) allowing for long-term B-cell survival in the absence of antigen. In addition it prevents the reactivation of EBV into the lytic phase of infection.[31]

In addition to EBV proteins, small nonpolyadenylated viral RNAs termed EBERs 1 and 2 and the BamHI-A rightward transcripts (BARTS) are expressed in all forms of latency. In addition, the expression of at least 17 distinct EBV-derived microRNAs has been reported.[32] The EBERs are the most abundant viral RNAs in latently infected cells. They enhance the oncogenic phenotype of EBV-transformed cells but are nonessential for EBV-mediated transformation.[33,34] The expression pattern of the microRNAs depends on the latency type and it is therefore likely that they play an important role during the life cycle of the virus.[32,35]

IMMUNE RESPONSE TO EBV

Healthy individuals mount vigorous humoral and cellular immune responses to primary EBV infection.[12,36] Although antibodies to the viral membrane proteins neutralize virus infectivity, the cellular immune response is essential for controlling virus-infected cells during both lytic and latent phases.

Humoral Immune Responses

Heterophile Antibodies

Heterophile antibodies, originally described by Paul and Bunnell, are present in 90%–95% of EBV infections at some point during the illness. However, in infants and children under the age of 4 with primary EBV infection, heterophile antibody responses are often not detected. Heterophile antibodies are IgM antibodies, which agglutinate erythrocytes from different species including bovine, camel, horse, goat, and sheep. EBV-induced heterophile antibodies have no reactivity against guinea pig kidney cells in contrast to naturally occurring antibodies (Forssmann antibodies) or antibodies present in patients with serum sickness and other conditions.

In addition to heterophile antibodies, cold agglutinins directed preferentially against the anti-I antigen on red cell membranes are frequently detected in the sera of IM patients; however, hemolytic anemia is rare. Other antibodies including anti-I, anti-N, Donath–Landsteiner antibodies, platelet antibodies and anti–smooth muscle antibodies have been described.

EBV-Specific Antibodies

EBV-specific antibody responses are detected with immunofluorescence assays developed in the first decades of EBV research. EBV antibodies are directed against (a) EBNA, (b) early antigen (EA), (c) the membrane antigen (MA) expressed on the surface of cells late in the lytic cycle, and (d) the viral capsid antigen (VCA) expressed within cells late in the lytic cycle.[37] Each antigen is a composite of several distinct viral proteins and attempts have been made to replace the above-mentioned assays with tests using specific viral proteins; however, no single test has attracted widespread use.

VCA-IgM and -IgG antibodies are usually present at the onset of clinical symptoms because of the prolonged viral incubation period (Table 54–1). VCA-IgM antibodies are a good marker for an acute infection because they rapidly disappear within 4 to 8 weeks. VCA-IgG antibodies persist for life and are commonly used to document prior EBV infection. IgG antibodies against EA are present at the onset of the clinical illness in approximately 70% of patients. EA antibodies are divided into methanol-sensitive (anti-D) and methanol-resistant (anti-R) antibodies, and the majority of EA antibodies detected are anti-D antibodies. The presence of anti-D antibodies is consistent with recent infection, because titers disappear after recovery. IgG antibodies to EBNA appear late in the course of almost all cases of EBV infection and persist throughout life and the presence early in a suspected case of primary EBV infection excludes the diagnosis. Aberrations in this pattern of serum reactivity are observed in many EBV-associated diseases and will be discussed under the specific disease sections. For example, the absence of EBNA antibodies despite previous EBV infection is one of the serologic markers suggestive for chronic active EBV infection (see section Chronic Active EBV Infection).

Cellular Immune Responses

In normal individuals primary EBV infection often results in a massive expansion of activated, antigen-specific T cells.[38–40] Using tetramer technology to enumerate antigen-specific T cells, it has been documented that the CD8 positive T-cell response may be dominated by T cells specific for a limited number of epitopes, as seen with T-cell responses against other herpesviruses.[40] T cells specific for epitopes derived from immediate early and several early EBV proteins of the lytic cycle are dominant during the acute phase of IM, and long-term persistence of EBV-specific, CD8-positive T cells has been documented after primary EBV infection.[12] As many as 5.5% of the circulating CD8-positive T cells in a healthy virus carrier may be

positive for a single EBV epitope, illustrating how persistent EBV infection can influence the composition of the host's T-cell pool.[41] Besides EBV-specific CD8-positive T cells, EBV-specific CD4-positive T cells play an important role in the control of EBV infections, and EBNA-1-specific CD4-positive T cells have been implicated in the control of newly infected B cells.[42] As for CD8-positive T-cell responses there is a marked hierarchy of immunodominance, with the majority of CD4-positive T cells' responses directed against EBNA-1 and to a lesser extent against EBNA-3C.[43,44]

EBV VACCINE DEVELOPMENT

At present there is only limited experience with human EBV vaccines.[12,45] In one study, nine seronegative children in Southern China were vaccinated with a recombinant vaccinia virus expressing the major EBV viral glycoprotein gp350.[46] All nine patients developed neutralizing antibodies and six patients remained EBV-negative over a 16-month period in contrast to none of the 10 controls. Another vaccine trial with a gp350 subunit vaccine has been completed but efficacy data are not yet available.[12] Although potentially ideal for preventing EBV-associated malignancies, vaccines providing life-long immunity against primary EBV infection may not be feasible because the type of immunity required to avoid repeated infection through mucosal surfaces is not clearly defined. Moreover, a recent study suggests that the natural immune response to EBV is not sufficient to protect healthy EBV-positive individuals from repeated infections with different EBV strains.[47]

Vaccine strategies for the immunotherapy of EBV-associated malignancies should seek to elicit or boost the EBV-specific cellular immune response against EBV latency.[48] Individuals likely to benefit from this approach are EBV-seronegative patients scheduled to undergo solid organ transplantation or patients who have an EBV-associated malignancy with a low tumor burden or are in remission. In a recent study to evaluate the latter strategy, sixteen nasopharyngeal carcinoma (NPC) patients with local recurrence or distant metastasis after conventional therapies received injections of dendritic cells pulsed with peptides derived from LMP2, one of the EBV proteins expressed in NPC. Peptide-specific T-cell responses were elicited or boosted in nine patients and a partial tumor reduction was observed in two patients.[49] In another trial, EBV-seronegative, HLA-B8 positive individuals were vaccinated with an MHC class I-restricted EBV peptide epitope derived from EBV latent viral protein EBNA-3A; the peptide vaccine was well tolerated but immunologic and virologic studies are pending.[45]

In the past, EBV vaccine development was impeded by the lack of a suitable animal model. Most vaccination studies so far have been done in cottontop tamarins, a species of New World monkeys that develop B cell lymphomas after intraperitoneal injection of EBV.[50] This model lacks key features of human EBV disease such as oral transmission and long-term viral persistence, which are considered to be important for vaccine development. Since 1997 a rhesus monkey model for acute and persistent EBV infection is available that takes advantage of the rhesus lymphocryptovirus, which belongs to the same herpes virus subgroup as EBV.[51] This animal model reproduces the salient features of human EBV infection, such as oral transmission, lymphadenopathy, atypical lymphocytosis, serologic responses to EBV proteins, and viral latency in B cells. In the future, this model has the potential to become a useful platform to test different vaccination strategies.

INFECTIOUS MONONUCLEOSIS

Epidemiology

EBV infections occur worldwide and in most populations 90% to 95% of adults have antibodies against EBV. Depending on geographic and socioeconomic factors, there is a wide variation in the age of primary EBV infections. Early, asymptomatic primary EBV infection occurs in individuals from lower socioeconomic groups and in third world countries. In higher socioeconomic groups in industrialized countries, the age of primary infection is often delayed until the second decade of life and clinically apparent IM is more prevalent.

Humans are the only source of EBV. EBV is present in the saliva of IM patients. A majority of EBV-positive adults shed virus into their saliva and this percentage is increased in immunocompromised patients such as solid organ transplant recipients. EBV is viable outside the body for 2 weeks at 4°C but is susceptible to drying; the virus has not been recovered from environmental sources, suggesting that close contact is needed for viral spread. The incubation period of IM is estimated to be 30 to 50 days.

Table 54–2 Clinical Manifestations of Infectious Mononucleosis

Manifestation	Percentage (Range)
Symptoms	
Sore throat	82 (70–88)
Malaise	57 (43–76)
Headache	51 (37–55)
Anorexia	21 (10–27)
Myalgias	20 (12–22)
Chills	16 (9–18)
Abdominal discomfort	9 (2–14)
Signs	
Lymphadenopathy	94 (93–100)
Pharyngitis	84 (69–91)
Fever	76 (63–100)
Splenomegaly	52 (50–63))
Hepatomegaly	12 (6–14)
Palatal enanthem	11 (5–13)
Rash	10 (0–15)
Jaundice	9 (4–10)

Adapted from Schooley RT: Epstein–Barr virus (infectious mononucleosis). In Mandell GL, Bennett JE, Dolin R (eds.): Principles and Practice of Infectious Diseases. Philadelphia, Churchill Livingstone, 2000, p 1599.

Clinical Manifestations

Primary EBV infection in infants and young children either is asymptomatic or accompanied by mild, nonspecific symptoms and signs such as fever, upper respiratory tract infection, pharyngitis with or without tonsillitis, and cervical lymphadenopathy. In contrast, approximately 50% of adolescents and young adults present with the clinical picture of IM. Frequently, a prodrome consisting of fatigue, malaise and low-grade fever is present for 1 to 2 weeks. Prominent pharyngitis with exudative tonsillitis is often the cardinal sign of IM; other signs and symptoms are listed in Table 54–2.[36,52] The adenopathy in IM most commonly affects the posterior cervical lymph nodes although diffuse adenopathy can occur. The enlarged lymph nodes are not fixed, may be tender to palpation, and lack overlying skin erythema. Hepatomegaly is uncommon; however splenomegaly develops in more than 50% of patients and is more prominent in the second to fourth week of the illness. Skin manifestations include a faint, morbilliform rash reminiscent of rubella and less commonly erythema multiforme and erythema nodosum. Most patients with primary EBV infection have symptoms for 2 to 4 weeks and recover without significant complication s or sequelae.

Complications of Primary EBV Infections

The incidence of complications associated with primary EBV infection is low, although any organ system can be affected.[53]

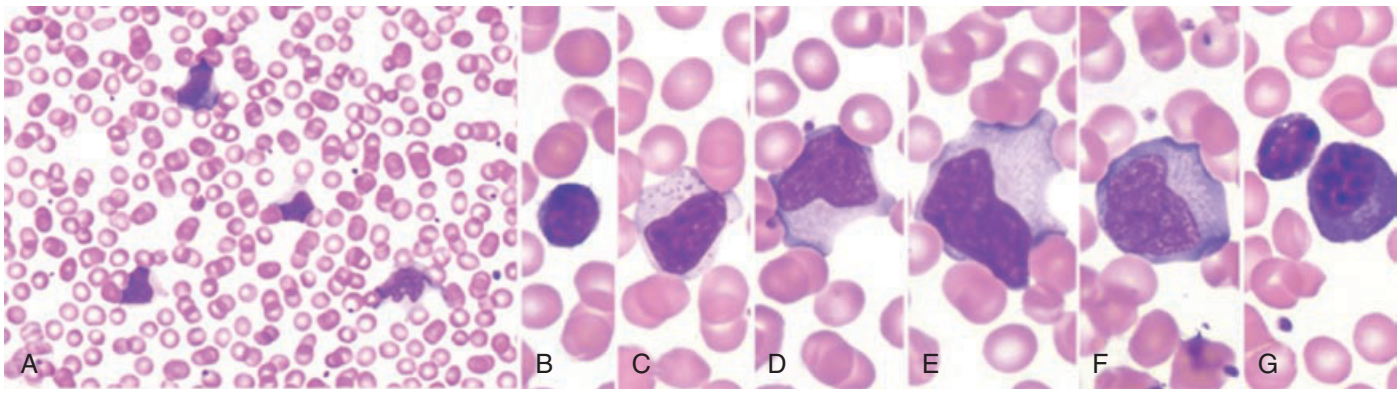

Figure 54–3 Peripheral blood smear in infectious mononucleosis (**A–G**). Low power (**A**) shows moderately high white blood cell count and high number of reactive, or "atypical" lymphocytes. Higher power (**B–G**) illustrates spectrum of lymphoid morphology, including small resting lymphocyte (**B**) for comparison, large granular lymphocyte (**C**), atypical forms (**D**, **E**, **F**), also referred to as "reactive" lymphs, and circulating plasma cell (**G**).

Hematologic Complications

Patients with IM may present with a wide range of hematologic findings besides the atypical lymphocytosis (Fig. 54–3). These include anemia, neutropenia, thrombocytopenia, and rare cases of aplastic anemia.[54]

Anemia

Autoimmune hemolytic anemia occurs in approximately 3% of patients with IM. It presents in the first 2 weeks of the illness, and the majority of patients recover within 1 to 2 months. Patients usually have a positive direct Coombs test. Most common anti-I antibodies are present; however anti-I, anti-N and Donath-Landsteiner antibodies have also been reported. In addition to hemolysis, IM-associated anemia can be caused by erythroblastopenia.

Neutropenia

Mild, self-limiting neutropenia is a common finding during the first 4 weeks of the disease. However severe neutropenia associated with fatal bacterial infections has been reported.

Thrombocytopenia

Mild thrombocytopenia (50,000–150,000/mm^3) is a common finding in patients with IM. It usually occurs within the first 2 weeks of presentation and resolves within 2 months. Severe thrombocytopenia with overt bleeding is rare; however, death from intracranial hemorrhage has been described. The etiology of the thrombocytopenia is not completely resolved, and a variety of explanations have been suggested. Because bone marrow examination shows normal or increased numbers of megakaryocytes, peripheral platelet destruction is most likely due to the presence of antiplatelet antibodies or platelet pooling and destruction within an enlarged spleen.

Splenic Rupture

Splenic rupture occurs predominately in males with an incidence of 1/1000 to 1/3000. The incidence of rupture is highest in the second and third week of illness and can be the first sign of IM. Clinical symptoms include abdominal pain or pain referred to either shoulder. Because abdominal pain is an unusual symptom of uncomplicated IM, a splenic rupture should be strongly considered in IM cases whenever abdominal pain is reported. Although a life-threatening complication, with current management the mortality rate is very low.[55]

Neurologic

Neurologic complications develop usually during the first 2 weeks of IM and can be the only manifestation of IM. EBV infection can cause a wide spectrum of neurologic diseases; including encephalitis, meningitis, Guillain–Barre syndrome, acute transverse myelitis, and peripheral neuritis. Patients with neurologic complications have an excellent outcome, with most patients having a complete recovery.

Other Organs

Although symptomatic heart disease with IM is uncommon, in one cohort of patients, unspecific ST- and T-wave abnormalities were found in 6% of patients. Renal involvement manifested as microscopic hematuria and proteinuria is seen in 10% to 15% of patients; however significant renal dysfunction is rare. Airway compromise due to hypertrophy of the adenoids and tonsils or mucosal inflammation and edema is uncommon but potentially fatal.

Diagnosis

Atypical lymphocytosis is the cardinal hematologic finding in IM (see Fig. 54–3).[54] It develops during the first week of the illness and peaks between the second and third week. Atypical lymphocytes represent 60% to 70% of the total white cell count, which ranges between 12,000/mm^3 and 18,000/mm^3. In general, the atypical lymphocytes are large and vary in size. Nuclei are large and eccentrically placed; the cytoplasm is basophilic and vacuoles are often present. The variable morphologic pattern of atypical lymphocytes in IM distinguishes them from the monotonous appearance of immature leukemic blasts. Atypical lymphocytosis is not pathognomonic for IM and is associated with other diseases like acute viral hepatitis, cytomegalovirus infections, mumps, toxoplasmosis, rubella, roseola, and drug reactions.

The diagnosis of EBV infection depends on serologic testing.[56] Tests for heterophile antibodies, including the monospot test and slide agglutination tests, are routinely available. The results of these tests are often negative in children less than 4 years of age, but they identify 90% of cases in older children and adults. Of the available EBV-specific serologic tests, VCA-IgM antibodies are most commonly determined to diagnose primary EBV infection in heterophile-negative IM cases; determining antibodies against EA may also be helpful (Table 54–1). VCA-IgG antibodies are positive during an acute infections as well as the convalescent period. The presence of anti-EBNA antibodies excludes an acute infection.[37] Isolation of EBV

from throat washings is feasible; however, it is of little diagnostic value because 10% to 20% of healthy adult EBV carriers may shed the virus.

Differential Diagnosis

In the majority of cases, the diagnosis of IM is straightforward. The differential diagnosis includes streptococcal and nonstreptococcal pharyngitis, acute infections with cytomegalovirus, human herpesvirus 6, hepatitis viruses, and toxoplasma. Depending on the presentation, other diseases may be considered such as HIV, rubella, and leukemia or lymphoma.

Treatment

Supportive therapy should include rest and analgesia in the acute stage of IM. Contact sports should be avoided until the patient has fully recovered and the spleen is no longer palpable. The use of corticosteroids is not indicated for uncomplicated IM; however, a trial of corticosteroids is warranted in patients with marked tonsillar inflammation and hypertrophy resulting in impending airway obstruction.[57] Although acyclovir reduces EBV shedding into oral secretions, treatment of IM with acyclovir has resulted in no clinical benefit.[58,59]

OTHER EBV-ASSOCIATED DISEASES

Most individuals recover from the acute phase of primary EBV infection with no long-term sequelae. In a minority of patients, a chronic disease follows the acute phase of IM. Mild/moderate chronic active EBV infections (CAEBV) present with fever, malaise, arthralgia, myalgia, and lymphadenopathy.[60] To establish the diagnosis of CAEBV, patients must have (a) signs and symptoms for at least 6 months and (b) an abnormal EBV serology with high antibody titers of VCA-IgG and EA-IgG and little or no antibodies against EBNA. Affected individuals may also have measurable EA-messenger-RNA or EBV-DNA in the peripheral blood, serum, or affected tissues. The life-threatening form of CAEBV is characterized by high fevers, hepatosplenomegaly, and extensive lymphadenopathy, followed by hepatic, cardiac, or pulmonary dysfunction.[61] These patients have very high EBV-VCA titers and EBV-DNA levels in their peripheral blood. Although EBV usually resides in B cells, in severe CAEBV either T cells or natural killer (NK) cells are infected, predisposing to lethal T-cell or NK-cell lymphomas.[62,63] Severe, often fatal CAEBV is more common in Japan, whereas mild/moderate CAEBV is more common in the western hemisphere. These patients do not have mutations in the SH2D1A gene (see section X-Linked Lymphoproliferative Disease) and the etiology of CAEBV remains poorly understood.[64] No effective therapy is available; however, sporadic clinical improvements of mild/moderate CAEBV have been reported after infusion of interleukin 2, high-dose immunoglobulin, antiviral drugs, anti–tumor necrosis factor (TNF)-α antibodies or steroids. We have infused autologous EBV-specific CTL in five patients with mild or moderate CAEBV, because of the successful use of donor-derived EBV-specific CTL for the prophylaxis and therapy of EBV-associated lymphoproliferative disease after hematopoietic stem cell transplantation (see section Lymphoproliferative Disease). Infusion of EBV-specific CTL resulted in resolution of fatigue, malaise, fever, lymphadenopathy and splenomegaly. Four of five patients had responses lasting from 6 to 36 months of follow-up, with 1 patient having recurrence of fatigue and myalgia 12 months after CTL therapy.[65] These results suggest that the infusion of EBV-specific CTL may play a role in the treatment of mild or moderate CAEBV; however, larger number of patients need to be treated with longer follow-up. For severe CAEBV in which EBV resides in the T- or NK-cell compartment, the use of EBV-specific CTL has been investigated anecdotally without encouraging results; nevertheless, further investigations are warranted. Current treatment protocols rely on chemotherapy followed by hematopoietic stem cell transplantation similar to therapeutic strategies developed for hemophagocytic lymphohistiocytosis.[66,67] However, chemotherapy alone might also be curative.[68]

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) encompasses a spectrum of genetic and acquired conditions that are characterized by uncontrolled T-cell and macrophage activation leading to infiltration of the liver, spleen, bone marrow, and central nervous system.[69,70] HLH is an aggressive and potentially life-threatening disease most often affecting infants from birth to 18 months of age, but cases of older children and adults have been reported. Familial HLH is a heterogeneous genetic disorder and in the majority of patients the genetic defect is not yet defined. Twenty to 40% of familial HLH cases are caused by mutations in the perforin gene.[71] Ten percent of cases are linked to chromosome 9q21.3-q22, and in addition male patients with HLH have been described who harbor germline mutations in SH2D1A, the gene responsible for X-linked lymphoproliferative disease.[72] Secondary HLH is caused by a variety of infectious agents, including viruses like EBV, CMV, and Parvovirus B19, bacteria, fungi, and parasites. EBV-associated HLH (EBV-HLH) is more commonly seen in the Japanese and Chinese population and is not associated with perforin or SH2D1A gene mutations.[73] In EBV-HLH CD8-positive T cells are infected with EBV in contrast to CAEBV, where CD4-positive T cells or NK cells are infected.[74]

Because there is no definitive diagnostic test for HLH, the International Histiocyte Society has developed criteria for establishing the diagnosis. The patient must have (a) fever, (b) cytopenia (two of three lineages), (c) splenomegaly, (d) hypertriglyceridemia and/or hypofibrinogemia, and (e) hemophagocytosis. Without aggressive therapy, familial HLH is uniformly fatal and high mortality rates have also been reported for secondary HLH. Curative treatment relies on hematopoietic stem cell transplantation.[75,76] The current treatment protocol of the International Histiocyte Society results in a 3-year survival rate of 62%. It consists of initial therapy with decadron, cyclosporine A, etoposide (VP16), and in selected patients intrathecal methotrexate; once the disease is in remission a hematopoietic stem cell transplantation from matched related and unrelated donors is performed.[75]

X-Linked Lymphoproliferative Disease

Mutations or deletions in the SH2D1A (src homology 2 domain protein 1A) result in X-linked lymphoproliferative disease (XLP; Duncan disease), an immunodeficiency characterized by fatal IM, agammaglobulinemia, or B-cell lymphoma.[77,78] SH2D1A interacts with SLAM (signaling lymphocyte activation molecule), which plays a central role in the stimulation of B and T cells. SH2D1A controls several distinct key T-cell signaling pathways, and mutant SH2D1A does not bind SLAM, suggesting that it is a natural SLAM inhibitor. Following infection with EBV, XLP patients mount a vigorous, uncontrolled polyclonal expansion of T and B cells. Infiltrating T cells cause extensive tissue destruction of the liver and bone marrow, resulting in death in 50% of XLP patients during primary EBV infection. Approximately 30% of patients have acquired hypogammaglobulinemia and 25% of patients develop malignant B-cell lymphomas that are often extranodal, involving the intestinal ileocecal region. It is important to realize that some patients with SH2D1A mutations may only present with hypogammaglobulinemia mimicking common variable immunodeficiency and a diagnosis of XLP should be considered when more than one male patient with hypogammaglobulinemia is encountered in the same family.[79] Currently, the only curative therapy for XLP is hematopoietic stem cell transplantation.[80–82]

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) develops frequently, although not exclusively, in HIV-positive patients.[83] It is a nonmalignant hyperplasia of epithelial cells and most patients present with white, corrugated lesions on the tongue. OHL besides IM is the only EBV-associated disease in which active viral replication is apparent and multiple strains are often present within the same lesion. Inhibiting EBV replication in vivo with antivirals such as valacyclovir results in resolution of OHL. However, after valacyclovir treatment, EBV replication recurs in normal tongue epithelial cells, indicating that productive EBV replication is necessary but not sufficient to induce OHL.[84]

EBV-Associated Malignancies

Over the past decades, EBV has been associated with a heterogeneous group of malignancies. Although there is strong circumstantial evidence linking EBV to these malignancies, the potential causative relationship between EBV and these tumors remains to be firmly established. The following section focuses on EBV-associated lymphoproliferative disease, Hodgkin disease, NHL including Burkitt lymphoma, and nasopharyngeal carcinoma. All EBV-associated malignancies are associated with viral latency, and spontaneous viral replication occurs at a very low frequency. Because antiviral agents, like acyclovir, only prevent viral replication and do not affect latency, these agents are of limited therapeutic value.[85]

Lymphoproliferative Disease

EBV-LPD develops in patients with congenital or acquired immunodeficiencies, including severe combined immunodeficiency, XLP, HIV infection, and immunosuppression in recipients of solid organ transplants (SOT) or hematopoietic stem cell (HSC) transplants.[86,87] Besides EBV and a dysfunctional cellular immune system, genetic alterations in B cells have also been implicated in the pathogenesis of PTLD, especially in SOT recipients, including microsatellite instability, DNA hypermethylation, aberrant somatic hypermutation and mutations in specific genes such as MYCC, BCL-6, N-ras, and p53.[88] Most cases of EBV-LPD are lymphomas of B-cell origin, histologic high-grade NHL of the immunoblastic or undifferentiated large cell type that respond poorly to cytotoxic therapy.[89] In the setting of solid organ transplantation, the reported incidence of EBV-LPD ranges from 1% to 25%, with the highest risk in seronegative recipients, patients receiving intensive immunosuppressive therapy, and patients receiving grafts with a high lymphoid content.[90] After HSC transplantation, the incidence of EBV-LPD varies with the transplant regimen and may be as high as 25%. Risk factors for the development of EBV-LPD include the use of stem cells from an HLA-mismatched family member or closely HLA-matched unrelated donor, T-cell depletion of the donor cells, intensive immunosuppression, and an underlying diagnosis of primary immunodeficiency.[91] The incidence is much lower when methods that also deplete B cells are employed.[92] The onset of EBV-LPD seems to be preceded by a large increase in virus load as well as the proliferation of EBV-infected B cells. Frequent monitoring of the EBV-DNA load in peripheral blood is a valuable diagnostic test for early detection of EBV-LPD after HSC or solid organ transplantation. The threshold level of EBV-DNA suggestive of impending EBV-LPD varies according to the PCR method of quantifying viral DNA.[93–95] However, it should be emphasized that not all patients with high EBV-DNA levels, especially those with a solid organ transplant, develop EBV-LPD. Several distinct patterns of EBV latent gene expression have been identified in the memory B cells of high-load EBV carriers, with type III latency conferring the highest risk for EBV-LPD development.[96] Besides EBV-DNA levels, determining the frequency of EBV-specific T cells or the functionality of T cells in patients with high EBV-DNA load might also assist in identifying patients who are at increased risk for developing EBV-LPD.[97,98] In addition, host factors like polymorphisms in the promoter regions of cytokines have been implicated in increasing the risk of developing EBV-LPD.[99] Thus, an elevated EBV-DNA load can lead to early diagnosis of EBV-LPD, with consequent reductions in mortality and treatment-related morbidity, although additional results such as clinical signs and symptoms as well as radiographic findings must be taken into account before therapy is initiated.

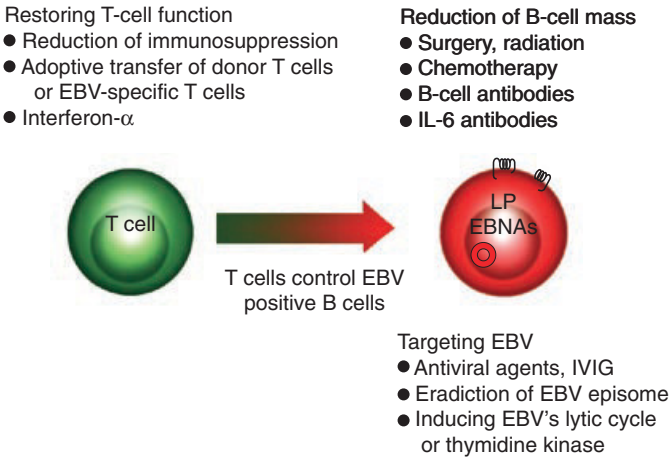

Figure 54–4 Treatment strategies for Epstein–Barr virus-associated lymphoproliferative diseases (EBV-LPD). For explanation of symbols see Fig. 54–1.

Treatment of Lymphoproliferative Disease

A variety of treatment approaches have been explored for EBV-LPD (Fig. 54–4).[86,100] These include (a) conventional chemotherapy, (b) reduction or withdrawal of immunosuppression, (c) adoptive transfer of T cells or EBV-specific cytotoxic T cells (CTL), and (d) infusion of monoclonal antibodies. Other potential strategies include the use hydroxyurea to eradicate EBV episomes or inducing the lytic cycle of EBV so that the lymphoma cells become sensitive to ganciclovir.[101–103] In solid organ transplant recipients, simple withdrawal of immune suppression can result in the regression of localized EBV-LPD by allowing recovery of the suppressed cellular immune system.[104] This approach is limited by the risk of graft rejection, nor is it useful post-HSC transplant because of the profound immunosuppression and the risk of inducing graft-versus-host disease (GVHD). Donor T-cell infusions have been used successfully to treat EBV-LPD post-HSC transplantation but carry the inherent risk of GVHD.[105] One strategy to prevent GHVD after T-cell infusion is the administration of donor-derived ex vivo expanded polyclonal EBV-specific CTL.[106,107] To determine whether adoptive transfer of donor-derived EBV-specific CTL is effective prophylaxis for EBV-LPD, EBV-specific CTL lines were infused into 56 recipients of HSC transplant.[106,108] Infused CTL induced no GVHD, survived long-term, and reconstituted immunity against EBV, and no infused patient developed EBV-LPD compared with an incidence of 11.5% in a comparable untreated control group. Immunotherapy with EBV-specific CTL was also used to treat six HSC transplant recipients who developed overt lymphoma. Five of these patients responded well with complete regression of bulky tumors, although infused CTL caused inflammation at the tumor site. One of the responders had central nervous system (CNS) PTLD, indicating that EBV-specific CTL can cross the blood–brain barrier to eradicate CNS lesions.[102] One patient died of progressive disease, a failure attributed to a deletion in the EBV protein EBNA-3B in the tumor virus causing resistance to killing by the infused CTL.[109]

In solid organ transplant recipients who develop EBV-LPD, donor-derived T cells are of limited value, because the tumor almost always arises in recipient B cells and donor T cells are unlikely to

survive in the recipient's hematopoietic system.[110] Initial studies using autologous or partly HLA-matched EBV-specific CTL for the treatment or prevention of EBV-LPD after SOT have shown promising results but need further investigation.[111–113] In our study, twelve SOT recipients at high risk for EBV-LPD, or with active disease, received autologous CTL infusions without toxicity. None of the treated patients developed PTLD. One patient with liver PTLD showed a complete response, and one with ocular disease has had a partial response stable for more than 1 year. However, the expansion and persistence of adoptively transferred EBV-specific CTL was limited in the presence of continued immunosuppression. Drawbacks of EBV-specific T-cell therapies are the facilities needed and the time required (3–4 months) for CTL production. Thus, reliable predictive parameters are needed to select patients who are at high risk for developing EBV-LPD allowing the early initiation of CTL lines.

In addition to cellular immunotherapy, monoclonal antibodies have been used for the treatment of EBV-LPD. Of 58 patients treated with CD21 and CD24 murine monoclonal antibodies in an European multicenter study, 35 (61%) entered complete remission, but these antibodies are no longer available.[114] Rituximab, a humanized CD20 monoclonal antibody, has been used successfully for the treatment of EBV-LPD as for other NHLs.[14,15,115] In a multicenter retrospective analysis of 32 patients with EBV-LPD developing after solid organ or HSC transplantation, rituximab was well tolerated and the overall response rate was 69%, with 20 complete responses and 2 partial responses.[14] These findings have been recently confirmed in a prospective, multicenter Phase II study for SOT patients with biopsy-proven PTLD.[15] Forty-three patients were treated with four weekly infusions of 375 mg/m^2 rituximab. At day 80, 86% of patients were alive and the response rate was 44.2%, including 12 complete responses/complete responses unconfirmed. The overall survival rate was 67% at 1 year. Other centers have reported similar results, with response rates ranging from 20% to 100%.[116,117] Besides B-cell antibodies, interleukin 6 monoclonal antibodies have been used successfully to treat EBV-LPD after solid organ transplantation.[118] Despite these promising results, the overall efficacy of monoclonal antibodies in the treatment of EBV-LPD after solid organ transplantation remains difficult to assess, because the majority of studies lacked controls and were confounded by other therapeutic interventions. As with T-cell therapies for EBV-LPD, the success of monoclonal antibodies will most likely depend on early diagnosis and intervention. Currently, the use of Rituximab seems to be a reasonable alternative in clinical situations where patients present with bulky disease, or EBV-specific CTL are not available.

EBV-Positive Hodgkin Disease and Non-Hodgkin Lymphomas

EBV is associated with Hodgkin disease as well as non-Hodgkin lymphomas (NHLs) in immunocompetent patients.[119,120] All EBV lymphomas are associated with the virus latent cycle (see Fig. 54–2). The majority of EBV-associated lymphomas in immunocompetent patients are latency type II and express EBNA-1, LMP-1 and LMP-2 except for Burkitt lymphoma, which is latency type I and only expresses EBNA-1.

Hodgkin Disease

Hodgkin disease is a malignant neoplasm of lymphoreticular cell origin and 40–50% of cases in immunocompetent individuals are associated with expression of EBV derived antigens in malignant Reed-Sternberg (H-RS) cells and their variants (see Fig. 54–5A,B).[121,122] EBV positive Hodgkin disease is more commonly seen in young children and in less developed countries. EBV association with Hodgkin disease differs by histologic subtype, being highest with the mixed-cellularity subtype. Evidence linking EBV to the pathogenesis of Hodgkin disease include the findings that (a) every H-RS cell in a EBV-positive tumor mass carries the virus and (b) the EBV genome is clonal, indicating that the malignant H-RS cells originated from a single EBV-infected cell. In addition LMP-1, one of the EBV proteins expressed in H-RS cells, activates the transcription factor NF-κB, which is thought to a play an important role in the pathogenesis of Hodgkin disease. EBV-positive HD patients also differ in their antibody response to the major EBV-associated antigens in comparison to healthy controls. The overall outcome of EBV-positive and EBV-negative Hodgkin disease is similar; with combination chemotherapy and radiation, the prognosis is excellent for low-stage disease and overall survival rate for advanced-stage disease are between 65% and 80%. Depending on age and histologic subtype, the presence of EBV might be associated with better survival.[123]

Non-Hodgkin Lymphomas

NHLs expressing type II latency include large B-cell lymphoma, CD30$^+$ Ki-1$^+$ anaplastic large cell lymphoma (ALCL) of B-cell type, T cell-rich B-cell NHLs and lymphatoid granulomatosis. The association of these lymphomas with EBV varies, ranging from 10% to 95%.[124–126]

EBV-associated NK/T-cell lymphomas include extranodal NK/T-cell lymphoma (nasal type), angioimmunoblastic lymphoma, and large granular lymphocyte (LGL) leukemia/lymphoma (NK- or T-cell type).[127,128] Between 30% and 100% of these lymphomas are EBV-positive, expressing a type II latency pattern. In addition, severe chronic active EBV (SCAEBV) infection of NK/T-cell type has been associated with fulminant forms of lymphoma, which are >95% positive for EBV.[62,129] The overall outcome of EBV-associated NHL depends on histologic subtype and risk factors present at diagnosis, but most are high-grade malignancies with an unfavorable prognosis using current treatment modalities.[125,130–132]

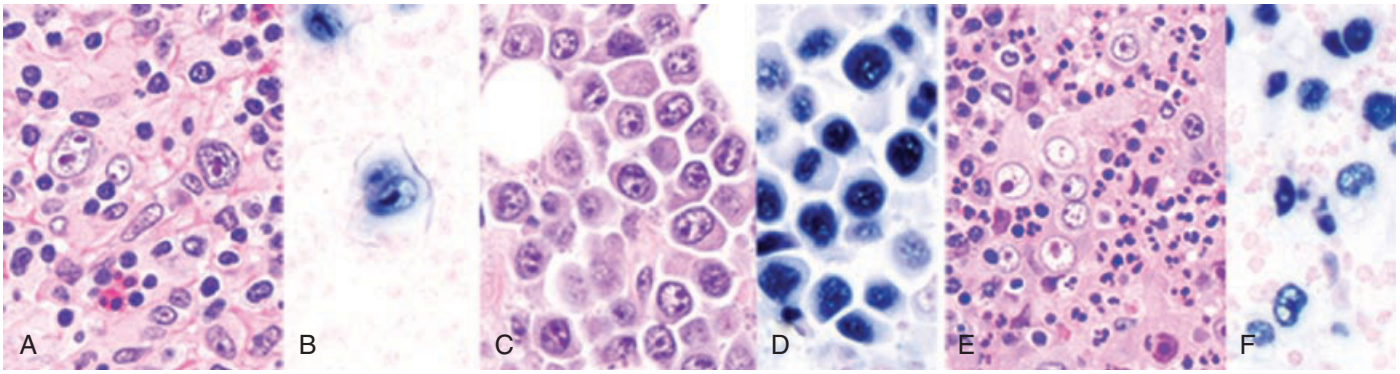

Figure 54–5 Examples of Epstein–Barr virus (EBV)-positive malignancies: Hodgkin lymphoma, nasopharyngeal carcinoma, and large B-cell lymphoma (**A–F**). Hodgkin lymphoma (**A**) and EBV-positive Reed–Sternberg cells (**B**). Large B-cell lymphoma (plasmablastic type) in an HIV+ patient (**C**), diffusely EBV-positive (**D**). Nasopharyngeal carcinoma (**E**), EBV-positive (**F**). (Note: all EBV studies are in situ hybridizations for EBV mRNA, EBER).

Adoptive Immunotherapy for EBV-Positive Hodgkin Disease and Non-Hodgkin Lymphomas in Immunocompetent Individuals

In contrast to EBV-LPD only a limited number of EBV-derived antigens, EBNA-1, LMP-1, and LMP-2, are present in EBV-positive Hodgkin disease and NHL. Nevertheless, EBV-specific CTL have been used to treat 20 patients with EBV-positive Hodgkin disease.[133–135] CTL localized to tumor sites, persisted for prolonged periods of time, and produced resolution of B symptoms. After CTL infusion, five patients were in complete remission at up to 40 months, two of whom had measurable disease at the time of CTL infusion. One additional patient had a partial response, and five had stable disease.[134] Although these results are encouraging, the antitumor activity of infused CTL was lower than in HSCT recipients treated for EBV-LPD. This lack of efficacy could be due in part to immunosuppressive factors secreted by H-RS cells or may simply be quantitative in that the method used for EBV-specific CTL generation produces CTL lines that are dominated by clones reactive to viral proteins not expressed in Hodgkin disease. To improve CTL efficacy, methods to expand CTL specific for the EBV proteins LMP1 and LMP2 expressed in Hodgkin disease and to genetically modify the expanded CTL to render them resistant against inhibitory cytokines have been developed.[48,136–139] The safety and efficacy of LMP2-specific CTL have been evaluated in patients with EBV-positive Hodgkin disease and EBV latency type II NHL.[140] So far 14 patients have been infused and we have observed an increase in the frequency of infused CTL in 8 of 10 evaluable patients. In addition, LMP2-specific CTLs were detected at tumor sites. Of six patients with detectable disease at the time of CTL infusion, five had clinical responses. These results indicate that LMP2-specific CTLs are safe, accumulate at tumor sites, and have antitumor activity.

EBV-Associated Non-Hodgkin Lymphoma in HIV Patients

Patients infected with HIV are at high risk to develop NHL. The incidence increases with age and the male-to-female ratio is approximately 2:1. Depending on certain histologic features, the EBV association ranges from 30% in systemic HIV-related Burkitt lymphoma (HIV-BL) to 70% to 80% in HIV-related immunoblastic lymphoma (HIV-IBL), and virtually all cases of primary central nervous system lymphoma (PCNSL) are EBV positive.[141–143] In biopsies of EBV-associated HIV-NHL, there is considerable variation in the number of EBV-positive cells, and the pattern of EBV latent gene expression varies among tumor types as in immunocompetent individuals (see Fig. 54–5C,D) . In HIV-infected patients, the development of EBV-associated HIV-NHL is preceded by a loss of functional EBV-specific CTL, suggesting that strategies to boost the endogenous EBV-specific T-cell response might prevent lymphomas.[144,145] Restoring CD4-positive T-cell counts in HIV patients with highly active retroviral therapy (HAART) has decreased the incidence of PCNSL and HIV-NHL.[146,147] The clinical experience with T-cell therapy for EBV-associated HIV-NHL is limited.

Burkitt Lymphoma

Burkitt lymphoma (BL) is a high-grade malignant small noncleaved B-cell lymphoma.[131] Histology usually reveals a "starry-sky" pattern resulting from numerous benign macrophages that have ingested apoptotic tumor cells. Although almost all endemic BLs in equatorial Africa are associated with EBV, the virus has been implicated less often in sporadic cases and in the United States only 20% of BL are EBV positive. In developing countries, an intermediate type of BL has been described, both in its clinical presentation and association with EBV, which varies from 25% to 80%. As with NPC and Hodgkin disease, there is strong circumstantial evidence linking EBV to BL. The EBV genome is clonal as in other EBV-associated malignancies.[148] The majority of BLs carry a translocation between the long arm of chromosome 8, the site of the MYCC oncogene (8q24), and the Ig heavy chain region on chromosome 14, t(8;14).[133] Although the t(8;14) translocation is seen in endemic as well as sporadic BLs, the exact location of the chromosomal breakpoints on chromosome 8 and 14 differ.[149] Other chromosomal translocations seen in BLs are between MYCC and the κ-light chain locus on chromosome 2, t(2;8), or the λ-light chain locus on chromosome 22, t(8;22).

Current treatment strategies rely on intensive chemotherapy, and overall survival depends on extent of disease at presentation, being 90% to 100% for local and 60% to 70% for advanced disease. The prospect for the development of an EBV-specific immunotherapy for BLs is problematic because lymphoma cells evade the immune system by downregulating the expression of EBV latency antigens, cell adhesion molecules, and MHC class I molecules. EBNA-1, the only EBV protein expressed in BL, autoregulates its own translation and inhibits HLA class I presentation because of an internal glycine-alanine repeat region.[150,151] However, the characterization of EBNA-1-specific CD4-positive T cells as well as rare CD8-positive T cells that can recognize BL through EBNA-1 has provided impetus to explore the role of CD4-positive T cells in the control and therapy of BL.[42–44,152] In addition, EBNA-1-specific CD4-positive T cells had potent antitumor activity in a murine model of Burkitt lymphoma.[153]

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) arises from the epithelial cells of the nasopharynx. The WHO classifies NPC into keratinizing squamous cell carcinoma (type 1), nonkeratinizing carcinoma (type 2), and undifferentiated carcinoma (type 3, most common). Type 2 and 3 carcinomas are associated with EBV (see Fig. 54–5E,F); however, environmental and genetic factors play an important role in oncogenesis, because the incidence of NPC varies 50- to 100-fold from Southern China to western countries.[11,154] EBV was initially linked to NPC by the observation that patients had elevated levels of VCA-IgG, VCA-IgA, and EA-IgG antibodies. Further studies showed that EBV-DNA is present in every tumor cell of type 2 and 3 carcinomas with remarkable consistency. As in Hodgkin disease, the EBV episome in an individual tumor is clonal.[155]

EBV antibody responses have been used to follow tumor burden in NPC patients; in addition, VCA-IgA antibodies and antibodies against EBV DNAse are predictive for NPC in high-risk populations.[156] More recently, detection of EBV-DNA in serum by different PCR methods has shown to be useful for the diagnosis, prognosis, and monitoring of NPC patients.[157] Most NPC patients are treated with radiation. Other modalities such as surgery, chemotherapy, and combined approaches may be appropriate in selected circumstances and a detailed discussion is beyond the scope of this chapter. In NPC, as for EBV-positive lymphomas, only a limited number of EBV latent antigens are expressed. A therapeutic vaccine study targeting LMP2 has been conducted and the results of this trial were discussed in the section EBV Vaccine Development. Three groups of investigators have reported on the use of autologous EBV-specific CTL for the adoptive immunotherapy of patients with recurrent/refractory NPC.[158–161] In one study, four NPC patients with advanced disease were infused and an increase in EBV-specific CTL precursor frequency was observed as well as a reduction in plasma EBV-DNA levels. No decrease in tumor size was observed; however, all patients had a large tumor burden.[158] In the second study, 10 patients were treated with EBV-specific CTL and in 6 of 10 patients, control of disease progression was achieved.[160] We have evaluated the use of EBV-specific CTL in patients with refractory or high-risk NPC in two Phase I clinical studies.[159,161] In the first clinical study, EBV-specific CTL was given alone and in the second clinical trial patients received a monoclonal antibody prior to CTL infusion to enhance T-cell expansion in vivo. Patients with EBV-positive NPC were eligible if they had recurrent, locally advanced-stage disease or metastatic disease. To date, 21 patients have received CTL and completed

their evaluation. Six patients were in remission at the time of EBV-specific CTL infusion and remain in remission 6 to 50 months post-CTL infusion. In the 15 NPC patients with active disease, we have observed responses in 10 of 15 patients; 4 patients are in complete remission 12 to 42 months after CTL infusion. Of the other 11 patients, 4 had stable disease (2–32 months), 1 had a partial response (12 months), and 6 had progressive disease. As for the adoptive immunotherapy for EBV-positive Hodgkin disease and NHL, current efforts are focused in increasing the frequency of LMP1- and LMP2-specific T cells in the CTL product and rendering T cells resistant to inhibitory factors secreted by NPCs such a Fas ligand.[162,163]

SUMMARY

Since its discovery in 1964, EBV has been linked to a heterogeneous group of diseases. EBV was the first human virus implicated in oncogenesis and the biology of the virus has been studied extensively on a cellular and molecular level. Over the last decade, successful immunotherapeutic approaches have been developed for EBV-associated lymphoproliferative disease using either monoclonal antibodies or the adoptive transfer of EBV-specific T cells. Further insights into the function of EBV proteins and host–virus interactions hold the promise of improving the outcome of patients with EBV-associated diseases in the future.

CHAPTER 55

CONVENTIONAL AND MOLECULAR CYTOGENETIC BASIS OF HEMATOLOGIC MALIGNANCIES

Vesna Najfeld

Over the past 35 years, cytogenetic analysis of malignant hematologic disorders has been one of the most rapidly growing areas in hematology. Chromosome studies and karyotype information provide both biologic and significant clinical value. Refinements in cell culture methods and the application of chromosome banding techniques have advanced our understanding of disease-specific abnormalities, and molecular cytogenetic methods now have made possible the identification of genes involved at translocation breakpoints in specific chromosomal rearrangements. These advances in molecular cytogenetic methods permit mapping of structural rearrangements even within a single gene[1,2] and fundamentally contribute to current knowledge of the biology of leukemia. This evolution in our understanding of cell biology has resulted in new terminology (Table 55–1). Application of conventional and molecular cytogenetic methods has identified 264 gene fusions involving 238 different genes in almost 35,000 reported patients with hematologic malignancies. This represents 75% of all gene fusions currently known in human neoplasia.[3] Application of these methods has played a pivotal role in the diagnosis, treatment, and prognosis of malignant hematologic diseases. This chapter discusses specific cytogenetic events and delineates molecular phenotypes that are important to understand the molecular pathogenesis of hematologic malignancies. Several genetic testing algorithms are suggested for clinical application of chromosome and fluorescence *in situ* hybridization (FISH) studies. The remarkable hypothesis put forward by Boveri[4] at the turn of the twentieth century, namely, that an abnormal chromosome pattern is intimately associated with the malignant phenotype of the tumor cell, has proved correct for many malignant disorders in general and for leukemia specifically. Knowledge of the molecular cytogenetic phenotype of hematologic malignancies has led to innovative and specifically tailored treatments. The first example of such gene-targeted therapy has already been successfully applied to chronic myelogenous leukemia (CML).[5,6]

METHODS

Cytogenetic Analysis

Cells arrested in metaphase are obtained by exposing marrow cells sequentially to mitotic inhibitors, hypotonic KCl, and fixative. Chromosomes obtained from leukemic marrow then are subjected to the most widely used banding method, trypsin-Giemsa banding (Fig. 55–1). The criteria used to define clonal abnormalities are listed in Table 55–1 and described in the International System for Human Cytogenetic Nomenclature.[7]

Fluorescence *In Situ* Hybridization

FISH is a molecular method that allows detection of the number, size, and location of DNA and RNA segments within individual cells in a tissue sample. It is based on the ability of single-stranded DNA to anneal to complementary DNA. In hematologic disorders, the target DNA is the marrow or peripheral blood nuclear DNA of interphase cells or the DNA of metaphase chromosomes that is fixed on a microscope slide. Other biologic material that may be involved in the leukemic process, such as spleen cells, ascites, and spinal fluid, are particularly useful for FISH studies. In lymphoma, the target DNA is a lymph node, and FISH studies are performed on touch preparation, frozen sections, or paraffin-embedded tissue.

Figure 55–2 shows four general types of FISH probes that are used alone or in combination to determine both numerical and structural rearrangements: (a) centromere enumeration probes, as the name implies, are used most frequently in interphase nuclei for detection of numerical chromosome anomalies, (b) whole chromosome painting probes are used only on the metaphase cells and are very useful in delineating complex rearrangements or the origin of marker chromosome, (c) subtelomeric probes, and (d) unique gene loci probes applied to both interphase and metaphase cells in single, dual, triple, or multiple colors to determine specific chromosomal rearrangements, deletions, or amplifications.

Four different FISH probe strategies are used in probe design for detection of chromosomal translocations in hematologic malignancies (Fig. 55–3): (a) conventional strategy, (b) extrasensitive strategy, (c) dual-fusion strategy, and (d) breakapart strategy. The first application of FISH technology for detection of chromosomal translocation in hematologic malignancy was in 1990, when the *BCR-ABL* hybrid gene was identified using two-color FISH in interphase cells as well as in metaphase marrow-derived CML cells.[8] In the standard strategy for interphase evaluation of chromosomal translocation, a DNA probe comprising sequences mapped proximally to the breakpoint in one of the chromosomes involved in reciprocal translocations is combined with a differentially labeled DNA probe that includes sequences mapped distantly to the breakpoint in the other chromosome. Positive nuclei for the translocation display one dual-color fusion signal, representing one of the derivative chromosomes generated by the translocation, and two single-color signals, one for each of the normal alleles. This standard FISH strategy has been used for detection of translocations in hematologic disorders at diagnosis.

For detection of residual disease, the conventional strategy lacks specificity because cells with random spatial colocalization of normal signals with different colors, found at a frequency from 1% to 10% of scored nuclei, are seen as false positive. To minimize this problem, an extrasensitive method was developed in which a probe for one abnormal chromosome is designed to generate an extra, smaller signal in positive nuclei. Hybridization with this strategy results in abnormal cells showing colocalization of two signals in dual colors, additional two signals in one single color and one signal in another single color. Application of the extrasensitive probe can discriminate between *BCR-ABL* fusion-positive blast crisis of CML and de novo acute lymphoblastic leukemia (ALL).

A dual-fusion strategy was developed not only to minimize false-positive results but also to detect additional deletions at the translocation breakpoints. The dual-color/dual-fusion strategy includes a probe set with DNA sequences that encompasses proximally and distally the translocation breakpoints on both chromosomes involved in translocation. The sequences for each chromosome are labeled with a specific color, and the translocation generates fused signals in both derivative chromosomes. Positive nuclei exhibit two copies of fusion signals and one copy of each of the single signals representing the normal alleles. If a third color is added for detection of particular sequences, such as deletion of chromosome 9 at the site of the Philadelphia (Ph) translocation (Figs. 55–8, *C,* and 55–12*)*, the

Table 55–1 Glossary of Cytogenetic and Fluorescence *In Situ* Hybridization Terminology

Aneuploidy	Abnormal chromosome number, either gain or loss
Balanced translocation	Exchange of chromosomal material that creates no extra or missing DNA
Banding	Set of dark and pale segments along the length of chromosomes, resulting from treatment with enzyme prior to staining Each chromosome is identified by its unique set of bands
Breakpoint	Specific site on a chromosome containing a break in the DNA that is involved in chromosomal structural rearrangement, such as translocation or deletion
Centromere	Constriction on the chromosome at the spindle site attachment During cell mitosis two copies of the DNA in each chromosome are separated by shortening of the spindle fibers attached to opposite sides of the dividing cell Position of the centromere determines whether the chromosome is metacentric (X shaped, e.g., 1, 3, 19, 20), submetacentric (centromere positioned more toward the short arms, e.g., 2, 4, 5, 6–12, 16–18, X), or acrocentric (inverted V shaped, e.g., 13–15, 21, 22, Y)
Centromere enumeration probe (CEP)	Highly repetitive α (or β) satellite DNA, located in the heterochromatin of the centromeric area of chromosomes CEP targets repetitive α (or β) sequences and produces bright compact signals; particularly useful for detection of numerical loss or gain of chromosomes
CGH	Comparative genomic hybridization, molecular cytogenetic technique that provides a copy-number karyotype at the chromosome and band level Array CGH is a higher-level CGH technology that provides gene copy information Variety of arrays include disease specialized, chromosome arm specific, and others.
Chromosomal rearrangement	Aberration in which chromosomes are broken and rejoined
Clonal abnormality	In cytogenetic analysis, two cells showing the same additional or structural abnormality or three cells with loss of the same chromosome In FISH analysis, any abnormality present after the probe has been validated and normal reference range established, above the normal reference range
Deletion	Segment of chromosome that is missing (terminal) or segment of chromosome missing between two breakpoints (interstitial)
DNA sequence	Order of nucleotides in a DNA segment, usually displayed from the 5′-triphosphate (5′ end) to the 3′-hydroxyl (3′ end) nucleotides
Enhancer	DNA sequence that increases the rate of transcription
Exon	Portion of gene that encodes protein
Fiber FISH	Application of FISH technology to extended DNA or free DNA fibers
FISH	Fluorescence *in situ* hybridization, a method for detection of the number and location of DNA sequences (genes) in tissue section or cell population
Fluorochrome	Fluorescence molecule that, when conjugated to a molecule, binds to a hapten to facilitate detection of the chromosomal probe By definition, a fluorochrome is a molecule that will become excited by the light of one wavelength
Gene construct	Recombinant DNA containing a gene of interest surrounded by sequences engineered to promote a measure of its expression
Gene map	Order of genes within a chromosome or entire genome
Genotype	Genetic constitution, usually with reference to particular alleles at a locus
Haploid	Half of a normal complement (i.e., 23 chromosomes)
Haploinsufficiency	Deletion or inactivation of one allele to produce disease due to inadequate activity of the remaining allele
Hybrid gene	Fusion of two different genes as a result of a structural chromosomal rearrangement that functions as one transcriptional unit
Hybridization	Method for rejoining (reannealing) complementary DNA or RNA strands
Hyperdiploid	Additional chromosomes (e.g., 47 or 48 chromosomes)
Hypermetaphase FISH	Application of FISH to accumulated large number of metaphase cells
Hypodiploid	Loss of chromosomes (e.g., 45 or 44 chromosomes)
I-FISH	Interphase fluorescence *in situ* hybridization, application of FISH to nondividing (resting) cells
Interphase	Stage of mitosis in which the cell is not dividing
Inversion	Structural chromosomal rearrangement as a result of two breaks occurring in the same chromosome Paracentric inversion refers to both breaks occurring on the same side of the centromere Pericentric inversion refers to breaks occurring on the opposite side of the centromere
Isochromosome	Structural chromosomal rearrangement that consists of doubling of one of the two chromosome arms (connected by the centromere) and loss of the other arm

Table 55–1 Glossary of Cytogenetic and Fluorescence *In Situ* Hybridization Terminology—cont'd

Karyotype	Arrangement of metaphase chromosomes from a particular cell according to size and banding so that the largest chromosome is placed first and the smallest one last (see Fig. 55–1)
kb (kilobase)	Unit of DNA/RNA length = 1000 base pairs of DNA
Locus	Unique location of a gene on a chromosome
Locus (sequence)-specific probe (LSI)	Probe targeted to unique sequence region of the chromosome Useful for localization of genes on normal chromosomes (gene mapping) and for detection of gene amplification, deletion, inversion, or translocation
Marker chromosome	Chromosome whose morphology cannot be identified using banding method Marker chromosomes are frequent in hematologic neoplasms
M-FISH	Multicolor FISH karyotyping, which allows identification of 24 different human chromosomes (22 autosomes, and the X and Y chromosomes) (see text for details)
Oncogene	Locus that is activated in association with tumor growth One abnormal allele is sufficient to cause tumor formation or cancer
PCR	Polymerase chain reaction, by which individual gene segments are amplified through sequential cycles of polymerization, heat denaturation, and reannealing
Pseudodiploid	Diploid number of chromosomes (46) accompanied by structural rearrangement
Recurrent abnormality	Structural or numerical abnormality observed in multiple patients with the same or similar disease Recurrent chromosome abnormalities in hematologic neoplasms have prognostic significance
Telomeric probe	Used to detect repeated DNA sequences present at the end of the chromosome, which is called the telomere Telomeric DNA contains 10–15 kb of TTAGGG repeats Adjacent to the telomere is a region called the proximal subtelomeric region, and centromeric to it is a unique chromosome telomeric region Chromosome-specific telomeric probes are useful for detection of cryptic translocations involving ends of chromosomes
Translocation	Structural chromosome abnormality resulting from a break in at least two chromosomes with an exchange of material In reciprocal or balanced translocation, no loss of chromosomal material occurs In unbalanced translocation, loss of chromosomal DNA occurs
Tumor suppressor gene	Locus that prevents tumor growth when at least one allele is functional Loss of both alleles, first through constitutional and then through somatic mutation, is associated with tumor formation or cancer
Whole chromosome painting probe (WCP)	Spans the entire length of chromosomal DNA sequences and, as the name implies, targets the entire length of DNA sequences Useful for identification of complex or cryptic structural rearrangements as well as for identification of marker chromosomes
Nomenclature	
p	= Short arm
q	= Long arm
+	When placed before the chromosome, denotes a gain of a whole chromosome (e.g., +8)
–	When placed before the chromosome, indicates a loss of a whole chromosome (e.g., –7); in rare situations, when placed after the chromosome, as in 5q–, indicates loss of a part of the long arms of chromosome 5
t	translocation
del	deletion
der	derivative
inv	inversion
i	isochromosome
mar	marker chromosome
con	connected
nuc ish	nuclear *in situ* hybridization
nuc ish 21q22(D21S65X2)	two copies of D21S65 DNA segment on chromosome 21
nuc ish 9q34(ABLx2),22q11.2(BCRx2) (ABL con BCRx1)	two ABL and two BCR loci, but one of each locus is juxtaposed on one chromosome as a result of t(9;22)

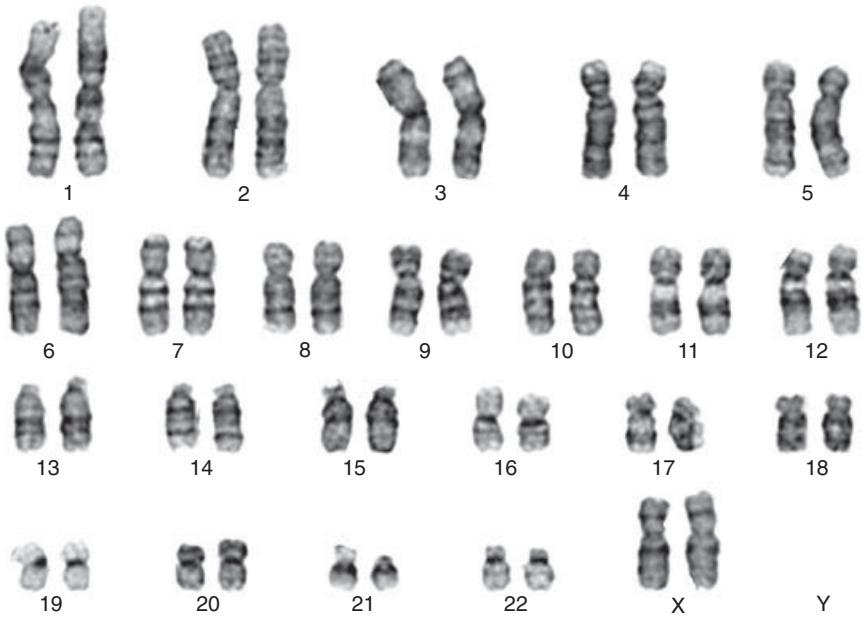

Figure 55–1 Normal arrangements of chromosomes in a karyotype from a bone marrow metaphase cell showing a slightly fuzzy morphology compared to a normal karyotype obtained from phytohaemagglutinin-stimulated peripheral blood cells.

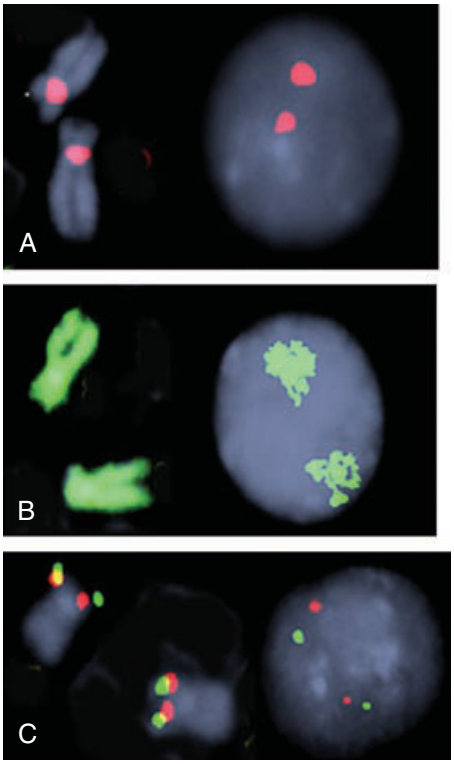

Figure 55–2 Types of chromosomal probes (see text for details). **A,** Pair of chromosome 12 (left) and interphase cell (right) after FISH study with centromere enumeration probe (CEP) showing two hybridization signals (red) in the centromeric area of chromosome and two tight signals in interphase cell consistent with disomy (normal copy number). CEP probes are most useful for detection of numerical abnormalities. **B,** Hybridization with whole chromosome 8 painting probe showing the hybridization signal (green) along the length of the entire chromosome 8 (left) and hybridization domains in interphase cell (right). Whole chromosome painting probes are useful for identifying unknown chromosomes in metaphase cells. **C,** Target of locus-specific indicators (LSI) are specific gene sequences such as *P53* seen after hybridization as two small signals (red) on chromosome 17, band p13. The main application of LSI probes are gene mapping, numerical enumeration in interphase cells, and detection of translocations. Telomeric probe, shown in green for the short arms of chromosome 17, are repetitive probes and are useful for detection of cryptic translocations involving ends of chromosomes. Chromosomes and nuclei are counterstained with DAPI (blue).

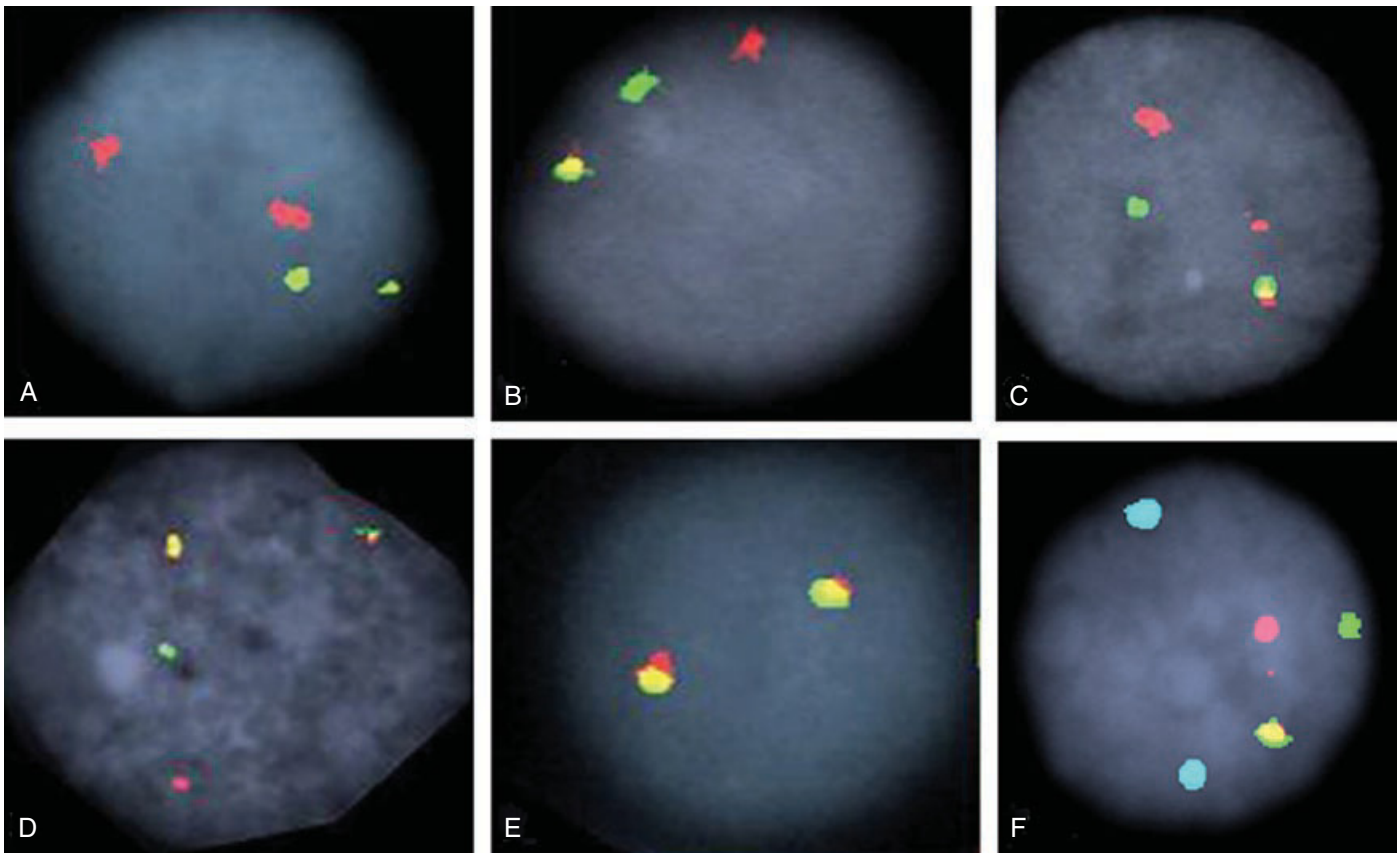

Figure 55–3 Four different probe strategies for detection of chromosomal translocations (see text for details). **A,** Normal cell after *in situ* hybridization with *BCR* (green) and *ABL* (red) showing a normal distribution of two red and two green single signals. **B,** Conventional fusion strategy after *in situ* hybridization shows one fusion (yellow) signal representing derivative chromosome generated by the translocation and one single-color signal, red and green for normal homologues in positive nuclei. **C,** An extrasensitive fusion approach generates an extra small (red) signal as well as a fusion signal (yellow) and one signal in single color (green and red) on normal homologues. **D,** Dual-fusion strategy generates two fusion signals (yellow) on two derivative chromosomes and one single-color signal on each of two normal chromosomes. **E,** "Breakapart" approach in a normal cell appears as two fusion signals (yellow). In this strategy, the 3′ end and the 5′ part of the gene are labeled in two colors. **F,** When the rearrangement occurs, the normal chromosome shows colocalization of red and green (yellow) as a result of the proximity of the sequences on the chromosome, whereas abnormal derivative chromosomes each have one single red and single green signal, indicating that the rearrangement occurred between the two ends of the gene separating the green and red signals on two different chromosomes. The third-color probe (blue) can be used as an internal control (usually CEP probe) to determine the disomic number of chromosomes.

lack of one copy of the third color is consistent with sequence deletion at the site of the translocation of one derivative chromosome. Dual-color/dual-fusion probes are very useful in differentiating various leukemia and lymphoma-associated translocations.

Multiple translocation partners are well known for genes commonly associated with leukemias such as *MLL*, retinoic acid receptor α *(RARA),* and the lymphoma gene *ALK,* and the fourth FISH strategy with "breakapart" probes was developed to address this issue. The breakapart probe includes DNA sequences mapped proximally and distally to the breakpoint within a critical gene (the 3′ end and the 5′ end) labeled with two different fluorochromes. The fused fluorescence signals represent a normal gene, whereas nuclei with rearrangements within the target gene show one single-color signal and one for each derivative chromosome, regardless of which chromosome is the partner in translocation.

One of the most significant advances in diagnostic leukemia cytogenetics has been the application of interphase FISH. *Interphase cytogenetics* is the term used to describe detection of chromosomal abnormalities in nondividing, interphase nuclei (Fig. 55–4).[9] Six aspects of interphase FISH are particularly useful. (a) Interphase cytogenetics allows screening of a large number of cells. This permits investigation of hematologic malignancies with a low mitotic yield, such as chronic lymphocytic leukemia (CLL) or multiple myeloma (MM). (b) Interphase cytogenetics permits detection of chromosomal rearrangements in peripheral blood samples, thus obviating the need for marrow aspiration. For instance, in CML, which rarely yields a large number of dividing cells in peripheral blood, conventional cytogenetics usually is uninformative. However, detection of *BCR-ABL,* a molecular equivalent of the Ph, in peripheral blood using interphase FISH provides reliable, fast, quantitative results (see Chronic Myelogenous Leukemia below). (c) Interphase FISH offers a quantitative assay for monitoring disease progression or detection of minimal residual disease after ablative chemotherapy or hematopoietic cell transplantation (HCT). (d) Use of specific probe sets allows detection of specific disease-associated abnormalities such as t(8;21), which denotes the M2 subtype of acute myeloid leukemia (AML), or t(15;17), which is associated with acute promyelocytic leukemia, in a very short time period, allowing for timely and appropriate therapy. (e) Abnormalities can be detected accurately in archival specimens kept up to 15 years. (f) Simultaneous use of interphase FISH and immunophenotyping is a powerful tool for investigation of lineage involvement in diseases such as myelodysplasia and to determine which cell population carries the specific chromosome abnormality. FISH nomenclature is described in the International System for Human Cytogenetic Nomenclature.[7]

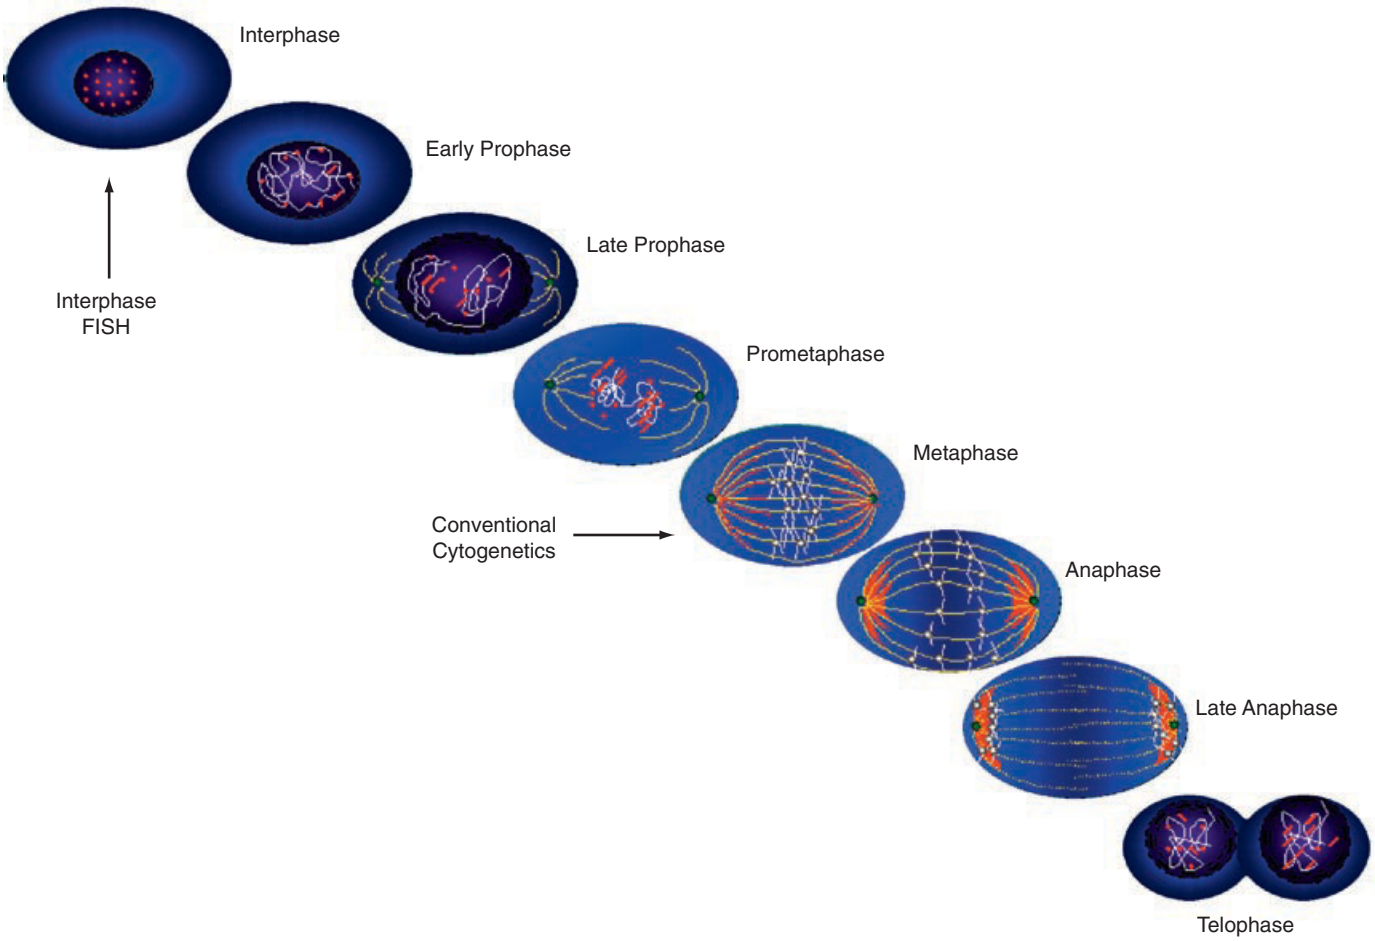

Figure 55–4 Schematic representation of cell division. Most clinical FISH studies are performed on nondividing interphase cells, whereas conventional cytogenetics is performed at the metaphase stage of cell division. *(Courtesy Dr. Ari Melnik, Mount Sinai Medical Center New York.)*

Higher resolution of chromosomal abnormalities can be achieved when fluorescently labeled probes are hybridized to extended DNA or free chromatin (chromatin strands released from their chromosomal scaffold) or free DNA fibers. This approach is termed *fiber FISH* (Fig. 55–5, top). The hybridized signals have the appearance of a "string of pearls" along the fiber rather than tight fluorescing spots observed in interphase cells. Although at the present time fiber FISH has limited clinical applicability because it requires special techniques of target DNA preparation on a glass slide, it has been successfully applied in basic studies, such as mapping chromosomal breakpoints of the *cyclin D* gene in mantle cell lymphoma and for detailed mapping of the breakpoint site region in the *BCL2* gene involved in follicular lymphoma.[10,11]

Multicolor karyotyping permits examination of the entire genome in a single analysis (Fig. 55–6). In 1996 it became possible to identify 24 different human chromosomes (12 autosomes and the X and the Y sex chromosomes), each with a unique color, with the help of fluorochrome-specific optical filters. This method is called *multicolor FISH* (M-FISH).[12] When interferometer-based spectral imaging is used, the method is called *spectral karyotyping*.[13] The starting point in both methodologies is the use of whole chromosome painting probes for each chromosome. Thus, each chromosome is labeled with a different combination of fluorescence dyes. The fluorochrome colors are not distinct enough for the unaided human eye to distinguish the combination with which the chromosome is labeled. In M-FISH, images are sequentially obtained using five different fluorochrome-specific optical filters. A computer program combines the data and displays each chromosome as if it were stained with a distinct color. Spectral karyotyping is based on the use of an interferometer (used by astronomers to measure the light spectra of distant stars) to determine the full spectrum of light emitted by each stained chromosome. A computer program then displays all the chromosomes simultaneously, each with its own unique color. These methods are applied with increasing frequency to resolve complex karyotypes, to detect cryptic translocations in patients with normal karyotype, and to define karyotypes with deletions.[14–17] Their clinical use may be limited because the cost of equipment and probes is beyond what can be afforded by most clinical laboratories. The M-FISH technology cannot be used to discriminate structural intrachromosomal rearrangements such as duplications, deletions, and inversions.

Another powerful method used for identifying locations of chromosomal gains, losses, deletions, or amplifications, without prior knowledge of the chromosomal target that may be altered, is *comparative genomic hybridization* (CGH). Briefly, isolated DNA from leukemic marrow or tumor tissue is labeled with a one-color fluorochrome (e.g., red), whereas DNA isolated from normal control tissue is labeled with a different color (e.g., green). These differently labeled DNAs are hybridized against each other in a competitive hybridization reaction onto normal metaphase spreads. Computer-assisted image analysis detects colors generated after hybridization, which indicate equal hybridization, relative excess, or deficiency of the target DNA (relative to control). The ratio of color intensity provides a "copy-number" karyotype. CGH has been successfully applied to

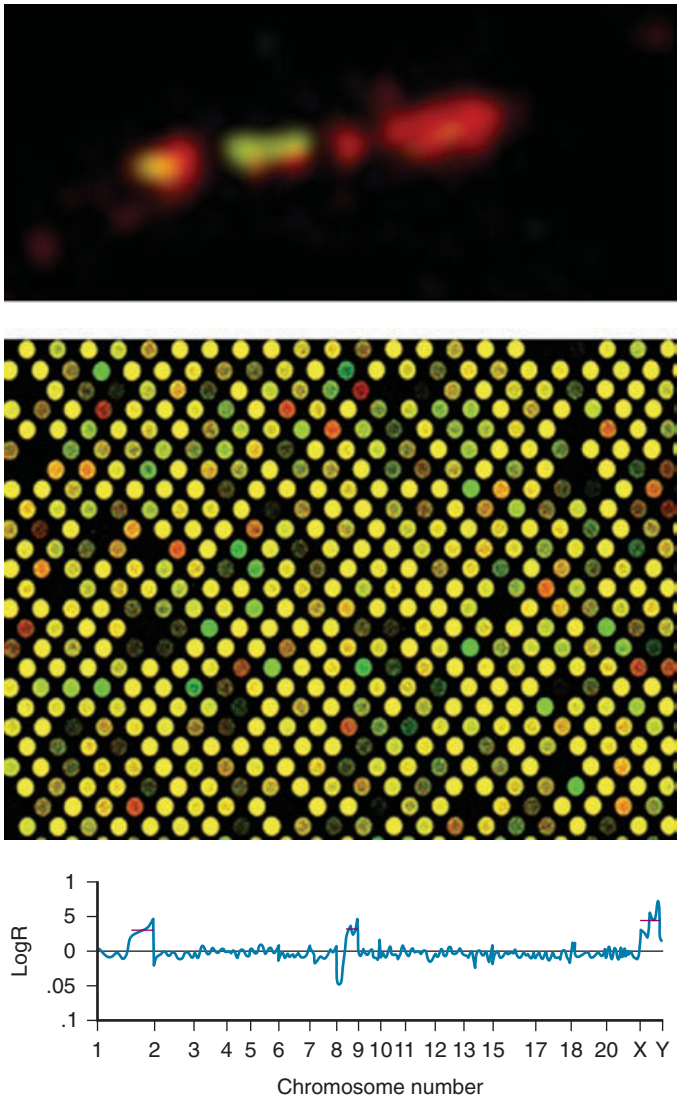

Figure 55–5 Top panels, Application of higher-resolution FISH, fiber FISH, to extended DNA fibers. The hybridization signals have the appearance of a "string of pearls" along the fiber rather than tight fluorescing spots observed in interphase nuclei. **Bottom panel,** Portion of array CGH image. The tumor or normal cell fragmented DNA sample was labeled with Cy5 or CY3, respectively. Yellow spot indicates the intensity signal of the genomic element on that spot in the tumor equals that of the normal cell reference. Red or green spot indicates intensity of the tumor and is greater or less than the reference, suggesting copy-number change for the genomic element on that spot. Graph underneath is the copy-number change profile. Y-axis is the log2 ratio of the intensity of each gene in the order of its position on the genome in tumor sample versus that of normal liver sample. Gained or lost regions are marked by red or green line, respectively. Gains of 1q and 8q and loss of 8p were observed in this tumor. *(Courtesy Dr. D. Weijia Zhang, Mount Sinai School of Medicine, New York, NY. In: Molecular Genetic Pathology. eds. Liang Cheng and David Y. Zhang Humana Press, Totowa, NJ, 2008.)*

many leukemias, but its clinical use remains limited because it cannot detect balanced translocations, which are the hallmark of many hematologic malignancies.[18,19] Nevertheless, CGH is the first efficient approach to scanning the entire genome for variations in DNA copy number.[20,21]

A newly emerging investigational method is a "microchip array" in which labeled DNA or RNA from the sample of interest is hybridized with defined target sequences immobilized on a solid support. The advantage of this method is the ability to screen genes that are amplified or deleted from the genome on a very large scale or, in the case of RNA, to learn whether such genes are expressed at a particular stage of disease. The first example of successful RNA application of the microchip array technique was the differentiation of AML from ALL based solely on gene expression.[22] As shown in Fig. 55–5 (bottom panels), in the "array CGH" procedure, large-insert genomic clones, oligonucleotides, or single nucleotide polymorphisms (SNPs) have replaced metaphase chromosomes used in the regular CGH.[23,24] Array CGH is a higher-resolution CGH technology and provides diagnostic information for diseases associated with DNA dosage. It also can be used to discover previously unexpected sites of gene dosage associated with specific hematologic malignancy type.[25–28] The concept of obtaining gene copy number from multiple genome locations in a single measurement has been used to characterize numerous hematologic malignancies in the last 3 to 4 years, and its clinical usefulness is demonstrated throughout this chapter.

These modern cytogenetics methods have increased the resolution at which chromosomal rearrangements can be identified. Whereas in conventional cytogenetics the target is the whole chromosomes in the metaphase spreads at a resolution of approximately 5 Mb, molecular cytogenetics methods may use analysis of interphase nuclei at a resolution of 50 kb to 2 Mb or fiber FISH analysis of chromatin strands at a resolution of 5 kb to 500 kb. Moreover, the current resolution of array CGH is restricted only by clone size and by the density of clones on the array, some of which may contain resolution at the level of a single nucleotide.

Conventional cytogenetics and FISH methodologies are complementary. Each has its own advantages and limitations in investigating genome rearrangements of malignant cells. Although conventional cytogenetics is the comprehensive study of all chromosomes, it requires a large number of dividing cells, which, in some diseases, such as myelofibrosis, is difficult to obtain. Furthermore, many small deletions or structural rearrangements are beyond the microscopic level of detection. FISH can be used in conjunction with conventional cytogenetics in both interphase and metaphase cells. It is a more sensitive method and can detect rearrangements smaller than 1 kb. The main disadvantage of interphase FISH is that it cannot be used unless a known abnormality is suspected. When the abnormality is known, interphase FISH can pinpoint the clonal aberration at the single-cell level in a very short period of time. Other investigative FISH methods provide further refinement.

Clonal Origin of Leukemia

The question of whether cell proliferation is monoclonal or polyclonal is fundamental to understanding the underlying etiology of hematologic malignancies. Markers of clonality are used to determine the origin of disease, to differentiate malignant from nonmalignant populations, to establish hematopoietic hierarchy, clonal evolution, and clonal remission, and to delineate steps involved in multistep pathogenesis.

The clonal origin of leukemias and lymphomas can be assessed by either intrinsic or extrinsic cellular markers. Intrinsic cellular markers are specific for a cell population, arising either during normal differentiation or as a part of disease process. For instance, cell surface-associated immunoglobulin (Ig) markers such as the λ or κ light chain or idiotypes and T-cell receptors (TCRs) can be useful for evaluating lymphoid diseases.[29,30] Application of Ig markers demonstrated for the first time that MM has a clonal development.[31] Somatic cytogenetic alterations are useful intrinsic markers for identifying abnormal clones and following disease progression. Thus, the observation of identical chromosome anomalies in different cells of the same tumor is evidence of clonality. Since the discovery of the Philadelphia chromosome (Ph) in 1960, it is well established that nonrandom, recurrent chromosomal abnormalities characterize many hematopoietic malignancies.[32] The finding of the Ph in different CML-derived hematopoietic cell lineages led to the hypothesis that CML might originate in a single precursor cell and may have a clonal development.[33,34] Moreover, the presence of additional recurrent chromosomal abnormalities in the Ph positive clone, such as trisomy 8, duplication of the

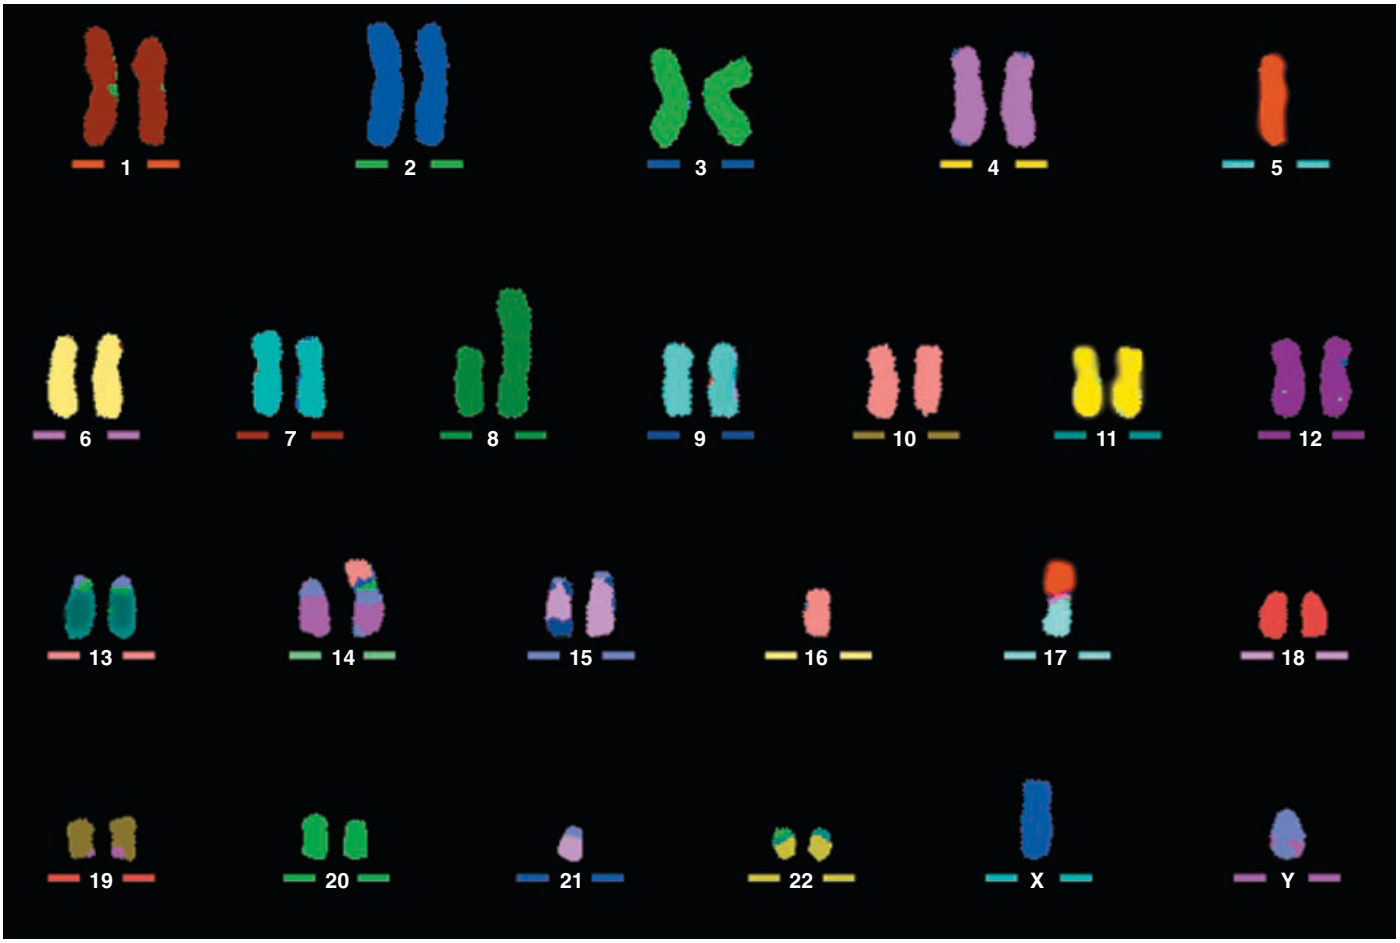

Figure 55–6 Multicolor metaphase FISH of a bone marrow cell from a patient with myelodysplastic syndrome documenting 43,XY,-5,der(8)t(8;8)(p23;q11.2),der(14;16)(p12;p11.1), inv(15)(q21;q24),der(17)t(5;17)(p13;p13),-21 karyotype. The origin of t(8;8) and der(14;16) could not have been determined by conventional cytogenetic study alone.

Ph, or trisomy 19, not only indicates the clinical worsening of the disease and the occurrence of the accelerated phase or blast crisis, but it demonstrate the subclonal evolution of the Ph positive clone. Currently, disease-associated somatic genomic mutation, such as rearrangements of *MLL*, *AML1,TEL/ETV6, PML-RARA*, and many others, can be identified by polymerase chain reaction (PCR)-based assays or by FISH assay and may serve, with or without conventional cytogenetics, as intrinsic marker of disease processes.

On the other hand, extrinsic marker systems use cellular mosaicism that is completely independent of the disease being studied and is not restricted to the cell lineages. Individuals with Turner or Klinefelter syndrome are mosaic for XX or XY and X cells or XXY and XY cells, respectively. The mosaicism created by X-chromosome inactivation in females is much more widely applicable and has provided fundamental insights into the pathogenesis of hematologic malignancies.[35] Original studies with X-linked glucose-6-phospate dehydrogenase (G6PD) as a marker of clonality was based on the Lyon hypothesis that, early in embryogenesis, one X chromosome in females is inactivated in somatic cells, and the activation status is stably transmitted to daughter cells during mitosis (Fig. 55–7).[36] The choice of maternal versus paternal X-chromosome inactivation is random; however, once it occurs it is maintained in all daughter cells.[37] Random X inactivation occurs by embryonic day 6.5 around the start of gastrulation and results in a mosaic pattern that characterizes adult females.[38–40] Therefore, an adult female is a mosaic for two cell populations, one expressing genes from an active X chromosome and the other expressing genes from the inactive X chromosome. Incidentally, mammalian X-chromosome inactivation is a mechanism that equalizes the dosage of X-linked genes between sexes.[36] Although the exact mechanism of X-chromosome inactivation remains to be elucidated, the process of X inactivation starts with methylation of CpG islands.[41–43] The inactivation process is believed to occur before differentiation of embryonic stem cell into various cell lineages. Hematopoietic cells do not originate from a single embryonic stem cell but from several progenitors, thereby allowing for mosaic expression from both X chromosomes.[43,44]

The observation that human females are heterozygous for the *G6PD* variant A and A$^-$ and that two mosaic cell populations may be distinguishable by electrophoretic mobility was first published by Davidson et al.[45] in 1963. The X-inactivation *G6PD* mosaic system was first applied to the study of clonality in human tumors in 1964 by Gartler and Linden.[46] They studied uterine leiomyomas and recognized that the presence of normal cells might mask the ability to detect individual clonal uterine leiomymas.[47] In females who are heterozygous for the *G6PD* polymorphism and have malignant hematologic disorder such as CML, the finding of a single *G6PD* type in marrow or blood cells and both the A and B type *G6PD* in normal tissue control demonstrated that CML has a clonal origin and provided evidence that the malignant transformation occurred in the stem cell common to most cell lineages.[33,34] Additional studies with heterozygous *G6PD* females who had CML demonstrated that some CML-derived B lymphocytes had a single *G6PD* type, but these clonal cells were Ph negative; thus, leukemic transformation predates development of the chromosomal abnormality. This observation provided evidence that CML has a multistep pathogenesis.[34,48,49] Application of *G6PD* studies to hematologic malignancies demonstrated clonal and stem cell origin for AML, ALL, Ph negative chronic myeloproliferative disorder (MPD), myelodysplastic syndrome (MDS), and

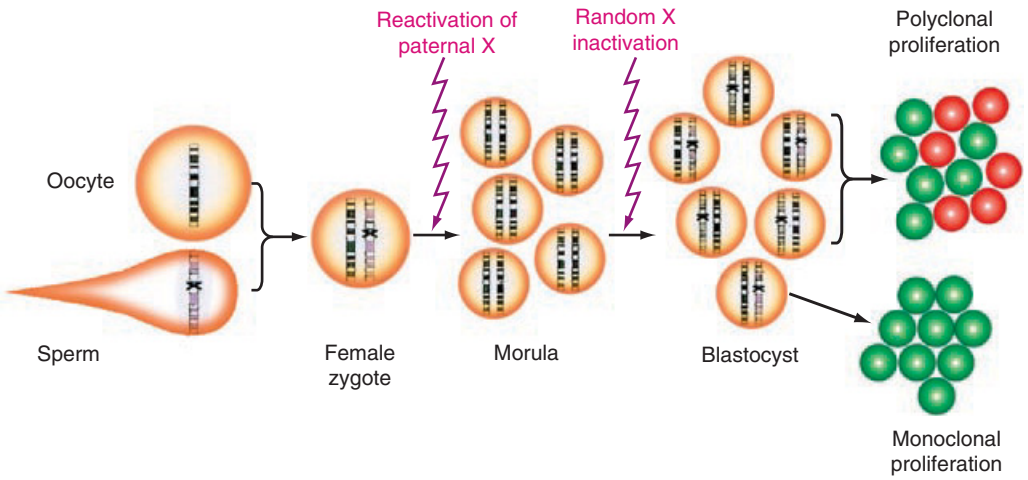

Figure 55–7 X-chromosome–linked enzyme glucose-6-phosphate dehydrogenase (G6PD) as a marker to investigate clonal development of human hematopoietic disorders. Early in embryogenesis, regions of all but one X chromosome are inactivated in each cell containing two or more X chromosomes. The choice of maternal versus paternal X chromosome for inactivation is random. Once the inactivation occurs, it is fixed and is stably transmitted to daughter cells during mitosis (Lyon hypothesis). Females who are heterozygous for the common B type and the less frequent A type, G6PD (localized on Xq27), are mosaic. This cellular mosaicism is used to study monoclonal versus polyclonal cell proliferation and development of malignant hematopoietic diseases. *(Courtesy Dr. W Raskind, University of Washington, Seattle, WA. From Zucker-Franlin D, Grossi CE [eds.]: Atlas of Blood Cells, 3rd ed. Edi-Ermes, Milan 2003.)*

CLL.[50–56] In some patients with AML, *G6PD* studies demonstrated a single enzyme phenotype without the presence of the diagnostic cytogenetic abnormality at the time of hematologic remission, indicating a clonal remission and a possibility of clonal preleukemic phase of AML. This observation provided evidence that, like in CML, a stepwise evolution occurs in AML.[57,58] In MDS, the *G6PD a*ssay demonstrated that lymphoid cells are part of the MDS clone.[55] Particularly informative were patients with myelofibrosis whose marrow cells had trisomy 8. In sharp contrast, cultured marrow fibroblasts had disomy 8 and expressed both B and A *G6PD* types in equal amounts as control skin fibroblasts, whereas marrow-derived granulocytes, erythrocytes, and platelets expressed only type A enzyme. This indicated that marrow fibroblasts were not clonal and were not part of the disease process.[59] *G6PD* studies were particularly useful in the investigations of red blood cells and platelets in hematologic malignancies because these cells cannot be studied by cytogenetics or DNA analysis because they do not have nuclei. Although it is now a "common knowledge" that hematological malignancies have a clonal development, it is greatly due to what is now known as classic Fialkow's work, whose profound insight contributed towards the current concepts and understanding.

Despite the importance of the *G6PD* approach, it is limited by the rarity of females who are heterozygous for the *G6PD* isoenzyme. An alternative and more extensive *DNA-based X-chromosome clonal assay* uses common polymorphic markers that are caused by changes in DNA methylation patterns that accompany inactivation of the X chromosome. These X-linked loci, such as phosphoglycerine kinase, hypoxanthine phosphoribosyltransferase, *DXS25* (M27β), and human androgen receptor (HUMARA), have been extensively used in assessment of clonality, and now it is possible to identify clonal cell populations in virtually all females.[60–66] DNA-based marker systems rely on a sequence polymorphism that has adjacent differences in methylation on the active and inactive X chromosomes.[60] The inactive X chromosome is more highly methylated than its active homologue, but this is only true for certain regions of genes as 10% to 20% of X-linked genes escape inactivation and can be found both in clusters and in isolation.[67–69] The most widely used *HUMARA assay* appears to maintain the stringent methylation differences. The number of CAG tandem repeats differentiates the maternal from the paternal X chromosome.[65,67]

The DNA-based X-chromosome clonal assay is limited to females younger than 60 years because they usually have 1:1 distribution of two mosaic cell population. A ratio greater than 3:1 is found in women older than 60 years, probably as a result of stem cell kinetics influenced by X-linked genetic factors.[70] When the ratio of two cell populations is greater than 3:1, this phenomenon is called a *skewed X-inactivation pattern.* With the HUMARA assay, acquired unequal or skewed X-chromosome inactivation (excessive lyonization) is found in 35% to 40% of women older than 60 years. Thus, X-chromosome–based clonality studies must incorporate age-matched controls.[70,71] Despite the enormous contribution of clonality assays to the understanding of disease processes, they usually are performed in research investigations and rarely are used as diagnostic tools.

Table 55–2 History of Discovery of Philadelphia Chromosome and BCR-ABL Fusion

1960	Philadelphia chromosome (Ph) is identified
1973	Ph is t(9;22)(q34;q11.2)
1983	*ABL* is translocated from chromosome 9 to chromosome 22
1984	*BCR* is localized to 22q11
1987	Ph' is BCR-ABL fusion

CHRONIC MYELOPROLIFERATIVE DISORDERS

The World Health Organization (WHO) classification characterizes myeloproliferative disorders (MPDs) as having clonal and effective hematopoiesis.[72] CML has a unique place among hematologic malignancies and is described separate from other Ph negative MPDs.

Chronic Myelogenous Leukemia

The knowledge about CML accumulated during the last 46 years serves as an example of molecular medicine (Table 55–2). The Ph chromosome is the first example of a specific chromosome abnormality associated with malignant disease. *ABL1* and *BCR* genes are the first oncogenes localized at the site of chromosomal breakpoints in t(9;22)(q34;q11). The *BCR-ABL1* fusion is the first example of a "hybrid" gene leading to the production of dysregulated tyrosine

kinase protein. When inserted into the mouse model, it is the prime example of a human aberrant gene that causes a disease resembling a human myeloproliferative disorder. Finally, imatinib mesylate, a specific tyrosine kinase inhibitor, is the first rationally designed gene-targeted therapy.[5,6,73]

The Ph, named in honor of Philadelphia, the city of its discovery, was described for the first time in 1960.[32] It represents a signature genomic rearrangement occurring in more than 95% of patients with CML. The Ph results from a balanced translocation t(9;22)(q34;q11.2) (Fig. 55–8, *A*).[74] The Ph arises postzygotically, being found only in hematopoietic tissue. The findings of the Ph in myeloid cells, erythroid cells, eosinophils, monocytes/macrophages, basophils, and B lymphocytes and the absence of the Ph in cultured marrow fibroblasts support the concept that the Ph results from a specific rearrangement in a multipotent hematopoietic stem cell and that it is an acquired rather than an inherited abnormality.[49] Of interest, the Ph is rarely identified in T cells. T lymphocytes are long-lived cells and may antedate the development of CML. These observations combined with *G6PD* studies in female patients who are heterozygous for this enzyme and have CML provide further evidence for the concept that CML is a clonal disease arising in a stem cell capable of differentiation into most of the hematopoietic cell lineages.[75,76]

In a review of 1129 Ph positive patients, the 9;22 translocation was identified in 1036 (92%) cases.[77] Karyotype analysis of marrow cells in patients with CML is a time-consuming task. However, it demonstrates not only the presence of the Ph but also other chromosomal rearrangements (clonal evolution) of clinical significance.[78]

The reciprocal nature of the Ph translocation was confirmed when studies showed that its molecular consequence is the translocation of the *ABL* gene from chromosome 9, band region q34, and subsequent fusion to the breakpoint cluster region (*BCR*) gene on chromosome 22, band q11 (see Fig. 55–8, *A,* second row). This creates a hybrid *BCR-ABL1* gene that is transcribed into a chimeric *BCR-ABL1* messenger RNA (mRNA) and translated into a specific chimeric protein.[79,80]

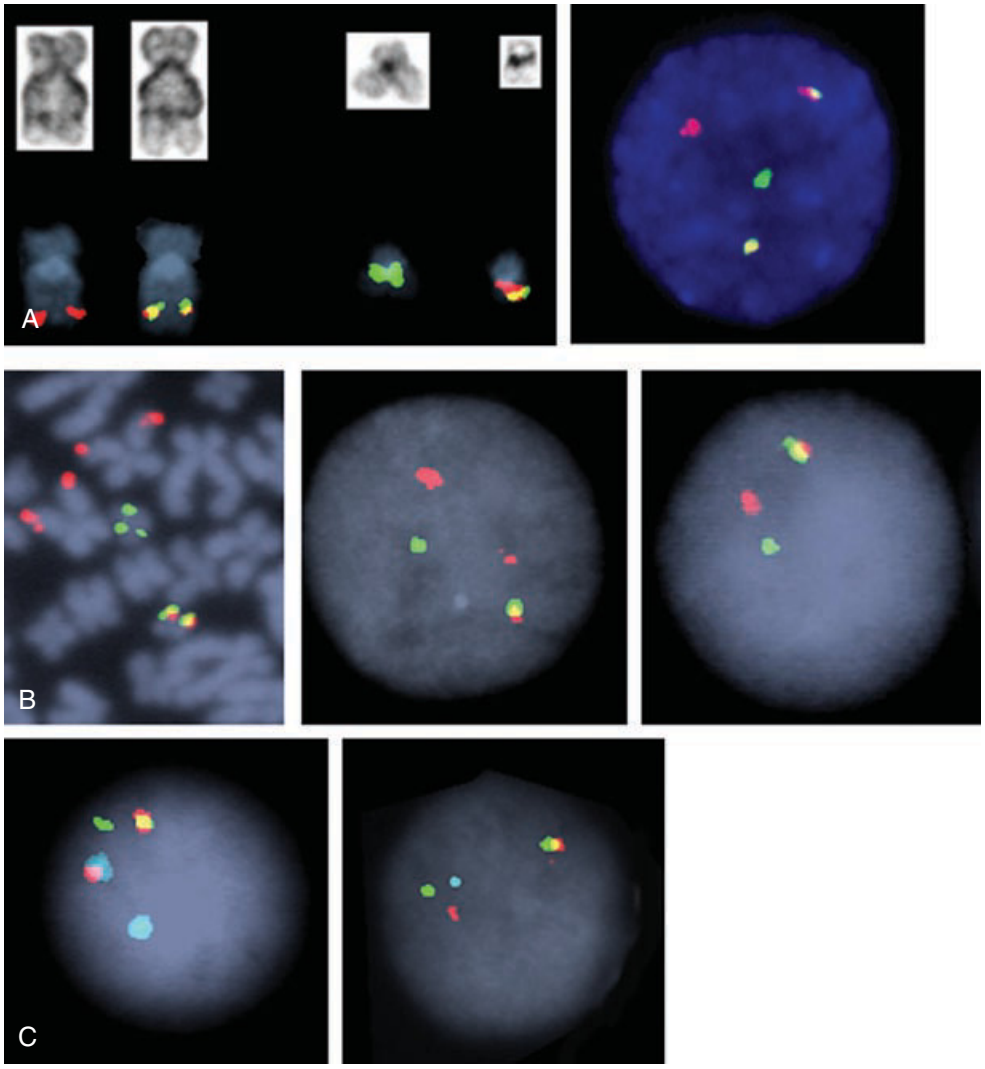

Figure 55–8 Identification of the Philadelphia (Ph) chromosome. **A,** Conventional cytogenetics (left) shows t(9;22)(q34;q11.2), and metaphase FISH with dual-color/dual-fusion *BCR-ABL* probe (underneath) shows two fusion signals (yellow) on abnormal chromosomes 9 and 22, one red single signal on normal homologue 9 and one single green signal on normal chromosome 22. Right, Nucleus after hybridization with dual-color/dual-fusion probe indicating two fusion signals. **B,** Metaphase cell (left) and interphase cell (middle) after hybridization with BCR-ABL extrasensitive probe indicating a fusion signal (yellow) on the Ph chromosome, *BCR* (green) on normal chromosome 22, *ABL* (red) signals on normal chromosome 9, and part of *ABL* on der(9) to reduce the number of false-positive cells. The interphase nuclei on the right is hybridized with a single-fusion BCR-ABL probe showing one fusion signal (yellow) and one single red and green signal on normal homologues. **C,** Two interphase nuclei after hybridization with triple-color BCR-ABL-ASS probe in which *ASS* is aqua. The left nuclei indicate a *BCR-ABL* fusion and disomy for *ASS.* The right nucleus shows deletion for *ASS* locus, consistent with deletion of der(9) (see Fig. 55–11).

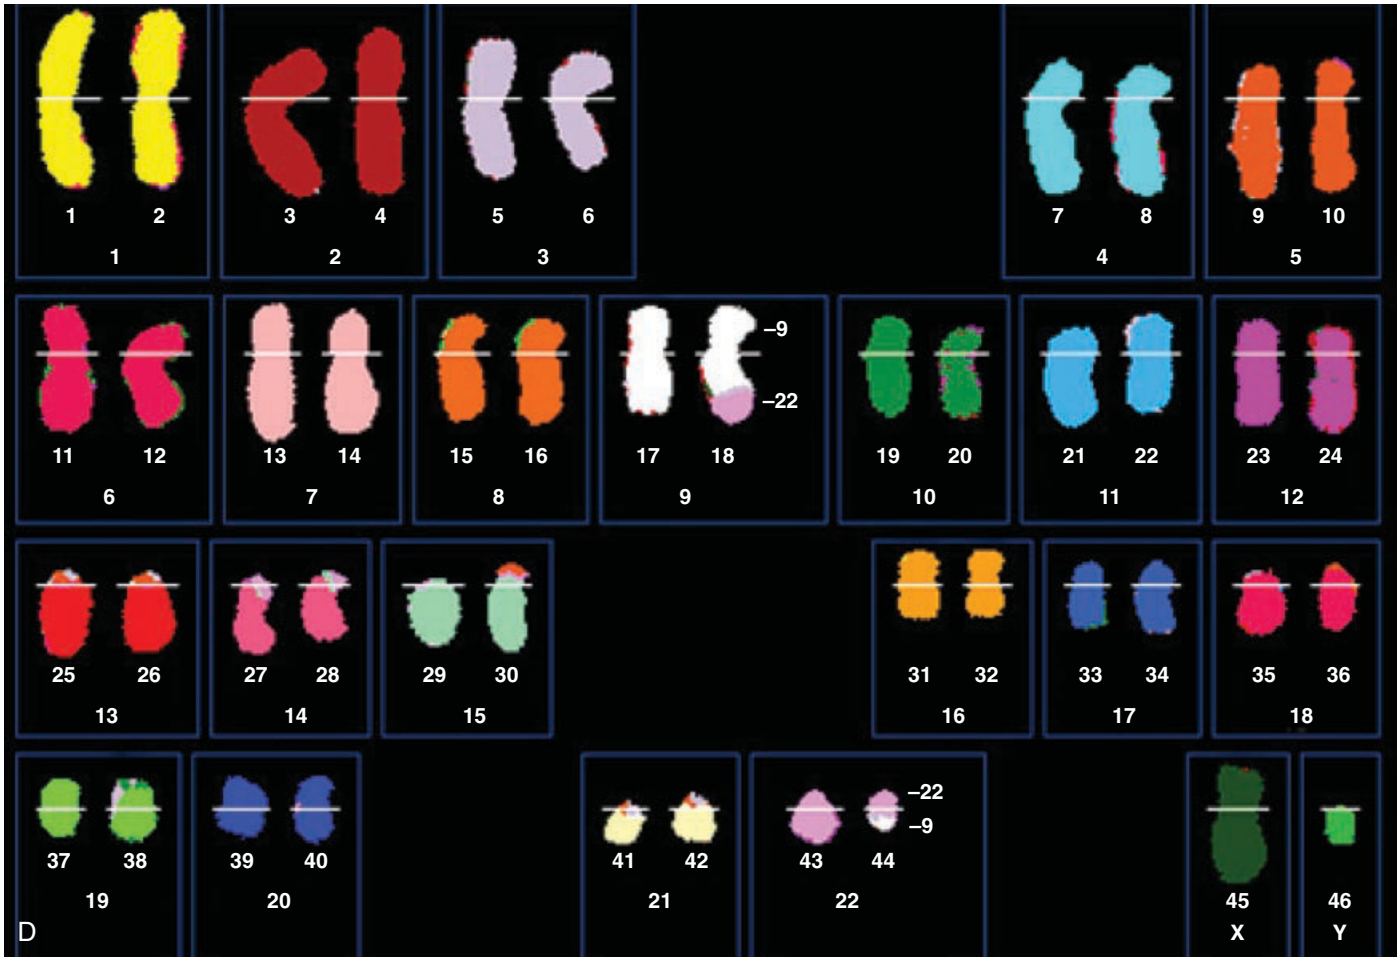

Figure 55–8, cont'd D, In multicolor FISH, identification of t(9;22) is indicated as an exchange of white and pink colors. *(M-FISH courtesy Dr. D. Zimonjic, NCI, NIH, Bethesda, MD. Adapted from Zucker-Franlin D, Grossi CE [eds.]: Atlas of Blood Cells, 3rd ed. Edi-Ermes, Milan 2003.)*

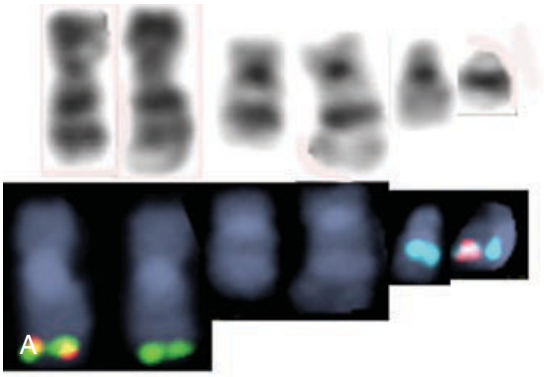
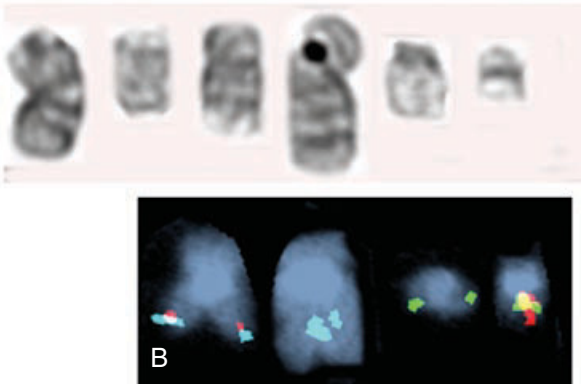


Three major breakpoint locations along the *BCR* gene on chromosome 22 result in three chimeric proteins. They include $P210^{BCR\text{-}ABL1}$, $P190^{BCR\text{-}ABL1}$, and $P230^{BCR\text{-}ABL1}$ and are associated with three distinct types of leukemia. $P210^{BCR\text{-}ABL}$ is found in the majority of patients with classic Ph positive, *BCR-ABL1* fusion-positive CML and approximately 30% of patients with Ph positive ALL. Expression of $P190^{BCR\text{-}ABL1}$ is seen in 20% to 30% of adult and 80% of children with ALL, in rare CML patients, and in the majority of patients with rare Ph positive AML, whereas expression of $P230^{BCR\text{-}ABL1}$ is associated with indolent chronic neutrophilic leukemia variant.[79–83]

The *BCR-ABL1* fusion is demonstrated in both standard and variant translocations, in cases where chromosome 9 involvement is cytogenetically not detectable, and when a masked Ph is present. In the majority of patients, the fusion of *ABL1* and *BCR* takes place on chromosome 22 (Fig. 55–9). However, a small group of patients are described in whom the *BCR* gene is translocated to chromosome 9, and the fusion of two genes is localized to 9q34.[84–86] The prognosis of these patients may be poorer, but at this time the number of reports is too small for a definitive conclusion**.** The *BCR-ABL1* fusion transcript is present in neutrophils, monocytes, eosinophils, erythrocytes, B cells, rarely in T cells, and in $CD34^+$ cells and is associated with increased proliferation of $CD34^+$ myeloid progenitor cells but not of other more mature myeloid precursors. These observations are consistent with previous Ph and *G6PD* studies and confirm that CML originates in a multipotent stem cell capable of differentiating to all hematopoietic cell lineages with the exception of T cells.[75,87,88] B-lymphoid differentiation and *G6PD* studies in CML provide evidence for the existence of clonal *BCR-ABL1* fusion-negative and Ph negative stage. The formation of *BCR-ABL1* and Ph occurs in the already abnormal and genetically unstable clone of pluripotent hematopoietic cells.[76,89] Thus, it is the preexisting genetic instability that predisposes to formation of *BCR-ABL1* and Ph. Once Ph formation occurs, it has a further selective growth advantage over normal cells, in the multistep pathogenesis, resulting in overwhelming *BCR-ABL1 positive*, Ph positive marrow cells at the time of diagnosis of CML.



In the 5% of patients with CML who are Ph negative by cytogenetic studies, like Ph positive patients, clonal and stem cell origin can be demonstrated, and molecular analysis reveals *BCR-ABL* fusion in approximately 2% to 3% of these patients (Fig. 55–10).[90,91] In the majority of Ph negative patients, an *ABL* insertion from chromosome 9 to 22q11.2 results in a BCR-*ABL1* fusion product without reciprocal translocation of sequences from chromosome 22 to chromosome 9. Approximately 2% of patients truly are Ph negative, *BCR-ABL* fusion negative. They may not have CML but rather another myeloproliferative disorder such as chronic myelomonocytic leukemia or refractory anemia with excess blasts.

The concept that the *BCR-ABL* fusion plays a central role in the pathogenesis of CML is strongly supported by two lines of evidence: (a) retroviral transduction experiments in which $P210^{BCR\text{-}ABL1}$ is expressed in murine marrow cells, resulting in a myeloproliferative disorder resembling CML; and (b) imatinib, a tyrosine kinase inhibitor, selectively inhibits the *BCR-ABL* fusion protein in mice and specifically inhibits the growth of human Ph positive cells in vitro and in vivo.[5,6,92,93] Although considered necessary, *BCR-ABL* may not be initial or sufficient to cause malignant transformation in CML.[49,89]

Genomic PCR and *Southern blot analysis* can determine the exact breakpoints of DNA fusion products. *Reverse transcriptase PCR* (RT-PCR) and *Northern blot analysis* allows detection of *BCR-ABL* tran-

t(9;17;22)(q34;q24;q11.2)

t(7;9;22;22) (q22;q34;q11.2;q13.3)

Figure 55–9 Identification of *BCR-ABL* fusion in patients with complex karyotypes. Partial karyotype from a patient with chronic myelogenous leukemia showing t(9;17;22) **(A)** and from a patient showing a four-way translocation with t(7;9;22;22) karyotype **(B)** indicating the *BCR-ABL* fusion is on the Philadelphia chromosome even in complex chromosomal translocations.

scripts at the RNA level. The $P210^{BCR\text{-}ABL1}$ protein can be demonstrated using antibodies against *BCR* and *ABL1* regions by *immunoprecipitation* or in *Western blot analysis.* Current FISH studies for detection of *BCR-ABL1* fusion at diagnosis uses a dual-color *BCR-ABL* ES probe or *BCR-ABL1* dual-fusion probe (Fig. 55–8, *A* and *B,* and Fig. 55–11). A triple-color *BCR-ABL1*-ASS probe is used for detection of deletions on both chromosomes 9 and 22. Approximately 12% to 15% of patients with CML have large deletions adjacent to the Ph translocation breakpoint on the derivative 9 chromosome, and initial reports demonstrated inferior survival in these patients (see Fig. 55–8, *C*).[94,95] Subsequent quantitative PCR and FISH studies demonstrated that deletions are heterogeneous and may involve both chromosomes 9 and 22 (majority of cases), only chromosome 9 (8% of patients with deletions; Fig. 55–12), or only chromosome 22 (4% of cases with deletions). They are associated with adverse prognosis, inferior survival, and higher probability of relapse after hematopoietic cell transplantation.[96,97] A multivariate analysis of 339 patients, with a median observation of 7 years, confirms that deletions on 9q alone, spanning the *ABL1-BCR* breakpoint, are significant independent predictors of adverse prognosis.[98]

At diagnosis of CML, conventional cytogenetics remains a gold standard because the chromosome analysis will identify not only the t(9;22) but also other chromosomal abnormalities that may indicate accelerated or blast phase of the disease or clonal proliferation of Ph negative cells.[99,100] The current international recommendation is that FISH studies should be performed at diagnosis in conjunction with conventional cytogenetics to determine deletion status on der(9q) and to identify patients who are *BCR-ABL1*$^+$ but have the Ph negative karyotype.[101]

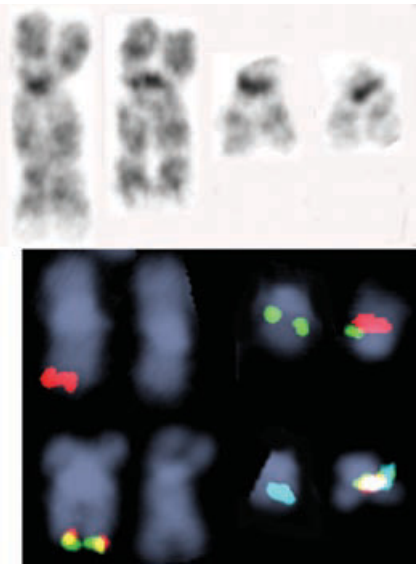


Figure 55–10 Partial karyotype from a patient with Philadelphia chromosome (Ph) negative chronic myelogenous leukemia (top) showing normal chromosomes 9 and 22. Two pairs of chromosomes 9 and 22 after hybridization with dual color (middle) and triple color (bottom) demonstrating *BCR-ABL* fusion on the Ph chromosome without apparent t(9;22). Tricolor strategy showed *ABL* and *ASS* in close proximity and appearing as fusion on normal 9 (bottom left chromosome) and *BCR-ABL-ASS* fusion (white) on normal 22.

Imatinib mesylate has revolutionized therapy for CML and, for many patients, has transformed a deadly disease into a chronic disorder that is compatible with normal life.[102] The standard method for monitoring a patient's response to therapy is conventional cytogenetic analysis of cells obtained from marrow aspirate. In the phase III International Randomized Study of Interferon versus STI571 (IRIS), 89% of patients had Ph negative marrow aspirates as determined by conventional cytogenetics at 5 years.[6] However, conventional cytogenetics has limited sensitivity. The degree of tumor load reduction is determined to be an important prognostic factor for patients with CML on therapy. CML patients without discernible Ph detected by conventional cytogenetics analysis may still harbor up to 10^{10} leukemic cells.[103]

Hypermetaphase FISH has greater sensitivity compared to conventional cytogenetics and may detect 31% of *BCR-ABL1*$^+$ metaphase cells in patients who are Ph negative as assessed by conventional cytogenetics.[104] Interphase FISH does not depend on the cycling status of cells, and use of double-fusion probes has reduced false-positive results to approximately 1%. However, if peripheral blood cells rather than marrow aspirate cells are used to monitor residual disease, the high percentage of *BCR-ABL1 f*usion-negative lymphoid cells may underrepresent actual residual tumor load. In most direct comparison studies, interphase FISH of peripheral blood compared to conventional cytogenetics of marrow in patients who are treated with interferon or imatinib showed good correlations ($r = 0.91–0.97$).[105,106] *Real-time quantitative PCR* (RQ-PCR) is by far the most sensitive method. It provides an accurate measure of the total leukemia cell mass and the degree to which *BCR-ABL1* transcripts are reduced by therapy, and it correlates with progression-free survival.[101,107]

The goal of therapy in CML is to achieve a molecular response as measured by the reduction or elimination of *BCR-ABL1* transcripts. In IRIS, at 5-year followup, complete cytogenetic response combined with major molecular response at 12 months is associated with a 97% progression-free survival rate. This compares with an 89% progression-free survival for those with complete cytogenetic response but without major molecular response.[6,108] Current international recommendations for optimal molecular monitoring of patients receiving imatinib treatment includes an RQ-PCR assay expressing the *BCR-ABL1* transcript levels on an internationally agreed scale.[101,109] These

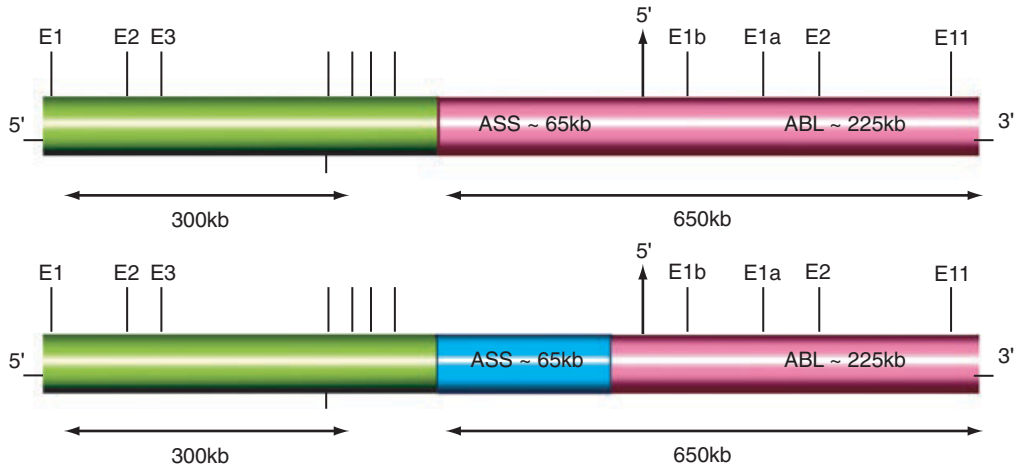

Figure 55–11 Schematic representation of the most frequently used BCR-ABL probes. Dual-color/single-fusion extrasensitive probe strategy, as indicated in text, uses a 650-kb probe in which two loci, *ABL* and *ASS,* both are labeled in red. *BCR-ABL* fusion-positive nuclei show three red signals: one small red signals on der(9), one red signal on normal homologue 9, and a third red signal in fusion with *BCR*. When a triple-color probe is applied, the *ASS* locus usually is labeled in aqua and the *BCR-ABL* fusion-positive cells show two aqua signals, unless there is deletion of der(9). The most useful application of triple-color probe is documentation of deletion of derivative chromosome 9.

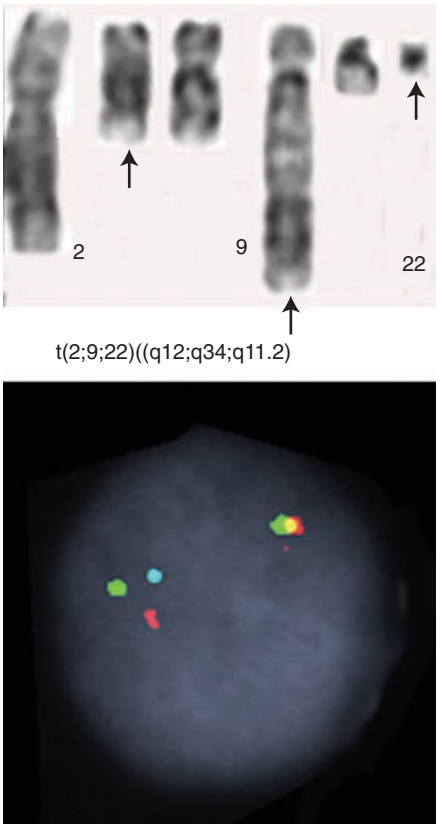

Figure 55–12 Application of triple-color *BCR-ABL-ASS* probe to cells from a patient with chronic myelogenous leukemia and t(2;9;22) karyotype (top). Interphase cell (bottom) shows *BCR-ABL* fusion signal (yellow) on the Philadelphia chromosome and one *ASS* (aqua) signal indicating loss of DNA sequences from derivative chromosome 9 as a result of this complex translocation.

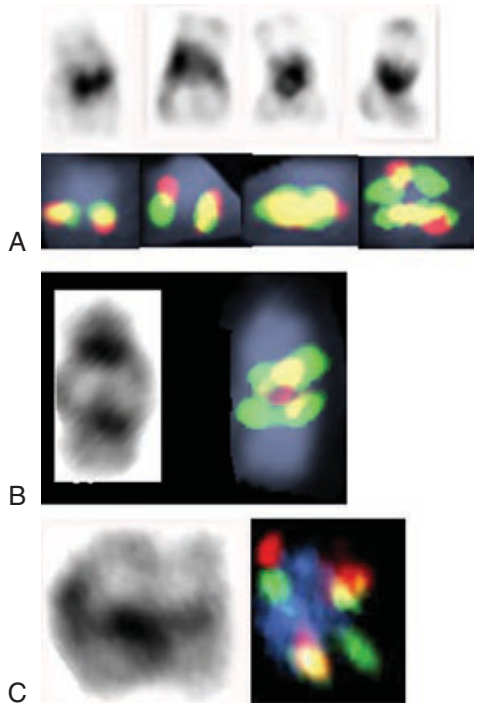

Figure 55–13 Examples of unusual Philadelphia (Ph) chromosomes associated with imatinib resistance and blast crisis of chronic myelogenous leukemia. **A,** Amplification of the Ph chromosome (top row) and the *BCR-ABL* fusion in a patient treated for 3 months with imatinib. The patient developed five copies of the Ph chromosome and 5 copes of the *BCR-ABL* fusion (yellow). B) G banding of dicentric Ph chromosome (left) dic der(22)t(9;22)(q34;q11.2) and after FISH studies (right) showing two copes of *BCR-ABL* fusion. C) G-banding of isoderivative Ph, ider(22)t(9;22)(q34;q11.2) (left) and after FISH studies showing two copies of *BCR-ABL* fusion (yellow) on the end of both arms.

recommendations are provisional and may require revision as new evidence emerges. It should be noted, however, that use of highly sensitive PCR-based technologies for detection of minimal residual disease is being questioned because of detection of *BCR-ABL1* transcripts in peripheral blood from normal subjects.[110,111] This finding raises the question of whether cure should be defined on a functional rather than a very sensitive molecular basis.[112]

The two major obstacles to successful imatinib-based therapies for patients with Ph positive, *BCR-ABL1* fusion-positive CML are the persistence of *BCR-ABL* fusion-positive cells and relapse of the disease due to emergence of resistance to imatinib.[108] Acquired resistance to imatinib treatment is manifested in two ways: amplification of *BCR-ABL1* fusion product (Fig. 55–13) and mutations in the ABL kinase

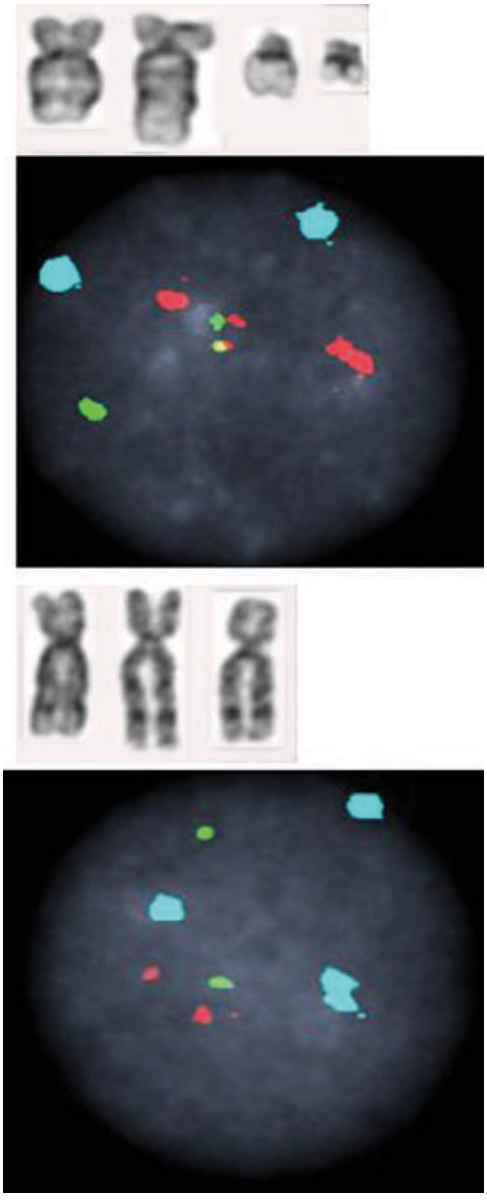

Figure 55–14 Two different cell populations from a patient treated with imatinib. One population shows t(9;22) (top row, partial G-banded karyotype) and the *BCR-ABL* fusion signal (yellow, second row) as well as disomy 8 (aqua). In contrast, the second population shows trisomy 8 (third row, partial G-banded karyotype) in the *BCR-ABL* fusion-negative cells (fourth row) showing disomy for the *BCR (green), ABL* (red) as well as trisomy for chromsome 8 (aqua) (see text for details).

domain. Currently 40 different ABL1 kinase domain mutations have been described.[112]

Between 5% and 8% of patients undergoing treatment with imatinib will develop chromosomal abnormalities such as trisomy 8, monosomy 7, del(20q), and other anomalies in *BCR-ABL1* fusion-negative cells.[113,114] Imatinib may induce chromosomal abnormalities in *BCR-ABL1*$^{-}$ cells. Alternatively, imatinib may uncover chromosomal abnormalities present prior to therapy after significant reduction of overlying Ph positive cells (Fig. 55–14). Presence of +8 and other chromosomal anomalies in Ph negative cells in patients treated with imatinib suggests that CML has a multistep pathogenesis and that clonal Ph negative cells precede development of the Ph positive clone (Fig. 55–15).[114] This important observation about the pathogenesis of CML demonstrates the power of conventional cytogenetics, even in the era of molecular assays, and should be used at least annually while patients are undergoing imatinib treatment.

Genetic Testing for Chronic Myelogenous Leukemia

At diagnosis of chronic myelogenous leukemia (CML), perform quantitative cytogenetic analysis of bone marrow aspirate, which is sine qua non because peripheral blood cells rarely contain blast cells at the time of presentation. If the bone marrow aspirate is a "dry tap," perform interphase fluorescence *in situ* hybridization (FISH) using either a BCR-ABL extrasensitive or BCR-ABL dual-fusion color probe. Triple-color BCR-ABL-ASS is particularly useful for identifying patients with deletion on either chromosome 9 or chromosome 22. To monitor patients with CML during therapy, use FISH to study blood or bone marrow to track changes in the percentage of cells with BCR-ABL fusion at 3-month intervals. Perform real-time quantitative polymerase chain reaction at 12 months. At relapse, perform a chromosome study to assess the karyotype of the malignant clone and to determine whether a new chromosomally abnormal clone has developed or a new subclone in the Philadelphia chromosome (Ph) positive clone.

CML patients who cannot tolerate or are resistant to imatinib may benefit from the second generation of tyrosine kinase inhibitors, such dasatinib and nilotinib. These agents bind to the *ABL* kinase domain in a matter distinct from that of imatinib and thereby retain activity against nearly all imatinib resistant mutations.[108,115]

In blast crisis of CML, 80% to 85% of patients show karyotypic evolution, that is, new chromosomal abnormalities in very distinct patterns are present in addition to the Ph. The most common changes include gain of chromosome 8 or 19, gain of a second Ph, i(17q), alone or in combination, to produce modal chromosome numbers of 47 to 50. Isochromosome 17q occurs almost exclusively in myeloid blast crisis. Other less frequently observed include monosomies of chromosomes 7 and 17, loss of Y, trisomies of chromosomes 17 and 21, and t(3;21)(q26;q22). Complete cytogenetic remission for patients in accelerated phase or blast crisis CML treated with imatinib is rarely accompanied by a normal karyotype; however, 6% to 17% of these patients may have some cytogenetic response[108] (see box on Genetic Testing for Chronic Myelogenous leukemia).

Ph-Negative Chronic Myeloproliferative Disorders

Ph negative MPDs are disorders arising in a single clone of multipotent precursor cells in which one or all myeloid lineages are abnormally amplified. Classic and more frequently encountered Ph negative MPDs include polycythemia vera (PV), primary myelofibrosis (PMF), and essential thrombocytopenia (ET). Less frequently encountered are neutrophilic leukemia, hypereosinophilic syndrome/chronic eosinophilic leukemia, systemic mast cell proliferations, atypical CML, and unclassifiable myeloproliferative disorders. Classic Ph negative MPDs exhibit overlapping clinical and cytogenetic features and have a variable tendency to evolve into acute leukemias. Their clonal origin and multistep pathogenesis are established with use of X-chromosome–based clonality assay demonstrating a single *G6PD* phenotype in all hematopoietic cell lineages with the exception of T lymphocytes.[52–55,59,116] These disorders are also characterized by the recently discovered somatic point mutation within the Janus kinase 2 *(JAK2)* gene. The substitution from guanine to thymine results in an amino acid change from valine (V) to phenylalanine (F) at position 617 in the JH2 domain, constitutively activating *JAK2*.[117–120] Up to 97% of PV patients are positive for the *JAK2* 617V > F mutation, as are approximately 50% of ET and PMF patients.[121] The observation that *JAK2* V617F mutation is present in all hematopoietic lineages, including T and B lymphocytes, suggests clonal development of Ph negative MPDs.[122]

Despite technologic advances, cytogenetic analysis of marrow cells from patients with Ph negative MPD remains a laborious and

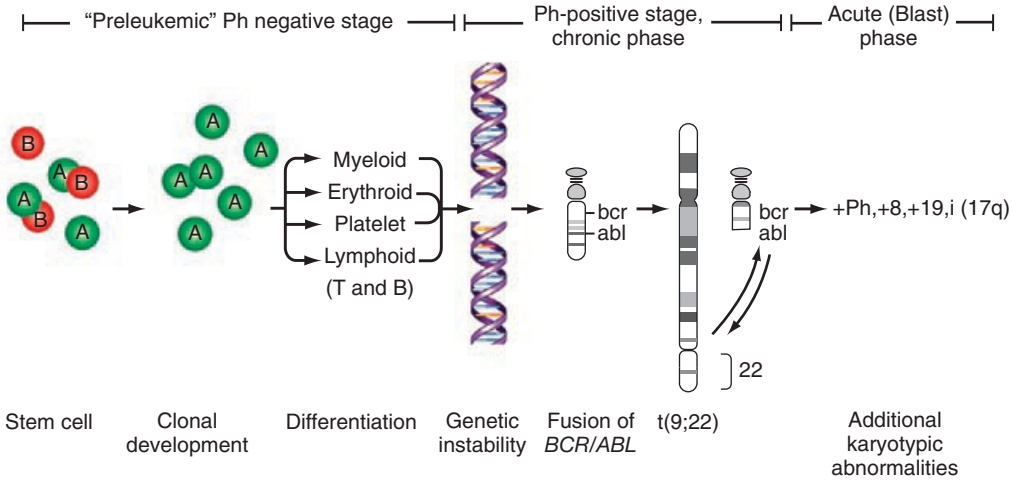

Figure 55–15 Hypothetical model of multistep pathogenesis of Philadelphia chromosome (Ph) positive chronic myelogenous leukemia. The first detectable event is a clonal proliferation of cells that are capable of differentiating to all hematopoietic lineages. These cells are genetically unstable and give rise to *BCR-ABL* fusion and the Ph chromosome. The blast crisis is characterized by nonrandom abnormalities occurring in a genetically unstable Ph positive clone. At least six events can be delineated. *(From Raskind.[35])*

time-consuming technology. Between 5% and 20% of marrow specimens may have a low mitotic yield or are otherwise uninformative due to a "dry tap." This is a particularly important problem in patients with myelofibrosis. The unifying concept of genetic instability in Ph negative MPD is a loss or a gain of genetic material. However, rare recurrent balanced translocations have been identified in MPDs (Table 55–3). In patients with these diseases, marrow cytogenetic studies should be performed because an abnormal MPD clone in the marrow may be present at a very low frequency and not in peripheral blood granulocytes. For example, del(20q)-bearing cells in some patients represent a subclone that is retained only in marrow and is not present in clonal peripheral blood granulocytes,[122] suggesting that examination of blood granulocytes is not a reliable surrogate for marrow cells in detecting karyotype abnormalities of myeloid cells using conventional cytogenetics methods.

At diagnosis, conventional cytogenetic examination of marrow cells reveals chromosome abnormalities in 20% to 25% of PV cases, 45% to 50% of PMF cases, and 8% of ET cases. In the case of PV, detection of the five most common chromosomal abnormalities may be increased to 29% in marrow cells and to 23% in peripheral blood granulocytes when more sensitive FISH methods are used.[123,124] Similar chromosomal abnormalities are found in all classic Ph negative MPDs; however, their frequencies differ in each of these disorders (Fig. 55–16). PV is more likely to exhibit +9/+9p and/or del(20q), whereas PMF is more likely to exhibit del(13q) and/or 12q abnormalities (Fig. 55–17).[125–127] Additionally, these rearrangements are observed in other myeloid neoplasms, such as MDS,[128] atypical Ph negative MPD,[129] and AML.[130]

Trisomy of chromosome 9 and gain of the short arms of chromosome 9 are most frequently observed in PV.[123] Different chromosomal rearrangements may contribute to trisomy, tetrasomy, or amplification of 9p (Fig. 55–18). Unbalanced der(9)t(1;9) resulting in trisomy of both 1q and 9p appears to be the most frequent and relatively specific abnormality observed in PV.[131–133] The prognostic clinical value of +9/+9p is not known, but it appears to occur exclusively in patients positive for the *JAK2* 617V > F mutation.[134,135] Duplication, triplication, or amplification of the mutated *JAK2* allele on the 9p24.1 chromosomal region as a result of +9/+9p may be associated with an increased level of constitutive signaling.[117] Loss of 9p heterozygosity as a result of uniparental disomy has been detected in 30% of PV patients.[136] Interestingly, the *JAK2* gene has been reported to be fused with three different genes, *TEL/ETV6,*[137] *BCR,*[138] and *PCM1,*[139] in atypical MPDs and lymphoid neoplasms. All of these fusion genes have *JAK2* rearrangements of either the JH1 or JH2 domain that produce a phenotype similar to the *JAK2* 617V > F mutation.

Deletion of the long arms of chromosome 20 is a recurrent nonrandom clonal chromosomal abnormality in Ph negative MPDs; it is found in MDS and rarely in AML.[123,140–142] Heterogeneity of this abnormality is suggested by the observation that two minimally deleted regions characterize different disorders. A 2.7-Mb region spanning D20S108 (proximal) and D20S481 (distal) is identified in Ph negative MPD, whereas a 2.6-Mb region spanning R52161 (proximal) and WI-12515 (distal) region is found in other myeloid malignancies.[143] A common overlapping region is 1.6 kb and as such may constitute the major mechanism for loss of heterozygosity. In myeloproliferative disorders, the sole del(20q) does not appear to adversely affect survival.[144–146] Interphase FISH greatly enhances detection of del(20q).[145] Its use is important because the abnormality, at least in PV, may be dormant for many years before del(20q) cells gain proliferative advantage.[123] Molecular cytogenetics using M-FISH, CGH, and genomewide screening failed to detect cryptic or occult 20q aberrations within the 20q11.2/q13.1 region in patients with PV and normal karyotype.[147] Deletion 20q is identified primarily in patients positive for the *JAK2* 167V > F mutation, but rare PV and ET patients with del(20q) are negative for the *JAK2* V167V > F mutation.[131,134,148]

Gain of chromosome 8 is a nonrandom recurrent abnormality not only in Ph negative MPD. It also is one of the three most frequent abnormalities in MDS and is present in 10% of patients with malignant hematopoietic disorders of both myeloid and lymphoid lineages. The prognostic significance in PV is unknown. Some patients with PV have trisomy 8 for more than 20 years.[149] The simultaneous presence of both +8 and +9 is observed in 3% to 4% of PV cases. It is rarely seen in any other hematologic malignancies.

The unbalanced translocation resulting in trisomy 1q is demonstrated in 11% of PV patients, 22% of PMF patients, and 14% of ET patients. It is the third most frequent abnormality in PV (Fig. 55–19).[131] Moreover, 70% of patients with PMF following PV show trisomy 1q as a result of unbalanced translocations. In all cases, a common trisomic region spanning 1q21q22 to 1q32 is present. PMF following PV is considered cytogenetically different from both PMF and PV.[150]

Deletions of the long arms of chromosome 13 are more frequent in PMF (25%–30% of abnormal karyotypes) than in PV (9%–13%) but also are found as recurrent abnormalities in MDS and lymphoid malignancies (different breakpoints).[126] Fine FISH mapping has defined commonly deleted region to 13q13.3–q14.3 encompassing

[a]Modified from reference 167.

RB1, D13S319, and *D13S25* loci. Cryptic 13q deletions do occur but are rare and easily identified with FISH in both marrow and peripheral blood. Most patients with del(13q) are negative for the *JAK2* 617V > F mutation.[134,148]

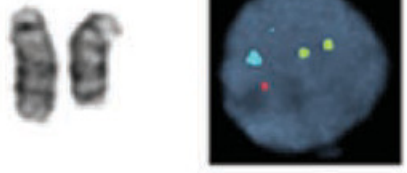
To compare the efficacy of chromosome studies and FISH, blood and marrow from 42 patients who had myelofibrosis were studied using both methods.[151] The FISH method used probes to detect common anomalies of chromosomes 5, 7, 8, 11, 13, 20, and 21. The results of these two methods were similar, but some patients had chromosome anomalies that were detected only by conventional cytogenetic studies. Although FISH analysis is not generally a substitute for conventional cytogenetic studies for Ph negative MPD, it is useful for patients with inadequate marrow specimens and for patients who would benefit from periodic testing to monitor disease status. Conventional cytogenetics can be useful in patients who are *JAK2*-negative, and the current recommendation is to perform cytogenetic studies at baseline in patients with PMF. WHO diagnostic criteria for ET include absence of Ph and *BCR-ABL1* fusion as well as absence of del(5q),t(3;3)(q21q26) and inv(3) (q21q26). Consequently, conventional cytogenetics is necessary for the diagnosis of ET.[152] A FISH test for *BCR-ABL1* fusion is particularly useful to rule out CML in the diagnosis of ET.

Microarray studies on isolated mature granulocytes or $CD34^+$ cells from patients with PV may demonstrate upregulated and downregulated genes; however, specific gene abnormalities that can distinguish PV patients from normal controls are not yet identified. In contrast, preliminary SNP studies of $CD34^+$ cells from nine patients with PV positive for the *JAK2* V617F mutation confirm previous cytogenetic observations that amplification of 9p in a region harboring the *JAK2* locus along with 17q12.3 region are the most common genomic gains. More specifically, 21 genes in recurrently amplified chromosomal regions have significantly elevated expression levels, including *NFIB* on 9p24, and seven genes in recurrently deleted regions have significantly depressed expression level, including *TOPI* on 20q12.[153]

Molecular detection of the *JAK2* 617V > F mutation in patients with clonal hematopoiesis is diagnostic for Ph negative MPD but does not differentiate among PV, ET, PMF, and rare cases of AML and MDS. No doubt the *JAK2* 617V > F somatic mutation is the major genetic contributor to the Ph negative MPD phenotype. However, in this rapidly evolving field, currently six lines of evidence indicate that the *JAK2* 617V > F somatic mutation is neither an initiating event nor the only genetic event resulting in the Ph negative phenotype. (a) From 3% to 7% of patients are negative for the *JAK2* 617V > F mutation, and approximately 50% of PMF and ET patients do not harbor the mutation. (b) Other novel *JAK2* mutations are described in 5% to 15% of Ph negative, *JAK2* V617F-negative MPD patients. One such mutation in *JAK2* exon 12 results in a myeloproliferative phenotype when transfected in a murine model. The *JAK2T7875N* activating mutation results in MPD with features of megakaryoblastic leukemia. The *JAK2ΔIREED* mutation, which involves a five-amino-acid deletion within the JH2 pseudokinase domain, is detected in B-cell precursor ALL, indicating that other *JAK2* mutations may contribute to the lymphoid leukemic phenotype.[154–157] (c) Chromosomal translocations that fuse *JAK2* to another protein are also capable of inducing both myeloproliferative and lymphoid disease. (d) Wild-type *JAK2* is identified in EPO-independent erythroid colonies in a proportion of PV patients with clonal hematopoiesis.[116] (e) Transformation of MPD to AML occurs in *JAK2* V617F-negative clones from patients with *JAK2* 617V > F-positive disease.[158] (f) Recurrent chromosomal abnormalities such as del(20q), trisomy 8, and 12q translocations are detected in a number of patients with PV, ET, and PMF who have *JAK2* 617V > F-negative disease (Fig. 55–20).[148,159]

Rare recurrent balanced abnormalities in atypical Ph negative MPD generally involve the *PDGFRB* gene found at 5q33, *FGFR1* gene on 8p11 (these disorders are referred to as myeloproliferative syndrome or stem cell leukemia syndrome), and *PDGFRA* gene on 4q12. The best described are t(5;12)(q33;p13) resulting in *ETV6-PDGFRB* fusion protein[160] and t(8;13)(p11;q12) resulting in the *ZNF198-FGFR1* fusion gene.[161]

The most frequent recurrent abnormality is the cryptic deletion on 4q12 as a result of *FIP1L1-PDGFRA* fusion gene reported to occur at frequencies ranging from 3% to 56% in patients with chronic eosinophilic leukemia/hypereosinophilic syndrome.[162] The disparity in frequencies reflects differing levels of stringency criteria in the diagnosis of disorders with hypereosinophilia as well as different methodology used for detection of *FIP1L1-PDGFRA* fusion. The



Chromosomal/FISH abnormality		PV	PMF	ET
			% abnormal

Figure 55–16 Most common recurrent chromosomal abnormalities and their approximate frequencies in three classic Philadelphia chromosome (Ph) negative myeloproliferative disorders: polycythemia vera, primary myelofibrosis, and essential thrombocythemia. *(From Silver RT, Tefferi A [eds.]: Myeloproliferative Disorders. Informa, New York, London 2007.)*

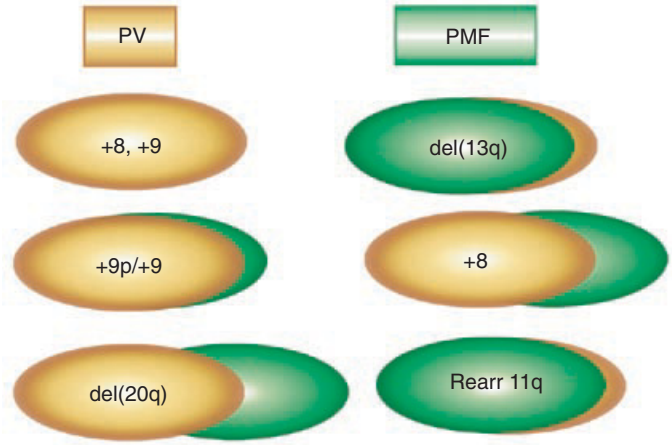

Figure 55–17 Overlapping chromosomal characteristics of polycythemia vera (PV) and primary myelofibrosis (PMF). Trisomy 9/+9p is more frequent in PV, whereas del(13q) is more frequent in PMF. Both abnormalities may be identified in the two diseases. Deletion(20q) is found at similar frequencies in PV and PMF.

Figure 55–19 Partial karyotype from a patient with primary myelofibrosis showing der(1)t(1;19) resulting in trisomy for 1q and 19p. Trisomy 1q in polycythemia vera is most often observed as a result of der(9)t(1;9) (see Fig. 55–18), but different forms of trisomy1q in Philadelphia chromosome (Ph) negative myeloproliferative disorder were described.

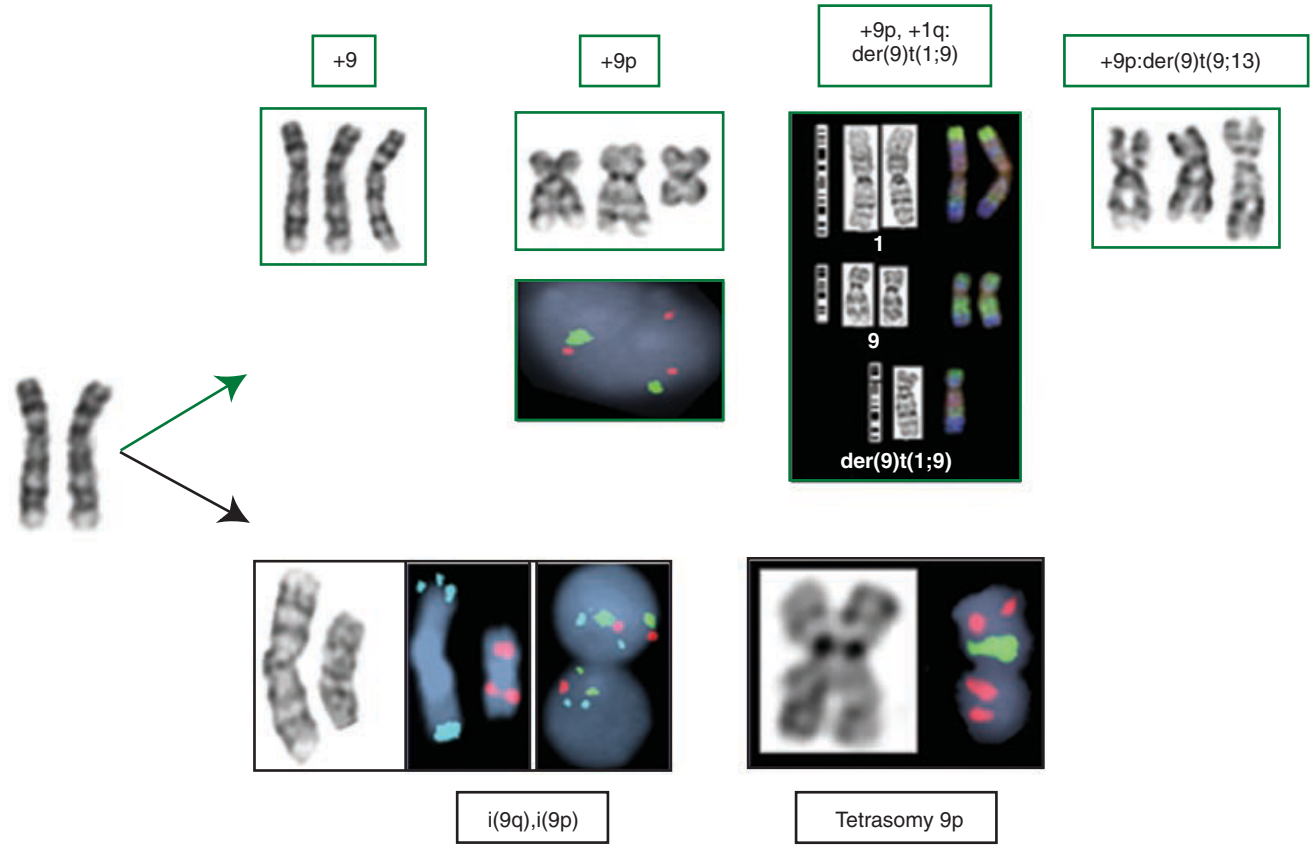

Figure 55–18 Abnormalities of chromosome 9 and 9p in polycythemia vera. Most frequent chromosome abnormality includes (top row) trisomy 9, isolated +9p (three red signals for 9p21 locus and two green CEP9 signals in interphase nuclei), der(9)t(1;9) resulting in trisomy 1q and 9p (documented by original Rx multicolor FISH), or a form of rare +der(9)t(9;13) resulting in trisomy 9p and 13q. Other rare 9p abnormalities include isochromosome (9q) and i(9p) (bottom row), G banding (left), and after FISH study (middle and right), indicating two *ASS* loci on both arms of i(9q) and two 9p21 loci on both i(9p) formation. Interphase FISH shows normal disomy for all tested loci. Isochromosome 9p in a patient with two normal chromosome 9 indicating tetrasomy 9p (G banding) and after dual-color FISH study showing two copes of 9p21 (red) on both arms and one copy of CEP9 (green) consistent with isochromosome 9p. *(Modified from V. Najfeld. In: Molecular Genetic Pathology. eds. Liang Cheng and David Y. Zhang Humana Press, Totowa, NJ, 2008.)*

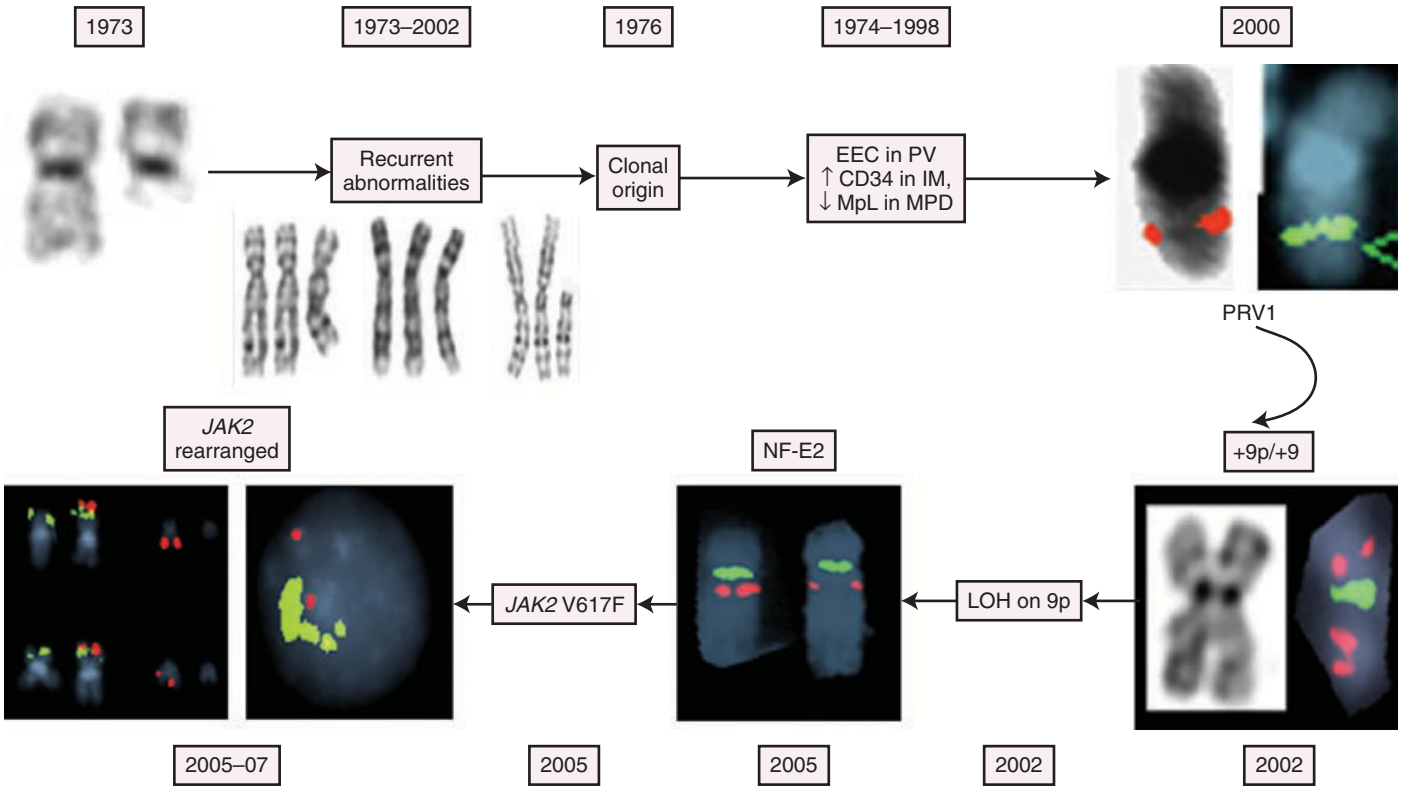

Figure 55–20 Chromosomal and molecular journey of Philadelphia chromosome (Ph) negative myeloproliferative disorder. In 1973, application of G banding to metaphase cells from patients with polycythemia vera resulted in identification of del(20q). During the next 20 years, other recurrent chromosomal abnormalities, such as +8, +9, and +1q, were identified using conventional cytogenetics. In 1973, *G6PD* isoenzyme studies demonstrated clonal origin of polycythemia vera. A number of biologic markers were identified between 1978 and 1998. Observation of increased *PRV1* constitutive activity in patients with myeloproliferative disorder represented the first step in molecular understanding and was followed by FISH findings that +9p is the most frequent abnormality. In the same year, Loss of hetezozygosity (LOH) on 9p was established for approximately 30% of polycythemia vera patients. Two years later, the role of the *NF-E2* gene on 12q was identified through array studies. In the spring of 2005, four papers demonstrated *JAK2* V617F point mutation in the majority of patients with polycythemia vera and in approximately 50% of patients with primary myelofibrosis and essential thrombocytopenia. In the period from 2005 to 2007, other *JAK2* molecular rearrangements, such as amplification and translocations, were documented, as were other point mutations. The exact molecular pathogenesis in Ph negative myeloproliferative disorder awaits elucidation.

most recent investigation of 376 patients with persistent unexplained hypereosinophilia revealed an 11% incidence of *FIP1L1-PDGFRA* fusion detected using highly sensitive RQ-PCR.[163] Patients with *FIP1L1-PDGFRA* fusion are characterized by male predominance, marrow fibrosis, increased number of mast cells, elevated serum tryptase levels, and favorable response to low doses of imatinib.[164–166] Most of these patients have a normal karyotype because a cryptic deletion of *CHIC2* locus on 4q12 is only 800 kb in size, but a more sensitive FISH technology and RQ-PCR will detect the majority of cases with this deletion at diagnosis. Moreover, the most recent commercially available tricolor FISH probe will detect not only deletion 4q12 as a result of *FIP1L1-PDGFRA* but will a rare *BCR-PDGFRA* fusion resulting from the t(4;22)(q12;q11.2) rearrangement (Fig. 55–21). Serial monitoring with RQ-PCR demonstrates exquisite sensitivity of *FIP1L1-PDGFRA*–positive patients to low-dose imatinib treatment.[163]

Conventional and molecular cytogenetic findings in atypical Ph negative MPDs as well as the presence of the *JAK2* 617V > F mutation in typical Ph negative MPDs provide support that abnormalities in tyrosine kinase genes are central to the molecular pathogenesis of these disorders[167] (see box on Genetic Testing for Ph-Negative Myeloproliferative Disease).

Genetic Testing for Ph-Negative Myeloproliferative D

At diagnosis, perform *JAK2* V617F real-time allele-specific polymerase chain reaction as well as cytogenetic analysis of marrow aspirate. Unstimulated peripheral blood can be used instead of marrow aspirate for patients with primary myelofibrosis. Perform fluorescence *in situ* hybridization (FISH) studies with BCR-ABL for patients with essential thrombocytopenia. FISH studies also can be performed when cytogenetics is uninformative for detection of most frequent abnormalities: +9, +9p,+8,del(13)(q14), and del(20)(q11q13). The panel of five probes includes CEP9, P21 at 9p21, CEP8, RB1, and D20S108. To monitor patients after therapy, use FISH study to detect diagnostic abnormality. At diagnosis and to monitor patients with hypereosinophilic syndrome, perform FISH using triple-color *FIP1L1* probe.

MYELODYSPLASTIC SYNDROMES

The MDSs are a clinically heterogeneous group of hematologic disorders with differing biology and clinical manifestations.[168] They have in common a clonal origin, dysplastic cellular morphology, abnormalities of cellular maturation, increased propensity to develop acute leukemia (20%–40%), and multistep pathogenesis.[55,169] Cytogenetic studies are important for patients with these disorders because the results can provide both diagnostic and prognostic information.[170–174] A chromosomally abnormal clone can be detected in 40% to 60% of patients with de novo MDS and in approximately 90% of patients with therapy-related MDS.[128,170] There appears to be a correlation between the frequency of chromosomal abnormalities and

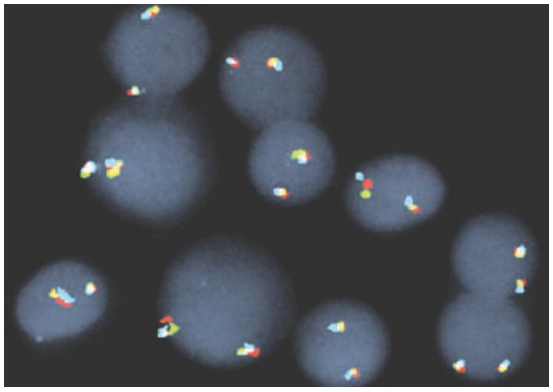

Figure 55–21 Bone marrow interphase nuclei after FISH studies using tricolor probe for chromosome 4, band region q12. The green color covers an approximately 750-kb region centromeric from *FLIP1L1.* The red probe is telomeric of the *FIP1L1* gene. The aqua color probe begins between exons 15 and 16 of the *PDGFRA* gene and extends toward the 4q telomere. In normal nuclei, as shown here, the probe appears as two tricolor fusions because of close proximity of probes in interphase DNA. Patients with Hypereosinophilie syndrome (HES) have fusion of *FIP1L1* and *PDGFRA* genes by interstitial deletion and produce one signal with green–aqua fusion and a missing orange signal. If the translocation involves the *PDGFRA* gene with loci on other chromosomes, the expected signal pattern is one orange–green fusion and one separate aqua signal.

the severity of disease. Approximately 35% of patients with less aggressive MDS, such as refractory anemia and refractory anemia with ring sideroblasts, have clonal chromosomal rearrangements, whereas approximately 60% to 70% of patients with refractory anemia with excess blasts in transformation have such chromosomal abnormalities. A single or complex chromosomal abnormality may be present initially, and evolutionary change may occur during the course of the disease. Even at diagnosis of MDS, complex genomic lesions involving five or more different chromosomes are not unusual. Despite heterogeneity of chromosomal defects (gain, loss, deletion, amplification, rare balanced translocations, transcriptional silencing via methylation or point mutation), the unifying concept of genetic instability in MDS is hemizygosity of specific genes or chromosomal regions. The most common chromosome anomalies in MDS involve del(5q)/−5, del(7q)/−7, trisomy 8, del(11)(q23),del(12p), +13/del(13q), t(11q23), del(12p), del(17p), del(20)(q11q13), +21, and idic(X)(q13) (Fig. 55–22).[72,128,173]

The clinical relevance and the power of conventional cytogenetics in MDS were recognized by the WHO classification for hematologic malignancies, which accepted a strong association between del(5)(q13q33) and 5q− syndrome, and idic(X)(q13) and refractory anemia with ring sideroblasts. The 5q− syndrome is a unique subtype of International Prognostic Scoring System low-risk MDS with a favorable prognosis, lack of other cytogenetic abnormalities, low rate of leukemic transformation, and more common occurrence in elderly females (Fig. 55–23).[174,175]

Among patients who do not have 5q− syndrome (with or without other chromosome abnormalities), interstitial deletions of the long arms of chromosome 5 occur in 10% to 15% and are among the most frequent chromosomal abnormalities in MDS (see Fig. 55–22, first row).[176,177] The finding of del(5q) in $CD34^+CD38^-$ cell indicates its occurrence in a stem cell capable of differentiating into myeloid and lymphoid cell lineages and represents an early event in the pathogenesis of MDS.[178] Data on 1432 patients with del(5q) show a great heterogeneity in breakpoints. FISH methods delineated the commonly deleted segment, currently estimated to be 1.5 Mb in size, on 5q31.1.[176–179,184] The clustering of genes responsible for growth and differentiation of hematopoietic cells and the recurrent nature of −5/del(5q) in MDS caused many investigators to speculate that a tumor suppressor gene(s) is located in the 5q31 or 5q22–23 band region. Despite numerous research efforts for more than 20 years, mutations in genes located in the chromosomal regions affected by del(5q) have been unsuccessful, in part because no homozygous deletion has been detected and because 5q31 is a very gene-rich region. To date, a tumor suppressor gene responsible for MDS on 5q has not been identified. Because the mechanism causing the interstitial del(5q) is elusive, perhaps haploinsufficiency or inactivation due to methylation, rather that a typical tumor suppressor gene, is involved in these patients.[180,181]

Patients with isolated del(5q) have more a favorable prognosis and live longer than do patients with additional chromosomal abnormalities.[177,182,183] Specifically, patients with del(5)(q13q31) have significantly longer survival than do patients with other 5q deletions, indicating that the type of 5q deletion may significantly affect prognosis and therapy.[183–184] Indeed, normal marrow karyotype is achieved in 44% of 148 patients with interstitial del(5q) treated with the novel lenalidomide agent Revlimid.[185] The sensitivity of del(5q) to Revlamid remains to be elucidated.

In de novo MDS, isolated monosomy 7 or 7q deletion (see Fig. 55–22, second row) occurs with a frequency of 1%. However, when it occurs with other chromosomal abnormalities, most commonly rearrangements of 3q or del(12p) (see Fig. 55–22, eighth row), the frequency increases to 5% to 10% of patients.[128,186] Monosomy 7 is present in all MDS subtypes and is seen predominantly in males with clinical characteristics similar to those of juvenile CMML. In pediatric patients with constitutional disorders associated with a predisposition to development of myeloid leukemia, such as individuals with Fanconi anemia, congenital neutropenia, neurofibromatosis type 1, Down syndrome, or Kostmann syndrome, −7/del(7q) may be seen as an isolated abnormality.[187,188] Therefore, the question as to whether these patients have genetic imprinting and preferentially lose chromosome 7 from one parent is relevant to understanding the origin of the genetic abnormality. Evidence unequivocally shows that preferential parental origin of the missing chromosome 7 is not present because approximately half of patients have loss of either the maternal or paternal homologue, excluding the genomic imprinting phenomenon as a cause for monosomy 7.[189] Embryonic origin of partial chromosome 7 deletion in monozygotic twins with juvenile chronic myelomonocytic leukemia has been reported.[190]

The presence of monosomy 7 or deletion 7q is associated with poor clinical outcome in MDS (Fig. 55–23). Allele typing studies implicated three regions in patients with deletion 7q that are most frequently deleted: 7q22, 7q31.1, and 7q31.3. Cytogenetic results indicated that retention of 7q31 band may be associated with longer survival (Fig. 55–24).[191] Consequently, there is speculation that a putative myeloid suppressor gene(s) is located in the regions that are frequently deleted. Because prototypic tumor suppressor genes have not been identified in patients with 7q deletions, an alternative explanation may be haploinsufficiency whereby the level of protein is critical, or a complex of two cooperating proteins is affected as a result of inactivation due to methylation.

Trisomy 8 (see Fig. 55–22, third row) is the third most frequent chromosomal abnormality in MDS. As a sole abnormality, it is found in 11% of patients with MDS and overall is found in 17%.[192] There is a significantly higher incidence of males with trisomy 8 than in females. Trisomy 8 is present in all age groups of patients with MDS. Although trisomy 8 is detected in $CD34^+CD38^-Thy\text{-}1^+$ hematopoietic stem cell of patients with MDS, a sizable fraction of stem cells is disomic but functionally abnormal, suggesting that trisomy 8 is a secondary event in MDS pathogenesis.[193] These findings provide evidence for a multistep pathogenesis of MDS, whereby gain of chromosome 8 is not an early event in stepwise evolution. Although trisomy 8 carries an intermediate risk when detected at diagnosis, findings suggest that MDS patients treated with the hypomethylating agent 5-azycytidine have a significantly better survival than patients with other chromosomal abnormalities.[194,195]

Deletions of 17p are seen in 3% to 4% of MDS and AML patients. These patients often display several other chromosomal rearrangements, including monosomy 17, isochromosome 17q, and unbalanced translocations between chromosome 17 and another chromosome. Approximately 30% of these deletions are therapy

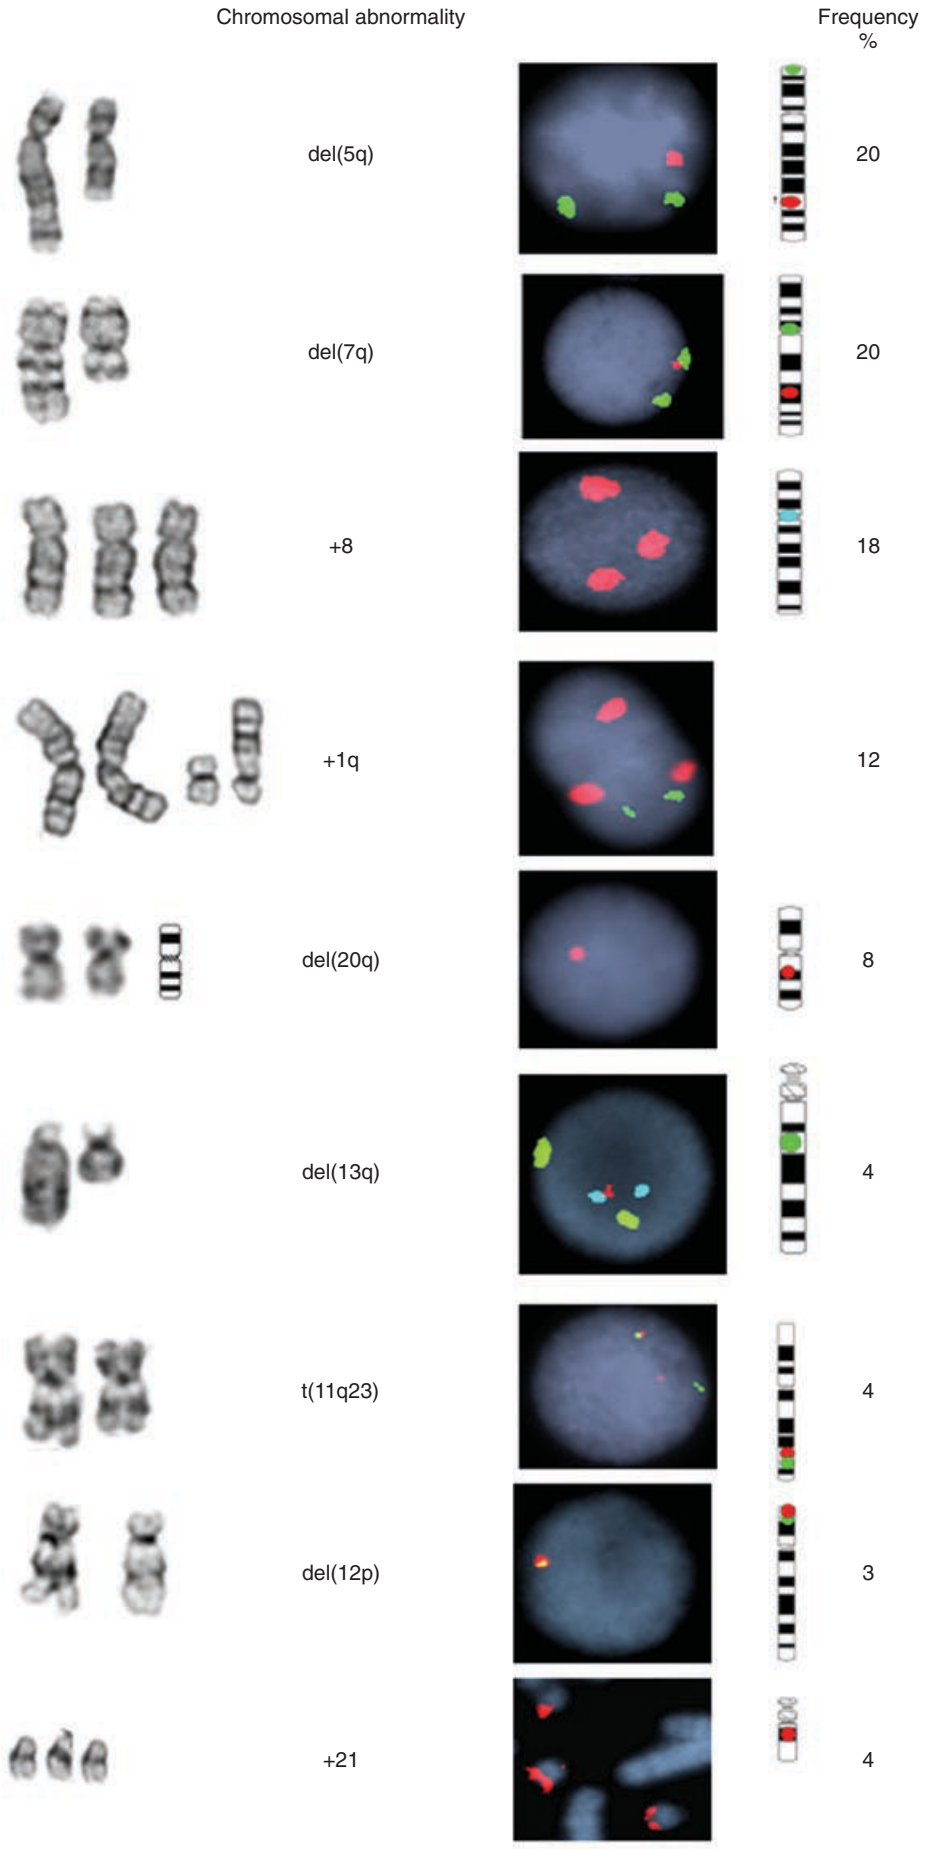

Figure 55–22 Most frequent nonrandom chromosomal abnormalities and their frequencies in myelodysplastic syndrome. G banding of chromosomal abnormalities (left) and their detection in interphase cells (middle). Schematic representation of chromosomes and probe locations for detection of recurrent abnormalities (right).

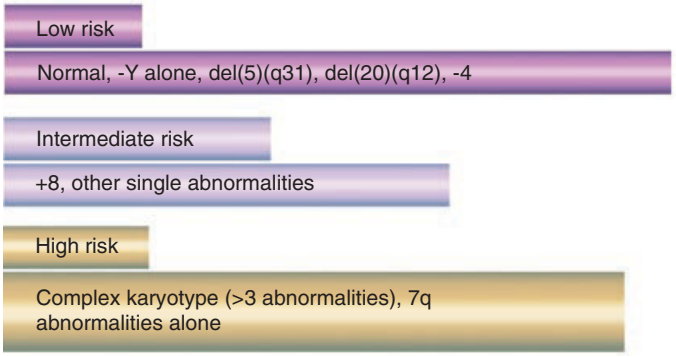

Figure 55–23 International Prognostic Scoring System (IPSS) for evaluating prognosis in patients with myelodysplastic syndromes.

related. Most patients who develop MDS or AML are treated with hydroxyurea, usually for a prolonged period of time. The extent of 17p deletion in all cases involves the *p53* gene. There appears to be a close correlation between dysgranulopoiesis (e.g., pseudo–Pelger-Huet hypolobulation) and small vacuoles in neutrophils with 17p abnormalities and *p53* deletion. Median survival of these patients is poor.[196,197]

The most frequent rearrangement of chromosome 3 involves two bands on chromosome 3, namely, simultaneously band 3q21 and 3q26, which produces either t(3;3)(q21;q26) or inv(3)(q21q26). These chromosomal rearrangements are present in de novo and therapy-related MDS as well as in AML and megakaryoblastic crisis of CML. The incidence of 3q rearrangements is 2% to 5%.[198–200] Characteristic clinical features include elevated platelet count, marked hyperplasia with dysplasia of megakaryocytes, and poor prognosis with minimal or no response to chemotherapy and a short survival. In addition to similar clinicopathologic features, patients with 3q21q26 chromosomal abnormalities share molecular heterogeneity in both the breakpoints and the expression pattern of the genes near these breakpoints. The chromosomal breakpoints, defined by FISH, in 3q26 are scattered over several hundred kilobases in either the 5′ or the 3′ region of the *EVI1* gene, whereas the breakpoints in the 3q21 region are restricted to two smaller different genomic clusters approximately 100 kb downstream of the *RPN1* gene.[201–203] *EVI1* overexpression is observed in the majority of patients, but some patients with the 3q21q26 rearrangement do not have detectable *EVI1* expression, and at least 9% of AML patients without 3q26 abnormalities show overexpression of *EVI1*.[198,204–206] Therefore, poor prognosis in these patients may be independent of *EVI1* expression despite the fact that extensive 3q26 breakpoint FISH mapping on both metaphases and interphase nuclei suggests *EVI1* involvement in numerous novel sporadic and recurrent 3q26 rearrangements.[207] A fusion transcript of *RPN1-EVI1* is rarely observed in patients with 3q21q26 rearrangements.[208] However, evidence suggests that overexpression of *GATA2* at 3q21 may be responsible for erythroid and megakaryocytic dysplasia observed in patients with 3q21q26 chromosomal abnormalities.[198,203]

The clinical significance of loss of the Y chromosome, observed in 10% of MDS patients and approximately 7% of elderly males without MDS, is undefined, although elderly males with MDS and loss of Y chromosome who achieve complete hematologic remission show the Y chromosome in their marrow cells.

Cytogenetic and FISH studies have relatively similar sensitivities in detecting an abnormal clone among patients with MDS. A FISH test for MDS should use probes to detect numeric and structural anomalies of chromosome 5, 7, 8, 11, 12, 13, and 20.[209–211] Occasional patients with normal chromosomes show an occult neoplastic clone by FISH. On the other hand, some patients exhibit a neoplastic clone by conventional cytogenetic studies that is not detected by FISH (see box on Genetic Testing for Myelodysplastic Syndrome and Fig. 55–22, column 4).

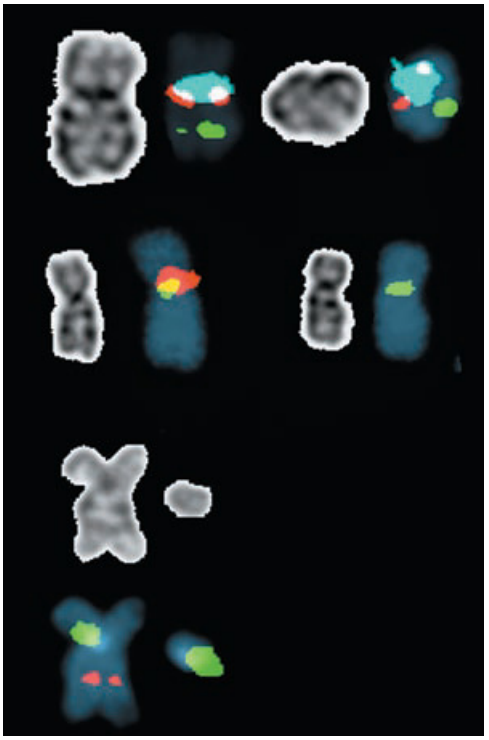

Figure 55–24 Examples of chromosome 7 abnormalities in myelodysplastic syndrome (MDS). Ring chromosome 7 is a recurrent but rare formation. In the case shown in the top row, FISH study (right) demonstrates retention of centromeric region (aqua), 7p12 (red), and 7q31 (green) regions. Retention of 7q31 region is associated with longer survival. Deletion 7p (second row) is less frequent than del(7q) and may be missed by conventional cytogenetics. Note loss of 7p12 band in the patient with MDS by FISH study (right), showing only the centromeric (green) signal and no red signal for the *EGFR* gene, localized at 7p12. Loss of both the short and long arms of chromosome 7 in pediatric and adult patients with MDS often may appear as a marker chromosome (third row), but FISH study with dual-color probes for centromere (green) and 7q31 (red) revealed the presence of only the centromeric region on the minute chromosome (fourth row).

Genetic Testing for Myelodysplastic Syndrome Disorder

The best genetic test at diagnosis is conventional cytogenetic studies. Fluorescence *in situ* hybridization is useful for some clinical situations, such as marrow samples lacking analyzable metaphases, or to follow the percentage of abnormal cells with known cytogenetic anomalies for patients undergoing treatment (see Figure 55–22 for selection of appropriate fluorescence *in situ* hybridization probes).

ACUTE MYELOID LEUKEMIA

AML refers to a group of heterogeneous diseases with respect to clonality, chromosomal aberrations, and response to treatment. AML develops clonally and has a multistep pathogenesis, although the pattern of expression in differentiative stem cell (as detected by *G6PD* and other DNA markers of clonality) is heterogeneous. In adults, at the time of diagnosis all hematopoietic cell lineages are clonal. In children younger than 16 years, erythroid cells and platelets often are not part of the leukemic clone.[50,62] Based on karyotype status, two major groups of AML can be discriminated: (a) those with an abnormal karyotype, which accounts for approximately 52% of patients and (b) those that demonstrate a normal karyotype by conventional

cytogenetics, which accounts for 48% of AML patients.[212] Among patients with an abnormal karyotype, 25% have balanced translocations [t(8;21),t(15;17),inv(16)], and 27% showed unbalanced abnormalities [–5/del(5q), –7/del(7q) or complex karyotype]. Within the normal cytogenetic category, 45% to 63% have *NPM* mutations (localized on chromosome 5, band q35), 23% to 33% show *FLT3* (localized on chromosome 13, band q12), 5% to 30% have *MLL* tandem duplications (localized on chromosome 11, band q23), and 8% and 19% have C/EBP α mutations (localized on chromosome 19, band q13.1).[213] The prognosis of patients with normal karyotype in the presence of each of these mutations is different (Table 55–4). Patients with *NPM* mutation alone have a favorable prognosis, with 60% of patients living longer than 11 years.[213,214] In contrast, the presence of *FLT3* and *MLL* mutations is associated with adverse prognosis, and coexistence of *FLT3* and *NPM* does not improve the prognosis. In childhood AML with normal cytogenetics, *NPM* mutations are relatively uncommon, occurring at frequency of 8%.[215] Gene expression profiling as a diagnostic or prognostic indicator in patients with AML and a normal karyotype has limited or moderate accuracy, which probably reflects the molecular heterogeneity of this AML subtype.[216,217]

The pretreatment karyotype in AML constitutes an independently prognostic determinant for attainment of complete remission and risk of relapse and survival.[218] Four broad cytogenetic risk categories of AML are applied in clinical practice: favorable, intermediate, unfavorable, and unknown (Fig. 55–25 and Table 55–5).[219,220] It is

Table 55–4 Gene Mutations in Patients with Acute Myelogenous Leukemia and Normal Karyotype

Gene Mutation	Frequency (%)	Prognosis
NPM	45–63	Favorable
FLT3	23–33	Adverse
MLL	5–30	Adverse
C/EBP	8–19	Favorable

Table 55–5 Cytogenetic Risk Categories in Acute Myelogenous Leukemia

Category	Abnormality
Favorable	t(8;21),[a] t(15;17), inv(16) with or without other abnormalities
Intermediate	Normal, +6, +8, +21, +22 –Y, del(9q)
Unfavorable	–5/del(5q), –7/Del(7q), abn(3q) t(9;22),t(6;9), abn(11q), 20q or 21q, abn(17p), complex karyotype

[a]Without deletion 9q or complex karyotype.

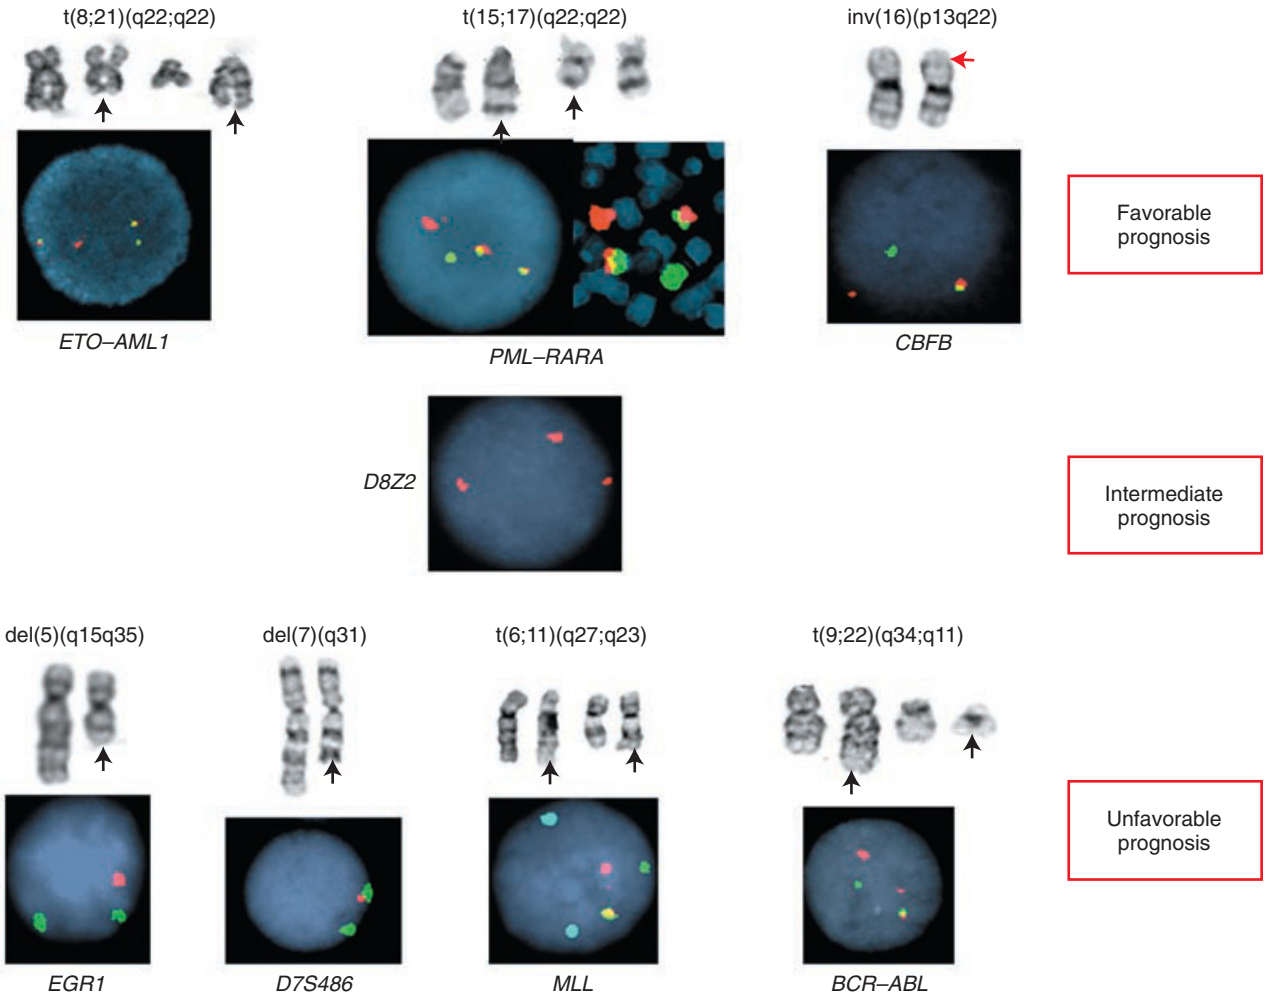

Figure 55–25 Prognostic cytogenetic risk categories in acute myeloid leukemia. Favorable prognosis includes t(8;21) and *ETO-AML1* fusion, t(15;17) and *PML-RARA* fusion, and inv(16) and rearrangements of *CBFB* on 16q22. Trisomy 8 is associated with intermediate prognosis. Unfavorable cytogenetic risk categories include monosomy 5/del(5q), –7/del(7q), and translocations of 11q23 and *MLL,* represented here by t(6;11), and the Philadelphia chromosome.

important to perform appropriate cytogenetic and FISH studies to establish the correct cytogenetic risk category. Patients displaying normal karyotype are in the intermediate prognostic category because their survival probabilities usually are lower than those with t(8;21), inv(16), t(16;16), or t(15;17).[221,222]

Tables 55–6 and 55–7 list show 166 recurrent chromosomal translocations in leukemia, including AML (Fig. 55–26, right). Because of their specific association with distinct subtypes of leukemia, some AML-specific translocations have been incorporated in the WHO classification as the criteria for subclassification of AML, including t(8;21), t(15;17), inv(16), and 11q23 rearrangements, regardless of the morphology or percent blast cells.[72]

The t(8;21)(q22;q22), described for the first time in 1973 and associated with the M2 subtype, may be present alone, although 30% to 35% of patients also display loss of Y chromosomes in males and loss of X chromosome in females (see Fig. 55–25, top left).[223] Another 20% of patients with t(8;21) show deletion of 9q12–23, including a commonly deleted segment that spans 7 to 8 Mb. Trisomies for chromosomes 4 and 8 together with t(8;21) are observed in 6% to 10% of patients. At the time of diagnosis, t(8;21) is present in 10% to 15% of adult patients with de novo AML and up to 40% in the M2 subtype of the French-American-British classification.[224] Virtually all patients with t(8;21) achieve complete remission. Additional cytogenetic abnormalities, irrespective of their nature or complexity, do not have a deleterious effect on remission, relative risk, and overall survival. The t(8;21) interrupts two genes—*RUNX1 (AML1*, *CBFA2)* on chromosome 21, band q22, and *ETO (e*ight, *t*wenty-*o*ne gene; also called *MTG8*-myeloid translocated gene) on chromosome 8, band q22—and joins them to form a new chimeric gene on the abnormal der[8] chromosome.[225,226] *RUNX1* is a gene on chromosome 21, also known as *CBFA2/AML1* because it encodes for a DNA-binding component of core-binding factor (CBF) and binds DNA through a specific sequence called the *runt* domain.[227] The *AML1* gene locus on chromosome 21 spans 120 kb; the *ETO* gene on chromosome 8 is distributed over 87 kb.[228,229]

The *AML1* gene has been identified in more than 32 chromosomal translocations in leukemia and plays a critical role during hematopoiesis. The fusion gene is located on the partner chromosome in the majority of *AML1* translocations. Its disruption is associated with the development of myeloid and lymphoid leukemias.[230] Therefore, *AML1* is viewed as a master regulatory switch that controls development of a definitive hematopoietic lineage. Moreover, the *AML1* transcription factor is critical for proliferation and differentiation of hematopoietic stem cells. Haploinsufficiency of *AML1* has been linked to a propensity to develop AML, and biallelic nonsense mutations in the *AML1* gene have been identified in most immature AMLs of the FAB M0 subtype.[231] The ETO protein belongs to the ETO family of proteins involved in protein–protein interactions but not in protein–DNA interactions.[232]

In the hybrid ETO-AML1 protein, the C-terminus of AML1 is replaced by the entire ETO protein. A main functional characteristic of ETO-AML1 chimeric protein is its ability to bind DNA containing AML1 binding sites and thereby exert a dominant negative inhibition of the endogenous AML1 protein.[233] The exact function of the ETO-AML1 fusion protein in the onset and progression of AML is not fully understood; however, accumulating evidence indicates that even a point mutation in the AML1 protein, responsible for assembling and organizing the machinery for hematopoietic gene expression at multiple sites in target genes, results in a block of differentiation of myeloid progenitors to granulocytes.[234] Most recent evidence indicates that *AML1/RUNX1* mutations are present in 46% of AML patients with the M0 subtype and in 80% of AML patients with trisomy 13.[235] As mentioned earlier, *FLT3* is localized on chromosome 13, and quantitation of *FLT3* transcript levels is associated with a fivefold increase in patients with *AML1/RUNX1* mutations and trisomy 13 compared to patients without trisomy 13. The exact cooperation of *FLT3* and *AML1/RUNX1* in leukemogenesis remains unknown. Multiple copies of *ETO-AML1* fusion have been demonstrated (Fig. 55–27).

Although 60% to 70% patients with t(8;21) achieve complete and long-term remission, monitoring minimal residual disease is important in identifying patients with a high risk of relapse. Multiparametric approaches, such as flow cytometry, RQ-PCR, and interphase FISH, are complementary methods and provide useful clinical information on relapse kinetics, although each has limitations.[236]

t(16;21)(q24;q22) is a rare but recurrent chromosomal abnormality associated with therapy-related AML or MDS. It was identified for the first time with FISH.[237] Studies using FISH and RT-PCR methods demonstrate fusion of *AML1* on 21q22 and *MTG16* (*m*yeloid *t*ranslocation *g*ene on chromosome 16) on chromosome 16, which produces an *AML1-MTG16* fusion gene on chromosome 16.[238] The breakpoints of both t(8;21) and t(16;21) occur within the

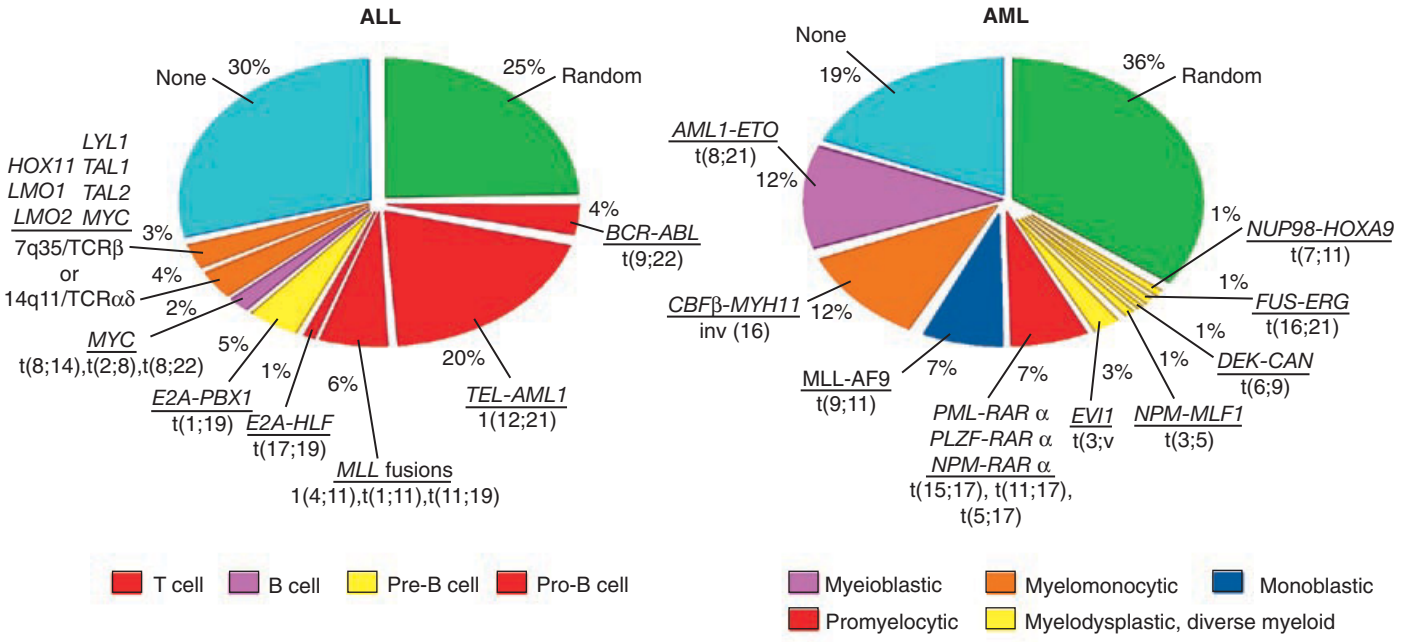

Figure 55–26 Distribution and frequency of chromosomal translocations and associated fusion transcripts in acute lymphoblastic leukemia and acute myeloid leukemia.

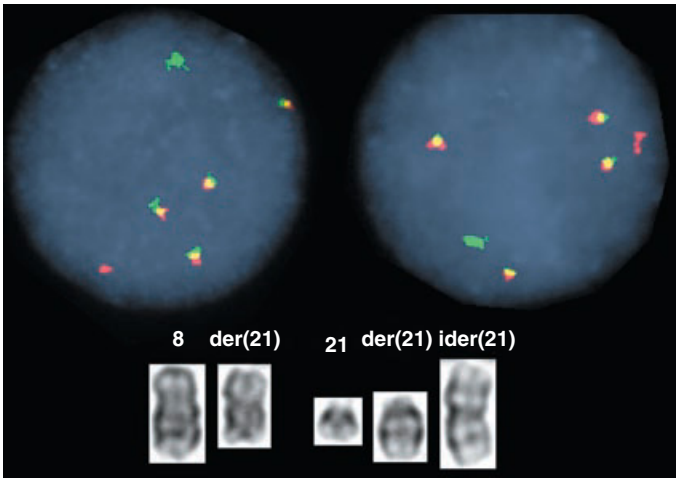

Figure 55–27 Four copies of *ETO-AML1 (RUNX)* fusion (yellow) shown in two interphase cells (top) from a patient with acute myeloid leukemia and t(8;21) (bottom) karyotype as well as ider(21). This formation is equivalent to the Philadelphia chromosome (Ph) duplication in the blast crisis of chronic myelogenous leukemia because of duplication of der(21) without accompanying t(8;21).

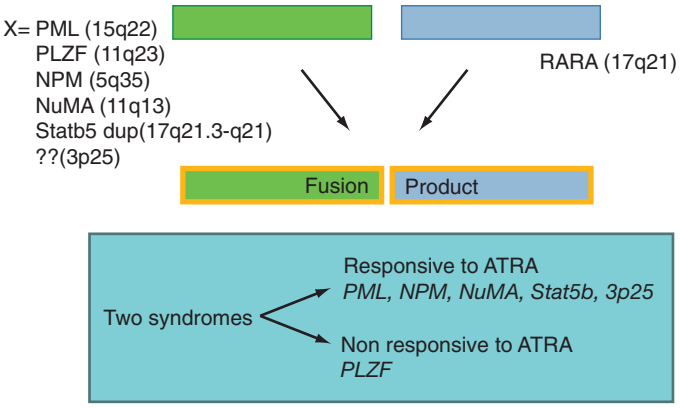

Figure 55–28 Molecular cytogenetic defects in acute promyelocytic leukemia are responsible for different response to all-*trans* retinoic acid differentiation therapy. Patients with t(11;17)(q23(q22) and *PLZF-RARA* fusion do not respond to all-*trans* retinoic acid differentiation therapy, whereas patients with classic t(15;17) and other four cytogenetic variants have exquisite sensitivity to differentiate in response to all-*trans* retinoic acid. *(Modified from V. Najfeld. In: Molecular Genetic Pathology. eds. Liang Cheng and David Y. Zhang Humana Press, Totowa, NJ, 2008.)*

same intron of the *AML1* gene. *AML1-MTG16* gene fusion results in the production of a protein that is very similar to the *AML1-ETO* (*AML1-MTG8*) protein in t(8;21).

(16;21)(p11;q22) is a rare chromosomal rearrangement associated with M1-M2 AML.[239] A proportion of patients may have additional abnormalities. This translocation fuses the *TLS/FUS* gene on chromosome 16, band p11, to the *ERG* gene on chromosome 22, band q22.[240] The *ERG* gene is a member of the ETS family of transcription factors and is a sequence-specific transcriptional activator. The presence of a fusion transcript is detected by RT-PCR, at the time of diagnosis, at relapse, and during remission. These observations are consistent with the impression that patients with t(16;21) have a poor prognosis and may benefit from early detection of this chimeric gene in order to determine the need for more aggressive therapy.

t(15;17)(q22;q21), recognized for the first time in 1977,[241] involves the *PML* (promyelocytic leukemia) gene on chromosome 15, band q22, and *RARA* on chromosome 17, band q21. This abnormality constitutes the genetic basis for approximately 97% of all cases of acute promyelocytic leukemia (see Fig. 55–25, middle panels).[242–245] The remaining 3% of cases include four rare variant translocations: t(11;17)(q23;q21),[246,247] t(11;17)(q13;q21),[248] t(5;17)(q35;q21),[249] and dup(17)(q21.3–q21).[250] Therefore, acute promyelocytic leukemia is associated with several different genetic rearrangements fusing the *RARA* gene with different partner gene in each case.[251–253] Variant *RARA* fusion partners include *PLZF* (promyelocytic leukemia zinc finger) gene on 11q23, *NPM* (nucleophosmin) gene on 5q35, *NuMA* (nuclear matrix-associated) gene on 11q13, and *STATb5* gene on 17q11. Based on these genomic rearrangements, a FISH assay, using a breakapart probe strategy with dual-color *RARA,* can identify two different clinical syndromes. These syndromes occur in patients who are not responsive to all-*trans* retinoic acid (ATRA) therapy and carry the *RARA-PLZF* fusion gene and in patients whose promyelocytes have exquisite sensitivity to differentiate in response to ATRA treatment and have one of the other three *RARA* fusion rearrangements (Fig. 55–28).[254–257] FISH study also identifies patients with cryptic translocations[258] and unusual chromosomal variants (Fig. 55–29). It is important to recognize patients who will or will not respond to ATRA so that appropriate therapy can be administered.

Acute promyelocytic leukemia is a disease characterized by accumulation of blasts blocked at the promyelocytic stage of granulocytic differentiation. Investigators have capitalized on this unique feature by designing highly effective therapy that blocks differentiation.[256,259]

Our current understanding of the molecular pathogenesis of acute promyelocytic leukemia is that *PML-RARA* behaves as a potent

transcriptional repressor and that supraphysiologic doses of retinoic acid can overcome this repression. In the presence of retinoic acid, *PML-RARA* behaves as a transcriptional activator.[260] In patients with variant *PLZF-RARA,* an additional corepressor complex binding site is present, and histone deacetylase inhibitors are used to restore sensitivity to retinoic acid.[257]

Accurate identification of the acute promyelocytic leukemia-associated genomic lesion at diagnosis is important because acute promyelocytic leukemia is a medical emergency that frequently presents with abrupt onset, high risk of early death (10%–20%), and potential for high cure rate (>80%) if appropriate treatment, based on genetic profile, is initiated. Initial workup may include conventional karyotyping, FISH studies, RT-PCR, and anti-PML antibodies.[261] Longitudinal monitoring of disease with RQ-PCR is currently recommended in order to provide early intervention should relapse occur.

In patients with 16q22 abnormalities such as inv(16)(p13;q22) and t(16;16)(p13;q22), the marrow contains an increased percentage of abnormal eosinophils. Combined May-Grünwald-Giemsa staining with FISH demonstrates that the abnormal eosinophils have inv(16) and, therefore, are part of the leukemic clone.[262,263] Trisomy 22 is a frequent accompanying abnormality.[264] Both inv(16) (see Fig. 55–25, top, right) and t(16;16) (Fig. 55–30) are abnormalities of the core-binding factor β *(CBFB)* gene at 16q22 and are associated with M4Eo subtype according to the French-American-British classification of AML. Both rearrangements result in fusion of *CBFB* and *MYH11* (myosin heavy chain) gene on 16p13. The exact role of the resulting hybrid protein, CBFB-SMMHC (smooth muscle myosin heavy chain) is unknown, but it probably is involved in impaired hematopoietic differentiation. Both t(8;21) and inv(16) rearrangements result in abnormal repression of CBF target genes. Both translocations have favorable prognosis, but they exhibit different leukemic morphologies.[265–269]

Approximately 4% of patients with *CBFB-MYH11* rearrangement do not have a cytogenetically detectable inv(16) or t(16;16). Cytogenetic detection of inv(16) may be difficult, and interphase FISH with dual-color *CBFB* probe at diagnosis is a crucial genetic test. Detection of *CBFB-MYH11* fusion by either RT-PCR or FISH is found in patients without eosinophilia[270]; therefore, *CBFB* testing should be included in the standard testing panel for genomic rearrangement in AML. The presence of additional abnormalities, such as trisomy 8, does not adversely affect clinical outcome. The *CBFB-MYH11* chimeric fusion is detected in utero with approximately 10 years of

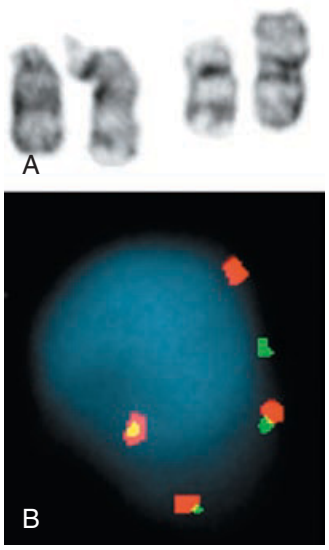

Figure 55–29 Partial karyotype from a patient with acute promyelocytic leukemia showing ider(17)t(15;17)(q22;q21) (top). The karyotype shows isochromosome for the long arms of chromosome 17 and deletion of the short arms. FISH studies revealed three copies of *PML-RARA* fusion in bone marrow nucleus (bottom), confirming that the first event in the pathogenesis was *PML-RARA* fusion, and the subsequent event was a structural rearrangement of isochromosome. *(From V. Najfeld. In: Molecular Genetic Pathology. eds. Liang Cheng and David Y. Zhang Humana Press, a part of Springer Science, Totowa, NJ, 2008.)*

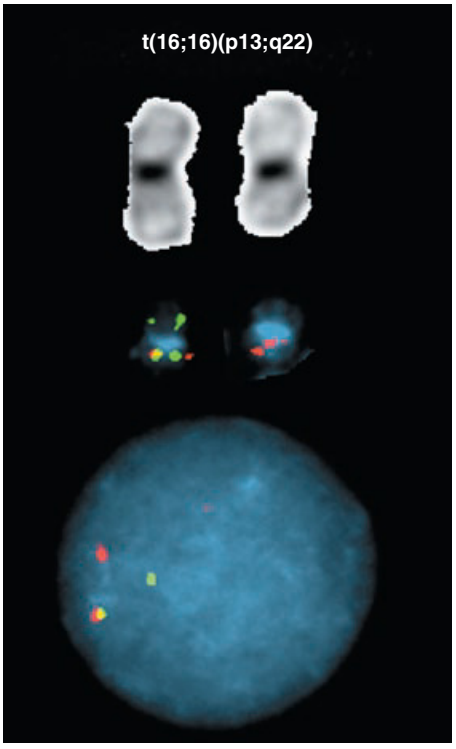

Figure 55–30 Partial G-banded karyotype from a patient with M4 acute myeloid leukemia showing t(16;16) (top), after FISH study using a "breakapart" *CBFB* probe (at 16q22) demonstrating that the 5′ end (red) of the gene remains on 16q of one chromosome 16, whereas the 3′ end (green) translocated to the short arms of the other chromosome 16. Separation of 5′ and 3′ ends as single signals is indicated in the bone marrow nucleus (bottom).

postnatal latency before development of childhood leukemia.[269] This observation suggests that formation of *CBFB-MYH11* is not enough to cause leukemia and that subsequent genetic events must occur before clinically recognizable leukemia is identified.

Less than 1% of patients with AML have Ph (see Fig. 55–25, bottom left). In rare patients with AML, late appearance of Ph either as a sole abnormality or in a clone showing t(8;21) is taken as evidence that Ph in these patients is a secondary event. The late-appearing Ph in AML is characterized by $P190^{BCR\text{-}ABL1}$ protein.[271,272]

The coexistence of Ph and inv(16) is a rare but recurrent finding in both CML and AML. In CML the fusion transcript is $P210^{BCR\text{-}ABL1}$, whereas in AML the fusion transcript is $P190^{BCR\text{-}ABL1}$. The presence of both Ph and inv(16) in AML seems to have a favorable prognosis, whereas in CML the coexistence of *BCR-ABL* and *CBFB-MYH11* suggests rapid transformation to blast crisis.[273]

The *MLL (m*yeloid *l*ymphoid *l*ineage, also called "mixed-lineage leukemia," also referred to as *ALL1* or *HRX)* gene, at 11q23 is responsible for 95% of all 11q23 translocations, including AML and ALL (Fig. 55–31 and Table 55–7). Approximately 20% of all translocations in human neoplasia involve the *MLL* gene.[274] The *MLL* abnormalities are found in approximately 15% of patients with AML and ALL. To date, 88 partner genes participate in *MLL* translocations, and 51 of these are characterized at the molecular level.[274–276] The most common translocations involving the *MLL* gene in AML (Table 55–7) are t(9;11)(p23;q23) (Fig. 55–31, *M)* resulting in *MLL-AF9* fusion and t(11;19)(q23;p13.1) (Fig. 55–31, *L)* producing the *MLL-ELL* fusion. A partial tandem duplication of the amino-terminus region of the *MLL* gene is associated in patients with or without trisomy 11 (Fig. 55–31, *B, C, F,* and *G).*[277] The *MLL* gene is encoded by 37 exons. 11q23 translocations cluster within an 8.3-kb region that encompasses exons 8 to 14 of *MLL* and fuses the N-terminal portion of *MLL,* which contains the AT hook and methyltransferase domains, to numerous different proteins. In infant and in therapy-related AML, the *MLL* genomic breakpoints cluster in the 3′ end, near exon 12. In childhood and adult de novo AML, the breakpoints usually occur in the 5′ end, between exons 9 and 10.[278–280] AML patients with *MLL* rearrangements have a poor prognosis despite treatment with aggressive multiagent chemotherapy.[218,281] Identical *MLL* rearrangements have been detected in three pairs of infant monozygotic twins, raising the possibility of in utero *MLL* rearrangements.[282]

Until recently the contribution of various *MLL* fusion partners to transformation was not known. The partner genes in the translocations did not appear to have any unifying characteristics that would clarify their role in leukemogenesis. However, two observations suggest that *MLL* fusion partners are not randomly chosen. First, a precise localization of genomic *MLL* breakpoints in 414 samples with *MLL* rearrangements, using a novel long-distance inverse PCR method, shows that the most frequent translocation fusion partners *(AF4, AF9, ENL, AF10)* belong to the same nuclear protein network involved in histone methylation.[274] Second, observation indicates that several chromatin structural elements, such as topoisomerase II cleavage sites, DNase I hypersensitive sites, and other chromatin sites, are associated with *MLL* rearrangements observed in infant and therapy-related AML.[283] These characteristics of *MLL* suggest that specific chromatin sites are functionally selected in *MLL* rearrangements rather than being randomly chosen.[274]

t(6;9)(p23;q34) is a rare cytogenetic abnormality, described for the first time in 1976 and subsequently reported in 1986 to be associated with AML and marrow basophilia.[284,285] Basophilic leukemia now is recognized by the WHO classification as a separate entity. In addition to t(6;9) other chromosomal abnormalities such as t(8;21)(q22;q22), del(12)(p11–13), t(X;6),(p11;q23), and t(2;6)(q23;p22) may be found in basophilic leukemia.[286] As a result of t(6;9), the 3′ part of the *CAN (NUP214,* nuclear pore complex protein 214 kd) gene located on chromosome 9, band q34, is fused to the 5′ part of the *DEK* gene located on chromosome 6, band p23. The resulting *DEK-CAN/NUP214* fusion gene is a derivative of chromosome 6.[287] The translocation breakpoints occur in a single intron of 8 kb in the *CAN* gene and in a single intron of 12 kb in

the *DEK* gene. As a result, the presence of the *DEK-CAN* fusion can be identified in blood or marrow cells by Southern blot analysis and PCR methods. Dual-color commercial FISH probes currently are not available for this translocation.

The nuclear pore complex is a massive structure that extends across the nuclear envelope, forming a gateway that regulates the flow of macromolecules between the nucleus and the cytoplasm. *NUP214* may serve as a docking site in the receptor-mediated import of substrates across the nuclear pore complex and plays a role in nuclear protein import, mRNA export, and cell cycle progression. The hybrid protein contains almost the entire DEK protein fused to the C-terminal two-thirds of the CAN protein. The role of DEK-CAN/NUP214 hybrid protein in leukemogenesis awaits elucidation.

The M7 or megakaryocytic subtype of AML is a clonal disease arising in a multipotent stem cell capable of differentiating along the megakaryocytic and granulocytic pathway. This acute leukemia subtype has a variety of genetic and morphologic characteristics.[288] The M7 subtype has an estimated frequency of 3% to 14% of all AML and is more frequent in children than in adults. In adults, megakaryocytic leukemia is frequently observed as a secondary leukemia after chemotherapy or leukemic transformation of several chronic MPDs, including CML. Approximately 65% of acute megakaryocytic leukemia is associated with myelofibrosis. No specific chromosomal abnormality is associated with the adult form of megakaryocytic leukemia. Approximately 50% of M7 AML patients have chromosomal abnormalities at diagnosis. Observed diverse abnormalities include 3q21–3q26 rearrangements, partial or total deletion of chromosomes 5 and 7, gain of chromosomes 8 and 19, and t(9;22). In multivariate analysis, M7 diagnosis in adults is an independent adverse prognostic factor for overall survival.[289,290]

Three manifestations of childhood megakaryocytic leukemia are observed. First is the t(1;22)(p13;q13) with constitutional trisomy 21 associated with *GATA1* mutation.[291] Children with constitutional trisomy 21 have 10- to 20-fold increased risk for developing leukemia. The incidence of developing M7 leukemia is up to 500 times higher in children with constitutional trisomy 21 than in children without it.[292] However, children with constitutional +21 and megakaryocytic leukemia have a more favorable prognosis compared to patients without constitutional +21. Somatic mutation of transcription factor *GATA1* in these patients leads to exclusive expression of a truncated form of *GATA1.* The second form of childhood acute megakaryocytic leukemia involves t(1;22)(p13;q13) encoding *OTT-MAL* (*RBM15-MKL1*) fusion protein in infants without constitutional trisomy 21 (Fig. 55–32). It is found in 22% of all patients with infantile M7 and 33% of all patients with FAB-M7.[293,294] Detection of t(1;22) is diagnostic. Adults with t(1;22)(p13;q13) encoding the *OTT-MAL* fusion transcript are not reported to date. Third, approximately 19% of infants with constitutional trisomy 21 (or mosaic +21C) and transient myeloproliferative disorder subsequently develop M7 leukemia at a mean age of 20 months.[292] With development of leukemia, these children acquire diverse chromosomal abnormalities, most notably tetrasomy 21 and trisomy 8. The t(1;22)

Figure 55–32 Partial bone marrow karyotype from two metaphase cells from a 4-week-old baby with M7 megakaryocytic leukemia showing a diagnostic t(1;22)(p13;q13) abnormality.

rearrangement has been observed in a set of monozygotic twins, suggesting an in utero origin in some cases.

Preliminary results using gene expression profiling are providing the first insight into the molecular pathogenesis of M7 leukemia in children with and without constitutional trisomy 21. These two groups of patients have distinct molecular phenotypes, with increased expression of chromosome 21 genes in patients with constitutional +21 compared to M7 leukemia patients without constitutional +21. The *AML1* (*RUNX1*) gene, localized on chromosome 21 and essential for normal megakaryopoiesis, is expressed at lower levels in children with constitutional +21 and M7 leukemia, indicating a mechanism that may contribute to a block in differentiation in megakaryocytic leukemia.[295]

Approximately 15% to 20% of patients with AML show a numerical gain or loss of a single chromosome as the sole primary karyotypic abnormality. Each of the autosomes and sex chromosomes contributes to the numerical changes. The most common trisomies in decreasing order of frequency are gain of chromosome 8, 22, 13, 21, and 11. The gain of chromosome 8, the most frequent abnormality seen in AML, is found as a sole abnormality in 6.3% and overall in 16%.[192] The incidence of +8 detected by FISH is reported to vary between 19% and 25%. The prognosis of AML with +8 depends on whether +8 occurs as an isolated abnormality or accompanies other cytogenetic aberrations. In the latter situations, +8 does not appear to adversely affect the favorable outcome of patients with t(15;17), inv(16)t(16;16), and t(8;21). In contrast, patients with +8 and a complex karyotype and/or an unfavorable aberration such as del(5q) or −7 usually have very poor outcome. Isolated +8 has been considered to be associated with either intermediate or unfavorable prognosis.[218]

Whether PCR-based molecular screening, conventional cytogenetics, or both, should be used at diagnosis of AML is an important question with major consequences for treatment strategy, monitoring therapy, and overall genetic risk assessment. A prospective comparison study demonstrated approximately 20% discrepancy between broad molecular screening using a multiplex RT-PCR system and cytogenetic testing. This discrepancy has the potential to influence treatment strategies.[296] Cryptic translocations detected as submicroscopic genetic lesions detected by RT-PCR may have no influence on prognosis or treatment strategy. In contrast, cytogenetic results influence treatment decisions by conferring unfavorable risk assignment on patients with negative broad molecular screening. These methodologies provide complementary genetic information for diagnosis, treatment, and followup.

Cytogenetic studies are valuable in assessing the effectiveness of therapy (see box on Genetic Testing for Acute Myeloid Leukemia and Fig. 55–25). In most patients with AML, a clonal cell population cannot be detected during remission. However, in some cases hematopoiesis remains clonal, with normal karyotype showing only a single *G6PD* enzyme type, hence the fourth aspect of AML heterogeneity.[35,57–58] When disease relapses, cells with the original chromosome anomalies are observed. If an appropriate FISH or RT-PCR test is available, these are the genetic tests of choice for predicting relapse because these methods are less expensive and more sensitive than chromosome studies.

Genetic Testing for Acute Myeloid Leukemia

At diagnosis, conventional cytogenetic studies should be performed. In addition, fluorescence *in situ* hybridization and molecular genetic tests are available to detect many classic chromosome anomalies that may be cryptic by conventional cytogenetics. The panel of chromosomal probes for acute myeloid leukemia at diagnosis includes *ETO-AML*, *PML-RARA*, *CBFB*, *BCR-ABL*, *MLL*, and for +8. These tests are performed at diagnosis to establish a benchmark for the percentage of neoplastic cells and are used in followup studies to help assess the effectiveness of therapy.

The biology of AML changes with age. The spectrum of cytogenetic abnormalities in the elderly includes a higher percentage of patients with abnormalities involving −5/del(5q), −7/del(7q), and 17p and a lower incidence of translocations associated with favorable prognosis and treatment outcome.[297] In addition, multidrug resistance is demonstrated in 57% of patients older than 75 years but in 33% of AML patients younger than 56 years. The different biology of AML in older patients may be a consequence of the age of hematopoietic stem cells, shortened telomere length (associated with older cells), and presence of fewer normal stem cells to compete with malignant clones and repopulate marrow following chemotherapy. Therapy-related AML and therapy-related MDS are distinctive clinical syndromes occurring as late complications after high-dose chemotherapy, radiation therapy, and autologous HCT.[298,299] In the best studied series of 306 patients with therapy-related leukemias, normal karyotype is observed in 8% and abnormal karyotype is detected in 92%.[300] From the cytogenetic point of view, two different categories of therapy-related AML and therapy-related MDS can be distinguished. The first is found in patients exposed to alkylating agents who developed therapy-related approximately 5 years after therapy. These leukemias are associated with the presence of monosomy 5/del(5q) or monosomy 7/del(7q). Many of these patients initially develop myelodysplastic features before transforming into a frank AML. Recurrent abnormalities of chromosomes 5, 7, or both account for 70% of all abnormalities observed in therapy-related leukemia.[301] These patients have a poor response to therapy and poor overall survival. A second group of patients develop therapy-related AML without prior MDS. Leukemia cells in these patients often exhibit 11q23 (3%) and 21q22 (3%) balanced rearrangements, attributed to late effects of topoisomerase II inhibitors combined with alkylating agents and radiation.[302] The leukemia may develop within a few months to 3 years after therapy. Polysomy (tetrasomy, pentasomy, hexasomy) of chromosome 8 defines a clinicocytogenetic entity associated with therapy-related myeloid malignancies and poor overall survival[303] (see box on Genetic Testing for Therapy-Related Neoplasms).

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL is a clonally derived disease involving progenitor cells with differentiation expression detected only in the lymphoid lineage.[51] ALL accounts for at least 85% of acute leukemias in children and 20% of acute leukemias in adults.[218] Most published series of patients with acute ALL indicate that more than 85% have an abnormal clone by conventional cytogenetic studies (see Fig. 55–26, left). Genomic rearrangements detected with intensive interphase FISH screening are found in up to 91% of cases.[304] Today cytogenetic analyses com-

bined with FISH and/or RT-PCR investigations are mandatory in most ALL treatment trials, and genetic findings play a pivotal role in proper risk stratification and treatment options.

Pretreatment cytogenetics is an independent prognostic factor in children and adults presenting with ALL and is important in determining risk categories. As shown in Fig. 55–33 and Table 55–8, the risk categories in children include (a) low risk: [hyperdiploidy (trisomies for chromosomes 4, 10, and 17) and t(12;21)/*TEL-AML1*]; (b) high risk: t(1;19)/*E2X-PBX1;* and (c) very high risk: t(9;22)/*BCR-ABL* and 11q23/*MLL* rearrangements.[311] In adults the low-risk category includes high hyperdiploidy and del(9p), whereas the high-risk category includes hypodiploidy/near triploidy, t(9;22)(q34;q11), t(4;11)(q21;q23), t(8;14)(q24;q32), and complex karyotype (five or more chromosomal abnormalities).[305,306]

Genetic Testing for Therapy-Related Neoplasms

The best genetic test for therapy-related myelodysplastic syndrome or acute myeloid leukemia is a conventional cytogenetic study. Fluorescence *in situ* hybridization studies with probes for loci on chromosomes 5 and 7, *MLL,* and *AML1* should be performed if therapy-related leukemia is suspected. This approach is useful for t(8;21), t(9;22), t(11;var), t(15;17), inv(16), –5/5q, –7/7q–, rearrangements of *ETV6* on 12p, and some others.

Approximately 20% of children and 26% of adults with B-cell ALL have a hyperdiploid number of chromosomes. Two groups are distinguished based on cytogenetics: (a) those with 51 to 55 chromosomes, whose prognosis is poorer, and (b) those with 56 to 67 chromosomes, whose prognosis is better. Both groups have a more favorable prognosis than do children with hypodiploidy or near-haploid ALL. In a study of 1880 children with ALL, patients with 45 chromosomes have an outcome similar to that of ALL patients with pseudodiploid or low hyperdiploid (47–50 chromosomes).[307] Children and adolescents with ALL and hypodiploidy with fewer than 44 chromosomes have a poor outcome despite contemporary therapy.[308] Gain of chromosomes 4, 8, 10, 17, 18, and 21 as well as other chromosomes are observed. Trisomy 21 is the most common numerical change in ALL, with an incidence of 1% to 2%.[309,310] Pretreatment cytogenetic analysis of more than 5400 children with ALL unequivocally shows that simultaneous trisomies for chromosomes 4, 10, and 17 are associated with long-term event-free survival (see Fig. 55–33, *D).*[311] In contrast to children who have a favorable prognosis when a hyperdiploid karyotype is present, such a favorable constellation has not been found in adult ALL. The reason may be that adult patients often have poor-risk chromosomal translocations, such as the Ph, which confer a poor outcome irrespective of otherwise good-risk ploidy groups. Modal chromosome numbers of 45 or less are rare (specifically, the near-haploid numbers of 24–36), but they do occur in less than 1% of cases and confer a poor prognosis**.** Similarly, ALL in adults presenting with low hyperdiploid/near-triploidy is associated with poor outcome.[306] Loss of chromosome 7

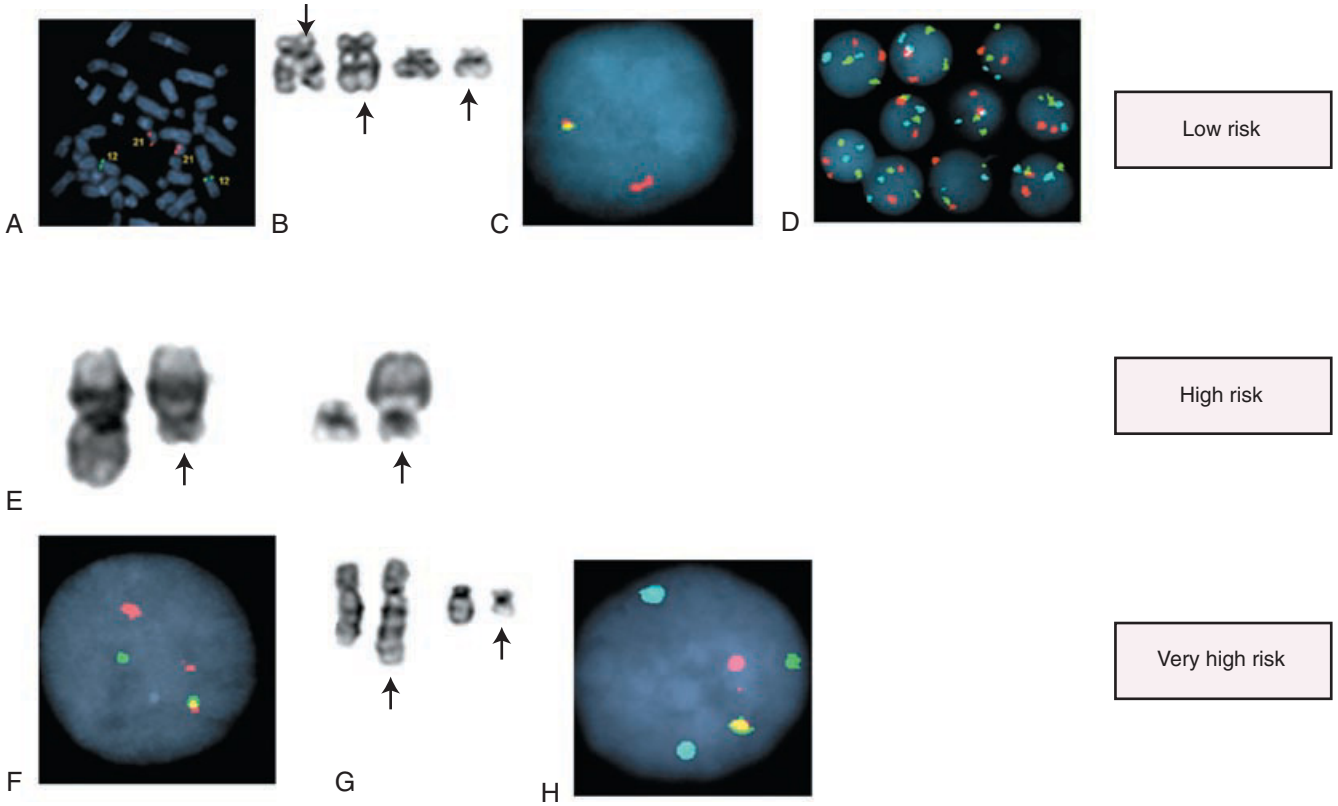

Figure 55–33 Prognostic cytogenetic categories in acute lymphoblastic leukemia. **A,** Localization of *TEL/ETV6* and *AML1* fluorescence probes to chromosomes from a normal bone marrow metaphase cell. *TEL/ETV6* is on 12p13 (green) and *AML1* is on 21q (red). **B,** Partial karyotype showing t(12;21)(p13;q22) *(arrows).* The *short arrow* at 12p indicates a possible *TEL* deletion from normal chromosome 12. **C,** FISH study showing loss of *TEL* (green) from normal 12 homologue in interphase nucleus, a frequent subclonal evolution in patients with t(12;21). **D,** Hyperdiploidy, specifically trisomies for chromosomes 4 (green), 10 (red), and 17 (aqua), is associated with low-risk cytogenetic category (see text for details) and is present in disomy in interphase cells (top left). **E,** Partial G-banded karyotype showing t(1;19)(q23;p13.3), which occurs in approximately 6% of patients with B-cell precursor childhood acute lymphoblastic leukemia. **F,** FISH hybridization to bone marrow nucleus showing *BCR-ABL* fusion (yellow). **G,** as a consequence of t(9;22), occurring in 5% of children and 20% to 25% of adults with acute lymphoblastic leukemia. **H,** Interphase nucleus after FISH study with tricolor probe. Dual-color/breakapart *MLL* shows separation of the 3′ end and the 5′ end as a result of 11q23 rearrangement. CEP11 (aqua) indicates disomy for chromosome 11, used as internal control. *MLL* rearrangements in acute lymphoblastic leukemia are associated with unfavorable prognosis.

Table 55–8 Frequencies of Cytogenetic Aberrations in Adult and Childhood ALL and Their Prognostic Relevance

		Adults		Children	
Cytogenetic Abnormality	**Genes Involved**	***Frequency (%)***	***Prognosis***	***Frequency (%)***	***Prognosis***
Normal karyotype	NA	15–36	Intermediate–good	31–40	Intermediate—good
High hyperdiploidy (>55)	NA	2–11	Good	23–26	Good
Low hyperdiploidy (>50)	NA	10–15	Poor	10–11	Intermediate
Near haploidy (<35)	NA	Rare	NA	1–4	Poor
Pseudodiploidy	NA	31–50	Poor	18–26	Intermediate
Hypodiploidy (35–44)	NA	4–9	Poor	6	Poor–intermediate
t(9;22)(q34;q11.2)	*BCR-ABL*	11–29	Poor	2–6	Poor
t(4;11)(q21;q23)	*MLL- MLL T2*	3–7	Poor	2	Poor
t(1;19)(q23;p13.3)	*TCF3-PBX1*	2–3	Poor	4–5	Poor

ALL, acute lymphoblastic leukemia; T-ALL, T-cell acute lymphoblastic leukemia.

is frequent in adult ALL. The majority of these patients also have t(9;22).

In childhood ALL, t(12;21), was first reported in 1994 as a fortuitous FISH finding.[312] This translocation is difficult to detect by conventional cytogenetics because the translocated portions of 12p13 and 21q22 have virtually identical G-banding patterns. In contrast, the *ETV6-AML1* (*ETV6-AML1*) fusion product of t(12;21) is detected using PCR or FISH in 17% to 41% of pediatric patients with ALL (see Fig. 55–33, *A–C*).[313] The *ETV6-AML1* fusion, found almost exclusively in children 1 to 15 years old with B-precursor ALL, represents the most frequent molecular rearrangement in childhood cancer. Children with the *ETV6-AML1* fusion gene have significantly lower rates of relapse compared with *ETV6-AML1*–negative patients.[314–316] *ETV6-AML1*–positive B-precursor ALL is characterized by a long duration of first remission and excellent cure rates. Prospective analysis demonstrates that the survival rate in t(12;21)-positive patients is significantly better when compared with negative cases; however, this abnormality in multivariate analysis is not found to be an independent predictor of outcome.[317] The *ETV6-AML1* fusion is rare in adult ALL. t(12;21)(p13;q22) fuses the helix-loop-helix domain of the *ETV6* gene, located on chromosome 12, band p13, to the DNA-binding and transactivation domain of the *AML1* gene, located on 21q22. FISH studies allow visualization of the fusion gene on 21q22. Fusion with *ETV6* converts *AML1* from an activator to a repressor of transcription. The *ETV6-AML1* fusion is frequently accompanied by the loss of the other normal unrearranged *TEL/ETV1* allele. This deletion probably represents a subclonal evolution.[318,319] *ETV6-AML1* has been detected in utero, probably in a committed B-cell progenitor, and is present in normal cord blood and peripheral blood samples at frequencies 100-fold greater than the risk of corresponding leukemia. The current view of development of *ETV6-AML1*–positive leukemia is that these early events are followed by a long "preleukemic" phase followed by loss of the normal *ETV6* homologue, which appears to be an important event in the multistep pathogenesis of this leukemia.[320–322] Currently, of the 397 children with *ETV6-AML1*–positive leukemia reported, approximately 60% harbor additional karyotypic abnormalities that contribute to the pseudodiploid or near-diploid karyotype in these cases. The most common secondary change, which occurs in approximately 50% of cases with additional abnormalities, is trisomy 21.[323]

A rare group of patients with B-precursor ALL has no fusion of *TEL* and *AML1*. Instead, marrow cells from these patients show three to 15 copies of the q22 band of chromosome 21, including the *AML1* locus. Amplification of the 21q22 band of chromosome 21 is a clonal marker of the leukemic cells (Fig. 55–34).[324] Following this initial observation, the British Childhood Leukemia Working Party prospectively screened 1630 patients with childhood ALL and identified 28 children with intrachromosomal amplification of chromosome 21 (iAMP21) (Fig. 55–34, *A*).[325] Children with iAMP21 have a common or pre–B-cell immunophenotype, median age of 9 years, and significantly inferior event-free and overall survival at 5 years compared with children exhibiting other cytogenetic subgroups. Even children with Ph positive ALL, known for its poor prognosis, have a better 5-year event-free survival compared to children with iAMP21. These children have a threefold increased risk for relapse and are twice as likely to die than their counterparts without iAMP21.

ETV6 or *TEL* (for *t*ranslocation, *E*TS, *l*eukemia") transcription factor gene, most frequently found in translocations, was first identified as a part of a *TEL*–platelet-derived growth factor receptor β fusion (*TEL-PDGFRB)* created by t(5;12)(q33;p13) in chronic myelomonocytic leukemia.[326] It was detected using FISH because, as mentioned earlier, of difficulties in detecting cytogenetic rearrangements at the 12p13 site. As a result of this translocation, the helix-loop-helix domain of *TEL/ETV6* is fused in frame to the *PDGFRB* transmembrane and tyrosine kinase domain. Fusion of *TEL/ETV6* to a tyrosine kinase also occurs as a result of t(9;12)(q34;p13), leading

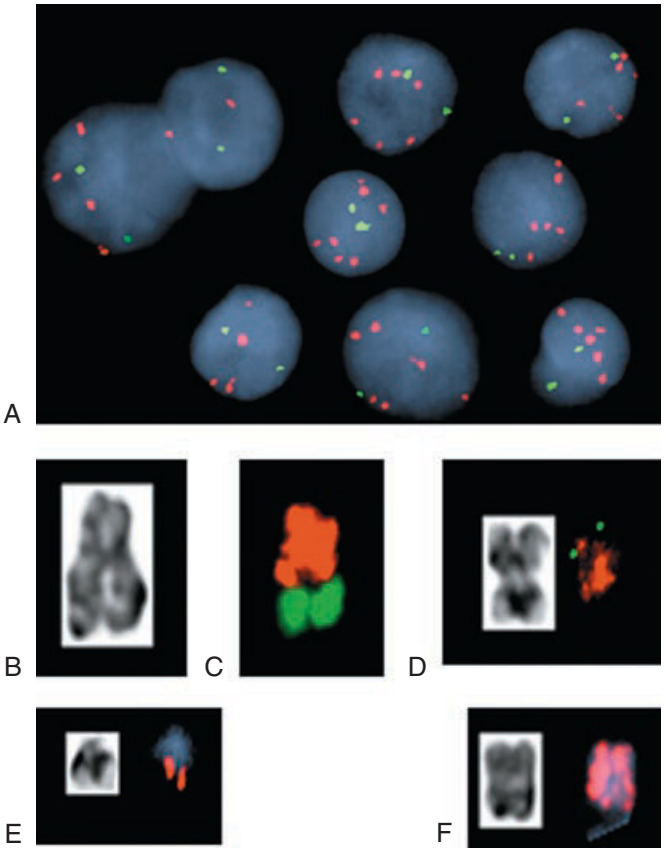

Figure 55–34 Detection of *AML1* and 21q22 amplification. **A,** Intrachromosomal amplification of *AML1* (red) (*TEL* [green], present in disomy) in a pediatric patient with pre–B-cell acute lymphoblastic leukemia. This finding is associated with poor prognosis. **(B)** G banding of der(18) chromosome and after FISH study **(C)** with WCP 18 (green) and LSI 21q22.13 (red) documenting der(18)t(18;21) and amplification of 21q22 region in a patient with myelodysplastic syndrome/acute myeloid leukemia. **D,** Amplification of 21q22 region in myelodysplastic syndrome may be present in another formation: der(21) (G banding, left). FISH study shows amplification of 21q22.13 locus (red) and identified der(21) as t(5;21) with 5p15.2 probe (green). **E,** Localization of 21q22.13 LSI probe on normal chromosome 21. **F,** Homogeneous staining region (hsr)(21), G banding (left), and after FISH study (right) with locus-specific probe for 21q22.13 (red) consistent with 21q22.13 band amplification in a patient with myelodysplastic syndrome.

to the *ABL-TEL* fusion that has been observed in patients with ALL, AML, and atypical CML.[327,328] More than 22 partner genes are known to participate in fusions with *ETV6/TEL,* primarily in ALL and less frequently in myeloid malignancies.

Other rearrangements involving 12p include deletions, duplications, and translocations and are observed most often as part of a complex karyotype, frequently associated with chromosome 5 and/or 7 abnormalities. Deletion of 12p13 is much more frequent in children than in adults with ALL and is observed in patients with myeloid disorders, specifically in adults with MDS.[329] Two other genes residing on 12p also are rearranged: *CCND2* is frequently amplified and *CDKN1B* is commonly often deleted.

Approximately 5% of children and 20% to 25% of adults with ALL have Ph, making it the most common structural rearrangement in adult ALL (see Fig. 55–33, *F* and *G*). The breakpoint on Ph is more centromeric than in CML (see Chronic Myelogenous Leukemia above). It includes the 5′ breakpoint on chromosome 22, distal to the first exon (falling between exon e1 and e2) of the *BCR* gene resulting in the $P190^{BCR\text{-}ABL1}$ variant, providing a diagnostic distinction between lymphoid blast crisis of CML and de novo ALL.[83,330,331] Ph positive ALL is characterized by the smallest *BCR*-ABL1 (P190) protein containing less BCR than the P210 and P230 fusion proteins. Among Ph positive patients with ALL, approximately 58% to 70% of adults and 80% of children have this genomic breakpoint variant. Up to 19% of Ph positive ALL patients may express both the P190 and the P210 *BCR-ABL1* fusions.[332] A number of earlier studies indicated that the P190 type of the *BCR-ABL1* breakpoint is associated with a more aggressive form of disease, with higher tyrosine kinase transforming ability than the P210 protein associated with CML.[333] Ph positive ALL was classified as a *stem cell* disorder because of the presence of the BCR-ABL transcript in both the myeloid and lymphoid lineages.[334] More recent reports suggest that the presence of the P190 protein does not confer a poorer prognosis.[306,323,333]

The *BCR-ABL1* fusion variants are easily detectable by FISH testing using the extrasensitive probe strategy, and *BCR-ABL1*$^+$ leukemia can be identified in up to 10% of Ph negative cases. Moreover, FISH testing will identify *ABL* rearrangements in *BCR-ABL1* fusion-negative ALL patients.[335] The role of imatinib used alone or in combination with conventional chemotherapy in elderly patients with de novo Ph positive ALL is being studied.[336] Initial gene expression profiling failed to identify specific genes associated with differences in overall survival of adult patients with $P190^+$ or $P210^+$ ALL.[337]

Reactivation of BCR-ABL kinase activity is most commonly associated with the emergence of point mutation in the *ABL* kinase domain implicated in resistance to imatinib treatment (see Chronic Myelogenous Leukemia above). Retrospective analysis reveals that 40% of newly diagnosed and imatinib-naive Ph positive ALL patients have kinase domain mutations, and 83% to 90% have identical mutation at relapse or at the time of hematologic or cytogenetic resistance to imatinib.[338,339] The frequency of the mutant allele is always below the level of detectability by direct cDNA sequencing method at diagnosis, and use of more sensitive methods, such as denaturing high-performance liquid chromatography, is recommended.

More than 60% of adult patients with Ph positive ALL show additional chromosomal abnormalities in the Ph positive clone. Most frequent are gain of Ph, monosomy 7, +8, +X, del(9p) as well as high triploidy.[306,340] The additional chromosomal abnormality has no effect on survival of Ph positive patients.

t(1;19)(q23;p13.3) occurs in 5% to 6% of patients with B-cell precursor childhood ALL. However, among patients with a pre-B (cytoplasmic immunoglobulin positive) immunophenotype, t(1;19) is found in approximately 25%. t(1;19) occurs in 2% to 3% of adults (see Fig. 55–33, *E*).[341–344] Cytogenetically, two forms of t(1;19) can be identified: 25% of cases have a balanced reciprocal t(1;19), whereas 75% of cases have a more common rearrangement of unbalanced der(19)t(1;19)(q23;p13.3).[345] The unbalanced der(19)t(1;19) arises from the initial trisomy of chromosome 1 followed by the t(1;19) translocation, with subsequent loss of the derivative chromosome 1.[346] More than 95% of t(1;19) is associated with the *E2A* (*TCF3*)-*PBX1* fusion gene. The *E2A* gene (originally identified by binding of E2A proteins to the kE2DNA sequence motif contained in the Ig κ light-chain enhancer) on chromosome 19, band p13.3, is fused to the *PBX1* (homeobox) gene on chromosome 1, band q23.[342–343,347] Approximately 1% of pediatric B-ALL patients have a variant t(17;19)(q21–q22;p13) translocation resulting in two different genomic rearrangements. The first is the fusion between the *HLF* gene (breakpoint in intron 3) on chromosome 17 and the *E2A* gene (within intron 13) on chromosome 19, associated with disseminated intravascular coagulation. The second is the breakpoint in intron 12 of *E2A* and intron 3 of *HLF* associated with hypercalcemia.[348] In contrast to *ETV6-AML1* rearrangements, which have a prenatal origin, current evidence suggests a postnatal etiology for t(1;19) translocations.[349]

Currently, it is thought that an unbalanced der(19) in pediatric patients with ALL is associated with significantly improved outcome compared to patients with balanced t(1;19), which remains an adverse prognostic factor.[344] In adults the prognostic relevance of t(1;19) is unclear, and both favorable and unfavorable outcomes have been reported.[350,351] In contrast, a variant t(17;19) rearrangement is associ-

ated with poor prognosis.[352] Both t(1;19) and t(17;19) are easily identifiable by conventional cytogenetics, FISH, and RT-PCR, and the latter two methodologies are particularly useful in posttreatment specimens that are cytogenetically normal.[353,354]

In ALL, the most frequent MLL translocations include t(4;11) (see Fig. 55–31, J) leading to MLL-AF4 fusion and t(11;19)(q23;p13.3) (Fig. 55–31, L) resulting in MLL-ENL fusion. These abnormalities are present in more than 80% of infant leukemia and 10% of childhood and adult leukemia.[274–276] MLL rearrangements are associated with poor outcome in both children and adults (see Acute Myelogenous Leukemia above and T-Cell Lymphoproliferative Diseases below).[306] t(4;11) is one of the most common 11q23 abnormalities, occurring in 2% of children and approximately two thirds of adults with *MLL*-associated translocations.

t(8;14)(q24;q32) is seen in fewer than 5% of all ALL patients (children and adults). Variant translocations t(8;22)(q24;q11) and t(2;8)(p12;q24) are seen in less than 1% of children and adults. These patients have $CD10^+$, $CD19^+$, $CD20^+$, surface IgM^+ immunophenotype and extremely poor prognosis. The same translocation is found in Burkitt lymphoma, and both entities likely represent the same disease with different manifestations. It has been reported that the majority of adult patients with t(8;14) die within 1 year of diagnosis.[306]

Approximately 2% of children and 8% of adult pre–B-cell precursor ALL show recurrent *IGH* translocations usually identified by FISH as t(8;14)(q11;q32), t(14;19)(q32;q13), inv(14) (q11q32/t(14;14)(q11;q32), and t(14;20)(q32;q13).[355] These five recurrent *IGH* translocations have in common deregulated expression of unmutated *CEBP* genes (CCAAT enhancer-binding protein transcription factors), and approximately 1% of all B-cell precursor ALL are characterized by novel *CEBP-IGH* fusions.

Abnormalities of the short arms of chromosome 9 (p21–22) occur at a frequency of 7% to 13%. In adults the presence of del(9p) appears to be associated with improved outcome, whereas in children will ALL del(9p) is associated with poor outcome (Fig. 55–35).[306] The most frequent abnormalities are co–deletions of two genes, $p15^{INK4B}$ and $p16^{INK4A}$, as well as the interferon α and β genes found in many, but not all, cases. Among the structural rearrangements involving the short arms of chromosome 9, t/dic(9;12)(p11–12;p11–13) is a rare recurrent abnormality associated with L1 morphology (FAB classification), pre–B-cell phenotype, and excellent prognosis.

Other chromosomal abnormalities detected in nonrandom fashion in adult ALL include deletions, both terminal and interstitial, of the long arm of chromosome 6, and isochromosomes of 7q, 9q, 17q, and 21q. Adult patients with ALL showing t(9;22), t(4;11), t(8;14), –7, +8 chromosomal aberrations have a poorer prognosis and significantly lower probability of long-term complete remission and survival than do patients with a normal karyotype or patients with other chromosomal rearrangements.

Gene expression profiling in childhood ALL suggests that ALL segregates according to cell lineage and primary genomic defects.[356] However, some clues about the genes that participate in drug resistance and influence treatment are provided by a comparison between gene expression profiling and response to therapy. In this study of 187 children with ALL, 14 functionally related genes with roles in regulation of cell proliferation were independently associated with risk of relapse.[357]

Epidemiologic and twin studies indicate a multistep pathogenesis of B-cell ALL in infants and children, with initial leukemogenic event(s) occurring in utero and subsequent genomic changes occurring postnatally.[358,359] Twin studies provide insight into the pathogenesis of pediatric leukemia because most common chromosomal translocations and their resultant gene fusions could be traced by molecular analysis of neonatal blood spots or Guthrie cards. If a unique gene fusion sequence is present in at least one cell per 30,000 in peripheral blood, it will be detected by sensitive PCR-based assay. The first in utero origin was demonstrated for *MLL* rearrangements in three children with ALL,[360] and the first demonstration that monozygotic twins shared the identical *TEL-AML1* fusion was demonstrated in a pair of twins diagnosed at age 3 with B-precursor ALL.[361] The concordance rate of twins who share monochorionic placenta and develop leukemia probably is 100%, whereas older twin children have a discordant rate of 90%, indicating that they need additional postnatal leukemic events.[359] The frequency of in utero origin of B-cell precursor ALL in non–twin children as measured by clonal *IGH* rearrangements is reported to be 71%,[362] supporting the notion that, in the majority of infants older than 1 year, development of ALL occurs in fetal hematopoiesis. Subsequent physiologic postnatal switch may eliminate these abnormal clones in the vast majority of the cases; however, a small number of children have "preleukemic" clone for some variable time, with later emergence of leukemia[360] (see box on Genetic Testing for Acute Lymphoblastic Leukemia).

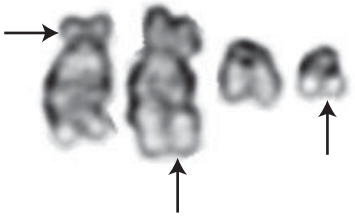

Figure 55–35 t(9;22)(q34;q11) *(arrows)* in a patient with acute lymphoblastic leukemia. Note the first chromosome 9 has deletion of the short arms, a frequent finding in both adult and pediatric acute lymphoblastic leukemia patients.

B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA

CLL is a clonal disease arising in a progenitor cell after the B-cell pathway has diverged from the myeloid and T-cell pathways.[56] Approximately 40% to 50% of patients have clonal abnormalities identified by conventional cytogenetics.[363,364] This may be an underestimate because chromosomal changes may occur in one or more cell subsets of the malignant clone. Classic cytogenetic analysis of B-CLL has remained difficult because of the low mitotic yield of neoplastic B cells despite the use of B-cell mitogens, such as 12-*O*-tetradecanoylphorbol-13-cetate (TPA) and stimulation with CD40 ligand and interleukin 4. Molecular cytogenetics, such as interphase FISH, CGH, and array CGH, have raised the detection rate to 80% to 90%.[365] Analysis of clinically relevant chromosomal loci, combined with immunophenotyping, mutation analysis of the immunoglobulin heavy-chain variable region (IgV_H), and *ZAP*-70 overexpression, are of prognostic importance even though oncogenic events that lead to the origin of B-CLL remain unknown (see box on Genetic Testing for B-Cell Chronic Lymphocytic Leukemia, Fig. 55–37, and Table 55–9). Although microarray and high-density SNP array studies have not identified genes involved in the pathogenesis of CLL, they clarify

Genetic Testing for Acute Lymphoblastic Leukemia

At diagnosis, conventional cytogenetic studies should be performed, especially for pediatric patients in whom solely numerical anomalies occur in 25%. Fluorescence *in situ* hybridization (FISH) and molecular genetic methods are valuable to detect certain cryptic chromosome anomalies, such as *TEL/AML1* fusion associated with t(12;21)(p12;q22). The panel of FISH probe at the diagnosis of pediatric acute lymphoblastic leukemia includes *TEL(ETV6)-AML1, MLL, BCR-ABL, P21* at 9p, and centromeric probes for chromosomes 4, 10, and 17. In adults, the role of hyperdiploidy as it relates to prognosis is uncertain, therefore thus FISH testing with centromeric probes is not useful. Establishing benchmarks with FISH and/or molecular testing is crucial for followup of patients during and after therapy.

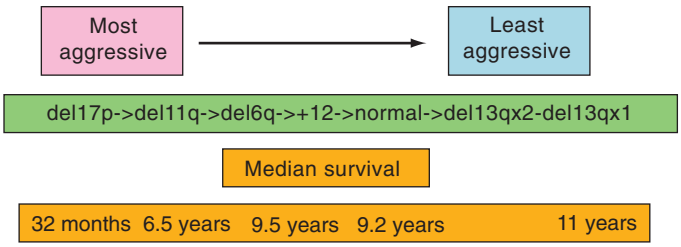

Figure 55–36 Survival of patients with specific genomic defects in chronic lymphocytic leukemia.

Genetic Testing for B-Cell Chronic Lymphocytic Leukemia

Interphase fluorescence *in situ* hybridization (FISH) is used in lieu of chromosome studies because FISH detection of abnormalities in chronic lymphocytic leukemia correlates with clinical risk groups and prognosis. FISH studies should be performed on blood for detection of trisomy 12, deletions of 11q22.3, 13q14.3, and P53 loci, as well as rearrangement of 14q32.3, *IGH* locus. The FISH test can distinguish between patients with B-cell chronic lymphocytic leukemia and those with the leukemic phase of certain lymphomas, such as mantle cell lymphoma and follicular lymphoma.

Table 55–9 Recurrent Chromosomal Translocations in B-Cell Lymphoproliferative Disorders

(1) Immunoglobulin (*IG*)-Related Translocations

Translocations	Genes Involved	Associated Diseases
t(2;8)(p12;q32)	*IGK-cMYC*	ALL (Burkitt)
t(4;14)(p16.3;q32.3)	*FGFR3-IqH*	Multiple myeloma
t(5;14)(q31;q32)	*IL3-IGH*	B-CLL
t(7;14)(q21;q32)	*IGH/-DK6*	B-CLL
t(8;14)(q24;q32)	*IGH/-cMYC*	ALL (Burkitt)
t(8;22)(q24;q11)	*IGL-CMYC*	ALL (Burkitt)
t(11;14)(q13;q32.3)	*CCND1-IGH*	Multiple myeloma
t(14;16)(q32.3;q23)	*IGH-MAF*	Multiple myeloma
t(14;19)(q32;p13)	*IGH-BCL-3*	B-CLL

(2) Lymphoma-Associated Translocations

t(11;14)(q13;q32.3)	*CCNDI-IGH*	Mantle cell
t(14;18)(q32.3;q21)	*IGH-BCL2*	Follicular
t(3;14)(q27;q32)	*BCL6-IGH*	Follicular
t(11;18)(q21;q21)	*API2-MALTI*	MALT
t(14;18)(q32.3;q21)	*IGM-MALT*	MALT
t(1;14)(p22;q32.3)	*BCL10-IGH*	MALT
3q27 rearrangements	*BCL 6*	Diffuse large B cell
t(14;15)(q32.3;q11–13)	*IGH-BCL8*	Diffuse large B cell
t(3;14)(p14;q32.3)	*FOXPIF-IGH*	MALT
t(9;14)(p13;q32.3)	*PAX5-IGH*	LPL

ALL, acute lymphoblastic leukemia; B-CLL, B-cell chronic lymphocytic leukemia; LPL, lymphoplasmacytoid lymphoma; MALT, mucosa-associated lymphoid tissue.

that CLL, despite its heterogeneous nature, is one disease entity with a common genetic phenotype resembling memory B lymphocytes.[366,367] Genetic testing is strongly recommended for all CLL patients, particularly in the context of novel therapeutic trials for CLL.[368]

Chromosome abnormalities detected by FISH are of prognostic significance.[365] Four genomic aberrations, as well as normal findings, are independent predictors of disease progression and survival. Genomic aberrations of prognostic significance include 17p deletion, 11q deletion, trisomy 12, and 13q deletion. Survival in these groups was 32, 79, 114, and 133 months, respectively, and the treatment-free interval was 8, 12, 33, and 92 months, respectively (Fig. 55–36). Survival of patients with a normal karyotype was 111 months, and the treatment-free interval was 49 months. Comparison of known prognostic features of B-CLL with interphase FISH results indicate that FISH-detected anomalies are frequent in B-CLL cases, even in Rai stages 0 to 1, but are more frequent among patients with progressive disease (88%) than in patients with stable disease (66%). Two risk groups are recognized: (a) low risk includes patients with normal karyotype or isolated del(13q), and (b) high risk includes patients with del(11q) and del(17p). Patients with +12 are high risk, but in contrast to del(11q) and del(17p), they respond to fludarabine-based therapies (Fig. 55–37).[369] Comparison of a quantitative PCR method with FISH for assessment of the four most frequent aneuploidies revealed a tight correlation in 103 of 110 patients examined, with FISH being more sensitive in detecting subclonal genetic evolution.[370]

The frequency of abnormalities of chromosome 13 in CLL detected by conventional cytogenetics is 10% to 15%.[371] However, with the application of FISH, smaller or larger deletions of band q14.3 are detected in up to 60% of patients over time.[372,373] When multiple DNA probes are used, D13S319 and D13S25 DNA markers are deleted more frequently in B-CLL than is *RB1*. Molecular analyses has detected deletions of 13q in cells that are cytogenetically normal as well as abnormal. Homozygous deletion of D13S25 and/or D13S319 DNA segments from the 13q14.3 band region is a rare but consistent finding in a subset of patients with B-cell CLL. The 13q14.3 deleted segment contains micro-RNA (miRNA) genes. Micro-RNA is made normally by cells, including B lymphocytes, and regulates the function of many genes. Preliminary findings demonstrate that all patients with homozygous 13q deletion have dramatic miRNA15a downregulation, whereas patients with hemizygous 13q deletion are indistinguishable from controls, providing the first molecular clues for the genetic basis and pathogenesis of CLL.[374,375] Trisomy 12 or 13q rearrangements are found separately in a substantial proportion of patients with CLL. They coexist in only 2% to 5% of patients, suggesting that each change may have a distinct pathogenetic route. The presence of del(13q) as the sole abnormality in CLL is associated with the most favorable prognosis, with a median survival of 11 years.

Among the first-degree relatives of patients with familial CLL, population studies demonstrate a sevenfold increased risk for developing CLL and a twofold increased risk for developing lymphoproliferative disorders, indicating genetic predisposition. More than 80 families with aggregation of CLL are reported. Linkage studies suggest a region of interest in band q22.1 of chromosome 13 (marker D13S156). Fine FISH mapping of six CLL-prone families (63 individuals) reveals deletion of 13q14 in 85% of patients with familial CLL, and four CLL families shared a 3.6-Mb minimal region in 13q21.33–q22.2. This region included 12 candidate genes, but thus far no mutations as determined using direct DNA sequence analysis are identified in patients with familial CLL.[376–379]

Trisomy 12 was the first reported recurrent abnormality in CLL. It is detected by classic cytogenetics in 7% to 15% of all cases. FISH assessment detects +12 in 15% to 20% of patients with CLL.[380] FISH studies are more representative of the true incidence of trisomy 12 because the interphase FISH methodology provides information on cells independent of their cycling status. Trisomy 12 may be present as the sole abnormality or in combination with other chromosomal rearrangements. Because only a proportion of cells are trisomic, normal cells or disomic neoplastic cells also may be present. Followup analysis over a 4-year period demonstrates clonal expansion of cells with trisomy 12 as the disease progresses. These observations suggest that trisomy 12 might be relevant in the cell activation process in CLL. The observation that trisomy 12 is documented in B cells and is absent from T lymphocytes and $CD34^+$ cells in the majority of patients is consistent with the original hypothesis that CLL has a clonal origin and that trisomy 12 arises in a progenitor cell already

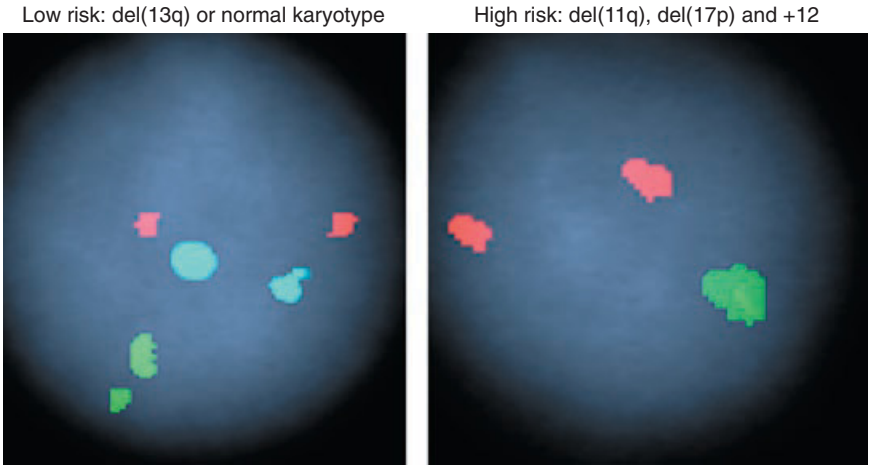

Figure 55–37 Panel of chromosomal probes used for detection of genomic defects in chronic lymphocytic leukemia. They include 13q14.3 (red), 13q34 (aqua), and CEP12 (all present in disomy; left) and 11q22.3 (*ATM,* green) and 17p13.1 (*P53;* red, right). Note only one copy of the *ATM* gene (green, right) consistent with deletion of sequences from the 11q22.3 band region, which is associated with unfavorable prognosis.

committed to the B-cell pathway.[381] Routine FISH genetic testing identifies patients with trisomy 12 because it uses the probe that is hybridized only to the centromeric area of chromosome 12. More sophisticated molecular cytogenetic methods may be useful. High expression of the *CLLU1* gene on 12q22 has been discovered in CLL samples from patients with or without trisomy 12. Overexpression of *CLLU1* in CLL patients without IgV_H hypermutation combined with restricted and CLL-unique expression pattern suggest that *CLLU1* is among the first disease-specific genes identified in CLL.[382]

The frequency of deletions of the long arm of chromosome 11 in CLL as detected by conventional cytogenetics is reported to be 5% to 8%. An interphase FISH study identified a clinical subset of B-cell CLL defined by deletion of 11q22.3–23.1 in 7% to 10% of these cases. FISH characterization of aberrations involved in 11q21–q23 demonstrate a minimal consensus deletion segment of 2 to 3 Mb, containing a number of genes including *ATM* at 11q22.3 (see Fig. 55–37, right). Up to 12% of patients have simultaneous deletions of *ATM* and *MLL* at 11q23. The *ATM* gene is responsible for ataxia-telangiectasia and functions as a cell-cycle checkpoint regulator. Somatic disruptions of both alleles of the *ATM* gene by deletion or point mutation are detected in approximately 34% of cases. This finding strongly suggests the pathogenic role of ATM in some patients with B-CLL.[383] A study revealed discontinuous deletions at 11q23.1–q23.3, indicating that genes in this region may have pathogenic significance because they constitute independent targets for amplification or deletion in cases of B-CLL. Patients with 11q deletion exhibit extensive lymphadenopathy, more rapid disease progression, a shorter treatment-free interval, inferior molecular remission, and reduced overall survival.[384]

Structural aberrations of chromosome 17 are observed in 4% of cytogenetically evaluable B-CLL cases. This abnormality frequently affects the short arm of chromosome 17, the site of the *P53* tumor suppressor gene. Monoallelic deletions of *P53*, detected by FISH, are present in 7% to 20% of patients and represent the strongest predictor of survival in B-cell CLL. The median survival time of these patients is only 32 months.[365] B-CLL in patients with deletion of the *P53* gene is associated with refractory advanced disease, resistance to treatment, and shorter survival. A comprehensive assessment of genetic and molecular features predicting outcome in previously untreated CLL patients receiving either fludarabine or fludarabine plus cyclophosphamide identified del(17)(p13) along with del(11q), but not IgV_H, CD38 expression, or ZAP-70 status, as significant risk factors for early relapse.[384]

Because the leukemic phase of certain lymphomas can clinically mimic B-CLL, FISH testing for translocation using an *IgH* probe is important. Fewer than 5% of patients with CLL/prolymphocytic leukemia morphology have t(11;14)(q13;q32), and these conditions usually transform into prolymphocytic leukemia. Moreover, *IGH* testing in CLL is important for detecting patients with recurrent del(14)(q24.1) associated with unmutated IgV_H status (66%) and trisomy 12 (47%).[385]

Current work provides solid evidence that chromosomal translocations detected by conventional cytogenetics independently predict treatment failure, treatment-free survival, and overall survival in untreated and cladribine-treated B-cell CLL patients.[386,387] When CLL-derived metaphase cells are obtained with systematic stimulation using B-cell mitogens and activators, balanced and unbalanced translocations are seen in 34% to 42% of patients. In multivariate analysis, unbalanced translocations are independently associated with risk of treatment failure. Because del(13q) usually is cryptic by conventional cytogenetics but easily detected with FISH studies,[388] both conventional cytogenetics and interphase FISH should be performed at baseline in patients with advanced CLL.

The validity of hierarchical interphase FISH categories at diagnosis in predicting overall survival of CLL patients is confirmed by long-term followup studies. Interphase FISH testing can identify approximately 27% of patients with clonal chromosomal evolution occurring after 5 or more years of followup, with approximately two third of patients acquiring del(13q) and del(17p).[389] These observations have important clinical implications for management of patients with highest-risk early-stage CLL.

MULTIPLE MYELOMA

MM is a malignancy of terminally differentiated B cells. These plasma cells have a very low proliferative rate, a characteristic that has limited its application in cytogenetic studies. Conventional karyotyping reveals chromosome abnormalities in 25% to 30% of newly diagnosed patients, especially in cases with exceptionally high plasma cell proliferative rates.[390] Karyotypes obtained from these cells usually are complex and exhibit more than 20 aberrations in approximately about 10% of cases.[391]

When reassessed by FISH, CGH, and multicolor karyotyping using a large panel of centromere-specific and translocation-specific probes, interphase plasma cell nuclei revealed chromosomal aneuploidy in almost all patients with MM or monoclonal gammopathy of unknown significance.[392–399] Even during complete clinical remission, 12% to 71% of cells still show a numerical gain or loss of chromosomes 3, 7, 8, 9, 11, 13 15, 21, and X.[400]

Analysis of numerical abnormalities reveals two broad groups of MM patients: hyperdiploid and nonhyperdiploid. Hyperdiploid MM is associated with trisomies of chromosomes 3, 5, 7, 9, 11, 15, 19, and 21 and fewer *IGH* translocations. Nonhyperdiploid MM is characterized by a high frequency of *IGH* translocations (>85%). Both

these groups are also present in monoclonal gammopathy of unknown significance, suggesting that they occur early in the evolution of disease.[397–399,401] The prognostic relevance of numerical abnormalities is difficult to ascertain because other adverse genetic changes frequently are present in the same clone. Even with the application of gene expression profiling, MM-specific oncogenes associated with hyperdiploidy have not been identified.[402–404] However, in such a genetically heterogeneous group, it is anticipated that molecular techniques such as array CGH may provide more precise and predictive tools.

An IGH rearrangement on 14q32.3 is found in most patients with MM. The rearrangement consists of complex and heterogeneous translocations with the breakpoint involving either the switch region of *IGH* or the V, D, or J gene (see Table 55–9). The primary translocations are due to somatic hypermutation or errors in the VDJ portion of the switch region recombination. The translocations include a promiscuous array of at least 20 nonrandom chromosomal partners and the characterization of these translocations have led to the identification of critical deregulated oncogenes (e.g., *BCL2*, cyclin D). In each translocation, a potent enhancer is juxtaposed to deregulated oncogenes. The most frequent *IGH* translocations include t(4;14)(p16.3;q32.3), t(11;14)(q13;q32.3), and t(14;16)(q32.3;q23) (Fig. 55–38).

Patients with a recurrent *CCND1-IGH* have an overexpression of cyclin D1. In contrast to mantle cell lymphoma, breakpoints on 11q13 in MM are not clustered but are scattered over a relatively large genomic region. Therefore, the *CCND1-IGH* commercial probe for MM involves another gene, *MYEOV*, that is distinct from the *CCND1-IGH* probe used for detection of t(11;14) in mantle cell lymphoma (Fig. 55–39, bottom left). In contrast to other abnormalities involving the *IGH* locus, clonal t(11;14) MM cells tend to be diploid. There appears to be an association of the t(11;14) with oligosecretory or light chain only, CD20 expression, and lymphoplasmacytic morphology.[397,405–407]

Approximately 15% of patients have a recurrent t(4;14)(p16.3;q32.3) abnormality. This cytogenetic abnormality is associated with IgA subtype, λ light chain, immature plasma cell morphology, and poor response to therapy. This abnormality is cytogenetically cryptic and is detected by FISH and other molecular cytogenetic methods.[397,398,407–410] Two genes on chromosome 4p16.3 and the *IGH* switch region on 14q32.3 are involved. The fibroblast growth factor receptor 3 gene *(FGFR3)* is detected on der(14), where it is overexpressed along with a fusion of the multiple myeloma set domain *(MMSET)* gene, located on 4p16.3.[410] This is the first example of a translocation that simultaneously deregulates two genes with oncogenic potential, the *FGFR3* gene detected on der(14) and the *MMSET* gene detected on der(4). *FGFR3* is 50 to 100 kb telomeric to *MMSET*. Loss of *FGFR3* on der(14) is detected in approximately 20% of cases.[411] A significant proportion of these patients display del(13q) in the same clone and are hypodiploid.

Genetic lesion	Frequency (%)
del(13)(q14.3)	10-20
†(11;14)(q13; q32.3)	15-30
†(14;16)(q32.3; q23)	2-8
†(4;14)(p16.3; q32.3)	15
del(17)(p13.1)	10

Figure 55–38 Most frequent structural chromosomal rearrangements in multiple myeloma and their frequencies.

Translocation (14;16)(q32.3;q23) had never been cytogenetically detected because of the telomeric positions of both loci. However, with FISH studies the incidence of t(14;16) has been estimated to be approximately 2% to 8%.[412] In this translocation, the *MAF* protooncogene is translocated from its normal position on 16q23 to chromosome 14, band q32.3, and is overexpressed. Rare variants t(14;20) and t(8;20) are included in this group because they share a similar gene expression signature and clinical outcome.[413,414] The clinical outcome of patients with t(14;16) is significantly shorter compared to a t(14;16)-negative cohort.[415]

Deletion of either band q14 or q14.3 *(RB1*, DNA marker *D13S319)* on chromosome 13 is detected in 10% to 20% of patients by conventional cytogenetics and in 50% by FISH (see Fig. 55–39, top right).[390,416,417] Microarray CGH data of the critical region on chromosome 13 is consistent with previous findings. Loss of the entire chromosome 13 (82%) is more frequent than is deletion of the long arms of chromosome 13.[418,419] The most commonly deleted region has not been delineated. The median percentage of plasma cells carrying del(13q), identified by FISH, ranges from 75% and 90%.[398,418,420,421] Deletion of 13q is associated with specific clinicopathologic features, including a higher frequency of λ-type MM, high plasma cell labeling index, female predominance, and inferior survival after standard chemotherapy.

Numerous studies have demonstrated that del(13q) represents an adverse prognostic marker in MM. However, molecular cytogenetics analyses revealed that del(13q) is present in 90% of patients showing t(4;14) or t(14;16); therefore, the apparent adverse impact of del(13q) may not be the only genomic defect influencing unfavorable prognosis in these patients.[422–424]

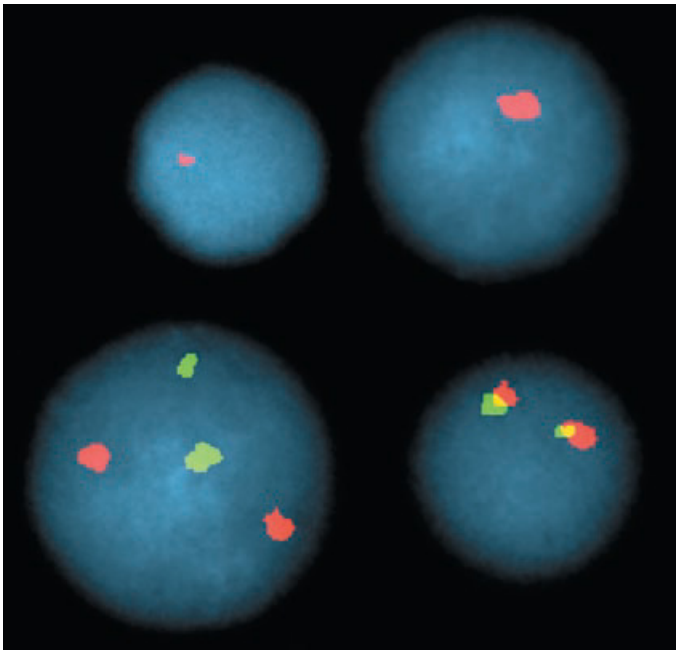

Figure 55–39 Composite image of marrow nuclei from a patient with multiple myeloma after hybridization with five probes. The following probes are the most frequently used for detection of genomic structural rearrangements in clinical testing of multiple myeloma. Left top cell has 17p13.1 deletion (one red signal). Right top nucleus also shows a single red signal after hybridization with D13S319 probe, consistent with deletion of 13q14.3 locus. The patient had codeletion of both loci, which is associated with unfavorable prognosis. Bottom left cell shows two green and two red signals after FISH study with *CCND1* and *IGH,* indicating disomy for both probes and lack of *CCND1-IGH* fusion. Also shown are confirmatory results (bottom right) obtained after application of breakapart *IGH* probe showing lack of separation of green and red signals, consistent with intact *IGH* gene.

The adverse prognostic impact of del(13q) detected by conventional cytogenetics versus interphase FISH remains controversial. Comparative analyses using conventional cytogenetics and metaphase and interphase FISH studies demonstrate different survival depending on whether del(13q) abnormality is detected by metaphase or only in interphase nuclei, or by both.[390,425]

Deletion of *P*53 at 17p13.1, which occurs in 10% of patients, is a powerful independent predictor of shortened survival in MM and is associated with stage III disease, clonal evolution, drug resistance, and genetic instability (see Fig. 55–39, top left). This deletion is not found in patients with other high-risk groups such at t(4;14), or t(14;16), and it appears mutually exclusive.[409] Patients characterized by *P53* deletion have significantly shorter overall survival irrespective of therapy administered.[406,426,427]

The gain of 1q21 locus is identified in 45% of cases of monoclonal gammopathy of unknown significance, 43% of newly diagnosed MM, and 72% of relapsed MM and represents one of the most frequent recurrent chromosomal abnormalities in MM.[428] Gain of 1q can be detected cytogenetically as isochromosome, duplications, or jumping translocations or detected with a 1q21-specific FISH probe.[429,430] Among 479 patients with newly diagnosed MM, 43% with amplq21 also have either a hypodiploid and hyperdiploid karyotype, del(13q) by FISH, immunoglobulin A predominance, and poor prognosis compared to patients lacking amp1q21.[428]

The molecular basis of MM is slowly emerging, but the precise role of oncogenes is not yet defined. In order to address this issue and to understand the molecular basis of aneuploidy, work has evaluated the role of centrosome amplification in plasma cell neoplasm. Preliminary evidence indicates that centrosome amplification is common in all stages of plasma cell neoplasm, including monoclonal gammopathy of unknown significance, and probably is integral to disease pathogenesis and genomic instability of MM.[431] The recently described gene Dickkopf-1 *(DKK1)* may be associated with the presence of lytic bone lesions in patients with MM.[432,433]

Molecular abnormalities such as *CCND1-IGH*, *IGH-MAF,* and *FGHR3-IGH* are found in approximately 40% of patients presenting with MM. In the remaining 60% of cases, chromosomal translocations cannot be identified, but hyperdiploidy is present. These presenting features are followed by further karyotypic instability and often include deletions/monosomy of chromosome 13 or chromosome 17, band region p13.1 (P53). Amplification of 1q21 represents a late event in this multistep process and is associated with a malignant phenotype. From a practical point of view (see box on Genetic Testing in Multiple Myeloma and Fig. 55–39), recommended basic genetic testing for newly diagnosed MM patients must include FISH testing for *CCND1-IGH,* deletions of *P53* and 13q13.4 loci, and rearrangements of *IGH*. Conventional cytogenetics can be performed to detect del(13q) in dividing metaphase cells as an indicator of a highly proliferating tumor. If progression of MM is suspected, FISH testing for amplification of 1q21 is recommended.

LYMPHOMA

Non-Hodgkin lymphoma (NHL) comprises a heterogenous group of disorders characterized by localized proliferation of lymphocytes. Analogous to other hematopoietic disorders, the pathogenesis of these malignancies is attributable to a multistep process involving progressive and clonal accumulation of genetic lesions. The majority of NHLs are of B-cell origin and involve translocations of immunoglobulin loci (see Table 55–9). *IGH* translocations usually are detected by cytogenetics, often in conjunction with FISH probes that span the *IGH* loci[434] and/or PCR-based technologies. These molecular abnormalities exhibit enormous complexity with multiple and complex translocations, deletions, and amplifications within one clone. The WHO recognizes that genetic anomalies represent one of the most reliable criteria for classification of malignant lymphomas. The most common associations between chromosome anomalies and specific lymphomas include t(14;18)(q32;q21) and follicular lymphoma; t(8;14)(q24;q32) and Burkitt lymphoma; t(11;14)(q13;q32) and mantle cell lymphoma; and t(11;18)(q21;q21) and mucosa-associated lymphoid tissue (MALT) lymphoma (see box on Genetic Testing for Non-Hodgkin Lymphoma and Fig. 55–40). However, identification of a specific translocation is not diagnostic of a specific lymphoma subtype. Chromosome studies are difficult and expensive for the study of lymphomas. Thus, many investigators use FISH and/or molecular genetic methods to study touch preparations or paraffin-embedded lymphoid tissue to detect important genetic anomalies in lymphomas.[435–437]

Approximately 85% to 90% of patients with follicular lymphoma and some patients with large cell lymphoma exhibit t(14;18)(q32.3;q21.3), which results in fusion of *BCL2* on 18q21 and *IGH* on 14q32 and represents one of the most common abnormality in NHL (see Fig. 55–40, *D*). Although the exact underlying mechanism is not known, t(14;18) results from a mistake of VDJ recombination and juxtaposes the *BCL2* oncogene with the nonexpressed *IGH* allele.[437] As a consequence, the *BCL2* gene comes under the control of *IGH* enhancer, causing dysregulated expression of *BCL2* protein, one of the proteins involved in regulation of apoptosis. The breakpoints within *BCL2* occur mostly within the 3′ region of the gene, whereas the breakpoints in *IGH* fall within the D_H and J_H regions. Although 75% of breakpoints are clustered within a remarkably narrow region of 15 to 20 bp at the 3′ end of the *BCL2* gene, they are frequently missed by standard PCR.[438] With regular and fiber FISH methods using *BCL2* breakpoint flanking probes, individual 5′ and 3′ breakpoints can be detected. *BCL2* rearrangements are detected with immunohistochemical staining for BCL2 protein.[11] With disease progression, 100% of patients have *BCL2* overexpression. Variant translocations, such as t(2;18)(p12;q21) and t(18;22)((q21;q11) involving the *IGK* or *IGL* gene, respectively, rather than *IGH*, also show overexpression of *BCL2.*[439]

Numerous secondary chromosomal abnormalities are identified by conventional cytogenetics, and at least five recurrent anomalies, each occurring in at least 20% of follicular lymphomas, may distinguish two subgroups of follicular lymphoma patients. Patients with t(14;18) showing additional trisomy for chromosome 2, 7, or 8 are associated with more favorable course of disease compared to patients with additional del(1p), del(1q), del(6q), der(18), del(22q), or gain

Genetic Testing for Multiple Myeloma

Chromosome studies of isolated plasma cells from the marrow are very useful at diagnosis. Perform interphase fluorescence *in situ* hybridization and molecular genetic studies for detection of *CCND1-IGH* [t(11;14)], del(13)(q14.3)/D13S319, del(17)(p13.1)/P53, and *IGH*/14q32.3. If *IGH* rearrangements are detected using a breakapart *IGH* locus, refine the partner and use the following set of probes: *MAF-IGH* for detection of t(14;16) and *FGFR3-IGH* for detection of t(4;14).

Genetic Testing for Non-Hodgkin Lymphoma

Fluorescence *in situ* hybridization (FISH) testing can be performed on touch preparations, paraffin-embedded tissue, or bone marrow cells if bone marrow is involved. Peripheral blood cells are not appropriate for genetic testing of non-Hodgkin lymphoma. Bone marrow cytogenetics at diagnosis is not useful but may be important for staging in some cases. Figure 55–40 lists the most useful FISH probes for detection of genomic defects in non-Hodgkin lymphoma. They include *CCND1-IGH, IGH-BCL2, MYC-IGH, BCL6, MYC* breakapart for detection of Burkitt variant not associated with t(8;14), and *MALT1* breakapart for detection of t(11;18). For patients with suspected anaplastic large cell lymphoma, *ALK* breakapart probe should be informative.

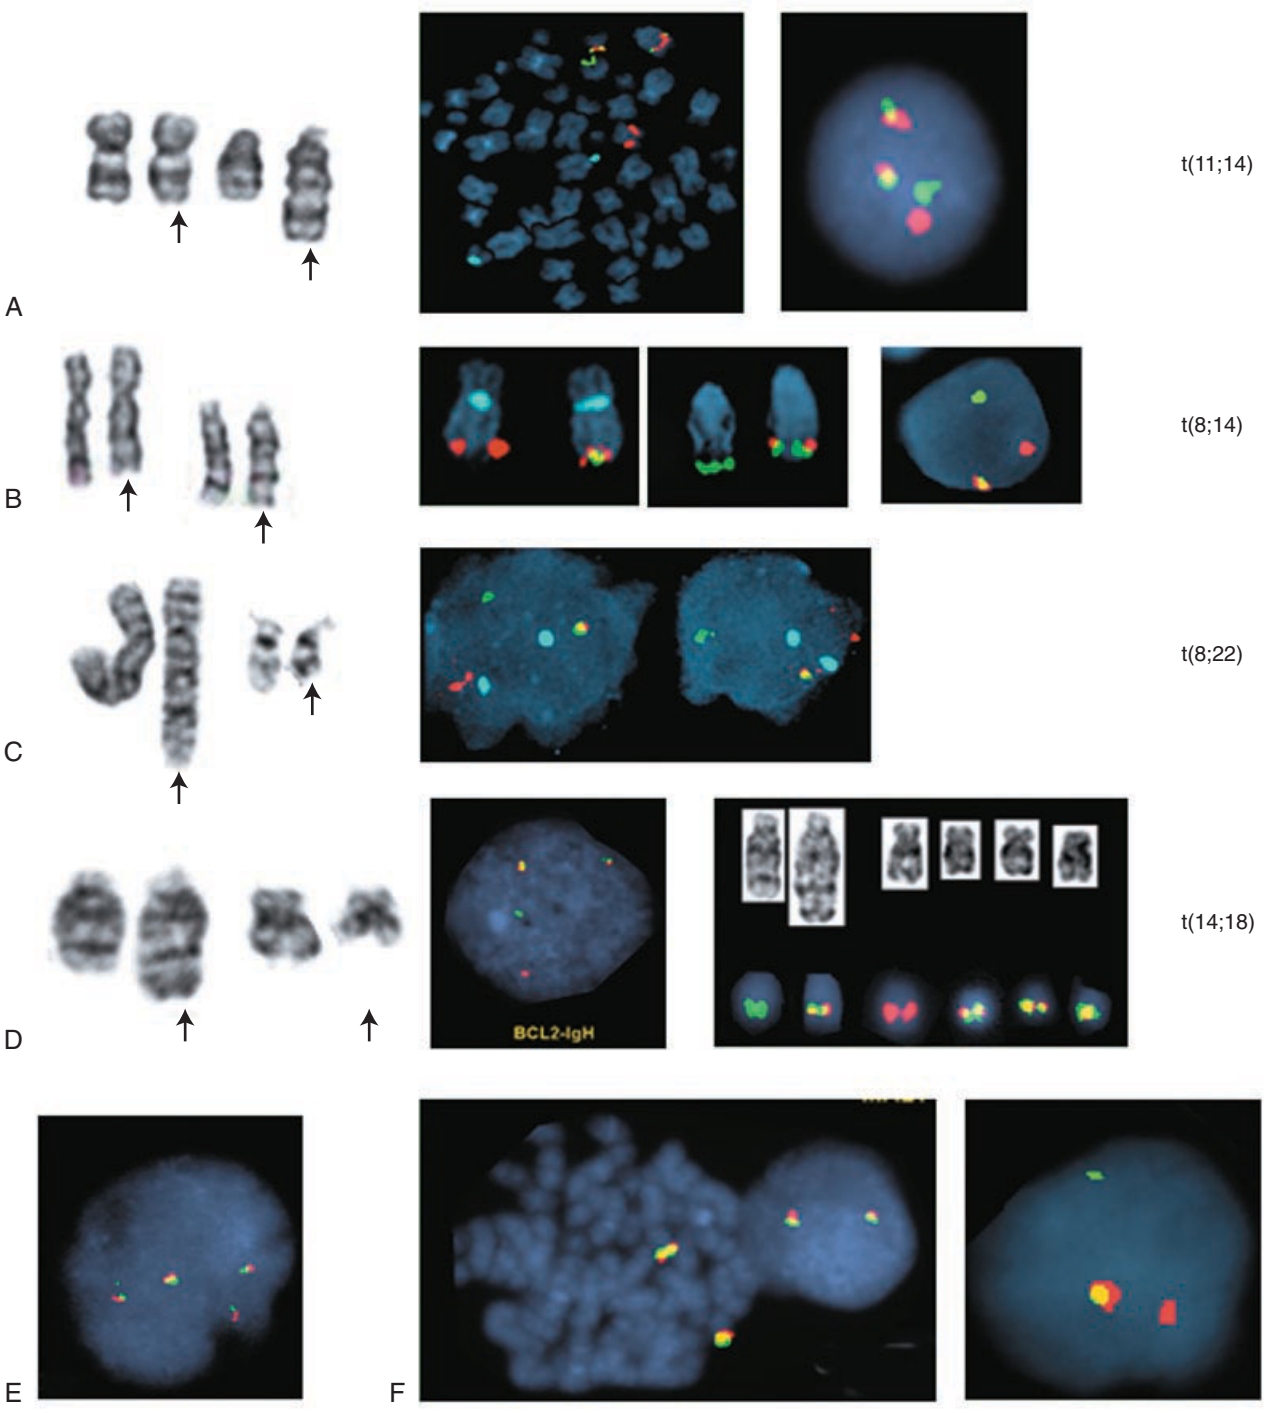

Figure 55–40 Most frequent chromosomal abnormalities in non-Hodgkin lymphoma. **A,** Partial G-banded karyotype of t(11;14)(q13;q32.3) (left), resulting in *CCND1-IGH* fusion (yellow) on metaphase (middle) and in interphase cell (right) present in the majority of patients with mantle cell lymphoma. **B,** Partial G-banded karyotype of t(8;14)(q24;q32.3) (left) resulting in *MYC-IGH* fusion [yellow on der(8) on isolated chromosomes]. Application of *MYC* breakapart probe shows separation of red and green signals consistent with MYC rearrangement. Approximately 80% of Burkitt lymphomas are characterized by t(8;14); **C,** Partial G-banded karyotype of t(8;22)(q24;q11), a variant of Burkitt lymphoma (left). Two interphase lymph node cells after hybridization with *MYC* breakapart probe and CEP8 (aqua). Separation of green and red signals is consistent with *MYC* relocation from 8q24 to 22q11: **D,** Partial G-banded karyotype of t(14;18)(q32.3;q21.3) (left) resulting in *IGH-BCL* fusion (two yellow signals, middle). A composite image on the right shows both a partial karyotype and FISH study of triplicated der(18)t(14;18) and three copies of *IGH-BCL2* fusion (yellow) as well as normal chromosome 14 and 18. Multiple copies of abnormal der(18) chromosome is associated with progressive disease similar to a duplication of the Philadelphia chromosome in the blast crisis of chronic myelogenous leukemia. **E,** Lymph node cell from a patient with diffuse large B-cell lymphoma (DLBCL) showing four copies of *BCL6* (breakapart probe). *BCL6* is localized at 3q27 and is numerically or structurally rearranged in 35% of DLBCL. **F,** Bone marrow metaphase and interphase cell hybridized with breakapart *MALT1* gene at 18q21 (left) indicating two fusion (yellow) signals when *MALT1* gene is intact. In contrast, rearrangement of the *MALT1* gene in MALT lymphoma usually is the consequence of t(11;18)(q21;q21.1)m as shown in the cell (right) with clear separation of the 3′ end (green) and the 5′ end (red).

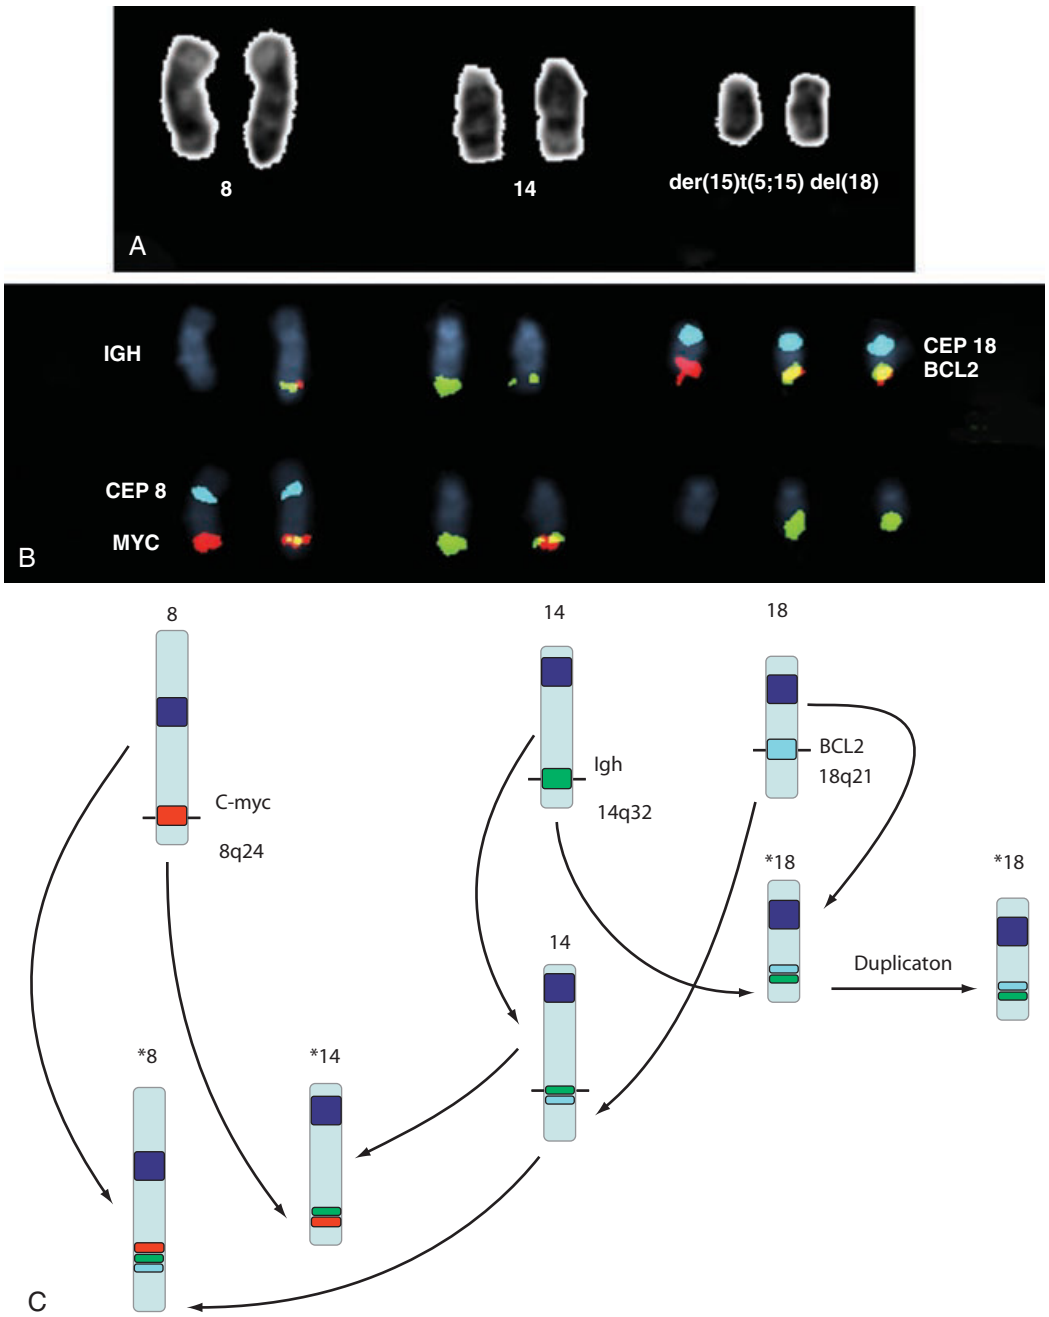

Figure 55–41 Identification of simultaneous *BCL2* and *MYC* rearrangements in high-grade B-cell lymphoma leukemia (see text for details). Partial G-banded karyotype (top) of chromosomes 8 and 14 and what is initially identified as der(15)t(5;15) and der(18). Partial karyotype of the same chromosomes after FISH study (bottom) with probes for *IGH* (green), CEP8 (aqua), and *MYC* (red) indicating *IGH-MYC* fusions (yellow) on both chromosomes 8 and 14. Sequential hybridization with CEP18 (aqua), *BCL2* (red), and *IGH* (green) also revealed *IGH-BCL2* fusion (yellow) on both der(15) and der(18), indicating that der(15) actually is a duplication of rearranged chromosome 18. **C,** Schematic representation of genomic events leading to duplication 18. Rearrangements of both *MYC* and *BCL2* show a complex molecular array.

of chromosome 12 and X, which is associated with inferior outcome. Unfavorable outcome of patients with loss of X chromosome is confirmed by CGH, and del(6)(q25–q27) is identified as the strongest predictor of poor prognosis and shorter survival time. Rearrangements of chromosome 1, such as del(1)(p32–36), +[1](p11–q44), and unbalanced translocations of der(1)(1;1)(p36;q11–23) regions are among the most frequent secondary chromosomal abnormalities in follicular lymphoma.[440–443] Progression of follicular lymphoma to diffuse large cell B-cell lymphoma occurs in 60% to 80% and is accompanied by accumulation of secondary abnormalities, of which homozygous del(9p) might be associated with histologic progression.[444]

The combination of *BCL-2* and *MYC* rearrangements resulting from t(8;14)(q24;q32) and t(14;18)(q32;q21) or variants in the same karyotype is characteristic of high-grade B-cell lymphoma/leukemia, which occurs in fewer than 2% of patients and is associated with aggressive histology and poor prognosis.[445,446] In these cases, a translocation within a single *IGH* allele separates the 3′ from the 5′ *IGH* enhancer element, with relocation of the *BCL2* 5′ *IGH* enhancer fusion to the der(8) and translocation of *MYC* adjacent to the 3′ *IGH* enhancer element that is retained on the der(14). The ISCN cytogenetic description der(8)t(8;14)(q24;q32) t(14;18)(q32;q21), der(14)t(8;14)(q24;q32), der(18)t(14;18)(q32;q21) does not reflect the complexity of the underlying molec-

ular rearrangements (Fig. 55–41A–C). Because one of the translocation may be cryptic, a combination of three FISH probes, labeled in three colors, is especially useful in identifying these complex translocations.

The *IGH-BCL* formation is believed to represent a very early event in the pathogenesis of follicular lymphoma. This notion is supported by the observation that t(14;18) is also found in peripheral blood in more than 50% of healthy individuals and may persist for at least 3 years without overt disease.[447–450] Because the incidence of follicular lymphoma in the United States is approximately one case per 24,000 persons per year, the occurrence of follicular lymphoma is relatively rare.[451] Gene expression profiling shows a distinct pattern associated with an indolent form of disease (median survival 11.1 years) and a more aggressive form (median survival 3.9 years), indicating that these different conditions may represent distinct stages in the evolution of follicular lymphoma.[452] These and other observations point to an immune response that may regulate the pace of the malignant process and may restrain the proliferation of t(14;18)-positive B cells in healthy individuals.[450,451] The molecular pathogenesis of follicular lymphoma may include formation of t(14;18) in a naive B cell. If stimulated by an exogenous agent such as a virus or autoantigen, a germinal center reaction may occur. Upon further stimulation by an antigen on the surface of a follicular dendritic cell, together with the T-cell, a memory cell may form. This type of cell represents the majority of t(14;18)-positive cells identified in the peripheral blood of normal individuals. Further oncogenic events and accumulation of different, recurrent chromosomal abnormalities in a stepwise pathogenesis may transform this cell into clinically recognizable follicular lymphoma.

Three translocations, all affecting the *MYC* gene at 8q24, have been recognized in Burkitt lymphoma. In 80% of patients a reciprocal translocation t(8;14)(q24; q32) is observed between the *MYC* gene and the *IGH* locus. In the remainder of patients, the reciprocal translocation t(8;22)(q24;q11) or t(2;8)(p12;q24) is observed juxtaposing MYC to one of the light-chain loci (κ on 2p12 and λ on 22q11). The t(8;14) translocation originally was described in Epstein-Barr virus $(EBV)^+$ tumor cells obtained from patients in Africa (see Fig. 55–40, *B* and *C*).[453] Variant translocations involving MYC with a variety of other non-*IG* loci subsequently have been reported.[454,455] In most patients with sporadic Burkitt lymphoma, the breakpoints on 8q24.1 are located 5′ of the coding region of the *MYC* gene. In contrast, in most cases of endemic Burkitt lymphoma and in variant translocations, the *MYC* breakpoints are a considerable distance centromeric or telomeric from the *MYC* coding exons.[456] As a result of the translocation, control of normal *MYC* is lost, and the intact protein is constitutively expressed throughout the cell cycle.

The *MYC* gene can function as both a transcriptional activator and a transcriptional repressor.[457] As a result of t(8;14) there is transcription of a truncated MYC protein, whereas in t(2;8) and t(8;22) the rearrangement of the *MYC* gene can occur within sequences downstream of the transcribed region. The exact molecular mechanism by which the rearranged *MYC* is activated is not fully elucidated, but its activation constitutes an important step in malignant transformation. An increased level of *MYC* constitutive synthesis in leukemic disorders is found not only as a result of translocation but also as a result of *MYC* mutations and amplification. Approximately 65% of Burkitt lymphomas demonstrate *MYC* point mutations. Overexpression of *MYC* is linked to amplification of *MYC* genes reported in plasma cell leukemia, AML, CML, and T-cell lymphoma.

The most common secondary change associated with t(8;14) is duplication of the long arms of chromosome 1, and these rearrangements are associated with disease progression.[458,459] A common duplicated region of 93 kb at 1q21.2 is defined by FISH studies.[460] This section of chromosome contains at least three putative oncogenes, including the *OTUD7B* gene. This gene encodes a cytoplasmic protein and functions as a negative regulator of the nuclear factor (NF)-κB transcription factor, known to be implicated as a critical pathogenic factor in lymphoma.[461]

Rearrangements of *MYC* now can be detected in nondividing cells as well as paraffin-embedded lymph node biopsies using a very sensitive interphase FISH assay for t(8;14), with less than 2% false-positive results. Genomic profiling study unequivocally demonstrated that the majority of patients with *MYC* rearrangements should be classified as Burkitt lymphoma even though pathologists called some of the cases diffuse large cell lymphoma.[462,463] However, these studies also indicate that rare cases with the Burkitt signature gene expression lack *MYC* rearrangements and have *BCL2* rearrangements, suggesting that in rare cases *MYC* rearrangement alone may not be sufficient for diagnosis of Burkitt lymphoma.

According to the WHO classification, a Burkitt-like lymphoma is a separate entity characterized by one of the Burkitt lymphoma translocations. However, many such cases fail to show Burkitt lymphoma translocations but do exhibit increased *MYC* expression.[464]

Approximately 35% of patients with diffuse large B-cell lymphoma (DLBCL) and approximately 5% to 10% of patients with follicular lymphoma have rearrangements in the *BCL6* gene normally residing at 3q27. Translocation of 3q27 is the third most frequent translocation in NHL, and at least 33 different partners have been described as participating in these rearrangements (see Fig. 55–40, *E).* The most frequent chromosomal band partners are 2p13, 4p13, 6p22, 7p12, 8q24, 13q14, 14q32, 18p11.2, and 22q11.[465–467] These translocations juxtapose different promoters derived from other chromosomes, with the *BCL6* coding domain causing persistent expression of *BCL6*.

Most of the breakpoints in 3q27 occur within a 10-kb region. The fact that the 3q27 region is affected in different lymphomas, irrespective of the translocation partner chromosomes, strongly suggests that alterations of *BCL6*, and not the reciprocal loci, are important in the pathogenesis. The alterations in 3q27 are too small for microscopic detection, so most of these rearrangements are detected by Southern blot analysis, PCR-based assay, or FISH.[468] *BCL6* functions as a transcriptional repressor of genes containing its binding sites; therefore, the mechanism responsible for the malignant phenotype is transcriptional deregulation. The prognostic significance of *BCL6* rearrangements is not clear, and different outcomes have been reported.[469–471]

Approximately 3% to 4% of DLBCLs have t(14;15)(q32;q11-13), which results in fusion of the *BCL8* gene on chromosome 15 to the V_H segment of the *IGH* locus.[472] The most common secondary abnormalities are trisomies of chromosomes 3, 5, 7q, 11, 12p, 18q, and Xq, observed in greater than 10% of cases. Amplification of *REL* (2p12–16), *MYC* (8q24), *BCL2* (18q21), *GLI*, *CDK4*, and *MDM2* (12q13–14) genes, identified by a combination of molecular cytogenetic methods, are most frequent associated with advanced stage disease.[473] The most frequent monosomies include chromosomes 13, 14, and 15. A complex karyotype may have an adverse impact on prognosis.

Modern molecular cytogenetic methods such as CGH identify three major subgroups in DCLBC. Patients with activated B-cell-like DLBCL (ABC-DCLBC) exhibit frequent trisomy 3, gains of 3q and 18q21–23, and loss of the 6q21–23 region. Patients with germinal center B-like (GCB) DLBCL have frequent gains of the 12q12 chromosomal region. Patients with primary mediastinal lymphoma (PMBCL) has gains of 2p14-p16 and 9p21-pter.[474] Apparently, only gains in several regions of chromosome 3 are significantly associated with inferior survival. Moreover, genomic gains involving the 3p11-p12 region have an independent prognostic power for survival based on previously defined optimal gene expression-based models.[474,475]

All patients with mantle cell lymphoma exhibit the t(11;14)(q13;q32) abnormality by FISH.[476,477] t(11;14)(q13;q32) is also found in a variety of other B-cell malignancies, including MM, splenic lymphoma with villous lymphocytes, and B-cell prolymphocytic leukemia. Most breakpoints on chromosome 11, band q13, are dispersed over a region approximately 130 kb centromeric to the *cyclin D1 (CCND1)* gene. At the molecular level, the *BCL1* locus *(CCND1)* on chromosome 11q13 is juxtaposed to an enhancer sequence within the immunoglobulin heavy-chain gene *(IGH)* on 14q32, leading to overexpression of the *cyclin D* gene, which is not

expressed in normal B and T cells or in other malignant lymphomas. The consequence of this translocation is overexpression of *cyclin D1*, a gene involved in cell cycle control.

Each method for detection of t(11;14), including cytogenetics, Southern blot, and PCR-based analyses, has limitations. Cytogenetics is hampered by a low mitotic index of neoplastic B cells. Southern blot and PCR-based analyses for 11q13 rearrangements are positive in only 50% to 60% of patients with mantle cell lymphoma because the breakpoints within 11q13 are scattered along a 130-kb distance. In practical terms, dual-color FISH has proved to be the most sensitive assay for detection of *IGH-CCND1* fusion, which is found in 100% of cases.[478,479] Furthermore, the *CCND1* fusion rearrangement can be detected in formalin-fixed, paraffin-embedded samples, making this method rapid, reliable, independent of cell cycle, and applicable to all cases of mantle cell lymphoma (see Fig. 55–40, *A*).[480]

Gene expression studies have identified a subset of patients with D1-negative mantle cell lymphoma, so called because of the lack *cyclin D1* expression and t(11;14).[481,482] However, both cyclin D1-positive and cyclin D1-negative patients have the same secondary genomic alterations when assessed with conventional cytogenetics, CGH, and array-based CGH.[479,483] These secondary chromosomal alterations include gains of 3q, 8q, and 15q and losses of 1p, 8p23-pter, 9p21-pter,11q21–23, and 13q. Some of the genes residing in these chromosomal regions are dysregulated and involved in cell proliferation, DNA repair mechanism of chromosome stability, and cellular homeostasis and apoptosis mechanisms. Unlike other lymphomas, in mantle cell lymphoma DNA amplifications of several chromosomal regions appear to be associated with a blastoid variant.[484] Loss of 9p21-pter, inactivation of P53, gain of 3q, and high *cyclin D* expression are reported molecular and cytogenetic markers of shorter survival and a more aggressive clinical evolution. The prognostic value of 3q27-qer gains and loss of 9q21–32 region are determined to be independent of the gene expression-based signature.[483] Extra copies of 3q are prognostic in patients with low proliferation, whereas loss of 9q has improved clinical value in subgroup of patients with high proliferation.

Marginal zone lymphoma and MALT lymphoma are considered the third most frequent NHL subtype. According to the WHO classification, they are subdivided into splenic marginal zone lymphoma, nodal marginal zone lymphoma, and MALT lymphoma. An etiologic link between low-grade gastric MALT lymphoma and the lymphoid reaction associated with *Helicobacter pylori* infection is well established.[485] Growing evidence suggests that chronic antigenic stimulation in autoimmune diseases, such as Hashimoto thyroiditis, contribute to an increased risk of developing MALT lymphoma.[486]

The most frequent and specific aberration occurring in MALT lymphomas is t(11;18)(q21;q21.1).[487] Although it has been described in other B-cell lymphomas, t(11;18) in MALT lymphoma usually is the only genetic lesion and does not show additional chromosomal anomalies.[488] It is the only recurrent translocation that does not involve *IG* genes even though it presents as a B-cell lymphoma. As a consequence of t(11;18), *API2* gene on chromosome 11, band q21, which encodes an inhibitor of apoptosis (also known as *IAP2, HIAP1,* and *MIHC),* and a novel gene *MALT1* on chromosome 18, band q21, characterized by several Ig-like C2-type domains, are often rearranged.[489] The resultant chimeric transcript consists of 5′-*API2* and 3′-MAT located on der(18). More than 90% of breakpoints in the *API2* locus occur in intron 7, whereas the breakpoints within *MALT1* are variable and occur in four different introns.[490] The *API2-MALT1* fusion is easily identified using a dual-color *API2-MALT1* FISH probe or the "breakapart" strategy of dual-color *MALT1* probe on lymph node biopsies (see Fig. 55–40, *F*). However, detection of deletions and duplications occurring at high frequencies in both the *API2* and *MALT1* genomic sequences requires more precise molecular cytogenetic methods.

t(1;14)(p22;q32) and its variant t(1;2)(p22;p12) occur in less than 5% of MALT lymphomas, typically display other chromosomal abnormalities, and are associated with an advanced stage of disease at diagnosis (reviewed in[491] and references within). This translocation relocates the entire *BCL10* gene from 1p22 to chromosome 14, bringing it under the control of an *IGH* enhancer. Currently, a specific probe for detecting *BCL10-IGH* fusion is not available, but *IGH* dual-color "breakapart" FISH strategy may determine *IGH* rearrangements without identifying the partner chromosome. The t(3;14)(p13;q32) abnormality, which results in fusion of the *FOXP1F* gene on chromosome 3 to *IGH*, is a rare rearrangement that causes *FOXP1F* overexpression. Its significance in lymphoma remains unknown. t(14;18)(q32;q21), which occurs in 2% to 18% of all MALT lymphomas, results in fusion of *IGH-MALT*.[491,492] The 18q21 breakpoint involving the *MALT1* gene is 5 Mb centromeric from the *BCL2* breakpoint on chromosome 18 associated with follicular lymphoma. In contrast to *API2-MALT1*$^{+}$ cases, patients with *IGH-MALT1* fusion have disease outside the gastrointestinal tract, presenting usually with ocular, skin, liver, or salivary gland tumors.[493] FISH studies are useful for detecting the *IGH-MALT* fusion in paraffin-embedded lymph node biopsies. Although a unifying concept linking MALT-associated translocations to the pathogenesis of MALT lymphoma is not available, compelling evidence links these translocations to constitutive activation of the NF-κB pathway.[461,491]

Lymphoplasmacytoid lymphoma (LPL) is a small lymphocytic lymphoma with plasmacytoid differentiation (CD5^{-}CD10^{-}) characterized by t(9;14)(p13;q32) in approximately 50% of cases.[494] As a result of this translocation, the paired homeobox 5 gene *(PAX5)* on 9p13 moves to the *IGH* locus on der(14), causing dysregulation of *PAX5*. Molecular characterization of t(9;14) revealed that the coding region of the *PAX5* gene remains intact in some patients. In those individuals, t(9;14) should be considered a regulatory mutation in which the *PAX5* gene is brought under the control of the *IGH* locus. In other cases, molecular studies of t(9;14) reveal that the breakpoint occurs upstream of the *PAX5* promoter, leading to insertion of the *IGH* enhancer upstream of the *PAX 5* gene.

Waldenström macroglobulinemia is a plasma cell dyscrasia characterized by a CD138,CD19 phenotype, with a lympho/plasmacytic clonal expansion in the marrow. The biologic nature is different from lymphoplasmacytoid lymphoma because patients do not display t(9;14)(p13;q32). Recurrent chromosomal abnormalities include deletion of the long arms of chromosome 6 in 55% of cases by cytogenetics[495] and in 21% of cases by FISH.[496] Trisomy 4 is present in approximately 20% of cases.[497] In contrast to other B-cell disorders, abnormalities of *IGH* at 14q32 as measured by FISH and Southern blot are rarely identified in Waldenström macroglobulinemia.

Not much progress has been made in delineating recurrent chromosomal abnormalities in Hodgkin lymphoma (HL). Less than 1% of the cells in HL are Reed-Sternberg cells, of B-cell origin, and the paucity of dividing tumor cells for karyotype analysis has represented a major obstacle for conventional cytogenetics. In one study, simultaneous fluorescence, immunophenotyping, and interphase FISH (FICTION) demonstrated numerical aberrations of CD30^{+} cells in all HL patients.[498] The most specific chromosomal abnormalities in HL are hyperdiploidy/tetraploidy with tremendous variations in chromosome number, indicating heterogeneity from patient to patient. Even with use of nine different centromeric probes, no specific numerical chromosomal abnormality has been identified. Deletions of 1p, 4q, 6q, and 7q are recurrent, and *JAK2,* located on 9p21, frequently is amplified in patients with HL.[499] Another gene, *c-REL,* on chromosome 2, band region p14-p15, is amplified in 50% of patients.[500] Interestingly, *c-REL* is under the influence of NF-κB transcription factor, and constitutive NF-κB activation is a critical prerequisite for HL/Reed-Steinberg cell survival and proliferation.[461] Thus, it appears that the unifying concept and the hallmark of HL is also constitutive NF-κB activation.

T-Cell Lymphoproliferative Diseases

This is a diverse group of hematologic disorders. The group includes T-cell ALL, T-cell CLL/promyelocytic leukemia as well as several

Table 55–10 Frequent Translocations and Mutations in T-Cell ALL[a]

Translocations	Genes Involved	Children	Frequency (%)	Adults

indolent or small T-cell disorders, large granular lymphocyte leukemia, natural killer leukemia/lymphoma, and anaplastic large cell lymphoma (ALCL)

T-cell ALL represents 15% of childhood ALL cases and 25% of adult ALL cases.[501] Table 55–10 lists recurrent cytogenetic and molecular genomic changes associated with T-cell ALL. Immunophenotypic and gene expression analyses are consistent with genetic heterogeneity in T-cell ALL, reflecting, to some degree, distinct stages of T-cell maturation arrest.

One of the common themes in T-lymphoid malignancies is the juxtaposition of T-cell receptor gene *(TCR)* enhancer element adjacent to a variety of transcription factors located at or near breakpoints on the partner chromosome. The chromosomal bands most frequently involved are 14q11, where *TCRA* and *TCRD* are located; 7q35, the site of *TCRB*; and 7p15, the site of the *TCRG*. TCR translocations are found in approximately 35% of T-cell ALL cases

(Table 55–11).[502,503] The rearrangements of *TCRB* and *TCRG* are relatively rare, whereas 14q11 rearrangements involving both *TCRA* and *TCRD* are frequent in T-lymphoid neoplasms.

In children, the overall frequency of T-cell ALL translocations is 40% to 50%, and several molecular/cytogenetic abnormalities have prognostic relevance. *TAL1* rearrangements include t(1;14)(p32;q11), t(1;7)(p32;q35), and rare t(1;3)(p32;p21) and t(1;5)(p32;q31). Generally, *TAL1* rearrangements are submicroscopic and best identified with FISH. They are observed in approximately 3% of patients with T-cell ALL and are more frequent in pediatric than in adult ALL. In children, rearrangements involving *TAL1* gene occur at a frequency of 20% and tend to be associated with better outcome.[504] *TAL2,* residing at 9q32, is detected in rare t(7;9)(q34;q32) as a result of juxtaposition of *TAL2* to *TCRB.*[505] *LYL1,* originally described as a fusion partner of TCRB in rare (7;19)(q34;p13), is associated with poor prognosis.[506] Rearrangements of *HOX11L2,* which include cryptic t(5;14)(q35;q32), t(5;7)(q35;q21), and other variants, occur at a frequency of 24% in children and represent a predictor of poor outcome, irrespective of treatment strategies.[504,506] Similarly, the presence of t(10;11)(p13;q14), which results in the *CALM-AF10* fusion gene and occurs at a frequency of 2% to 5% in children, may be associated with poor outcome.[504,507] Abnormalities of *HOX11* are more common in adults (31%) than in children (7%) and are associated with t(10;14)(q34;q24) and t(7;10)(q34;q24). According to the French collaborative study, t(10;14) is the most frequent chromosomal translocation in patients with T-cell ALL. It is associated with excellent outcome in both children and adults.[504,508] In t(10;14) the homeobox-contain gene *HOX11 (TCL3)* is fused with *TCRD.* The coding regions of *HOX11* are not disturbed by the translocation. In the variant translocation t(7;10)(q35;q24), *HOX11* is juxtaposed to *TCRB,* which results in overexpression of normal *HOX11* mRNA by bringing *HOX11* under the influence of *TCR* promoter sequences.

MLL rearrangements are present in 8% of T-cell ALL cases. The most frequent *MLL* translocation partners in T-cell ALL include *ENL,* which results from t(11;19)(q23;p13.3) and is associated with better prognosis than are other fusion partners.[305] Gene expression profiling data characterized T-cell ALL with *MLL* rearrangements as a distinct molecular subtype with specific molecular signature.[506,509] Homeobox genes, regulators of embryonic development, are known targets of *MLL* and are overexpressed in patients with T-cell ALL and *MLL* rearrangements.[510]

Deregulation of *NOTCH,* tyrosine kinase genes *(ABL1, JAK2),* and *LIM* domain genes *(LMO1, LMO2)* also is common in T-cell ALL. NOTCH has been discovered to be a fusion partner of *TCRB* in t(7;9)(q34;q34.3). These mutations are present in 56% of T-cell ALL cases.[511]

The *LIM* family of genes is found at the breakpoint of rare but consistent chromosomal translocations in T-cell ALL. *LMO1,* located at 11p15, is involved in t(11;14)(p15;q11). *LMO2,* located at 11p13, is involved in t(11;14)(p13;q11) and t(7;11)(q35;p13). As an oncogenic transcription regulator, *LMO2* overexpression in erythroid and T cells leads to differentiation arrest, which is a prerequisite for development of T-cell malignancies.

The *C-MYB* gene, localized on chromosome 6, band q23.3, in normal cells, is rearranged in rare T-cell ALL subtype observed in young patients (median 2.2 years). Two types of recurrent *C-MYB* genomic alterations are found in T-cell ALL: (a) a reciprocal t(6;7)(q23;q34) that results in juxtaposition of *C-MYB* near to *TCRB* regulatory sequences on chromosome 7; and (b) short genomic tandem duplication, identified using genomewide copy-number analysis.[512] Both rearrangements are cytogenetically cryptic. The breakpoints in t(6;7) are subtelomeric and usually missed. The translocation was discovered using a locus-specific FISH probe for C-MYC. The tandem *MYB* duplication is cryptic using both conventional cytogenetics and locus-specific FISH. It is mapped using high-density oligonucleotide array CGH. Discovery of *MYB* highlights the strength of high-density array CGH in identifying cryptic copy-number abnormalities associated with leukemia.

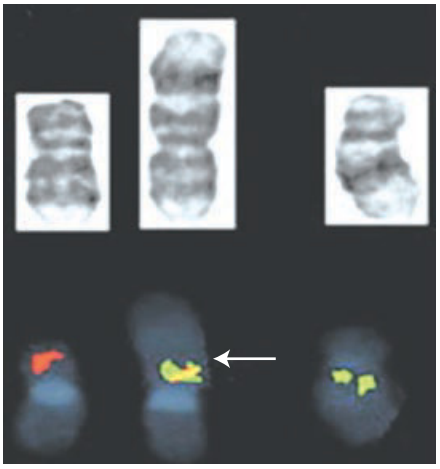

Figure 55–42 Partial karyotype of t(9;12)(p24;q23) (top) and after FISH study (bottom) with *JAK2* (red) and *TEL/ETV6* (green) showing *JAK2-TEL* fusion (yellow) at 9p24.

Although only 1% of Ph positive ALL consist of patients with T-cell ALL, the *ABL1* gene, which is involved in *BCR-ABL1* fusion-positive B-cell ALL and CML, is also involved in fusion with *NUP21,* creating *NUP214-ABL1* chimeric gene, which is identified in up to 6% of T-cell ALL cases.[513] Additionally, this fusion gene is found amplified only in T-cell ALL. When identified with FISH using *ABL1* probe, it appears as an amplified episome between the chromosomes in metaphase cells. RT-PCR also can be used for its detection.[514,515] In rare cases of T-cell ALL, *JAK2* has been identified as a partner chromosome with *ETV6* in t(9;12)(p24;q13) (Fig. 55–42), one of the three JAK2 fusion transcripts seen in hematologic malignancies (see Ph-Negative Myoproliferative Disorders above and Table 55–3).

Numerical changes are rare except for tetraploidy, which occurs in less than 5% of cases and is of unknown prognostic significance. In contrast, cryptic cytogenetic abnormalities revealed by FISH are frequent in ALL. They include deletion of 9p21 *(INK4/ARF)* and 1p32 regions. Deletion of 6q is less common, and the region 6q16 appears to be the common deletion band region.

In contrast to childhood B-cell ALL, the majority of childhood T-cell ALL cases develop after birth. In utero origin of this leukemia is rare. Dramatic treatment advances has been achieved in children with T-cell ALL in the last 4 decades.[516] Initial results with gene expression profiling to determine specific molecular prognostic markers for children with T-cell ALL who may benefit from more intense therapy identified that expression of three genes, *CFLAR, NOTCH2,* and *BTG 3,* at the time of diagnosis may accurately predict disease outcome. All three genes are involved in regulation of apoptosis and cellular proliferation.[517] Expression of *NOTCH2,* but not of the other two gene abnormalities, is implicated in T-cell ALL. Genomewide expression profiling at the time of diagnosis likely can identify novel molecular markers that may be used to predict the clinical outcome of patients.

T-cell CLL and *prolymphocytic leukemia* are characterized by T-cell leukemia 1 gene *(TCL1)* rearrangements. They include inv(14)(q11q32.1), t(14;14)(q11;q32.1), and t(7;14)(q35;q32.1). In patients showing these karyotypic changes, *TCL1* is found to be dysregulated.[518]

Adult T-cell leukemia/lymphoma is associated with human T-cell lymphotropic virus type 1. The most frequent genetic lesions include altered expression of *CDKN2* (cyclin-dependent kinase inhibitor) gene on 9p21 (15%–20%) and loss of heterozygosity at 6q15–q21. The most frequent chromosomal gains are 3p, 7q, and 14q and loss of 6q and 13q. Translocations involving 14q32 or 14q11 are frequently observed. Patients with more chromosomal gains than losses show significantly shorter survival.[519]

Natural killer lymphoma/leukemia, a group of highly aggressive hematolymphoid malignancies of natural killer cell lineage, exhibit

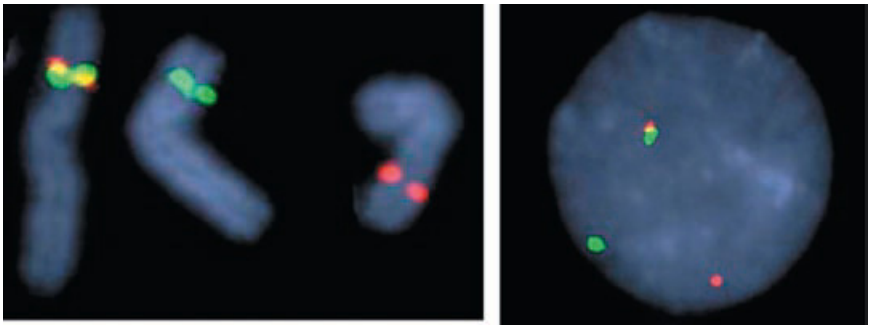

Figure 55–43 FISH study with breakapart *ALK* gene at 2p23 in a patient with anaplastic large cell lymphoma. Partial karyotype shows a normal chromosome 2 (left) with yellow signal, as the 3′ end and the 5′ end of *ALK* gene are in close proximity on chromosome 2. The other chromosome 2 homologue (middle) has only a single green signal (5′ end) as a result of t(2;5)(p23;q35), the most frequent translocation in anaplastic large cell lymphoma. The 3′ end (red) of the *ALK* gene is translocated to 5q35. Abnormal *ALK* gene is also shown in interphase cell (right).

chromosomal rearrangements in greater than 80% by conventional karyotyping. The most frequent abnormalities include del(6)(q21–23) and gain of the X chromosome. FISH, CGH, and spectral karyotyping confirmed the presence of del(6) in $CD3^{-}CD56^{+}$ tumor cells.[520] Other less common but recurrent karyotypic changes include isochromosome 1q, 6p, and 17q as well as del(11q), 13q, and 17p and trisomy 8.

Angioimmunoblastic T-cell lymphoma and *unspecified peripheral T-cell lymphoma* are the most frequent nodal T-cell lymphomas. Losses of 5q/10q/12q, identified by CGH, characterize a subtype of peripheral T-cell lymphoma associated with a better prognosis. Gain of 11q13 may represent a primary change in angioimmunoblastic T-cell lymphoma. In general, chromosomal imbalances are more common in unspecified peripheral T-cell lymphoma than in angioimmunoblastic T-cell lymphoma. Both disorders may share similar genomic imbalances.[521,522]

The molecular basis of *ALCL* is the result of t(2;5)(p23;q35), which fuses part of the nucleophosmin gene *(NPM)* on 5q35 with part of the anaplastic lymphoma kinase *(ALK)* receptor tyrosine kinase gene on 2p23 to produce a chimeric *NPM-ALK* gene.[523] This encodes a chimeric NPM-ALK protein that has a constitutively activated kinase. ALK is thought to play a direct role in the malignant transformation of lymphoid cells, probably by aberrant phosphorylation of intracytoplasmic substrates because accumulation of the ALK protein is observed only in cytoplasm. The WHO classification of lymphoid tumors considers ALCL as a distinct clinical entity, with t(2;5) detected by cytogenetics in 60% to 85% of patients. The *NPM-ALK* fusion is identified by FISH (Fig. 55–43) and by RT-PCR assay in 88% of pediatric patients and 60% of adult patients.[524] The other cases of ALCL have variant translocations. They include rearrangements of the 2p23 region: t(1;2)(q25;p23), t(2;5)(q37;q31), t(2;19)(p23;p13), and inv(2)(p23q35), all associated with *ALK* gene expression. They also include rearrangements of the 5q35 region: t(1;5)(q32;q35), t(3;5)(q12 ;q35), and t(3;5)(q25;q34–35).[525] Detection of *ALK* rearrangements by FISH corresponds to a cytoplasmic staining pattern associated with translocations other than t(2;5).

As a result of these variant rearrangements, three new fusion genes have been identified. *ATTIC-ALK* is a fusion gene resulting from inv(2)(p23q35). This translocation fuses *ALK* and 5-aminoimidazole-4-carboxamide ribonucleotide formyltransferase/IMP cyclohydrolase *(ATIC).* This molecular variant is detected by RT-PCR and is the most common *ALK* variant. *TFG-ALK* is a consequence of t(2;3)(p23;q21), which fuses *TRK*-fused gene *(TFG)* with *ALK* at the same breakpoint as found in t(2;5). In t(1;2)(q25;p23), the *TPM3* gene on chromosome 1, which encodes nonmuscular tropomyosin, is fused to *ALK,* producing the *TPM3-ALK* fusion gene.

Prognosis of patients with t(2;5) or variant translocations is excellent but is clearly different from *ALK*-negative ALCL. The true nature of *ALK*-negative ALCL remains obscure. Gene expression profiling showed that ALK^{+} ALCL and ALK^{-} ALCL have different gene expression profiles, indicating that different, as yet unknown, oncogenic mechanisms may be associated with each type.[526] Interestingly, C/EBPβ transcription factor, which is implicated in leukemogenesis of AML, is constitutively active and overexpressed in patients with ALK^{+} ALCL but not in ALK^{-} patients or other lymphomas.[527] C/EBPβ expression is transcriptionally induced through the kinase activity of *NPM-ALK,* which provides insight into the molecular pathogenesis of ALK^{+} ALCL.

A variety of genomic rearrangements are seen in the T lymphocytes of patients with *mycosis fungoides* and *Sézary syndrome.* However, specific cytogenetic abnormalities are not associated with these disorders. Most frequent abnormalities involve loss of chromosome 10, deletion of 1p, isochromosome 17q, additions of 17p and 19p, and translocations involving 1p, 10q, and 14q. Both CGH and M-FISH identify chromosome 10, region 10q22–26, as the most frequent abnormality in these disorders.[528,529]

Posttransplant lymphoproliferative disorder (PTLD) is a morphologically diverse group of lymphoid disorders that occurs in immunosuppressed organ transplant recipients. Chromosomal abnormalities are detected in 51% to 72% of B-cell diseases and in almost all T-cell proliferations as measured by CGH, FISH, and conventional karyotyping. Although a variety of recurrent genomic imbalances is observed, the unfavorable prognostic effect on survival is observed in two main WHO morphologic groups, monomorphic PTLD (M-PTLD) and polymorphic PTLD (P-PTLD), and can be correlated with the grafted organ.[530,531] Generally three groups of nonrandom abnormalities are of importance. The pathogenetic role of abnormalities known to be involved in lymphomas, such as 8q24 and *MYC,* 17p13 and *P53,* and 18q21 associated with *BCL2* and *MALT1,* and those associated with large genomic imbalances, such as 2p24–25, 9q22–34, 12q22–24, and 14q32, await elucidation. Trisomy for chromosomes 9 and 11 appears to be associated with EBV^{+} PTLD and prolonged survival. In contrast, PTLD patients showing MYC rearrangements are associated with Burkitt lymphoma and an aggressive clinical course. PTLD associated with T cells develops late after transplantation. These disorders are EBV^{-} and have poor outcome and short survival.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Molecular and cytogenetic analyses can be used to characterize the origin of engrafted cells and the development and evolution of recurrent malignancies after allogeneic HCT. Newly developed hematopoietic cells that emerge after allogeneic HCT may be of host, donor, or both origins. Genetic studies of posttransplant hematopoiesis are called *chimerism* analysis. This term was introduced into medicine by Anderson et al.[532] in 1951 to indicate an organism whose cells are derived from two or more distinct zygote lineages.[533] Chimerism should be distinguished from mosaicism, which is characterized by two or more different cell populations originating from one zygote. Monitoring chimerism in recipients of allogeneic HCT is essential to

identify early engraftment, monitor residual disease in leukemia patients, predict relapse, and optimize posttransplantation therapy in case of graft failure.

Historically, karyotype analysis was used to evaluate engraftment after sex-mismatched allogeneic HCT. Polymorphism of chromosomes 1, 9, and 16 as well as satellite polymorphism of chromosomes 13, 14, 15, 21, and 22 were used to differentiate donor from recipient cells in sex-matched allogeneic HCT. Karyotype analysis not only could identify chimerism also but recurrence of hematologic malignancies. However, it is time-consuming process and has low sensitivity (5%). In the past 2 decades, many methods for detection of chimerism have been developed. All follow the basic principle of using the differences in polymorphic genetic markers to distinguish donor from patient hematopoiesis. These methods, such as restriction fragment length polymorphism, red cell phenotyping, and interphase FISH, do not offer the possibility to study all patients. The most widely used technique is PCR for variable number of tandem repeats/short tandem repeats (VNTR/STR-PCR). This technique has a moderate sensitivity of 3% to 5%, and the quantitation of donor and recipient cells may be cumbersome. The method that allows study of chimerism in all patients involves fluorescence labeling of the primers and resolution of PCR products with capillary electrophoresis. It provides high quantitative accuracy with 1% to 5% sensitivity. Real-time PCR or RQ-PCR for analysis of the *SRY* gene on the Y chromosome allows identification of male cells in the background of 100,000 female cells, providing a high sensitivity for mixed chimerism. However, this approach is limited to the 50% of patients who receive sex-mismatched transplants. Nevertheless, it remains the most sensitive and fastest method for chimerism analysis, providing reliable quantitative results within 2 hours.[534]

Detection of SNPs by chimerism analysis (SNP-PCR) is highly sensitive. In one study using 11 different SNP loci, SNP-PCR analysis identified independent predictors of relapse after HCT.[535] The two most commonly used methods for detection of chimerism after HCT are fluorescence-based PCR amplification of short tandem repeats (STR-PCR) and interphase FISH (Fig. 55–44). Both methods have high quantitation accuracy and reproducibility The sensitivity of both methods approaches 1%; however, STR-PCR is sex independent and can be applied to all patients.[536,537] FISH analysis, on the other hand, permits simultaneous evaluation of chimerism and residual disease in the same cell when high sensitivity is not a requirement. FISH analysis for diagnostic genomic abnormalities in conjunction with conventional cytogenetics remains useful and reliable in determining the presence of residual disease.

Leukemia relapse occurring in donor cells after allogeneic HCT is a rare complication reported in 0.12% to 5% of cases.[538] It was first described in 1971, and more than 50 cases have been reported.[538,539] Careful genetic analysis of relapse cells is essential. VNTR, restriction fragment length polymorphism, or FISH XY analysis alone may not definitively assign the origin of the leukemic clone because genomic deletions or amplifications of chromosomal segments may occur during the transplantation or disease process.[540] The increased use of unrelated cord blood as a source of stem cells for allogeneic HCT raises the concern that hematopoietic progenitors containing preleukemic clonal molecular rearrangements may be inadvertently transplanted.[541] Systematic screening of unselected cord blood samples revealed putative preleukemic rearrangements such as *ETV6-AML1* and *AML1-ETO*. Specific mechanisms that result in development of donor cell leukemia are unknown. A common cytogenetic abnormality has not been recognized, and almost half of cases are associated with a normal karyotype.[538] Nevertheless, these patients must be carefully evaluated using an array of molecular methods for determination of leukemia in donor cells (see box on Genetic Testing for Hematopoietic Cell Transplantation).

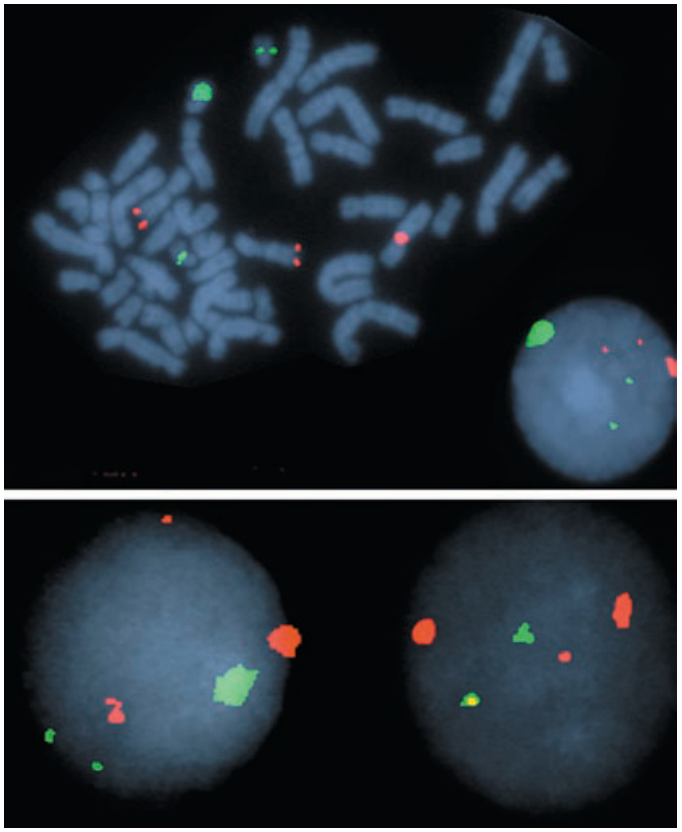

Figure 55–44 Detection of engraftment and residual disease with FISH in sex-mismatched hematopoietic cell transplantation. Metaphase and nondividing cell (blue) after DAPI counterstaining, hybridized with X (large red) and Y (large green) for detection of engraftment and with *ABL* (small red) and *BCR* (small green) for detection of residual chronic myelogenous leukemia (top panel) left nucleus (bottom panel) is showing a donor male (XY) cell origin and lack of *BCR-ABL* fusion. In contrast, a host female (XX), BCR-ABL fusion (yellow)-positive cell is shown on the right. Combination of XY FISH probes with diagnostic genomic markers is a powerful and fast FISH method for simultaneous detection of chimerism and minimal residual disease.

Genetic Testing for Hematopoietic Cell Transplantation

Testing consists of either variable number of tandem repeats/short tandem repeats polymerase chain reaction (PCR) for detection of engraftment in patients with sex-matched hematopoietic cell transplantation (HCT) or single nucleotide polymorphism PCR, which has a high sensitivity. In sex-mismatched HCT, both interphase fluorescence *in situ* hybridization (FISH) with XY probes and real-time quantitative PCR for analysis of *SRY* gene on the Y chromosome can be used for detection of engraftment. Detection of both engraftment and minimal residual disease is best accomplished by FISH simultaneously using probes for XY and the probe for diagnostic genetic defect, such as XY and BCR-ABL.

FUTURE DIRECTIONS

The question of how initial genetic damage in hematopoietic stem cell disorders causes a cascade of other genetic events leading to development of malignancy is unresolved for many diseases. However, major advances have been made, and molecular unraveling of the Philadelphia chromosome led to the rationally designed imatinib treatment that transformed CML from a fatal disease into a chronic disorder compatible with normal life in many patients. Molecular diversity is currently the genetic hallmark of many leukemias, even within a single disease entity such as AML or T-cell ALL. We are at

the threshold of understanding other genetic events and common genetic pathways. Such an understanding is crucial to designing molecular interventions for specific abnormalities of genetic pathways underlying hematologic malignancies.

CHAPTER 56

PHARMACOLOGY AND MOLECULAR MECHANISMS OF ANTINEOPLASTIC AGENTS FOR HEMATOLOGIC MALIGNANCIES

Stanton L. Gerson, Kapil N. Bhalla, Steven Grant, Kavita Natarajan, Richard J. Creger, and David DeRemer

Treatment of hematologic malignancies has undergone a continuing scientific revolution in the past 5 years as new targets identified through studies of the molecular and cell biology of these malignancies have spawned the discovery of mechanistic-based therapeutics. A surprising number of these have progressed from discovery, validation, animal modeling, and successful clinical testing. In addition, there has been a broadening of the spectrum of agents to include small molecules, peptides, antibodies, radiolabeled molecules, and complex delivery systems. This updated chapter provides information on all new therapeutic agents available for the treatment of hematologic malignancies. It reviews the "classic" agents as well as the new, targeted agents. Both cytotoxic and growth-inhibitory agents are covered; however, the use of therapeutic antibodies is reviewed within the disease chapters.

CELL KINETICS, THE CELL CYCLE, AND TUMOR GROWTH

Hematologic malignant cells proliferate more than their normal counterparts. The cell cycle consists of a series of stages through which normal and neoplastic cells proceed during the course of cellular replication (shown schematically in Fig. 56–1). It is divided into G_1 (pre-DNA synthetic phase), S phase (in which DNA replication takes place), G_2 (post-DNA synthetic phase), and mitosis (M), during which chromosomal division and segregation occurs.[1] In addition, nonproliferating, resting cells are said to reside in G_0, a phase that may theoretically last for an indefinite period. Such cells remain in G_0 until they are induced to enter the cell cycle (at G_1) by specific triggers, for example, hematopoietic growth factors. The *growth fraction* of a tumor represents the percentage of cycling cells relative to the total cell population and is given by the formula $[G_1 + S + G_2 + M]/[G_0 + G_1 + S + G_2 + M]$. The *noncycling fraction* is given by the formula $[G_0]/[G_1 + S + G_2 + M]$. Growth fractions of various neoplasms range from less than 10% in the case of certain slowly growing solid tumors to more than 90% in the case of certain hematologic malignancies (eg, Burkitt lymphoma). The *generation* time represents the time required for a cell to proceed through a single cell cycle (generally 24–36 hours for hematopoietic tissues). Surprisingly, in the case of AML, the generation time of leukemic blasts is not significantly shorter than that of normal hematopoietic progenitors, and may in fact be longer. The proliferative advantage of malignant hematopoietic cells (and of many nonhematopoietic tumors) stems, at least in part, from the fact that a higher percentage of cells are in cycle at any one point in time (ie, the growth fraction is higher). The *doubling time* represents the period required for a tumor to double in mass and is, in general, inversely related to the tumor's growth fraction. Tumor-doubling times range from greater than 120 days in the case of some solid tumors (eg, lung and colon) to less than 2 weeks (in the case of some leukemias and lymphomas). Tumor-doubling times are influenced by multiple other factors, including the rate of spontaneous cell death (or apoptosis) and the availability of appropriate nutrients. The importance of these considerations stems from the fact that tumors with high growth fractions and short doubling times tend to be more sensitive to chemotherapy than slowly growing neoplasms with low growth fractions and long doubling times. It is unlikely to be a coincidence that many advanced neoplasms that are potentially curable by chemotherapy (eg, hematologic malignancies such as leukemia, lymphoma, and testicular cancer) fall into the former group; conversely, most incurable advanced malignancies (eg, non-small-cell lung cancer, colon cancer) fall into the latter.

The transition of neoplastic cells through the cell cycle, as in the case of their normal counterparts, is governed by a complex network of proteins consisting of cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors.[2] The progression through S phase is regulated primarily by CDK2 in association with cyclins A and E; the progression through G_2M is regulated by CDK1 ($p34^{cdc2}$) and cyclin A and cyclin B; and progression through G_1 involves CDKs 4 to 6 in conjunction with cyclin D. CDK inhibitors fall into two major categories: The low-molecular-weight inhibitors (pINK14, 15, 16, 17, and 18), which primarily inhibit cyclin D (and to some extent, CDK2) complexes, and the higher-molecular-weight inhibitors, p21, p27, and p57, which are more universal in their actions and inhibit most or all CDKs.[3] Signals for progression of cells through G_1S are clearly essential for maintenance of the neoplastic phenotype. In the commonly accepted model of G_1S progression, inactivation of the retinoblastoma protein (PRB) is required. In quiescent cells, PRB is in an active dephosphorylated state and bound to the transcription factor E2F. Phosphorylation of PRB by CDK4 and CDK6 and CDK2 leads to release of E2F, which is then free to activate diverse genes essential for S-phase progression, such as *MYC* (also known as c-Myc), *TYMS* (thymidylate synthetase), and *DHFR* (dihydrofolate reductase). Conversely, induction of CDK inhibitors (eg, by TGFB [formerly known as TGFB] or differentiation-inducing agents) results in inactivation of CDK4 and CDK6 and CDK2, dephosphorylation of PRB, inactivation of E2F, and inhibition of the progression through S phase. Aberrant expression of cyclins and CDK inhibitors is commonly encountered in human malignancies, including those of hematopoietic origin, and it has been postulated that the resultant cell-cycle dysregulation contributes to the neoplastic phenotype.

In addition to cellular growth control, cell-cycle proteins are intimately involved in the regulation of programmed cell death (apoptosis) and checkpoint control mechanisms.[4] Consequently, cell-cycle regulatory proteins can exert a major influence on the response of neoplastic cells to various cytotoxic agents. For example, when cells undergo DNA damage, they may arrest in G_2M or G_1, during which repair occurs, or if the damage is too severe, the cells undergo apoptosis. In particular, the tumor suppressor gene *TP53* and its downstream inducible target p21 have been implicated in the G_1 arrest process following genotoxic insult.[5] During the last several years, it has been shown that dysregulation of various cell-cycle regulatory proteins can have a major impact on the sensitivity of neoplastic cells to various chemotherapeutic agents. Loss of the *TP53* gene renders cells resistant to diverse chemotherapeutic agents, presumably by preventing cells from undergoing repair in G_1 and thereby inhibiting the cell death processes and allowing DNA damage to accumulate, culminating in cellular transformation. Conversely, transfection of

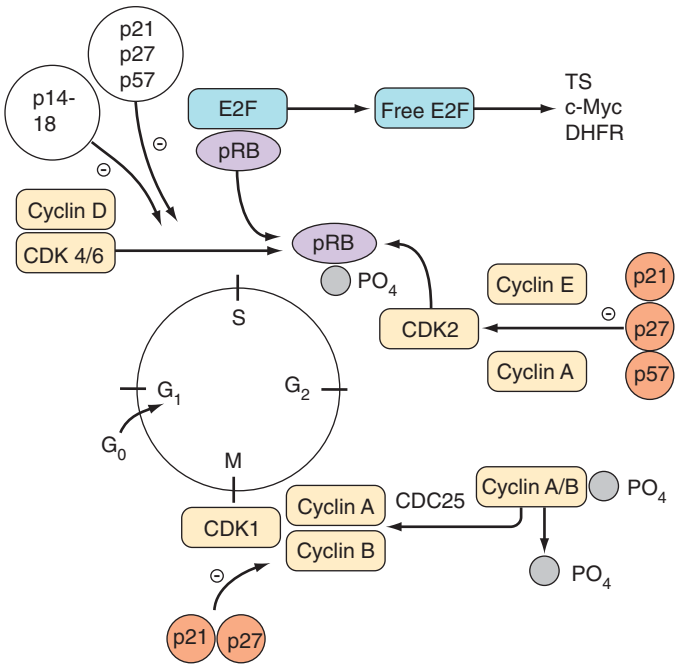

Figure 56–1 Progression through the cell cycle is controlled through complex interactions between cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors. Progression across the G_1S interface and through S phase involves the E2F transcription factor, which activates numerous enzymes (eg, thymidylate synthase, dihydrofolate reductase) required for DNA replication. The retinoblastoma protein (pRb) in its dephosphorylated state binds to and inactivates E2F in conjunction with DP proteins, thereby inhibiting S-phase progression. Conversely, phosphorylation of pRb antagonizes binding to E2F, allowing S-phase events to proceed. Phosphorylation of pRb results from activation of (1) cyclin-dependent kinase-2 (CDK2):cyclin A/E and (2) CDK4/6:cyclin D complexes. The former complexes are inhibited by the CDKIs p21, p27 (and p57), whereas the latter are inhibited by the low-molecular-weight CDK inhibitors (p14-18), but also by p21 and p27. The complex formed by CDK1 ($p34^{cdc2}$) and cyclins A and B regulates G_2M progression and is inhibited by the "universal" CDK inhibitor, p21. Moreover, its phosphorylation status, which plays a major role in determining activity, is regulated by the phosphatase cdc25. Proteins such as pRb, E2F, p21, and p27 can influence the response of cells to chemotherapeutic agents by controlling cell-cycle progression, and possibly via cell cycle-unrelated actions.

P53-negative cells with wild-type P53 restores responsiveness to most drugs.[6] Dysregulation of the CDK inhibitors p21 (a downstream target of P53) and p27 increases the sensitivity of neoplastic cells to various cytotoxic agents, possibly by uncoupling S-phase progression and mitosis.[7,8] In this model, loss of CDK inhibitor p21 or p27 prevents cells that have sustained DNA damage from arresting in G_1 and allows them to progress inappropriately through S and ultimately G_2M, eventually leading to cell death. Mutations in the E2F protein have been shown to lengthen S phase and increase the sensitivity of malignant cells to S phase-specific agents.[9] Furthermore, cells lacking functional PRB have been shown to be significantly less sensitive to the actions of antimetabolites, including methotrexate.[10] Aside from regulating cell-cycle status and the susceptibility of neoplastic cells to cell-cycle-specific agents, cell-cycle regulatory proteins can actively contribute to the cell death response.

The growth of tumors is best described by Gompertz's law, rather than classic exponential kinetics. For neoplasms that grow exponentially, the tumor growth rate remains constant as the number of cells increases. However, in the in vivo setting, the growth of tumors is limited by various factors such as vascular supply, nutritional requirements, and possibly physical restraints. Consequently, the rate of tumor growth declines as the number of cells increases. To the extent that tumor-doubling times are inversely correlated with drug responsiveness, large, late-stage tumors would be predicted to be less susceptible to cytotoxic drugs than their earlier, higher growth fraction counterparts. It is important to note that most chemotherapeutic drugs kill by *first-order kinetics*. This indicates that a given drug dose kills a constant fraction, rather than number, of tumor cells. The implication of this phenomenon is that it requires the same drug dose to reduce the number of tumor cells from 10^4 to 10^1 cells as it does to reduce the tumor burden from 10^{10} to 10^7 cells.

Recent emphasis on leukemic and lymphoma stem cells has raised a new cellular target for therapeutics and the analysis of available agents provides another level of analysis of efficacy both in clinical and preclinical settings. This progress remains premature and at the moment, the value of targeting leukemia, lymphoma, and myeloma stem cells either in clinical trial design or therapeutic development are not clear. However, for noncurative diseases, a focus on this cell subpopulation may lead to curative therapies. Regardless of targeted therapies, the ability to identify and track such cells will improve appreciation of minimal residual disease and the need for more focused therapies. One factor in common for most malignant stem cells is the overexpression of the ABC transporters. ATP binding cassette transporters (ABC transporters) are often highly expressed in early hematopoietic stem cells and other tissue stem cells that are CD44 positive. Inhibition of these transporters would seem a logical approach to therapeutically targeting leukemic stem cells. Progress in this area will be discussed in the section on MRP and the ABC transporters.

Cytotoxic agents may be divided into several categories with respect to their effects on the cell cycle or the cell-cycle specificity of their actions, or both.

1. *Non-cycle-active drugs* kill both cycling and noncycling cells in all phases of the cell cycle. Examples include steroids and antitumor antibiotics (except bleomycin).
2. *Cycle-active, non-phase-specific drugs* are more active against cycling cells and can kill cells in each phase of the cell cycle. However, such cells may preferentially kill cells in a particular phase of the cell cycle. Examples include alkylating agents, cisplatin, and 5-fluorouracil.
3. *Cycle-active, phase-specific drugs* primarily kill cells in a specific phase of the cell cycle. Examples include most antimetabolites, which are active against cells engaged in DNA synthesis (S-phase cells), and microtubule-active drugs (eg, vinca alkaloids, taxanes), which kill cells in G_2M.

An example of a cytokinetically rational approach to chemotherapy involves the combination of a non-cycle-active agent (eg, daunorubicin) with a cycle- and phase-specific agent (eg, cytosine arabinoside [ara-C], fludarabine, decitabine, clofarabine and nelarabine). From a theoretical standpoint, administration of a non-cycle-active agent may reduce tumor mass, leading in turn to an increase in the growth fraction via recruitment of cells into cycle. Such cells would then be more susceptible to a cycle- and phase-specific agent, particularly one administered over a prolonged interval. In the case of hematopoietic malignancies, attempts have been made to recruit neoplastic cells into the more susceptible S phase of the cell cycle through the use of *hematopoietic growth factors*. The success of such a strategy may be limited by several factors, including the inability of growth factors to increase the S-phase fraction significantly, the lack of selectivity of this strategy, and the theoretical possibility that growth factors may protect neoplastic cells from apoptosis.

Unfortunately, cytokinetic differences between normal and neoplastic tissues have been difficult to identify and exploit. Both normal hematopoietic stem cells and hematologic malignancy stem cells also share a low proportion of cells in cell cycle of G1. However, prolonged dosage schedules can provoke these malignant cells into cell cycle and may explain the efficacy of these approaches. Consequently, rapidly dividing normal tissues such as gastrointestinal epithelium and normal hematopoietic progenitors tend to be very sensitive to

most chemotherapeutic agents. As a result, mucositis and myelosuppression represent frequent dose-limiting toxicities for many cytotoxic drugs.

TUMOR CELL HETEROGENEITY OF HEMATOLOGIC MALIGNANCIES

Whereas hematopoietic malignancies are of *clonal* origin (ie, they are derived from a single transformed cell), individual neoplastic cells from a patient's malignancy exhibit a great deal of phenotypic diversity and secondary mutations that affect proliferation, drug sensitivity, and resistance. Although this diversity arises from progeny of clonal populations, and subsets of stem cells have been identified, in animal models it has been shown that the clones themselves can give rise to frequent progeny that can transmit clonal malignancy in transplantation settings, suggesting that at least in these settings, rarefied stem cells are not required to transmit the malignant phenotype. Perhaps these cells even have conflicting phenotypes to the more common malignant cell. For instance, perhaps leukemia stem cells are more quiescent, have higher levels of protective proteins such as efflux pumps for drugs and higher levels of DNA repair proteins or antiapoptosis proteins than the more abundant cell making up the circulating population of cells. Tumor cell heterogeneity arises as a consequence of spontaneous mutational events, changes in gene promoter methylation, impact of abnormal expression of transcription factors, lymphoid reactivity, and cytokine responsiveness. In fact, these can be reinforced if they provide a survival, tissue homing, or proliferative advantage for the affected cells and their progeny.[11] For example, a mutation or change in expression that renders a hematopoietic cell clone autonomous or growth factor-independent would be expected to render such cells less susceptible to adverse environmental conditions, for example, growth factor withdrawal. Similarly, one would also predict that a genetic change facilitating cell-cycle entry or disruption of cellular maturation would ultimately lead to overgrowth of affected clones. For obvious reasons, mutations that interfere with drug metabolism or the cell death pathway itself would provide a net survival advantage, particularly under the selection pressure of cytotoxic drug treatment.

Malignant myeloid and lymphoid cells have many reasons to have increased mutations rates. Genomic instability can arise from dysregulation of the cell cycle, disruption of replication, loss of DNA repair enzymes such as mismatch repair, which gives rise to microsatellite instability and loss of checkpoint regulation. These processes give rise to intraclonal emergent point mutations, translocations, and intragenic loss that not only result in the malignant transformation but also to disruption of genomic stability and selection in favor of proliferative and apoptosis resistance subclones.

Common mechanisms may be involved in events associated with malignant transformation and the development of mutations that result in tumor heterogeneity. For example, the cell-cycle checkpoint and tumor suppressor gene, *TP53*, is induced during DNA damage, leading to G_1 arrest and, if the damage is too severe to repair, cell death by apoptosis. The presumed goal of this process is to eliminate cells that develop deleterious mutations as a result of damage to the genome. Loss of *TP53* may not only increase cellular survival by inhibiting the cell death process, but may also promote the transmission of mutations in cells that would otherwise be deleted. In this manner, a defect of the cell death pathway can have multiple consequences: (a) selection of cells exhibiting a growth advantage over their normal counterparts, (b) development of drug resistance, and (c) promotion of mutations that result in either (a) or (b) as well as neoplastic cell heterogeneity.

A model for understanding the relationship between tumor growth rate, the occurrence of spontaneous mutations, and the development of drug resistance was first described by Goldie and Coldman, and is referred to as the Goldie and Coldman hypothesis.[12] In this model, the size of a tumor depends on a complex interaction between tumor growth rate and cell loss, the latter stemming from the status of the cell death process, exhaustion of available nutrients, and outstripping of the blood supply. As tumors increase in size, the cell death rate tends to increase. The heterogeneous nature of such mutations makes it likely that multiple mechanisms of resistance will develop as well. From an operational standpoint, this model has clear implications for the rational design of therapeutic strategies and provides a basis for early and intensive therapy, as proposed by Hyrniuk and Bush.[13] The successful implementation of this strategy is exemplified by the administration of dose-intensive multidrug regimens (ie, the Stanford 5 regimen in Hodgkin disease, in non-Hodgkin lymphoma [NHL]), and combinations of cytotoxic and immune therapies, such as CHOP-rituximab, which are potentially curative when given early in the course of the disease. Other examples include combined use of multitargeted agents such as lenesolid and bortezomib for myeloma, fludarabine and rituximab for chronic lymphocytic leukemia, or maneuvers to overcome resistance of pretreated disease outside of cell-based therapies. However, as predicted by the model, administration of these or other intensive regimens in patients with relapsed or late-stage disease generally fail because of a generalized resistance of tumor cells to all classes of chemotherapeutic agents.

DEVELOPMENT OF CHEMOTHERAPEUTIC AGENTS

The modern quest for anticancer agents for hematologic malignancies began with the nitrogen mustard class of compounds developed from the chemical warfare agent sulfur gas used in World War I. Since that time, the National Cancer Institute and the pharmaceutical industry have developed complex techniques for drug development, screening, and evaluation.[14] Initial screening consisted of toxicity assessment against murine tumor cell lines.[15] Current screening is directed toward numerous cell targets including receptor and downstream signaling kinases, inducers of cell death pathways including those at the cell surface, mitochondrial DNA and nuclear DNA, DNA processing and repair proteins including topoisomerases and telomerase and histone deacetylase inhibitors, cell-cycle proteins, agents that block protein processing and degradation, and the mitosis and spindle machinery. Killing cells remains the backbone of chemotherapeutic approaches to human malignancies, although a number of differentiating agents, kinase inhibitors, and cytostatic agents have now entered the chemotherapy armamentarium. In addition, agents that target tumor angiogenesis have impressive efficacy. Although cytotoxic alkylating agents cause myelosuppression, newer agents cause more systemic side effects.[16] Secondary leukemias induced by hematopoietic progenitor cell damage occur with the older alkylating agents,[17] topoisomerase inhibitors,[18,19] and combination chemotherapy and radiation[20] but are not seen with the newer classes of compounds. The emphasis on targeted therapeutics in current drug development is focused in two areas: Newly recognized fusion or mutant specific to the malignant cell, such as bcr-abl in CML and the activated JAK2V617F mutation present in myeloproliferative disorders, and fundamental antiapoptotic pathways such as bcl-2.

Screening for Antitumor Activity Among Chemotherapeutic Agents

Current approaches to the discovery of new agents to treat hematologic malignancies relies on the large National Cancer Institute (NCI) Division of Cancer Treatment initative to maintain a large cell bank of malignancies for drug testing. NCI has evaluated more than 60,000 compounds for cytotoxic and growth inhibitory activity using a standard human tumor cell line screen[21,22] that includes K562, MOLT-4, and HL-60.[23] Routine exposure of such tumor cell lines to drug dilutions at 10^{-4} to 10^{-8} molar concentrations are performed with a 48-hour drug incubation followed by a monitoring of the tumor cell growth rate.[22] Following an initial in vitro screen, human tumor cell activity is evaluated using a series of athymic mouse

xenograft studies targeting tumors from tissues that show promise in in vitro assays.[24] Drugs with promising efficacy and novel mechanisms of action then go on to formulation and toxicology testing and ultimately are developed for phase I clinical testing[22,25] through the NCI Cancer Therapy Evaluation Program. Weinstein and colleagues[22] used the database to identify clustered cytotoxic activity among agents based on similar cytotoxicity profiles against the 60-cell panel. Among many observed clustered responses, agents with clustered activity against p53 wild-type or mutant cells, multiple drug resistance (MDR-1), gene-expressing cells, and agents that cause G_1 checkpoint arrest have been identified. With this information, a better understanding of mechanisms of drug action and disease-specific responses can be proposed.

More recently, these and other cell lines are being used, along with cell line banks of human hematologic malignancies for high throughput screening efforts that are especially useful for noncytotoxic screens that result in evaluation of agents that affect gene expression, differentiation, migration, and other cell-based assays. In addition, drug discoveries that start as a survey of specific pathway inhibition, such as signaling kinsases (bcr-abl, JAK2, PDGF, kit, and FLT3) and src kinases, represent new approaches validated by the discovery of therapeutic agents such as imatinib and related agents, dasatinib and AMN107.

Human tumor xenografts have been used as a requisite screen in preclinical testing of new chemotherapeutic agents. For leukemia and lymphoma cell lines, increase in life span is used as an end point measured at the percent increased life span (ILS), ((T − C/C) × 100), where T is the life span after drug treatment and C untreated.[26] The best predictive mouse systems are primary malignancies grown in immunodeficient mice and mice with specific chromosomal translocations and oncogenes that mimic human disease. In mice with severe combined immune deficiency (SCID), the RPMI 8226 human myeloma cell line and the multidrug-resistant subline, 8226-C1N, inoculated intraperitoneally led to a lifespan that was numbered in days and the tumor cells in vivo were completely resistant to treatment with doxorubicin.[27] Zhang and colleagues[28] established a human acute promyelocytic leukemia ascites model in the SCID mice and found responses to all-transretinoic acid. Other investigators have used the SCID leukemia model to test antisense oligonucleotide strategies[29] for such tumor-specific genes as *BCR-ABL*[30] in CML. Use of primary and serially passaged human leukemias and myelomas in the SCID model have facilitated drug screening. In both instances, infusion of antisense constructs increased the ILS significantly and led to clinical studies with these agents. Others have used the SCID model for B-cell lymphomas to study chemotherapy or lymphotoxins.[31] Although these models have not entered the NCI drug screen, they represent significant systems to test new agents, in particular novel gene therapy and immunotoxin approaches.

Phase I Clinical Trial Design

New anticancer agents are assessed through a series of clinical trials termed *phase I*, *phase II*, and *phase III* (Table 56–1). The purpose of phase I clinical trials is to establish the safe and optimal biochemically active dose of the compound in question with acceptable toxicity that can be used in disease-targeted phase II testing. During phase I development, pharmacokinetics and pharmacodynamic measures are studied in detail so that appreciable information can be forthcoming from the very first set of patients targeted for treatment and to allow confirmation of these observations in larger phase II disease-focused trials. Dose schedule and route of administration are key considerations in early phase I development. Numerous considerations have guided dose escalation strategies that accompany phase I trial development. The starting dose is typically approximately 10% of the lethal dose (LD)10 in animals adjusted for species dose-equivalency. In classic phase I development, a modified Fibonacci dose schedule is used.[32] Groups of three patients are treated at each of the following doses until the maximum tolerated dose is observed: 1N (the starting dose), 2N, 5N, 7N, 9N, 12N, 16N. Typically, the maximum tolerated dose is defined as the maximum tolerated dose not causing irreversible toxicity of any type and causing less than grade 4 toxicity in any organ. For some myeloablative strategies used in high-dose therapy, grade 4 myelosuppression, mucositis, and diarrhea are acceptable, but only with careful consideration of supportive care including the use of hematopoietic growth factors, antidiarrheal agents, narcotics, and IV alimentation to manage patients through severe mucositis. Typically, if one dose-limiting toxicity is observed, the patient cohort is expanded to six patients; and if two patients develop dose-limiting toxicity, typically defined as grade 4 toxicity except as previously noted, then further entry at this dose is not pursued and the next lower dose level is used to establish the maximum tolerated dose with a total of six patients accrued at that dose level.

Table 56–1 Clinical Trial Design

Phase I
Evaluate safety by dose escalation, multiple dose schedules. Establish maximum tolerated dose and dose-limiting toxicity. Consider use of hematopoietic support if myelosuppression is dose limiting.
Phase II
Establish response (complete, partial, objective) in specific diseases.
Phase III
Compare new treatment with established regimen for the disease in randomized trials.

Alternative strategies of drug escalation have included the use of toxicity grades to enhance dose escalation in early drug development; that is, if no toxicity is observed, fewer patients may be accrued to each dose.[33–35] Using the modified Fibonacci scheme, one patient is entered at each dose level until grade 2 toxicity is observed, at which point cohorts of three patients are entered at each level. Early in drug development, level skipping may take place if no toxicity is observed. The overall impact of this is to reduce the number of patients treated at suboptimal doses of therapy and to enhance the ultimate number of patients evaluated at biologically active doses.

With the rapid development of new anticancer agents in preclinical and early clinical testing, emphasis has shifted toward mechanism-based targeted therapeutics. These phase I trials evaluate both toxicity and "drug-effect" end points.

Phase II Drug Development

Phase II drug development utilizes the established phase I dose to define therapeutic efficacy, typically in a two-stage design. If an expectant response rate in excess of 20% is deemed clinically significant, 15 patients are accrued, and if two or more responses are seen, accrual is continued to a total of 26 patients to establish the definite response rate.[36] At this point, combination therapies are instituted in an effort to optimize therapeutic efficacy. For instance, topotecan was found in phase I testing to have efficacy against refractory leukemias leading to combinations of topotecan with ara-C and other agents.[37–39] Likewise, fludarabine was initially evaluated as a single agent for activity against low-grade lymphomas and acute and chronic leukemias, and is now used in combination with ara-C for the treatment of acute lymphocytic leukemia and with chlorambucil for the treatment of chronic lymphocytic leukemias (CLLs).[40–42] In the past, strategies for combination chemotherapeutic agents have included the use of non-cross-resistant agents with nonoverlapping toxicities. However, more recently, mechanism-based therapeutics has become the focus of drug development. For instance, with the combination of fludarabine and cisplatin, fludarabine may inhibit nucleotide excision repair and enhance persistence of cisplatin-induced DNA adducts, resulting in increased antitumor efficacy in CLL.[43] Likewise,

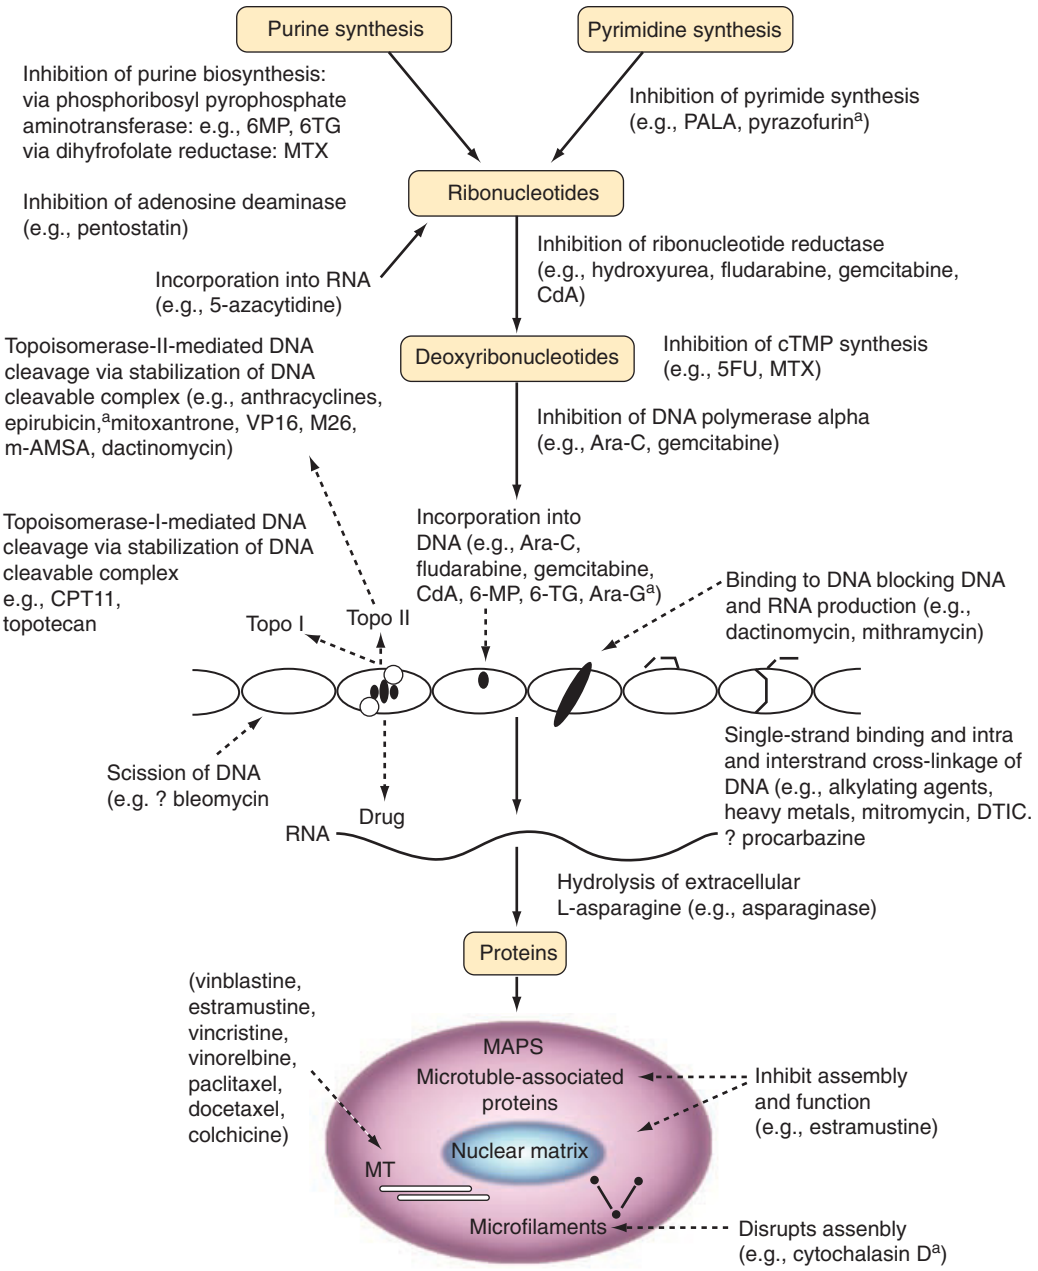

Figure 56–2 Overview of sites and mechanisms of action of the most useful chemotherapeutic agents.

combining a receptor kinase inhibitor with a cell-cycle inhibitor may potentiate efficacy in leukemias.

Most phase III trials randomize between an established standard therapy and a new therapy that has appeared promising in the phase II setting. These studies are usually multiinstitutional and many involve large national and international cooperative groups. The end point of these studies is disease response, survival, and patient tolerance. Linking multiple centers removes the vagaries of reports from single centers, which remain the focus of phase II trials. Phase III trials are important for positive and negative results.

PHARMACOLOGY OF CHEMOTHERAPEUTIC AGENTS

As noted earlier, although cytotoxic anticancer agents may be divided into several categories based on the cell-cycle specificity of their action, in keeping with traditional classification they are more appropriately divided into alkylating agents, antimicrotubule agents, antimetabolites, inhibitors of topoisomerases, platinum analogs, and miscellaneous agents. The pharmacology and cellular mechanisms of action of these agents are schematically presented in Fig. 56–2. Targeted therapeutics such as imatinib and bortezomib are discussed in later sections.

Alkylating Agents

Drug treatment for cancer began with the use of the mustard class of alkylating agents, initially mechlorethamine (nitrogen mustard), which entered into clinical use in the mid-1940s.[44] Alkylating agents are used in many regimens but are rapidly being supplanted by newer classes of agents.

Nitrogen Mustard

The nitrogen mustard class includes mechlorethamine, cyclophosphamide, 4-hydroperoxy cyclophosphamide, ifosfamide,

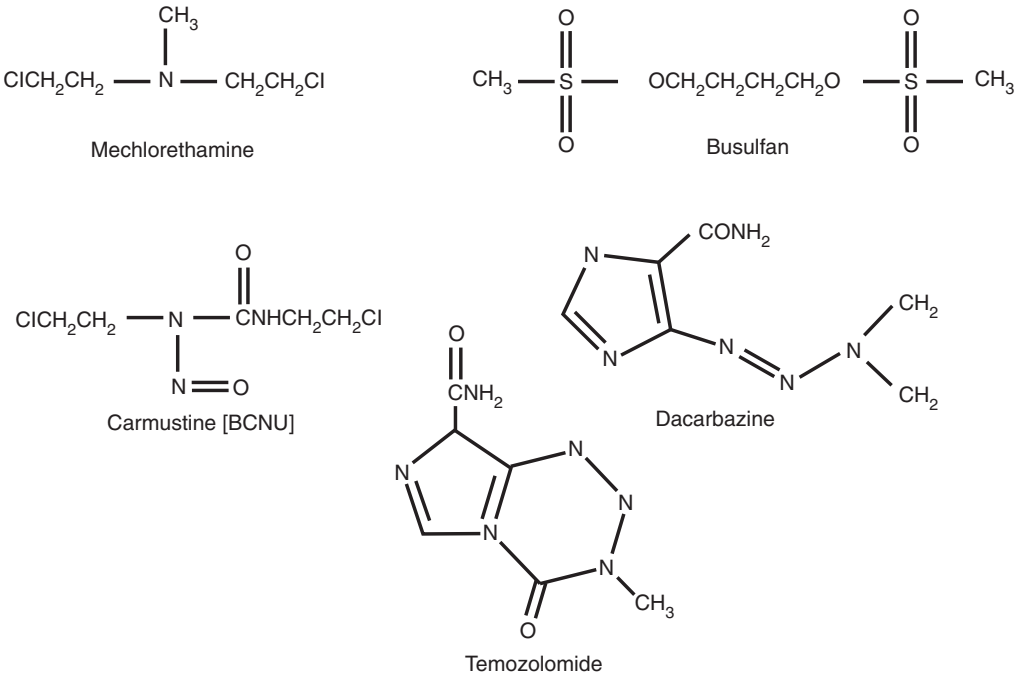

Figure 56–3 Structure of common alkylating agents.

chlorambucil, and melphalan. These all share a common bis-chloroethyl group attached to nitrogen and a substituted "R" group that provides drug specificity (Fig. 56–3). All nitrogen mustards react with DNA in an SN_2 reaction, a bimolecular nucleophilic displacement reaction, also called a second-order reaction.[45] Although numerous sites are targeted for alkylation, including protein, membranes, RNA, and DNA, the latter appears to be most critical for cytotoxic effects. Nucleophiles in DNA, including nitrogen (N), oxygen (O), and phosphate (P), attract the chloroethyl moiety attached to the R-N backbone, and the chlorine is displaced by the nucleophilic atom to form an aziridinium moiety.[46] The remaining chloroethyl group is then attracted to a second nucleophilic atom, forming a second aziridinium intermediate leading to a second alkylation, forming a cross-link. Both intrastrand and interstrand cross-links are formed.[47] Although the nitrogen mustards also attack DNA at other nitrogens, including N^1 and N^3 of the adenosine and N^3 of thymidine, it appears that the N^7 guanine position is the most critical for cytotoxic cross-link formation.[48] Clinical use of mechlorethamine has largely fallen out of favor since the MOPP regimen (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) has been replaced by ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) in Hodgkin disease.[48] Local use of mechlorethamine occurs in a dermatologic suspension for the treatment of cutaneous T-cell lymphomas.[49]

Cyclophosphamide is a nitrogen mustard with a ringed structure off the end-chloroethyl backbone that decreases spontaneous decomposition (see Fig. 56–3). Enzymatic activation is required through multifunction P450 enzymes in the liver. Phenobarbital and corticosteroids may alter activation. Bioavailability of cyclophosphamide orally and intravenously is quite similar, although most use of the drug is by bolus IV injection. Cyclophosphamide is detoxified through oxidation to 4-keto-cyclophosphamide and carboxyphosphamide by aldehyde dehydrogenase.[45] Cyclophosphamide is used in doses as little as 50 to 100 mg/day orally, and in bolus doses of 400 to 700 mg/m^2 for solid tumors and 750 mg/m^2 in combination with doxorubicin and vincristine and prednisone as part of the CHOP regimen for NHLs.[50] It is also used at doses of up to 60 mg/kg daily for 4 days in autologous and allogeneic bone marrow transplantation protocols.[51–53] Cyclophosphamide is used in numerous protocols for NHLs and high-dose therapy regimens designed to eradicate tumor and bone marrow in patients with lymphomas and leukemias, and those undergoing bone marrow transplantation. It is commonly used with granulocyte colony-stimulating factor (G-CSF) for mobilizing hematopoietic stem cells to be collected before autologous transplantation.

Cyclophosphamide is metabolically activated by cytochrome P450 mixed function oxidases in the liver to 4-hydroxycyclophosphamide.[54] 4-Hydroxycyclophosphamide is further converted to aldophosphamide and then to phosphoramide mustard, the alkylated species, and acrolein. Acrolein is a highly reactive aldehyde and the cause of hemorrhagic cystitis. Mercaptoethane sulfonate (mesna)[55] is used to prevent recurrence and to provide prophylaxis against hemorrhagic cystitis due to cyclophosphamide and ifosfamide and is now standard for doses of cyclophosphamide and ifosfamide above 1000 mg/m^2. Mesna is given in divided doses every 4 hours or as a continuous infusion for 18 to 24 hours in a dose equivalent to either cyclophosphamide or ifosfamide.[55] Other than hemorrhagic cystitis, bone marrow suppression is dose limiting and can be rescued by reinfusion of autologous or allogeneic hematopoietic progenitor cells.[56,57] Other toxicities observed include alopecia and cardiac toxicity,[58] which is unusual and most often seen after high-dose therapy.

4-Hydroperoxycyclophosphamide is a chemically stable form of the reactive intermediate of cyclophosphamide, 4-hydroxycyclophosphamide, is more toxic to committed hematopoietic progenitors such as colony-forming unit–granulocyte/macrophage (CFU-GM), burst-forming unit–erythroid (BFU-E), and colony-forming unit–erythroid (CFU-E), but spares early progenitors, presumably on the basis of their expression of the detoxifying enzyme aldehyde dehydrogenase, which is quite high in early progenitor populations.[58,59]

Melphalan, or phenylalanine mustard, has an amino acid side chain that alters its cellular uptake and stabilizes its structure, allowing oral administration (see Fig. 56–3). It is available in both oral and IV dosing and has a similar intracellular pathway to DNA cross-linking as cyclophosphamide and the other nitrogen mustards. Melphalan uptake into cells is by means of a neutral amino acid transporter.[60,61] Its rate of cross-link formation is much slower than that of mechlorethamine, presumably because of delayed metabolism. Orally, melphalan is used predominantly in the treatment of multiple myeloma and intravenously in high-dose regimens for multiple myeloma.[60]

Chlorambucil has been used for more than 40 years for the treatment of chronic lymphocytic leukemia[62] but is being replaced by fludarabine and rituximab. Chlorambucil is the phenylbutyric acid derivative of nitrogen mustard and is very stable, entering the cell by

diffusion rather than by a specific uptake mechanism. It is typically administered orally on a daily basis or intermittently. It appears to have greater bioavailability than melphalan and a more consistent half-life of approximately 2 hours.

Busulfan is an alkylsulfonate, unique among alkylating agents because of two sulfur groups and the lack of a chloroethyl moiety (see Fig. 56–3). Busulfan, like the nitrogen mustards, reacts predominantly at the N^7 position of guanine and produces an N^7–N^7 biguanyl DNA cross-link, although the precise nature of this cross-link appears different than that of the nitrogen mustards.[63] This may explain the different clinical utility of busulfan than the nitrogen mustards. The pharmacokinetics of busulfan is important for its use in high-dose therapy for ablation of the bone marrow in patients undergoing autologous transplantation for acute leukemia or allogeneic transplantation. Busulfan clearance does not appear to be accurately predicted by creatinine clearance. Because the incidence of venoocclusive disease is lower in patients receiving high-dose busulfan with predosing pharmacokinetics performed, this is now recommended in high-dose regimens, the target being an AUC of 800 to 1200 ng h/mL.[64,65] Busulfan is a potent stem cell toxin, killing both early and late hematopoietic progenitor cells and damaging the bone marrow stroma.[66,67] Other toxicities of busulfan include nausea and vomiting, and pulmonary interstitial and intraalveolar edema, leading to fibrosis.[68,69] The pulmonary fibrosis is distinct from the interstitial pneumonitis, which accompanies allogeneic bone marrow transplantation and is not related to cytomegalovirus or other viral infections.

Nitrosoureas

There are four chloroethyl nitrosoureas and one methyl nitrosourea in clinical use. The chloroethyl nitrosoureas were derived from methyl nitrosourea by Montgomery.[70] These agents are different from the nitrogen mustards in that they alkylate through an SN^1 reaction, forming a highly reactive intermediate in the presence of N, O, and P nucleophiles in DNA. The commonly used clinical agent is (2-chloroethyl)-*N*-nitrosourea (BCNU).[71,72] *N*-[(4-amino-2-methyl-5-pyrimidinyl) methyl]-*N*-(2-chloroethyl)-*N*-nitrosourea (ACNU) is commonly used in Japan.[73] A third agent, *N*-(2-chloroethyl)-*N*-cyclohexyl-*N*-nitrosourea (CCNU), is used predominantly as an oral nitrosourea in children with brain tumors.[74] All of these compounds have high hydrophobicity, actively penetrating the blood–brain barrier.

The DNA alkylation sites[75,76] include N^7 and O^6 of guanine. Chloroethylation at the O^6 position of guanine appears critical to cytotoxicity. DNA cross-linking by chloroethyl nitrosoureas include at 1-(3-cytosinyl), 2-(1-guanyl) ethane, and 1-2-bis(7-guanyl) ethane.[72,74] The former appears to be responsible for much of the cytotoxicity observed with the chloroethyl nitrosoureas. It is formed after alkylation at the O^6 position of guanine. This adduct undergoes intramolecular rearrangement to a circular intermediate, N^1. O^6 ethanoguanine is formed, which can then rearrange by attack at the opposite hydrogen-bonded base N^3 of cystine forming the interstrand cross-link.[77] This is a unique DNA cross-link and is poorly recognized by DNA repair processes, leading to marked cytotoxic potency of this cross-link.

The pharmacokinetics of the chloroethyl nitrosoureas has been evaluated in both conventional and high-dose schedules. A very short half-life has been detected, which is quite variable, but an association between the AUC of BCNU and pulmonary toxicity has been observed.[78,79] BCNU is predominantly used for high-dose treatment of recurrent lymphomas.[80,81] In both settings, it is an effective form of therapy with sustained complete remission rates of approximately 40% to 60%. Doses of between 600 and 1000 mg/m^2 have been safely administered. The chloroethyl nitrosoureas cause profound and cumulative bone marrow suppression at conventional doses of 120 to 150 mg/m^2, limiting treatment to three to five cycles at 6-week intervals.[78,82–84]

Complications of high-dose BCNU therapy include pulmonary toxicity and renal toxicity at doses higher than 600 mg/m^2. Pulmonary toxicity, as evidenced by a decrease in the DL_{CO}, occurs in up to 40% of patients and is symptomatic in 10% to 15% of patients.[78–80] It can be managed with steroids during the inflammatory but not fibrotic phase and is lethal in some cases.[80,85] Fibrosis is associated with an early interstitial infiltrate followed by evidence of hyaline membrane formation and replacement of the chronic inflammatory cells by fibrosis over a 4- to 6-week period.[86] Renal dysfunction associated by nitrosourea therapy occurs less frequently than severe cumulative myelosuppression and pulmonary fibrosis and is typically seen at doses above 1000 mg/m^2. Interstitial nephritis with glomerulosclerosis, interstitial fibrosis, and dropout of tubules have been reported[87,88] with BCNU or CCNU.

Methylating Agents

Four methylating chemotherapeutic agents are available for clinical use. These include procarbazine, dacarbazine (DTIC), streptozotocin, and temozolomide. Procarbazine and DTIC are triazines.[89] Streptozotocin is a monofunctional methyl nitrosourea derivative with an attached sugar moiety,[15,90] and temozolomide is an imidazotetrazine synthesized in England in the 1960s, reaching clinical trials in the late 1980s.[91] All react with DNA by undergoing SN^1 reactions forming a methyldiazonium ion, resulting in methylation of N^7 guanine, O^6 guanine, O^4 and O^2 thymine, and N^3 adenine.[92–94] None form DNA cross-links. However, all induce high levels of DNA methylation. N^7 methylguanine is unstable, leading to ring opening and both spontaneous and enzymatically mediated depurination. Repair proceeds through the base excision repair system.[95,96] Recognition by the *N*-methylpurine glycosylase results in removal of the adducted base with formation of an abasic site that is recognized by the apurinic (AP) endonuclease, which then cleaves the backbone at the apurinic site. Subsequently, the free 5′ sugar is released by DNA lyase with repair initiated by beta polymerase and DNA ligase.[95] Base excision repair effectively removes N^7 methylguanine and N^3 methyladenine and restores DNA to normal. These lesions appear to contribute little to cytotoxicity and appear to be up to 500-fold less potent as cytotoxic adducts than O^6 methylguanine.[94]

O^6 methylguanine mispairs with thymine during DNA synthesis, resulting in a lesion recognized by the mismatch repair system.[94,97] This system consists of two sets of enzyme homologs of mismatch repair in prokaryotes, mutS and mutL.[97] Mispair recognition proteins are MSH6, MSH3 and MSH2, homologs of the mutS system in bacteria. MSH2 and MSH3 form a stable heterodimer with MSH6.[97] Recognition of the mispair recruits additional proteins to the complex, including MLH1 and PMS1/PMS2, which are homologs of mutL in bacteria. These proteins initiate exonuclease cleavage of a long patch in the newly synthesized strand of DNA. This is then repaired by polymerases delta and epsilon. Unfortunately, if the O^6 methylguanine adduct is not removed before repair synthesis, a thymine is again inserted opposite the O^6 methylguanine and the repair process begins again, resulting in an aberrant episode of repair and multiple single-strand breaks.[94,97–100] Cell protection from methylating agents arises either by removal of O^6 methylguanine (vide infra) or inactivation of the mismatch repair system.[94] Cells expressing high levels of the DNA repair protein for O^6 methylguanine, O^6 alkylguanine DNA alkyltransferase are approximately 10-fold more resistant to methylating agents than alkyltransferase-negative cells.[94,101] Mismatch repair-mediated single-strand patches promote chromosomal aberrations, homologous and nonhomologous recombination, and induction of apoptosis in a p53-dependent and p53-independent manner.[102] Absence of one or more protein components of mismatch repair, leading to the phenotype of replication error repair (RER), is commonly observed in hereditary colon cancer as well as endometrial cancer, gastric cancer,[97,102] and approximately 15% of lymphomas.[103,104] Cells lacking mismatch repair are up to 100-fold more resistant to methylating agents than cells with mismatch repair, regardless of alkyltransferase activity.[94] Acquisition of mismatch repair defects is associated with acquired resistance to methylating

agents and cisplatin, which is also recognized by this protein complex.[94,97–100]

Procarbazine was originally synthesized as a monoamine oxidase inhibitor but has been used since the 1950s for the treatment of Hodgkin and NHLs, as well as in combination therapies for gliomas.[105–108] Recent use has been superseded by newer agents. Patients receiving procarbazine form O^6 methylguanine DNA adducts with depletion of the alkyltransferase enzyme, a suicide protein that removes the methyl group in irreversible stoichiometric reaction.[109] Chromosomal breaks, single-strand breaks, and chromosomal aberrations and sister chromosome exchanges observed after procarbazine treatment support its association with treatment-related myelodysplasia and leukemia.[110,111]

DTIC is metabolically activated by cytochrome P450 microsomal oxidoreductases, ultimately leading to formation of the methyldiazonium ion and DNA methylation.[92] DTIC is used in combination with doxorubicin, vinblastine, and bleomycin (ABVD) in Hodgkin disease[43] and is also used in metastatic malignant melanoma in combination with BCNU, cisplatin, and tamoxifen.[112] Activation of DTIC requires hydroxylation of one terminal methyl group caused by demethylation forming 5(3-methyltriazeno)-imidazole-4-carboxamide (MTIC), with spontaneous decomposition to the methyldiazonium ion, which alkylates the DNA, as noted earlier.[113–115] Like procarbazine, DTIC has been shown to form N^7 methylguanine and O^6 methylguanine DNA adducts in human peripheral blood lymphocytes and to deplete alkyltransferase through repair of O^6 methylguanine DNA adducts. A correlation has been found between tumor response and formation of O^6 methylguanine DNA adducts,[116] indicating the importance of this lesion in clinical antitumor effects. Maximum tolerated doses of DTIC are approximately 1000 mg/m^2, with myelosuppression and gastrointestinal toxicity (including severe watery diarrhea) as the most common side effects.[117,118]

Temozolomide represents an imidazotetrazinone.[91,119,120] It differs from DTIC in that it is chemically degraded to the monomethyl triazine, MTIC, at neutral pH and does not require P450 enzymatic demethylation.[121] Compared with DTIC in phase I and phase II trials, temozolomide has much more consistent pharmacokinetic parameters, including peak serum concentrations, volume of distribution and clearance, and conversion to MTIC.[91,119,120] Clinical studies found considerable activity in acute leukemias. Dose-limiting toxicity was thrombocytopenia and, less frequently, neutropenia, with maximum tolerated doses of 1000 mg/m^2 given over 5 days on a daily or twice daily regimen.[91,119,120] Nausea and vomiting were the other common side effects, easily controlled with antiemetics. Formation of O^6 methylguanine has been documented in clinical trials with temozolomide with much more rapid depletion of the alkyltransferase, suggesting that temozolomide may be more effective than the other methylating agents according to its ability to form higher levels of toxic O^6 methylguanine DNA adducts. Early-phase clinical trials using temozolomide in patients older than 60 years with acute myeloid leukemias indicated that the drug is well tolerated and has a modest response rate.[122] A second study has shown that combination therapy including temozolomide, which may induce neoantigens, is also effective.[123] The investigational alkylating agent cloretazine is also in phase II trials in acute leukemia.[124]

Alkylating Agent-Induced Leukemias

Alkylating agents induce dose-limiting myelosuppression, and thus it is not surprising that these agents also cause sublethal DNA damage to hematopoietic progenitors, causing mutational events leading to both myelodysplastic syndromes and malignant transformation to preleukemic and leukemic states. A concern has been the use of hematopoietic growth factors after exposure to alkylating agents. There is evidence of increased cytotoxicity to hematopoietic progenitors during simultaneous exposure to these agents and growth factors.[75] Treatment-related acute myeloid leukemia (T-AML) accounts for approximately 15% of all adult AML. Approximately 50% of T-AML patients have a preleukemic phase as compared with only 10% of patients with de novo AML.[35] Complete remission rates are 15% to 30% in patients with T-AML,[125] and remission duration is a mean of 2 months. Chromosomal abnormalities are common in T-AML, with more than 90% of cases expressing a chromosomal rearrangement, loss, or addition.[20]

Historically, patients with Hodgkin disease treated with mechlorethamine and procarbazine in the MOPP regimen or with CCNU are at highest risk if exposed to radiation as well as an alkylating agent combination.[76] Patients with polycythemia vera treated with chlorambucil are at much higher risk than patients treated with phlebotomy alone, which can contribute to a shift in treatment strategy.[126] Patients with myeloma and ovarian cancer have developed T-AML, especially following prolonged exposure to alkylating agents.[127] The recent introduction of temozolomide for the treatment of glioblastoma multiforme is of concern given its use as a 5 day per month or daily regimen for an extended period of time. There have been a number of reports of secondary leukemia in this patient population indicating that the mutagenic effect of temozolomide seen preclinically will need to be monitored in treated patients.[128,129] Patients treated with alkylating agents for benign diseases such as nephritis, lupus, psoriasis, rheumatoid arthritis,[130] and Wegener granulomatosis[131] also have an increased risk of T-AML. The mean latency between exposure and T-AML from alkylating agents is 4 to 5 years,[17,20,126,127,132] in contrast to T-AML from etoposide, which has a latency as short as 1 year.[133] The cumulative risk for developing T-AML is between 10% and 17% at 4 to 6 years for myeloma treated with melphalan, and between 2% and 10% at 7 to 10 years in patients with Hodgkin disease.[76] More recently, alkylating agent-associated T-AML has been recognized in patients with breast[134,135] and colon[136] cancer. A series of nonrandom chromosomal aberrations associated with T-AML have been identified.[132] Loss or deletion of all or part of the long arm [q] of chromosomes 5 or 7[127] are common, as are trisomy chromosome 8, and deletions of the short arm of chromosomes 12 and 17, and 21.[20]

Antimicrotubule Agents

The antimicrotubule drugs include vinca alkaloids (eg, vincristine, vinblastine, and vinorelbine), taxanes (eg, paclitaxel and docetaxel), and a unique synthetic compound (estramustine).

The vinca alkaloids are naturally occurring (vincristine and vinblastine) or semisynthetic (vinorelbine) nitrogenous bases derived from the pink periwinkle plant, *Catharanthus roseus*.[137] Paclitaxel was originally isolated from the bark of the Pacific yew, *Taxus brevifolia*.[138] Paclitaxel can also be isolated from other members of the *Taxus* genus and from a fungal endophyte that grows on the Pacific yew.[139] Docetaxel is derived semisynthetically from 10-deacetyl-baccatin III, which is obtained from the needles of the European yew, *Taxus baccata*.[140]

Vincristine and vinblastine bind to the protein tubulin at a site distinct from that of the taxanes and, at low concentrations, inhibit microtubule dynamics. At higher concentrations, these vinca alkaloids disrupt microtubules and mitotic spindle, resulting in cell-cycle mitotic arrest and apoptosis of cells (see Fig. 56–3). In contrast, after binding to a-tubulin, taxanes kinetically stabilize microtubule dynamics at their plus ends, as well as shift the equilibrium toward tubulin polymerization into micrutubule bundles. This also causes mitotic arrest and apoptosis of cells.[141] The mitotic arrest caused by antimicrotubule drugs is associated with phosphorylation of the BCL2 protein and increased intracellular levels of the BCL2-associated X protein (BAX), which promote apoptosis.[141]

These agents are used in the management of lymphomas and leukemias and continue to be used in the mainstay of clinical chemotherapeutic regimens. Because of their mechanism of action, they are best used in combinations where potentiation of efficacy with other classes of agents such as antimetabolites and DNA-damaging agents provide better therapeutic responses and well-tolerated treatments, particularly in the relapsed setting. A recent phase II study combining fludarabine with paclitaxel achieved a 60% overall

response rate with 32% complete remissions in 28 patients with relapsed non-Hodgkin lymphoma with moderate toxicity other than a high incidence of neutropenia and fever, and a prolonged complete remission (CR) duration of 32 months.[142]

Antimetabolites

The antimetabolites consist of low-molecular-weight compounds that interfere with micromolecular synthesis. As a group, they may be contrasted with agents such as the anthracycline antibiotics, which interfere with macromolecular synthesis. The nucleoside analogs exhibit structural similarities to naturally occurring nucleosides and are incorporated into either DNA or RNA with lethal consequences. Alternatively, they block key enzymes in de novo purine or pyrimidine biosynthesis. The antimetabolites in use in hematologic disorders can be divided into the following broad categories:

1. Inhibitors of de novo purine or pyrimidine synthesis (eg, hydroxyurea)
2. Folic acid analogs (eg, methotrexate)
3. Pyrimidine analogs (eg, ara-C, 5-azacytidine, gemcitabine)
4. Purine analogs (eg, 6-thioguanine, 6-mercaptopurine, fludarabine, chlorodeoxyadenosine, deoxycoformycin, clofarabine, nelarabine).

These categories are not mutually exclusive; for example, some nucleoside analogs (eg, ara-C and 6-thioguanine) also inhibit enzymes involved in DNA or deoxyribonucleotide biosynthesis. As noted previously, the antimetabolites are predominantly cycle-active agents and in most cases are phase-specific, being primarily active against cells in S phase. Because the growth fraction of hematologic malignancies tends to be higher than that of nonhematologic malignancies, antimetabolites are particularly useful in the former disorders. In contrast to alkylating agents, antimetabolites have limited carcinogenic and leukemogenic potential. The fluorinated pyrimidines (eg, 5-fluorouracil) are generally not employed in hematologic disorders and will not be discussed here.

Clofarabine (2-chloro-2′-arabino-flouro-2′-deoxyadenosine) is a purine analog with demonstrated activity in relapsed acute leukemias. To be active, it requires cellular uptake, conversion to the triphosphate nucleotide. It then decreases ribonucleotide reductase, alters nucleotide precursors, inhibits and reduces the function of antiapoptotic proteins such as Bcl-X(L), Mcl-1, and Bax with dephosphorylation of akt,[143] and causes inhibition of DNA synthesis. It appears more active against B-cell than T-cell malignancies but also has activities in AML and MDS.[144] Reversible liver toxicity and myelosuppression can be dose limiting.

Nelarabine (9-beta-D-arabinofuranosylguanine) is the most recently FDA-approved purine analog for the treatment of refractory T-cell leukemias and lymphomas. It preferentially accumulates in T-cells and is incorporated into DNA, causing chain termination and inhibiting DNA synthesis. The FDA approved the drug after analyzing the results of two phase II clinical trials, one in pediatric T-cell acute lymphoblastic leukemia (ALL) and the other in adults with T-cell lymphoblastic lymphoma. In both cases patients had relapsed after at least two induction regimens. Because complete remissions were seen in 13% of the 39 pediatric patients and in 18% of the 28 adult patients, the FDA granted approval.[145] Neurologic toxicity is dose limiting. Good response rates including complete remissions have been seen in refractory T-cell leukemias.[145–148]

Inhibitors of DNA Topoisomerase I and II

The inhibitors of DNA topoisomerases I and II are some of the most commonly used antineoplastic agents in the treatment of hematologic malignancies, and include such drugs as doxorubicin, daunorubicin, mitoxantrone, etoposide, and topotecan. Before describing the specific inhibitors, a brief review of the drug targets (topoisomerase enzymes) will be presented (Table 56–2).

DNA Topoisomerase I

Topoisomerase I is a ubiquitous enzyme whose function in vivo is to relieve the torsional strain in DNA, specifically, to remove positive supercoils generated in front of the replication fork and to relieve negative supercoils occurring downstream of RNA polymerase during transcription.[149–151] Topoisomerase I is catalytically active as a 100-kd monomer and is concentrated in nucleoli, although lower amounts are found in a diffuse nuclear distribution. The gene for this enzyme is located on human chromosome 20q12-13.2. Topoisomerase I does not require adenosine 5′-triphosphate (ATP) for catalytic activity. It binds double-strand DNA over 15 to 25 bp (with a preference for supercoiled or bent DNA), followed by cleavage of one DNA strand and forming a transient covalent phosphotyrosyl bond at the 3′-end of DNA. DNA torsional strain is then relieved by a

Table 56–2 Characteristics of Mammalian DNA Topoisomerases

	Topo I	Topo IIα	Topo IIβ
Size of monomer	100 kd	170 kd	180 kd

"controlled rotation" mechanism (see Fig. 56–1) subsequent to which the cleaved DNA is religated. The three-dimensional crystal structure of human topoisomerase I, both in covalent and noncovalent complexes with DNA, has defined the structural elements of the enzyme that contacts DNA.[85,86] The association between topoisomerase I and the –3′ end of cleaved DNA has been termed the *cleavable complex*, and it is this complex that is stabilized by topoisomerase I inhibitors.

DNA Topoisomerase II

Two isoforms of human topoisomerase II (alpha and beta) exist. They act as homodimers to cleave double-strand DNA and they require ATP for full activity.[149,151–153] Their role in vivo is to relieve torsional strain in DNA, and their cellular distribution is determined by nuclear localization signals contained in the C-terminal domain.[154,155] These isoforms are distinct in that they have different-size monomers (see Table 56–2), their genes are on separate chromosomes, their nuclear distribution is different, and only the α-isoform shows cell-cycle variations in amount and activity (with maximal activity in G_2/M). The mechanism of action of topoisomerase II involves several steps (Fig. 56–4): DNA recognition and binding (curved and supercoiled DNA, as well as DNA crossovers, are preferred); the sequential cleavage of the two strands of DNA with covalent attachment of a monomer to each 5′-end of the cleaved DNA; passage of another DNA duplex through the break site (eg, to relieve DNA torsional strain or decatenate daughter chromosomes at the end of replication); religation of the cleaved DNA; and ATP hydrolysis-dependent enzyme turnover. The binding of ATP by topoisomerase II is required for the strand passage reaction. Again, the association between topoisomerase II monomers and the 5′ end of the cleaved DNA has been termed the *cleavable complex*, the stabilization of which generally correlates with the cytotoxic activity of specific topoisomerase II inhibitors.

Because topoisomerase I and II inhibitors convert their respective enzymes into DNA-damaging agents, it is usually true that the more enzyme target a cell contains (provided it is in the nucleus), the more cytotoxic the specific inhibitor is. An exception to this generalization is found in CLL cells, which have abundant topoisomerase I, yet are not very sensitive to topoisomerase I inhibitors. This is because topoisomerase I inhibitors are S phase specific and CLL cells have very few cells in S phase. Finally, in addition to topoisomerase I and II, a mammalian DNA topoisomerase III has recently been described and found to be essential for early embryogenesis in the mouse.[156] In addition to the presumed lethality of a homozygous deletion of the topoisomerase II gene, topoisomerases I and III appear to be essential for cell growth and division in mammals.[157,158] The specific role of topoisomerase III in humans is not known at present.

DNA Topoisomerase I Inhibitors

Camptothecin is a plant alkaloid first identified in 1966 from the tree *Camptotheca acuminata.* Early clinical studies with camptothecin were stopped primarily because of hemorrhagic cystitis, resulting from conversion of the sodium salt form given to the active lactone form owing to the acidic pH in the bladder. Renewed interest in camptothecin occurred in 1985 when topoisomerase I was identified as the target of this drug,[158] and as new more water-soluble analogs became available. At present, there are two topoisomerase I inhibitors approved by the FDA as second-line agents for the treatment of ovarian carcinoma and colorectal cancer; these are topotecan and irinotecan (CPT-11), respectively. Other analogs, including 9-aminocamptothecin, are currently in clinical trials (Fig. 56–5). With respect to hematologic malignancies, topotecan has been shown to be active in the treatment of myelodysplastic syndromes[159] and inactive in the treatment of CLL.[39] Responses to topotecan have also been seen in refractory multiple myeloma[160] and in refractory acute leukemia.[161,162]

There are several recent reviews of topoisomerase I inhibitors and the clinical trials using these agents.[163–166] The lactone forms of topotecan and SN-38 (the active form of CPT-11 generated in vivo by the action of a carboxylesterase) are as much as 1000-fold more active

Table 56–3 Mechanism(s) of Action of Antineoplastic Agents That Are Primarily Topoisomerase II Inhibitors

Drug	Topo II Inhibition Poison	DNA Suppressor	Free Radical Intercalation	Formation

inhibitors of DNA topoisomerase I than are their carboxylate forms. The lactone form predominates at an acidic pH. Topoisomerase I inhibitors stabilize the DNA–enzyme cleavable complex and thus inhibit DNA religation, but it is the production of DNA double-strand breaks that result from a collision of the DNA replication fork with the ternary drug–enzyme–DNA complex that is the lethal event (see Fig. 56–4).[167–169] Topoisomerase I inhibitors are considered S phase-specific agents because they require ongoing DNA synthesis to exert their cytotoxic effect.

DNA Topoisomerase II Inhibitors

Inhibitors of DNA topoisomerase II are some of the most commonly used agents in the treatment of hematopoietic malignancies, and their biochemical and pharmacologic properties have recently been reviewed by several investigators.[170–173] There now exist three general types of topoisomerase II inhibitors (Table 56–3). The first are the topoisomerase II *poisons*, typified by etoposide, whose activity results in the stabilization of cleavable complexes. The second group are the *catalytic inhibitors*, represented by aclarubicin, merbarone, and the bis-2,6-dioxopiperazine derivatives (ICRF-193, ICRF-159, ICRF-187); these are drugs that, except for aclarubicin, do not bind DNA and do not stabilize cleavable complexes but rather interfere with some aspect of topoisomerase II catalytic activity (eg, ICRF-187 inhibits topoisomerase II adenosine triphosphatase [ATPase] activity). The final class includes drugs that can inhibit both DNA topoisomerases I and II, and are represented by intoplicine[174] and saintopin.[175]

DNA topoisomerase II poisons, the most frequently used drugs in the clinical setting (see Fig. 56–5 for structures) are most likely cytotoxic because they trap DNA topoisomerase II complexes on nascent DNA in the nuclear matrix.[176,177] Recent evidence suggests that the topoisomerase II poison-stabilized enzyme–DNA complex acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells,[178] whereas other experiments in yeast show that although DNA synthesis is a major determinant for cell killing by topoisomerase I inhibitors, topoisomerase II poisons may be cytotoxic during other phases of the cell cycle as well.[179,180]

Drug Resistance to Topoisomerase Inhibitors

Essentially all of the topoisomerase II poisons (see Tables 56–2 and 56–3) are substrates for the drug efflux pump p-glycoprotein (PGP), and many are substrates for multidrug resistance protein (MRP) and lung resistance-related protein. In addition, several point mutations and gene deletions have been defined in the gene for topoisomerase II resulting in the production of an enzyme with altered catalytic and/or cleavage activity.[181,182] The third mechanism is a decrease in expression of the enzyme such that there is less target for the inhibitor to "convert" to a DNA-damaging agent. This can result from a proliferation-dependent or cell cycle-dependent decrease in topoisomerase II,[183] from a specific attenuation of topoisomerase II,[184,185] or from an intrinsic absence of topoisomerase II (identified in some acute and chronic leukemias). The fourth resistance mechanism involves alterations in the subcellular distribution of the enzyme. Truncation of the COOH-end of topoisomerase II has resulted in the cytoplasmic distribution of enzyme caused by a loss of nuclear localization signals, so that the enzyme cannot interact with DNA in the presence of an inhibitor and the cell is resistant.[186–188] However, mutations in the gene for topoisomerase II do not appear to be a common clinical event, as only a single patient with AML has been found to have a point mutation. CLL cells are resistant to topoisomerase II inhibitors because they express very low levels of the protein.

Platinum Analogs

During a study of the effects of electric current on growing bacteria, the antibacterial and, later, the antitumor activities of the platinum compounds were fortuitously discovered. The antitumor agent, cisplatin, and its cis-carboxylester analog, carboplatin, are heavy metal platinum complexes. Both are activated by displacement of their ligands (cisplatin : chloride and carboplatin : carboxylester) by water to form positively charged aquated platinum complexes. This allows platinum to stably bind DNA, RNA, proteins, or other critical biomacromolecules (see Fig. 56–2). With DNA, platinum complexes form covalent links to the N^7 position of guanine and adenine. The N^7 adducts at d(GpG) or d(ApG) result in intrastrand or interstrand DNA cross-links that bend the DNA helix and inhibit DNA synthesis. The cytotoxicity of platinum analogs correlates with the total platinum binding to DNA, as well as with the intrastrand or interstrand cross-links. This results in DNA damage, which triggers apoptosis of sensitive cells.

Cisplatin and carboplatin are used in the treatment of refractory lymphomas as part of high-dose and intensification therapy.

Miscellaneous Agents

Among the agents included in this category, only plicamycin, bleomycin, procarbazine, L-asparaginase, gallium nitrate, and

glucocorticoids are of current interest to the hematologist; these are discussed in Appendix 56–6.

Targeted Agents

Imatinib Mesylate and Other Kinase Inhibitors

Imatinib mesylate (formerly GCP57148; Gleevec; STI571) is a phenylaminopyrimidine that was developed as an inhibitor of the BCR-ABL tyrosine kinase, which is expressed in the cells of most patients with CML.[189] The role of the BCR-ABL kinase in the pathogenesis of CML and its use in CML treatment are discussed in detail in Chapter 69, and will not be dealt with in depth here.

Imatinib mesylate represents the prototypical molecularly targeted agent in that it is directed specifically against the BCR-ABL kinase, which is selectively expressed in CML but not normal cells.[190] Imatinib mesylate is not absolutely specific for the BCR-ABL kinase, inasmuch as it also inhibits other kinases, including KIT (formerly designated c-KIT), PDGF, and TEL-ARG.[191] Radiographic crystallographic studies revealed that imatinib mesylate binds to the ATP-binding site of the kinase and stabilizes it in an inactive form. The 50% inhibitory concentration (IC_{50}) of imatinib mesylate for BCR-ABL is in the submicromolar range, and substantially lower than the supramicromolar levels achievable in the plasma of patients receiving the drug by the oral route.

Exposure of BCR-ABL$^+$ leukemic cells to imatinib mesylate not only blocks their proliferation but also induces apoptosis.[192] Such a finding suggests that these cells have become "addicted" to constitutive activation of BCR-ABL for their survival. This is believed to be secondary to activation of a large number of downstream BCR-ABL survival pathways, including those related to STAT5A (previously designated STAT5), MEK/ERK, NF-kB (nuclear factor-κB), AKT, and BCL2L1 (also known as Bcl-xL), among others.[193,194] In addition to promoting survival in BCR-ABL$^+$ cells, activation of these pathways also confers resistance to conventional cytotoxic drugs.[195]

Despite the success of imatinib mesylate in the treatment of chronic phase CML and, to a lesser extent, accelerated or blast phase CML, the preexistence or development of resistance represents a major therapeutic challenge. This success is further tempered by the emergence of mutations within the abl kinase rendering cells resistant to Inhibition, and intolerance due to skin rash, diarrhea, heart failure. In many patients with bcr-abl + ALL, abl kinase mutations are present at the time of diagnosis and emerge with imatinib treatment.[196] Resistance to imatinib can take multiple forms, including the development of standard multidrug resistance mechanisms (eg, PGP-related), *BCR-ABL* gene amplification, increased levels of the BCR-ABL protein, and perhaps most commonly, mutations in the BCR-ABL kinase domain (eg, $_{thr}315_{ile}$), which alter the conformation of the kinase domain and inhibit imatinib mesylate binding.[197–199] A recent study of 171 patients failing imatinib identified 62 patients with mutations in 23 amino acids, most commonly the phosphate-binding loop in the abl kinase gene.[200] In addition, mutations distant to the kinase domain can occur that also have the net effect of antagonizing BCR-ABL binding.[201] Very recently, a new form of imatinib resistance has been described characterized by loss of the BCR-ABL kinase and a reciprocal upregulation of the SRC kinases LYN and HCK.[202] A recent study in an experimental model of Ph-positive CML has shown that targeting multiple kinases improves therapeutic outcome.[203]

One logical approach to enhancing imatinib mesylate activity or overcoming resistance, or both, is to combine it with more conventional cytotoxic agents including ara-C, interferon, and others.[204,205] Clinical trials based on this strategy are currently underway. An alternative approach is to combine imatinib mesylate with other novel agents that interrupt various survival signaling or cell-cycle regulatory pathways. In this regard, potentiation of imatinib mesylate activity in BCR-ABL$^+$ cells has been reported when combined with MEK inhibitors,[206] the CDK inhibitor Flavopiridol,[207] histone deacetylase inhibitors (eg, suberoylanilide hydroxamic acid [SAHA]),[208,209] farnesyl transferase inhibitors,[210] arsenic trioxide,[211] and the FRAP1 inhibitor rapamycin.[212] Clinical trials involving regimens combining imatinib mesylate with Flavopiridol, farnesyl transferase inhibitors, 17-allylaminodemethoxy geldanamycin (17-AAG), arsenic trioxide, and FRAP1 inhibitors are currently underway. Finally, an alternative approach to circumvent imatinib mesylate resistance involves the use of non-cross-resistant agents such as the tyrphostin adaphostin,[213,214] or the SRC tyrosine kinase inhibitor (PD 173955).[215] Another approach is combining an mTor inhibitor, rapamycin, or the novel RAD001 agent, which in preclinical models improves the efficacy of imatinib.[216]

Dasatinib is the second abl kinase inhibitor approved for the treatment of CML. Dasatinib is an oral abl, kit, and src kinase inhibitor that induces responses in most patients who are treated in the chronic and accelerated phase of CML.[217,218] As a multikinase inhibitor, it can be expected to have a higher response rate and perhaps to have broader toxicity profile. However, it is well tolerated, with some patients experiencing pulmonary edema, pleural effusions, skin rashes, and neutropenia. Few patients are removed from treatment for these reasons. There is a high response rate in patients with wild-type sequences of bcr-abl and also in patients with imatinib resistance mutations in the abl protein.[219] Resistance to dasatinib has been observed most likely as a result of mutations at positions 315 or 317 of the abl kinase.[220] Other agents such as nilotinib, AMN 107, are also kinase inhibitors in clinical trials for imatinib-intolerant or imatinib-resistant settings. AMN107 is a much more potent abl-kinase inhibitor and is well tolerated in early trials. As a more potent agent, it will be of interest to define whether it has a better tolerance and efficacy profile compared to imatinib.[221]

Hypomethylating Agents

Promoter methylation within CpG islands regulates gene expression in all cells. Disruption of normal gene expression profiles accompanies the malignant transformation, giving rise to complex patterns of gene expression. As a consequence, promoters of many genes have an altered pattern of methylation resulting in either gene activation or gene repression. The link between these concepts and the interest in agents that alter promoter methylation began with the realization that azacytidine, an agent used sparingly for myeloid leukemias, had efficacy when given at low doses either intravenously or subcutaneously for extended periods of time and that in these cases, altered gene expression accompanied responses. Both azacytidine and 5-aza-2′-deoxycytidine (decitabine) act by irreversible inhibition of the DNA methyltransferases responsible for methylation of the cytidine in CpG islands[222] and are thus S phase-specific agents. Wijermans et al first described that a related compound, 5-aza-2′-deoxycytidine, was effective when given as a continuous infusion to elderly patients with high-risk MDS, with a 54% response rate.[223] The mechanism of action included both direct change in promoter methylation[222,224] and independent changes, with up to 70% genomewide demethylation, suggesting either that genes with altered expression either up- or downregulated a second set of genes through altered pathways such as induction of WAFp21, p15, and p16 or in a more direct fashion through altered transcription factor expression.[225–227] More recent studies have identified activity of these agents in both acute and chronic myeloid leukemias.[228–230] Most often, partial responses or short-lived complete responses are seen in AML with complete responses more common in MDS. Recent studies also describe a number of extended therapy regimens. Kantarjian et al reported a comparison of 20 mg/m^2 decitabine intravenously for 5 days with 20 mg/m^2 subcutaneously daily for 5 days and 10 mg/m^2 intravenously for 10 days. The 5-day IV dose schedule was judged superior on the basis of clinical outcome with 39% complete remissions, a higher proportion of reactivation of p15 and induced hypomethylation as well as clinical tolerance.[231]

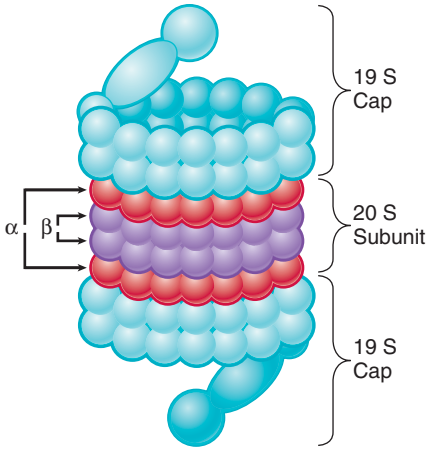

Figure 56–6 26S Proteasome.

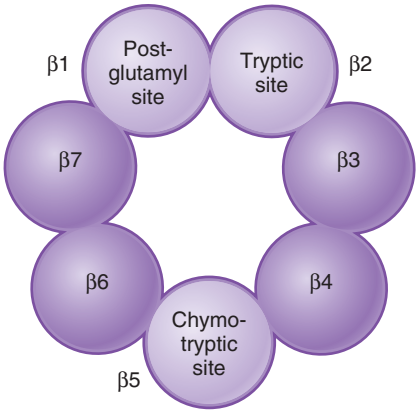

Figure 56–7 Cross section of beta ring of the 20S of the 26S proteasome.

Ubiquitin–Proteasome Inhibitors

The 26S proteasome is the central proteolytic machinery of the highly conserved ubiquitin proteasome system. In eukaryotic cells, whereas the lysosomal pathway degrades extracellular proteins imported into the cell through endocytosis or pinocytosis, the proteasome controls the degradation of intracellular proteins. Numerous studies have demonstrated that the ubiquitin–proteasome system controls basic cellular functions such as cell-cycle progression, signal transduction, and programmed cell death. Hence the interest in therapeutic interventions that manipulate proteasomal activity and potentially restore cellular homeostasis into transformed cells.

Ubiquitin is a highly conserved 76-amino-acid polypeptide that is expressed in all eukaryotic cells.[232] Under the sequential action of E1 (ubiquitin-activating enzyme), E2 (ubiquitin-conjugating enzyme), and E3 (ubiquitin ligase), ubiquitin is activated and covalently conjugated to potential proteasome substrates via an isopeptide bond between the C-terminal glycine residue of ubiquitin and the ε-amino group of internal lysine residues in target proteins.[232] The same set of enzymes also catalyzes the formation of the isopeptide bond between G76 and the lysine residue (K48) of previously conjugated ubiquitin, leading to formation of a polyubiquitin chain. Polyubiquitinated substrates are usually targeted for proteasomal degradation.[232–235]

The 26S proteasome is a large (2000-kd) threonine protease present in the nucleus and cytoplasm of all eukaryotic cells.[236,237] This ATP-dependent, multicatalytic protease eliminates damaged or misfolded proteins and regulates cyclins and cyclin-dependent kinase inhibitor cell-cycle regulatory proteins as well as other proteins that govern the transcription factor activation, apoptosis, and cell trafficking. Its structure consists of two parts: The 20S core and the 19S cap regulatory particle (Fig. 56–6). The 19S cap is involved in the recognition, binding, and unfolding of ubiquitinated proteins, and in the regulation of the opening of the 20S core.[238,239] The 20S core is a cylinder composed of four stacked heptameric rings, each containing seven different α or β subunits (α7β7β7α7) (Figs. 56–6 and 56–7). Three different active sites are located inside the cylindrical core within the β-subunit rings. At least three distinct proteolytic activities are associated with the proteasome: Chymotryptic, tryptic, and peptidylglutamyl.[236,240–242] Following release from the substrate, the polyubiquitin chain is hydrolyzed into single ubiquitin moieties whereas tagged proteins are degraded to small peptides. Both the assembly of the 26S proteasome and the degradation of protein substrates are ATP dependent.[239,240]

Transformed cells are much more sensitive to blockade of the proteasome than are normal cells; the exact mechanism of this selective susceptibility is not fully understood. Early studies revealed that proteasomes are abnormally highly expressed in rapidly growing metazoan embryonic and human neoplastic cells, but not in their well-differentiated and normally growing cells. The selectivity of proteasome inhibitors is not solely dependent on proliferative status, as both transformed and normal fibroblasts have similar growth rates although proteasome inhibitors are selectively toxic to SV-40-transformed cells.[243] Cyclins A, B, D and E, cyclin-dependent kinase inhibitors (p21, p27), inhibitory proteins (I-κB), oncogenes (*FOS*, *MYC*), and tumor suppressors (eg, cyclin B1, p21WAF1/CIP1, p27, p53) are known substrates for the ubiquitin–proteasome pathway. The specificity of the ubiquitin proteasome is such that the degradation of individual substrates can be upregulated without affecting the proteolysis of others. Different classes of proteasome inhibitors have been described thus far and include peptide aldehydes (MG132, PSI, LLnV, ALLN, CEP1612, Z-LLF), streptomyces metabolite (lactacystin), dipeptidyl boronic acid bortezomib, vinyl sulfone tripeptides (NLVS), and natural products like Epoxomycin.[244,245]

Proteosome Targeted Agents (Bortezomib)

Bortezomib (pyrazylcarbonyl-Phe-Leu-boronate), the first in this class of agents to enter clinical trials, is a dipeptidyl boronic acid that is a specific and selective inhibitor of the 26S proteasome. The Boron atom interacts reversibly with the catalytic threonine residue of the proteasome, primarily inhibiting its chymotrypsin-like activity.[244] The inhibition of the ubiquitin–proteasome pathway with bortezomib was demonstrated to arrest the growth of malignant cells (breast, colon, prostate tumor cell lines, Burkitt lymphoma, adult T-cell leukemia, Lewis lung carcinoma, CLL, and myeloma cell lines) and sensitize them to chemotherapeutic agents (5-fluorouracil, cisplatin, taxol, doxorubicin, CPT-11, and gemcitabine). Bortezomib mediates these effects through multiple mechanisms by regulating the expression of proteins involved in cell-cycle progression ($P21^{cip1}$, $P27^{Kip1}$), oncogenesis (P53, I-κB), apoptosis (BCL2, BIRC2, BIRC3, BIRC4, BAX), and more recently DNA repair (DNA-PKcs, ATM).[245–247] Loss of I-κB destabilizes NF-κB, reducing expression of a critical plasma cell cytokine stimulatory molecule, IL-6. The process of cell death appears to be p53-independent and to result in mitotic catastrophy although classical caspase 8-dependent apoptosis pathway has also been implicated.[248] A recent study found a strong correlation between immunoglobulin production and apoptotic sensitivity to bortezomib, suggesting that the active requirement for protein folding in the endoplasmic reticulum provides a direct target and explains sensitivity to proteasome inhibition. It also suggests a selective mechanism that could explain the emergence of less differentiated myeloma cells with decreased immunoglobulin production during treatment.[249,250] These processes also increase oxidative stress and contribute to apoptotic signaling, explaining the sensitivity of myeloma plasma cells to proteasome inhibition.[251]

Preclinical Studies With Bortezomib. Screening of the National Cancer Institute (NCI) tumor cell lines revealed that bortezomib is active against a broad range of tumor types. The average growth inhibition of 50% (GI_{50}) value for bortezomib across the entire NCI cell panel (60 human derived cell lines) was 7 nM.[244] Among solid

tumor cell lines, those of the prostate, breast, colon, and pancreas were exquisitely sensitive to proteasomal inhibition. PC-3 prostate carcinoma cells, treated with bortezomib, underwent growth arrest in G2-M phase with a parallel increase in P21 levels and decreased activity but not the levels of CDK-4. Bortezomib treatment also led to caspase activation, PARP cleavage, and apoptotic cell death with an IC_{50} of 20 nM. Bortezomib exhibited synergistic effect when combined in SN-38 and radiation in colon tumor cells and in mouse xenografts. Similarly, pancreatic tumor xenografts were sensitive to the cytotoxic effect of bortezomib, in particular when combined with gemcitabine or CPT-11. Cytotoxic activity was reported as well in Lewis lung carcinoma cells and nasopharyngeal squamous cell carcinoma cells. In most of these studies, increase in the cellular levels of P21WAF1, P27KIP1, P53, and I-κB was observed.[252–256]

In hematologic malignancies, proteasome inhibitors exhibited cytotoxic activity in a wide range of cell lines, including multiple myeloma, U937 human monoblast leukemia, HL-60 promyelocytic leukemia, Jurkat T-cell leukemia, K562 CML, Ramos Burkitt lymphoma, and primary B-cell CLL.[246,257–259] In multiple myeloma cells, bortezomib induced p53 and MDM2 protein expression, induced phosphorylation (Ser15) of p53 protein, and activated JUN NH2-terminal kinase (JNK), which in turn activated caspase 8 and caspase 3. Bortezomib was also shown to activate the intrinsic (mitochondria/cytochrome C/caspase 9) and extrinsic (JNK/death receptor-activated caspase 8) apoptotic pathways of the myeloma cells. Bortezomib blocked TNF-induced NF-κB activation through inhibition of IκB degradation. TNF-induced intracellular adhesion molecule (ICAM)-1 expression on RPMI8226 and MM.1S cells was also inhibited. The unfolded protein response not only is increased in plasma cells producing large quantities of immunoglobulin but also induces a stress apoptosis response.[260] Bortezomib also induces osteoblast activity through the Runx2/Cbfa2 pathway.[261] Furthermore, bortezomib inhibits RANKL-induced osteoclastogenesis through inhibition of P38 kinase.[262] Increased osteoblast activity should help restore the clinical osteoporosis with or without the use of bisphosphonates. Moreover, it prevented the adherence of myeloma cells to bone marrow stromal cells and the NF-κB-dependent production of IL-6. Importantly, bortezomib demonstrated synergistic activity with dexamethasone, thalidomide, melphalan, and doxorubicin, and did not appear to be a substrate for multidrug-resistance transporters.[263–266] However, as shown by Hideshima and colleagues, NF-κB blockade could not account for all of the antimyeloma activity of bortezomib, and clearly other mechanisms contribute to its antineoplastic effects.[266–268] Finally, IC_{50} concentration of bortezomib in myeloma cells had no effect on peripheral blood mononuclear cells from healthy volunteers and did not affect cultured bone marrow stromal cells. This did not preclude the clinical observation of myelosuppression during treatment with bortezomib as a single agent.

Pharmacology of Bortezomib. Bortezomib is primarily metabolized through cytochrome P450 (CYP) and not via phase II pathways, for example, glucuronidation and sulfation. In vitro studies indicated that the primary metabolic pathway is deboronation mediated by CYP3A4. Bortezomib was also metabolized by CYP2D6, but the rate of metabolism was slower than that observed with CYP3A4. Deboronated metabolites have been shown to be inactive in the 20S proteasome assay. Bortezomib rapidly exits the plasma compartment with more than 90% cleared within 15 minutes of IV administration. In whole-body autoradiography of [^{14}C] boretezomib-treated rats, the central nervous system, testes, and eyes appeared to be protected from bortezomib. Bortezomib specifically and selectively inhibits proteasome function by binding tightly ($K_i > 0.6$ nM) and reversibly to the enzyme's chymotrypsin-like site.[242,269] In ex vivo 20S proteasome activity bioassays, proteasome was inhibited within 1 hour of bortezomib administration, and baseline proteasome activity was restored within 48 to 72 hours. Intermittent but high inhibition (>70%) of proteasome activity was better tolerated than sustained inhibition.[270,271] Thus, a twice-weekly clinical dosing regimen is better tolerated. Nonetheless, this dose schedule is often associated with significant myelosuppression and onset of peripheral neuropathy. Reducing the dose schedule to a weekly regimen ameliorates these toxicities and appears to increase patient tolerance without jeopardizing clinical efficacy.

Clinical Studies With Bortezomib. In several phase I clinical studies, antitumor activity was reported in patients with squamous cell carcinoma of the nasopharynx, bronchoalveolar carcinoma, renal cell carcinoma, prostate cancer, NHL, and multiple myeloma.[271,272] Richardson and coworkers reported on the activity of bortezomib in the treatment of relapsed and refractory myeloma patients.[273] In a large multicenter nonrandomized phase II study, 202 patients were treated with a bolus IV infusion of bortezomib (1.3 mg/m^2). Of the 202 patients, 27% achieved a complete or partial response as defined by the Blade criteria; an additional 7% achieved a minimal response. The median time to response was 1.3 months and the median time to progression among patients who achieved a partial or complete response was 13 months. The median survival among all patients was 16 months. In a multivariate analysis, only age and the percentage of plasma cells in the bone marrow at the time of enrollment predicated response to bortezomib. A recent study further defines the safety of using bortezomib in older patients with myeloma.[274] The most common grade 3 to 4 adverse events were thrombocytopenia (31%), fatigue (12%), neuropathy (12%), and neutropenia (14%).[273] The thrombocytopenia, although significant with a mean drop of more than 60%, was rapidly reversible and associated with shorter platelet survival rather than a direct toxic effect on megakaryocytes.[275] The randomized phase III clinical trial compared bortezomib with dexamethasone and concluded that there was a significant advantage for bortezomib-treated patients.[276] A response rate of 38% was seen with a greater than a median 6-month time to progression. A second trial added dexamethasone after two cycles of bortezomib with an overall response rate of 88%.[277] Additional clinical trials have shown the efficacy of bortezomib in multiple myeloma in combination with other cytotoxic agents, including dexamethasone, melphalan, liposomal doxorubicin, lenalidomide, and thalidomide. A recent study showed a significantly prolonged time to disease progression in patients with myeloma who had undergone at least one prior treatment regimen of bortezomib plus liposomal doxorubicin (Doxil) compared to bortezomib alone.[278] The combination of melphalan and bortezomib is well tolerated, with an overall response rate of 68% in pretreated patients.[279] Combining bortezomib, thalidomide, and dexamethasone is also well tolerated, with an overall response rate of 53% in pretreated patients.[280] These combinations are also being explored in other hematologic malignancies (CLL, mantle cell lymphoma, and indolent NHL). In relapsed mantle cell lymphoma, an overall response rate of 33% was noted with a mean time to progression of 9 months.[281]

Newer Proteasome Inhibitors

The success of bortezomib in multiple myeloma and mantle cell lymphoma has stimulated interest in newer-generation proteasome inhibitors such as NPI-0052[282] and PR-171.[283] For example, PR-171 is an irreversible inhibitor of the proteasome and can be administered on a daily × 5 day schedule, potentially yielding more sustained plasma concentrations of the drug. Efforts to define the activity of these second-generation proteasome inhibitors in multiple myeloma and non-Hodgkin lymphoma are currently planned or underway.

Immunomodulatory Agents

Thalidomide and Lenalidomide

These related compounds provide effective therapy for multiple myeloma. They have complex mechanisms of action. Further details on their therapeutic impact are found in the chapter on multiple myeloma.

Thalidomide has been in clinical use for more than 50 years and has well documented and sometimes serious side effects of severe birth defects, somnolence, an axonal length-dependent peripheral neuropathy,[284] orthostatic hypotension, neutropenia, bradycardia

and occasional heart block, and increased HIV load in HIV-positive patients. Thrombosis risk is elevated in patients on either agent, giving rise to the recommended use of an anticoagulant regimen such as low-molecular-weight heparin or coumadin.[285] It is an oral immunomodulatory agent. Experimental studies have identified that thalidomide reduces expression of the cellular inhibitor of apoptosis protein and potentiates proapoptotic processes such as TRAIL/po2L.[286] Thalidomide also reduces NF-κB and I-κB expression, thereby reducing IL-6 expression.[287] In addition, thalidomide decreases VEGF and reduces angiogenesis and vessel density in the marrow of patients with multiple myeloma.[288] The lack of a simple mechanism of action has been confusing in the clinical setting because it is unclear which if any biomarker is an appropriate correlate of clinical success or toxicity. Nonetheless, efficacy is certainly seen clinically and validated in SCID models of human myeloma.[289] Recent data point to its clinical efficacy in solid tumors and myelodysplastic syndrome.

Lenalidomide was identified as an analog of thalidomide with more potent immunomodulatory functions but less side effects, and it has emerged as a more potent agent.[290,291] Both have similar antiangiogenic properties, block IL-6 production, and reduce NF-κB and I-κB levels. Lenalidomide also induces caspase 8-mediated apoptosis, and mitochondrial-mediated cell death. In addition, lenalidomide induces T-cell activation and NK activity, providing some measure of anticancer immune response.[290] It leads to similar and dose-dependent peripheral neuropathy as thalidomide and more significant marrow suppression, both of which are dose limiting. It is also associated with a significant increased risk of thrombosis, leading to recommendations for the use of anticoagulation in this population. Hypersensitivity rash occurs in up to 10% of patients.[292,293] However, a variety of dose schedules provide a flexible therapeutic approach and a high response rate in relapsed settings with an overall response rate of 25% and median overall survival of 28 months.[294] Excellent results with 31 of 34 patients achieving an objective response combining lenalidomide 25 mg/m^2 for 21 days and dexamethasone 40 mg daily for 4 days on days 1, 9, 17, of the 28-day cycle.[295] Ongoing studies are evaluating combination therapy with Doxil,[296] bortezomib, and melphalan.[297] Both thalidomide and lenalidomide are under evaluation for the treatment of primary amyloidosis, MDS, chronic lymphocytic leukemia, and solid tumors. In amyloidosis, the combination of lenalidomide and dexamethasone resulted in a well-tolerated regimen with an overall response rate of 67%, including complete hematologic remissions.[298] Lenalidomide has been approved by the FDA for the treatment of 5q minus myelodysplastic syndrome based on studies indicating more than a 40% response rate owing to the rate of transfusion independence that occurred in this group of patients.[299] In a randomized trial of patients with relapsed or refractory multiple myeloma comparing dexamethasone and lenalidomide to dexamethasone alone, a much higher and sustained response rate of 58% was observed. Effective dose ranges appear to be 5 to 25 mg daily for 21 days on a 4-week cycle, with a range of patient tolerance and adverse reactions that in large part are dose dependent.

TARGETING APOPTOSIS SIGNALING IN HEMATOLOGIC MALIGNANCIES

In humans, the processes of cell division and cell death are tightly coupled so that no net increase in cell numbers occurs. Alterations in the expression or function of the genes that control cell division and cell death can upset this delicate balance, and are hallmarks of cancer, contributing to expansion of neoplastic cells. Although conventional anticancer drugs either cause cell-cycle perturbation or DNA damage, they do not directly interact with the intracellular machinery for apoptosis. Tumor selectivity of such agents is largely caused by the increased sensitivity to apoptosis of tumor cells following DNA damage or cell-cycle perturbation. Novel therapeutic agents or strategies that target critical regulators or effectors of apoptosis are under development and clinical testing, and these agents or strategies have the potential to exert selective cytotoxicity against cancer cells.

Caspases are the "executioners" for apoptosis. These are proteases that exist as inactive zymogens and are activated by proteolytic cleavage of their proforms in response to a variety of death stimuli (explained in the next section). This processing occurs at conserved aspartic acid residues, thus generating the enzymatically active caspases.[300] Caspase activation is organized as a cascade, with upstream initiator and downstream effector caspases.[300] Upstream initiator caspases contain large prodomains that interact with specific proteins involved in triggering the cascade. The downstream caspases, which function as the ultimate effectors of apoptosis, possess small prodomains and are activated predominantly by proteolytic cleavage by upstream caspases. The irreversible cleavage of specific protein death substrates by the downstream effector caspases directly or indirectly accounts for the biochemical and morphologic changes that are recognized as apoptosis.

At least three pathways of caspase activation leading to apoptosis have been elucidated (Fig. 56–8): (a) the receptor-initiated apoptosis pathway, where the TNF family of cytokine receptors activate initiator caspases such as caspase 8; (b) the mitochondria-initiated apoptosis pathway, where cytochrome C and other pro-death effectors are released from mitochondria into cytosol that results in activation of caspase 9; and (c) a pathway of caspase activation, which involves a serine protease, granzyme B, that directly cleaves and activates several caspases, including procaspase 3.

Proapoptotic Targets of Anticancer Agents

Most cancer cells have active antiapoptotic pathways that prevent cell death in response to growth, checkpoint, DNA damage, and metabolic stimuli. A number of current anticancer agents in development target these pathways and are designed to be effective alone or in combination with other agents that disrupt the cell cycle, DNA synthesis, invoke DNA damage, etc.

Death Receptor-Initiated Apoptotic Signaling

Several TNF family receptors are known to transduce signals that result in apoptosis. These include TNFRSF1A (also known as CD120a and previously designated TNFR1), TNFRSF6 (also known as CD95, APO-1, or FAS), TNFRSF25 (also designated TRAMP and known as DR3 or APO3), TNFRSF10A (also known as DR4 or TRAIL-R1), and TNFRSF10B (also known as DR5 or TRAIL-R2). These receptors, also called death receptors, are characterized by the presence of a death domain within their cytoplasmic region, and have been shown to trigger apoptosis upon binding to their cognate ligands or specific agonist antibody.[301] The activating ligands for these death receptors are structurally related molecules that also belong to the TNF gene superfamily such as TNFSF6 (also known as Fas ligand), TNF, and TRAIL.

Ligation of death receptors produces receptor trimerization and formation of death-inducing signaling complex (DISC). This is composed of TNFRSF6, FADD (Fas [TNFRSF6]-associated via death domain), and procaspase 8, an apical signaling complex that mediates receptor-induced apoptosis. FADD binds directly to FasR, TNFRSF10A or TNFRSF10B, and indirectly to TNFRSF1A via TRADD (TNFRSF1A-associated via death domain protein). FADD is essential for cell death signaling from all three receptors. FADD interacts through its C-terminal death domain to cross-link TNFRSF6, TNFRSF10A, or TNFRSF10B receptors and recruits procaspase 8 and procaspase 10, or TRADD, through its N-terminal death effector domain to the DISC (Fig. 56–8). Oligomerization of caspase 8 within the DISC results in a high local concentration of the zymogen. The induced proximity under these crowded conditions generates low levels of intrinsic proteolytic activity of caspase 8, enough to allow the various proenzyme molecules to mutually cleave each other.[302] Processing of caspase 8 removes the DED-

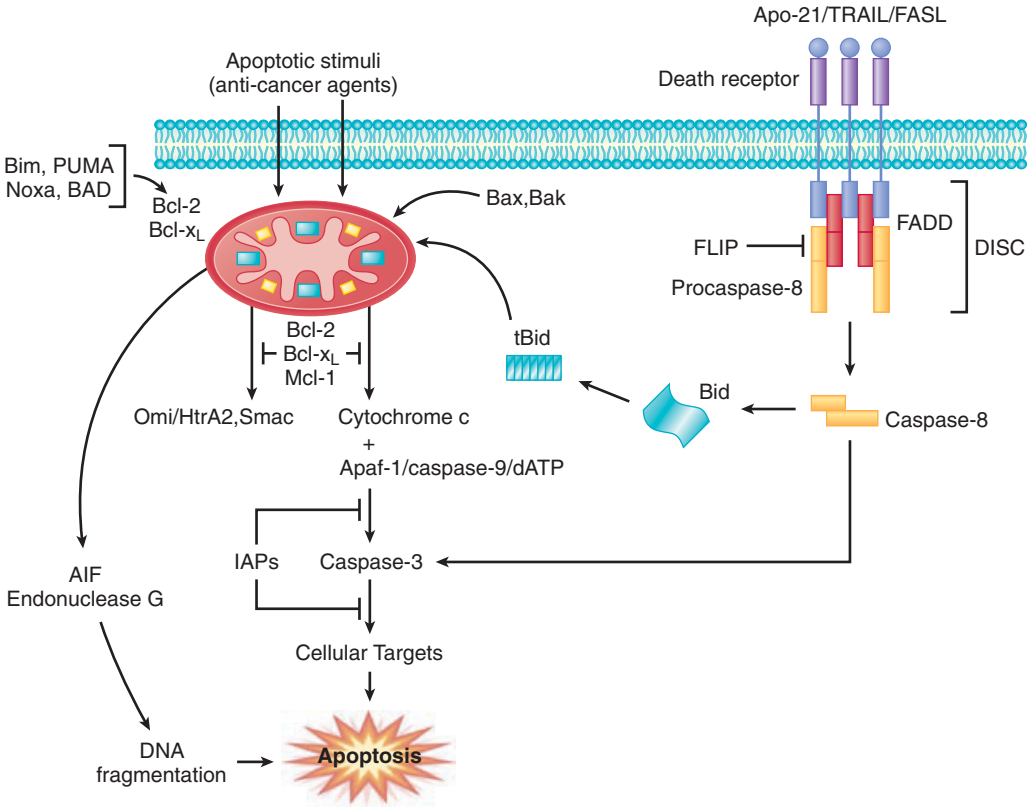

Figure 56–8 Schematic representation of apoptotic pathways.

containing prodomain, thus releasing the activated protease into the cytosol, where it can cleave and activate other downstream procaspases. In certain types of cells (type I), enough caspase 8 is activated by the activation of the death receptor to cause apoptosis. In other cell types, such as hepatocytes (type II), a high level of caspase 8 activation is not achieved and the apoptotic signal is amplified by the mitochondrial pathway.[303] The active caspase 8 cleaves the cytosolic p22Bid into a BH3-only domain containing, proapoptotic, truncated p15 tBid fragment, which translocates to the mitochondria and triggers the release of cyt c into the cytosol.[304] Recently, cleavage by caspase 8 has been shown to cause exposure of a glycine residue on p15Bid that is myristoylated, thereby targeting p15 Bid to the mitochondria.[305] Thus, N-myristoylation acts as an activating switch that enhances tBid-induced release of cyt c and apoptosis. The ability to cleave Bid may not be limited to caspase 8. Other caspases, such as caspase 3, as well another proteases, such as Granzyme B and lysosomal proteases, have been shown to activate Bid.[304] This indicates that Bid probably serves to amplify the caspase cascade rather than to initiate it (Fig. 56–8).

The Fas ligation has also been shown to initiate an alternative pathway to apoptosis, involving activation of c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK).[306,307] After ligation, Fas recruits an adaptor protein called Daxx that interacts with the apoptosis signal-regulating kinase 1 (ASK1), activating the transcription factors AP-1 and ATF-2. Once activated, ASK-1 launches a phosphorylation cascade that culminates in the activation of c-Jun N-terminal kinase (JNK).[308] Activated JNK phosphorylates substrates such as c-Jun, p53, and a pro-death Bcl-2 member Bim.[309] This, in turn, has been shown to trigger the mitochondrial or death-receptor-initiated apoptotic signaling.[310]

Mitochondria-Initiated Apoptotic Signaling

Mitochondria sequester a potent cocktail of proapoptotic proteins. These proteins promote apoptosis either by activating caspases, for example, by cyt c, or by inducing DNA fragmentation, for example, by endonuclease G or apoptosis-inducing factor (AIF), or by neutralizing cytosolic inhibitors of apoptosis or IAPs, for example, by SMAC or Omi/HtrA2.[311,312] On induction of apoptosis, unlike other proapoptotic proteins, mitochondrial AIF translocates to the nucleus to induce DNA fragmentation and apoptosis. Cyt c is a well-known component of the mitochondria electron transfer chain. Cyt c is released from the mitochondria during apoptosis. After release into the cytosol, cyt c binds to Apaf-1 (Apoptosis activating factor), a cytosolic adapter protein that contains a caspase recruitment domain (CARD), a nucleotide-binding domain, and multiple WD-40 repeats. Binding of cyt c to Apaf-1 increases its affinity for dATP or ATP by approximately 10-fold. It also triggers the oligomerization of Apaf-1 into a multimeric Apaf-1/cyt c complex, also called the apoptosome. This exposes the CARD domain of Apaf-1, which recruits several molecules of procaspase 9, inducing their autoactivation. Only the caspase 9 bound to the apoptosome is able to efficiently cleave and activate downstream executioner caspase, caspase 3.

Smac/DIABLO is a 25-kd mitochondrial protein that is released from mitochondria into the cytosol during apoptosis.[313] Smac contains mitochondria-targeting sequence at its N-terminus. This sequence is removed on import into the mitochondria, generating the mature Smac protein. In the mitochondria-initiated and common effector pathways of apoptosis, the processing and proteolytic activity of caspase 9 followed by caspases 3 and 7 are inhibited by the IAP (inhibitor of apoptosis) family of proteins.[314] IAP family members include XIAP, cIAP1, cIAP2, and survivin. All IAPs contain at least one BIR domain, although some contain three. Another region, the RING domain, has ubiquitin ligase activity and promotes the self-degradation of IAPs through the proteasomes in response to some apoptotic stimuli.[315] Furthermore, during Fas death receptor-mediated apoptosis, XIAP is cleaved by activated caspase 3 into the amino-terminal BIR1 and 2 and BIR3-RING finger fragments.[313] BIR3 domain binds and sequesters the monomeric and inactive caspase 9, thereby inhibiting its activation.[316] Overexpression of XIAP inhibits anticancer drug (including Ara-C)-induced caspase activity

and apoptosis.[317] In contrast, downregulation of XIAP sensitizes cancer cells to apoptosis induced by chemotherapeutic drugs.[318] The antiapoptotic activity of NF-κB has also been shown to be mediated by the induction of IAPs.[319] The first four amino acids of the mature Smac, Ala-Val-Pro-Ile (AVPI) binds to the BIR (baculovirus repeat) domain of IAP (inhibitor of apoptosis protein) proteins.[320] The four amino acids (AVPI) of Smac that bind to the BIR3 domain of XIAP are similar to the XIAP-binding sequence of active caspase 9. In addition, Smac has also been shown to form a stable complex with the BIR2 domain of XIAP. Smac binds to the linker-BIR2 domain and presumably disrupts its inhibition of the active caspase 3 and caspase 7 by steric hindrance. On induction of apoptosis, another mitochondrial protein, Omi/HtrA2 (a serine protease), is released from the mitochondria and can induce caspase-independent cell death.[321] Additionally, like Smac, the mature Omi protein contains a conserved IAP-binding motif (AVPS) at its N-terminus. Omi complexes with XIAP at high stoichiometry and promotes apoptosis by neutralizing the caspase-inhibitory effect of XIAP. Recently, Omi has also been shown to process XIAP and promote its proteasomal degredation.[322]

The Bcl-2 family of proteins is divided into three subfamilies.[323] Members of the subfamily that includes Bcl-2, Bcl-x_L, and Mcl-1 inhibit apoptosis (Fig. 56–8). The Bax subfamily members that promote apoptosis including Bax and Bak share with Bcl-2 three of the four Bcl-2 homology domains, BH1 to BH3.[324] A C-terminus hydrophobic tail is responsible for the localization of these proteins to the outer membranes of the mitochondria and endoplasmic reticulum. The third BH3-only subfamily of proteins that includes Bid, Bim, and Bad also promotes apoptosis by binding and inactivating pro-survival Bcl-2 family members.[325,326] The prosurvival Bcl-2 family members, to a variable degree, are bound to the membranes of the mitochondria, endoplasmic reticulum (ER), and the nuclear envelope. Recent studies have shown that, in the event of an apoptotic stimulus, BH3-only proteins require Bax and Bak to trigger mitochondrial apoptotic signaling.[324–326] For example, the exposed BH3 domain of tBid oligomerizes with Bak and Bax, causing their mitochondrial membrane insertion and cyt c release. In response to apoptotic stimuli, Bax and Bak undergo conformational change and form membrane-associated homooligomers, disrupting the outer membrane of the mitochondria and ER and releasing the pro-death molecules into the cytosol. Besides tBid, Humanin peptide has been shown to activate Bax. Bcl-2 can block these events involving Bax activation by titrating tBid or Bim and/or heterodimerization with Bax and preventing mitochondrial permeabilization.[327]

Induction of $P53^{wt}$ in cells triggers apoptosis by transcriptional activation of pro-death effectors, including Bax, Noxa, Puma, Apaf-1 and DR5 and by transcriptional repression of Bcl-2 and IAPs. P53-dependent apoptosis has also been shown to occur in the absence of any gene transcription or translation.[328] In response to apoptotic stimulus such as irradiation, p53 translocates to the mitochondria, where it directly induces permeabilization of the outer membrane by forming complexes with the protective Bcl-2, resulting in the release of cyt c into the cytosol.[329] The E2F transcription factor, normally restrained by the Rb tumor suppressor to inhibit cell proliferation, has been shown to induce apoptosis though p53-dependent and p53-independent mechanisms.[330] These mechanisms include transcriptional activation of ARF (the alternate reading frame product of the INK4a/ARF tumor suppressor locus) or p73 (a member of the p53 family), repression of Mcl-1, and inducing the levels of caspase proenzymes.[331,332]

Selective Antitumor Agents or Strategies

BCL2 Family of Proteins as Targets for Anticancer Drug Design

The antiapoptotic protein BCL2 was originally identified through involvement in the t(14;18) chromosomal translocation found in human follicular lymphoma.[333] Since this elucidation, overexpression of BCL2 has been shown in both hematologic and solid malignancies and mediates resistance to traditional chemotherapeutic agents, radiation, and other antitumor treatments (Table 56–4).[334]

Table 56–4 Effectors of Apoptosis Pathways as Targets for Cancer Therapy

Receptor-Mediated Pathway	Mitochondrial Pathway Targets or Agents
At the death receptors:	Antisense oligos to BCL2 (Genasense)
TNFSF10	BH3 mimetic (peptides)
Anti-DR5 and anti-DR4 Antibodies	BCL2/BCL2L1 small molecule Antagonists
CDDO	Tea polyphenols

Bcl-2 Antisense

Initial efforts to construct antisense deoxyoligonucleotides (ASODN) evolved from Reed.[334] Liposomal antisense Bcl-2 oligonucleotide (Bcl-ASODN) has been shown to cause apoptosis in many types of cancer and leukemia. Bcl-2-ASODN also sensitized tumor cells in vitro and in vivo to chemotherapeutic drugs.[335,336] Thus far the most promising agent to target Bcl-2 is Genasense (oblimersan sodium; G3139), an 18-mer phosphorothioate oligodeoxynucleotide antisense compound. Clinical studies suggest safety and efficacy in solid and hematologic malignancies. In a recent phase III trial, 241 patients were randomly assigned to receive oblimersan 3 mg/kg/day as a 7-day continuous infusion in addition to fludarabine/cyclophosphamide versus fludarabine/cyclophosphamide. This study met its primary objective by demonstrating a significantly superior complete remission or nodular partial remission (CR/nPR) (17% vs 7%; $P = 0.025$); however, no significant differences in overall response rates as well as time to progression were found.[337] Similar results of another phase III study were reported when the addition of oblimersan to high-dose dexamethasone did not improve overall survival or time to progression in myeloma patients.[338]

BH3 Peptide/Mimetics or Bcl-2/Bcl-xL Small-Molecule Antagonists

Another strategy to create Bcl-2 inhibitors has focused on developing small molecules that mimic the action of the endogenous Bcl-2-binding death agonists. Compounds that mimic the BH3-only class of death agonists such as Bad inhibit the survival proteins Bcl-2 and Bcl-x_L but do not appear to have independent proapoptotic activity. Degterev et al identified two classes of novel small molecule cell-permeable inhibitors of the Bcl-x_L-BH3 domain (BH3I). Their studies demonstrated that BH3Is induce apoptosis by preventing BH3 domain-mediated interaction between proapoptotic and antiapoptotic members of Bcl-2 family.[339] Two natural products have been suggested to antagonize the antiapoptotic function of Bcl-2 or Bcl-x_L. Tetrocarcin A was reported to inhibit mitochondrial functions of Bcl-2 and suppress its antiapoptotic activity.[340] In another report, Antimycin-A was shown to mimic activity of BH3 peptides and selectively induce apoptosis in cell lines overexpressing Bcl-x_L.[341] Certain green tea catechins and black tea theaflavins were identified as potent inhibitors (K_i in the nanomolar range) of the antiapoptotic Bcl-2 family of proteins.[342] On the basis of the high-resolution three-dimensional structure of the target receptor, small organic molecules that bind to this interface have been designed. One of the newly designed BH3 mimetics, ABT-737, binds to Bcl-2, Bcl-xL, and Bcl-w with high affinity ($K_i < 1$ nM) but not to Mcl-1.[343] Preclinical data demonstrate cytotoxic activity in B lymphoid tumor cell lines, human follicular lymphoma, myeloma, and CLL as well as synergism with other chemotherapy agents.[343,344] Also, ABT-737 effectively kills

AML blast, progenitor, and stem cells without disturbing normal hematopoietic cell development.[345] Obatoclax (GX15-070) has demonstrated binding to multiple antiapoptotic Bcl-2 members including Mcl-1.[346] As a single agent, GX15-070, induces cytotoxic responses against patient-derived myeloma cells. Combination studies with melphalan, dexamethasone, and bortezomib have also shown promise in myeloma and mantle cell lymphoma cell lines.[346,347]

Apo-2L/TRAIL

Although TRAIL is a member of the TNF family, differences exist between TRAIL and other major death ligands, including TNF-α and FasL. Unlike Fas, whose expression is limited to certain tissues, TRAIL receptors are widely expressed. In a study by LeBlanc and Ashkenazi, soluble TRAIL induced apoptosis in a variety of leukemia and solid tumor cell types.[302] In contrast, normal tissues including prostate, colon, fibroblasts, and smooth muscle cells were unaffected by exposure to TRAIL; however, TNF or FasL induced fulminant liver damage. Also, in vivo studies indicate that TRAIL interacts synergistically with both chemotherapy and radiation, as well as inducing apoptosis regardless of p53 status.[302]

Clinical Studies

In two phase I clinical studies, PRO1762 (rhApo2L) demonstrated antitumor activity in both solid and hematologic malignancies. Patients received PRO1762 for 5 consecutive days every 3 weeks up to 8 cycles at doses of 0.5 to 15 mg/kg. Following 586 administered doses, no dose-limiting toxicities or clearly attributable toxicities have been noted. In 32 of 51 patients, posttreatment tumor assessment was reported to show 17 (53%) with stable disease and 13 (41%) with progression. Maximum concentrations (C_{max}) achieved at doses greater than 4 mg/kg were equivalent or greater to preclinical models. Hepatic metastases did not appear to influence pharmacokinetics. Enrollment continues for further dose optimization.[348,349]

Anti-DR5 or Anti-DR Receptor Antibodies

Evidence suggests that decoy receptors TRAIL-3 and TRAIL-4 interfere with TRAIL-induced apoptosis, leading to proliferation and survival signals.[350] Therefore, specific targeting of DR4 and DR5 with a specific agonistic antibody may have an advantage as a result of selective binding and activation of death receptors without interaction of decoy receptors. Three fully human monoclonal antibodies are under development: HGS-ETR1 (mapatumumab; anti-DR4), HGS-ETR2 (anti-DR5), and HGS-TR2J (anti-DR5).[351]

Clinical Studies

In one phase II study, 40 patients with relapsed or refractory NHL received HGS-ETR1 divided into two treatment groups: 3 mg/kg every 21 days (8 patients) or 10 mg/kg (32 patients) every 21 days for 6 cycles.[352] All three patients with follicular lymphoma had a clinical response (1 CR, 2 PR). Additionally, 12 of 40 patients (30%) had stable disease, whereas the remainder had progressive disease at the time of first evaluation. Patients tolerated therapy well with no reported discontinuations due to drug toxicity. Results of two phase I studies administering HGS-ETR2 in solid malignancies have been presented, HGS-TR2J is currently being evaluated in phase I trials.

Neutralization of IAPs by Smac Mimics

The N-terminal tetra- or heptapeptide in Smac reverses inhibition of caspase 9 by XIAP. It also promotes the proteolytic activation of procaspase 3 and the enzymatic activity of mature caspase 3.[353] Consistent with this, human acute leukemia cells show that the ectopic overexpression of the full-length Smac or treatment with N-terminus Smac tetrapeptide enhances Apo-2L/TRAIL-induced effector caspase activity and apoptosis.[354] A recent report demonstrated that Bax-dependent release of Smac, not cyt c from mitochondria, mediates the mitochondrial involvement in Apo-2L/TRAIL-induced apoptosis.[355] These findings suggest that the cytosolic Smac or its N-terminus peptide may bypass Bcl-2 or Bcl-x_L inhibition and promote caspase 3 activation by Apo-2L/TRAIL. Low-molecular-weight Smac mimetic compounds with high affinity for the BIR3 domain of IAPs have been developed.[284,356] In human myeloma xenograft models, a novel Smac mimetic, LBW242, inhibits tumor growth even in the presence of myeloma growth factors such as IL-6 and IGF-1.[357] Like Smac, Omi (through its N-terminal AVPS motif) binds and neutralizes XIAP, thereby potentiating the caspase-dependent pathway of apoptosis. Omi has also been shown to induce cell death via its serine protease activity, independent of caspases Apaf-1 or IAPs.[322] Hence, treatment with Omi peptide may be effective against tumors in which Apaf-1 is not expressed because of promoter-based hypermethylation and gene silencing. A second- generation ASODN (AEG35156/GEM460) against XIAP has demonstrated significant antitumor activity and is currently in phase I studies in combination with cytarabine/idarubicin in the treatment of leukemia.[358]

Survivin

Survivin is a 16-kd protein that contains a single BIR domain, followed by a C-terminal, long α-helical region that is required for its binding to the microtubules in the mitotic spindle. Survivin is phosphorylated on Thr34 by CDK1-cyclin B1, and survivin levels and activity increase during G_2/M phase in a cell-cycle-dependent manner. Overexpression of survivin inhibits caspase activity and apoptosis induced by Fas, Bax, and anticancer drugs.[359] Overexpression of survivin has been shown in various cancers and is not expressed in normal terminally differentiated tissue. Survivin expression has also been correlated with poor clinical outcome in AML and other cancers.[360] These observations have made survivin an attractive target for new therapies. The first targeted antagonist of survivin was an ASODN reported in 1999.[361] Preclinical data of ASODN (LY2181308) has demonstrated caspase 3-dependent apoptosis, cell-cycle arrest at G2/M, and sensitization to chemotherapy-induced apoptosis.[361–363] Owing to these encouraging results, phase I clinical studies have been started for LY2181308. In addition to ASODN, other therapeutic strategies that target survivin include gene therapy, siRNA, hammerhead ribozymes, gene therapy, and immunotherapy.[364]

Cyclin-Dependent Kinase Inhibitors as Therapeutic Targets

Orderly progression through the cell cycle is regulated by the coordinate expression of a variety of genes and proteins. In a commonly accepted model of cell-cycle regulation, the decision of a cell to progress through the cell cycle is determined by the activity of cyclins, levels of which fluctuate throughout the cell-cycle traverse, cyclin-dependent kinases (eg, CDKs 1-9), and several endogenous small molecule CDK inhibitors (eg, $p21^{CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$) (see Fig. 56–1). In general, CDK1, in association with cyclins A and B, is involved in G_2M progression, whereas CDK2, CDK4, and CDK6, in association with A, D, and E, are involved in G_1S progression.[365] Activation of CDKs results in phosphorylation of the retinoblastoma protein (PRB), which leads to its dissociation from the E2F transcription factor. Once freed, E2F triggers the transcription of diverse genes involved in cell-cycle progression (thymidylate synthase and dihydrofolate reductase, among numerous others).[366] Endogenous small-molecule inhibitors such as $P21^{CIP1}$ and $P27^{KIP1}$ bind stoichiometrically to CDKs and inhibit their activity.[367] Activity of CDKs can also be regulated through inhibitory phosphorylations of these proteins (eg, on threonine 14 or tyrosine 15 residues) or, conversely, activating

phosphorylations on threonine 160 or 161 (mediated by CDK5 or cyclin-dependent activating kinase [CAK]). Interference with the activation of CDKs results in dephosphorylation of PRB, leading in turn to binding and inactivation of E2F and inhibition of cell-cycle progression.

Cell-cycle dysregulation is a cardinal characteristic of cancer in general,[368] and hematopoietic malignancies in particular. A classic example of this phenomenon is the regular association of increased expression of cyclin D_1 in mantle cell lymphoma.[369] Regulation of the cell cycle has been found to be closely related to apoptosis. Disruption of the cell-cycle traverse has been shown to be a potent cell death stimulus in a wide variety of neoplastic cell types, including those of hematopoietic origin. A corollary of this observation is that agents that interfere with the cell cycle, in addition to blocking cell-cycle progression, can be potent inducers of programmed cell death. For these reasons, inhibitors of the cell cycle have become logical targets for therapeutic intervention in hematologic and other malignancies. Cell-cycle inhibitors can be subdivided into several categories. For example, they can act directly, as in the case of CDK inhibitors, or indirectly, as in the case of histone deacetylase inhibitors, compounds that block cell-cycle progression by inducing endogenous cell-cycle inhibitors such as $P21^{CIP1}$ The latter agents are discussed later in this chapter. CDK inhibitors can also be classified as specific (ie, directed against a particular CDK, such as CDK2) or those that nonspecifically inhibit most CDKs (eg, flavopiridol). The development of cell-cycle inhibitors has primarily focused on CDK inhibitors, several of which have entered clinical trials in humans, including those involving hematopoietic malignancies. A brief summary of the status of CDK inhibitors, with an emphasis on hematologic malignancies, follows.

Flavopiridol

Flavopiridol (L86-8275) is a semisynthetic flavonoid derived from the Indian plant *rohitukine*. It was the first CDK inhibitor to enter clinical trials in humans.[370] Flavopiridol binds to the ATP-binding site of CDKs, resulting in reversible, competitive enzyme inhibition at concentrations of less than 100 nM. As noted earlier, flavopiridol is a relatively nonspecific CDK inhibitor and inhibits all CDKs, although it is less effective against CDK7. Flavopiridol induces G_1S or G_2M arrest, presumably a consequence of inhibition of CDK1 and CDK2.[371] flavopiridol may also act to block cell-cycle progression by downregulating cyclin D_1 levels or by inhibiting the CDK-activating complex (CDK7), or both.

In addition to blocking cell-cycle progression, flavopiridol has been shown to be a potent inducer of apoptosis in malignant hematopoietic cells (eg, acute and chronic leukemia) at low concentrations (eg, u100 nM).[372] Moreover, flavopiridol has shown activity against a variety of multiple myeloma cell types in vitro.

Recently, the proapoptotic actions of flavopiridol have been attributed to its capacity to inhibit the positive transcription elongation factor-β (PTEF-β), cyclin T/CDK9 complex by inhibiting phosphorylation of the carboxy-terminal domain of RNA polymerase II.[373] This leads to downregulation of several antiapoptotic proteins, including BIRC4, $P_{21}{}^{CIP1}$, and, in the case of multiple myeloma cells, Mcl-1.[374] flavopiridol has also recently been shown to block the antiapoptotic actions of the IAP family member survivin.[375]

In clinical studies, flavopiridol was initially administered as a 72-hour continuous infusion every 2 weeks, with a maximally tolerated dose of 40 mg/m^2. Steady-state plasma levels in excess of those necessary to inhibit CDKs and induce apoptosis in leukemia cells (eg, 350 nM) were achieved.[376] Dose-limiting toxicities were fatigue, diarrhea, nausea, and myelosuppression. However, the occurrence of thromboembolic phenomena and the general lack of single-agent activity have limited enthusiasm for administering flavopiridol by this schedule. More recently, flavopiridol has been administered as a daily IV bolus for 1, 3, or 5 days every 3 weeks with manageable toxicity, and other schedules are being examined,[377] including a hybrid schedule with half the dose administered as an IV bolus and the other half as a more prolonged infusion. When administered as a daily bolus infusion for 3 days every 3 weeks, flavopiridol exhibited modest activity in patients with mantle-cell lymphoma.[378] Very recently, a novel pharmacologically directed schedule of flavopiridol has been developed in which half of the dose (eg, 30 mg/m^2) is administered as a 30-minute bolus loading infusion and 30 mg/m^2 as a 4-hour infusion.[379] In a phase I study, objective response rates of 45% were obtained with this schedule in patients with progressive CLL, including some with high-risk disease. Because of the rapidity of response, particularly in patients with high white blood cell counts, aggressive measures designed to avoid tumor lysis syndrome (eg, hydration, alkalinization of the urine, administration of rasburicase) is advisable. Efforts are now underway to employ this novel flavopiridol schedule in combination with other agents, and in other hematologic malignancies.

Because of limited single-agent activity, combination regimens involving flavopiridol are being explored in hematologic malignancies. On the basis of preclinical evidence of synergism with the antimetabolite ara-C, a regimen combining flavopiridol on a daily IV bolus schedule followed by high-dose ara-C has been initiated in patients with acute leukemia and has shown some activity.[380] In a successive phase II study, flavopiridol was administered as a 1-hour bolus infusion of 50 mg/m^2 daily × 3 days prior to administration of high-dose ara-C (day 6) and mitoxantrone (day 9). Complete response rates of more than 50% were obtained in patients with high-risk AML.[381] More recently, evidence of synergism between flavopiridol and other signal transduction modulators has become the focus of considerable attention. For example, the observation that flavopiridol interacts synergistically with imatinib mesylate in CML cells, including some that are imatinib mesylate resistant,[207] has prompted the initiation of a phase I trial of flavopiridol and imatinib mesylate in patients with progressive BCR-ABL$^+$ hematologic malignancies. Evidence that flavopiridol interacts synergistically with histone deacetylase and proteasome inhibitors in human leukemia cells has appeared,[382,383] and clinical trials combining flavopiridol with the histone deacetylase inhibitor vorinostat or the proteasome inhibitor bortezomib in patients with refractory AML/MDS and multiple myeloma/indolent non-Hodgkin lymphoma are currently underway.

UCN-01

UCN-01 (7-hydroxystaurosporine) was originally developed as a selective PKC inhibitor but was subsequently shown to exert multiple other activities that may be more closely related to its antiproliferative and lethal effects. For example, UCN-01 broadly inhibits CDKs at submicromolar concentrations and arrests cells in G_1S.[384] Recently, UCN-01 has been shown to be a potent inhibitor of the CHEK1 (also known as CHK1) kinase at low (eg, <100 nM) concentrations[385] and as a result an abrogator of both the G_2M and G_1S checkpoints.[163,386] By inhibiting CHEK1, UCN-01 blocks phosphorylation of the cd25C phosphatase, thereby sparing it from proteasomal degradation. This leads in turn to activation of p34cdc2 as a consequence of inhibition of an inhibitory phosphorylation on tyrosine 15.[387] More recently, UCN-01 has been found to be an inhibitor of the PDK1 and AKT kinases,[388] important components of a pathway that exerts multiple antiapoptotic functions.

In preclinical studies, UCN-01 has been shown to induce apoptosis in both myeloid and lymphoid leukemia cells through a process associated with activation of CDK1 and CDK2. In addition, UCN-01 interacts synergistically with various DNA-damaging agents in both hematopoietic and nonhematopoietic cells. For example, antileukemic synergism between UCN-01 and ara-C or fludarabine has been observed in several human leukemia cell lines.[367–369] An interesting recent development is the finding that exposure of human hematopoietic cells to UCN-01 results in activation of the MEK1/2/ERK1/2 pathway, and that inhibition of this process (eg, by pharmacologic MEK inhibitors) results in a dramatic increase in apoptosis. For example, highly synergistic interactions between the MEK inhibitor

PD184352 (CI-1040) and UCN-01 have been observed in human leukemic and myeloma cells.[389,390] Antileukemic synergism between UCN-01 and the HSPCA (also known as Hsp90) antagonist 17-AAG has also been reported.[391]

Initial clinical trials of UCN-01 involved a 72-hour continuous infusion schedule every 2 weeks. Dose-limiting toxicities included nausea, vomiting, hypotension, hyperglycemia, and pulmonary toxicity. The recommended phase II dose was 37 to 42 mg/m^2/day for this schedule.[392] Unexpectedly, UCN-01 was found to have an extremely long half-life owing to prolonged binding to plasma 1 acidic glycoprotein. Nevertheless, free UCN-01 levels were achievable that exceeded those necessary to inhibit CHEK1 (eg, 75–100 nM). Subsequently, the regimen was modified so that following the first dose, subsequent doses were administered for 36 rather than 72 hours. To date, single-agent UCN-01 has shown some activity in patients with NHL.[393] More recently, a 3-hour infusional schedule has shown promise in maintaining high plasma levels of free UCN-01.[394]

In view of evidence of synergism between UCN-01 and DNA-damaging agents, several combination regimens are currently undergoing evaluation in patients with hematologic malignancies. A phase I trial of UCN-01 and ara-C was initiated in patients with refractory acute leukemia but was placed on hold secondary to the occurrence of cardiovascular toxicity. Trials combining UCN-01 with either gemcitabine or fludarabine are currently ongoing in patients with lymphoid malignancies (eg, CLL and NHL). Based in part on preclinical evidence of synergism,[395] a trial of UCN-01 and perifosine in patients with refractory leukemia has been initiated. Finally, newer Chk1 inhibitors (eg, AZD7762) with potentially superior pharmacokinetic characteristics than UCN-01 have recently entered the clinic.

CYC202

Roscovitine is a purine analog CDK inhibitor that is primarily active against CDK1, CDK2, and CDK5.[396] CYC202 is the R-enantiomer of roscovitine. In preclinical studies, CYC202 was found to induce cell-cycle arrest (in G1) and apoptosis in several tumor types. It also displayed significant activity in a human colorectal carcinoma xenograft model.[397] In malignant hematopoietic cells (ie, multiple myeloma), CYC202 lethality has been closely correlated with Mcl-1 downregulation via a transcriptional mechanism.[398]

Phase I trials of CYC202 have recently been initiated in humans. Two schedules have been examined: (a) daily by mouth for 7 days, repeating every 21 days, and (b) twice daily for 5 days, repeating every 21 days, with the duration of administration increasing in the second phase of the trial. Toxicities for both schedules include nausea, vomiting, skin rashes, and hypokalemia. Maximum tolerated doses have not yet been reached.[399,400] Very recently, a schedule of CYC202 twice daily × 7 days every 21 days has been shown to be tolerable.[401]

Currently, little information is available at either the preclinical or clinical level concerning the activity of CYC202 in hematologic malignancies. However, given the susceptibility of malignant hematopoietic cells to CDK inhibitor-mediated apoptosis, a possible role for CYC202 in malignant hematopoietic disorders warrants further investigation.

BMS 387032

BMS 387032 is a small-molecule CDK inhibitor discovered through high-throughput screening that is primarily active against CDK2.[402] In preclinical studies, BMS 387032 has shown potent antiproliferative activity against ovarian and breast cancer cells in vitro.[403] As is the case with other CDK inhibitors, BMS 387032 induces cell-cycle arrest, PRB dephosphorylation, and, under some circumstances, apoptosis. One issue that will have to be addressed in the case of BMS 387032 is the implications of findings suggesting that at least in some tumor cell lines, CDK2 may be dispensable for cell-cycle progression.[404]

Several phase I trials of BMS 387032 have been initiated. BMS 387032 has been administered as either a 24-hour or 1-hour infusion every 3 weeks.[405,406] Dose levels of 4 to 59 mg/m^2 have proved to be tolerable; the maximum tolerated dose for either of these schedules has not been reached. Toxicities have been mild and include rash, nausea and vomiting, diarrhea, and fatigue. A limited number of responses have been noted in patients with solid tumors, and combination trials are planned for the future.

As in the case of CYC202, the activity of BMS 387032 in hematologic malignancies has not yet been established. Nevertheless, based on the theoretical considerations cited earlier, BMS 387032 deserves evaluation in these disorders.

Farnesyltransferase Inhibitors

RAS proteins represent low-molecular-weight proteins that bind GTP and are located at the cell membrane. They are critically involved in the regulation of signal transduction pathways implicated in the control of cell proliferation, differentiation, and survival.[407] One of the key effectors of RAS proteins is the serine-threonine kinase RAF1, which is recruited to the cell membrane by activated RAS, and in turn activates the survival/proliferation-associated kinases MEK1/2 (mitogen-activated kinase 1/2) and ERK (extracellular signal-regulating kinase).[408] RAS is also involved in regulation of the AKT pathway, which exerts multiple antiapoptotic functions.[409]

There are four separate RAS proteins: H-RAS, N-RAS, K-RAS4A, and K-RAS4B. Of these, H-RAS mutations are most commonly encountered in hematopoietic malignancies (ie, myeloid leukemia).[409] Because of the frequency of RAS mutations in human neoplasia and the importance of RAS downstream targets (eg, RAF1/MEK/ERK and AKT) in the survival of neoplastic cells, the RAS pathway has become a logical target for therapeutic intervention.

To function, Ras must be localized to the cell membrane. This in turn requires posttranslational modifications of the RAS protein, most notably farnesylation. This primarily involves addition of a 15-carbon isoprenoid farnesol to the C terminus of RAS following recognition of a CAAX motif. This process is catalyzed by the enzyme farnesyl transferase. Inhibitors of farnesyl transferase (FTIs) thus block RAS farnesylation, preventing the protein from associating with the plasma membrane and subsequently participating in downstream signaling events.[410]

Initial preclinical studies suggested that FTIs inhibited the proliferation and survival of several tumors driven by RAS mutations. However, it soon became clear that tumors with H-RAS mutations were more sensitive to FTIs than those with N-Ras or K-RAS mutations.[375] Furthermore, the antiproliferative effects of FTIs did not always correlate well with their effects on RAS farnesylation or the presence of Ras mutations. Two possible explanations may account for these findings. First, alternative prenylation events, for example, geranyl-geranylation of the RAS protein may also promote its membrane localization, particularly in cells bearing N-RAS or K-RAS mutations, and could theoretically confer resistance to FTI lethality. Second, several other non-RAS candidate proteins have been identified in which interference with farnesylation might contribute to FTI-associated lethality. These include small GTPases (eg, RHO family members) and a variety of nuclear proteins (eg, CENP-E and CENP-F).[411]

To date, four FTIs have undergone extensive clinical evaluation: R115777, BMS-214662, L-778, 123, and SCH 66336.

R115777

R115777 (Zarnestra) is an orally active FTI that has undergone extensive evaluation in patients with solid tumors and hematologic malignancies. In patients with hematologic malignancies, the generally accepted dose and schedule is 600 mg/m^2 orally twice daily for

21 days repeated at monthly intervals or for 28 days repeated at 6-week intervals. Dose-limiting toxicities include myelosuppression, nausea, vomiting, diarrhea, rash, neurotoxicity, and fatigue. In a series of phase I and II studies, promising activity has been observed in patients with AML, ALL, CML, and myelodysplastic syndrome. For example, in one study, 6 of 22 patients with CML achieved complete or partial responses, and 2 of 8 patients with myelofibrosis achieved objective responses.[412] In a phase I trial of R115777 in patients with refractory or high-risk acute leukemia, an overall response rate of 29% was achieved.[413] Responses in patients with multiple myeloma have also been seen but have been modest.[414] Interestingly, blasts obtained from a number of leukemic patients who responded did not exhibit RAS mutations, suggesting that the lethal effects of R115777 may proceed, at least in part, through RAS-independent pathways.[414] On the basis of these promising initial results, several combination regimens involving R115777 in patients with hematologic malignancies are under development.

SCH 66336

SCH 66336 (lonafarib) is an orally active tricyclic FTI that inhibits farnesyltransferase at concentrations in the low nM range. In preclinical studies, it has demonstrated significant activity against a variety of solid tumor types, particularly those driven by H-RAS.[415] However, it has also shown preclinical activity in CML and ALL model systems.[416,417] Several phase I trials of SCH 66336 have been carried out in patients with solid tumor and hematologic malignancies. The maximally tolerated dose appears to be 200 to 300 mg/m^2 twice daily with nausea, vomiting, diarrhea, fatigue, and renal dysfunction representing the dose-limiting toxicities. Clinical responses were observed in 6 of 16 patients with CML, advanced myelodysplastic syndrome, CMML, AML, and ALL.[418] In phase II studies involving a schedule of 200 mg/m^2 twice daily, responses were observed in patients with MDS and high-risk AML.[419]

One particularly exciting development is the discovery that SCH 66336 interacts synergistically with the BCR/ABL kinase inhibitor imatinib mesylate to induce apoptosis in BCR/ABL$^+$ cells.[210] On the basis of such findings, a clinical trial has been initiated in which SCH 66336 is combined with imatinib mesylate in patients with progressive BCR/ABL$^+$ hematologic malignancies.

BMS-214662

BMS-214662 is a parenterally administered FTI that demonstrated impressive preclinical activity against a panel of solid tumor cell types, particularly those bearing H-RAS mutations.[420] In studies involving hematologic malignancies, the maximally tolerated dose was 118 mg/m^2 administered weekly.[421] Dose-limiting toxicities are similar to those of other FTIs. In one trial, reduction in the percentage of bone marrow blasts to less than 5% was observed in 18% of patients.[422] Interestingly, as in the case of R115777, responses have been noted in patients whose cells lacked RAS mutations.

Inhibitors of the RAF1/MEK/ERK Pathway

The MAPK (mitogen-activated protein kinase) pathways consist of three parallel serine-threonine kinase modules that are intimately involved in the control of cell survival, proliferation, and differentiation. Two of these, JUN N-terminal kinase (JNK) and p38 MAPK, are activated in response to environmental stresses including DNA damage and osmotic stress, whereas p42/44 MAPK (also known as ERK; extracellular signal-regulating kinase) is primarily induced by growth factors and other mitogenic stimuli.[423] Although exceptions exist, JNK and p38 MAPK primarily exert proapoptotic functions, whereas ERK activation is generally associated with cell survival.[424] The only well-defined activator of ERK is the serine-threonine kinase MEK1/2 (mitogen-activated protein kinase kinase 1/2), whereas numerous ERK targets have been identified, including ELK-1, CREB, BCL2, Bad, FRAP1 (also known as mTOR), and caspase 9 among numerous others. The activating effects of MEK1/2 on ERK are opposed by phosphatases that dephosphorylate and inactivate the enzyme (eg, MAP kinase phosphatase 1/2 [MKP1/2]).[425]

The major activator of MEK1/2 is the serine-threonine kinase RAF, of which three forms exist: RAF1, B-RAF, and A-RAF. RAF can be activated by Ras (discussed earlier) as well as through various RAS-independent pathways, including PKC, KSR, as well as the SRC and JAK family of kinases among others.[426] The activation of RAF involves several processes, including recruitment to the plasma membrane, phosphorylation on serine and threonine residues, and dimerization. Interference with any of these processes can lead to inhibition of Raf activation as well as downstream targets.

Dysregulation of the RAF/MEK/ERK pathway has been observed in most hematopoietic malignancies, including acute leukemia, CLL, multiple myeloma, and lymphomas.[408,427] Consequently, there has been considerable interest in the development of pharmacologic inhibitors of the RAF/MEK/ERK pathway in these disorders. In addition to their potential intrinsic activity against malignant hematopoietic cells, there is evidence that such agents might also enhance the activity of conventional cytotoxic drugs.

Raf Inhibitors

Initial approaches to RAF inhibition focused on efforts to destabilize the protein. For example, geldanamycin and the related compound 17-AAG act as inhibitors of HSPCA, a chaperone protein necessary for Raf processing and stabilization. Interference with HSPCA results in destabilization and proteasomal degradation of RAF as well as numerous other proteins, including AKT.[428] Interestingly, mutant kinases appear to be particularly sensitive to 17-AAG-mediated degradation. For example, 17-AAG has been shown to be a highly effective inducer of BCR/ABL degradation and of induction of apoptosis in BCR/ABL$^+$ leukemic cells.[429] There have also been suggestions that 17-AAG-mediated Raf downregulation may contribute to lethality in such cells.[430] Based on these and other data, clinical trials combining 17-AAG and imatinib have been initiated in patients with refractory/progressive CML and related malignancies.

Oxime derivatives KF25706 and KF58333 also disrupt the RAF pathway through a mechanism similar to that of 17-AAG and geldanamycin, that is, destabilization of the RAF protein.[431] More recently, however, a Raf kinase inhibitor, BAY43-9006 (sorafenib), has been developed and has entered phase I and II clinical trials in humans.[432–434] Whether this compound, which has recently been approved for the treatment of renal cell carcinoma, acts primarily or solely as an RAF inhibitor is unclear, and its activity has been ascribed to "off-target actions," including inhibition of VEGF. In preclinical studies, induction of leukemic cell death by sorafenib has been shown to stem from inhibition of translation and downregulation of the short-lived antiapoptotic protein Mcl-1[435] and induction of endoplasmic reticulum stress.[436] Whether sorafenib will display significant activity in hematopoietic malignancies, either alone or in combination with other agents, remains to be determined. Phase II trials of sorafenib in chronic and acute leukemias, and in non-Hodgkin lymphoma are currently underway.

MEK1/2 Inhibitors

Several MEK1/2 inhibitors have been evaluated and have now entered clinical trials. The first of the MEK1/2 inhibitors to be developed was PD98059, a compound that binds to MEK1 and blocks its phosphorylation. PD98059 does not compete with ATP for binding to the enzyme. In preclinical studies, PD98059 has been shown to inhibit the proliferation of and induce apoptosis in leukemia and other malignant hematopoietic cell types.[437] Another MEK inhibitor is U0126, a compound whose mode of action appears to be similar to that of PD98059.[409,438]

Because these agents exhibit limited solubility, attempts have been made to develop alternative MEK1/2 inhibitors suitable for in vivo administration. One such agent, PD184352, has shown activity against human colon cancer cells in a murine xenograft model.[439] Phase I trials of PD184352 (designated CI-1040) have been initiated. However, CI-1040 has now been supplanted by other non-ATP competitive MEK1/2 inhibitors with superior pharmacokinetic characteristics, including PD325901 and AZD6244.[440] AZD6244 has recently shown activity in a multiple myeloma xenograft model.[441]

In addition to exerting antiproliferative effects toward human leukemia cells, MEK inhibitors also increase the lethality of conventional cytotoxic agents (eg, ara-C), resulting in synergistic interactions.[442] One particularly interesting finding is that MEK1/2 inhibitors appear to be very effective in enhancing the antileukemic potential of several novel molecularly targeted agents. For example, PD184352 has been shown to interact synergistically with imatinib in BCR/ABL$^+$ cells, including those resistant to imatinib as a result of increased BCR/ABL expression.[206] Similar findings have recently been observed in the case of the second-generation Bcr/Abl kinase inhibitor dasatinib.[437] In addition, as noted earlier, synergistic interactions between PD184352 and UCN-01 have been reported in human leukemia and myeloma cells,[383,390] and MEK1/2 inhibitors have been found to potentiate the antileukemic activity of small-molecule Bcl-2 antagonists.[437] Collectively, these findings raise the possibility that the ultimate role of MEK1/2 inhibitors in hematologic malignancies may be to enhance the activity of other targeted agents.

PI3K/AKT Inhibitors

The phosphoinositide-3 kinase (PI3K) /AKT (PKB) pathway is involved in the regulation of diverse cellular functions including cell growth, protein synthesis, cell-cycle regulation, glucose metabolism, and motility. PI3K catalyzes the conversion of phosphatidylinositol diphosphate to phosphatidylinositol triphosphate, which activates, through PDK1, the phosphorylation and activation of AKT.[443] The dual-specific phosphatase PTEN opposes the actions of PI3K, and is mutated in many cancers.[444] Activation of AKT signals to multiple downstream targets, generally resulting in prosurvival actions. Targets of AKT involve proteins involved in cell survival (eg, Bad, procaspase 9, CREB, forkhead transcription factors [FHKR], IB), cell-cycle regulation ($p21^{CIP1}$, $p27^{KIP1}$, cyclin D_1), glycogen synthesis (GSK3), and protein synthesis (FRAP1, $p70^{S6K}$).[445] Because of the frequency of PTEN mutations in transformed cells and the dependence of numerous cancers on an intact PI3K/AKT pathway for survival, the PI3K/AKT cascade has become an attractive target for therapeutic intervention.

There is evidence that dysregulation of the PI3K/AKT pathway is a key proliferative pathway in hematopoietic malignancies. For example, the fusion protein nucleophosmin/anaplastic large cell lymphoma (NP-ALK) constitutively activates the PI3K/AKT cascade and has been shown to play a functional role in NP-ALK-related transformation.[446] In addition, inhibitors of PI3K have been shown to be potent inducers of apoptosis in human leukemia and other malignant hematopoietic cells.

PI3K Inhibitors

The most widely used pharmacologic inhibitors of PI3K are the fungal metabolite wortmannin and the flavonoid derivative LY294002.[447] Both inhibit the ATP-binding site of PI3K and interfere with its activity at submicromolar concentrations. These agents are not completely specific for PI3K, however, and variably inhibit other kinases, for example, DNA-PK. Although these agents have shown in vitro and in vivo activity in preclinical model systems, including leukemia, poor pharmacokinetic properties and a relative lack of selectivity have limited their therapeutic potential. However, derivatives of these compounds are currently under development and may eventually prove to be of use in hematopoietic malignancies. For example, PI3K inhibitors such as PX-866 are either in or will shortly enter clinical trials.[448]

AKT Inhibitors

The approach to inhibition of the AKT pathway has focused on agents that act either directly or indirectly. The latter type of agent is exemplified by HSPCA antagonists such as 17-AAG, which disrupts HSPCA chaperone function and results in the degradation of client proteins. For example, downregulation/inactivation of AKT has been implicated in the lethal actions of 17-AAG in human breast cancer cells.[449] It has also been shown to be involved, at least in part, in the lethality of 17-AAG toward human leukemia cells.[430] Because HSPCA antagonists such as 17-AAG are so pleiotropic in their actions, it seems very likely that downregulation of proteins other than AKT (eg, RAF1, BCR/ABL) are involved in antileukemic actions.

The search for specific inhibitors of AKT as chemotherapeutic agents remains the subject of great interest. Although AKT kinase inhibitors have been described,[413] their activity in hematologic malignancies remains to be determined. Several newer agents have been described that appear to act by disrupting the membrane translocation of AKT, and in so doing, preventing its activation. Such agents include perifosine, an alkyl-lysophospholipid,[450] which has entered clinical trials in humans. In addition, novel phosphatidylinositol derivatives have been described that interfere with the activation of AKT, presumably through disruption of its membrane translocation.[451] In preclinical models, perifosine has shown promise in multiple myeloma.[452] The potential of these agents may lie not only in their intrinsic antitumor activity, but possibly as potentiators of cytotoxic drug action.

FRAP1 Inhibitors

FRAP1 (also known as mTOR; mammalian target of rapamycin) is a large (280-kd) serine-threonine kinase that belongs to the family of PI3K-related kinases.[453] A FRAP1-dependent, amino acid or growth factor-signaling pathway controls the initiation of protein translation in mammalian cells.[453,454] It is well recognized that growth factor signaling initiated through the receptor tyrosine kinases (RTKs) or due to the activity of cytosolic tyrosine kinases (TKs), such as BCR-ABL, results in the activation of the PI3K/AKT signaling.[455,456] AKT has been shown to phosphorylate and inactivate TSC2 (tuberous sclerosis 2; also known as tuberin), thereby disrupting its interaction with TSC1 (or hamartin) (Fig. 56–9).[457] Inhibition of TSC1-TSC2 complex de-represses RHEB, which is a small G protein that activates FRAP1.[458] When RHEB is in an active GTP-bound state, its localization to the membrane stimulates FRAP1-mediated phosphorylation of the downstream eukaryotic initiation factor 4E (eIF4E) binding protein 1 (4E-BP) and ribosomal protein S6 kinase 1 (S6K1) (1,2) (see Fig. 56–9). However, the association of FRAP1 with the 150-kd Raptor (regulatory associated protein of FRAP1) is necessary for the phosphorylation of 4E-BP and S6K1.[459,460] Both 4E-BP and S6K1 are involved in the initiation of cap-dependent mRNA translation. At their 5′ termini, the cellular mRNAs contain a cap structure (m7GpppN, where N is any nucleotide), which promotes the binding of the ribosome to the AUG initiation codon of the mRNA.[454] This function of the cap is mediated by the trimeric complex eIF4F that has three subunits, including eIF4A (with cofactor 4B), eIF4G, and eIF4E, which together help unwind the inhibitory secondary structure in the 5′ untranslated region (5′UTR) of the mRNAs.[454] The hypophosphorylated 4E-BP binds tightly to and inhibits 4E, resulting in the inhibition of 4E-dependent translation of cap-containing mRNA. In contrast, FRAP1-mediated phosphorylation of 4E-BP causes its dissociation from 4E, enabling the latter to participate in the cap-dependent translation of mRNAs. FRAP1-mediated phosphorylation and activation of S6K1 results in the

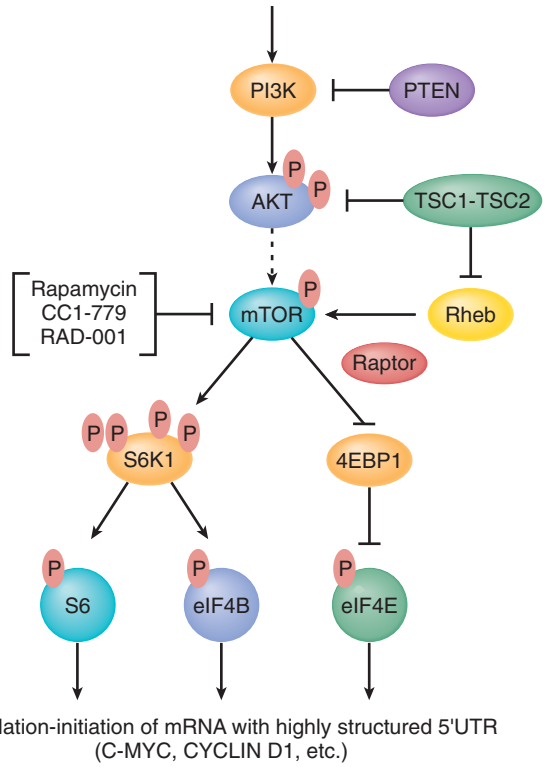

Figure 56–9 Rapamycin or its analogs inhibit mTOR and the downstream phosphorylation of S6K1 and 4EBP1, thereby attenuating the translation initiation of mRNAs with highly structured 5′UTR. Activation of the receptor (FLT-3) or cytosolic tyrosine kinase (eg, Bcr-Abl) can lead to increased activity of PI3K/AKT. Although it can directly phosphorylate mTOR, AKT activity inhibits the TSC1–TSC2 complex, thereby derepressing Rheb and activating mTOR. The phosphorylation and activation of S6K1, and phosphorylation and inactivation of 4E-BP through Raptor, results in the phosphorylation of S6, eIF4B, and eIF4E, which are involved in the cap-dependent translation of mRNAs with highly structured 5′URT.

phosphorylation of the ribosomal S6 protein and eIF4B (see Fig. 56–9).[454] AKT has also been shown to directly activate S6K1.[461] S6K1 activity is involved in regulating the translation of a group of mRNAs that have highly structured 5′UTR, including those mRNAs that have a 5′TOP (terminal oligopyrimidines, a stretch of 4–14 pyrimidines).[454] The presence of highly structured 5′UTR, including a 5′TOP, dictates a stringent translation regulation.[453,454] Therefore, it is clear that the increased activity of PI3K/AKT, either due to the upstream signaling through receptor or cytosolic TKs or the loss of the tumor suppressor phosphatase gene *PTEN*, results in the phosphorylation and activation of FRAP1 signaling.[462,463] This, through S6K1 and 4E-BP phosphorylation, enhances the translation of mRNAs with structured 5′UTR (eg, MYC and cyclin D_1) or 5′TOP (eg, ribosomal elongation factor 1a and poly [A] binding protein).[451,455]

Rapamycin is a lipophilic macrolide fungicide that binds intracellularly to a small ubiquitous protein termed FKBP12 (FK506-binding protein, molecular mass of 12 kd).[453,459,463] Rapamycin is known to possess antimicrobial, immunosuppressant, and antitumor activity.[463] Rapamycin-FKBP12 complex binds and inhibits FRAP1 and its downstream signaling through S6K1 and 4EBP.[453,459,463,464] Rapamycin has been shown to inhibit growth and induce apoptosis of cancer, leukemia, and lymphoma cells owing to its inhibitory effect on FRAP1 signaling and the downstream inhibition of the translation of mRNAs with a 5′TOP or complex secondary structure in their 5′UTRs, which are involved in cell proliferation.[464–467] It also blocks T-cell activation and has been proposed as an agent for the treatment of graft-versus-host disease. However, rapamycin has poor aqueous solubility and chemical stability, which has hampered its clinical development as an anticancer agent.[464] Recently, more soluble ester analogs of rapamycin, for example, CCI-779 (Wyeth Ayerst, PA) and RAD001 (Novartis Pharma, Basel, Switzerland), have been developed. Preclinical studies have shown that similar to rapamycin, these agents also inhibit phosphorylation of S6K1 and 4E-BP, resulting in cell-cycle G_1 phase arrest of a variety of cancer and leukemia cell types.[468,469] This is also associated with attenuation of cyclin D1 levels or upregulation of p27 and inhibition of cyclin A-dependent kinase activity.[470,471]

CCI-779 and RAD001 have been evaluated in phase I studies in patients with solid tumors.[464,472] The main toxicities have been skin rash, thrombocytopenia, and reversible deterioration in the liver function. Although partial responses have been observed in patients with renal and non-small-cell cancers, minor responses have been observed in NHLs. These studies suggest that the optimal therapeutic dose of CCI-779 may be lower than the maximal tolerated dose.[464] In a pharmacodynamic study in patients with renal cancer, inhibition of S6K1 activity in the peripheral blood mononuclear cells could be correlated with time to disease progression.[473] Phase I and II studies of these promising agents in the hematologic malignancies have not been carried out. In these studies, the dose selection could be guided by the pharmacodynamic end points in peripheral blood mononuclear cells. It is clearly important to investigate the clinical antitumor activity of FRAP1 inhibitors in hematologic malignancies that are dependent on FRAP1 signaling and/or its downstream effectors, including S6K1, MYC (eg, Burkitt lymphoma), and cyclin D (eg, mantle-cell lymphoma), for their growth and survival.[474,475] This may be due to upregulation of PI3K/AKT activity, as seen in malignancies with the loss of PTEN (eg, multiple myeloma) or due to increased activity of the upstream tyrosine kinase (eg, BCR-ABL, KIT, and FLT3).[455,475,476] There may also be merit in investigating whether cotreatment with FRAP1 inhibitors would enhance the activity of conventional cytotoxic agents. These studies will define the future role of FRAP1 inhibitors against hematologic malignancies.

Histone Deacetylase Inhibitors

Histone acetyl transferases control gene expression through the modification of chromatin structure through acetylation of chromatin-bound histones. Regulation of acetylation is through histone deacetylation. Without the ability to fine-tune histone binding to chromatin regions, gene expression is perturbed. Inhibition of this process by a group of agents termed histone deacetylation inhibitors alters gene expression in both normal and malignant cells. Often the result is differentiation of malignant cells or induction of apoptosis.

Posttranslational Histone and Nonhistone Protein Modifications and Gene Transcription

Nucleosomes are regularly repeating, structural units of chromatin, which are essential in packaging eukaryotic DNA. Each unit is composed of 146 base pairs of DNA tightly wrapped around a core histone octamer.[477] Each histone octamer consists of 2 units each of histones H2A, H2B, H3 and H4 and each nucleosome in turn is connected to its neighbor by a short segment of linker DNA, approximately 10 to 80 base pairs in length. Histone H1 binds and stabilizes linker DNA.[478] Each core histone has an amino (N) terminal tail, which is lysine rich and positively charged. Specific amino acid residues at the N-terminal undergo a variety of enzymatic posttranslational modifications.[479] Modifications can also occur within the globular domain of histones that make extensive contacts with DNA.[480] Histone code is the name given to the combination of several biochemical modifications affecting different histone residues that specify chromatin function. However, it has been suggested that

Table 56–5 Human Histone Deacetylases

Characteristics	Class I	Class IIa	Class IIb	Class III
Members	HDAC1, 2, 3, 8, 11	HDAC4, 5, 7, 9	HDAC6, 10	SIRT1, 2, 3, 4, 5, 6, 7
Localization	Nuclear	Nucleo-cytoplasmic	Nucleo-cytoplasmic	Nuclear/cytoplasmic/mitochondrial
Substrates	Histones p53 (HDAC1) NF-κB (HDAC3)	Histones Hsp90	Histone Tubulin Hsp90?	Histones Tubulin (SIRT2) p53 (SIRT1) TAF(I)68 (SIRT1)
Binding site inhibitors	Zn^{++} TSA SAHA/LAQ824 Depsipeptide Trapoxin Butyrate VPA	Zn^{++} TSA SAHA/LAQ824 Trapoxin Butyrate VPA	Zn^{++} TSA SAHA/LAQ824 Tubacin	NAD^{+} Nicotinamide

various postsynthesis histone modifications be considered an epigenomic alphabet. Each modification is a letter and the combination of modifications at a specified genomic region is a word that may have different functional meanings depending on the context.[480]

Histone acetyl transferases (HATs) and histone deacetylases (HDACs) are two classes of enzymes that mediate the acetylation and deacetylation, respectively, at evolutionarily conserved N-terminal lysine residues.[481] Acetylated histones are negatively charged and do not bind as tightly to negatively charged DNA, thereby facilitating gene transcription. In contrast, deacetylated histones bind closely to DNA, preventing transcription.[482] Acetylation status of chromatin and hence gene transcription is dictated by balanced activity of HATs and HDACs. Acetylation of core histone bases has also been implicated in chromatin assembly, DNA repair, and replication timing of specific genomic regions.[483–485] Cross talk also exists between acetylation and ubiquitination. HDACs, thus, can decrease the half-life of substrates by exposing the lysine residue for ubiquitination.[486–489] Other crucial functions affected by the delicate balance between HATs and HDACs include activation of the apoptotic program via interaction between Ku70 and BAX, protein localization (nuclear vs cytoplasm) and DNA binding of transcription factors like p53, E2F1, GATA1, RelA, YY1 and hormone receptors.[480,490,491] There is a growing list of nonhistone proteins, whose function is modulated by HATs/HDACs. These include HIF-1α, β-catenin, α-tubulin, Ku70, importin-α 7, cortactin, and most recently heat shock protein (hsp) 90.[492–501] HATs and HDACs can be classified into subfamilies according to the presence of highly conserved structural motifs. Please refer to Table 56–5 for details.

Aberrant Histone Acetyl Transferase and Histone Deacetylase Activity in Hematologic Malignancies

Aberrant activity of HATs and HDACs resulting in aberrant gene transcription is a hallmark of many cancers, including many hematologic malignancies.[490,502] Several chromosomal translocations in leukemia that produce chimeric fusion oncoproteins have been shown to recruit HDACs to promoters, repress genes involved in cell-cycle growth inhibition and differentiation. For example, PML-RARα in acute promyelocytic leukemia (APL) and AML1-ETO generated by t(8;21) translocation in AML recruit HDACs to their target genes, resulting in chromatin modification and repression of genes, leading to blocked differentiation and inhibition of apoptosis.[502] HDACs have also been found in complexes with proteins that regulate cell-cycle checkpoints such as Rb and its family members.[490,502] Resistance to chemotherapy can occur because of increased levels of thioredoxin, a thiol reductase, and decreased levels of thioredoxin-binding protein (TBP-2) in many cancers; HDAC inhibitors (HDIs) can reverse this phenomenon.[503] These examples create a strong rationale to develop inhibitors of HDAC activity that would correct transcriptional deregulation of genes involved in cell-cycle regulation and apoptosis.

Mechanisms of Anticancer Activity of Histone Deacetylase Inhibitors

Treatment with HDIs modulates expression of 2% to 10% of a selective subset of genes in various cell types with as many genes upregulated as are downregulated.[504–507] Normal cells are more resistant than cancer cells to the effects of HDIs.[508] HDI-induced cell cycle arrest and apoptosis is usually correlated with upregulation of p21, p27, and p16 and attenuation of cyclin A and D levels leading to decreased activity of CDK4 and CDK2.[209,497,509] Induction of GADD45α and β and upregulation of TGF-β, which inhibits c-Myc, may also contribute to the cell-cycle arrest in G1 or G2.[497,510,511] Promoter regions of p21 and the telomerase catalytic unit TERT have been shown to contain SP1 sites that bind HDAC-recruiting transcription complexes.[497] HDIs also activate the mitochondrial apoptotic pathway by transcriptional activation of apoptotic proteins like TBP2, Bad, Bim, Bid, BAK, Bax, caspases 3 and 9, and repression of antiapoptotic proteins like thioredoxin, bcl-2, XIAP and Mcl-1.[512,513] HDIs have also been shown to upregulate Fas and the Apo-2L/TRAIL receptors DR4 and DR5, downregulate c-FLIP, and enhance Apo-2L/TRAIL-induced DISC and apoptosis.[514–517]

Treatment with HDI alone or in combination with other agents like ATRA has been shown to overcome the inhibition of differentiation due to chimeric fusion oncoproteins such as PML-RARα. PLZF-RARα, or AML-ETO.[502,510,518,519] HDIs have also been shown to induce the expression of gelsolin, an actin-binding protein involved in morphologic and cytostructural changes associated with differentiation.[519,520]

Several HDIs were shown to induce acetylation of hsp90 and inhibit its chaperone association with important prosurvival client proteins such as AKT and c-Raf.[209,497,501] This directs these client proteins to polyubiquitylation and proteasomal degradation, thus contributing to the lowering of the threshold for apoptosis in cancer cells. Inhibition of HDAC6 results in marked accumulation of ubiquitinated proteins (inhibition of the aggresome), via acetylation of α-tubulin, which in turn results in increased cellular stress and cytotoxicity.[521]

There is evidence to suggest that treatment with HDIs leads to tumor regression not only by directly inhibiting cell-cycle progression

Table 56–6 Histone Deacetylase Inhibitors

Name	Type of Compound	Cell Culture (Activity)	Animal Tumor Models	Clinical Trial
Butyrates	Short-chain fatty acids	Yes (uM)	Yes	Phase I/II
Valproic acid	Short-chain fatty acid	Yes	Yes	Phase I/II
Trichostatin A	Hydroxamic acid	Yes (nM)	Yes	—
Pyroxamide	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
Oxamflatin	Hydroxamic acid derivative	Yes (uM)	Yes	—
Suberoylanilide hydroxamic acid (SAHA)	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I/II
TPX-HA analog (CHAP)	Hydroxamic acid derivative	Yes (nM)	Yes	—
LAQ824	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
MS-275	Benzamide derivative	Yes (uM)	Yes	—
CI-994 (N-acetyl dinaline)	Benzamide derivative	Yes	Yes	Phase I
Depsipeptide (FR901228, FK-228)	Cyclic tetrapeptides	Yes (nM)	Yes	Phase I/II
Trapoxin	Cyclic tetrapeptides	Yes (nM)	—	—
Apicidin	Cyclic tetrapeptides	Yes (nM)	Yes	—

Activity reported as "Yes" indicates that the compound has been shown to inhibit HDAC activity, that is, growth of transformed cells in culture and in vivo tumor growth in animal studies. (—) indicates no data reported. CI-994 is reported to inhibit histone deacetylation but does not directly inhibit HDAC.

and apoptosis, but also indirectly by exerting antiangiogenic and immune modulatory effects via downregulation of HIF-1α and VEGF.[497,502,522] HDIs also affect cancer cell migration, invasion, and metastasis by altering expression of extracellular matrix proteins and metastasis genes in favor of reduced cell invasion.[513]

Classes of Histone Deacetylase Inhibitors

Several structurally diverse classes of naturally occurring and synthetic compounds have been investigated for their ability to inhibit HDAC activity (Table 56–6).[523] These include short-chain fatty acids (eg, valproic acid), hydroxamic acid derivatives (eg, vorinostat), synthetic benzamides (eg, MS-275), and cyclic tetrapeptides (eg, romidepsin). The various classes of HDIs studied so far are listed in Table 56–6 and described below.

Short Chain Fatty Acids

Sodium butyrate (SB), a well-studied member of this class of compounds, induces in vitro growth arrest and differentiation of human leukemia cells at millimolar concentrations.[524] Its clinical development has been hampered by its short half-life and difficulty in achieving millimolar levels in vivo. Phenylbutyrate, another derivative of butyric acid, is able to induce in vitro growth arrest and differentiation of leukemia cells at clinically achievable submillimolar concentrations.[525,526] Importantly, at these levels, phenylbutyrate is able to synergize with retinoids in inducing cell cycle arrest and differentiation of myeloid leukemia cells.[527] Valproic acid (VPA), a well-tolerated antiepileptic, was shown to be effective as an HDI at levels ranging between 0.5 and 2.5 mM.[510]

Two phase I trials have looked at phenylbutyrate in patients with AML and MDS. No responses were noted in either study, with neurotoxicity being the dose-limiting toxicity. Several studies have employed valproic acid as monotherapy or in combination with other agents in hematologic malignancies.[511,528] As monotherapy in MDS, response rates have been as high as 16% using the IWG criteria. Responses have been higher in low-risk MDS groups and low-risk karyotypes. Neurotoxicity has been the major side effect. Other side effects of VPA include thrombocytopenia, weight gain, asthenia, and rarely hepatic failure and pancreatitis.[529]

However, in general, because they possess short side chains, this class of HDIs are unable to make significant contact with the catalytic pocket of HDACs, and this may account for the low potency of these compounds.[502]

Vorinostat and Other Hydroxamic Acid Derivatives

Members of this class are some of the most potent HDIs.[504] They contain a functional group that interacts with the critical zinc atom at the base of the catalytic pocket of the class I and II HDACs.[490,502] These HDIs also possess a hydrophobic cap and an aliphatic side chain that interacts with the edge and fits into the hydrophobic catalytic pocket, respectively, of the HDACs. Members of this class inhibit both class I and II HDACs.[490,523] Vorinostat (SAHA, Zolinza) is a second-generation polar-planar compound that induces in vitro growth arrest, differentiation, and/or apoptosis of a variety of cancer, leukemia, and multiple myeloma cell types.[490,504] In phase I studies, vorinostat was administered intravenously to patients with solid tumors or hematologic malignancies daily × 3 or daily × 5 for up to 3 weeks.[530] The maximum tolerated dose of vorinostat in patients with hematologic malignancies was 300 mg/m^2 daily × 5 for 3 weeks; thrombocytopenia and leukopenia were the notable toxicities. Responses were seen in patients with lymphoma and bladder cancer. Thirty-nine patients with advanced hematologic malignancies were enrolled in a trial composed of 2 cohorts looking at IV and oral (PO) formulations of vorinostat.[531] The median age of patients in the IV cohort was lower than that in the oral cohort. Up to 70% of patients had diffuse large B-cell lymphoma. Median number of prior treatments was seven and five in the IV and PO cohorts respectively. A substantial number of patients had undergone a prior stem-cell transplant. Most patients tolerated vorinostat well. Major adverse events of the oral formulation included fatigue, diarrhea, anorexia, and dehydration, whereas myelosuppression and thrombocytopenia were more prominent with the IV formulation. The mechanism of thrombocytopenia is unlike conventional chemotherapy; the drug appears to impair megakaryocytic differentiation. In the IV cohort, three patients with Hodgkin Disease (HD) had a benefit, whereas in the PO cohort, three heavily pretreated patients with diffuse large B-cell lymphoma and one patient with cutaneous T-cell lymphoma (CTCL) and one with HD each experienced a clinical benefit.[531]

A phase II trial, evaluated vorinostat in thirty-three heavily pretreated patients with CTCL[532] enrolled in three different dose groups. Dosing schedules were either 400 mg PO daily, 300 mg daily × 3 days followed by 4 days' rest or 300 mg twice a day for 14 days followed by 7 days' rest. Intent-to-treat analysis revealed a response rate

of 24.2%; there were no CRs; eight patients achieved PR, including four with Sezary syndrome. Additional patients had minor responses and disease stabilization; a substantial number had relief from pruritis. Median time to response, duration of response, and time to progression were 11.9, 15.1, and 30.2 weeks respectively.[532] Vorinostat was approved by the FDA for patients with refractory CTCL at a dose of 400 mg daily, which had the most favorable safety profile in the above study.

Several other hydroxamic acid-based hybrid polar HDIs have been developed and tested both in vitro and in vivo tumor models and in clinical trials.[490,523] LBH 589 and LAQ824 are novel cinnamic hydroxamic acid analogs. LBH589 induces apoptosis in a dose-dependent manner on human CML blast crisis K562 cells and acute leukemia MV4-11 cells with the activating length mutation of FLT-3.[533] Exposure to LBH 589 is associated with hyperacetylation of H3, H4, Hsp 90, increase in p21, and induction of cell-cycle G1 phase accumulation.

Fifteen patients with a median age of 63 years and refractory AML, ALL, or MDS received IV LBH 589 in a phase I trial at the following dose levels (mg/m^2): 4.8, 7.2, 9.0, 11.5, and 14.0.[534] Grade III QTc prolongation was observed in four patients at the 14.0 mg/m^2 level and in one patient at the 11.5 mg/m^2 level. QTc prolongation was asymptomatic and reversible on drug discontinuation. Other toxicities included nausea, diarrhea, vomiting, hypokalemia, and thrombocytopenia. Eight of 11 patients with peripheral blasts had transient reductions in blast counts, which increase shortly after drug discontinuation.[534] LBH589 has shown to be highly effective in CTCL. In a recent abstract, at an MTD of 20 mg M, W, F, two patients achieved CR, four attained PR, and one patient had SD for an overall response rate of 60%.[535]

Synthetic Benzamide Derivatives

Although structurally diverse, these compounds contain a benzamide moiety.[523] Two important members of this class of HDIs are MS-275 and CI-994.[536] MS-275 exerts antiproliferative effects at micromolar levels against pancreas, breast, colorectal, lung, and ovarian cancer cell types.[537] It has been shown to induce TGF-β receptor, which may enhance the antitumor effects of TGF-β.[538] DLT was reached with the starting dose of 2 mg/m^2 daily × 28 days in a 42-day cycle.[539] Pharmacokinetic data revealed a 30- to 50-fold longer half-life in humans than that predicted from animal models. Twenty-eight patients were subsequently treated on a q14 day schedule with no complete or partial responses noted. Fifteen patients had stable disease. Toxicities common to HDAC inhibitors like nausea, vomiting, and fatigue were noted; no symptomatic cardiac toxicity was noted. Hypoalbuminemia, thought to be due to decreased production and lymphopenia were noted. Three episodes of herpes simplex virus stomatitis were noted in patients who received more than one course; one patient with CTCL experienced herpes zoster recurrence.[539] A recent phase I trial of MS-275 in patients with advanced leukemias reported an MTD of 8 mg/m^2 weekly for 4 weeks every 6 weeks.[540] Dose-limiting toxicities included neurotoxicity and infections. No CR or PR was noted by standard criteria. Another compound, CI-994, also has broad antitumor activity against murine and human xenograft models, and is undergoing clinical evaluation in phase I and II trials.[541]

Cyclic Tetrapeptides

The main members of this class of agents are depsipeptide (Romidepsin, FK228, FR901228)) and apicidin.[522,542] Depsipeptide is a potent HDI that exerts in vitro antitumor effects at nanomolar levels against several cancer cell types. It also induces apoptosis of human acute leukemia and CLL cells.[543] Additionally, depsipeptide was shown to exert antiangiogenic effect by modulating the expression of genes involved in angiogenesis.[544] A phase I study of depsipeptide in patients with CLL and AML at a dose of 13 mg/m^2 IV on days 1, 8, and 15 of a 4-week cycle showed antitumor activity in several patients, though no CRs or PRs were observed.[545] Response was greater in patients with CLL than AML. There were no life-threatening toxicities, but constitutional symptoms characteristic of HDAC inhibition were observed in the majority of patients. This fact brings forth an important aspect of putting patients on chronic therapy with HDAC inhibitors, that is, managing chronic toxicity. Another important clinical aspect is the sequence of use of HDAC inhibitors. Depsipeptide was shown to upregulate MDR1 and induce doxorubicin resistance when used with ATRA in APL cells.[546] However, prior treatment with doxorubicin followed by ATRA/depsipeptide resulted in increased cell death.[546] A phase I study of apicidin is another cyclic tetrapeptide that has been shown to exert antiproliferative effects against several human cancer cell types associated with upregulation of p21$^{CIP1/WAF1}$ and gelsolin.[542]

Combinations of Histone Deacetylase Inhibitors With Other Agents

Histone Deacetylase Inhibitors With Conventional Cytotoxic Agents

Because treatment with HDI lowers the threshold for apoptosis by multiple mechanisms, it would be expected to enhance the apoptotic effects due to conventional chemotherapeutic agents, which generally trigger apoptosis by perturbing the cell cycle and/or inducing DNA damage. Combination of HDI and conventional chemotherapy has resulted in enhanced cytotoxicity in a variety of solid tumor cell lines.[547,548] SB was shown to induce the topoisomerase α expression and sensitize human leukemia cells to etoposide.[549] Cotreatment with phenylbutyrate increases the activity of conventional chemotherapeutic agents such as cytarabine, etoposide, and topotecan against non-Hodgkin lymphoma, CLL, and multiple myeloma cells.[550] Recently, the combination of vorinostat and valproic acid was studied in MOLT4 and HL60 cell lines.[547] It was hypothesized that exposure of cells to the idarubicin prior to HDI would result in disruption of matrix attachment complexes, thereby facilitating HDI access to polynucleosomes, which are involved in temporal control of gene expression. The combination resulted in increased cell loss, but the sequence of drug exposure on cells did not appear to play a role.

Histone Deacetylase Inhibitors With DNA Hypomethylating Agents

DNA methyltransferase (DNMT) induces transcriptional silencing by promoting cytosine hypermethylation of CpG islands in the promoter regions of genes.[551] Aberrant methylation is now well known to silence the expression of tumor suppressor genes (TSGs). The silenced TSGs can be reexpressed by treatment with demethylating agents, for example, 5′-azacytidine and 5′-aza-2′-deoxycytidine (DAC or decitabine), which inhibit DNMT by inducing a stable complex formation between the enzyme and DAC-substituted DNA.[551,552] DNMT and a group of methyl cytosine-binding proteins, for example, MECP2, can also recruit and direct HDACs to the chromatin associated with silenced genes.[552] DNA methylation is a dominant gene-silencing process, and methylated genes show resistance to reexpression by treatment with HDIs alone.[553,554] However, a combined treatment with a DNMT inhibitor and an HDI such as TSA or depsipeptide has been shown to synergistically derepress silenced TSGs such as p16 and p15, resulting in increased growth inhibition and apoptosis of tumor cells.[545–556] Additionally, in the multiple myeloma U266 cells, combined treatment with phenylbutyrate and DAC restored the expression of p16 and induced apoptosis.[557]

In one of the first clinical studies done to verify the above concept, patients with AML or MDS were treated with SQ Aza-CR for 5, 10, or 14 days followed by a 7-day IV infusion of phenylbutyrate.[558] Treatment cycles were repeated every 28 days unless toxicities supervened. Thirty-two of thirty-six screened patients were enrolled. Of the 29 evaluable patients, 11 responded. There were four CRs and one PR, with three patients having a complete cytogenetic response.

Injection site reactions with azacitidine and neurotoxicity with phenylbutyrate were seen that reversed on drug discontinuation. Bisulfite sequencing of the p15 promoter in bone marrow DNA during the first treatment cycle showed heterogenous allelic demethylation in three responding patients.[558] This denoted ongoing demethylation in responding patients versus no demethylation in nonresponders. Six responders with pretreatment methylation of p15 or CDH-1 promoters showed evidence of demethylation during the first treatment cycle.

Issa et al conducted a phase I/II study of decitabine in combination with valproic acid in patients with previously treated and untreated AML.[559] A total of 54 patients received decitabine at a dose of 15 mg/m^2 IV × 10 days. Valproic acid was administered at escalating doses PO for 10 days. A response rate of 22% was noted including 19% CRs and 3% CRs with incomplete platelet recovery. Of 10 older patients with AML, 4 patients had a CR and 1 patient achieved a PR. Induction mortality in this group was 2%. A major cytogenetic response was noted in six of eight responders. Duration of remission was 7.2 months, with an overall survival of 15.3 months in responders. Studies are underway to determine optimal dosing of these novel agents, best sequence of combination treatments, and combination with more potent HDIs like LBH.[560]

Histone Deacetylase Inhibitors With Other Differentiation-Inducing Agents

HDIs have also been tested in combination with ATRA against APL cells expressing PML-RARα or PLZF-RARα. Enhanced differentiation and significant apoptosis due to the combination has been reported.[518] TSA combined with ATRA is especially effective against ATRA-resistant PLZF-RARα-containing APL cells.[518] Similarly, phenylbutyrate was shown to reverse ATRA resistance in a patient with APL.[490] Primary leukemia blasts also demonstrate differentiation following combined treatment with ATRA and TSA or VPA.[519] The combination was noted to induce RARα-targeted genes, suggesting that in AML cells HDIs release a block to RARα-mediated gene expression involved in differentiation.

Valproic acid with ATRA either as upfront therapy or ATRA added to VPA in nonresponding patients was looked at in 58 older patients with AML who were deemed unfit for conventional chemotherapy.[528] The RR was 5% by the IWG criteria for AML but 16% if IWG criteria for MDS was used. A smaller Italian trial looked at sequential valproic acid followed by ATRA in a similar patient population as the aforementioned trial. ATRA was added when adequate concentration of VPA was achieved. Six of 11 evaluable patients had a hematologic improvement. Neurotoxicity was the major adverse event in the trial.[561]

Histone Deacetylase Inhibitors With Cell Cycle and Cell-Signaling Modulators

Both vorinostat and SB have also been combined with the cell cycle-dependent kinase (CDK) inhibitor flavopiridol. The combination of HDI and flavopiridol dramatically increased apoptosis of cultured and primary AML cells, resulting in a synergistic cytotoxic response.[382,562] Because treatment with flavopiridol also transcriptionally downregulates several antiapoptotic gene expressions, this may be responsible for the synergistic effect observed with the combination. Recent studies have shown that treatment with vorinostat or LAQ824 attenuates the mRNA level of *bcr-abl* and promotes polyubiquitylation and proteasomal degradation of Bcr-Abl.[209,563] In addition, a combined treatment with LAQ824 and Bcr-Abl tyrosine kinase inhibitor imatinib or PD180970 was shown to induce apoptosis of imatinib-sensitive or imatinib-refractory CML cells.[563] Similarly, the combination of vorinostat and dasatinib on cultured human, primary CML or murine pro-B BaF 3 cells, expressing unmutated or mutated form of bcr-abl showed enhanced apoptosis.[562] The more potent TKI, AMN107, has also been studied with the HDI, LBH589, in cells with ectopic expression of *bcr-abl* and mutated clones (T315I, E255K) that are imatinib resistant.[564] Taken together, these preclinical findings support the rationale to study the safety and efficacy of the combinations of these HDIs with specific inhibitors of progrowth and survival signaling triggered by oncoprotein tyrosine kinases.

Histone Deacetylase Inhibitors With Other Novel Agents

On the basis of the ability of HDIs such as vorinostat to lower the threshold for apoptotic signaling initiated both by the extrinsic and mitochondrial pathways of apoptosis, the activity of these agents in combination with Apo-2L/TRAIL has been preclinically tested against human leukemia cells. Cotreatment with vorinostat or LAQ824 significantly enhanced APO-2L/TRAIL-induced apoptosis of cultured and primary acute leukemia cells.[514] A similar effect was also seen for vorinostat plus APO-2/TRAIL in multiple myeloma cells.[565]

Recently, the combined effects of HDIs such as SB or vorinostat with the hsp-90 antagonist, 17-AAG were determined in human leukemia cells.[566] The combination was highly synergistic in inducing the mitochondrial pathway of apoptosis. The synergistic effect of the combination was associated with downregulation of Raf-1 and phospho-AKT, as well as inactivation of MEK and ERK1/2. More recently, the combination of the potent HDI LBH589 and 17-AAG was studied in CML blast crisis K562 cells and AML MV4-11 cells with the FLT-3 mutation.[533] 17-AAG induced polyubiquitylation and proteasomal degradation of FLT-3 and bcr-abl by reducing their chaperone association with hsp90. The combination resulted in increased apoptosis of primary imatinib-resistant cells, cells carrying the T315I mutation, and AML cells with the FT-3 mutation. In a separate study, coadministration of minimally toxic concentrations of the proteasome inhibitor bortezomib with either SB or vorinostat resulted in marked increase in caspase activation and apoptosis of Bcr-Abl-positive leukemia cells sensitive or resistant to imatinib.[567] Synergistic cytotoxicity was also noted with LBH589 in combination with bortezomib against MM cells sensitive and resistant to dexamethasone as well as primary patient MM cells. Another novel strategy was explored in a study combining the HDI NVP-LAQ284 with the VEGFR TKI, PTK787/ZK222584.[568] The combination resulted in significant inhibition of prostate and breast tumor growth in vivo. NVP-LAQ824 was shown to downregulate angiogenesis-related genes like HIF-1α, VEGF, Ang-2/tie-2, and survivin. The combination was thought to be more effective because of actions on independent, parallel pathways as well as vertical inhibition of the VEGF pathway.[568] Taken together, these findings suggest that combined hsp90/histone deacetylase, proteasome/histone deacetylase, or histone deacetylase/VEGF inhibition may be a promising strategy against leukemia or other hematologic malignancies where these agents have individually shown promising activity.

Heat Shock Protein Inhibitors

The "heat shock response" was first described by Ferruccio Ritossa in 1962. He made the crucial observation that certain regions of the chromosomes of the fruit fly *Drosophila* puffed out in response to a sudden increase in temperature.[569,570] The gene products encoded on these chromosomes were later termed heat-shock proteins (HSPs). Contrary to most cellular proteins, HSP production increases several-folds in response to environmental stresses, including heat shock, nutrient deprivation, oxidative stresses, heavy metals, and alcohol exposure. They form multimolecular complexes with variable cellular proteins, regulating their correct folding, repair, degradation, and function; hence, the HSPs' more accurate designation is "molecular chaperones."[571,572] A number of multigene families of HSPs exist and their individual products vary in cellular expression, function, and localization. They are classified according to their molecular weight, for example, HSP90, HSP70, and HSP27. Exceptions to this rule are the chaperones identified as glucose-regulated proteins (GRP94 and GRP75).[573] Heat shock proteins (HSPs, also designated as

molecular chaperones) are highly conserved proteins that form multimolecular complexes that regulate the functional activity of client proteins that mediate numerous signal transduction pathways. A number of multigene families of HSPs exist and their individual products vary in cellular expression, function, and localization.[571,572] They are classified according to their molecular weight, for example, HSP90, HSP70, and HSP27. HSP90 has received considerable attention as a target for cancer therapy.[573]

HSP90 regulates the function and stability of many key signaling proteins that help cancer cells to escape the inherent toxicity of their environment, to evade the effects of chemotherapy, and to protect themselves from the results of their own genetic instability.[573,574] In humans, HSP90 consists of four genes, cytosolic HSP90α and HSP90β, GRP94, and HSP75/tumor necrosis factor-associated protein 1 (TRAP1).[575] The monomer HSP90 consists of conserved 25-kd N-terminal and 55-kd C-terminal domains. The N-terminus contains a highly conserved ATP-binding domain. Dimerization of these nucleotide-binding domains is essential for ATP binding and hydrolysis.[576] Phosphorylation leads HSP90 to interact with cochaperones such as HSP70 and p23 to form heteroprotein complexes which is essential for various protein functions. Such proteins include several transcription factors (eg, steroid hormone receptor, retinoid receptors, and hypoxia inducible factor HIF-1α), serine/threonine and tyrosine kinases (eg, c-SRC/v-SRC, RAF-1, ERB2, EGFR, MEK, CDK4, AKT, BCR-ABL, LCK, FAK, c-MET), and other proteins with various functions (eg, mutant p53, catalytic subunit of telomerase hTERT, TNFR1, and RB).[577] HSP90 inhibition leads to misfolded client proteins that are involved in malignancy to be polyubiquitinated and degraded by proteosomes.[578] Significant interest in HSP90 inhibition has led to the following compounds.

Benzoquinone Ansamycins (Herbamycin A, Geldanamycin, 17-AAG)

The first class of HSP90 inhibitors to be discovered was the benzoquinone ansamycins, which include herbamycin A and geldanamycin. These natural products were first isolated from the actinomycete broths in the 1970s.[579] Hemamycin A was later shown to reverse the malignant phenotype of *v-Src* transformed fibroblasts, with potent antitumor activity in vitro and in vivo animal models. The effects of this drug on other tyrosine kinases, including $p210^{bcr\text{-}abl}$, were also described, leading to the frequent use of herbimycin A as a general tyrosine kinase inhibitor. However, Whitesell and colleagues later identified HSP90 as the prominent benzoquinone ansamycin-binding protein, and they described the ability of these drugs to disrupt the complex between v-Src and HSP90, resulting in destabilization of v-Src protein and its eventual loss from treated cells.[580] Subsequent immunoprecipitation and x-ray crystallography studies showed that geldanamycin competes at the ATP-binding site and inhibits the intrinsic ATPase activity of HSP90, preventing the formation of mature multimeric HSP90 complexes capable of chaperoning client proteins (Fig. 56–10).[576,581] As a result, the client proteins are ubiquitinated and targeted for proteasomal degradation. Although clearly active in human tumor xenograft models, preclinical evaluation of geldanamycin demonstrated significant hepatotoxicity at therapeutic drug levels.[582] Screening for geldanamycin analogs resulted in the discovery of 17-allylamino-17-demethoxygeldanamycin (17-AAG), a semisynthetic geldanamycin derivative in which an allyl amino group replaces the methoxy in the 17 position (Fig. 56–10). 17-AAG has a significantly improved toxicity profile but like geldanamycin retains the ability to inhibit HSP90.[583] In addition, 17-AAG has been shown to have greater affinity for binding to HSP90 from cancer versus normal host cells.[584]

Preclinical Studies of 17-AAG′: 17-AAG exhibited significant antiproliferative and cytotoxic effects against a wide panel of transformed cell lines, inhibiting pathways that regulate cell-cycle progression, apoptosis, invasion, and angiogenesis. In the NCI in vitro cancer screen, the mean GI_{50} for 17-AAG was 0.19 μM, with greater than average sensitivity in melanoma, leukemia, non-small-cell lung, ovarian, breast, prostate, and renal cancer panels.[585]

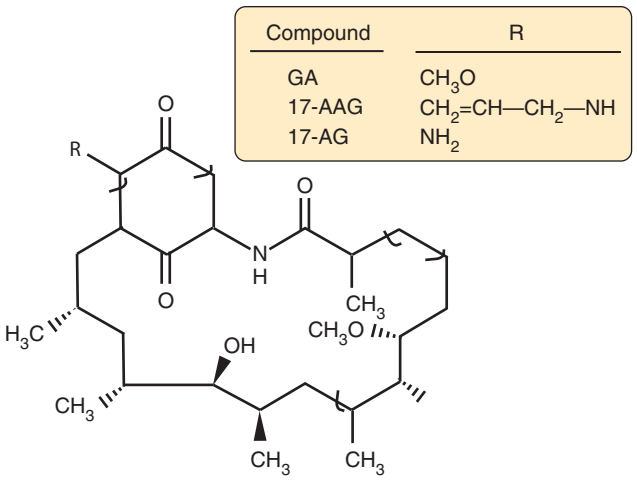

Figure 56–10 Chemical structure of geldanamycin (GA), 17-allylamin-17-demethoxygeldanamycin (17-AAG), and 17-amino-geldanamycin (17-AG).

Benzoquinone ansamycins have been reported to induce G1 as well as G2/M block. In a panel of breast cancer cell lines, 17-AAG and geldanamycin caused a G1 arrest.[586,587] This G1 block resulted from downregulation of signaling pathways controlling cyclin D or CDK4/cyclin D1 activity, in particular depletion of tyrosine kinases (ERBB2, EGF receptor), degradation of c-RAF-1 with reduced phosphorylation of extracellular signal-regulated kinase (ERK). A G2/M block has been reported in RB-deficient cells treated with 17-AAG; however, the requirement for RB deficiency appears to be cell dependent. A number of G2 checkpoint kinases such as WEE1 and MYT1 have also been identified as HSP90 client proteins.[588]

HSP90 plays a crucial role in regulating apoptosis. 17-AAG induced cytosolic accumulation of cytochrome C and cleavage and activation of caspases 9 and 3, triggering apoptosis in HL-60/Bcr-Abl with ectopic expression of p185-Bcr-Abl and K562 with endogenous p210-Bcr-Abl cells. 17-AAG treatment led to proteasomal degradation of Bcr-Abl in these cells along with AKT depletion.[589] However, high ectopic expression of HSP70 inhibits 17-AAG-induced Bax conformation change, mitochondrial localization, and apoptosis.[560] This is important due to 17-AAG and other analogs of geldanamycin (17-DMAG and IPI504) or radicicol induce HSP70 levels.[590,591] Therefore, strategies leading to abrogation of HSP70 induction would further antileukemic effects of HSP90 inhibitors.

In addition to their modulation of the cell cycle and programmed cell death, geldanamycin and 17-AAG have been implicated in the regulation of invasion, metastasis, and angiogenesis. 17-AAG treatment of H322 and H358 cells enhanced E-cadherin expression and inhibited secretion of MMP-9 and VEGF. Geldanamycins have also been shown to inhibit the HGF/SF-MET signaling pathway, resulting in decreased cell motility and invasion of c-MET transformed cells.[592] HSP90 inhibitors also significantly reduce VEGF secretion by decreasing HIF1α expression as well as inducing degradation of all three VEGF receptors.[593,594]

Combination studies incorporating 17-AAG have shown promise. In lung and colorectal cell lines, combinations of 17-AAG with cisplatin, doxorubicin, or paclitaxel have been synergistic or additive.[595,596] In addition, 17-AAG has shown synergy with novel agents, including imatinib, bortezomib, ERK inhibitors, and SAHA.[533,597–599] Combined treatment of LBH589, a histone deacetylase inhibitor, with 17-AAG exerted synergistic effects in AML and CML cells with decreased Bcr-Abl, p-AKT, AKT, and p-STAT5 levels.[533]

Metabolism of 17-AAG: In human and murine microsome assays, three metabolites of 17-AAG were identified: 17-aminogeldanamycin (17-AG), a diol, and an epoxide.[600] The 17-AAG diol is

the major metabolite in human hepatic microsomes, followed by 17-AG. Cytochrome P450 (3A4) was identified as the enzyme responsible for 17-AAG metabolism. Acrolein, a known nephrotoxin, is a by-product of 17-AG. Also, the 17-AG metabolite has shown biological activity equivalent to that of the parent compound. The quinone-metabolizing enzyme DT-diaphorase has been shown to alter 17-AAG's antitumor properties. A positive correlation between DT-diaphorase expression levels and growth inhibition by 17-AAG has been established.[585] Transfection of an active DT-diaphorase gene NQO1 into a human carcinoma cell line increased 17-AAG's growth-inhibitory activity 32-fold. Polymorphisms of the NQO1 gene, which is found in 5% to 20% of the population, as well acting as a substrate for p-glycoprotein efflux pump may limit 17-AAG's clinical efficacy.

Clinical Investigation With 17-AAG: Several phase I trials in adult patients have investigated different scheduling regimens of 17-AAG.[601–605] Administration of 17-AAG on daily × 3 schedule or daily × 5 schedule has been associated with dose-limiting toxicities, namely, hepatotoxicity, diarrhea, and thrombocytopenia at substantially lower doses (40–56 mg/m^2).[603,605] Grade III GI toxicities including nausea, vomiting, and diarrhea are associated with the formulation of 17-AAG, which contains 4% DMSO. No objective clinical responses were reported on the daily × 5 or weekly schedule; however, in xenograft models the effects of 17-AAG on HSP90 client proteins lasted up to 72 hours, suggesting that twice-weekly dosing might be more effective. Thus, additional trials have evaluated twice weekly and weekly × 3 every 4 week schedules. A recent study recommended phase II doses of 175 to 200 mg/m^2 given twice weekly. This schedule was associated with a persistent increase of HSP70; however, no consistent changes in PBMC phosphorylated Akt, HSP90, or Raf-1 during treatment.[604] Combination phase I studies of 17-AAG with docetaxel, irinotecan, imatinib, trastuzumab, and bortezomib, are currently ongoing.

Clinical Investigation With Tanespimycin (KOS-95): Tanespimycin (KOS-953) or (17-AAG in Cremophor) has demonstrated major responses and stable disease in relapsed and refractory multiple myeloma. In a multicenter phase I study, the combination of tanespimycin and bortezomib demonstrated antitumor activity in myeloma patients.[606] Patients received a 1-hour infusion of tanespimycin on days 1, 4, 8, 11, and 21 following bortezomib. The group receiving 1.3 mg/m^2 bortezomib + 340 mg/m^2 tanespimycin is being expanded following 1/10 patients experiencing a DLT (myalgias/cramps). Grade III to IV toxicities include anemia, back pain, and thrombocytopenia, all of which are reversible. HSP70 induction was observed in PBMCs prior to day 11. A phase II study of this combination in refractory myeloma is planned.

Clinical Investigation With IPI-504: Because 17-AAG suffers from poor aqueous solubility and must be administered with DMSO or newer Cremophor formulations, synthesis of HSP90 inhibitors with more favorable pharmaceutical properties is needed. IPI-504, the highly soluble hydroquinone hydrochloride derivative of 17-AAG, has been shown to be 4000-fold more soluble than 17-AAG.[607] In preclinical studies, single agent IPI-504 as well as in combination with bortezomib has shown antitumor effects in xenograft models of multiple myeloma.[608] Also, treatment with IPI-504 resulted in BCR-ABL protein degradation, decreased numbers of leukemia stem cells, and prolonged survival of leukemic mice bearing the T315I mutation.[609] A phase I study has been initiated in relapsed myeloma patients. IPI-504 is administered over 30 minutes on days 1, 4, 8, and 11 every 21 days. Thus far, 15 patients have been treated, with doses ranging from 90 to 300 mg/m^2, no dose-limiting toxicities have been observed to date.[610]

Clinical Investigation With Alvespimycin (KOS-1022): Alvespimycin (KOS-1022) is a second-generation HSP90 inhibitor that has begun phase I trials in IV and oral schedules.[611] Escalating doses of alvespimycin were given intravenously over 1 hour twice weekly every 3 weeks. Alvespimycin demonstrated antileukemic activity with tolerable toxicity at 24 mg/m^2 twice weekly. In 23 patients with AML, 3 patients experienced complete response and 1 patient demonstrated stable disease while on study × 9 cycles. Clinical trials of alvespimycin in combination with trastuzumab in solid malignancies are also ongoing.

17-DMAG: The water-soluble stable geldanamycin derivative, 17-(dimethylaminothylamino)-17-demethoxygeldanamycin (17-DMAG), has demonstrated more potent in vitro and in vivo antitumor activity than 17-AAG.[612] In addition, 17-DMAG offers three potential advantages over 17-AAG: (a) aqueous solubility eliminates formulation problems associated with 17-AAG, (b) 17-DMAG undergoes limited metabolism, and (3) it has higher oral bioavailability.[613] Phase I studies evaluating 17-DMAG have been recently initiated.

Other HSP90 Inhibitors

In addition to benzoquinone ansamycins and the semisynthetic analog 17-AAG, several other compounds were found to bind HSP90 and disrupt its chaperone function.

Radicicol: Radicicol, a macrocyclic antibiotic isolated from *Monosporum bonorden*, binds the N-terminal domain of HSP90 competing with its natural ligand, ATP.[614] Although a more potent inhibitor of HSP90 ATPase compared to geldanamycin, radicicol lacks antitumoral activity in vivo owing to its unstable chemical nature. Oxime-derivative compounds, which retain the HSP90 inhibitory activity and have a more stable chemical structure, were developed.

Novobiocin: Novobiocin, a coumarin antibiotic, binds the C-terminus domain of HSP90, as opposed to N-terminus binding with geldanamycin and radicicol.[615] However it was shown to retain inhibitory activity against HSP90 and degrade its client-signaling proteins. Thus, it appears that N- and C-terminal domains are both essential for HSP90 chaperone functions.

Bryostatin 1: Bryostatin 1 (NSC339555) is a macrocyclic lactone isolated from the marine bryozoan *Bugula neritina*. It originally attracted attention in view of its activity against a wide variety of tumor types in an NCI screen. In hematopoietic cells, bryostatin 1 displays the unique capacity to inhibit the growth of human leukemia cells[616] while stimulating the growth of their normal counterparts.[617]

Bryostatin 1 has been shown to act like the phorbol ester phorbol myristate acetate (PMA) in that it binds to and activates the serine-threonine kinase protein kinase C.[618] However, in contrast to PMA, it is a weak inducer of leukemic cell maturation[619] and in fact blocks PMA-mediated differentiation.[620] This may reflect the ability of bryostatin 1, on chronic administration, to downregulate PKC activity.[621]

In preclinical studies, bryostatin 1 has shown activity against continuously cultured and primary human leukemia and lymphoma cells when administered at nanomolar concentrations.[622,623] In addition, bryostatin lowers the threshold for leukemic and lymphoma cell apoptosis in response to conventional cytotoxic agents. The latter include ara-C, fludarabine, vincristine, paclitaxel, and chlorodeoxyadenosine.[624–628] It is postulated, although not definitively established, that such actions may reflect bryostatin 1-mediated downregulation of PKC, which exerts antiapoptotic actions.[629] More recently, bryostatin 1 has been shown to interact synergistically with more novel agents, including flavopiridol, through a process that may involve induction of TNF.[630] In clinical studies, bryostatin 1 has been administered according to several schedules, including a 1-hour infusion, a 24-hour infusion, and a split day 1 and 4 course weekly × 3 every 4 weeks[631,632] or a 24-hour infusion weekly for 8 weeks.[633] More recently, bryostatin 1 has been administered as a 72-hour continuous infusion every 2 weeks.[634] The maximally tolerated doses for the former schedules are 40 to 50 μg/m^2 and 120 μg/m^2 (40 μg/m^2/day for 3 days) for the latter.[631–633] Dose-limiting toxicity consists of myalgias, which are cumulative and which do not respond well to standard analgesic therapy. Other toxicities include fatigue, hepatotoxicity, nausea and vomiting, and phlebitis.

Bryostatin 1 as a single agent has shown some although limited activity. For example, when administered as a 120-hour continuous

infusion every 2 weeks at a dose of 120 μg/m^2, 3 of 25 patients with CLL or NHL achieved a CR or objective PR.[633] On the other hand, out of nine patients with multiple myeloma, none responded to this bryostatin 1 dose and schedule.[635]

Results have been somewhat more promising when bryostatin 1 was combined with established cytotoxic drugs. For example, administration of bryostatin 1 as a 24-hour infusion (50 μg/m^2) immediately before and after a split course of high-dose ara-C resulted in 4 CRs in 23 patients with highly refractory disease.[636] Administration of escalating doses of bryostatin 1 as a 1-hour infusion immediately before or after a 5-day course of fludarabine (doses of 16–25 mg/m^2/day) resulted in 17 of 53 objective responses, including six in patients who had progressed on fludarabine previously.[637] Neither sequence was clearly superior to the other. Finally, in a phase I study, patients with B-cell malignancies were treated with a 24-hour continuous infusion of bryostatin 1 followed by a bolus injection of vincristine every 2 weeks. The maximally tolerated dose of bryostatin 1 was 50 μg/m^2.[638] Of the 24 evaluable patients, 5 patients had durable CRs or PRs, and an additional 5 patients had stable disease. Collectively, these findings suggest that bryostatin 1 may have a role in hematologic malignancies when combined with established cytotoxic agents.

DRUG RESISTANCE TO CHEMOTHERAPEUTIC AGENTS/MULTIDRUG RESISTANCE

Although many hematologic malignancies develop resistance to a specific class of chemotherapeutic agents, especially to targeted therapeutics, through the development of kinase region point mutations, emergence of resistance to multiple cytotoxic chemotherapeutic agents is also common among hematologic malignancies. Etiology of resistance includes specific drug resistance mechanisms, overexpression of the ABC transports such as MDR-1 for drug efflux, and overexpression of antiapoptotic proteins. The Goldie–Coldman hypothesis predicts that drug-resistant tumor cell clones survive because of a favorable spontaneous mutation, which occurs in approximately one in a million cells. Because 1 g of tumor contains 1×10^9 cells, it becomes obvious that high tumor burden states have a tremendous number of mutations, which can contribute to drug resistance. This is the rationale for using combination chemotherapy at specific dose intervals to maximize dose intensity.

Drug resistance mechanisms have been discovered and subsequently defined at the molecular level by investigators working in vitro with tumor cell lines selected in the presence of specific antitumor agents, by analysis of primary samples of untreated and treated hematologic malignancies, and through screening of tumor banks. Classes of resistance include acquired protein deficiency, loss of sensitivity to apoptotic signals, and age-related defects in the cellular pathways that normally lead to apoptosis.

P-Glycoprotein (ABC-B1 transporter)

Structure and Function

The ABC superfamily of membrane transporters mediates the cross membrane flux of xenobiotics, naturally occurring toxic compounds, drugs, peptides, and ions. ABC stands for ATP-binding cassette transporter family. They have profound impact on homeostasis and are critically important to proliferation and differentiation signals in normal progenitor cells. They also mediate drug sensitivity.[639] The terminology remains challenging because many earlier works referred to PGP and MRP, whereas the more recent consensus on the ABC superfamily has created a more simple approach going forward. PGP (ABC B1 transporter) has been the subject of intense biochemical and clinical studies since it was first discovered in drug-resistant cell lines more than 20 years ago.[640] The biochemistry of PGP has been reviewed in detail by several investigators.[641–643] This phosphorylated glycoprotein has a molecular mass of approximately 170 kd and is localized to the plasma membrane where it functions as a drug efflux pump (see Table 56–7). The ATP-dependent extrusion of antineoplastic agents confers a relative level of resistance to the cell that overexpresses PGP. Recently, the family of drug-transporting proteins has been more carefully characterized, leading to the use of the terms ATP-binding cassette transporters.[644] The observation of double minute chromosomes and homogeneously staining regions in several MDR cell lines suggested that gene amplification is involved in PGP-mediated MDR. The human *MDR1* gene, which codes for PGP and is involved in antitumor drug resistance,[645,646] and the human *MDR2* gene (the product of which is expressed by hepatocytes) are located very near each other on human chromosome 7q21.1. The human *MDR1* gene has 28 exons and codes for a protein of 1280 amino acids. The PGP molecule has two homologous halves, each with a hydrophobic region containing six transmembrane domains and a hydrophilic region containing an ATP-binding site. The N-linked glycosylation occurs on the extracellular side (Fig. 56–11). PGP is a member of the ABC superfamily, which includes, among more than a hundred others, the multidrug resistance-associated protein (MRP); the pf*mdr* pump in *Plasmodium falciparum*, which results in chloroquine resistance; STE6, the transporter of the "a" peptide mating factor in yeast; the cystic fibrosis transmembrane conductance regulator (CFTR); and the TAP-1 and TAP-2 proteins that transport antigenic peptides for association with class I molecules and surface antigen presentation.[642,643] MRP has been demonstrated in several MDR mammalian cell lines and in human tumors (see below), whereas a recent study[647] in human tumor cell lines has shown TAP overexpression associated with MRP as well as drug resistance resulting from transfection of the *TAP* genes.

PGP has a broad specificity for hydrophobic compounds and can both reduce the influx of drugs into the cytosol and increase efflux from the cytosol. To accomplish the former, this "hydrophobic vacuum cleaner" must detect drugs and expel them while they are still in the plasma membrane. Drugs are thought to be effluxed from the cytosol through a single barrel of the PGP transporter, although an exact mechanism has been lacking. A recent study has utilized electron microscopy to generate an initial structure of PGP to 2.5-nm resolution.[648] The structure was further refined by three-dimensional reconstructions from single particle image analysis of detergent-solubilized PGP and by Fourier projection maps of small crystalline arrays of PGP. This demonstrates that PGP is monomeric, with the shape of a cylinder 10 nm in diameter with a maximum height (in the plane of the membrane) of 8 nm (Fig. 56–11). Approximately one-half of the PGP molecule is within the membrane, as the lipid bilayer is approximately 4 nm in depth. When viewed from the extracellular surface of the membrane, PGP is pteroidal with a large central pore 5 nm in diameter. This large aqueous chamber in the membrane that is open to the extracellular space is closed on the cytoplasmic side presumably by the two 3-nM intracellular lobes (putative nucleotide-binding domains) and the hydrophilic cytoplasmic loops between the transmembrane domains. Thus, this large pore has a "gate" on the cytoplasmic side of the membrane that can regulate the transport of different-sized substrates.

Substrates of PGP include (see Table 56–7)[642,647] anthracyclines (doxorubicin, daunorubicin, epirubicin, and idarubicin); anthracenediones (mitoxantrone); aminoacridines (*m*-AMSA); taxanes (taxol and taxotere); epipodophyllotoxins (VP-16 and VM-26); *Vinca* alkaloids (vincristine, vinblastine, and vinorelbine); bortezomib.[649] and actinomycin D. Mitomycin C and one of the topoisomerase I inhibitors (topotecan) are both weak substrates for PGP. Several drugs reverse the resistance mediated by PGP overexpression and sensitize cells to the cytotoxic effects of antineoplastic agents. These drugs compete with antitumor agents for efflux from the cell, effectively increasing the intracellular concentration of the cytotoxic drug, and include Immunosuppressants (cyclosporin A, FK 506, rapamycin, PSC 833), calcium-channel blockers (verapamil, nifedipine), antiarrhythmics (quinidine), and other miscellaneous agents.[642,643,650,651] Several of these MDR-modulating agents have been used in clinical trials in an effort to sensitize resistant tumor cells (see below).

Table 56–7 Characteristics of Three Mechanisms of Multidrug Resistance That Result From Overexpression of P-Glycoprotein (PGP), Multidrug Resistance-Associated Protein (MRP), or Lung Resistance-Related Protein (LRP)

	PGP	MRP	LRP
Gene on chromosome	7q21.1	16p13.1	16p11.2
Protein			
Molecular mass	170 kd	190 kd	110 kd
Cellular location	Plasma membrane	Plasma membrane	Cytoplasm >> nuclear membrane
Function	Efflux pump, chloride channel	Drug transporter	Major vault protein (nucleocytoplasmic transport?)
Energy source	ATP	ATP	
Post-translational modifications	N-glycosylation, phosphorylation	N-glycosylation, phosphorylation	*No* N- or O-glycosylation
Analogs	Member ABC superfamily	Member ABC super-family; GS-X pump, MOAT, LTC_4 transport	
Drug resistance phenotype			
Antitumor agents	Act-D, AMSA, dauno, dox, epi, ida, mito-C (low), mtz, nav, tax, txtr, tpt (low), vbl, vcr, VM-26, VP-16	Act-D, chlor, CDDP-GSH, dauno, dox, epi, mel, tax (low), vbl (low), vcr, VM-26, VP-16	Carbo, CDDP, dox, mel, vcr, VP-16
Other drugs	Colch, rhod	As, Cd, colch (low), GSH conjugates, GSSG, LT_4, Sb	
Reversing agents	CSA, FK506, nifed, PSC833, quin, rap, verap	CSA, gnstn, indo, nicard, prbn, PSC833, verap, VX-710	
Normal hematopoietic tissues with increased expression	NK (CD56+) T cells, suppressor T cells (CD8+), B cells, CD34+ stem cells	PBMNs (esp. T cells), rbc membranes; liver and spleen low level	Macrophages
Prognostic significance	AML, MM, NHL	AML (inv 16)	AML, ALL

ABC, ATP-binding cassette; act-D, actinomycin D; As, arsenicals; carbo, carboplatin; Cd, cadmium; CDDP-GSH; cisplatin glutathione conjugate; chlor, chlorambucil; colch, colchicine; CSA, cyclosporin A; dauno, daunomycin; dox, doxorubicin; epi, epirubicin; gnstn, genistein; GS-X, glutathione conjugate; GSSG, oxidized glutathione; ida, idarubicin; indo, indomethacin; LTC_4, cysteinyl leukotriene; mel, melphalan; mito-C, mitomycin C; mtz, mitoxantrone; MOAT, multispecific organic anion transporter; NK, natural killer; nav, navelbine; nicard, nicardipine; nifed, nifedipine; prbn, probenecid; quin, quinidine; rap, rapamycin; rhod, rhodamine; Sb, antimonials; tax, taxol; txtr, taxotere; tpt, topotecan; vbl, vinblastine; vcr, vincristine; verap, verapamil; VM-26, teniposide; VP-16, etoposide.

Methods of Detection

Several monoclonal antibodies that recognize PGP and are commercially available for routine analyses have been described.[642,643,652] Monoclonal antibodies C219[653] and JSB-1[654] recognize internal epitopes of PGP, whereas antibodies MRK16[655] and UIC2[656] detect external antigens and are more suited for FACS analysis.

P-Glycoprotein Expression in Normal Human Tissue

High levels of expression of *MDR1*/PGP have been found in the epithelia of several human tissues with excretory function, suggesting that PGP is normally involved in transporting both exogenous toxic compounds and endogenous metabolites.[642] These tissues include the adrenal cortex, renal proximal tubule epithelium, biliary hepatocytes, small and large intestinal mucosa, pancreas, and endothelial cells of the brain and testis. Normal human hematopoietic tissues with high levels of *MDR1*/PGP include $CD34^+$ progenitor cells, $CD56^+$ (NK) cells, and $CD8^+$ (T-suppressor) cells.[657,658] Lower levels of expression have also been observed in $CD4^+$ (T-helper) cells, $CD19^+$ B cells, and $CD14^+$ cells (monocytes).

P-Glycoprotein Expression in Human Malignancies

Increased expression of PGP has been observed in several human tumors, especially those malignancies that arise in tissues that normally have high levels of PGP expression. A recent analysis of 61 human tumor cell lines (from leukemia, CNS tumors, melanoma, breast cancer, ovarian cancer, colon cancer, lung cancer, and kidney cancer), which were not selected for resistance to antitumor agents, demonstrated coexpression of two or three of the MDR proteins (PGP, LRP, or MRP) in 64% of the cell lines.[659] PGP and LRP were overexpressed in 3% of the tumors; MRP and LRP in 43%; and PGP, LRP, and MRP in 18%. The cell lines with the highest levels of drug resistance were found to overexpress all three proteins. Whether this is true in primary human tumors awaits further investigations.

Acute Myeloid Leukemia

An earlier meta-analysis of studies that examined the expression of *MDR1*/PGP in blasts of patients with AML[660] found that 40% (105/261 patients) who were PGP positive achieved a CR, whereas 81% (192/238) PGP-negative patients obtained a CR. An analysis of 96 untreated patients with AML showed that PGP expression predicted induction failure ($P < 0.0001$) and decreased overall survival ($P < 0.001$), as did unfavorable cytogenetics.[661] PGP expression was not detected in patients with favorable cytogenetic abnormalities [t(15;17), inv(16), t(8;21)], was found in 29% of those samples with a normal karyotype, and expressed in 62% of patients with an unfavorable cytogenetic abnormality. PGP was also detected in 63% of those with secondary AML, compared with 25% of those with de novo disease.[662] PGP analysis with the MRK16 antibody in 211 elderly patients (older than 55 years) with untreated AML once again showed that PGP expression is significantly associated with a decreased CR rate and resistant disease.[663] Patients in this report with de novo PGP-negative AML with favorable cytogenetics have a CR rate of 81%, compared with 12% for those with secondary AML, which is PGP-positive and has unfavorable cytogenetics. Recent clinical trials using the PGP substrate PSC833 acting as a competitive inhibitor have not shown the dramatic benefit expected, especially in older patients with acute leukemias.[664,665]

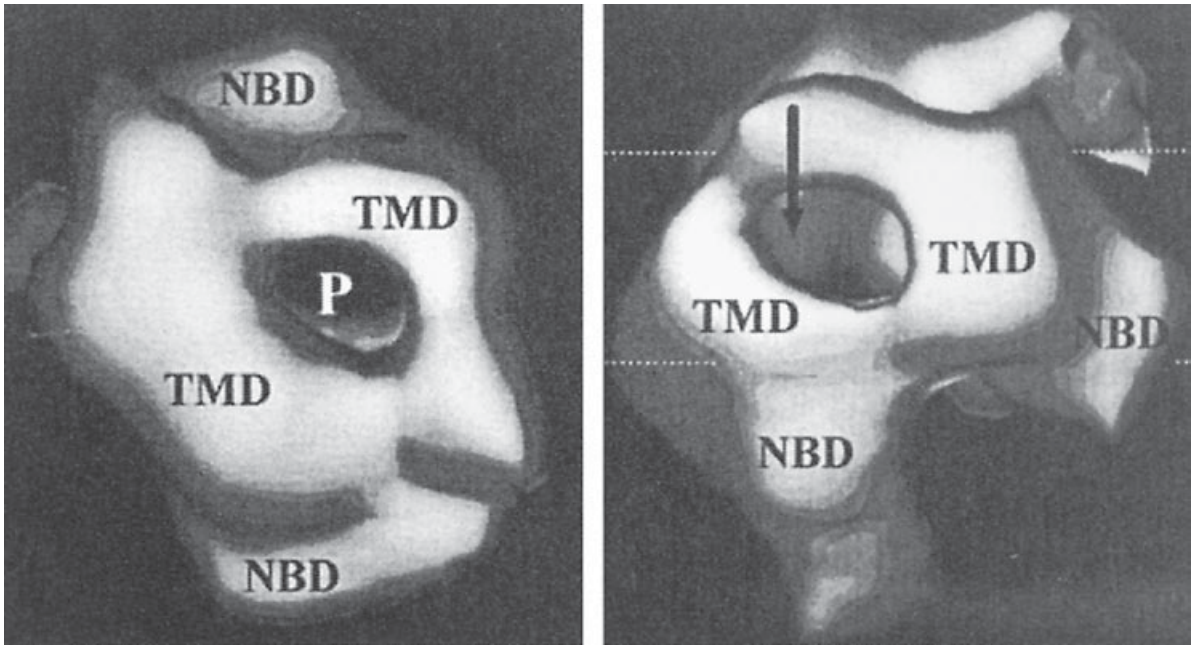

Figure 56–11 Structure of P-glycoprotein determined by electron microscopy; a computer graphic representation of the three-dimensional reconstruction is shown as a shaded surface representation of the structure. The straight arrow shows the putative ATP-binding domains. P represents the aqueous pore open at the extracellular face of the membrane. TMD, two thumbs, each of which probably corresponds to one of the two transmembrane domains. NBD, 3-nm lobes projecting from the structure at the cytoplasmic face of the membrane, probably corresponding to the two nucleotide-binding domains. **A,** View perpendicular to the extracellular surface of the lipid bilayer; **B,** side view of P-glycoprotein in which the approximate position of the lipid bilayer is indicated by the two horizontal dashed lines. Arrow, asymmetric opening providing access from the lipid phase to the aqueous core of the protein. *(Reproduced with permission from Rosenberg MF, Callaghan R, Ford RC, Higgins CF: Structure of the multidrug resistance P-glycoprotein to 2.5 nm resolution determined by electron microscopy and image analysis. J Biol Chem 272:10685, 1997.)*

Impact of P-Glycoprotein in Other Hematologic Malignancies

The role of PGP in the drug resistance of NHL, myeloma, and ALL is ill-defined.[666–669] CLL is another chronic leukemia where few PGP-related antineoplastic agents are used. However, a single study has shown a correlation between *MDR1* expression and survival, in which the 10 B-CLL patients who were *MDR1* positive had a median survival of 19 months compared with 46 months for the 17 patients who were *MDR1* negative ($P < 0.01$). Nonetheless, a recent study identified bortezomib as a substrate for PGP raising the possibility that myeloma PGP levels affect clinical response.[649] There have not been recent studies of the role of PGP in drug resistance in non-Hodgkin lymphoma in the past 5 years.

Clinical Studies With Modulators of P-Glycoprotein

The clinical trials that have employed various modulators of PGP have been reviewed by several investigators.[650,651,670] An early study in VAD-refractory multiple myeloma resulted in short-lived partial responses to VAD plus racemic verapamil in 5 of 22 patients.[671,672] Four of the five responders overexpressed PGP; however, cardiac side effects precluded further dose escalation of IV *R,S*-verapamil. Continuous IV infusion of cyclosporin A (CSA) with VAD in VAD-resistant myeloma patients resulted in 7 of 15 responses, which were more common in those who overexpressed PGP.[673] A randomized SWOG phase III study of VAD and oral verapamil in 120 patients with refractory myeloma demonstrated a 41% and 36% response in the VAD and VAD/verapamil arms, respectively, with median survivals of 10 and 13 months.[674] Continuous-infusion CSA has been dose-escalated in combination with daunorubicin and ara-C.[675] A transient hyperbilirubinemia was seen in 62% of the patients; these same patients had increased serum daunorubicin levels and a higher response rate. A complete response was seen in 26 of 42 patients; however, the MDR phenotype was not found to influence the response. A study of PSC833 in patients with acute leukemia treated with cytarabine, daunorubicin, and etoposide showed a modest benefit in patients under 45,[664] raising the potential of developing an effective strategy in patients more than 60 years of age in whom PGP expression in leukemic cells is more common.

Multidrug Resistance-Associated Protein (ABC G2 Transporter)

Structure and Function

The multidrug resistance-associated protein (MRP) was first described in 1992 in the doxorubicin selected small-cell lung cancer cell line,[676] and its biochemical characteristics and biologic properties have been reviewed.[677] It has now been classified within the larger context of ABC transporters, termed ABC G2 transporter.[644] Because much of the literature use the MRP nomenclature, we refer to this herein except for the studies using the ABC terminology. This N-glycosylated plasma membrane phosphoprotein has a molecular mass of 190 kd (1531 amino acids) and is a member of the ABC transporter superfamily (see Table 56–7 and Fig. 56–12). This transporter has 18 transmembrane domains (12 in the amino end and 6 in the carboxyl end) and is coded on human chromosome 16p13.1.

The overexpression of MRP has been shown in vitro to result in different levels of drug resistance to several classes of antineoplastic agents,[677–681] represented by actinomycin D, chlorambucil, melphalan, CDDP, daunomycin, doxorubicin, epirubicin, VM-26, VP-16, and vincristine. Low levels of resistance have also been reported to taxol, vinblastine, and colchicine. In addition to antitumoral agents, MRP (and its isoforms) are capable of transporting heavy metals

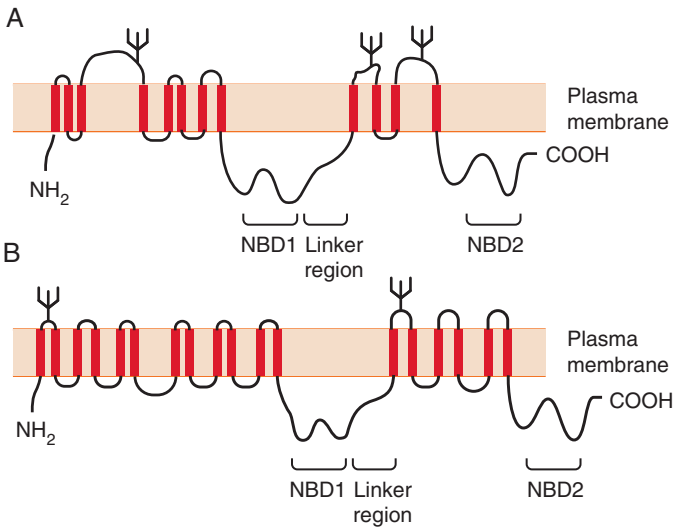

Figure 56–12 Models of multidrug resistance protein (MRP) membrane topology. MRP possesses features common to all members of the ATP-binding cassette transporter superfamily, in that each half of the protein is predicted to consist of several transmembrane domains followed by a cytosolic nucleotide-binding domain (MBD). The first model (**A**) is based on computer-assisted hydropathy analyses of the human MRP amino acid sequence and predicts that MRP is composed of 12 transmembrane domains (*solid bars*), eight of which are within the NH-2 proximal half of the protein. The second model (**B**), based on a comparison of human and murine MRP with other ATP-binding cassette transporters, suggests that there are up to four additional transmembrane domains in the NH2-proximal half of the protein. *(Adapted from Loe DW, Deley RG, Cole SPC: Biology of the multidrug resistance-associated protein, MRP. Eur J Cancer 32A:945, 1996.)*

(arsenicals, cadmium, and antimonials) as well as glutathione conjugates and cysteinyl leukotriene. Compounds reported to modulate MRP-mediated drug resistance in vitro include the calcium channel blocker verapamil, nocardipine, the protein kinase C inhibitor GF109203X, the cyclosporin analog PSC 833, the tyrosine kinase inhibitor genistein, the gyrase-inhibiting antibiotic difloxacin, and amiodarone.[677] More recently, VX-710, a nonmacrocyclic ligand of the FK506-binding protein FKBP12 and a potent modulator of PGP-mediated MDR, has been found to restore sensitivity of MRP-expressing HL60/ADR cells to the cytotoxic action of doxorubicin, VP-16, and vincristine.[682] The NSAID indomethacin has also been shown to significantly increase the sensitivity of HL60/ADR cells to doxorubicin and vincristine and may be a specific inhibitor of MRP.[683]

MRP Expression in Hematologic Malignancies

The expression of MRP mRNA (measured by an RNase protection assay) and/or the level of MRP protein (by immunohistochemistry) has been assessed in 148 patients with hematopoietic malignancies.[684–686] MRP mRNA expression was found to be significantly increased in 84% of patients with CLL and in 30% of those with AML. The vast majority of patients with ALL, CML, multiple myeloma, hairy cell leukemia, and NHL were found to have low levels of MRP mRNA expression in the malignant cells. MRP protein was assayed using monoclonal antibody MRPr1, and the results generally followed those of the message with increased expression in most patients with CLL. A study of 40 patients with refractory lymphoma and 16 with newly diagnosed lymphoma suggests a limited role for MRP mRNA expression in drug resistance in NHL, as 15 paired samples in the refractory group showed no difference in MRP expression pre- and post-EPOCH treatment.[687] In addition, the untreated patients had MRP mRNA levels that were no different from the pre- or post-EPOCH patient levels. A study of 49 patients with AML and 29 with ALL demonstrated significantly higher expression of MRP in ALL ($P < 0.007$) and in secondary AML ($P < 0.016$), but not in de novo AML.[688] Although there was initial enthusiasm for the likely association between the biology of hematologic malignancies, expression of MRP, and clinical response to therapeutic agents, there has been loss of interest in modulating expression of MRP or in developing targeted agents that block its function. For instance, between 2003 and 2007 there are few publications providing evidence of therapeutic impact of MRP expression or its modulation on the treatment of hematologic malignancies. One study provided an update on the expression of MRP in hematologic malignancies.[689] A second identified a new MRP inhibitor in preclinical models that could have therapeutic impact.[690] This group used a drug targeting the peripheral benzodiazepine receptor (pBR) ligand, PK11195. This molecule promotes mitochondrial apoptosis and blocks P-glycoprotein (PGP)- and ABC transporter-mediated drug efflux and potentiates apoptosis in malignant cells. MRP mRNA expression was found to be significantly ($P < 0.05$) elevated at second and later relapses (but not before treatment or at first relapse) in a group of 60 patients (52 children and 8 adults) with ALL.[691] Finally, 14 patients with relapsed AML were found to have a twofold increase in blast MRP mRNA relative to 29 patients with newly diagnosed AML ($P < 0.01$).[692] Paired blast samples (obtained at diagnosis and at relapse) from 13 AML and 4 ALL patients showed a twofold increase in 80% of the patients at relapse, suggesting that the expression of the MRP transporter at relapse may be involved in drug resistance.

The larger family of transporters, the ABC group including ABC G2 and ABC B1, are overexpressed in leukemic cells and in many malignant stem cells.[693] In fact in addition to CD44, high levels of ABC transporters assist in the characterization and isolation of the transplantable subpopulation of malignant stem cells. Brendel and coworkers found that both imatinib and nilotinib used to block the abl kinase in CML were effective blocking the ABC transporter in CML cells.[694] This suggested both that these agents might function in part by blocking expression of an important leukemic stem cell protein and that they would potentiate CML cells to other agents transported by the ABC system.

DNA Repair Pathway Mechanisms of Drug Resistance

O^6-Alkylguanine-DNA Alkyltransferase (MGMT)

As noted previously, the nitrosoureas and methylating agents are cytotoxic in large part due to formation of DNA adducts at the O^6 position of guanine.[695] The most efficient means of protection from the cytotoxicity of adducts at the O^6 position of guanine is rapid repair by the O^6-alkylguanine-DNA alkyltransferase (AGT or MGMT).[695] This protein serves as the stoichiometric acceptor protein for O^6-alkylguanine DNA monoadducts, transferring the alkyl group from DNA to the active site of the protein, inactivating the protein, and restoring DNA to normal.[695,696] However, the N^1G-N^3C DNA cross-link that follows chloroethylation is not a substrate for AGT. There is a striking correlation between drug resistance and alkyltransferase activity.[109,697] Of interest, high levels of AGT are found in many leukemias,[698] whereas low AGT is observed in normal human CD34 cells,[122] perhaps explaining why nitrosoureas are not used in leukemia management and why nitrosoureas are effective myeloablative agents used in high-dose chemotherapy regimens. Recently, a novel inhibitor of AGT, O^6-benzylguanine (BG) has been used to sensitize human tumors to BCNU.[697,699,700] Recent studies indicate activity of the combination of BG and BCNU in myeloma and in cutaneous lymphomas.[701] Therapeutic benefit from the methylating and alkylating agent cloretazine appears to be related to lower levels of AGT.[124] Likewise, temozolomide has some therapeutic efficacy in leukemia in a manner inversely related to AGT levels in the tumor cells.[122]

Mismatch Repair

The spectrum of drug resistance and sensitivity to methylating agents does not end with AGT. Recent evidence suggests that methylating agent-induced cell death involves an aborted effort at mismatch repair. Karran and others, in mammalian systems, have shown that the replicative DNA polymerase and the repair polymerase pauses at O^6-mG and preferentially inserts a thymine (T) at the site.[98,702] The O^6-mG:T base pair is recognized by the mismatch repair (MMR) system, which initiates base excision repair (BER, see below). In human cells, the MMR complex consists of at least 6 proteins involved in the recognition and repair of mismatch lesions: HMLH1, hMSH2, hMSH3, hPMS1, hPMS2, and GTBP (GT-binding protein, also called MSH6), all of which appear to be homologs of MMR proteins found in *E Coli* and in yeast.[97,703,704] Following binding recognition, an endonuclease removes a patch of approximately 100 to 1000 bp containing the T mismatch, DNA polymerase δ or γ fills in the patch, with reinsertion of a T opposite the O^6-mG and a DNA ligase closes the strand break.[97] Because the O^6-mG:T is re-formed, cytotoxicity ensues as a result of repetitive efforts at DNA repair and induction of both chromosomal breakage, rearrangements, energy depletion, and apoptosis.[705] Drug resistance based on mutation or loss of expression of an MMR protein, owing to mutation within one of the gene coding regions, or promoter methylation leading to loss of gene expression, has been noted in solid tumors and in leukemias and lymphomas. The mutator phenotype was originally described in cells with acquired resistance to methylnitrosourea, methylmethanesulfonate or *N*-methyl-*N*-nitroso-*N*-nitrosoguanidine, which were tolerant to G→A point mutations according to the inability to repair O^6-mG[601] and are cross-resistant to 6-thioguanine (6-TG) used in childhood leukemia maintenance regimens, which forms the 6-TG:T mismatch.[98,99]

MMR Mutations and Methylating Agent Resistance

Mismatch repair defects in humans were initially described in hereditary nonpolyposis colon cancer, or HNPCC, which comprises approximately 15% of all colon cancer,[97,104,704] lymphomas, and relapsing acute leukemias.[682] The genetic defect results in a high rate of spontaneous mutations within microsatellite DNA, resulting in the replication error (RER) phenotype arising as the expansion or contraction of mono-, di-, or trinucleotide repeats within the microsatellites.[97] Tumor cells defective in MMR are remarkably resistant to temozolomide regardless of AGT activity or its inhibition by BG, confirming the importance of MMR in sensitivity to methylating agents.[94] Of interest, MMR mutant cells are also two- to threefold resistant to cisplatin,[706] perhaps because the cisplatin DNA adduct is bound by the MMR complex, slowing its recognition and repair by the nucleotide repair pathway and increasing its cytotoxicity.[707] Such MMR-deficient cells also exhibit microsatellite instability, a measure of genomic instability and the propensity to develop further mutations during therapy leading to subclones of resistant cells. Loss of PMS2 has been identified in a family of childhood lymphomas.[708] Microsatellite instability is seen in acute leukemias and in T-cell leukemias,[709,710] suggesting both that these malignancies have lost MMR function and that they are more prone to drug resistance and acquisition of additional mutations that give rise to further drug resistance. Evidence of microsatellite instability and loss of MMR is much more common in treatment-related leukemias,[711] again providing a mechanism of drug resistance.

Base Excision Repair

Methylating agents such as procarbazine and temozolomide form large numbers of N^3-A and N^7-G adducts in addition to O^6-mG (with TMZ, the relative amounts are 72 N^7mG: 8 O^6mG: 5 N^3mA). Thus, under normal circumstances, cells process many more N^7mG and N^3mA lesions than O^6mG lesions, even though the latter appears much more cytotoxic, except in MMR defective cells. Repair of N^3-A and N^7-G adducts through BER is efficient and normally leads to cell survival rather than cell death. Adducts are recognized by the methylpurine glycosylase (MPG) with removal of the base, generating an abasic (or AP) site. The AP site is then cleaved by the class II hydrolytic endonuclease (or apurinic endonuclease, APE) generating a single strand break with a 5′PO_4 which becomes the substrate for DNA polymerase-β, and to a lesser extent, polymerases δ and γ, followed by DNA ligase (reviewed by Sancar[95]). Other compounds induce nucleotide pool imbalance leading to misincorporation of bases that become substrates for BER. These compounds include folate antagonists such as Methotrexate, 5-FU, and to a lesser extent, nucleoside analogs such as fludarabine. Misincorporation of uracil after 5-FU inhibition of thymidilate synthase also leads to BER.[712] Compounds to disrupt BER, such as methoxyamine,[713,714] are now being developed and may lead to combination therapy for hematologic malignancies.

DRUG RESISTANCE TO ANTIMETABOLITES

Although overlap exists, antimetabolites can be classified into nucleoside analogs that are incorporated into RNA and/or DNA and agents that inhibit de novo purine and pyrimidine biosynthetic pathways. Mechanisms of resistance to these agents fall into several broad categories. For example, many antimetabolites are prodrugs in that they must be converted intracellularly into active nucleotide forms in order to exert their cytotoxic actions. Consequently, events that interfere with cellular accumulation of drug and/or nucleotide formation will reduce activity. Examples include decreased transport of methotrexate or decreased nucleotide formation of Ara-C and 6-thioguanine by reductions in activity of deoxycytidine kinase or HGPRT, respectively. Alternatively, enhanced drug catabolism reduces cytotoxicity. Examples include the deamination of Ara-C (to inactive Ara-U) by cytidine deaminase or catabolism of 6-TG by thiopurine methyltransferase. A third mechanism of resistance stems from the presence of increased intracellular levels of a competing metabolite (eg, dCTP in the case of Ara-C, or hypoxanthine or guanine in the case of 6-TG). Fourth, alterations in the level of activity of a target enzyme or the presence of a mutant form that is less inhibitable will also confer resistance. Examples include increased activity or a mutant form of DHFR (in the case of methotrexate), an altered DNA polymerase α (in the case of Ara-C), or increased activity of ribonucleotide reductase (through overexpression of either subunit). Finally, cytokinetic factors represent a common theme in the case of most (but not all) antimetabolites in that a reduction in the S-phase fraction generally leads to reduced drug sensitivity. Note that these resistance mechanisms are agent specific and are distinct from the more general modes of resistance (eg, increased expression of BCL2) associated with defects in the distal cell death pathway.

FUTURE THERAPEUTIC IMPLICATIONS OF CANCER BIOLOGY

Future treatment strategies against hematologic malignancies are likely to be directed against those cellular targets that are responsible for the altered biology and transformed phenotype of cancer versus normal cells. This altered biology results from the accumulation of genetic mutations and alterations secondary to the unique genomic instability of cancer cells. Major development is taking place targeting protein kinases, translocation fusion proteins, promoter demethylation and histone deacetylation, immunomodulator proteins such as lenazolid, and inhibitors of cytokines such as IL-6 that are overexpressed in hematologic malignancies. As noted above, defects in the DNA repair pathway and in cell-cycle checkpoints that cause inappropriate progression through the cell cycle facilitate the genomic instability of cancer cells. These too are critical to transformation, and agents that overcome these abnormalities are important targets for drug development.

Because dysregulated cell-cycle progression is a common feature of neoplastic cells, several strategies are being developed and tested

to exploit this as a therapeutic target. These strategies include the use of drugs that inhibit the function of the mitotic kinase $p34^{cdc-2}$ (CDK1), for example, flavopiridol or inhibitors of the dual-specific phosphatase cdc25, which dephosphorylates and activates $p34^{cdc-2}$. Flavopiridol also inhibits CDK2 and CDK4 by binding to the hydrophobic, adenine binding pocket of the ATP site of these G_1-S kinases, thereby inducing G_1 arrest. An additional strategy is to inhibit mitogenic signaling mediated by oncogene products such as activated Ras, Raf, and Bcr-Abl. Antisense oligonucleotides to RAF, BCR-ABL, MYB, RAS, and BCL2 are being tested for their antitumoral effects alone or in combination with other cytotoxic drugs. Inhibitors of Ras farnesylation exert their antitumoral effects by, as yet, unclear mechanisms.

The relentless growth of tumors and leukemia requires the delivery of nutrients and growth factors through new blood microvessels (angiogenesis). Inhibitors of angiogenesis have an exciting potential in cancer and leukemia therapy. Bevacizumab (anti-VEGF) is approved for solid tumors and is being evaluated in hematologic malignancies. These agents target the vascular endothelial growth factors (eg, VEGF, bFGF, and PDGF) or their receptor-mediated signaling (eg, SU 5416).

APPENDIX 56–1

CLINICAL PHARMACOLOGY OF ALKYLATING AGENTS

MECHLORETHAMINE (Mustargen)

Chemistry: Mechlorethamine, also called nitrogen mustard, is a water-soluble and alcohol-soluble analog of sulfur mustard gas. It is a bifunctional chloroethylating agent that alkylates DNA, RNA, and protein.

Absorption, Fate, and Excretion: The parent compound is highly reactive and has a biologic half-life of approximately 15 minutes. The principal route of degradation is spontaneous hydrolysis, but some enzymatic demethylation also occurs.

Preparation and Administration: Mechlorethamine is supplied in vials of 10 mg with 100 mg of sodium chloride, and is reconstituted with 10 mL sterile water to yield a 1-mg/mL solution, ideally prepared immediately before use. However, the manufacturer considers the drug expired 1 hour after reconstitution. The drug is injected over a few minutes through a tubing as a freely running IV infusion. For topical application (eg, in mycosis fungoides), 10 mg of drug is dissolved in 60 mL of tap water. Alternatively, a 10 mg% ointment has been used by dissolving the drug in 95% ethyl alcohol and petrolatum (Aquaphor). Mechlorethamine is a powerful vesicant. In the event of extravasation, vigorous irrigation followed by 0.25% sodium thiosulfate injection at the site of extravasation should be attempted. Ice packs may be placed for 6 to 12 hours to minimize the local reaction.

Toxic Effects: Myelosuppression is the dose-limiting systemic side effect. This worsens with each additive cycle. Severe nausea and vomiting, infertility, alopecia, and pain at the site of injection, which can sometimes spread to involve the venous system (tracking), are also common. Occasionally, a macular papular rash is observed, but this does not appear to be allergic in nature and does not contraindicate continuation of therapy. Infertility is common, but may be reversible. Infrequent adverse effects include alopecia, anorexia, weakness, and diarrhea. The drug has also been shown to induce chromosomal abnormalities and may contribute to the development of secondary leukemias, as seen in patients treated with this agent as part of the MOPP regimen.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: Mechlorethamine is incorporated in many chemotherapy combinations used in the treatment of Hodgkin disease (MOPP [mechlorethamine, vincristine, procarbazine, prednisone] and MOPP/ABV [Adriamycin, bleomycin, and vinblastine] hybrid) and in some NHLs (prednisone, etoposide, methotrexate, doxorubicin [Adriamycin], cyclophosphamide, Leucovorin [PROMACE]/MOPP). However, its use has largely been supplanted by other agents.

CYCLOPHOSPHAMIDE (CYTOXAN)

Chemistry: Cyclophosphamide is a cyclic phosphamide ester of mechlorethamine. Once metabolically activated, it alkylates DNA, forming cross-links.

Absorption, Fate, and Excretion: The drug is relatively well absorbed orally, with approximately 75% oral bioavailability. The parent compound is not active. The drug is metabolized by the hepatic CYP system, which ultimately generates at least two active compounds: Phosphoramide mustard and acrolein. The latter appears to be responsible for cyclophosphamide's bladder toxicities. The plasma half-life of cyclophosphamide varies from 4 to 6.5 hours. Approximately 15% of the drug is excreted unchanged in the urine. Dose reduction should be considered in patients with severe renal failure.

Preparation and Administration: Cyclophosphamide is supplied as 25- and 50-mg tablets and as a powder for parenteral administration in 100-, 200-, and 500-mg and 1- and 2-g vials. It is dissolved by adding 5 mL of preservative-free sterile water for every 100 mg of drug. Cyclophosphamide is chemically stable for 24 hours at room temperature and for 6 days if refrigerated.

Toxic Effects: Marrow suppression is the major side effect. The myeloid series is primarily affected, although thrombocytopenia also occurs at high doses and alopecia is common. Nausea and vomiting can be severe and are usually delayed, occurring 6 to 8 hours after administration. Hemorrhagic cystitis occurs in 10% of patients receiving nontransplant doses and is apparently due to the formation of the urotoxin acrolein. Because of this potential side effect, patients should be well hydrated. Mesna disulfide (sodium 2-mercaptoethanesulfonate disulfide) has also been used on a weight equivalent basis to ameliorate cyclophosphamide-induced bladder toxicity. Other potential toxic effects include stomatitis, skin and nail hyperpigmentation, interstitial pulmonary fibrosis, and the syndrome of inappropriate secretion of antidiuretic hormone. Rare episodes of acute congestive heart failure have been reported. After bone marrow transplant doses, hemorrhagic cystitis is common and cardiac toxicity (cardiomyopathy) may be seen. Late sequelae include bladder fibrosis (more common with daily [oral] therapy), bladder cancer, leukemogenesis, and infertility.

Potential Drug Interactions: Corticosteroids may increase P450 enzyme-induced metabolism and is often avoided in high-dose therapy. When combined with doxorubicin, it may increase cardiac toxicity. This may be prevented by amifostine. In animal studies, conflicting results were reported when the P450 enzyme inducer, phenobarbital, was given with cyclophosphamide. Most investigators, however, have observed a reduction in the amounts of active metabolites. Conversely, when cimetidine (but not ranitidine) was administered in leukemia-bearing mice before treatment with cyclophosphamide, a significant prolongation of their survival and higher plasma concentrations of alkylating metabolites were observed. Although one should remain alert for these potential drug interactions, none has been demonstrated in humans. Cyclophosphamide reduces serum pseudocholinesterase levels, which may prolong the neuromuscular blocking effects if given simultaneously. Caution must be exercised when administering high doses of these two drugs to critically ill patients. Life-threatening hyponatremia may develop when used in conjunction with indomethacin, although the precise incidence is unknown.

Therapeutic Indications in Hematology: Cyclophosphamide is a key drug in the treatment of lymphomas and myeloma. It is incorporated in many chemotherapy regimens, including CHOP, MACOP-B, PROMACE/CYTABOM, CVP, and VMCP (see chapter for details). In addition, cyclophosphamide is the drug most

commonly used in preparatory regimens for bone marrow transplantation. It is also used in solid tumors and as an immunosuppressant in nonmalignant conditions such as glomerulonephritis and systemic lupus erythematosus.

IFOSFAMIDE (IFEX)

Chemistry: Ifosfamide is an oxazaphosphine nitrogen mustard that differs from cyclophosphamide by the placement of chloroethyl groups.

Absorption, Fate, and Excretion: As in the case of cyclophosphamide, the parent compound is inactive and is metabolized by the cytochrome P450 system in the liver. The metabolism of ifosfamide is influenced by the dose and schedule of administration. When administered as a single bolus, 60% is eliminated into the urine, 53% as unchanged inactive drug. When administered daily for 5 consecutive days, 56% is excreted into the urine, 15% as the inactive parent compound. The half-life is 7 hours when administered daily for 5 consecutive days, and 15 hours when given as a single bolus dose. There is poor penetration across the blood–brain barrier. Its longer half-life and slower metabolic activation allows higher doses to be given.

Preparation and Administration: The drug is provided in 1-g vials and should be reconstituted in sterile water or bacteriostatic water to a final concentration of 50 mg/mL. Ifosfamide can be diluted further in 5% dextrose, normal saline, or Ringer's solution for injection to achieve concentrations of between 0.6 and 20 mg/mL. The solution should be infused over 30 minutes. To prevent hemorrhagic cystitis, patients must receive mesna disulfide for protection against urotoxicity and must be kept well hydrated (2 L/day). Mesna is a thiol compound that is rapidly oxidized to dimesna in vivo. Mesna and dimesna are filtered by the glomeruli, reabsorbed in the proximal tubule, and finally secreted back into the tubular lumen of the kidney. In the tubules, approximately one-third of the filtered dimesna is readily converted back to mesna. The free sulfhydryl group of this compound reacts with the urotoxic metabolite acrolein produced by both ifosfamide and cyclophosphamide (see Fig. 55–6). This reaction creates a nontoxic acrolein-mesna thioether that is safely eliminated in the urine. Mesna has also been shown to inhibit the degradation of ifosfamide or cyclophosphamide to acrolein.

Mesna has been given in combination with ifosfamide in different doses and schedules. One recommended schedule employs IV bolus injection in a dosage equal to 20% of the ifosfamide dose (on a milligram-to-milligram basis) at the time of ifosfamide administration and 4 and 8 hours after each dose of ifosfamide. Mesna has also been given by continuous infusion with excellent results. The two agents may be mixed together in the same IV solution; however, mesna is not compatible with cisplatin.

Toxic Effects: With the use of mesna to protect against urotoxicity, myelosuppression—especially leukopenia and, to a lesser extent, thrombocytopenia—is the dose-limiting side effect. Renal tubular acidosis can occur. Central nervous system effects, observed in approximately 10% of patients treated, include somnolence, confusion, depressive psychosis, and hallucinations. Less commonly, dizziness, disorientation, and cranial nerve dysfunction occur. Nausea and vomiting are common. Low serum albumin and elevated serum creatinine may enhance central nervous system toxicity. As with cyclophosphamide, such side effects as alopecia, leukemogenesis, and infertility also occur. Cardiac toxicity is rare.

Potential Drug Interactions: Because ifosfamide is also metabolized by the P450 system, physicians should remain alert for the same type of potential drug interactions that have been reported with cyclophosphamide. A recent report advises close monitoring of warfarin anticoagulant control in patients receiving ifosfamide/mesna.

Therapeutic Indications in Hematology: Ifosfamide was recently approved for treatment of patients with refractory testicular cancer. In hematologic malignancies, its major indication is in the treatment of refractory lymphomas.

MELPHALAN (Melphalan)

Chemistry: Melphalan is synthesized from nitrogen mustard and phenylalanine. It is a bifunctional chloroethylating agent that forms DNA cross-links.

Absorption, Fate, and Excretion: The oral bioavailability of melphalan is quite variable, 20% to 50% of the drug being excreted in the stool. Some patients show virtually no oral absorption. This fact is particularly pertinent in the treatment of myeloma patients, in whom a lack of response to melphalan may be due simply to poor oral absorption. Melphalan has a half-life of approximately 90 minutes. It is extensively metabolized, with only approximately 10% to 15% of an administered dose excreted unchanged in the urine.

Preparation and Administration: Melphalan is commercially available in 2-mg tablets and in IV formulation for high-dose therapy.

Toxic Effects: The dose-limiting toxicity is myelosuppression, manifested by leukopenia and thrombocytopenia and generally occurring 2 to 3 weeks after therapy. Recovery may take 6 weeks, however, in patients who have been heavily pretreated with chemotherapy drugs or radiotherapy, or both. Nausea, vomiting, and alopecia are uncommon side effects and are usually mild. Occasionally, amenorrhea and azoospermia, pulmonary fibrosis, dermatitis, and secondary malignancies (eg, leukemia) occur, especially in patients receiving the drug over the long term. At cumulative doses of less than 600 mg, the incidence of second hematologic malignancy is probably less than 2% but may be greater than 15% at higher doses. Higher doses used in transplant patients result in gastrointestinal toxicity that is dose limiting. At these doses, the syndrome of inappropriate secretion of antidiuretic hormone, pneumonitis, and hepatic venoocclusive disease have been observed.

Potential Drug Interactions: Administration of high-dose IV melphalan with cyclosporine increases the risk of cyclosporine nephrotoxicity.

Therapeutic Indications: The major use of melphalan is for the treatment of multiple myeloma, either as a single agent or in combination with other alkylating agents and prednisone (eg, the MP and VMCP regimens). The IV formulation has been approved for isolated limb perfusion in melanoma. It is used in high-dose protocols for myeloma and solid tumors at doses of 140 to 200 mg/m^2.

CHLORAMBUCIL (Chlorambucil)

Chemistry: Chlorambucil is an aromatic derivative of mechlorethamine.

Absorption, Fate, and Excretion: Chlorambucil is well absorbed after oral administration. It is extensively metabolized in the liver to its major metabolite, phenylacetic acid mustard (PAAM), which also has bifunctional alkylating activity. The half-lives of chlorambucil and PAAM are 1.5 and 2.5 hours, respectively; less than 1% of either chlorambucil or PAAM is excreted in the urine.

Preparation and Administration: Chlorambucil is commercially available as 2-mg tablets.

Toxic Effects: Treatment is usually well tolerated, with myelosuppression the dose-limiting toxic effect. Patients on a daily oral

schedule should have biweekly complete blood counts (CBCs). Nausea and vomiting are uncommon, but mild alopecia and skin rashes occasionally occur. As with the other alkylating agents, azoospermia (especially above cumulative dose of 400 mg), amenorrhea, and secondary leukemia are potential risks of prolonged therapy. Rare cases of pulmonary fibrosis have also been reported.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: The major uses are in the treatment of Waldenström macroglobulinemia, low-grade lymphomas, CLL, and Hodgkin disease. Except for CLL, chlorambucil has been supplanted by newer agents.

BUSULFAN (Myleran)

Chemistry: Busulfan is an alkylsulfonate bifunctional alkylating agent not chemically related to mechlorethamine. It forms DNA intrastrand and interstrand cross-links.

Absorption, Fate, and Excretion: Busulfan is well absorbed after oral administration. When given by the IV route, greater than 90% is cleared from the plasma after 3 minutes. The drug is extensively metabolized to inactive compounds that are excreted renally. The major metabolite is methane sulfonic acid, although more than 10 other not fully identified metabolites exist. Virtually no intact busulfan is found in the urine. The biologic half-life of busulfan is approximately 2.5 hours.

Preparation and Administration: The drug is commercially available as 2-mg tablets.

Toxic Effects: Although at low doses the major effect of busulfan is on the granulocytic series, at high doses all three hematologic series are affected. As compared with the other alkylating agents, its nadir of myelosuppression may be relatively late, in a range of 11 to 30 days. Hematologic recovery is also prolonged and may take approximately 54 days. A relatively common side effect is an Addisonian-like syndrome characterized by skin hyperpigmentation and weakness, but without abnormalities in adrenal function. Cumulative pulmonary toxicity has been well described and consists of a mixed alveolar and interstitial pneumonitis. As with the other alkylating agents, infertility and leukemogenesis can occur. Nausea and vomiting are rare. At high doses it is associated with hepatic venoocclusive disease in up to 19% of patients. Seizures may also occur and are controlled by diphenylhydration.

Potential Drug Interactions: A metabolic interaction may take place between busulfan and various anticonvulsant medications; however, further description of the specific effects are awaited.

Therapeutic Indications in Hematology: Busulfan is used mainly in the treatment of CML. More recently, high-dose busulfan has been incorporated into preparatory regimens for bone marrow transplantation. Blood level monitoring with adjustment for higher close levels improved therapeutic outcome and reduced toxicity.

CARMUSTINE (BCNU)

Chemistry: Carmustine, also called BCNU (1,3[bis]-2-chloroethyl-nitrosourea), decomposes spontaneously into a chloroethyl hydroxide that can alkylate the DNA, and into an isocyanide molecule, which may produce carbamylation of proteins. Cytotoxicity is due to DNA cross-links.

Absorption, Fate, and Excretion: Intravenously administered carmustine is rapidly metabolized, with a half-life of 70 minutes. Approximately 30% to 80% of metabolites are eliminated in the urine within 24 hours. The drug or its metabolites, or both, readily cross the blood–brain barrier, resulting in cerebrospinal fluid concentrations within the range of 15% to 70% of plasma levels. Peak serum levels vary widely in patients treated at 200 to 600 mg IMF.

Preparation and Administration: Carmustine is commercially available in 100-mg vials as a white lyophilized powder. The drug is reconstituted with 3 mL of absolute alcohol provided by the manufacturer and 27 mL of sterile water, and can be further diluted with normal saline or 5% dextrose in water. It should be used immediately after reconstitution and can be infused over 1 to 2 hours.

Carmustine is chemically stable for 3 hours at room temperature and for 24 hours when refrigerated.

Toxic Effects: Myelosuppression is the dose-limiting toxic effect and tends to increase with successive cycles of therapy. Leukopenia and thrombocytopenia are characteristically delayed and reach their maximum between the 3rd and 6th weeks after drug administration. Nausea and vomiting can be severe. Abnormal liver function tests may be found, but the abnormalities are usually mild and reversible. Two rare but serious toxic effects include cumulative pulmonary/interstitial pneumonitis progressing to fibrosis and progressive renal damage, which are dose related. Secondary leukemias can also occur 5 to 10 years after treatment. Patients who receive greater than 1100 mg/m^2 are at increased risk of pulmonary fibrosis. Carmustine is not a vesicant, but rapid infusion often produces a burning sensation at the injection site.

Potential Drug Interactions: Cimetidine may enhance the myelosuppressive effect of carmustine. Carmustine may decrease the pharmacologic effects of phenytoin. In rats with intracerebrally implanted tumors, pretreatment with phenobarbital eliminated the antitumor activity of carmustine. The reduction in carmustine antitumor activity correlated with increased carmustine metabolism, which is apparently the result of hepatic microsomal enzyme induction.

Therapeutic Indications in Hematology: Carmustine in combination with other cytotoxic agents may be used in the initial treatment of Hodgkin disease (BCVPP regimen) and multiple myeloma (VBAP regimen). In high-dose therapy, it appears in BEP, for relapsed lymphomas.

LOMUSTINE (CCNU)

Chemistry: Lomustine, also called CCNU, is a nitrosourea derivative with choloroethyl and cyclohexyl side chains.

Absorption, Fate, and Excretion: The drug is rapidly absorbed from the gastrointestinal tract and is rapidly and completely metabolized. Its active metabolites have prolonged plasma half-lives, within a range of 16 to 48 hours. Approximately 50% of an administered dose is detectable (as metabolites) in the urine within 24 hours, and 75% is detectable within 4 days. Active metabolites cross the blood–brain barrier and can be detected in significant concentrations in the cerebrospinal fluid.

Preparation and Administration: The drug is commercially available in 10-, 40-, and 100-mg capsules.

Toxic Effects: The toxicity profile of lomustine is similar to that of carmustine. Because lomustine can produce vomiting, and the drug is given orally, special attention should be directed to emesis control. If the patient vomits soon after ingestion, the vomitus should be inspected for the presence of intact capsules. The drug should be given again if capsules are identified with certainty. Secondary leukemias are reported 3 to 10 years after use.

Potential Drug Interactions: These are similar to those of carmustine.

Therapeutic Indications in Hematology: Lomustine is occasionally used as second-line treatment for patients with Hodgkin disease and NHL, and for childhood gliomas.

STREPTOZOCIN (Zanosar)

Chemistry: Streptozocin is a naturally occurring nitrosourea derived from *Streptomyces acromogenes*. The drug is a glucosamine-1-methyl-nitrosourea, which, unlike the other nitrosoureas, methylates DNA and is cytotoxic owing to induced mismatch repair.

Absorption, Fate, and Excretion: After IV administration, the drug is rapidly metabolized, with no intact drug detectable in the plasma after 3 hours. Its half-life is 40 hours. Within the first 24 hours after administration, approximately 10% of the parent compound is excreted in the urine.

Preparation and Administration: The drug is commercially available in 1-g vials and is reconstituted with either 9.5 mL of normal saline or 5% dextrose in water for injection to form a 100-mg/mL solution. IV infusion of the drug over 30 to 45 minutes usually prevents discomfort at the injection site. Patients should be kept well hydrated to preclude renal tubular toxicity.

Toxic Effects: Although nausea and vomiting have been considered by some investigators to be the limiting toxic effects, in most phase I trials nephrotoxicity was the principal dose-limiting effect. Nausea and vomiting are severe and require aggressive antiemetic support. Streptozocin may also aggravate duodenal ulcers. Renal toxicity frequently occurs and includes mild proteinuria, glycosuria, hypophosphatemia, renal tubular acidosis, and occasionally irreversible azotemia. Although the myelosuppressive effect of streptozocin is mild, it can potentiate the bone marrow suppression of other cytotoxic drugs. Slight increases in hepatic enzymes can also occur. Occasionally, patients (primarily those with insulinomas) may experience transient alterations in glucose metabolism.

Potential Drug Interactions: Streptozocin can potentiate the hyperglycemic effect of glucocorticosteroids. Phenytoin therapy decreases the cytotoxic effect of streptozocin on the pancreatic b cells, leading to potential interference with its therapeutic effect in patients with pancreatic islet cell tumors. Streptozocin is a potent renal toxin, and every effort should be made to avoid concomitant administration of other nephrotoxins.

Therapeutic Indications in Hematology: Streptozocin has been used in the initial treatment of Hodgkin disease and, less commonly, in NHLs.

DACARBAZINE (DTIC)

Chemistry: Dacarbazine is also called DTIC [5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide]. After undergoing metabolic activation by microsomal enzymes in the liver, it acts primarily as an alkylating agent.

Absorption, Fate, and Excretion: After IV administration, the drug is extensively metabolized. Activated DTIC has an elimination half-life of 5 to 7 hours. Approximately 40% to 50% of the parent drug is found in the urine within the first 24 hours after administration.

Preparation and Administration: DTIC is commercially available in 100- and 200-mg vials, which must be protected from light and stored at a temperature of 2°C to 8°C. The drug is reconstituted with normal saline or sterile water to produce a 10-mg/mL solution. It can be administered as a slow IV push or by infusion over 15 to 30 minutes.

Toxic Effects: Myelosuppression, primarily represented by leukopenia, is the dose-limiting toxic effect. Use of the drug leads to considerable problems with emesis and requires aggressive antiemetic support. A flu-like syndrome consisting of fever, malaise, and myalgias may occur. Direct sunlight during the first 2 days after drug administration may result in facial flushing, facial paresthesias, and light-headedness. Hepatotoxicity and diarrhea have also been reported. Pain along the injection site can occur if the drug is rapidly infused, but can usually be lessened by prolonging the infusion rate. Secondary leukemias are reported between 3 and 10 years after use.

Potential Drug Interactions: DTIC activation may be enhanced by phenytoin or phenobarbital although the clinical significance of this potential interaction remains uncertain. There may be a potential (as yet poorly characterized) drug interaction with levodopa, whereby the response to levodopa is diminished.

Therapeutic Indications in Hematology: DTIC is used primarily in the treatment of Hodgkin disease as part of the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and DTIC) regimen and for melanoma.

PROCARBAZINE

Chemistry and Mechanism of Action: Procarbazine is a substituted hydrazine derivative with a chemical structure similar to that of the monoamine oxidase inhibitors (MAOIs). Accordingly, procarbazine exhibits weak MAOI effects. Procarbazine itself is inert and must undergo metabolic activation to generate cytotoxic reactants, the mode of action of which is not clear. They may inhibit transmethylation of methyl groups of methionine into tRNA or may also directly damage DNA. Hydrogen peroxide, formed during the autooxidation of procarbazine, may attack protein sulfhydryl groups contained in residual proteins tightly bound to DNA.

Absorption, Fate, and Excretion: Procarbazine is rapidly and completely absorbed by the oral route, with peak plasma levels occurring within 60 minutes. It penetrates well into the cerebrospinal fluid. The drug is readily metabolized in the liver and has a plasma half-life of 10 minutes after IV injection. The major sites of elimination are the kidneys, where approximately 70% of the drug is excreted as *N*-isopropylterephthalamic acid and less than 5% is excreted unchanged.

Preparation and Administration: Procarbazine is commercially available as 50-mg capsules.

Toxic Effects: The usual dose-limiting toxic effect is myelosuppression. Occasionally nausea and vomiting may be dose limiting, although tolerance to those effects may develop during continued administration. Other less common side effects include paresthesias, headache, dizziness, depression, apprehension, insomnia, nightmares, hallucinations, drowsiness, ataxia, foot drop, decreased reflexes, tremors, coma, confusion, convulsions, skin rash, alopecia, myalgia, and arthralgia. Procarbazine may possibly be leukemogenic.

Potential Drug Interactions: Combination chemotherapy that includes procarbazine may result in a decrease in digoxin plasma levels. Because procarbazine is a weak MAOI, hypertensive reactions could theoretically occur following concurrent ingestion of sympathomimetics, levodopa, tricyclic antidepressants, or foods with high tyramine content (eg, dark beer, yogurt, cheeses, and red wines). However, such reactions have not been reported. Concomitant use of narcotics or other strong sedatives may result in exaggerated depressant effects, leading to coma and possibly death. Procarbazine also interacts with alcohol, causing a disulfiram-like reaction.

Therapeutic Indications in Hematology: Procarbazine is often used in combination with other cytotoxic agents in the treatment of

Hodgkin disease (MOPP and MOPP derivatives) and to a lesser extent in the treatment of NHLs (PROMACE-MOPP).

TEMOZOLOMIDE

Chemistry and Mechanism of Action: Temozolomide is not active but undergoes rapid nonenzymatic conversion at physiologic pH to the reactive compound monomethyl 5-triazino imidazole carboxamide (MTIC) which is also the active methyl group-donating metabolite of dacarbazine. Unlike dacarbazine, formation of MTIC from temozolomide does not required metabolic activation (liver) and thus, there is much more consistent conversion from temozolomide to the methyl donating MTIC. The cytotoxicity of MTIC is thought to be primarily due to alkylation of DNA. Alkylation (methylation) occurs mainly at the O6 and N7 positions of guanine. Cytotoxicity results from processing of these lesions by methylguanine methyltransferase, mismatch repair, and base excision repair.

Absorption, Fate, and Excretion: Temozolomide is rapidly and completely absorbed after oral administration; peak plasma concentrations occur in 1 hour. Food reduces the rate and extent of temozolomide absorption.

Temozolomide exhibits a mean elimination half-life of 1.8 hours and exhibits linear kinetics over the therapeutic dosing range. Temozolomide is spontaneously hydrolyzed at physiologic pH to the active species, 3-methyl-(triazen-1-yl)imidazole-4-carboxamide (MTIC) and to temozolomide acid metabolite. MTIC is further hydrolyzed to 5-amino-imidazole-4-carboxamide (AIC) which is known to be an intermediate in purine and nucleic acid biosynthesis and to methylhydrazine, which is believed to be the active alkylating species. Approximately 38% of the administered temozolomide total radioactive dose is recovered over 7 days; 37.7% in urine and 0.8% in feces. The majority of the recovery of radioactivity in urine is as unchanged temozolomide (5.6%), AIC (12%), temozolomide acid metabolite (2.3%), and unidentified polar metabolite(s) (17%). Overall clearance of temozolomide is approximately 5.5 L/hour/minute.

Preparation and Administration: Temozolomide is given orally with each capsule containing either 5, 20, 100, 140, 180, or 250 mg of temozolomide. The inactive ingredients for TEMODAR capsules are lactose anhydrous, colloidal silicon dioxide, sodium starch glycolate, tartaric acid, and stearic acid.

Toxic Effects: Bone marrow depression, including neutropenia, lymphopenia, anemia, and thrombocytopenia, occurs frequently with Temozolomide. Mild transaminase elevations of up to 40% of patients and hyperbilirubinemia of up to 19% are seen, mild to moderate headache is among the most commonly reported adverse effects along with moderate nausea and vomiting although this may be secondary to the use of antiemetics.

Drug Interactions: None described.

Therapeutic Indications in Hematology: Temozolomide may have some activity in both acute myelogenous leukemia and acute lymphocytic leukemia, but the correct dose is presently unknown. Temozolomide has no activity in Non-Hodgkin lymphoma.

APPENDIX 56–2

CLINICAL PHARMACOLOGY OF ANTIMICROTUBULE AGENTS

VINCRISTINE (Oncovin) AND VINBLASTINE (Velban)

Chemistry and Mechanism of Action: Both vincristine and vinblastine are asymmetric dimeric compounds that bind to the protein tubulin at a site distinct from that for the taxanes. At low concentrations, vincristine and vinblastine inhibit microtubule dynamics. At higher concentrations, they disrupt microtubules that constitute the mitotic spindle, resulting in metaphase arrest. They are relatively M phase specific. Owing to their lipophilicity, vinca alkaloids are rapidly taken into cells and achieve several-hundred-fold higher intracellular than extracellular concentrations. Overexpression of the multidrug resistance transporters PGP or MRP can reduce the intracellular accumulation, whereas alterations in the α or β tubulins can affect drug–target interaction for vinca alkaloids.

Absorption, Fate, and Excretion: After IV injection, both drugs are rapidly distributed to the body tissues, especially the red blood cells and platelets. Their elimination follows a triphasic pattern. The elimination half-lives are as follows: α, less than 5 minutes; β, 50 to 155 minutes; and γ, 20 to 85 hours. Both vinca alkaloids are primarily eliminated through the liver into the bile and feces, making patients with obstructive liver disease more susceptible to toxic effects. A 50% reduction in the dose is recommended for serum bilirubin concentrations of 1.5 to 3.5 mg/dL. Dose modification for renal dysfunction is not indicated. After brief IV bolus administration, peak plasma vincristine concentrations of 100 to 400 mM are achieved, which decline to less than 10 mM in 2 to 4 hours. Continuous infusion doses of 1.0 mg/m^2/day produce vincristine plasma concentrations ranging from 1 to 10 nM.

Preparation and Administration: Vincristine is commercially available in 1-, 2-, and 5-mg vials. Each milliliter contains 1 mg vincristine sulfate, 100 mg mannitol, 1.3 mg methylparaben, and 0.2 mg propylparaben. Vincristine is a powerful vesicant that should be administered only intravenously into a freely running infusion of normal saline or dextrose solution. If the drug is given by continuous infusion, it must be infused through a central IV line. In case of extravasation, infusion should be discontinued and any residual drug aspirated through the line. The manufacturer also recommends infiltrating the area with 1 to 2 mL of hyaluronidase, 150 U/mL, and then applying warm compresses for 72 hours to facilitate dispersion of the drug. Vinblastine is commercially available as a lyophilized powder and a 1-mg/mL solution in 10-mg vials. The lyophilized drug is reconstituted by adding sodium chloride for injection (which may be preserved with either phenol or benzyl alcohol) to the 10-mg vial. Administration of vinblastine should follow the same guidelines described for vincristine.

Toxic Effects: Vincristine's dose-limiting toxic effect is neurotoxicity, which appears to be related to its relative polarity. Peripheral neurotoxicity usually manifests as sensory impairment, decreased deep tendon reflexes, and paresthesias. Less commonly, severe painful dysesthesias, ataxia, foot drop, and cranial nerve palsy (eg, affecting the extraocular and laryngeal muscles) can occur. Autonomic neurotoxicities include constipation, abdominal cramps, and ileus, which may be prevented by use of mild laxatives. Alopecia occurs frequently, but myelosuppressive effects are minimal. Rare side effects include inappropriate secretion of antidiuretic hormone and ischemic cardiac toxicity. Vinblastine's dose-limiting toxic effect is myelosuppression, with leukopenia more pronounced than thrombocytopenia. Anemia is uncommon. Neurotoxicity can also occur but is significantly less common than with vincristine. Vinblastine is also a vesicant.

Potential Drug Interactions: Both vinca alkaloids have been reported to increase the accumulation of methotrexate and etoposide in tumor cells. Acute shortness of breath and bronchospasm can occur when vincristine or vinblastine is given in conjunction with mitomycin C. Because asparaginase may impair the hepatic clearance of vincristine, it is preferable to administer the vincristine 12 to 24 hours before the L-asparaginase. Vincristine may decrease the absorption and plasma levels of orally administered drugs such as digoxin. Dilantin may increase the cytotoxicity of vincristine in multidrug-resistant tumor cells; however, this remains to be demonstrated in the clinic. When concurrently administered, erythromycin may increase the toxicity of vinca alkaloids, especially vinblastine.

Therapeutic Indications in Hematology: The vinca alkaloids are among the most important drugs in the treatment of hematologic malignancies. They have a broad spectrum of activity and are often incorporated into many chemotherapy regimens used in the treatment of ALL, Hodgkin disease, NHLs, CLL, and multiple myeloma.

VINORELBINE (Navelbine)

Chemistry and Mechanism of Action: Vinorelbine is a semisynthetic derivative of vinblastine (5′ -nor-hydrovinblastine) with an eight-member catharanthine ring. Similar to other vinca alkaloids, it also binds to tubulin, inhibits microtubule assembly, and produces a mitotic arrest of cells. This occurs at concentrations that relatively spare axonal microtubules, which may reduce neurotoxicity.

Absorption, Fate, and Excretion: Short (6–10 minutes) IV infusions of 30 mg/m^2 produce peak plasma concentrations approximately 1.0 μg/mL with a triphase decay. Rapid α (<5 minutes) and β (49–168 minutes) half-lives result in a rapid decline in the plasma concentration in the first hour posttreatment, followed by a prolonged terminal half-life of 18 to 49 hours, reflecting slow efflux from the peripheral compartment. The volume of distribution at steady state is 20 to 75.6 L/kg. The drug is extensively bound to platelets, lymphocytes, and plasma proteins. The major site of metabolism is the liver, with 33% to 80% of the drug excretion in feces and approximately 20% in urine.

Preparation and Administration: Vinorelbine is available for injection in single use as 10 mg/mL in 1- or 5-mL vials without preservatives. The calculated dose is diluted to 1.5 to 3.5 mg/mL for a slow injection (6–10 minutes) by a syringe with 5% dextrose or 0.9% saline, or between 0.5 or 2.0 mg/mL in an IV bag. Because vinorelbine is a strong vesicant, it should be administered through a freely flowing IV access avoiding all extravasation.

Toxic Effects: Vinorelbine shares many of the principal toxicities of vinblastine. Myelosuppression is dose limiting but not cumulative, with nadirs occurring 7 to 10 days after administration.

Anemia and thrombocytopenia occur infrequently. Because of lower affinity for axonal versus spindle microtubules, neurotoxicity is less prominent with vinorelbine. Mild to moderate peripheral neuropathy and constipation occurs in approximately 30% of patients, and the incidence of neuropathy increases with the duration

of treatment. Mild to moderate nausea and vomiting is seen in 33% of patients. Stomatitis and diarrhea are less frequent. Transient elevations of transaminases have been reported. Among the miscellaneous side effects noted are chest pain with or without electrocardiographic changes (6%—most with underlying cardiac disease), as well as bronchospasm and dyspnea (5%). Alopecia is seen in 10% of patients.

Therapeutic Indications in Hematology: Objective responses have been observed in approximately 33% of patients with Hodgkin disease or NHLs.

PACLITAXEL (Taxol) AND DOCETAXEL (Taxotere)

Chemistry and Mechanism of Action: Both paclitaxel and docetaxel are complex diterpene alkaloid esters consisting of a taxane system linked to an oxetane ring and a C-13 side chain that is necessary for their cytotoxic effects in mammalian cells. After binding to the N-terminal 31 amino acids of the β-tubulin subunit in the tubulin oligomers or polymers, these taxanes kinetically stabilize microtubule dynamics at plus ends. They also decrease the lag time and shift the equilibrium toward tubulin polymerization into microtubule bundles. The disequilibrium of tubulin-microtubule polymerization results in mitotic arrest and apoptosis of cells. Taxane-induced mitotic arrest is associated with phosphorylation of BCL2 protein and increased intracellular levels of free BAX protein, which promote apoptosis. As compared with paclitaxel, docetaxel demonstrates 1.9-fold greater affinity for tubulin-binding sites and greater potency in mediating BCL2 phosphorylation.

Absorption, Fate, and Excretion: Taxanes generally are administered by IV infusion lasting over 3, 24, or 96 hours (paclitaxel) or 1 hour (docetaxel). Depending on the dose and schedule, peak plasma concentrations of paclitaxel range between 0.05 and 15.0 mM. Its steady-state volume of distribution ranges between 48 and 182 L/m^2, with rapid uptake in almost all tissues except the central nervous system and 98% plasma protein binding. Plasma decay for paclitaxel is biphasic, with α and β half-lives of 0.34 and 5.8 hours, respectively. Saturable distribution and elimination appear to be responsible for paclitaxel's nonlinear pharmacokinetics. This means that paclitaxel dose escalation in shorter schedules may result in disproportionate increases in area under the concentration–time curve and peak plasma concentration. It is metabolized to 6 hydroxy paclitaxel by the CYP3A isoform of the PU_{50} mixed-function oxidases in the hepatic microsomes. Total fecal and urinary excretion of paclitaxel and its metabolites is approximately 70% and 10%, respectively. Although dose modification is not necessary for renal insufficiency, a 50% reduction in dose is recommended even for moderate hyperbilirubinemia or significant elevations in hepatocellular enzymes. When administered as a 1-hour IV infusion, docetaxel has linear pharmacokinetics that fit a three-compartment model. Similar to paclitaxel, docetaxel also has a high clearance rate (0.36 L/h), steady-state volume of distribution (67.3 L/m^2), and terminal half-life of 12 hours. Docetaxel also has high protein binding (97%) and extensive tissue distribution. The drug or its metabolites also have high fecal (80%) and low urinary elimination (5%). Metabolism of docetaxel also primarily occurs in hepatic microsomal P450 mixed-function oxidases, CYP3A, CYP2B, and CYP1A.

Preparation and Administration: Paclitaxel is available as a 30 mg/5 mL single-dose vial in polyoxyethylated castor oil (Cremophor EL) 50% and dehydrated alcohol, USP 50%. The contents of the vial must be diluted before use. Docetaxel for injection is available as a concentrate in polysorbate 80 in two vial contents (23.6 mg/0.59 mL or 94.4 mg/2.36 mL), along with the appropriate diluent (1.83 or 7.33 mL) in separate vials. Adding diluent that is 13% (w/w) ethanol in water for injection to the concentrate produces a final premix concentration of 10 mg docetaxel/mL. The required amount of premix is transferred by a calibrated syringe into 0.9% saline or 5% dextrose to produce a final concentration of 0.3 or 0.9 mg/mL. The IV infusion is administered over 1 hour.

Toxic Effects: Hypersensitivity reaction (HSR) was noted in up to 30% of patients in the early phase I studies. HSR occurs early in the first or second infusion and may be caused by vehicle Cremophor EL or paclitaxel itself. HSR consists of dyspnea, bronchospasm, urticaria, and hypotension. Most HSRs regress completely after stopping the infusion and treatment with antihistamines, fluids, and vasopressors. Prolonged infusions (>3 hours) and premedication (dexamethasone 20 mg orally, 12 and 6 hours before treatment, diphenhydramine 50 mg, and ranitidine 150 mg IV 30 minutes before treatment) have reduced the incidence of major HSRs to less than 3%. Patients with a history of HSR may be rechallenged with paclitaxel at a markedly slower infusion rate, 20 mg dexamethasone IV every 6 hours for 4 doses prior to treatment. Although not formulated in Cremophor EL, HSRs can occur in up to 25% of patients receiving docetaxel. Most HSRs are minor, consisting of flushing, chest tightness, and low back pain. Premedication with dexamethasone 8 mg orally twice daily for 3 days, starting a day before treatment with docetaxel, considerably reduces the incidence of HSRs and fluid retention. Neutropenia is the main toxicity of paclitaxel and docetaxel, but it is not cumulative. With higher doses of paclitaxel (250 mg/m^2 over 24 hours), this can be ameliorated with subsequent administration of G-CSF. Severe thrombocytopenia and anemia are rare. Symmetric, distal, peripheral sensory neuropathy is usually seen with higher doses or multiple doses of paclitaxel. This often limits chronic use of paclitaxel. Diffuse areflexia and neuronopathy are less commonly seen. Higher doses can also cause motor and autonomic neuropathy as well as myalgias, especially in patients with preexisting neuropathy or when paclitaxel is used with cisplatin. Severe peripheral neuropathy or myalgias are less common after repetitive docetaxel at 100 mg/m^2. Cardiac rhythm abnormalities, especially brady arrhythmias and (rarely) heart blocks, have been reported secondary to paclitaxel treatment. A direct causal link between paclitaxel and myocardial ischemic episodes and tachyarrhythmias has not been established. Although noted, a direct link has also not been established between the occurrence of cardiac conductance abnormalities or ischemia and docetaxel treatment. Nausea, vomiting, diarrhea, and stomatitis are uncommon and generally mild to moderate. Alopecia is universal with both drugs. Skin toxicity is more severe and common with docetaxel. It is characterized by an erythematous pruritic maculopapular rash affecting forearms and hands. Onychodystrophy with discoloration, ridging, and brittleness of fingernails also occurs. Docetaxel can cause cumulative fluid retention resulting in peripheral edema, third-space fluid collection, and weight gain, which usually resolves slowly after stopping docetaxel. Concurrent treatment with dexamethasone, as noted earlier, delays the onset and decreases the incidence of these side effects.

Potential Drug Interaction: When paclitaxel infusion (24 hours) is administered following cisplatin, there is a 33% reduction in the clearance rate of paclitaxel. This produces suboptimal antitumor cytotoxicity and more profound neutropenia. Hence, the sequence of paclitaxel followed by cisplatin is commonly recommended. The use of carboplatin following paclitaxel has been reported to cause less thrombocytopenia than carboplatin alone. Mucositis is more pronounced when paclitaxel is used before doxorubicin, a sequence that reduces the clearance of doxorubicin. Hematologic toxicity is more prominent with the sequence of cyclophosphamide followed by paclitaxel, as compared with the reverse sequence of administration. Anticonvulsants such as phenytoin and phenobarbital induce the metabolism of paclitaxel and docetaxel by the P450 mixed-function oxidases. Conversely, in vitro studies have shown that inhibitors of the P450 system can interfere with the metabolism of both drugs. These inhibitors include erythromycin, testosterone, ketoconazole, and fluconazole.

Therapeutic Indications in Hematology: Both paclitaxel and docetaxel have significant activity against previously treated patients with NHLs. Paclitaxel is also very active against HIV-associated Kaposi's sarcoma.

APPENDIX 56–3

CLINICAL PHARMACOLOGY OF ANTIMETABOLITES

CYTOSINE ARABINOSIDE

Chemistry and Mechanism of Action: Cytosine arabinoside (1′-β-D-arabinofuranosylcytosine; ara-C) is a nucleoside analog that differs from its naturally occurring counterpart (2′-deoxycytidine) by virtue of the presence of a hydryoxyl group in the 2′-β configuration. The altered reactivity of the resulting arabinosyl sugar moiety confers on ara-C its cytotoxic activity. Ara-C enters the cell by a facilitated nucleoside diffusion mechanism, and is converted to its nucleoside monophosphate form, ara-CMP, by the pyrimidine salvage pathway enzyme, deoxycytidine kinase. This represents the rate-limiting step in ra-C metabolism. Ara-C may also be catabolized intracellularly to an inactive form, ara-U, by the enzyme cytidine deaminase. Ara-C is ultimately converted to its lethal triphosphate derivative, ara-CTP, by a mono- and di-phosphate kinase. Ara-CTP is an inhibitor of DNA polymerases α, β, and γ, and is also incorporated into replicating DNA strands, leading to inhibition of chain initiation and elongation, and premature chain termination. The extent of incorporation of ara-C into DNA closely correlates with lethality in leukemic cells. Although ara-C is generally thought of as a prototypical S phase-specific agent, its ability to interfere with DNA repair polymerases (eg, β and γ) as well as lipid biosynthetic enzymes may account for lethal effects in noncycling cells.

Absorption, Fate, and Excretion: Following IV administration, ara-C is rapidly deaminated to an inactive form, ara-U, by cytidine deaminase. This enzyme is present in the plasma, liver, and kidney, but is present at very low levels in the CNS. The initial plasma half-life of ara-C has been estimated to be 10 to 12 minutes. Approximately 90% of the administered ara-C dose is excreted by the kidney as ara-U or other inactive metabolites. The terminal half-life of ara-C is approximately 2 to 3 hours. CNS ara-C levels following a 2-hour infusion approximate 50% of plasma concentrations. Steady-state plasma concentrations following standard-dose therapy (eg, 100–200 mg/m^2/day as a continuous infusion) approximate between 10^{-7} and 10^{-6} M. When ara-C is given as a high-dose bolus infusion (eg, 1–3 g/m^2 over 1–3 hours), plasma levels as high as 100 μM can be achieved.

Preparation and Administration: Ara-C is provided as a sterile, lyophilized powder for reconstitution in vials containing 100 mg, 200 mg, 1 g, or 2 g of material. The powder is reconstituted with sterile bacteriostatic water for injection with benzyl alcohol (0.945%) added as a preservative. When reconstituted in this way, solutions are stable for up to 48 hours under controlled temperatures (eg, between 15°C and 30°C or 60°–86°F). Material reconstituted without preservative should be used immediately. For intrathecal injection, ara-C should be reconstituted in a diluent that does not contain preservative, for example, preservative-free 0.9% sodium chloride, USP, and used immediately.

Toxic Effects: Ara-C is primarily toxic to rapidly dividing tissues; consequently, myelosuppression and gastrointestinal toxicity represent the major side effects of this agent. Patients receiving ara-C regularly experience leukopenia, anemia, and thrombocytopenia, with nadirs appearing 7 to 14 days after drug administration. Gastrointestinal toxicity includes nausea and vomiting, abdominal pain, mucositis, and a chemical hepatitis characterized by elevation of liver function enzymes. The latter is generally reversible. Patients receiving ara-C as a high-dose infusion (eg, 1–3 g/m^2 repeated every 12 hours for a total of 6–12 doses) experience standard toxicities and several unique ones. These include alopecia, an exfoliative dermatitis, a chemical conjunctivitis (generally ameliorated by the prophylactic administration of a steroid or saline ophthalmic solution), a respiratory distress-like syndrome (characterized by the appearance of rales, an abnormal radiogram, and pulmonary insufficiency), and cerebellar toxicity. The latter, which is characterized by nystagmus, ataxia, and other cerebellar signs, may be irreversible, and its appearance mandates discontinuation of therapy. Intrathecal administration of ara-C has been rarely associated with toxicities described below for methotrexate.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: Ara-C represents a mainstay in the treatment of AML (eg, as part of the "7 and 3" regimen in which it is given in conjunction with daunorubicin).

It is also incorporated into some induction regimens for ALL.

High-dose ara-C (HIDAC), either alone or in combination with anthracycline antibiotics, is frequently employed in the treatment of refractory or relapsed AML or ALL. HIDAC has also been used in some salvage regimens for NHL (eg, ESHAP). Chronic low-dose ara-C has been used in the treatment of patients with the myelodysplastic syndrome.

METHOTREXATE

Chemistry and Mechanism of Action: Methotrexate (*N*-4-[[(2,4-diamino-6-pteridinyl)methyl]methylamino]benzoyl]-L-glutamic acid) represents a member of a class of compounds referred to as antifolates. Methotrexate is a potent inhibitor of dihydrofolate reductase, an enzyme responsible for the reduction of dihydrofolates to tetrahydrofolates. The latter are required in 1-carbon transfer reactions involved in de novo purine and pyrimidine biosynthesis, including conversion of deoxyuridylate (dUMP) to thymidylate (dTMP) by thymidylate synthase. As in the case of most antimetabolites, methotrexate is primarily active against S-phase cells. Methotrexate is transported across cell membranes by an energy-dependent, temperature-sensitive, concentrative process involving folate-binding proteins, after which it is polyglutamylated by the enzyme folylpolyglutamyl synthetase. Polyglutamylation of methotrexate enhances its intracellular retention and in some studies has been shown to correlate with the sensitivity of leukemic cells to this agent. The mechanism by which methotrexate kills cells may stem from interference with DNA synthesis (leading to a "thymine-less death") secondary to DHFR inhibition; disruption of purine biosynthesis; or a combination of these actions. The lethal actions of methotrexate may be reversed by reduced folates such as 5-formyltetrahydrofolate (leucovorin). The possibility that tumor cells may exhibit impaired transport of such reduced folates serves as the basis for strategies involving administration of high-dose methotrexate in conjunction with leucovorin rescue.

Absorption, Fate, and Excretion: In adults, oral absorption is dose dependent, with mean bioavailability approximating 60% at doses ≤30 mg/m^2. At higher doses (eg, ≥80 mg/m^2), bioavailability is less. Peak plasma concentrations occur 1 to 2 hours following oral administration. Methotrexate bioavailability approximates 100% for parenteral routes of administration; with these routes,

peak plasma methotrexate levels are achieved within 30 to 60 minutes after administration. For each route, the steady-state volume of distribution ranges from 40% to 80% of body weight. Methotrexate tends to accumulate in third-space fluids (eg, ascites or pleural effusions) and can result in prolonged release and accompanying toxicity. Consequently, it is generally not advisable for patients with fluid accumulations to receive methotrexate. Methotrexate competes with reduced folates for transport across cell membranes; however, at high doses (eg, ≥100 mg/m^2), passive diffusion is the primary mechanism through which intracellular accumulation occurs. Methotrexate is approximately 50% protein bound, and does not penetrate the CNS barrier when administered orally or parenterally at conventional doses. However, when given by the intrathecal route, high CNS levels are achieved. Administration of high-dose methotrexate with leucovorin rescue can also result in therapeutic CNS levels.

The primary route of excretion is renal, with 80% to 90% of the drug appearing unchanged in the urine within 24 hours following IV administration. The terminal half-life of methotrexate is 4 to 10 hours for patients receiving low-dose therapy and 8 to 15 hours for those receiving high-dose therapy. Because of the primary renal rate of excretion and the possibility of nephrotoxicity, methotrexate should be withheld or administered at reduced doses in patients with impaired renal function. Patients receiving high-dose methotrexate therapy should be hydrated and their urine alkalinized before administration to reduce the risks of toxicity.

Preparation and Administration: Methotrexate is available in multiple formulations: (a) tablets, containing 2.5 mg methotrexate and inactive ingredients (lactose, magnesium stearate, and pregelatinized starch; (b) methotrexate sodium injection, available in vials of 25, 50, and 250 mg, containing benzyl alcohol as a preservative, sodium chloride, and water for injection. Preservative-containing solutions should not be used for intrathecal or high-dose administration; (c) methotrexate sodium injection without preservative, which can be used for intravenous, intraarteriolar, intrathecal, and high-dose administration; (d) lyophilized powder, which is provided in 20-mg vials, and is reconstituted with preservative-free sodium chloride or 5% dextrose in water to a final concentration not exceeding 25 mg/mL.

For intrathecal administration, solutions of 1 to 1.5 mg/mL should be prepared using preservative-free 0.9% sodium chloride as the diluent. For high-dose therapy, leucovorin rescue is required to prevent significant toxicity. Leucovorin is administered 12 to 24 hours after the methotrexate at a dose of between 15 and 25 mg intravenously, intramuscularly, or orally every 6 hours until the methotrexate dose declines to levels of less than 5×10^{-7} M.

For patients receiving intermediate or high-dose methotrexate (eg, ≥500 mg/m^2), serum methotrexate and creatinine levels should be monitored at 24-hour intervals. If, after 48 hours, serum methotrexate levels are greater than 5×10^{-7} M but less than 1×10^{-6} M, leucovorin is continued at a dose of 25 mg/m^2 every 6 hours for 8 doses until methotrexate levels decline to below 5×10^{-7} M. If levels are greater than 1×10^{-6} M but less than 2×10^{-6} M at 48 hours, the dose of leucovorin is increased to 100 mg/m^2 every 6 hours × 8 doses. For methotrexate levels ≥2×10^{-6} M at 48 hours, the dose of leucovorin is 200 mg/m^2 every 6 hours × 8 doses.

Toxic Effects: Methotrexate primarily exhibits its toxic effects toward proliferating tissues. Consequently, dose-limiting toxicities include bone marrow suppression (leukopenia, thrombocytopenia, anemia), mucositis, and diarrhea. High-dose therapy is occasionally accompanied by transient elevations in liver function tests, whereas chronic low-dose therapy is more often associated with hepatic fibrosis. Standard-dose therapy is rarely associated with nephrotoxicity, but acute renal failure can be seen with high-dose therapy secondary deposition of 7-*OH*-methotrexate in the renal tubules. The risk of methotrexate nephrotoxicity is significantly reduced by insuring adequate hydration and alkalinization of the urine. Other reported toxicities include a maculopapular rash, and an idiosyncratic pulmonary toxicity characterized by cough, fever, dyspnea, hypoxia, and interstitial infiltrates.

A necrotizing leukoencephalopathy has been reported in patients receiving methotrexate who have had prior cranial irradiation. Intrathecal methotrexate has been associated with several toxicities, including (a) chemical arachnoiditis; (b) motor paralysis accompanied by cranial nerve dysfunction, seizures, and coma; and (c) chronic demyelinating syndrome. Each of these may be exacerbated by prior craniospinal irradiation.

Potential Drug Interactions: Methotrexate exhibits many potential drug interactions that are related to plasma protein binding. For example, many compounds are known to displace methotrexate from serum albumin, potentially increasing its bioavailability. These agents include sulfonamides, salicylates, tetracyclines, chloramphenicol, and phenytoin. However, the clinical implications of such interactions are not clear. Nonsteroidal antiinflammatory drugs should not be administered in conjunction with methotrexate when the latter is given at intermediate or high doses, owing to the potential for elevation and prolongation of methotrexate plasma concentrations. Penicillins can reduce renal clearance of methotrexate and should be used with caution in this setting. Probenecid may also reduce renal transport of methotrexate. Administration of methotrexate can also reduce the clearance of theophyllines, and concomitant use of these agents requires careful monitoring. Increases in methotrexate toxicity have been observed in some patients receiving trimethoprim/sulfamethoxazole, possibly as a consequence of enhanced antifolate effects. Administration of folates in vitamin preparations may reduce the efficacy of methotrexate by bypassing DHFR inhibition. Methotrexate may increase the toxicity (and potentially the activity) of various antineoplastic agents in a schedule-dependent manner (eg, when given before 5-FU).

Therapeutic Indications in Hematology: Methotrexate is widely employed in the treatment of ALL, particularly in the maintenance phase. Methotrexate is frequently administered intrathecally in patients with CNS leukemia, and prophylactically in certain patients with ALL. It also represents a component of various multidrug regimens used in the treatment of NHL (eg, M-BACOD, PROMACE-CYTABOM).

HYDROXYUREA

Chemistry and Mechanism of Action: Hydroxyurea is an inhibitor of the ribonucleotide reductase system that catalyzes the rate-limiting step in the de novo biosynthesis of purine and pyrimidine deoxyribonucleotides, that is, the conversion of ribonucleotide diphosphates to their deoxyribonucleoside diphosphate derivatives. Ribonucleotide reductase consists of two subunits: a binding and allosteric effector component and an iron-binding catalytic component. Hydroxyurea binds to and inactivates the catalytic subunit of the enzyme. Like most antimetabolites, hydroxyurea is an S phase-specific agent, and blocks cells in the G_1S phase of the cell cycle. Exposure of cells to hydroxyurea leads to a depletion of deoxyribonucleotide triphosphate (dNTP) pools, the extent of which correlates with DNA synthesis inhibition and cell death. Two consequences of hydroxyurea administration include potentiation of the metabolism/cytotoxicity of nucleoside analogs (eg, ara-C) as a result of dNTP pool depletion and elimination of amplified genes present extrasomally in double minute chromosomes.

Absorption, Fate, and Excretion: Hydroxyurea is generally administered orally, although IV regimens are currently being investigated. The drug is readily absorbed from the gastrointestinal tract, with peak plasma levels as high as 2.0 mM occurring approximately 2 hours after oral administration. Serum concentrations decline to undetectable levels after 24 hours. The drug is primarily excreted via the renal route, with 75% to 80% of the drug appearing in the urine 12 hours later. The drug penetrates the CSF, although it has not been

established that therapeutic levels are achieved following standard oral administration.

Preparation and Administration: Hydroxyurea is provided as 500-mg capsules. The drug is stored at room temperature in tightly capped containers and protected from heat.

Toxic Effects: The most common adverse reactions include myelosuppression (leukopenia, thrombocytopenia, anemia), gastrointestinal symptoms (eg, nausea and vomiting, stomatitis, anorexia, appetite disturbances), and dermatologic toxicity, such as rashes, skin ulcerations, and facial erythema. Rarer toxicities, generally seen at high doses, include neurologic disturbances, such as drowsiness, dizziness, headache, and convulsions, altered renal function, and alopecia. The mutagenic potential of hydroxyurea is unknown, and the drug should be avoided when possible in pregnant women.

Potential Drug Interactions: As noted earlier, hydroxyurea may increase the toxicity of certain nucleoside analogs. Hydroxyurea may also serve as a radiosensitizing agent; consequently, patients receiving concurrent radiation therapy may experience enhanced toxicity.

Therapeutic Indications in Hematology: Hydroxyurea has become, along with interferon-α, the mainstay of therapy in patients with chronic or accelerated phase CML. It is currently recommended for initial therapy of CML over busulfan and may prolong the chronic phase of this disease compared with the latter agent. Hydroxyurea has also been successfully used in the treatment of other myeloproliferative disorders, including myeloid metaplasia and myelofibrosis, polycythemia vera, and essential thrombocytosis. Its leukemogenic potential is uncertain, however, and it should be used with caution, particularly in younger patients. Hydroxyurea has also been shown to reduce the incidence of painful crises in individuals with sickle cell anemia in a subset of patients, a phenomenon that may result from increases in red blood cell fetal hemoglobin levels.

FLUDARABINE

Chemistry and Mechanism of Action: Fludarabine phosphate is a fluorinated derivative of the nucleotide analog 9′-β-D-arabinofuranosyladenine (ara-A) that is resistant to deamination by the degradative enzyme cytidine deaminase. It is converted intracellularly to its triphosphate derivative, which inhibits ribonucleotide reductase, as well as DNA polymerase α and DNA primase. Fluoro-ara-ATP is also incorporated into DNA, a process that appears to be essential for the induction of apoptosis in leukemic cells. Fludarabine is toxic to S-phase cells, but its ability to interfere with DNA repair may contribute to lethality in their noncycling counterparts.

Absorption, Fate, and Excretion: Following IV injection, fludarabine phosphate is rapidly deaminated (ie, within minutes) in the plasma to its nucleoside derivative, 2′-fluoro-ara-A, which is then converted intracellularly to its nucleotide form, 2′-fluoro-ara-AMP by the pyrimidine salvage pathway enzyme, deoxycytidine kinase. The half-life of 2′-fluoro-ara-A is approximately 10 hours; the primary mode of elimination is renal, with 25% of the total dose appearing in the urine as unchanged 2-fluoro-ara-A. Total body clearance of fludarabine is inversely correlated with serum creatinine.

Preparation and Administration: Fludarabine is supplied as a sterile powder in 50-mg vials containing 50 mg of mannitol and sodium hydroxide to adjust the pH to 7.7. Material is reconstituted in 2 mL of sterile water to yield a 25 mg/mL solution for injection. The material may be stored at 4°C (40°F); because the reconstituted solution contains no antimicrobial preservative, drug should be administered within 8 hours of formulation.

Toxic Effects: The most common dose-limiting toxicity is myelosuppression (neutropenia, thrombocytopenia, and anemia). Other toxicities include fever, chills, infection, nausea, and vomiting. Rarer toxicities include malaise, fatigue, anorexia, and weakness. Patients with CLL receiving fludarabine have experienced serious opportunistic infections and tumor lysis syndrome. The most serious toxicity of fludarabine when administered at high doses (>40 mg/m^2/day for 5 days) is irreversible neurotoxicity, including cortical blindness, necrotizing leukoencephalopathy, and death. This phenomenon has rarely if ever been seen in patients receiving conventional doses (eg, 25 mg/m^2/day for 5 days). Rare reports of interstitial pneumonitis have appeared.

Potential Drug Interactions: Fludarabine has been shown to potentiate the intracellular metabolism and activity of ara-C, although the toxicity of this combination may also be enhanced. No other interactions have been reported.

Therapeutic Indications in Hematology: Fludarabine has shown marked activity in both untreated CLL and in disease refractory to standard alkylating agent therapy. Fludarabine has also shown activity as a single agent, and particularly in combination with others (eg, mitoxantrone, cytoxan) in indolent NHL.

2′-CHLORODEOXYADENOSINE

Chemistry and Mechanism of Action: 2′-Chlorodeoxyadenosine (CdA; cladribine) is a derivative of deoxyadenosine that differs from its parent compound by the presence of a chlorine moiety at the 2′-position of the purine ring. It is transported intracellularly by facilitated nucleoside diffusion and phosphorylated by the pyrimidine salvage pathway enzyme deoxycytidine kinase. CdA is relatively resistant to deamination by cytidine deaminase. CdA is readily converted to its triphosphate derivative, 2′-chlorodeoxyadenosine-5′-triphosphate, particularly in cells of lymphoid origin, and is incorporated into tumor cell DNA by DNA polymerase α. CdATP is also an effective inhibitor of ribonucleotide reductase, which may contribute to lethal effects. CdA induces cell death (apoptosis) in both cycling and noncycling cells, possibly by promoting DNA fragmentation and by depleting cells of ATP or NAD, or both.

Absorption, Fate, and Excretion: Relatively little pharmacokinetic information concerning CdA is available. The drug is most commonly administered as a 7-day continuous infusion or as a 2-hour infusion over 5 days. Bioavailability of CdA following subcutaneous administration approximates that of the IV route, but is less than that after oral administration. Renal excretion appears to be the major route of elimination. When given as a 2-hour infusion, CdA has a relatively long terminal half-life (eg, approximately 6 hours), and plasma concentrations following such a schedule may approximate those associated with the continuous infusion. CSF levels are approximately 25% of plasma concentrations.

Preparation and Administration: For daily infusions, CdA is diluted under sterile conditions in bags containing 500 mL of 0.9% sodium chloride injection, USP. The use of 5% dextrose solutions is not recommended because of enhanced degradation of the drug. For preparation of longer infusions (eg, 7 days) the use of bacteriostatic sodium chloride injection, USP, is recommended. Once prepared, solutions of CdA should be refrigerated at a temperature between 4°C (40°F) and 8°C (47°F) for no more than 8 hours prior to administration.

Toxic Effects: The major toxicity of CdA is myelosuppression, which is primarily observed following intermittent rather than continuous infusion. Other toxicities include fever, generally beginning several days after initiation of therapy, and increased susceptibility to opportunistic infections. Rare side effects include nausea and hepatic and renal toxicity.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: CdA has shown significant activity in CLL and hairy cell leukemia. However, response rates in the former disorder appear to be somewhat less than those obtained with fludarabine; moreover, patients who have progressed on fludarabine therapy infrequently respond to CdA. Other diseases in which CdA has shown activity include NHL and Waldenström macroglobulinemia.

2′-DEOXYCOFORMYCIN (Pentostatin; DCF)

Chemistry and Mechanism of Action: 2′-Deoxycoformycin is an adenosine analog that is a highly effective inhibitor of the purine biosynthetic enzyme adenosine deaminase (ADA). It is transported across cell membranes by facilitated nucleoside diffusion, where it binds tightly to ADA. Inhibition of ADA results in accumulation of deoxyadenosine metabolites, most notably dATP. dATP exerts its toxic effects through inhibition of ribonucleotide reductase and induction of global imbalances in deoxyribonucleotide triphosphate pools. These result in interference with DNA synthesis and repair. 2′-Deoxycoformycin is particularly toxic to certain lymphoid cells with low levels of ADA activity. It is also toxic to both cycling and resting cells; the mechanism underlying its cytotoxicity toward quiescent cells is unknown.

Absorption, Fate, and Excretion: After IV injection of 2′-deoxycoformycin, the plasma clearance follows a biphasic pattern, with a terminal elimination half-life of 3 to 15 hours. Protein binding is limited. The drug is only partially metabolized, with approximately 60% to 80% of the drug appearing unchanged in the urine after 24 hours. The total body clearance of 2′-deoxycoformycin correlates well with creatinine clearance. Patients with impaired renal function may require reductions in the 2′-deoxycoformycin dose.

Preparation and Administration: 2′-Deoxycoformycin is unstable when reconstituted in solutions of pH less than 5.0. Consequently, it is customarily reconstituted in normal saline. 2′- Deoxycoformycin is provided in vials containing 10 mg of drug, 50 mg of mannitol, and sodium hydroxide to adjust the pH to <7.0. It is administered as an IV infusion over 20 to 30 minutes. Hydration is recommended before and after 2′-deoxycoformycin administration.

Toxic Effects: The major toxicities of 2′-deoxycoformycin include myelosuppression, nausea and vomiting, immunosuppression, acute renal failure, keratoconjunctivitis, fever, and elevations of liver function enzymes. At high doses, neurologic toxicity, including somnolence, seizures, and coma have been reported, although these are seen infrequently in patients receiving standard dose therapy. When administered at such doses (eg, 4 mg/m^2 biweekly), side effects are relatively minor.

Potential Drug Interactions: 2′-Deoxycoformycin may augment the toxicity of ara-A (vidarabine) as a consequence of inhibition of ADA.

Therapeutic Indications in Hematology: 2′-Deoxycoformycin is primarily used in the treatment of hairy cell leukemia, where response rates of up to 90% have been reported, even in patients refractory to other therapy, including α interferon. Activity has also been reported in other lymphoid malignancies, such as T-cell lymphoma, CLL, prolymphocytic leukemia, and Waldenström macroglobulinemia, although its precise role in the treatment of these disorders remains to be fully evaluated.

6-THIOGUANINE

Chemistry and Mechanism of Action: Thioguanine (6-TG) is a guanine analog in which the 6′-hydroxyl group is replaced by a sulfhydryl group. It interferes with de novo purine biosynthesis at multiple levels. Following transport across the cell membrane by facilitated diffusion, 6-TG competes with hypoxanthine and guanine for phosphorylation by hypoxanthine-guanine phosphoribosyltransferase (HGPRT) and is converted to its nucleotide form, 6-thioguanylic acid (TGMP), which accumulates within cells. TGMP inhibits several purine biosynthetic enzymes, including glutamine-5-phosphoribosylpyrophosphate aminotransferase and IMP dehydrogenase. 6-TG nucleotides are also incorporated in DNA and RNA, where they function as fraudulent bases. It is presently unknown which of these actions (interference with purine interconversions, blockade of de novo purine biosynthesis, or nucleic acid incorporation) is primarily responsible for 6-TG cytotoxicity, although DNA incorporation appears to play a significant role. 6-TG is considered to be an S phase-specific agent.

Absorption, Fate, and Excretion: Following oral administration, the bioavailability of 6-TG is variable, ranging from 14% to 46% of the administered dose (mean = 30%). Peak plasma levels are achieved 8 hours after administration and decline slowly thereafter. The average plasma disappearance of 6-TG is approximately 80 minutes, with a range of 25 to 240 minutes. Relatively little unchanged material appears in the urine; the major excreted product is the methylated derivative 2-amino-6-methyl thiopurine. CNS penetrance after parenteral administration is minimal.

Preparation and Administration: 6-TG is available in tablet form for oral administration. Each tablet contains 40 mg of 6-TG and inactive ingredients including gum acacia, lactose, magnesium stearate, potato starch, and stearic acid. IV preparations are available only in experimental settings.

Toxic Effects: The major dose-limiting toxicity of 6-TG is myelosuppression. Other less common toxicities include gastrointestinal disturbances (nausea and vomiting, anorexia, diarrhea), jaundice, and elevated liver function tests.

Potential Drug Interactions: In contrast to 6-MP, the metabolism of 6-TG is not modified by allopurinol, and consequently dose adjustments do not have to be made when these agents are administered concurrently.

Therapeutic Indications in Hematology: The primary indication for 6-TG is in the treatment of AML, generally in conjunction with other agents (eg, daunorubicin and ara-C). However, it has not been firmly established that addition of 6-TG to such regimens improves therapeutic efficacy. 6-TG also has activity in CML, although it has been supplanted by other agents (eg, hydroxyurea, interferon α) in this disorder.

6-MERCAPTOPURINE

Chemistry and Mechanism of Action: 6-Mercaptopurine (1,7-dihydro-6*H*-purine 6-thione monohydrate; 6-MP; purinethol) is an analog of the purine bases adenine and hypoxanthine. It is both an antineoplastic and immunosuppressive agent. Like 6-TG, 6-MP and its metabolites act at multiple levels to interfere with purine biosynthesis and interconversions. It competes with hypoxanthine and guanine for HGPRTase, and, following conversion to thioinosinic acid (TIMP), blocks conversion of IMP to xanthylic acid and IMP to AMP. Both TIMP and another metabolite, 6-methylthioinosinate (MTIMP) inhibit glutamine-5-phosphoribosylpyrophosphate aminotransferase. 6-MP is also incorporated into RNA and DNA, thereby functioning as a fraudulent base. It is unknown which of these actions is primarily responsible for the lethal actions of 6-MP, although available evidence points to DNA incorporation as a prime determinant of cytotoxicity.

Fate, Absorption, and Excretion: Following oral administration, the bioavailability of 6-MP is highly variable, presumably due to

interpatient differences in gastrointestinal absorption, which averages 50% of the administered dose. Extensive catabolism by hepatic xanthine oxidase also contributes to drug elimination. Approximately 50% of the administered 6-MP or its metabolites are recovered in the urine. The volume of distribution generally exceeds the total body water. Following IV administration, the plasma disappearance half-life was 47 minutes in adults. Plasma protein binding is modest (approximately 19%), and CNS penetrance is minimal.

Preparation and Administration: 6-MP is supplied as tablets for oral administration. Each tablet contains 50 mg of 6-MP and the inactive ingredients corn and potato starch, lactose, magnesium stearate, and stearic acid. An IV preparation containing 500 mg of 6-MP per vial is available for investigational use.

Toxic Effects: The major dose-limiting toxicity of 6-MP is myelosuppression. This is dose-related, and is manifested by leukopenia, thrombocytopenia, and anemia. The hematologic effects of 6-MP may be delayed, so it is important to withdraw the medication temporarily at the first sign of unusual hematologic toxicity. Individuals with an inherited disorder of thiopurine methyltransferase deficiency may be particularly susceptible to 6-MP-mediated hematopoietic suppression. Other toxicities include hepatotoxicity (elevated liver function tests, cholestasis, hepatic necrosis, ascites), nausea, vomiting, mucositis, fever, rash, and diarrhea. The hepatotoxicity, which occurs in 10% to 40% of patients, requires close monitoring, and discontinuation of therapy until recovery occurs. Patients receiving 6-MP uniformly experience immunosuppression.

Potential Drug Interactions: Allopurinol, an inhibitor of xanthine oxidase, significantly reduces the catabolism of 6-MP when the latter is given orally, leading to major increases in plasma concentrations. Allopurinol does not alter the pharmacokinetics of IV 6-MP, presumably because the absence of first-pass metabolism of 6-MP when administered by this route. When administered in conjunction with allopurinol, the dose of 6-MP should be reduced by one-third to one-fourth. Increased toxicity has been reported in patients receiving concurrent 6-MP and trimethoprim-sulfamethoxazole. 6-MP may also modify the effects of warfarin.

Therapeutic Indications in Hematology: The major use for 6-MP is in the maintenance phase of treatment for ALL. 6-MP has also been used in the treatment of patients with ITP or autoimmune hemolytic anemia refractory to all other forms of therapy.

5-AZACYTIDINE

Chemistry and Mechanism of Action: 5′-Azacytidine is an analog of the nucleoside cytidine, differing from the parent compound by virtue of the presence of nitrogen at the 5′ position of the heterocyclic ring. 5′-Azacytidine is transported across the cell membrane by facilitated nucleoside diffusion and is converted to its nucleotide monophosphate form, 5′-aza-CMP, by the pyrimidine salvage pathway enzyme uridine-cytidine kinase. 5′-Azacytidine is also a substrate for the degradative enzyme cytidine deaminase. It is ultimately converted to its lethal derivative, 5′-aza-CTP, which is incorporated into RNA, and to a lesser extent, DNA. The lethal actions of 5′-azacytidine are believed to result from its ability to interfere with protein synthesis through disruption of RNA processing. The chemical instability of the 5′-azacytidine ring structure is also felt to contribute to the cytotoxicity of this compound.

Absorption, Fate, and Excretion: The drug distributes into a volume corresponding to the total body water after IV administration, and is also well absorbed following subcutaneous injection.

It is extensively deaminated in the plasma and liver and displays minimal plasma binding. Peak plasma concentrations following IV injection approximate 1.0 mM. The initial half-life of 5′-azacytidine (and/or its metabolites) is approximately 4 hours, although the drug is rapidly converted to various derivatives within minutes of administration. There is minimal CSF penetrance.

Preparation and Administration: 5′-Azacytidine is an investigational agent provided by the National Cancer Institute as a group C drug for patients with refractory AML. It is supplied in 100-mg vials and is reconstituted in 19.9 mL of sterile water for injection. When further diluted to a concentration of 0.2 to 2 mg/mL in normal saline, 5% dextrose in water, or lactated Ringer's solution, 10% of the drug undergoes decomposition within 3 hours. Consequently, the drug should be administered immediately after reconstitution and not stored. When administered as a continuous infusion, fresh solutions should be prepared every 3 to 4 hours.

Toxic Effects: The major toxicity of 5′-azacytidine has been leukopenia and, to a lesser extent, thrombocytopenia. Nausea and vomiting, often refractory to standard antiemetic therapy, have also been encountered, most frequently in patients receiving bolus infusions. Gastrointestinal toxicity is ameliorated by administering 5-azacytidine as a continuous infusion. Other potential side effects include diarrhea, fever, hepatotoxicity (most frequently in patients with preexisting hepatic disease), neuromuscular toxicity, rash, and hypotension.

Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: 5′-Azacytidine is primarily used in the treatment of refractory AML, with response rates ranging from 17% to 30% when used as a single agent. 5′-Azacytidine has also yielded clinical responses in a subset of patients with the myelodysplastic syndrome when administered as a low-dose continuous infusion. In early trials, low-dose 5′-azacytidine has increased fetal hemoglobin levels in some patients with sickle cell anemia and thalassemia; however, its mutagenic potential has limited the use of this agent in nonmalignant conditions.

GEMCITABINE

Chemistry and Mechanism of Action: Gemcitabine (2′,2′-difluorocytidine monohydrochloride) is a nucleoside analog that differs from 2′-deoxycytidine by virtue of the presence of fluorine atoms in the 2′α and 2′β positions of the cytidine ring. It is transported across the cell membrane by facilitated nucleoside diffusion, phosphorylated by deoxycytidine kinase, and ultimately converted to its lethal metabolites, dFdCDP and dFdCTP. The diphosphate form (dFdCDP) inhibits ribonucleotide reductase, leading to disruption of dNTP pools, and resultant interference with DNA synthesis and repair. The triphosphate form (dFdCTP) competes with dCTP for incorporation into DNA. Reductions in dCTP pools (secondary to ribonucleotide reductase inhibition) result in self-potentiation of gemcitabine action. Incorporation of gemcitabine into DNA in S phase inhibits elongation of the replicating strand, leading to DNA chain termination. The lethal actions of gemcitabine in leukemia cells have been related to the induction of apoptosis, and are not restricted to cells actively engaged in DNA synthesis. Gemcitabine has been shown to be considerably more potent in inducing apoptosis in cultured human leukemia cells than ara-C.

Absorption, Fate, and Excretion: In studies involving intravenously administered labeled gemcitabine, up to 98% of the drug was recovered in the urine after 1 week. The excreted dose was composed of a minor fraction (gemcitabine; <10%) and inactive metabolites (eg, 2′-deoxy-2′,2′-difluorouridine). Plasma protein binding was minimal. In studies involving both short and long gemcitabine infusions, the pharmacokinetics were found to be linear and best described by a two-compartment model. Plasma half-life and clearance are influenced both by age and gender. For short infusions, half-lives varied from 32 to 94 minutes; for longer infusions, half-lives varied

from 245 to 638 minutes. Volume of distribution was approximately 50 L/m^2 for short infusions and 370 L/m^2 for long infusions.

Preparation and Administration: Vials of gemcitabine contain 200 mg or 1 g of the HCL derivative formulated with mannitol (200 mg or 1 g) and sodium acetate (12.5 mg or 62.5 mg) as a sterile lyophilized powder. HCL or NaOH have been used for pH adjustment.

Toxic Effects: The major dose-limiting toxicity of gemcitabine is myelosuppression, although anemia and thrombocytopenia have also been encountered. Other toxicities include nausea and vomiting, transient elevations in liver function tests, mild hematuria, proteinuria (and in rare cases, HUS), fever, rash, dyspnea, edema, and a flu-like syndrome. Other infrequent toxicities included alopecia, parasthesias, and bronchospasm.

Potential Interactions: Gemcitabine may function as a radiosensitizing agent, and can increase the toxicity of ionizing radiation. No other interactions are known.

Indications in Hematology: The primary indication for gemcitabine is in the treatment of patients with pancreatic carcinoma. However, as an experimental agent, gemcitabine is being evaluated for the treatment of ALL and CLL.

NELARABINE

Arabinofuranosylguanine (Ara-G)

Chemistry and Mechanism of Action: Nelarabine is a pro-drug of the deoxyguanosine analog 9′-β-D-arabinofuranosylguanine also known as ara-G. Accumulation of a metabolite ara-GTP in leukemic blasts allows for incorporation into deoxyribonucleic acid (DNA), leading to inhibition of DNA synthesis and cell death.

Absorption, Fate, and Excretion: Nelarabine is demethylated by adenosine deaminase (ADA) to ara-G, then mono-phosphorylated by deoxyguanosine kinase and deoxycytidine kinase, and subsequently converted to the active 5′-triphosphate, ara-GTP. Nelarabine is only available in an IV formulation. Nelarabine and ara-G are both partially eliminated by the kidneys. Approximately 5% to 10% of nelarabine is excreted by the kidney compared to 20% to 30% of ara G. Nelarabine exhibits a half-life of 30 minutes and ara G, the active metabolite, has a half-life of 3 hours.

Preparation and Administration: Nelarabine for injection is supplied as a clear, colorless, sterile solution in glass vials. Each vial contains 250 mg of nelarabine (5 mg nelarabine per mL) and sodium chloride (4.5 mg/mL) in 50 mL water for injection, USP. Nelarabine is not diluted prior to administration. The dose is transferred into polyvinylchloride (PVC) infusion bags or glass containers and administered as a two-hour infusion in adult patients or as a one-hour infusion in pediatric patients.

Toxic Effects: Bone marrow suppression encompassing all cell lines causing anemia, leucopenia, thrombocytopenia, and neutropenia occurs in all patients. Neurologic complications of nelarabine including asthenia, altered mental states including severe somnolence, central nervous system effects including convulsions, and peripheral neuropathy ranging from numbness and paresthesias to motor weakness and paralysis. Demyelinating disease of the central nervous system may occur when combining nelarabine with other drugs that may have central nervous system toxicity. Nausea and vomiting are seen and antiemetics are necessary.

Drug Interactions: Pentostatin has been shown to be a strong inhibitor of adenosine deaminase (ADA) in vitro. Concurrent administration of nelarabine and pentostatin may result in reduced ADA-dependent conversion of nelarabine to its active moiety, thereby potentially decreasing nelarabine efficacy and/or altering nelarabine adverse event profile. Therefore, concomitant administration of nelarabine and pentostatin is not recommended.

Therapeutic Indications in Hematology: Nelarabine is effective in T-cell acute lymphoblastic leukemia, T-cell lymphoma, and T-cell lymphoblastic lymphoma. The dose in adults of nelarabine is 1500 mg/m^2 administered intravenously over 2 hours on days 1, 3, and 5 repeated every 21 days. The pediatric dose of nelarabine is 650 mg/m^2 administered intravenously over 1 hour daily for 5 consecutive days repeated every 21 days. The proper number of cycles for adult or pediatric patients has not been determined.

CLOFARABINE

Chemistry and Mechanism of Action: Clofarabine is a purine nucleoside antimetabolite formulated in unbuffered normal saline with a pH range of 4.5 to 7.5. It inhibits DNA synthesis by decreasing cellular deoxynucleotide triphosphate pools by inhibiting ribonucleotide reductase, terminating DNA chain elongation and inhibiting repair through incorporation into the DNA chain by competitive inhibition of DNA polymerases.

Absorption, Fate, and Excretion: Clofarabine is 47% bound to plasma proteins, primarily albumin. Clofarabine is phosphorylated intracellularly to the cytotoxic active form (clofarabine triphosphate) by deoxycytidine kinase. The terminal half-life is estimated to be 5.2 hours with the metabolite clofarabine triphosphate, yielding a half-life greater than 24 hours, and 49% to 60% of the dose is excreted in the urine unchanged. Systemic clearance and volume of distribution at steady state were estimated to be 28.8 L/hour/m^2 and 172 L/m^2, respectively.

Preparation and Administration: Clofarabine is supplied in a 20-mL, single-use vial that contains 20 mg clofarabine in 20 mL unbuffered normal saline at a concentration of 1 mg/mL. Clofarabine should be filtered through a sterile 0.2 μm syringe filter and diluted with 5% dextrose injection, USP, or 0.9% sodium chloride injection, USP, prior to IV infusion to a final concentration between 0.15 mg/mL and 0.4 mg/mL.

Toxic Effects: Bone marrow suppression encompassing all cell lines causing anemia, leucopenia, thrombocytopenia and neutropenia occurs in all patients. A capillary leak syndrome also known as systemic inflammatory response syndrome (SIRS) thought related to cytokine release leading to respiratory distress, hypotension, pleural effusions, pericardial effusions, and multiorgan failure may occur in a small number of patients. Elevations of liver transaminases are seen and are transient (typically, less than 2 weeks' duration) and occurred within 1 week of clofarabine initiation. Elevations in bilirubin may also occur.

Drug Interactions: None described.

Therapeutic indications in Hematology: Clofarabine is effective in treating acute lymphocytic leukemia. The recommended pediatric dose is 52 mg/m^2 administered by IV infusion over 2 hours daily for 5 consecutive days. Treatment cycles are repeated following recovery or return to baseline organ function, approximately every 2 to 6 weeks. Clofarabine has been used in adults at a dose of 40 mg/m^2 administered by IV infusion over 2 hours daily for 5 consecutive days. Clofarabine has also been used in combination with cytarabine. As this drug is excreted to a major extent by the kidneys extreme caution should be used in patients with renal dysfunction.

APPENDIX 56–4

TOPOISOMERASE I INHIBITORS AND TOPOISOMERASE II INHIBITORS

TOPOISOMERASE II INHIBITORS

Etoposide (Vepesid), Etoposide Phosphate (Etopophos), Teniposide (Vumon)

Chemistry and Mechanism of Action: Etoposide (VP-16), etoposide phosphate, and teniposide (VM-26) are semisynthetic derivatives of epipodophyllotoxin. The mechanism of action of these drugs appears to be related to their ability to stabilize a topoisomerase II–DNA cleavable complex, which acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells.

Absorption, Fate, and Excretion: *Etoposide* has an oral bioavailability of 25% to 75%. Its terminal half-life is 6 to 8 hours, with approximately 30% to 40% excreted in the urine, two-thirds as unchanged drug. There is no accumulation with consecutive daily administration, but cytotoxicity has strict schedule dependency. Clinical studies suggest that in patients with a plasma creatinine level greater than 130 mol/L, the etoposide dose should be reduced by more than 25%.

Etoposide phosphate is rapidly and completely converted in vivo to VP-16 by the activity of phosphatase, and has been shown to have the same pharmacokinetics as VP-16. Because of its increased water solubility, etoposide phosphate can be given intravenously in much less volume. In addition, the metabolic acidosis and hypotension seen with the infusion of VP-16 are not seen with this prodrug.

Teniposide has a multiphasic pattern of clearance from plasma with a terminal half-life of 9.5 to 21 hours. Unlike those of etoposide, metabolites of teniposide account for greater than 80% of the drug excreted in the urine. Like etoposide, there is significant interpatient and intrapatient variation in clinical pharmacokinetics. There are currently no formal recommendations for dose modification in patients with renal insufficiency.

Preparation and Administration: *Etoposide* is commercially available as 50-mg capsules and in vials of 50 and 100 mg at a concentration of 20 mg/mL. When the drug is diluted with normal saline or 5% dextrose in water to a concentration of 0.2 or 0.4 mg/mL, it is stable for 96 or 48 hours, respectively. Etoposide must be administered slowly over more than 30 minutes to prevent hypotension.

Etoposide phosphate is available commercially as single-dose vials containing etoposide phosphate equivalent to 100 mg of etoposide. When it is diluted with water, 5% dextrose, or normal saline to a concentration of 10 to 20 mg/mL, it can be administered without dilution over 5 to 10 minutes. When reconstituted, etoposide phosphate is stable for 24 hours at room temperature or under refrigeration.

Teniposide is supplied in 50-mg vials for IV use only. The IV solution may be taken orally but is unpalatable. Currently, no oral preparation is available in the market; however, for investigational purposes each 50-mg vial may be dissolved in 50 to 100 mL of syrup or juice. To achieve optimal absorption, a single oral dose of 60 mg/m^2, which may be repeated at 6-hour intervals, is advised. As with etoposide, rapid infusion can produce hypotension.

Toxic Side Effects: Myelosuppression, especially leukopenia, is the dose-limiting toxic effect of *etoposide* and *teniposide*. Nausea and vomiting are usually mild and easily prevented with antiemetics. Rapid infusion of etoposide (<30 minutes) may cause hypotension. Anaphylactoid reactions (eg, bronchospasm) occur in less than 2% of patients and may be related to the cremaphor vehicle. Alopecia occurs in approximately 20% of patients treated with etoposide. This side effect is more common with teniposide. When the drug is given in bone marrow transplantation doses, mucositis and diarrhea are prominent and may be dose limiting.

Potential Drug Interactions: Theoretically, any drug that increases the S-phase fraction will increase the cytotoxicity of epipodophyllotoxins and other topoisomerase inhibitors. Conversely, drugs that inhibit DNA synthesis antagonize the effect of *etoposide* and *teniposide* (eg, 5-fluoro-2′-deoxyuridine given before etoposide in some human cancer cell lines decreases the cytotoxicity of the latter). More recent in vitro data suggest that synergistic cytotoxic effects are seen when VP-16 is given after a topoisomerase I inhibitor, which appears to upregulate the amount of topoisomerase II enzyme. Antagonistic effects have been reported when a topoisomerase II inhibitor is given before a topoisomerase I inhibitor. In hematology, etoposide and teniposide may inhibit the intracellular ara-CTP formation leading to reduced ara-C cytotoxicity. Potentiation of teniposide activity has been seen with methotrexate and dipyridamoles. There is at least a twofold increase in the clearance of teniposide with concomitant administration of phenobarbital or phenytoin. Cyclosporine and other PGP antagonists (PSC 833) potentiate the cytotoxic effects of etoposide.

Therapeutic Indications: *Etoposide* is employed in the treatment of NHLs and as a second-line treatment for Hodgkin disease. It is also incorporated in the preparatory regimens for bone marrow transplantation of refractory lymphomas (CBV) and acute leukemia. *Teniposide* has been approved as a front-line agent with combination chemotherapy for childhood ALL. Combination chemotherapy with teniposide has been used successfully in some cases of refractory adult ALL and acute monocytic leukemia, but duration of remission is not significantly different from that with other standard salvage regimens. In NHL, teniposide has shown comparable activity to vincristine. *Etoposide phosphate* has been given in both standard-dose and high-dose (as a single agent) chemotherapy regimens and appears to have the same pharmacokinetics and antitumor activity as VP-16.

Daunorubicin

Chemistry and Mechanism of Action: Daunorubicin is an anthracycline that inhibits DNA topoisomerase II, acting as a poison at lower concentrations and a suppressor of cleavable complex formation at higher doses. Daunorubicin is also a DNA intercalator and generates reactive oxygen intermediates.

Absorption, Fate, and Excretion: After IV injection, daunorubicin undergoes rapid tissue uptake and concentration. It is rapidly metabolized in the liver, where approximately 25% of the drug concentrates and has a half-life of 20 to 50 hours. The principal metabolite is daunorubicinol, which also displays antineoplastic activity. Biliary excretion accounts for approximately 75% of the drug and metabolite elimination. Patients with significant hepatic dysfunction should receive an attenuated dose of daunorubicin.

Preparation and Administration: Daunorubicin is supplied with 100 mg of mannitol in 20-mg vials, from which it is reconstituted with 4 mL of sterile water for injection. The vial should be

protected from sunlight. Daunorubicin is a powerful vesicant that should be administered into the tubing of a freely flowing IV infusion of either 5% dextrose in water or normal saline. In the event of extravasation, as much infiltrated drug as possible should be aspirated from the tissue, and cold compresses should be maintained on the site for several hours. Despite these measures, skin grafting may be necessary. Daunorubicin is not physically compatible with heparin, and the two drugs should not be coadministered in the same IV tubing. The patient should be informed that daunorubicin may impart a red color to the urine for up to 72 hours after administration.

Toxic Effects: Myelosuppression, predominantly leukopenia, is the dose-limiting toxic effect. Mucositis, nausea and vomiting, and alopecia are common. Facial flushing, conjunctivitis, and lacrimation may occur in rare cases. Erythematous streaking near the site of injection occurs as a benign local allergic reaction and should not be confused with extravasation. The drug can produce a severe local reaction (eg, pneumonitis, esophagitis) in previously irradiated areas, even when both therapies are not administered concomitantly (radiation recall). Cardiac toxicity is a unique characteristic of the anthracycline antibiotics and can be acute or chronic. In the acute form, abnormal ECG changes such as ST-T wave elevation and arrhythmias may be seen. Transient reduction in the ejection fraction can also occur acutely and is often associated with pericarditis (pericarditis-myocarditis syndrome). The chronic form of anthracycline cardiac toxicity is related to the cumulative dose. The dose limit of doxorubicin is generally considered to be 450 to 500 mg/m^2, where the risk of clinical cardiotoxicity is between 1% and 10%. The corresponding cumulative dose limit for daunorubicin is 900 to 1000 mg/m^2. The cardiac toxicity is clinically characterized by congestive heart failure, usually refractory to medical therapy. Cardiac irradiation or the administration of cyclophosphamide may increase the risk of cardiotoxicity. The cardiotoxic effects appear to be related to the formation of free radicals and not to the inhibition of DNA topoisomerase II. The cardioprotective agent dexrazoxane (Zinecard) is now available and recommended to be started at a doxorubicin cumulative dose greater than 350 mg/m^2.

Potential Drug Interactions: Daunorubicin is not physically compatible with heparin or dexamethasone. The drug interactions described for doxorubicin (description follows) probably occur with daunorubicin as well.

Therapeutic Indications in Hematology: Daunorubicin is used in combination with other drugs in the treatment of AML and ALL.

Doxorubicin (Adriamycin)

Chemistry and Mechanism of Action: Doxorubicin is also an anthracycline glycoside antibiotic. It differs from daunorubicin at C-8, where a hydroxyacetyl group replaces an acetyl group. Because of this, doxorubicin is also called hydroxyl daunorubicin. Its mechanisms of action also involve stabilizing DNA–topoisomerase II complexes, DNA intercalation, and free radical formation.

Absorption, Fate, and Excretion: Doxorubicin has a triphasic plasma clearance with a half-life of approximately 30 hours. The drug is extensively metabolized in the liver to yield an active metabolite (doxorubicinol) and a number of inactive metabolites (aglycones). Within 7 days, more than 50% of an injected dose is excreted in the bile, but only 5% to 10% of the drug is excreted in the urine. Penetration into the cerebrospinal fluid is poor.

Preparation and Administration: Doxorubicin is commercially available in vials of 10, 20, 50, 150, and 200 mg. The lyophilized powder is reconstituted with either normal saline or sterile water for injection to yield a 2 mg/mL solution. The reconstituted solution must be protected from sunlight. The drug should be injected slowly into the tubing of a freely running IV infusion of normal saline or 5% dextrose in water. Erythematous streaking along the vein is often an indication that the administration rate is too rapid. The drug is a powerful vesicant, and in case of extravasation the measures described for daunorubicin should be followed.

Toxic Effects: The toxic effects are similar to those of daunorubicin. It is important to emphasize that weekly low-dose regimens or administration by continuous infusion can decrease the risk of cardiotoxicity with doxorubicin.

Potential Drug Interactions: When used in combination with other drugs as treatment for leukemia or lymphoma, doxorubicin may decrease the oral bioavailability of digoxin. It is not physically compatible with heparin or 5-fluorouracil. Barbiturates may increase the plasma clearance of doxorubicin and decrease its cytotoxic effect. Doxorubicin is compatible with vincristine, and the two drugs can be administered together in the same IV solution.

Therapeutic Indications in Hematology: Doxorubicin is one of the most important drugs in the treatment of hematologic malignancies. It is used in the treatment of Hodgkin disease (ABVD regimen), NHLs (CHOP, MACOP-B), and multiple myeloma (VBAP, VAD).

Idarubicin (Idamycin)

Chemistry and Mechanism of Action: Idarubicin, also called 4′-demethoxydaunorubicin (4-DMDR), is an analog of daunorubicin in which the methoxy group from the aglycone has been replaced with hydrogen. Idarubicin is also a topoisomerase II inhibitor and generates free radicals.

Absorption, Fate, and Excretion: The elimination half-life of the parent compound is 11.3 hours and that of the primary metabolite, 13-epirubicinol, is 40 to 60 hours. The major metabolite is as active as idarubicin. The oral bioavailability of this drug is approximately 30%; 80% of the drug is excreted in the urine as 13-epirubicinol.

Preparation and Administration: Idarubicin is supplied in 5- and 10-mg vials from which it is reconstituted with sterile water or normal saline to obtain a 1 mg/mL solution. The drug should be infused from 10 to 15 minutes through the tubing of a freely running IV infusion. Extravasation precautions should be instituted during administration. The oral formulation remains investigational.

Toxic Effects: The side effects of idarubicin are similar to those of daunorubicin and doxorubicin but are of lesser intensity at equal myelosuppressive doses.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: Idarubicin in combination with ara-C is equivalent, if not superior, to combination chemotherapy with daunorubicin in the treatment of adult AML and myelodysplastic syndromes. Idarubicin has been approved for use in combination therapy for adult AML.

Mitoxantrone (Novantrone)

Chemistry and Mechanism of Action: Mitoxantrone is a synthetic anthracenedione. Its mechanism of action appears to involve primarily the inhibition of DNA topoisomerase II. Its reduced potential for free radical formation may explain the decreased cardiotoxicity of this drug.

Absorption, Fate, and Excretion: Mitoxantrone is excreted via the renal and hepatobiliary systems, but the hepatobiliary elimination accounts for approximately 30% of active drug elimination and appears to be of greater importance. The half-life is quite variable,

with a range of 23 to 42 hours. Patients with severe hepatic dysfunction have been shown to eliminate the drug more slowly.

Preparation and Administration: Mitoxantrone is commercially available as a 2 mg/mL solution in 10-mL, 12.5-mL, and 15-mL vials (20, 25, and 30 mg per vial, respectively). The drug is further diluted in normal saline or 5% dextrose in water for injection and is administered for approximately 15 to 30 minutes into the tubing of a freely running IV infusion. As with the anthracyclines, erythema or streaking along the vein of infusion indicates that the drug is being infused too rapidly. Although mitoxantrone is not a vesicant, there have been rare reports of tissue necrosis following extravasation.

Toxic Effects: Myelosuppression, principally leukopenia, is the dose-limiting toxic effect. Thrombocytopenia is relatively mild. Nausea, vomiting, and alopecia are usually mild and occur in less than 30% of patients treated. Rarely, mucositis and elevation of liver enzymes occur. The drug imparts a blue color to the urine of patients treated. One of the primary advantages of mitoxantrone, in comparison with doxorubicin, is its reduced incidence of cardiac toxicity. Occasionally patients will develop congestive heart failure after treatment with mitoxantrone in the absence of prior anthracycline exposure, although the incidence appears to be less than 5%.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: Mitoxantrone is approved for induction therapy of AML in adults.

Amsacrine

Chemistry and Mechanism of Action: Amsacrine, or 4′-(9-acridinylamino) methanesulfon-*m*-anisidide (AMSA) is a synthetic aminoacridine derivative. Amsacrine is a DNA intercalator and also inhibits the activity of DNA topoisomerase II.

Absorption, Fate, and Excretion: When given intravenously, this drug has an initial half-life of 30 minutes and a terminal half-life of 7.9 hours. It is 50% protein bound after 2 hours. It is metabolized by conjugation with glutathione, and approximately 50% of the drug is eliminated in the bile. The remainder of the drug is eliminated via the urinary route as metabolites and parent drug.

Preparation and Administration: Amsacrine is an investigational agent supplied by the National Cancer Institute as a group C drug. It is provided in a dual pack containing two sterile liquids that must be combined before use. One vial contains 1.5 mL of 50 mg/mL of AMSA in anhydrous *N*,*N*-dimethylactamide and the other contains 13.5 mL of 0.0353 mL lactic acid diluent. When these are combined, the resulting orange-red solution contains 5 mg/mL of AMSA. Because of the *N*,*N*-dimethylactamide solvent, plastic syringes should not be used with the undiluted AMSA solution.

Toxic Effects: The dose-limiting toxic effect is myelosuppression, predominantly affecting granulocytes. Alopecia is common, and nausea, vomiting, and mucositis can occur. Cardiotoxicity, manifested as a decrease in ejection fraction, acute arrhythmias, or ECG changes was reported in 2.3% of 3200 patients, but most of these patients had been heavily pretreated with anthracyclines. Hypokalemia seems to enhance amsacrine cardiotoxicity and if present should be corrected prior to administration of the drug.

Potential Drug Interactions: The reconstituted solution is physically incompatible with chloride-containing solutions.

Therapeutic Indications in Hematology: Amsacrine is a group C investigational drug approved for the treatment of refractory AML, although it is being evaluated in combination with other cytotoxic agents in the initial treatment of this disease. As a group C drug, amsacrine must be administered as a single agent.

TOPOISOMERASE I INHIBITORS

Topotecan (Hycamtin)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH, the carboxylate form of topotecan is favored, and at a pH less than 7, the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In less than 1 hour after infusion, most of the circulating drug in the plasma is in the carboxylate form as a result of the physiologic pH. The terminal half-life of the lactone form of this S phase-specific agent is 2.6 hours, whereas the terminal half-life of the total drug is 3.3 hours. In an IV dose, 36% is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. CSF levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for a creatinine clearance less than 60 mL/min, but no adjustment is necessary for a bilirubin up to 10 mg/dL.

Preparation and Administration: Topotecan is commercially available as 4-mg vials that are reconstituted with 4 mL of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function tests. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Phase II studies suggest that topotecan has activity in myelodysplastic syndromes, AML, and multiple myeloma.

Irinotecan (Camptosar or CPT-11)

Chemistry and Mechanism of Action: CPT-11 is a prodrug that has a bulky piperidino side chain at C-10 that is cleaved in vivo by a carboxylesterase-converting enzyme to generate SN-38. SN-38 is approximately 1000-fold more potent a topoisomerase I inhibitor than CPT-11. The lactone forms of both SN-38 and CPT-11 are more potent inhibitors of topoisomerase I than the carboxylate forms, which is felt to be the mechanism of action of these drugs as described for topotecan.

Absorption, Fate, and Excretion: The terminal half-life of the lactone form of CPT-11 is 7 hours and that of the total drug, 10.5 hours. The terminal half-life of SN-38 lactone is 8.7 hours and that of the total drug, 14.7 hours. Of a dose of irinotecan, 22% is excreted unchanged in the urine. SN-38 is excreted into the bile and can undergo glucuronidation. The plasma protein binding of CPT-11 is

reported to be between 30% and 68%, whereas that of SN-38 is 95%.

Preparation and Administration: Irinotecan is available as a 100-mg single-dose vial with 20 mg/mL irinotecan. This preparation also contains 45 mg of sorbitol per mL and 0.9 mg lactic acid per mL with the pH adjusted to 3.5. This solution can be diluted with 5% dextrose in water (preferred) or in normal saline to a final concentration of 0.1 to 1.2 mg/mL. The solution is stable for up to 24 hours at room temperature or 48 hours when refrigerated. The dose should be modified for severe diarrhea.

Toxic Effects: The major toxic effect of irinotecan is diarrhea. This can be early-onset diarrhea, occurring within hours of administration, or during the infusion, which can be associated with cramping, vomiting, flushing, and diaphoresis. These side effects are due to the cholinergic effects of CPT-11 and can be managed with atropine. Severe later-onset diarrhea can be treated with high-dose loperamide, which has been found to decrease the incidence of grade 4 diarrhea from 20% to 2%. Diarrhea has been found to be the dose-limiting toxicity when irinotecan is given on a weekly schedule, and neutropenia is the dose-limiting toxicity when the drug is given every 3 weeks. Also seen are alopecia, nausea, vomiting, mucositis, fatigue, increased liver function tests, and rare cases of pulmonary toxicity.

Potential Drug Interactions: As described for topotecan, in vitro data suggest some synergism when topoisomerase I inhibitors precede topoisomerase II inhibitors or follow alkylating agent administration.

Therapeutic Indications in Hematology: Phase I and phase II studies have shown responses in refractory leukemia and lymphoma.

APPENDIX 56–5

CLINICAL PHARMACOLOGY OF PLATINUM ANALOGS

CISPLATIN (Platinol)

Chemistry and Mechanism of Action: Cisplatin [cisdiaminedichl oroplatinum(II)] is an inorganic heavy metal complex. This complex can have *cis*- and *trans*-isomers; the *cis*-isomer is the active antitumor drug. In the relatively higher chloride concentrations of plasma, cisplatin is uncharged in the dichloroform and passes through plasma membranes. Intracellularly, the low chloride concentrations allow the displacement of the chloride ligands by water to form the positively charged aquated complex. This forms covalent cross-links between two nucleophilic atoms of macromolecules such as the N^7 positions of guanine and adenine in DNA. The cytotoxicity of cisplatin correlates closely with total platinum binding to DNA, to interstrand cross-links, and to the formation of intrastrand bidentate N^7 adducts at d(GpG) and d(ApG), resulting in intrastrand cross-links that bend the DNA helix and inhibit DNA synthesis. Cisplatin damage to DNA induces apoptosis of sensitive cells.

Absorption, Fate, and Excretion: Following its IV injection, the drug concentrates in the liver, kidneys, and bowel. Plasma levels of cisplatin decay in a biphasic manner, with an initial half-life of 25 to 49 minutes and a terminal half-life of 58 to 73 hours. Although 15% of the administered cisplatin is excreted unchanged in the urine, up to 90% of the administered dose of the drug can be recovered from the urine.

Preparation and Administration: Cisplatin is commercially available as a lyophilized powder, supplied in 10- and 50-mg vials also containing mannitol, sodium chloride, and hydrochloric acid, and as an aqueous solution in 50- and 100-mg vials. Reconstitution of the powder for injection is achieved by adding sterile water to make a 1 mg/mL solution. The reconstituted solution should be further diluted in normal saline (usually 500 mL to 1 L) and administered over 1 to 3 hours. To prevent nephrotoxic effects, 25 to 50 g of mannitol is often added to the saline solution, and patients are aggressively hydrated before and after cisplatin infusion. Magnesium sulfate (12–24 mEq) is commonly added to the saline solution to preclude the development of hypomagnesemia.

Toxic Effects: Nephrotoxicity is the dose-limiting toxic effect. Cisplatin produces a dose-dependent impairment of renal tubular function, manifested by an increase in serum creatinine as well as potassium and magnesium wasting. The renal dysfunction is usually reversible, but repeated treatments may produce a cumulative and permanent mild-to-moderate impairment of renal function. Administration of other nephrotoxic agents such as aminoglycosides, even between courses, can potentiate its toxicity. Nausea and vomiting are usually severe and require the use of aggressive antiemetic support. When doses greater than 70 mg/m^2 are used, it is also important to protect against delayed nausea and vomiting by administering antiemetic agents (eg, prochlorperazine plus dexamethasone) for 3 days after therapy. Myelosuppression is usually mild. High-frequency hearing loss, tinnitus, and frank deafness may occur. Peripheral neurotoxicity, characterized by paresthesias or sensory loss in a glove-and-stocking distribution or as muscular weakness, is relatively common in patients who receive total cumulative doses of greater than 500 mg/m^2. The peripheral neuropathy may take many months to resolve, if it does at all. Vestibular toxicity and anaphylactic reactions may occur rarely.

Potential Drug Interactions: Aminoglycosides and amphotericin may enhance cisplatin nephrotoxicity. Caution should be exercised when cisplatin is administered with bleomycin and methotrexate, as cisplatin-induced renal damage may delay the excretion and thus increase the toxicity of these agents.

Therapeutic Indications in Hematology: Cisplatin is used in the treatment of refractory lymphomas, usually in combination with ara-C and high-dose dexamethasone.

CARBOPLATIN (Paraplatin)

Chemistry and Mechanism of Action: Carboplatin is a second-generation platinum (II) complex. Its mechanism of action is very similar to that of cisplatin. However, the carboxyl ester groups in this platinum complex are less easily displaced and less chemically reactive. The peak levels of DNA cross-linking also occur 6 to 12 hours later for carboplatin than for cisplatin.

Absorption, Fate, and Excretion: Carboplatin is primarily eliminated through the kidneys. Its elimination is slower than cisplatin with a terminal half-life between 2 and 6 hours. After IV injection, approximately 60% of the total drug is excreted within 24 hours.

Preparation and Administration: Carboplatin is commercially available as a lyophilized powder in 50- and 150-mg vials containing carboplatin and mannitol. It is reconstituted with sterile water to a final concentration of 10 mg/mL. For injection, further dilution with 5% dextrose and water or normal saline to a concentration of 0.5 or 2 mg/mL, it is stable for 8 hours at room temperature. Carboplatin is often administered by IV injection over 15 to 30 minutes. Patients with reduced renal function (creatinine clearance of <60 mL/min) should have the dose of carboplatin decreased according to the formula described by Egorin et al:

For previously untreated patients:

$$\text{Dosage (mg/m}^2) = (0.091)\,(\text{creatinine clearance} / \text{body surface area}) \times [\text{pretreatment platelet count} - \text{platelet nadir desired} / \text{pretreatment platelet count} \times 100] + 86$$

For heavily pretreated patients:

$$\text{Dosage (mg/m}^2) = (0.091)\,(\text{creatinine clearance} / \text{body surface area}) \times [(\text{pretreatment platelet count} - \text{platelet nadir desired} / \text{pretreatment platelet count} \times 100) - 17] + 86$$

A formula developed by Calvert and colleagues also takes into account the patient's pretreatment renal function, as follows:

$$\text{Dose (mg)} = \text{target AUC (mg/mL} \times \text{min) H [GFR (mL/min)} + 25]$$

where the dose in mg (not mg/m^2 body surface area) equals target AUC (area under the plasma clearance curve) × GFR (glomerular filtration rate) + 25

In previously untreated adults, the AUC can be estimated at 7 when carboplatin is used alone, and 4.5 when used in combination. If AUC is set lower, less toxicity is expected.

Toxic Effects: The dose-limiting toxic effect is myelosuppression, thrombocytopenia being more significant than leukopenia. Carboplatin leads to less emesis than cisplatin. Although nausea and vomiting are common, they can be easily controlled with antiemetics. At high doses such as those used for bone marrow transplantation, hepatotoxicity, renal dysfunction, and moderate to severe cytotoxicity can occur.

Potential Drug Interactions: None has been reported.

Clinical Indications in Hematology: Carboplatin has been recently approved for the treatment of ovarian cancer. It is also used to treat small cell lung, testicular, head-and-neck, and genitourinary cancers. High-dose carboplatin is presently under evaluation in acute leukemias and lymphomas.

APPENDIX 56–6

CLINICAL PHARMACOLOGY OF MISCELLANEOUS AGENTS

ARSENIC TRIOXIDE

Chemistry and Mechanism of Action: The mechanism of action of arsenic trioxide is not completely understood. Arsenic trioxide causes morphologic changes and DNA fragmentation characteristic of apoptosis in NB4 human promyelocytic leukemia cells in vitro possibly mediated by activation of cysteine-proteases (caspases). Arsenic trioxide also causes damage or degradation of the fusion protein PML/RAR-alpha.

Absorption, Fate, and Excretion: The metabolism of arsenic trioxide involves reduction of pentavalent arsenic to trivalent arsenic by arsenate reductase and methylation of trivalent arsenic to monomethylarsinic acid and monomethylarsinic acid to dimethylarsinic acid by methyltransferases. The main site of methylation reactions appears to be the liver. The pharmacokinetics of trivalent arsenic, the active species, have not been characterized.

Preparation and Administration: Arsenic trioxide is available in 10-mL, single-use ampules containing 10 mg of arsenic trioxide.

It is formulated as a sterile, nonpyrogenic, clear solution of arsenic trioxide in water for injection using sodium hydroxide and dilute hydrochloric acid to adjust to pH 8. TRISENOX should be diluted with 100 to 250 mL 5% dextrose injection, USP, or 0.9% sodium chloride injection, USP, arsenic trioxide should be administered intravenously over 1 to 2 hours. The infusion duration may be extended up to 4 hours if acute vasomotor reactions are observed. A central venous catheter is not required.

Toxic Effects: Arsenic trioxide has electrocardiographic abnormalities including QT interval prolongation, T-wave flattening, and atrioventricular block. Nonspecific edema and weight gain have been reported. Dry skin, pruritis, and rashes have occurred relatively frequently. Anemia, thrombocytopenia, and neutropenia are also observed.

Drug Interactions: Arsenic trioxide can cause QT interval prolongation and complete atrioventricular block. QT prolongation can lead to a torsade de pointes-type ventricular arrhythmia. The risk of torsade de pointes is related to the extent of QT prolongation, and concomitant administration of QT-prolonging drugs may exacerbate this phenomenon.

Therapeutic Indications in Hematology: Arsenic trioxide is effective in newly diagnosed acute promyelocytic leukemia, FAB M3.

Moreover, in patients who are refractory to or have relapsed from retinoid and anthracycline chemotherapy, arsenic trioxide has some activity as a single agent for relapsed or refractory multiple myeloma. Arsenic trioxide produced hematologic improvement in a subset of patients with myelodysplastic syndrome.

BORTEZOMIB (VELCADE)

Molecular Formula: $C_{19}H_{25}BN_4O$ molecular weight 384.24 g/mol Bortezomib (*N*-pyrazinecarbonyl-L-phenylalanine-L-Leucine boronic acid).

Absorption, Fate, and Excretion: Following IV administration of 1.3 mg/m^2 dose, the median estimated maximum plasma concentration of bortezomib was 509 ng/mL (range = 109–1300 ng/mL). The mean elimination half-life of bortezomib after first dose ranged from 9 to 15 hours at doses ranging from 1.45 to 2.00 mg/m^2 in patients with advanced malignancies. In vitro studies with human liver microsomes and human cDNA-expressed cytochrome P450 isozymes indicate that bortezomib is primarily oxidatively metabolized via cytochrome P450 enzymes, 3A4, 2D6, 2C19, 2C9, and 1A2. The major metabolic pathway is deboronation to form two deboronated metabolites that subsequently undergo hydroxylation to several inactive metabolites.

Preparation and Administration: Bortezomib for injection is supplied as a lyophilized powder for reconstitution. Each sterile single-use vial contains 3.5 mg of bortezomib and 35 mg of mannitol USP. Each vial is reconstituted with 3.5 mL normal (0.9%) saline such that the reconstituted solution contains bortezomib at a concentration of 1 mg/mL. The pH of the reconstituted solution is between 5 and 6. The drug is given without any further dilution as an IV bolus over 3 to 5 seconds. Intact vials of lyophilized bortezomib for injection are stored in a refrigerator at 2°C to 8°C (35°F to 47°F) and protected from light. Stability studies are ongoing to monitor each clinical lot. Product should be administered immediately after reconstitution. The solution as reconstituted is stable for 43 hours at room temperature. Bortezomib is administered as an IV bolus (over 3–5 seconds) twice weekly for 2 weeks followed by a 1-week rest period.

Toxic Effects: The most commonly reported adverse events were asthenic conditions (including fatigue, malaise, and weakness; 65%), nausea (64%), diarrhea (51%), decreased appetite (including anorexia; 43%), constipation (43%), thrombocytopenia (43%), peripheral neuropathy (including peripheral sensory neuropathy and peripheral neuropathy aggravated; 37%), pyrexia (36%), vomiting (36%), and anemia (32%). Fourteen percent of patients experienced at least one episode of grade 4 toxicity, with the most common being thrombocytopenia (3%) and neutropenia (3%).

Potential Drug Interactions: No formal drug interaction studies have been conducted with bortezomib. In vitro studies with human liver microsomes indicate that bortezomib is a substrate of cytochrome P450 3A4, 2D6, 2C19, 2C9, and 1A2. Bortezomib may inhibit 2C19 activity (IC_{50} = 18 μM, 6.9 μg/mL) and increase exposure to drugs that are substrates for this enzyme. Patients who are concomitantly receiving bortezomib and drugs that are inhibitors or inducers of cytochrome P450 3A4 should be closely monitored for either toxicities or reduced efficacy. Patients on oral antidiabetic agents receiving bortezomib treatment may experience hypo- or hyperglycemia and require close monitoring of their blood glucose levels and adjustment of the dose of their antidiabetic medication. Finally, patients should be cautioned about the use of concomitant medications that may be associated with peripheral neuropathy (such as amiodarone, antivirals, isoniazid, nitrofurantoin, or statins), or with a decrease in blood pressure.

Therapeutic Indications in Hematology: Bortezomib is FDA approved for the treatment of multiple myeloma patients who have

received at least two prior therapies and have demonstrated disease progression on the last therapy.

DASATINIB

Chemistry and Mechanism of Action: Dasatinib is an orally active tyrosine kinase inhibitor against BCR-ABL, SRC family, c-KIT, EPHA2, and PDGFR-beta. The primary mechanism of resistance to dasatinib is the T315I mutant clone.

Absorption, Fate, and Excretion: Dasatinib is orally absorbed and extensively metabolized in human liver microsomes, primarily by cytochrome P450 CYP3A4 to an active metabolite. CYP3A4 is the primary enzyme responsible for the formation of the active metabolite. Flavin-containing monooxygenase 3 (FMO-3) and uridine diphosphateglucuronosyltransferase (UGT) enzymes are also involved in the formation of dasatinib metabolites. In human liver microsomes, dasatinib was a weak time-dependent inhibitor of CYP3A4. The exposure of the active metabolite, which is equipotent to dasatinib, represents approximately 5% of the dasatinib AUC.

Preparation and Administration: Dasatinab is an oral agent usually taken twice daily without regard to meals.

Toxic Effects: Treatment with dasatinib is associated with severe thrombocytopenia, neutropenia, and anemia and platelet dysfunction. Also seen is fluid retention, including pleural and pericardial effusion, pulmonary edema, severe ascites, and generalized edema. Prolonged QT interval has been observed as well as extensive skin rashes.

Drug Interactions: Dasatinib is a CYP3A4 substrate. Administering with drugs that are CYP3A4 inhibitors may cause increased dasatinib plasma concentrations and subsequent increase in toxicities. Drugs that induce CYP3A4 activity may decrease dasatinib plasma concentrations and decrease its effectiveness. The solubility of dasatinib is pH dependent. Simultaneous administration of SPRYCEL with antacids should be avoided and there should be 2 hours' separation in the administration of dasatinib and antacids. Long-term suppression of gastric acid secretion by H2 blockers or proton pump may reduce dasatinib exposure and antacids are preferred. Dasatinib is a time-dependent inhibitor of CYP3A4; therefore, CYP3A4 substrates may have their plasma concentration altered by dasatinib.

Therapeutic Indications in Hematology: Treatment with dasatinib results in hematologic and cytogenetic responses in patients with lymphoid blast crisis (LBC), Philadelphia chromosome-positive (Ph+), chronic myeloid leukemia (CML), and Ph+ acute lymphoid leukemia (ALL), as initial treatment and in disease resistant or intolerant to imatinib.

PLICAMYCIN

Chemistry and Mechanism of Action: Plicamycin, also called mithramycin, forms complexes with DNA and inhibits DNA-directed synthesis of RNA. Plicamycin also inhibits the effect of parathyrin on osteoclasts. The hypocalcemic effect is independent of the antitumor effect.

Absorption, Fate, and Excretion: The pharmacology of plicamycin has been poorly described. Within 15 hours of IV administration, 40% is excreted in the urine. The elimination half-life has been estimated to be approximately 2 hours.

Preparation and Administration: Plicamycin is commercially available as a lyophilized powder in 2.5-mg vials, from which it is reconstituted with 4.9 mL of sterile water for injection. This dose should be further diluted in 1 L of 5% dextrose in water or normal saline and infused over 4 to 6 hours.

Toxic Effects: When plicamycin is employed as an antitumor agent, its most common side effects include myelosuppression, elevated liver enzymes, increased serum creatinine and proteinuria, and coagulopathy due to decreased clotting factors II, V, VII, and X. The drug also causes nausea and vomiting, diarrhea, stomatitis, headache, and irritability. Cutaneous toxicity may occur in up to one-third of patients, manifested by progressive blushing of the face and thickening and coarsening of the skinfolds. The drug can produce severe local irritation if extravasation occurs.

Potential Drug Interactions: None has been reported.

Therapeutic Indications in Hematology: Plicamycin is primarily used to treat hypercalcemia of malignancy. Claims of antitumor activity in the blast phase of CML have been made but have not been confirmed.

BLEOMYCIN

Chemistry and Mechanism of Action: Bleomycin is a glycopeptide. Its antitumor effect correlates with its ability to cause scission of both double- and single-stranded DNA via activated oxygen formed by the iron–bleomycin complex. Bleomycin also affects DNA repair by inhibiting DNA ligase.

Absorption, Fate, and Excretion: Bleomycin is rapidly distributed throughout the body and concentrates in the skin, lung, kidney, peritoneum, and lymph nodes. Its plasma half-life is 2 to 4 hours. Within 24 hours of injection, approximately 50% of an administered dose is excreted unchanged in the urine. Bleomycin elimination correlates well with creatinine clearance; accordingly, patients with renal failure should receive a reduced dose. In the tissues, bleomycin is inactivated by bleomycin hydrolase. Tissues lacking this enzyme, such as lung and skin, are more susceptible to the drug's toxic effects.

Preparation and Administration: Bleomycin is commercially available in vials containing 15 U (approximately equivalent to 15 mg), from which it is reconstituted for injection with 3 to 5 mL of sterile water, normal saline, 5% dextrose in water, or bacteriostatic water. For IV infusion, the reconstituted solution can be further diluted with either normal saline or 5% dextrose in water and administered over 5 minutes. Bleomycin can also be administered by the subcutaneous, intravenous, intramuscular, intracavitary, and intraarterial routes. Because patients with lymphomas are at an increased risk of anaphylactoid reactions, which may not occur until 12 hours after administration, the first 2 doses should be intramuscular "test doses"‘ of 1 to 2 mg. If no reactions occur, full doses may be given.

Toxic Effects: The most serious toxic effect is interstitial pneumonitis, which is dose related and occurs in approximately 10% of patients treated with cumulative doses of greater than 350 to 400 U. The interstitial pneumonitis may evolve into life-threatening pulmonary fibrosis. Pulmonary toxicity is more common in patients older than 70 years, in those receiving a total dose of greater than 400 U, and in those who received prior radiotherapy to the lung. It is important to emphasize, however, that the pulmonary toxicity is unpredictable; it has been reported in patients who had none of these risk factors and has occurred in a patient after administration of only 20 U. Some reports suggest that an increased concentration of inspired oxygen acts synergistically with bleomycin to produce pulmonary fibrosis. During critical illness and perioperatively, therefore, an attempt should be made to maintain the inspired oxygen concentration at 21%. The early phases of the pulmonary toxicity are clinically manifested by dyspnea and fine rales. Although corticosteroids

are often employed in this setting, it is not clear that they are of benefit.

Mucocutaneous toxicity occurs in 50% of patients treated and is manifested by hyperpigmentation, pruritic erythema, mucositis, desquamation of the plantar surface skin of the hands and/or feet, ridging of the nails, and alopecia. The mucositis can be severe and is the acute dose-limiting toxic effect. Febrile reactions, which occur a few hours after bleomycin administration and may last 4 to 12 hours, are also common. Fever becomes less frequent with continued use of the drug and can usually be prevented by concurrent administration of glucocorticosteroids (eg, 100 mg of hydrocortisone). Bleomycin has virtually no myelosuppressive effect. Anaphylactoid reactions are observed in approximately 1% (up to 8% in some series) of patients with lymphomas treated with bleomycin.

Potential Drug Interaction: Bleomycin, administered with other drugs for the treatment of lymphorrhea, can decrease the oral bioavailability of digoxin and the pharmacologic effect of phenytoin and certain anesthetic drugs.

Therapeutic Indications in Hematology: Bleomycin is often incorporated in the chemotherapy regimens of Hodgkin disease (ABVD and MOPP-ABV hybrid regimens) and NHLs (MACOP-B, PROMACE-CYTABOM, M-BACOD, and CHOP-Bleo).

ASPARAGINASE

Chemistry and Mechanism of Action: Asparaginase contains the high-molecular-weight enzyme L-asparaginase amidohydrolase, type EC-2, derived from *Escherichia coli*. Asparaginase hydrolyzes serum asparagine to nonfunctional aspartic acid and ammonia, depriving tumor cells of a required amino acid; thus, tumor cell proliferation is blocked by the interruption of asparagine-dependent protein synthesis. The drug appears to be most active in the G_1 phase.

Absorption, Fate, and Excretion: Asparaginase is not absorbed orally. Its plasma half-life varies from 8 to 30 hours and is not influenced by dosage, age, sex, surface area, or renal or hepatic function.

Preparation and Administration: Asparaginase is commercially available in vials containing 10,000 IU of asparaginase in 80 mg of mannitol. For IV use, the drug should be reconstituted with 5 mL of either sterile water or sodium chloride for injection and injected in the tubing of a freely running infusion of either normal saline or 5% dextrose in water over 30 minutes. For intramuscular or subcutaneous use, each vial should be reconstituted with 2 mL of sodium chloride for injection to obtain a 5000-U/mL solution. For dosages that exceed 2 mL, use of two injection sites is recommended. For both IV and intramuscular administration, the drug must be used within 8 hours of reconstitution, and only if it is clear. Because of the possibility of hypersensitivity reactions (particularly in patients with lymphomas), an intradermal skin test is recommended before initial administration of asparaginase or when 1 week has elapsed between doses. For this test, 2 IU should be injected intradermally and observed for a wheal or erythema for 1 hour. A negative skin test, however, does not preclude possible development of a hypersensitivity reaction. It is recommended that oxygen, epinephrine, and corticosteroids be available at the bedside during administration of the drug. For allergic patients, the *E coli* form of asparaginase should be replaced by the asparaginase derived from *Erwinia carotovora*, provided by the National Cancer Institute as an investigational group C agent.

Toxic Effects: The toxicity of asparaginase is reported to be greater in adults than in children. Anorexia, nausea, or vomiting occurs in approximately one-third of patients. Most of the other side effects can be divided into two main groups, those related to hypersensitivity reactions to the foreign protein and those resulting from decreased protein synthesis. The hypersensitivity reaction is characterized by urticaria, laryngeal edema, bronchospasm, or hypotension and may occur with the initial dose of the drug, even if the skin test is negative. More commonly, however, allergic phenomena are observed after multiple courses of treatment. Adverse effects related to the inhibition of protein synthesis include hypoalbuminemia and decreases in serum fibrinogen, prothrombin, antithrombin III, and other coagulation factors, which may lead to both clotting and hemorrhagic complications; decreased serum insulin with hyperglycemia; and decreased serum lipoproteins. In ≤25% of patients, cerebral dysfunction, characterized by confusion, stupor, and frank coma, can occur. Although the neurotoxic effects resemble those of ammonia toxicity, they are apparently due to low concentrations of either L-asparagine or L-glutamine in the brain. Acute pancreatitis, which may progress to severe hemorrhagic pancreatitis, may occur in 15% of patients. Elevation of liver enzymes and serum bilirubin is almost universal and is histologically represented by fatty metamorphosis. Liver toxicity, although usually not clinically significant, has resulted in occasional fatalities. Asparaginase can occasionally produce renal functional impairment with oliguric renal failure.

Potential Drug Interactions: When asparaginase is administered immediately before or concurrent with methotrexate, it decreases the cytotoxic effect of the latter. When administered to patients with acute leukemia 9 to 10 days before or shortly after methotrexate, however, asparaginase appears to enhance the cytotoxic effect of methotrexate. Concurrent administration of asparaginase with vincristine may increase vincristine's neurotoxic effects, but this effect appears to be less pronounced when asparaginase is given after vincristine. The effects of asparaginase on liver function may potentially interfere with the activation or metabolism of other cytotoxic agents.

Therapeutic Indications in Hematology: Asparaginase is used in combination therapy for remission induction of patients with ALL.

GALLIUM NITRATE

Chemistry and Mechanism of Action: Gallium nitrate is a group IIA metal salt, of which the mechanism of action is not completely understood. Its selective cytotoxic effects in humans are probably related to its predominant concentration in certain malignant tumors. Gallium nitrate binds to intracellular calcium and magnesium sites. Transferrin binding appears to be necessary to produce the cytotoxic effect.

Absorption, Fate, and Metabolism: Gallium nitrate is primarily eliminated by renal excretion and follows a biphasic pharmacokinetic pattern. The reported half-life is within a range of 6 to 36 hours.

Preparation and Administration: Gallium nitrate is an investigational agent supplied as a 25 mg/mL solution in 20-mL vials (500 mg per vial), which also contain trisodium citrate and sodium hydroxide to adjust the pH. Gallium nitrate can be administered by slow IV infusion, although in the treatment of hypercalcemia it is usually given by continuous infusion for 5 to 7 days.

Toxic Effects: When gallium nitrate is given as a single bolus injection, the dose-limiting toxicity is renal impairment. The renal toxicity is significantly minimized when the drug is given by continuous infusion. Other toxic effects include mild myelosuppression, hypocalcemia (when not desired), nausea, vomiting, diarrhea, and mucositis. Rarely, gallium nitrate can produce neurotoxic effects such as hearing loss, visual disturbances, paresthesias, and mental status changes.

Potential Drug Interactions: None has been reported.

Clinical Indications in Hematology: Gallium nitrate has shown promising results in the treatment of hypercalcemia associated with malignancy, in prevention of bone loss in patients with multiple myeloma, and in the treatment of refractory lymphomas.

GLUCOCORTICOIDS

Chemistry and Mechanism of Action: Glucocorticoids are synthetic compounds derived from the natural adrenal hormone, cortisol. Glucocorticoids mediate their biologic actions predominantly by binding to their cytosolic receptor, which then translocates to the nucleus. There, as a homodimer, it binds to specific DNA sequences located in the regulatory regions of a number of genes. Gene transcription can be upregulated or downregulated by glucocorticoids. They can also inhibit binding of the AP-1 transcription factor to its DNA consensus sequence site. Lymphocytes treated with glucocorticoids undergo apoptosis mediated by glucocorticoid receptors. An early cytostatic phase is marked by growth inhibition and cessation of proliferation due to inhibition of cellular uptake of glucose, amino acids, and nucleosides as well as inhibition of macromolecular synthesis. This is followed by a cytolytic phase characterized by chromatin condensation and internucleosomal DNA cleavage.

Absorption, Fate, and Excretion: Many synthetic glucocorticoids are available, the three most commonly used in hematology being prednisone, dexamethasone, and methylprednisolone. The glucocorticoids are well absorbed orally and are primarily metabolized in the liver. Unlike the other two glucocorticoids, the activity of prednisone is dependent on hepatic conversion to the 11-hydroxy form (prednisolone). The biologic half-lives of prednisone and methylprednisolone are approximately 12 to 36 hours, whereas dexamethasone has a biologic half-life of 36 to 72 hours. Plasma half-lives for all three drugs are within the range of 3 to 4 hours. Compared with cortisol, the relative antiinflammatory potencies of dexamethasone, methylprednisolone, and prednisone are 25, 5, and 4, respectively, for equivalent doses.

Preparation and Administration: Prednisone is available only for oral administration, whereas methylprednisolone and dexamethasone are available in oral and parenteral dosage forms.

Toxic Effects: When glucocorticoids are used for less than 14 days, as is often done when they are employed in combination with other cytotoxic agents, the most common side effects include euphoria, insomnia, psychosis, hyperglycemia, hypokalemia, increased appetite, metabolic alkalosis, proximal muscular weakness, and fluid retention with edema formation and hypertension. When used on a chronic basis, glucocorticoids also may induce a "Cushingoid" appearance, easy bruisability, peptic ulcers, osteoporosis, subcapsular cataracts, and increased susceptibility to infections related to impaired cellular immunity. Because of this, H_2 blockers, antifungal agents (eg, ketoconazole), and/or sulfamethoxazole trimethoprim have been employed in certain glucocorticoid chemotherapy combinations.

Potential Drug Interactions: Glucocorticoids interact with a variety of drugs, including barbiturates, oral contraceptives, erythromycin, hydantoins, rifampin, isoniazid, and salicylates. Given the wide range of doses of glucocorticoids used, however, these interactions are of no major clinical relevance.

Clinical Indications in Hematology: Glucocorticoids have direct anticancer activity in many hematologic malignancies, including ALL, CLL, Hodgkin disease, NHLs, and plasma cell neoplasms. Because of their efficacy and toxic profiles, which do not overlap with the toxic effects of the other cytotoxic agents, glucocorticoids are employed in many chemotherapy regimens. In addition, they are useful in the management of hypercalcemia secondary to myeloma and lymphomas and are of paramount importance in the treatment of autoimmune hematologic disorders.

BRYOSTATIN

Chemistry and Mechanism of Action: Bryostatin is a macrocyclic lactone that activates protein kinase C by causing translocation of the enzyme from the cytoplasmic to the membrane-associated active fraction during short-term exposure and protein kinase C membrane depletion and inactivation at long-term exposure.

Absorption, Fate, and Excretion: There is no reliable assay for determining the fate of bryostatin in humans.

Preparation and Administration: Bryostatin is supplied and prepared as a two-part formulation. Vial one contains 0.1 mg of lyophilized bryostatin as a white powder and is combined with 1 mL of a PET diluent (60% polyethylene glycol 400, 30% dehydrated ethyl alcohol, and 10% polysorbate 80). This solution must be further diluted with 9 mL of 0.9% sodium chloride injection and yields a 10-μg/mL solution of bryostatin. Polyvinyl chloride (PVC) bags should not be used, as there may be leaching of a plasticizer and some limited adsorption. The drug may be further diluted with 0.9% sodium chloride, or dextrose 5% in water, to a concentration of 0.15 μg/mL to 0.75 μg/mL in a glass or polyolefin container. Non-PVC tubing is recommended.

Toxic Effects: Dose-limiting myalgias, eye pain, and photophobia are frequently seen. Phlebitis is common with peripheral administration. Fatigue, headache, nausea and vomiting, along with diarrhea, are also seen. Thrombocytopenia, neutropenia, and anemia occur, although infrequently.

Drug Interactions: No known reports.

Therapeutic Indications in Hematology: Bryostatin has activity against myeloid leukemia, CLL, NHL, and multiple myeloma. Enhanced tumor effect has occurred with the combination of bryostatin with vincristine, cisplatin, and cytarabine.

FLAVOPIRIDOL

Chemistry and Mechanism of Action: Flavopiridol is a semisynthetic flavone and selective inhibitor of CDKs 1, 2, 4-7, PKC, PKA, and PDGF causing cell-cycle arrest. It also may inhibit CDK9/TEFb, which causes downregulation of McI-1, BIRC4, cyclin D1, and p21CIP1.

Absorption, Fate, and Excretion: Flavopiridol is 94% protein bound and is metabolized by the UDP glucuronyltransferase isoenzymes. Its half-life varies with infusion duration and ranges from 3.5 hours (1-hour infusion) to 27 hours (72-hour infusion).

Preparation and Administration: Flavopiridol is supplied as a 10 mg/mL yellow-greenish solution in a 5-mL vial. Contents may be diluted in either 5% dextrose injection or 0.9% sodium chloride injection to achieve a final concentration of 0.09 to 1 mg/mL. If the drug is administered through peripheral IV access, a concentration of less than 0.5 mg/mL is thought to decrease thrombotic complications. Flavopiridol has been administered as a 1-, 24-, and 72-hour infusion.

Toxic Effects: Grade 4 neutropenia and grade 3 lymphocytopenia occur and are more common with shorter durations of infusion. Thrombocytopenia is seen infrequently. Secretory diarrhea is a dose-limiting toxicity and may last for up to 3 days. Orthostatic hypotension is a frequently seen occurrence. Thrombosis with the 72-hour infusion duration was far more common than in the shorter infusion durations. A fatigue rate approaching 75% has been reported. Other toxicities include pleuritic chest pain, hyperbilirubinemia, and nausea.

Potential Drug Interactions: Paclitaxel in combination with flavopiridol has been associated with severe dose-limiting neutropenia.

Therapeutic Indications in Hematology: Flavopiridol's place in therapy is still being assessed. It has activity and use in hematologic malignancies including mantle cell lymphoma, leukemias, and multiple myeloma. It may cause potential solid tumors in combination with other agents.

TANESPIMYCIN (17-AAG, GELDANAMYCIN, NSC 330507)

Chemistry: Tanespimycin is a water soluble, benzoquinone ansamycin antibiotic that binds to heat shock protein 90.

Fate, Absorption, and Excretion: Tanespimycin has a mean terminal half-life of 2.3 hours and is primarily metabolized by liver microsimal enzymes, specifically CYP3A4. One metabolite, 17-AG is known to be active and has a mean terminal half-life of 4.6 hours. Peak plasma concentrations of 17-AAG and 17-AG occur at 30 and 60 minutes, respectively. 10.6% of 17-AAG and 7.8% of 17-AG is recovered in the urine over a 72-hour period.

Preparation and Administration: Tanespimycin is available as a single use amber vial containing 50 mg of Tanespiycin in 2 mL of dimethylsulfoxide. Prior to administration, the Tanespimycin concentrate must be completely thawed at room temperature (over approximately 1 hour). Incomplete thawing affects the concentration of the drug due to changes in volume. Tanespimycin concentrate must be diluted to 1 mg/mL by withdrawing 2 mL and adding it to 48 mL of EPL diluent 2% egg phospholipids with 5% dextrose in water. A clear solution should be obtained with gentle mixing. Shaking should be avoided to prevent foaming. No further dilution is required and the final solution should be dispensed in a glass bottle. A 0.45 micron filter may be used, but is not required. The infusion should be completed within 8 hours of mixing. Intact vials of Tanespimycin should be stored in the freezer (−10 to −20°C). EPL diluent should be stored in the refrigerator (2 to 8°C) and not frozen. Administration is by intravenous infusion.

Toxicity: Anemia, diarrhea, nausea, vomiting, fatigue, transaminitis, and muscle pain.

Drug Interactions: Tanespimycin is metabolized by CYP3A4. Agents that alter CYP3A4 activity may affect drug levels and metabolism although this has not been shown to affect clinical use.

Therapeutic Uses: Lymphoma and leukemia, in clinical trials.

IMATINIB (GLEEVEC)

Chemistry and Mechanism of Action: Imatinib, a phenylaminopyrinadine derivative, is a selective protein tyrosine kinase inhibitor effecting BCR-ABL tyrosine kinase. This enzyme is found commonly in CML and in some clones of ALL. Imatinib also inhibits the kinases for PDGF, SCF, and KIT.

Absorption, Fate, and Excretion: Imatinib is well absorbed and achieves peak levels within 2 to 4 hours and follows linear pharmacokinetics at the standard doses. The cytochrome P450 is the major route of metabolism with CYP3A4 being the primary pathway. An *N*-desmethyl piperazine is the main metabolite and is active. Pediatric patients follow the same pharmacokinetics as in adults.

Preparation and Administration: Imatinib is available in a film-coated tablet. In its pure form, it is a white to brownish to yellowish powder and is soluble in aqueous buffers of less than 5.5.

Toxic Effects: Gastrointestinal effects are common and include nausea and diarrhea. Muscle cramps are seen in one-third of all patients receiving imatinib. Myelosuppression reflected as thrombocytopenia, anemia, and neutropenia occurs, with thrombocytopenia and neutropenia seen more frequently in patients in accelerated phase or blast crisis. Fluid retention is dose related and is exhibited as edema and weight gain, but pleural and pericardiac effusions are also seen. Fatigue and headache, although low grade, occur in 25% of patients.

Potential Drug Interactions: Drugs that inhibit CYP3A4 may increase imatinib plasma concentrations; these include ketoconazole, itraconazole, erythromycin, and clarithromycin. CY3A4 inducers that may decrease plasma concentration of CY3A4 are dexamethasone, rifampin, phenytoin, and carbamazepine. Imatinib increases concentrations of simvastatin, cyclosporine, and warfarin, along with other medications that are metabolized by CYP3A4.

Therapeutic Indications in Hematology: Imatinib is considered first-line therapy in Philadelphia-positive CML and has activity in accelerated or blast-phase CML. Some effect has been shown in ALL as well as hypereosinophilic syndrome and polycythemia vera.

TOPOTECAN (HYCAMTIN)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH, the carboxylate form of topotecan is favored, and at a pH less than 7 the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In less than 1 hour after infusion, most of the circulating drug in the plasma is in the carboxylate form because of the physiologic pH. The terminal half-life of the lactone form of this S phase-specific agent is 2.6 hours, and the terminal half-life of the total drug is 3.3 hours. Thirty-six percent of an IV dose is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. CSF levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for a creatinine clearance less than 60 mL/min, but no adjustment is necessary for a bilirubin up to 10 mg/dL.

Preparation and Administration: Topotecan is commercially available as 4-mg vials that are reconstituted with 4 mL of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function tests. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Topotecan has activity in myelodysplastic syndromes, AML, CML, and multiple myeloma.

VORINOSTAT (ZOLINZA)

Chemistry and Mechanism of Action: Vorinostat is a histone deacetylase (HDAC) inhibitor. It inhibits HDAC 1, HDAC2, HDAC3 and HDAC6 at nanomolar concentrations. Inhibition prevents removal of the acetyl groups from lysine residues in target histones and transcription factors. Loss of deacetylase function results in persistence of acetyl groups on histones, resulting in larger segments of open chromatin and a general increase in gene expression. Often this promotes differentiation and cell cycle arrest with apoptosis. The number of genes affected continues to grow so that the impact of vorinostat is complex.

Absorption, Fate, and Excretion: Reported pharmacokinetics after a 400-mg oral administration are an AUC of 5.5 micromolar-hours, a C_{max} of 1.2 micromolar, and T_{max} of 2 to 10 hours. Fatty meals decrease rate of absorption but increase in overall drug levels. There is no recommended dosing relative to meals. Vorinostat is heavily plasma protein absorbed. It undergoes glucuronidation hydrolysis and later beta oxidation to inactive metabolites. Little is excreted unchanged.

Preparation and Administration: Oral dosing of 400 mg is standard, with food. If side effects are noted, reduce the dose to 300 mg. There is no approved pediatric dosing.

Toxic Effects: Many side effects are noted. Common are fatigue, thrombocytopenia, muscle spasms and anorexia. Serious reported adverse effects in clinical trails included pulmonary embolism, in 4.7% and anemia in 2.3%.

Potential Drug Interactions: Vorinnostat can prolong coumadin effect, raising the INR. It can also induce glucose intolerance.

Therapeutic Indications in Hematology: Vorinostat is approved for cutaneous manifestations of cutaneous T-cell lymphoma who have become refractory to standard treatments. It is being tested in other disorders such as myeloma and leukemias to determine whether it works through the histone deacetylases and/or through altered expression of numerous proteins.

CHAPTER 57

RADIATION THERAPY IN THE TREATMENT OF HEMATOLOGIC MALIGNANCIES

Andrea K. Ng and Peter M. Mauch

HISTORICAL BACKGROUND

In 1895, x-rays were first described by German physicist Wilhelm Conrad Roentgen. Shortly after, in 1898 Antoine Henri Becquerel discovered radioactivity, and in the same year the Curies isolated radium. The therapeutic potential of x-rays was first demonstrated in 1897, when German surgeon Wilhelm Alexander Freund showed the disappearance of a hairy mole after x-ray treatments. In the early part of the century, radiation therapy consisted of primitive equipment, crude dosimetry, and little knowledge of normal tissue or tumor radiation biology. Although initial tumor shrinkage was achieved, the superficial characteristics of radiation therapy deposited high doses in the skin and subcutaneous tissues, causing skin burns and ulceration, and underdosed deeper tumor tissues, resulting in suboptimal long-term control. By 1930, the development of reliable orthovoltage machines enabled treatment of deeper tumors. The concept of fractionated radiation therapy was also developed in the 1930s. However, even with the more penetrating beams, adequate treatment of tumors deep in the abdomen or chest frequently was associated with complications to the skin, muscles, heart, or bowel. Modern high-energy megavoltage equipment became available in the 1950s with cobalt-60 (^{60}Co). The linear accelerator, designed from microwave technology developed for radar in World War II, was first used in the United States by Kaplan and his group at Stanford University in the late 1950s.

Many of the principles and early techniques of radiation therapy for hematologic malignancies came from pioneering work in Hodgkin lymphoma. Vera Peters, in 1950, was the first physician to present definitive evidence that radiation therapy was a curative modality for early-stage Hodgkin lymphoma.[1] She did this by identifying patients with limited-stage disease who were cured with high-dose, fractionated radiation therapy. Patients received 1800 to 5000 Roentgen to areas of involvement, with the highest dose given to patients with early-stage disease. She reported 5- and 10-year survival rates of 88% and 79%, respectively, for patients with stage I Hodgkin lymphoma, rates that were notably high for a disease in which virtually no one survived 10 years. The early success of radiation therapy in the treatment of lymphoma and Hodgkin lymphoma provided encouragement for treatment of other tumors. These developments in radiation therapy are detailed in the next sections.

RADIATION PHYSICS

Types of Radiation

Electromagnetic Radiation

The ionizing radiation (photons) used in clinical treatment is part of the electromagnetic spectrum.[2] The energy of x-rays, described in terms of electron volts (eV), chosen for therapy is such that they eject an electron from the target tissue, thus the term *ionizing radiation*. High-energy radiation is produced by linear accelerators from radioactive decay. The photons produced from radioactive decay are called gamma rays. They are identical to the x-rays produced by linear accelerators. Radioactive isotopes can be produced that emit gamma rays at sufficient energy and dose rates to be used in clinical external-beam therapy. The most common isotope for external-beam irradiation is ^{60}Co (half-life 5.26 years). This isotope was in use before the availability of linear accelerators. The decay of ^{60}Co to nickel produces two gamma rays of energy that are 1.17 and 1.33 MeV. Linear accelerators generate photon beams by bombarding a target with electrons. Higher-energy and thus more penetrating x-rays can be produced. Furthermore, linear accelerators have a smaller source and as a result, can produce a much sharper beam edge compared with the cobalt machine.

Particle Radiation

High-energy electrons are one of the most frequently used particle radiation in cancer treatment. They can be produced directly from a linear accelerator with the proper extraction technique. The typical energy range for electrons is 6 to 20 MeV, which allows treatment of superficial tumors up to a depth of 5 cm, with a characteristic sharp drop in dose beyond the prescribed depth.

Neutrons, protons, helium, carbon ions, and pi-mesons are other particles used for experimental radiation therapy.[3] Because of their mass and charge, these particles can be sharply localized in tissue (Bragg peak). They are, therefore, useful for precise localization, usually of relatively small lesions. However, their use is limited and are available only in a few centers in the country.

Radiation Treatment Planning and Delivery

Radiation treatment requires a precise knowledge of normal anatomy and a detailed knowledge of growth patterns of tumors. Patient treatment plans are developed at a simulator before commencement of radiation therapy. The conventional simulator contains a diagnostic x-ray tube, usually with fluoroscopic capabilities, but otherwise it has geometry similar to that of the treatment unit. Bony landmarks, or other anatomical structures visible fluoroscopically, are typically used to guide treatment field design. Three-dimensional conformal radiation therapy (3D CRT), which provide a 3D model of the patient's anatomy and tumor, allows more accurate tumor targeting while sparing neighboring critical normal organs.[4–7] Beams' eye view display is used to select optimal beam directions and design beam apertures. Intensity-modulated radiation therapy (IMRT) is increasingly adopted in a number of disease sites.[8,9] This technique is based on the use of optimized nonuniform radiation beam intensities incident on the patient, allowing dose "sculpting" and dose "painting," and has the potential to further improve the therapeutic ratio and reduce radiation toxicity. Despite the relatively low doses used in the treatment of hematologic malignancies, there may be a role for IMRT in specific clinical scenarios in which limitation of dose to surrounding normal structures is critical.[10–12] Other innovative treatment delivery systems that not only optimize dose distribution but also take into account organ motion by integrating onboard imaging systems are becoming increasingly more available.[13]

The introduction of whole-body positron emission tomography (PET) scanning using ^{18}F-fluorodeoxyglucose has a major impact on initial cancer staging and assessing response to therapy. The accuracy of tumor targeting could be improved by incorporating PET scan

information into the radiation treatment plan. The fusion of PET data with computed tomography (CT) simulation information allows simultaneous outlining of the treatment volumes with higher anatomic accuracy.[14] New-generation simulators are designed to include both x-ray–based CT and PET and will simplify multiple-source data acquisition. Future application of this new technology may include establishing the optimal radiation dose based on the level of residual metabolic activity.

RADIATION BIOLOGY

Four R's of Radiation Biology

The laboratory and clinical findings of classic radiation biology have been defined in terms of the four R's of repair, redistribution, repopulation, and reoxygenation.[15]

Repair

Two basic types of repair have been defined operationally: sublethal damage repair and potentially lethal damage repair. A radiation cell survival curve is characterized by a shoulder region and a terminal exponential portion (Fig. 57–1). In the shoulder region, a minimum number of targets must be hit before cell death occurs. This is defined as sublethal injury. Sublethal damage repair refers to the repair that occurs within the shoulder region, with the reappearance of another shoulder during that time. Potentially lethal damage repair refers to the increase in survival over time after a single treatment. If the cells remain in situ for a number of hours posttreatment, the proportion of surviving cells will increase. It is likely that similar biochemical mechanisms are involved to some extent for both, although the importance to clinical outcome of each of these repair processes is not completely understood.[16,17]

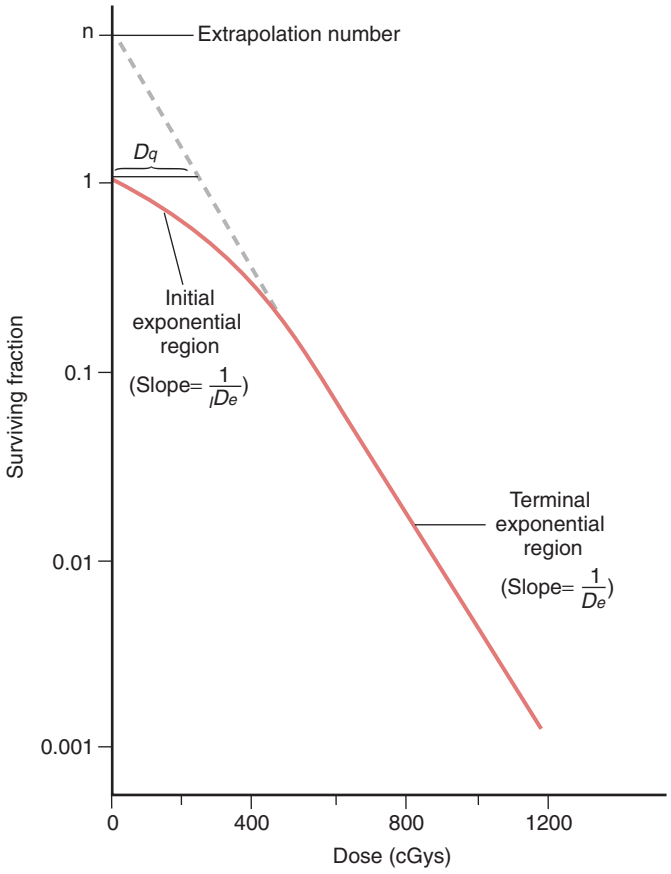

Figure 57–1 Cell survival curve. (*Adapted from Withers HR: Biologic basis of radiation therapy. In: Perez CA, Brady LW (eds.): Principles and Practice of Radiation Oncology, 2nd ed. Philadelphia, JB Lippincott, 1992, p 72*).

Redistribution

Redistribution refers to the synchronization of the cell cycle that occurs after a single dose of radiation. Cells have decreasing radiosensitivity as from M/G2 to G1, to early S to late S phase. The relative radioresistance of S phase has prompted the combined use of radiation with S-phase–specific drugs. An example is the delivery of radiation therapy concurrently with cycle active agents such as 5-FU in gastrointestinal malignancies.

Repopulation

Tumors and normal tissues repopulate during a course of irradiation. Normal tissue repopulation is observable with the healing of mucosal and skin reactions that takes place despite continuing radiation. The repopulation of tumors has been inferred from split-course radiation regimens in which there are a few weeks of no treatment between treatment segments. In settings in which the total dose is the same, local control is worse for split-course than for continuous treatment.

Reoxygenation

Hypoxic cells are relatively radioresistant. For the same portion of cell killing, hypoxic cells require 2 to 3 times the dose as the same cells treated in normoxic conditions.[18] It would be expected that the proportion of hypoxic cells would increase rapidly after a few treatments as the more sensitive oxygenated cells are killed. In general, however, this is not the case. A process called reoxygenation takes place that maintains the proportion of hypoxic cells at a relatively constant number. The exact mechanism of reoxygenation is not known, but likely involves shifts in blood flow. Without reoxygenation, radiation therapy probably would not cure many solid tumors.

Fractionation and Dose

The standard fractionation scheme for radiation therapy is 180 to 200 cGy per day, 5 days per week. The total dose depends on the clinical setting and type of tumor. The approximate dose needed for a probability of more than 95% local control for indolent non-Hodgkin lymphoma is 3600 to 4000 cGy, and 4000 to 5000 cGy for more aggressive histologies. Accelerated fractionation refers to keeping the same total dose, but decreases the time over which it is given. Such a regimen might be used for a rapidly growing or chemotherapy-refractory tumor. Hyperfractionation uses a small single dose given two to three times per day such that the total time is approximately the same as with standard fractionation, but the total dose must be higher to obtain the same effect. The lower dose per fraction spares late-responding tissues relative to tumor. Accelerated hyperfractionation is a hybrid regimen of delivering small doses two to three times per day over a shortened time period. In considering the total dose received by a patient, it is imperative to consider the dose per fraction, the number of doses per week, the total dose, the total treatment time, and when considering retreatment, the time elapsed since completion of the previous course of therapy. In the palliative setting, hypofractionation (high dose per fraction), such as 3000 cGy in 10 fractions, is useful for more aggressive histology. For lymphoma of indolent histology, a good response and effective palliation can be achieved with doses as low as 400 cGy in two fractions.[19,20]

Clinical Radiation Tolerance

The extent and frequency of injury to normal tissues depend on both radiation dose and volume treated. The risk can be enhanced by surgery and chemotherapy. Precise organ tolerances are not known, but estimates can be derived from published case reports and small series.

Central Nervous System

Brain tolerance is approximately 5500 to 6000 cGy in small fractions, but small volumes can tolerate higher doses. Radiation myelitis can occur at doses in excess of 5000 cGy. The combined use of certain cytotoxic agents may increase the risk of spinal cord injury. The peripheral nervous system has a higher tolerance, and is uncommon unless fields have been overlapped.

Heart

Radiation injury to the heart may involve a number of different cardiac tissues. Cardiac injury is rare unless the entire heart is treated to more than 3000 cGy. Anthracycline enhances the risk of myocardial injury, and the total cardiac dose is limited to 1500 cGy in patients who received anthracycline-containing chemotherapy. A more detailed discussion of late cardiac and pulmonary injury is presented in the section on Hodgkin lymphoma.

Lung

Fractionated doses as low as 2000 cGy or single doses as low as 800 cGy can cause radiation pneumonitis. Acute radiation pneumonitis can occur up to 6 months after treatment and is characterized by dry cough, dyspnea and low-grade fever, and radiographic changes within the radiation fields. Long-term fibrosis and loss of pulmonary function depends on the presence of underlying lung pathology, and the use of chemotherapeutic agents, in particular bleomycin, may lower the threshold of clinical radiation lung injury.[21,22] Using 3D radiation planning, dose-volume histograms of the lungs can be generated. In a typical mantle field, 25% to 30% of lungs may receive up to 2000 cGy, but most patients remain asymptomatic in this dose range.

Kidney

A portion of the kidney that receives a total dose in excess of 2000 cGy will permanently lose function. The development of late hypertension or renal failure depends on the volume of kidney irradiated. Even if a portion of one kidney is treated to a high dose, it is rare to see any clinical signs or symptoms. If cisplatin is administered after kidney irradiation, the toxicity of platinum may be increased.

Liver

The irradiation of a large segment of liver to a dose in excess of 3000 cGy produces a clinical syndrome of hepatomegaly, ascites, and elevated liver function tests. Radiation injury is similar to that of venoocclusive disease, a syndrome that occurs with the high-dose alkylating agent regimens used in some stem cell transplantation programs. If not fatal, radiation hepatopathy completely resolves.

Gastrointestinal Tract

The gastrointestinal tract is modestly sensitive to irradiation, with small-bowel tolerance lower than that of esophagus or large bowel. During radiation therapy, patients receiving large abdominal or pelvic fields get some degree of bowel irritation. Permanent gastrointestinal injury occurs at doses above 4500 cGy, and may require surgical excision of the damaged bowel segment, but this should done only after a trial of conservative management.

Other Organs

Virtually all organs are susceptible to injury. The following are the lower limits for a permanent injury for some other organs: bone marrow stroma, 4000 cGy; spleen with functional asplenia, 4000 cGy; ovary, 2000 cGy; skin, 5500 cGy; salivary and endocrine glands, 4500 cGy; bladder, 6000 cGy; peripheral nerve, bone, and muscle, 6000 cGy; oral cavity mucosa, 6000 cGy. Acute reactions (eg, bowel, skin, mucus, hair, blood count depression) occur 2 to 3 weeks after the start of treatment. These systems may recover despite an early decrease in function and the continuation of therapy. Conservative management helps a patient get through treatment with a minimum of treatment breaks. As a rule, the presence or extent of an acute reaction does not predict the likelihood of a late reaction. A major concern after treatment with radiation or chemotherapy is the development of secondary malignancies. The risk is especially well documented in long-term survivors of Hodgkin lymphoma, which is discussed in more detail in the chapter on Hodgkin lymphoma.

SPECIFIC USES OF RADIATION THERAPY FOR TREATMENT OF HEMATOLOGIC AND LYMPHOID MALIGNANCY

Early-Stage Hodgkin Lymphoma

Historically, radiation therapy alone has been the mainstay of treatment in patients with early-stage Hodgkin lymphoma, with disease control rates of 80% to 85%. With the development of less toxic and better tolerated chemotherapy regimens, combined modality therapy is currently the standard treatment for early-stage Hodgkin lymphoma. The major advantages of this approach are that it obviates the need to perform staging laparotomy, allows treatment with smaller radiation fields, and randomized trials have shown it to be associated with greater freedom from treatment failure. Radiation therapy-related issues include the optimal radiation field size and dose in the setting of combined modality therapy (Table 57–1).

Three randomized trials have been conducted comparing involved-field versus extended-field radiation therapy after chemotherapy in early-stage Hodgkin lymphoma.[23–25] The median follow-up time ranged from 39 to 116 months, and all three trials showed no significant difference in failure-free survival between the treatments arms. The Italian trial and the German Hodgkin's Lymphoma Study Group (GHSG) HD8 trial results suggested that the use of a more limited radiation field was associated with a lower risk of second malignancy, although longer follow-up time is needed to confirm the findings.[24,25] In addition to reducing radiation field size in combined modality therapy, lower radiation doses are also being studied as part of the treatment reduction effort in early-stage Hodgkin lymphoma. The European Organisation for Research and Treatment of Cancer (EORTC) H9F trial is a three-arm trial in which all patients receive six cycles of epirubicin, bleomycin, vinblastine, and prednisone (EBVP II).[26] After a complete response, patients were randomized to receive no further treatment, 36 Gy, or 20 Gy of involved-field irradiation. Patients with a partial response all received 36 Gy of involved-field irradiation with or without a 4 Gy boost. No difference in 4-year event-free survival was detected between 20 Gy and 36 Gy doses, although the no radiation therapy arm was closed early owing to a higher than expected relapse rate. The GHSG HD10 and HD11 trials on low-risk and high-risk early-stage patients, respectively, showed no differences between 20 Gy and 30 Gy of involved-field radiation therapy.[27] These results are only available in abstract form

with a short follow-up, and additional time is needed to establish the safety of 20 Gy of radiation treatment.

Investigators have also explored the omission of radiation therapy in patients with early-stage Hodgkin lymphoma through randomized trials.[26,28–32] However, five of six available randomized trials that included early-stage Hodgkin lymphoma patients have shown a significantly inferior disease-free survival with chemotherapy alone, with two of the trials closing the chemotherapy-alone arm early owing to a high relapse rate.[26,28–30,32] Treatment with chemotherapy alone in this population is therefore not recommended as standard therapy at this time.

Table 57–1 Trials on Optimal Radiation Dose and Field Size for Early-Stage Hodgkin's Disease

Trial	Prognostic Group	Treatment Arms
GHSG HD 10	Favorable	ABVD × 2 vs ABVD × 4 → 20 Gy IFRT vs. ABVD × 2 vs ABVD × 4 → 30 Gy IFRT
EORTC H9F	Favorable	EBVP II × 6 → 20 Gy IFRT vs. EBVP II × 6 → 30 Gy IFRT vs. EBVP II alone
GHSG HD 11	Unfavorable	ABVD × 4 vs. BEACOPP × 4 → 20 Gy IFRT vs. ABVD × 4 vs. BEACOPP × 4 → 30 Gy IFRT
EORTC H8U	Unfavorable	MOPP/ABV × 4 vs. MOPP/ABV × 6 → IFRT vs. MOPP/ABV × 4 → STNI

ABVD: adriamycin, bleomycin, vinblastine, and dacarbazine; BEACOPP: bleomycin, etoposide, adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone; COPP: cyclophosphamide, vincristine, procarbazine, and prednisone; EBVP: epirubicin, bleomycin, vinblastine, and prednisone; IFRT: involved-field radiation therapy; MOPP: mechlorethamine, oncovin, procarbazine, and prednisone; STNI: subtotal nodal irradiation.

Early-Stage Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma is a heterogeneous disease. The two most common histologic subtypes are diffuse large B-cell lymphoma and follicular lymphoma, accounting for three-quarters of all cases of non-Hodgkin lymphoma.[33,34] Radiation therapy plays an important role in both of these subtypes of non-Hodgkin lymphoma in patients with limited-stage disease. Another subtype of non-Hodgkin lymphoma in which the role of radiation therapy is increasingly recognized is marginal zone lymphoma or mucosa-associated lymphoid tumor (MALT).[35]

Stage I–II Diffuse Large B-Cell Lymphoma

Historically, patients with localized diffuse large cell lymphoma, many of whom were staged surgically, were treated with radiation therapy alone, with a cure rate of less than 50%.[36] Since 1980, doxorubicin-based combination chemotherapy regimen with or without radiation therapy became the treatment of choice, yielding significantly improved relapse-free survival and overall survival rates.[37–40]

To date, there have been four randomized trials that compared chemotherapy alone with combined chemotherapy and radiation therapy in patients with stage I–II aggressive lymphoma.[41–44] Although these four trials appeared to address a similar question in a group of patients with localized disease, each of these trials differ in patient characteristics, study design, and number of cycles or type of chemotherapy in the treatment arms (Table 57–2).

The Southwest Oncology Group (SWOG) 8637 trial compared eight cycles of CHOP (Cytoxan [cyclophosphamide], hydroxydaunorubicin [Adriamycin], Oncovin [vincristine], and prednisone/prednisolone) alone versus three cycles of CHOP followed by radiation therapy.[41] Despite a progression-free and overall survival benefit with combined modality therapy initially, updated results showed no difference between the two arms because of late relapses in the abbreviated chemotherapy and radiation therapy arm.[45] The Groupe

*Updated in abstract form: at median f/u of 8.4 y, FFS curves overlap at 7 y, and OS curves overlap at 9 y.

d'Etude des Lymphomes de l'Adulte (GELA) 93–1 trial (age < 60) showed a significant event-free and overall survival with doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone (ACVBP) (which has a theoretical dose intensity of at least 150% of that of three cycles of CHOP) compared with three cycles of CHOP followed by radiation therapy.[43] Rather than showing that there is no role for radiation therapy in localized diffuse large cell lymphoma, the results of these two trials essentially showed that radiation therapy cannot replace inferior and inadequate chemotherapy.

Both the Eastern Coast Oncology Group (ECOG) trial and the GELA LNH 93–1 trial employed the same chemotherapy on both comparison arms and were therefore appropriately designed to test the role of consolidative radiation therapy.[42,44] The ECOG trial used eight cycles of CHOP, and randomization to radiation therapy or no further therapy was only for patients who had a complete response to the chemotherapy.[42] Patients on the GELA 93–1 trial (age > 60) were randomized upfront to four cycles of CHOP alone versus four cycles of CHOP followed by radiation therapy.[44] In the ECOG trial, despite some slight arm imbalance with more bulky disease in the combined modality therapy arm and the somewhat suboptimal adherence to the assigned treatments, there was a significant disease-free survival benefit favoring the addition of radiation therapy. There was a 12% gain in overall survival at 6 years with the addition of radiation therapy, although it was not statistically significant as this trial was only powered to detect a 20% difference in disease-free survival. The GELA 93–1 trial showed no event-free or survival benefit with the addition of radiation therapy after four cycles of CHOP. In this trial the addition of radiation therapy reduced isolated relapse at initial sites from 13% to 5%. The benefit of improved local control with the addition of radiation therapy will translate into a disease-free and overall survival improvement only with effective systemic therapy that allows the eradication of occult distant disease. To meaningfully clarify the role of radiation therapy in localized aggressive lymphoma, the most informative trial will be one that employs CHOP and rituximab, which is considered the current standard systemic therapy for diffuse large B-cell lymphoma.[46–48]

Stage I–II Follicular Lymphoma

A number of studies have shown that radiation therapy alone can result in long-term cure in 30% to 40% of patients with stage I–II follicular grade I–II lymphoma. Large series reporting results of treatment for limited-stage follicular lymphoma are shown in Table 57–3.[49–58] The median radiation doses vary from 30 to 40 Gy in eight of the nine series, with the two largest series reporting a median dose of 35 Gy.[49,50] Infield recurrences range from 0% to 11%, with higher percentages occurring in patients with bulky disease or who receive a radiation dose of less than 30 Gy.[55,57] A variety of field sizes have been used ranging from involved fields to total nodal irradiation. There were no differences in survival by field size utilized. Freedom from recurrence was better in the Stanford University study with total nodal irradiation[51] and in the Royal Marsden Hospital study with larger field sizes.[56] The most common fields used were involved or regional fields (including the immediate adjacent prophylactic nodal sites). The use of smaller (involved or regional) fields preserves the ability to effectively treat patients who have later recurrence with the same histology or who transform to a higher grade histology. More than half the patients with early-stage disease will eventually develop recurrent disease and increasingly, there will be new and more effective approaches for these patients.

Stage I–II Mucosa-Associated Lymphoid Tumor Lymphoma

The indolent extranodal marginal zone or MALT lymphomas most commonly involve the gastrointestinal tract, salivary glands, breast, thyroid, orbit, conjunctiva, skin, and lungs.[59–64] As this subtype of lymphoma tends to remain localized for long periods of time, local treatment (surgery or local/regional irradiation) is very effective at long-term control of disease and provides the opportunity for cure. In particular, low doses of radiation therapy (30 Gy) to involved

†Included patients who received chemotherapy.

nodal regions or extranodal sites almost always will control sites of disease. These doses are somewhat lower than used for patients with localized follicular grade I–II disease. Three recent retrospective studies provide dose control data for this type of lymphoma. Schechter and colleagues first reported in a small series of 17 patients with gastric MALT that low doses of radiation (median 30 Gy, range 28.5–43.5 Gy) were associated with a 100% probability of local control.[59] Tsang and colleagues reported local control data in 70 patients with stage I (62) and stage II (8) MALT presenting in the stomach and other sites treated to a median dose of 30 Gy (range 17.5–35 Gy).[65] The most common doses used were 25 Gy (mostly orbit presentations) and 30 Gy. The overall local control rate was 97%. Of the two local recurrences, one occurred after 17.5 Gy and the other after 30 Gy. The 5-year disease-free and overall survival rates were 76% and 96%, respectively. In a report by Hitchcock and colleagues, 66 patients with stage I–IV marginal zone lymphoma were evaluated.[66] The median radiation dose was 33.5 Gy. All 35 stage I–II patients who received radiation therapy as initial treatment achieved local control. Among stage I–II patients the 5-year progression-free and overall survival rates were 75% and 93%, respectively. The available data support the use of 30 Gy, which results in a local control rate of nearly 100%. Although there is limited data with lower doses such as 25 Gy, there is a suggestion that local control rates are high with this dose as well. This should allow for modification of dose in settings where normal tissue risks are somewhat higher (orbit, salivary glands).

1. Preferred Treatment for Early-Stage Diffuse Large B-Cell Lymphoma Treated with Combined Modality Therapy

Use of involved fields

After a complete remission after six to eight cycles of CHOP or CHOP-R: 36 Gy if initial bulky disease; 30 Gy for the remainder of patients.

After three to four cycles of CHOP or CHOP-R: 35 to 40 Gy
After a partial remission: 40 Gy

2. Preferred Treatment for Early-Stage Follicular Grade 1 and 2 Lymphoma

Use of involved or regional fields

Carefully planned radiation therapy to limited fields with modest doses can significantly reduce the risk of significant damage to the marrow reserve, the risk of developing a treatment related malignancy, and the risk of long-term toxicity to other normal tissues such as the salivary glands, lungs, heart, kidneys and bowel.

The recommended dose is 30 to 36 Gy with a boost to areas of initial involvement to 36 to 40 Gy. Bulky disease should be treated to the upper end of the range; 30 to 36 Gy should suffice for smaller disease.

3. Preferred Treatment for Early-Stage Mucosa-Associated Lymphoid Tumor or Extranodal Marginal Zone Lymphoma

Use of radiation therapy alone to involved nodal regions or extranodal sites

Doses of 30 Gy result in a near 100% local control rate. Although there are limited data with lower doses such as 25 Gy (except for orbital MALT), local control rates can be high with this dose as well. This should allow for modification of dose in settings where normal tissue risks are somewhat higher (orbit, salivary glands).

Although there are high complete response rates with chemotherapy for marginal zone lymphoma, there is little evidence that it is curative. Therefore, outside of clinical trials, chemotherapy should be reserved for patients with stage III–IV disease. Asymptomatic individuals with generalized disease may be considered for observation, similar to patients with generalized follicular lymphoma.

Leukemia and Myeloma

The primary treatment for the leukemias and multiple myeloma is systemic therapy. The overall management of these disease entities is described elsewhere in this book. The role of radiation therapy in the management of these patients is complex and depends on the overall treatment plan. Therefore, only a few of the principles of radiation therapy are included here.

Acute Lymphoblastic Leukemia and Lymphoma

The predominant role for radiation therapy in the management of acute lymphoblastic leukemia (ALL) is for central nervous system (CNS) prophylaxis given the pattern of relapse. For childhood ALL, there is increasing movement away from using cranial irradiation because of concerns of delayed neurocognitive dysfunction and growth compromise.[67,68] However, recent data suggest that CNS-directed chemotherapy, even in the absence of cranial irradiation, is associated with attentional dysfunction in survivors of childhood ALL.[69,70] Adult ALL is much less common and is associated with a far worse prognosis, and long-term sequelae from the radiation treatment is less of an issue. Prophylactic cranial irradiation dose of 1800 cGy is recommended in these patients as part of CNS prophylaxis. Radiation therapy is occasionally used for palliation or for salvage for CNS or testicular relapse. In these cases, doses of 2400 to 3000 cGy are recommended.

Solitary Plasmacytomas and Multiple Myeloma

Solitary plasmacytomas may occur in bone or in soft tissue. Radiation therapy produces long-term local control of more than 80%.[71] Traditionally, doses of 4000 to 5500 cGy have been used, although a recent multiinstitutional study of 258 cases of solitary plasmacytoma failed to show a dose-response beyond 3000 cGy.[72]

Radiation therapy is often used as palliation for patients with bony lesions from multiple myelomas. A typical palliative regimen might be 3000 cGy over 2 weeks. The dose and fractionation must be tailored to the clinical setting. A patient with newly diagnosed multiple myeloma who is expected to live many years should be treated with a higher total dose and a lower dose per fraction. In patients presenting with cord compression, longer-course radiation therapy had been shown to be associated with significantly better functional outcome.[73]

COMMONLY USED RADIATION TREATMENT FIELDS IN HEMATOLOGIC MALIGNANCIES

The radiation field designs frequently employed in lymphoma therapy include:

1. Mantle field: This treatment field and its variations are the most commonly used treatment field in patients with supradiaphragmatic Hodgkin lymphoma. It includes the submental, cervical, supra- and infraclavicular, axillary, hilar and mediastinal lymph nodes (Fig. 57–2). The dose inhomogeneity in a mantle field is a result of variation in separation of a patient's upper body, and the irregularly contoured lung blocks that affect the scatter doses to different areas within the field.[74,75] For instance, the dose to the cervical and axillary regions tends to be higher because of decreased patient thickness in the soft tissue of the neck and axilla, whereas the dose toward the inferior border of the mantle field tends to be lower, because of the thicker separation in that region of the body as well as loss of scatter doses due to the adjacent lung blocks.[76] Some of the techniques that are employed to minimize dose inhomogeneity include the use of an extended source-to-node distance of 110 cm or greater, and by the use of higher-

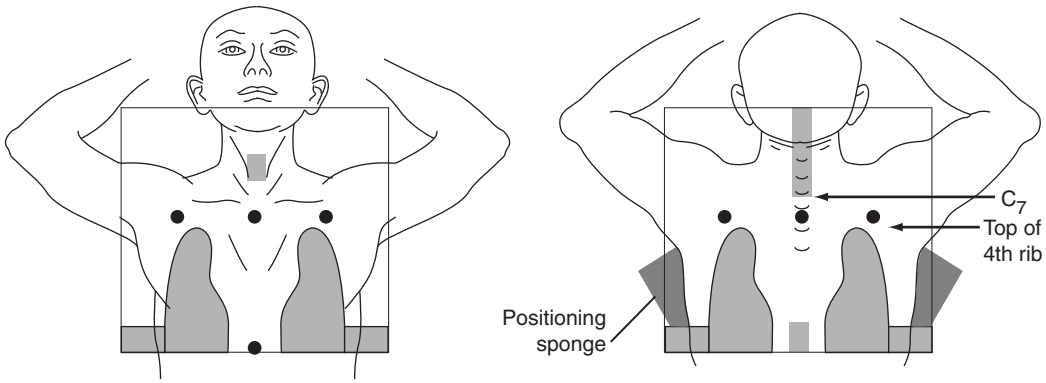

Figure 57–2 A typical mantle irradiation field.

energy megavoltage machines. However, the energy used is limited by the need to ensure adequate doses to superficial nodes, which can fall within the "build-up" regions of the radiation beams, and be potentially underdosed if energy higher than 6 MV is used.

2. Mantle and paraaortic (MPA) ± splenic field: Also known as subtotal nodal or lymphoid irradiation, it treats the paraaortic lymph nodes in addition to the mantle field. The spleen is included in the treatment field in patients who do not undergo surgical staging and splenectomy.
3. Total nodal irradiation (TNI) or total lymphoid irradiation: This encompasses most of the lymphoid tissue, with the addition of a pelvic field to the mantle and paraaortic field. However, other nodal groups, such as the brachial, epitrochlear, popliteal, sacral, and mesenteric nodes are not specifically included in the total nodal irradiation field. MPA radiation therapy and TNI are used less frequently today because of the widespread use of chemotherapy.
4. Inverted-Y field: This is used in patients presenting with infradiaphragmatic lymphoma, and includes treatment to the paraaortic and pelvic lymph nodes.
5. Involved-field radiation: By definition, this includes at least the entire contiguous lymph node group, but may also contain the next echelon of nodes. For example, in a patient presenting with an enlarged cervical lymph node, an involved field treatment would include the entire ipsilateral cervical chain and the supraclavicular region, as these nodes are considered one region (Fig. 57–3). In a patient with mediastinal involvement, the field would include the mediastinal, hilar, subcarinal and medial supraclavicular nodes. Although the hilar nodes are scored separately traditionally, the hilar and subcarinal nodes are included in the mediastinal field (Fig. 57–4). In addition, the medial supraclavicular nodes are included in order to cover the upper mediastinum (top of T1). The current definition of involved-field irradiation with detailed description of specific examples were recently summarized by Yahalom et al.[77]

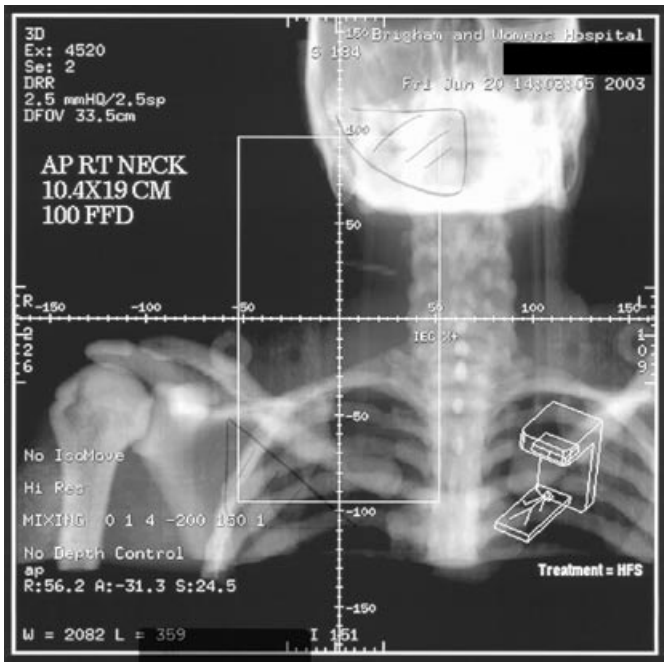

Figure 57–3. Involved field to the cervical and supraclavicular nodal chain in a patient with cervical node involvement only.

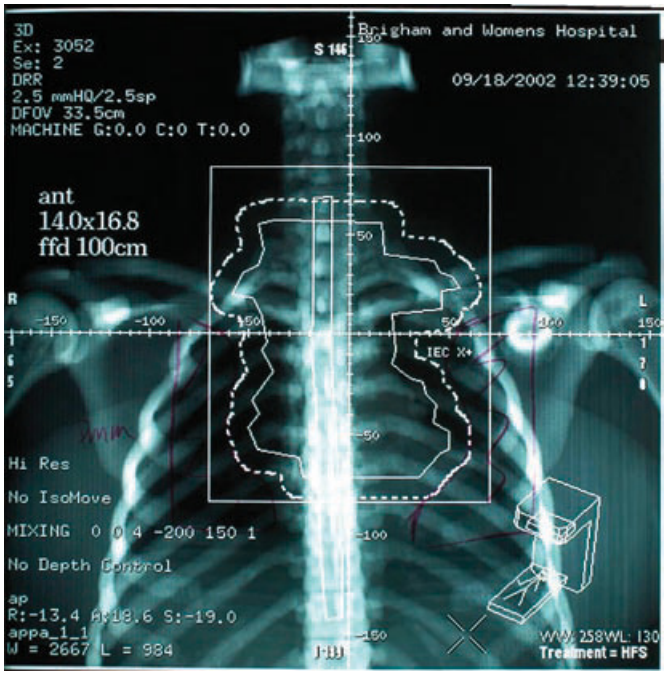

Figure 57–4 Involved field to the mediastinum.

FUTURE DEVELOPMENTS

Over the last several decades, tremendous advances have been made in the field of radiation oncology. Modern radiation biology has evolved from initial in vivo cell survival essays for tumor and normal tissues to detailed knowledge of the cellular, molecular, and genetic effects of radiation. Exciting research efforts have been made and clinical applications are ongoing in areas including hypoxia,[78] hyperthermia,[79] radiation sensitizers/protectors,[80,81] and radiolabeled monoclonal antibodies.[82,83] Treatment planning and delivery have also made significant progress in recent years. Three-dimensional conformal treatment planning, including IMRT, has greatly improved tumor targeting while sparing normal tissues. However, careful consideration needs to be given for its use in the lymphoma population, which typically includes younger patients, as the improved dose conformation comes at the expense of low doses spread through a larger volume of normal tissues.[11] Advances in functional imaging in

recent years have led to increasing use of PET scan for staging and posttherapy follow-up of lymphoma patients. The incorporation of functional imaging with radiation planning can improve target delineation, and the future will likely involve use of biological and functional parameters in determining the optimal radiation dose.[84]

CHAPTER 58

CLINICAL USE OF HEMATOPOIETIC GROWTH FACTORS

Jacob M. Rowe and Irit Avivi

INTRODUCTION

Hematopoietic growth factors are glycoproteins that can be produced by recombinant DNA technology. They have many potential clinical uses in patients with both malignant and nonmalignant hematologic disorders.

The development of in vitro marrow clonogenic culture systems led to the discovery of a family of interacting hematopoietic growth factors which have been demonstrated to have critical physiologic roles for controlling hematopoiesis in vivo (Table 58–1). Of the many hematopoietic growth factors that have been cloned, to date only erythropoietin (EPO), granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF) have seen widespread clinical use.

Other growth factors evaluated for clinical use, for example, interleukin 2 (IL-2), IL-3, IL-11, macrophage colony-stimulating factor (M-CSF), stem cell factor (SCF), IL-6 and IL-1, were generally found to be too toxic for extended clinical use.

ERYTHROPOIETIC GROWTH FACTORS

Recombinant human erythropoietin (rHuEPO) is a purified glycoprotein that stimulates erythroid blood cell development.[2,3] It is produced from mammalian cells into which the gene coding for human erythropoietin has been inserted, and is indistinguishable from human erythropoietin by biologic activity and immunologic reactivity.[2] Endogenous erythropoietin is the only hematopoietic growth factor that behaves like a hormone. Produced mostly in the kidneys,[4–6] but also in the liver,[7] and several other tissues (eg, neuronal and glial cells of the central nervous system, retina, bone marrow macrophages),[8,9] erythropoietin interacts with the erythroid progenitor cells in the bone marrow to promote their proliferation and maintain their viability (Table 58–1).[3,10] Production of erythropoietin in humans is regulated by tissue oxygenation such that hypoxia or anemia stimulates erythropoietin production whereas erythrocytosis suppresses it.[11,12] Hypoxic stimulation results in the production of hypoxia inducible factor (HIF-1), the major factor responsible for transcriptional activation of erythropoietin production (see Chapter 68). Through the interaction of EPO with receptor-bearing cells within the bone marrow, physiological oxygen demands are translated into increased red cell production. In general, plasma erythropoietin concentrations reflect erythropoietin production and can be used to define deficient states in which anemia may be amenable to correction by administration of recombinant EPO (Table 58–2).

Subtypes of Recombinant Human Erythropoietin (rHuEPO) in Clinical Use

Recombinant human erythropoietin introduced into the clinical setting almost 2 decades ago, binds to the dimerized EPO receptor on the surface of the erythroid progenitor cells, inducing a conformational change in the receptor, resulting in the stimulation of several intracellular pathways, for example, JAK-2 kinase on the STAT-5 molecule, responsible for proliferation and inhibition of apoptosis of erythroid progenitor cells. Both epoetin alfa and beta were shown to be highly effective in patients with cancer-associated anemia and anemia caused by renal dysfunction, providing an increase in hemoglobin (HB) level, decrease in red blood cell transfusion requirements, and improvement in quality of life. Both products (epoetin alfa and beta), administered three times weekly, have the same sequence of amino acids but differ in their branching and carbohydrate attachment. Longer-acting versions of rHuEPO (darbepoetin alfa, pegylated-epoietin beta) permit less frequent injections, without adversely affecting treatment efficacy.[13]

Darbepoetin alfa administered once weekly, at a dose of 2.25 μg/kg for 12 weeks has been approved for the treatment of cancer and kidney failure-related anemia.[14,15] General recommendations on the use of rHuEPO are presented in the box below.

General Recommendations for Therapy With rHUEPO

1. The cause of anemia must be clearly established prior to initiation of recombinant erythropoietin (rHuEPO). Even if EPO deficiency has been demonstrated, other factors such as iron deficiency, B_{12}, or folate deficiency must be corrected.
2. In general, rHuEPO therapy should only be given in those conditions where data from clinical trials (preferably Phase III) have demonstrated its efficacy.
3. Recombinant erythropoietin should only be given to patients who have a symptomatic anemia (Hb 9–11 g/dL) or are transfusion-dependent (Hb <9 g/dL). This category also includes patients who are candidates for blood transfusions.
4. In general, begin with a dose at the lower level known to be effective. Escalate after 1 month if this has been inadequate.
5. The target hemoglobin is not always a "normal hemoglobin." A hemoglobin level of 11 g/dL appears to be optimal for patients receiving rHuEPO for chronic renal failure, improving quality of life with a relatively low incidence of serious complications. The targeted hemoglobin level for patients with cancer-associated anemia is considered to be 12 to 13 g/dL (according to the EORTC 2006 guidelines), although large phase III studies are absent.
6. Once-weekly administration of rHuEPO (or even longer—darbepoetin) may replace the more frequent administration of rHuEPO.
7. A longer-acting "EPO," administered every 3 to 4 weeks, has been recently confirmed in phase III clinical trials to be safe and effective and might substitute the current rHuEPO derivatives.

Table 58–1 Biologic Activities of the Hematopoietic Growth Factors

Factor	Bioactivities
Erythropoietic factors	
EPO	• EPO and EPO receptors are mainly expressed by the kidney, but also by the liver, neurons, astrocyte, brain endothelial cells, microglia, retina, and trophoblasts • Stimulates clonal growth of CFU-E and a subset of BFU-E • Suppresses apoptosis in erythroid progenitor cells • Induces release of reticulocytes from marrow • Induces globin synthesis in erythroid precursor cells • Stimulates murine megakaryocyte colony growth and terminal maturation in vitro but not in vivo
Granulopoietic factors	
GM-CSF G-CSF	• Stimulates multilineage hematopoietic progenitor cells • Stimulates BFU-E growth • Stimulates granulocyte, macrophage, and eosinophil colony growth • Stimulates functional activity of eosinophils, neutrophils, monocytes, and macrophages • Induces IL-1 gene expression in neutrophils and peripheral blood mononuclear leukocytes • Costimulates T-cell proliferation with IL-2 • Induces or coinduces TNF-α gene expression with IFN-γ in monocytes. • Stimulates proliferation of myeloid leukemic cells • Stimulate growth of certain nonhematopoietic cancer cells in vitro • Induces migration and proliferation of vascular endothelial cells in vitro • Stimulate growth of progenitor cells committed to the neutrophil lineage • Stimulates neutrophil maturation of certain leukemic cells • Activates phagocytic function of mature neutrophils • Stimulates quiescent pluripotent hematopoietic progenitor cells to enter G_1-S phase • Stimulates mobilization of stem cells and progenitors from hematopoietic niches into peripheral blood • Maintenance of steady-state neutrophil numbers
Megakaryocytopoietic factors	
TPO IL-11	• Stimulates in vitro growth of CFU-Mk, megakaryocytes, and platelets • Stimulates clonal growth of individual $CD34^+CD38^-$ cells • Synergizes with SF, IL-3, and FL • In single $CD34^+CD38^+$ cells, TPO synergizes with SF and IL-3 but not Flt3 ligand; no increase in colony growth or colony size is seen when TPO is added to multicytokine combinations • Increases megakaryocyte ploidy in vitro and in vivo • Enhances the proliferation and differentiation of yolk-sac erythroid lineage precursors • Stimulates production of PDGF, platelet factor 4 and β-thromboglobulin from megakaryocytes • Supports continuous growth of cytokine-dependent human leukemic cell lines • Stimulates adhesion of hematopoietic progenitor cells to fibronectin by activation of VLA-4 and VLA-5 • No direct effect on platelet aggregation but primes the response to ADP, epinephrine, and thrombin; also increases platelet release of ATP and thromboxane B_2 production and platelet expression of CD62 (P-selectin) • Stimulates proliferation of c-mpl-positive AML blasts • Stimulates $CD4^+$ T cell-dependent proliferation of antigen-specific plaque-forming B cells • Shortens the duration of G_0 of primitive hematopoietic progenitor cells • Acts synergistically with IL-3 or SF to stimulate the clonal growth of erythroid (BFU-E and CFU-E) and primitive megakaryocytic (BFU-Mk) progenitors • Increases the ploidy of cultured megakaryocytes • Increases peripheral platelet and neutrophil counts

AML, acute myeloid leukemia; BFU, burst-forming unit; CFU, colony-forming unit; EPO, erythropoietin; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; TPO, thrombopoietin.

Table 58–2 Clinical Use of Recombinant Erythropoietin

Absolute Recommendation	Often Useful	Possibly Useful
1. Anemia of chronic renal failure 2. Anemia associated with cancer in patients receiving chemotherapy/radiotherapy with Hb level less than 11 g/dL, if symptomatic 3. Anemia of chronic disease, including with symptomatic anemia due to cancer, not receiving chemotherapy 4. Low-risk myelodysplasia	1. Anemia of multiple myeloma 2. Myelodysplasia 3. Anemia of HIV infection	1. Perisurgical (alone or followed by preoperative autologous blood donation) 2. Post allogeneic bone marrow transplantation 3. Anemia of prematurity

rHuEPO in Patients with Renal Failure

As one would expect, nonfunctioning kidneys fail to produce rHuEPO in the quantity sufficient to support red blood cell production.[16,17] The use of rHuEPO over the past 2 decades represents one of the most important advances in the management of patients with advanced renal disease with or without dialysis.[18–21] Not only has this resulted in freedom from transfusion dependency and elimination of many of the associated risks,[18] but it has also led to a significant improvement in quality of life for these patients.[22,23] More than 95% of hemodialysis patients respond to rHuEPO and are able to achieve a hematocrit level of 33% to 36% within 3 months of the initiation of such therapy.[18] Although rHuEPO is not dialyzable, it is commonly administered intravenously (70 U/kg per week) or subcutaneously (lower dose) at the end of each dialysis.[14–26] Practically, treatment dosage is scheduled according to the severity of anemia and response to therapy. The variability in the required rHuEPO dose is related to the enormous variation in the steady-state plasma rHuEPO level at any given level of anemia.

Initially, based on theoretical considerations, there was serious concern that rHuEPO treatment might accelerate the progression of renal failure and thus rHuEPO was often withheld from predialysis patients with renal failure. The results of several prospective studies have been published and it is now standard practice to offer rHuEPO to all patients with chronic renal failure if they have significant anemia and are symptomatic.[18] Patients failing to respond to the subcutaneous rHuEPO at the initial dose of 70 U/kg/week are recommended to be considered for dose escalation. Recent prospective randomized trials suggest that the targeted HB level should be around 10.5 to 11.5 g/dL,[20,21] providing a significant reduction in RBC transfusion requirements, without "paying the price" of increased serious adverse events such as hypertension, myocardial infarction, stroke, congestive heart failure associated with a higher HB level of 13 g/dL or more.[21] Furthermore, neither improvement in quality of life[21] nor preservation of cardiovascular function (eg, cardiac hypertrophy) were better in patients attaining a higher HB level.[20,21] Raised HB levels may increase blood viscosity, enhancing the risk for thrombosis. Furthermore, the altered shape of red cells and their decreased deformability may also contribute to the higher viscosity reported in patients with kidney dysfunction.

During treatment with rHuEPO it is essential to maintain adequate iron stores. Hemodialysis patients often receive iron therapy intravenously, as recommended by the National Kidney Foundation[26,27]; however, the use of an oral iron preparation is perfectly acceptable. Inadequate iron store is the commonest cause of a poor response to rHuEPO. Other, less common causes of a poor response to rHuEPO are inadequate folic acid stores, intercurrent infections, or excessive splenic hemolysis.

Cancer Patients Receiving Chemotherapy

Anemia is a frequent finding in patients with cancer and should be carefully assessed. Additional causes of anemia, iron deficiency, active bleeding, nutritional deficiencies, or hemolysis should be corrected before initiating rHuEPO therapy. rHuEPO therapy should be considered in patients with cancer-related anemia treated with chemotherapy/radiotherapy, presenting with HB levels lower than 9 g/dL, providing a significant reduction in RBC transfusion requirements and improvement in quality of life.[28–32] The use of rHuEPO for patients with less severe anemia (between 9 and 11 g/dL) should be determined by individual clinical circumstances, whereas it is unclear whether an increase in hemoglobin above 12 to 13 g/dL is of clinical benefit.[32] Once this level is achieved, maintenance doses should be titrated individually.[32] Recent data suggest that rHuEPO is likely to be also beneficial in patients with cancer-related anemia not receiving chemotherapy.[32]

Current guidelines recommend an administration of subcutaneous rHuEPO thrice weekly (150 U/kg) or once-weekly darbepoetin for at least 3 to 4 weeks (see box). Response is expected in less than 8 weeks of therapy; escalation in rHuEPO dosage may be considered on an individual basis in patients who fail to respond to initial dose and should be gradually titrated once the hemoglobin level reaches 12 g/dL.[32] The role of iron supplements remains debated. The recently reported EORTC guidelines have failed to find convincing evidence for increased erythropoietic response with the addition of oral iron supplements, but reported some evidence for improved responses with the addition of intravenous iron.[32] However, the doses and schedules for intravenous iron supplements are not well defined yet.[32] Nevertheless, for the majority of ambulatory patients receiving rHuEPO, in whom intravenous iron supplementation is impractical, the use of oral iron supplementation continues to be acceptable.

The risk of both thromboembolic events and hypertension are slightly elevated in patients treated with rHuEPO with chemotherapy-induced anemia, but there are no data for increased risk for patients with pure red cell aplasia.[32]

It is still uncertain if rHuEPO treatment has any significant impact on tumor progression and long-term outcome.[32] The rHuEPO receptor is expressed by several cancer cell lines[33] (eg, breast carcinoma, gastric cancers, tumors of the female reproductive system, and CNS), raising the theoretical possibility of rHuEPO inducing tumor growth, by inhibiting tumor cell apoptosis through several intracellular signaling pathways (eg, JAK-STAT),[34] and by improving oxygenation of tumor cells. In contrast, improvement in tumor oxygenation may increase the effectiveness of radiotherapy and chemotherapy agents (dependent on oxygen tension in the tumor microenvironment) or shut down the hypoxia-inducible factor 1-alpha–vascular endothelial growth factor angiogenesis pathway that promotes tumor growth and metastasis, thereby increasing response to therapy and tumor regression.[35]

However, these in vitro effects, and possible competing interactions, have not been demonstrated in human cancer in vivo. Furthermore, the different rHuEPO subtypes, rHuEPO alpha, beta, or darbepoetin, as well as differing doses targeted to achieve different HB levels might have different effects on the growth of different tumor subtypes.[35]

Despite possible theoretical considerations, the available data do not clearly support a clinical concern for tumor progression with the use of rHuEPO.[32] The cumulative data confirm its ability to reduce transfusion requirement and to improve quality of life. rHuEPO is thus currently recommended for use in cancer patients receiving chemotherapy.[28–32,36]

Anemia Due to Malignant Disease

Myelodysplastic Syndrome

Myelodysplastic syndromes (MDSs) comprise a heterogeneous group of clonal myeloid stem cell disorders characterized by peripheral cytopenias and dysplasia of bone marrow progenitor cells. MDS occurs primarily among older adults with a median age between 65 and 70. The most important clinical problems arise from chronic anemia (80%) and from red cell transfusion-induced iron overload, bleeding due to low platelet counts, and infections as a consequence of neutropenia. A significant number of patients succumb to these complications of cytopenia prior to the onset of overt acute myeloid leukemia. Younger adults are often considered for an allogeneic stem cell transplantation, whereas older adults are mainly treated supportively with growth factors, for example, rHuEPO with or without G-CSF, and blood transfusions in the absence of an effective curative therapy apart from allogeneic transplantation.

A double-blind prospective randomized trial, comparing rHuEPO versus placebo, showed a significantly increased response rate in MDS patients treated with rHuEPO (14/37 vs 4/38, $P = 0.007$),[37] most noticeable in patients with refractory anemia (RA). However, there were no statistical differences in response rate among patients with refractory anemia with ring sideroblasts (RARS) or refractory anemia with excess of blasts (RAEB). A baseline rHuEPO level above

Recommendations for the Use of Recombinant Human Erythropoietin (rHUEPO) in Patients With Cancer

1. The two major goals of erythropoietic protein therapy are improvement of quality of life and prevention of transfusions.
2. The use of rHuEPO is recommended as a treatment option for patients with chemotherapy-associated anemia and a hemoglobin concentration that has declined to a level less than or equal to 10 g/dL. Red blood cell transfusion is also an option depending on the severity of anemia or clinical circumstances.
3. For patients with less severe chemotherapy-associated anemia (those with hemoglobin concentration below 12 g/dL but who have never fallen below 10 g/dL), the decision whether to use epoetin immediately or to wait until hemoglobin levels fall closer to 10 g/dL should be determined by clinical circumstances. Red blood cell transfusion is also a therapeutic option when warranted by severe clinical conditions.
4. Although there is no absolute evidence of an increased response to erythropoietic proteins with the addition of oral iron supplementation, this modality is commonly used in ambulatory patients in an attempt to enhance the erythropoietic effect. Intravenous iron supplement has been convincingly demonstrated to improve response to rHuEPO.
5. There are no predictive factors of response to erythropoietic proteins that can be routinely used in clinical practice if functional iron deficiency or vitamin deficiency is ruled out; a low serum EPO level (in particular in hematologic malignancies) is the only verified predictive factor of some importance. Values must be interpreted relative to the degree of anemia present. Further studies are needed to define the value of hepcidin, c-reactive protein, and others.
6. Patients with cancer-related anemia not receiving chemotherapy might be considered for rHuEPO. The recommended starting dose for subcutaneous rHuEPO is 150 U/kg thrice weekly for a minimum of 4 weeks, with individualized consideration given for dose escalation to 300 U/kg thrice weekly for an additional 4 to 8 weeks in those who do not respond to the initial dose. An alternative weekly dosing regimen (40,000 U/week), based on common clinical practice, can be considered. Dose escalation of weekly regimens should be under similar circumstances to thrice-weekly regimens.
7. Continuing rHuEPO treatment beyond 6 to 8 weeks in the absence of response (e.g., less than 1–2 g/dL rise in hemoglobin), assuming appropriate dose increase, has been attempted in nonresponders but does not appear to be beneficial. Patients who do not respond should be investigated for underlying tumor progression or iron deficiency. As with other failed individual therapeutic trials, consideration should be given to discontinuing the medication.
8. Hemoglobin levels can be raised to (or near) a concentration of 12 g/dL, at which time the dosage of rHuEPO should be titrated to maintain that level or restarted when the level falls to near 10 g/dL. Insufficient evidence to date supports the "normalization" of hemoglobin levels to above 12 g/dL.
9. There is evidence from one well-designed, placebo-controlled randomized trial that supports the use of rHuEPO in patients with anemia associated with low-risk myelodysplasia. Treatment with rHuEPO for myeloma, non-Hodgkin lymphoma, or chronic lymphocytic leukemia patients experiencing chemotherapy-associated anemia should follow the recommendations outlined above.

*Not included into the EORTC guidelines yet, but proven by several large studies.

Suggested Management of Anemic Patient With Myelodysplastic Syndrome (MDS)

There is no role for prophylactic therapy using recombinant EPO (rHuEPO), with or without G-CSF, among MDS patients who do not have symptomatic anemia.

For patients who are symptomatic and/or transfusion-dependent, the baseline EPO levels should be obtained.

Patients who have an EPO level less than 200 mU/L should be started on EPO at a dose of 150 U/kg daily, subcutaneously, or high dose darbepoetin.

Recent data support this approach even with an EPO level less than 500 mU/L.

If the response has not been inadequate, then G-CSF at the dose 1 μg/kg/day subcutaneously should be considered.

If there is no response to this combination after 4 to 6 weeks, the dose of rHuEPO may be escalated to 300 U/kg/day.

If no response is demonstrated after 2 months, then EPO should be discontinued. There is no point in attempting this therapy again at a future point.

Patients who have responded to any dose of rHuEPO, or to a combination of EPO and G-CSF, should be maintained on this dose for 3 months.

If the hemoglobin is maintained on this dose, then a judicious attempt at gradual reduction of the rHuEPO dose may be attempted.

Most responses to erythropoietin, with or without G-CSF, are not maintained for more than 12 months.

Most patients with an endogenous level of erythropoietin more than 500 mU/L will not respond to rHuEPO, with or without G-CSF. However, because there is a small subgroup of patients who respond to rHuEPO, it is reasonable to begin with a trial of rHuEPO with G-CSF for 3 months. Among this group, rHuEPO should be offered to patients who are transfusion-dependent and symptomatic.

If no response is seen, then the therapy with these growth factors should be discontinued.

200 mU/L is predictive of a nonresponse.[37] Based on these data, rHuEPO is currently recommended for low-risk MDS patients with endogenous rHuEPO levels below 200 mU/L.[38]

Recent phase II studies reported a high response rate to high-dose darbepoetin in low-risk MDS patients (35%–55% major responses),[39,40] higher than reported with EPO-alpha (10%–20%), almost comparable with that observed with an rHuEPO–G-SCF combination (39%–60%).[41]

Of interest, synergy between granulocyte colony-stimulating factor (G-CSF) and rHuEPO has been demonstrated for the production of normal as well as MDS erythroid precursors.[42] A concurrent administration of rHuEPO and G-CSF appeared to produce a high erythroid response rate (39%), with durable responses being documented in low-risk patients. rHuEPO–G-CSF therapy was not shown to increase the risk for transformation to AML compared with that observed in historical controls treated conservatively, without rHuEPO or G-CSF.[41]

In a randomized trial, the combination of rHuEPO and G-CSF administered sequentially was shown to produce a higher erythroid response rate (38%) than the regimen of rHuEPO alone.[42] It has also been shown that patients responding to rHuEPO and G-CSF tend to have a significantly lower serum rHuEPO level (<500 mU/L).[43] However, these criteria are not exclusive and patients with higher rHuEPO levels are also known to respond.

Myeloma, Lymphoma, and Chronic Lymphocytic Leukemia

There are currently several, however small, randomized trials that examined the value of rHuEPO in myeloma, chronic lymphocytic leukemia (CLL) and non-Hodgkin lymphoma (NHL) patients, irrespective of the chemotherapy that was given.[44–50] Two of these studies included myeloma patients only[44,47] and another study reported on aggressive lymphoma patients, whereas the rest of the recruited patients had various lymphoproliferative disorders including myeloma. The combination of heterogeneous groups of patients and different parameters assessed for evaluation of response, make interpretation of these studies somewhat difficult. However, the fact that each of these trials reported a significant reduction in RBC transfusion requirements and an improvement in quality of life in patients receiving rHuEPO suggests that rHuEPO is valuable and beneficial in these clinical situations.

One of the major concerns nowadays is the potential risk of developing thromboembolic (TE) events in myeloma patients treated concurrently with rHuEPO and thalidomide. rHuEPO has been recently reported to be an independent risk factor for venous thromboembolism in patients with various types of cancers.[51] Thalidomide, especially when given in combination with chemotherapy and steroids, is associated with a high risk of thrombosis (20%–40%). Therefore, the coadministration of rHuEPO and thalidomide-containing regimens may potentially increase the risk for TE significantly. However, the current data related to this subject is limited[52] and further studies are warranted to clarify this issue.

Anemia of Prematurity

Anemia of prematurity, although multifactorial in origin, is characterized by inappropriately low rHuEPO levels. It usually responds to rHuEPO at a dose of 250 to 400 U/kg subcutaneously three times a week.[53,54] However, both retrospective and prospective randomized trials have failed to detect a significant clinical benefit for rHuEPO treatment compared with placebo; although rHuEPO did facilitate a reticulocyte recovery, there was no significant reduction in transfusion requirements despite early treatment with rHuEPO and iron supplements.[54–57] Furthermore, early administration of rHuEPO has been recently suggested to increase the risk of premature retinopathy (ROP).[56]

A recent randomized trial suggested the addition of B_{12} supplementation to a combination of folic acid, intravenous iron, and rHuEPO results in a higher HB level as compared to an identical combination without B_{12}; however, there was no difference in RBC transfusion requirements.[58]

In contrast, there are a few prospective randomized trials that reported a significant reduction in transfusion requirements in very-low-birth-weight infants in stable condition.[59] These differences may arise from patient selection such as the clinical condition of the patient, patient weight, as well as differences in rHuEPO dosage and iron supplementation.

It seems likely that rHuEPO is of value in treating the anemia of prematurity; however, more studies are needed to determine the clinical parameters that are associated with response. Nevertheless, with no convincing evidence of the clinical benefit of such therapy and in consideration of accumulating data regarding potential contribution of rHuEPO to the development of ROP, early administration of rHuEPO is currently not recommended outside of clinical studies.

Autologous Blood Donation

The use of rHuEPO to prime patients for autologous red blood cell donation has been perceived as a major step toward reducing the risks associated with blood transfusions.

Administration of rHuEPO preoperatively has been demonstrated to promote an increase in the number of autologous units collected.[60–64] Furthermore, patients having an autologous RBC donation supported by rHuEPO required a lower number of allogeneic RBC transfusions as compared with those undergoing an autologous RBC donation without rHuEPO support ($P < 0.005$).[64]

Another strategy is to administer rHuEPO 14 to 17 days prior to operation without performing an autologous RBC donation (possible/feasible in patients whose baseline level is relatively low), aiming to increase the preoperative HB level and thereby reduce the number of allogeneic RBC required.[65,66] A recent prospective study comparing this strategy with autologous blood donation without rHuEPO supports showed no significant difference in the incidence of allogeneic transfusions between the two groups.[67]

It appears that preoperative treatment with rHuEPO provides an effective method for autologous blood donation as well as achieving a reduction in the postoperative transfusion requirements.[65,66] However, owing to its high cost, a relatively low number of red blood cell transfusions routinely required following the majority of operations and the absolute reduction in RBC number required (often one unit only), rHuEPO support with or without RBC donation has failed to become common practice. This strategy is usually reserved for patients with rare blood types or those known to be at a high risk for a significant bleeding following surgery.

Stem Cell Transplantation

Serum rHuEPO levels following high-dose chemotherapy initially increase[68] but gradually decline with red cell engraftment.[69] Therefore, early use of rHuEPO following transplant, when erythroid precursors are depleted and endogenous rHuEPO level is relatively high, is unlikely to be of value.[70–74] In contrast, rHuEPO applied following engraftment might be much more effective. Recent publications suggest that rHuEPO therapy is highly effective following conventional allogeneic stem cell transplantation[75] but to a lesser extent following a reduced-intensity allogeneic stem cell transplantation (RIC).[76] rHuEPO therapy is most effective following a conventional allograft when administered between days 35 and 100 post transplant,[75] whereas the maximal effect following RIC appears much earlier.[76,77] The lower number of RBC transfusions required following an RIC along with the high cost of rHuEPO suggests that rHuEPO therapy should be more often considered as a therapeutic option in

the conventional myeloablative allograft setting and to a lesser extent with reduced-intensity conditioning.

A reduction in RBC transfusion requirements has been reported when rHuEPO was started on day 30 post transplant following autologous stem cell transplantation.[78,79] Alternatively, rHuEPO administered prior to high-dose therapy has also been suggested to significantly reduce the number of RBC transfusions required following transplant.[80]

Despite these encouraging results, rHuEPO is rarely used in patients undergoing high dose chemotherapy and autologous stem cell transplantation, mostly because of the rapid erythropoietic reconstitution achieved nowadays with peripheral blood stem cell transplantations along with the high cost of rHuEPO.

rHuEPO in the Critically Ill Patient

Critically ill patients have inappropriately low rHuEPO levels, contributing to their anemia. Several studies conducted to assess the potential benefits of exogenous rHuEPO supplementation showed a significant reduction in the number of red blood cell transfusions required, but with no effects on outcome in terms of ICU infection rates or mortality.[81,82] Larger prospective studies, aiming to assess the impact of rHuEPO dosing and iron supplements[83] on patient outcome and define subgroups of critically ill patients in whom rHuEPO might also improve overall survival are warranted.

rHuEPO Therapy in Patients with AIDS

In patients with human immunodeficiency virus (HIV), anemia is the most common hematologic abnormality. In general, as HIV disease progresses, the prevalence and severity of anemia increases. Anemia has been shown to be a significant predictor of progression to the acquired immunodeficiency syndrome and is independently associated with a reduced quality of life and increased risk of death.

Anemia can be caused by several mechanisms, including medication, dietary deficiencies, infections, neoplasms, and blood loss. Management of anemia includes correction of the underlying causes, blood transfusion, and erythropoietin therapy. However, blood transfusions and iron supplementation may activate HIV expression. rHuEPO is an effective means of improving hemoglobin levels and reducing transfusion requirements, especially in patients who have relatively low (<500 mU/L) endogenous erythropoietin levels.[84]

Resolution of HIV-related anemia has been shown to improve the quality of life,[85] physical functioning, and energy and lessen fatigue in individuals with HIV.[86,87] The use of highly active antiretroviral therapy has also been associated with a significant increase in hemoglobin concentrations and a decrease in the prevalence of anemia.[88]

Novel Strategies for Stimulating Erythropoiesis and Potential New Treatments for Anemia

Continuous Erythropoietic Receptor Activator

Continuous erythropoietic receptor activator is an "extremely long-acting EPO" with a half-life of 130 hours, which can therefore be delivered every 3 to 4 weeks. Having successfully completed a phase III trial of its clinical development,[89] continuous erythropoietic receptor activator is the next erythropoietic agent that is likely to be officially approved for treatment of renal failure-associated anemia.[90] Patients with renal insufficiency, particularly those receiving dialysis, as well as patients receiving chemotherapy every 3 weeks for different types of cancers, might benefit from having less frequent rHuEPO injections.[91]

Erythropoietin-Mimetic Peptides (Hematide)

Hematide is a synthetic, dimeric peptidic erythropoiesis-stimulating agent covalently linked to polyethylene glycol developed for the treatment of anemia associated with renal failure and cancer. Having a unique amino acid sequence, unrelated to that of recombinant erythropoietin, Hematide is unlikely to induce a cross-reactive immunologic response against endogenous erythropoietin, resulting in a pure red cell aplasia.

Hematide binds and activates the human rHuEPO receptor, stimulating the proliferation and differentiation of human red cell precursors in vitro. Recent studies confirmed its safety and potential efficacy in healthy volunteers[92] resulting in a dose-dependent increase in both reticulocyte and HB levels. These encouraging results support the design of phase II studies in patients with anemia related to cancer and chronic kidney dysfunction.[93]

Other Strategies for Stimulating Erythropoiesis

Hemopoietic Cell Phosphatase Inhibitors

Hemopoietic cell phosphatase is an intracellular enzyme that negatively regulates the JAK-STAT signaling. Inhibition of hemopoietic cell phosphatase, therefore, enhances erythropoiesis,[94] providing another mechanism for inducing erythropoiesis.

Hypoxia-inducible factor stabilizers

Oxygen-dependent regulation of endogenous rHuEPO production is mediated by hypoxia-inducible factor (HIF), an alpha, beta transcription factor. HIF beta is constantly expressed, whereas HIF alpha concentrations are dependent on oxygen levels. Under normal oxygen level, both the amount of HIF alpha and its ability to stimulate EPO gene transcription are inhibited by oxygen-dependent hydroxylation. Inhibition of these hydroxylation reactions stabilizes HIF, mimicking hypoxia, thereby inducing erythropoiesis. Recently, an orally active hydroxylase inhibitor was reported to induce rHuEPO production and stimulate rHuEPO in normal volunteers[95] and patients with renal failure not yet on dialysis.[96]

rHuEPO Potential Uses Outside Erythropoiesis

As previously mentioned, rHuEPO was traditionally thought to be an erythroid-specific hormone; however, messenger RNA for rHuEPO and its receptor are detected in neuronal and glial cells of the central nervous system and in the retina. rHuEPO was found to protect neurons from harmful stimuli[97] and to induce neuronal proliferation following injury.[98] Preclinical studies showed that rHuEPO is able to cross the blood–brain barrier and decrease infarct size in experimental stroke animal model.[99–101] This potential advantage was also suggested by a single clinical trial[102] demonstrating a tendency for a reduction in neurologic impairment. Results from ongoing studies, assessing the impact of rHuEPO with or without G-CSF (and other GF), should be awaited before introducing GF as a common therapeutic strategy for stroke.[103]

MYELOID GROWTH FACTORS

Myeloid growth factors, mainly G-CSF and GM-CSF, have multiple potential roles in the therapy of patients with hematologic malignancies. Guidelines for their use have been published by the American Society of Clinical Oncology in 1996[104] and have been updated on several occasions.[105,106] Similar guidelines have also been published by the National Comprehensive Cancer Network.[107] The following are the areas with the greatest clinical experience:

Table 58–3 Controlled Trials of Growth Factors After Induction Therapy in Acute Myeloid Leukemia

Study	*N*	Reduction in days to ANC 1000/μL	Documented Reduced Morbidity	Leukemia Stimulation
GM-CSF (sargramostim)				
Büchner[112]	86	6–9*	+	No
Rowe[113]	117	6*	+	No
GM-CSF (molgrastim)				
Stone[114]	379	2*	+	No
Zittoun[115]	53	–		Yes
Löwenberg[116]	316	5*		No
Witz[117]	209	6*		No
Löfgren[118]	110	8*		No
G-CSF (lenograstim)				
Dombret[119]	173	6*	+	No
Link[120]	187	6*		No
Goldstone[121]	803	5*		No
Amadori[122]	722	5*		No
G-CSF (filgrastim)				
Ohno[123]	67	12*	+	No
Ohno[124]	58	6*	+	No
Heil[125]	521	5*	+	No
Godwin[126]	234	3–4*	+	No
Usuki[127]	270	6*		No
Lehrnbecher[128]	317	5*		No
Estey[129]	197	13*		No

ANC, absolute neutrophil count; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.
*$P \leq 0.05$.

Potential Uses of Growth Factors in Acute Myeloid Leukemia

- Reducing period of neutropenia
- Recruitment of cells into S-phase of the cell cycle (priming)
- Enhancement of antimicrobial function
- Induction of differentiation of leukemic cells
- Direct antileukemic effects
- Interruption of autocrine-paracrine loops
- Stem cell protection

1. Acute myelogenous leukemia
2. Acute lymphocytic leukemia
3. Stem cell transplantation
4. Myelodysplasia
5. Chemotherapy-induced neutropenia
6. Aplastic anemia

Acute Myeloid Leukemia

Multiple potential uses exist for the administration of colony-stimulating factors in the treatment of acute myeloid leukemia (AML). Because of the potential for cytokine stimulation of acute leukemia cells,[108–111] there was initially great hesitation for conducting clinical trials with colony-stimulating factors in acute leukemia patients. These early reports demonstrated unequivocally the potential for augmenting leukemia blast cell proliferation by GM-CSF, G-CSF, and IL-3. Much of the early work highlighting this concern used experiments demonstrating blast cell proliferation and leukemia progenitor cell differentiation in culture systems containing these growth factors. It is not surprising, therefore, that when clinical trials finally did get underway they were conducted in older patients where the risk of death from marrow aplasia was great enough to outweigh the potential risk of stimulating leukemia cells.

Reducing Period of Neutropenia

Over the past 15 years, 18 major controlled trials of growth factors used after induction therapy in AML have been reported (Table 58–3).* Studies have been grouped according to the product used. Most importantly, the concern for safety has been laid to rest. Apart from one very small study, the preponderance of the data from all of these clinical trials shows that the administration of growth factors at any time after induction therapy for acute leukemia is safe. This safety has been demonstrated not only by the published results of the effects on the success of induction therapy, but also follow-up of these studies have failed to show any increase in the relapse rate among patients who went into complete remission with growth factors when compared with patients who did not receive growth factors.[131] All of these studies, with the exception of one small trial, demonstrated a significant reduction in the time required to reach an absolute neutrophil count of 500/μL or 1,000/μL. Several studies reported varying degrees of reduction in morbidity, and one study showed a significant reduction in mortality.[112,118,122,123,125–127] Despite these 16 well-controlled clinical investigations including more than 4500 patients, controversy still abounds over the use of growth factors in AML. The results obtained are not consistent, and the conclusions of the various authors differ. A meta-analysis cannot be performed because of differences in the design and conduct of these clinical trials. Particularly important may be differences in patient age, induction regimen, disease state, and stage of the disease. Also important is the timing of the growth factor administration, particularly in relation to the documentation of marrow hypoplasia. Differences in study product may exist, even among different preparations of the same cytokine. Finally, the statistical endpoints used in these studies need to be considered carefully. Some of the studies were designed and sized to show differences in hematopoietic recovery, for example, but not to show differences in complete response rate or survival. It is also possible that at least in some of the studies, patient selection may have

Variability in the Design and Conduct of Clinical Studies of Cytokines in Acute Myeloid Leukemia

- Patient age
- Induction regimen used
- Disease state
- Timing of growth factor administration
- Documentation of marrow hypoplasia
- Differences in study product
- Statistical endpoints
- Patient selection

affected interpretation of the data. Thus, it is simply impossible to compare published results.

Among studies investigating the use of growth factors during consolidation therapy, very few have shown benefit. Because patient numbers in these trials were small and because the studies were not sized to show differences in neutrophil recovery during consolidation, failure to demonstrate such a difference does not imply that cytokines do not work when administered during consolidation therapy. In fact, the largest trial of growth factors in AML,[125] which had an adequate sample size to assess reduction in neutropenia, demonstrated a statistically significant shortening of neutropenia among patients receiving growth factors during consolidation. Similar results were also reported by the Cancer and Leukemia Group B when cytokines were given after consolidation therapy with diaziquone and mitoxantrone[132] and in a report of the GOELAM study.[133]

Over the past 4 years, several studies have evaluated the cost-effectiveness of cytokine therapy when used during induction therapy. Table 58–4 outlines these clinical studies and their correlative cost analyses. Most studies in adults demonstrated a cost-benefit for growth factors although a cost-effectiveness study using the more toxic *Escherichia coli*–derived GM-CSF was an exception.[138] Thus, one of the major considerations for withholding the use of cytokines in AML may no longer be compelling.

There are few areas in clinical medicine where so many prospective clinical trials have been carried out to answer a single question, yet at the end the data remain equivocal. Although the major reason for the reluctance to initiate clinical trials of cytokines in the AML was a concern for safety, it can now be stated unequivocally that this concern was unwarranted. With the apparent benefit of cytokine therapy reported in so many studies and the uniform finding of an improved neutrophil recovery time, it is not clear why there is a continued hesitation to use cytokines in AML patients. The probability of infection and the risk of increased morbidity and mortality correlate directly with severity of neutropenia, although these observations may at times not be easy to demonstrate objectively. It is therefore difficult not to acknowledge the benefit of cytokine therapy to a patient undergoing induction therapy because its use is associated with an improved neutrophil recovery time of approximately 1 week. A sense of well-being among patients (and physicians) was achieved after appreciating that neutrophil recovery will be hastened and cannot be ignored and, therefore, it seems that cytokines (GM-CSF or G-CSF) should be administered to all patients undergoing induction therapy for AML who are at high risk for therapy-related morbidity and mortality. The earlier published data were analyzed on the basis of an expectation of major differences in response rate or survival. This is clearly not the issue or the reason for the use of growth factors. Rather, cytokines need to be considered as important supportive care measures, much like, for example, central venous catheters. These indwelling catheters are not cost-effective and they increase rather than decrease infections; nevertheless, virtually all physicians use them for the comfort and well-being of the patients. These same considerations might be employed as a rationale for the use of cytokines in this setting.

Enhancement of Antimicrobial Function

Considerable speculation in preclinical investigations has focused on the potential for enhancing antimicrobial therapy with cytokines. In vitro, GM-CSF increases phagocytic and fungicidal activity of neutrophils against *Candida albicans* and *Torulopsis glabrata*.[139,140] Similarly, in vitro exposure of peripheral blood mononuclear cells to GM-CSF increases phagocytosis of *Cryptococcus neoformans*, and exposure of monocytes to GM-CSF results in increased killing of *C Albicans* and *Aspergillus fumigatus*.[141] The mechanism of increased activity against *Candida* and *Aspergillus* appears to be unrelated to increased phagocytosis; rather, it is due to increased oxidative metabolism and production of toxic superoxide anions by monocytes.[141]

Clinical data that support the use of cytokines in fungal infections have been limited to several early phase I and II trials. A hint of effectiveness was suggested by an Eastern Cooperative Oncology Group phase III study of cytokines in the AML.[113] In this study, 20 of 117 patients had unequivocally documented fungal infections and the overall mortality in the GM-CSF group was 13% compared with 75% in the placebo group (Table 58–5).[142] Most of these patients,

as expected, had *Aspergillus* or *Candida* infections and there was no difference in the fungal prophylaxis administered to the two groups. Basically, most patients receiving GM-CSF survived their fungal infections, whereas most of those receiving placebo died. Clearly, caution is mandatory when dealing with relatively small numbers, but these data are intriguing. It is not known whether these results are due to direct stimulation of monocyte activity by GM-CSF or to earlier neutrophil recovery, as initially hypothesized during the design of the study.

Recruitment of Cells Into S-Phase of the Cell Cycle (Priming)

Over the past decade, several groups have attempted to determine whether hematopoietic growth factors can be used to prime leukemic blasts by increasing the proportion in the active phase of the cell cycle, thereby theoretically increasing their susceptibility to S-phase-active agents such as cytosine arabinoside. In vitro studies have shown that growth factors such GM-CSF, G-CSF, stem cell factor (c-kit ligand), and interleukin-3 (IL-3) can increase the fraction of leukemic blasts in the S-phase. The effect that in vivo priming might have on leukemic blasts in their ultimate response to chemotherapy is unclear, despite a multitude of phase II and phase III studies. Detailed analysis of these studies shows that the clinical data remain conflicting and confusing. It is important to understand that in vitro data must be cautiously interpreted when they are described without concurrent controls. The finding of an increased number of blasts or recruitment into the S-phase of the cell cycle following the administration of a cytokine must be compared carefully with control patients, because untreated patients with AML often change their cell-cycle kinetics and increase their blast cell counts. Table 58–6 outlines the 15 controlled studies that have evaluated the role of cytokines as priming agents for AML.* This clearly shows the enormous variability in patient selection, cytokine used, type of therapy administered, and, of course, the results. Despite the vast number of clinical trials examining the use of cytokines as priming agents for AML, the results remain confusing. Only one study demonstrated stimulation of leukemia and a lower response rate among patients receiving priming therapy with *E coli*-derived GM-CSF[130] but considerable caution is needed when interpreting this study—it was not prospectively controlled and the control group consisted of a historical cohort of patients treated on several different studies. It is of interest that in the two studies that have demonstrated a statistically significant clinical benefit for priming with cytokines, this benefit was confined to disease-free survival and there was no effect on the initial response rate.[117,148] In one of the studies this benefit was limited to patients with intermediate cytogenetic abnormalities.[148] To confuse the issue further, a more recent study reported an improved initial response rate after priming with G-CSF.[122]

Table 58–5 Incidence of Infection With Granulocyte-Macrophage Colony-Stimulating Factor vs Placebo

Thus, the body of evidence has established the safety of cytokines when used as priming agents, and the results of one study should not negate this overall conclusion. In contrast to the established role of growth factors following induction therapy to ameliorate morbidity, no clear role of hematopoietic growth factors as priming agents as yet has been defined, and the use of cytokines as priming agents in AML cannot be recommended outside of well-designed clinical studies.

Growth Factors for Acute Myelogenous Leukemia (AML)

- Data from a multitude of prospective clinical trials have demonstrated that growth factors are safe when given at any time during induction therapy for AML.
- Growth factors given after induction therapy shorten the period of neutropenia by anywhere from 2 to 7 days.
- Six of the 16 major randomized studies have shown a significant reduction in morbidity if growth factors are administered during induction.
- No major study has shown a detrimental effect from growth factors.
- Studies of cost-effectiveness, although limited in scope, have also, in most instances, demonstrated a benefit for growth factors.
- Although glycosylation may confer important biological properties, both the glycosylated and nonglycosylated G-CSF preparations and GM-CSF seem to be equally efficacious in reducing the period of neutropenia. However, nonglycosylated *Escherichia coli*-derived GM-CSF is more toxic than all other growth factors for AML and should not be used.
- GM-CSF has a potential advantage when neutropenia is accompanied by fungal infection, and consideration should be given to the preferential use of GM-CSF in such instances.
- The data suggest that the best time to administer growth factors is after marrow aplasia has been demonstrated on day 10 to 14 of bone marrow. Thus, growth factors are recommended, as a supportive care measure, both following induction and consolidation therapy for AML.
- In contrast to the role of growth factors following induction therapy to ameliorate morbidity, no clear role for growth factors as priming agent has yet been defined and the use of cytokines for priming cannot be recommended outside of a well-designed clinical trials.

Acute Lymphocytic Leukemia

The use of growth factors for patients with acute lymphocytic leukemia (ALL) has largely bypassed the controversy that was described in AML patients. The data suggest that the use of cytokines in ALL, either during induction[151–153] or in subsequent intensification therapy,[134,154,155] reduces the period of neutropenia, and in several prospective, randomized studies affects the morbidity and even mortality (Table 58–7). Thus, it has become fairly established to recommend the use of growth factors, G-CSF or GM-CSF, at every stage of the comprehensive therapy for ALL patients where profound life-threatening neutropenia is expected as part of the therapeutic course.

Stem Cell Transplantation

There are three major uses of growth factors in patients undergoing bone marrow transplantation: enhancement of neutrophil recovery, prevention or therapy of graft failure, and mobilization of stem cells.

Enhancement of Neutrophil Recovery

Over the past 15 years it has been unequivocally established that growth factors given after the infusion of autologous or allogeneic bone marrow grafts significantly shorten the period of neutropenia and reduce the duration of hospital stay (Table 58–8). Various randomized studies show significant reduction in duration of neutropenia of anywhere from 4 to 7 days with a similar shortening in the length of the overall hospital stay.[159,162–168,] There are differences in Table 58–8 between the recovery after GM-CSF and G-CSF that do not reflect differences in study product; rather, they reflect evolving clinical practice. Most of the early studies with GM-CSF were conducted using bone marrow as the source of stem cells, whereas most of the published randomized studies with G-CSF used mobilized peripheral blood stem cells. Although not shown in Table 58–8, the available data with growth factor administration after allogeneic bone marrow transplantation—based on several phase II and phase III studies—confirm that in this setting there is also a more rapid neutrophil recovery and reduced hospital stay.[169,170]

In general, the efficacy of enhanced neutrophil recovery is similar whether glycosylated or nonglycosylated G-CSF is used (lenograstim or filgrastim) or glycosylated GM-CSF (sargramostim). The nonglycosylated GM-CSF (molgramostim) is more toxic and should probably not be used. During the last decade there have been multiple

trials attempting to use other cytokines post-stem cell transplantation. These involved predominantly the combination of GM- and G-CSF therapy, concurrently or sequentially, or combinations involving interleukin 3. Although various combinations of IL-3 with GM- or G-CSF appeared to promote accelerated hematopoietic recovery, the toxicity of IL-3 does not seem to warrant routine use of IL-3 alone, in combination, or as a hybrid (PIXY 321), in routine clinical practice. In any event, the evolving clinical practice of mobilized peripheral blood stem cell grafts has made use of growth factors following autologous transplantation less of a critical issue.

Graft Failure

Graft failure, as well as poor graft function leading to prolonged cytopenias, increases the risks of bone marrow transplantation and affects patient survival. Graft failure, either primary or secondary, was more common during the early days of bone marrow transplantation where the constitution of cells in the graft was somewhat empiric. With current technologies and measurement of precise numbers of CD34-positive cells in the graft, graft failure is far less common. Nevertheless, a small proportion of patients undergoing allogeneic transplantation or, less commonly, autologous transplantation fail to engraft. Studies with GM-CSF have shown that growth factors significantly reduce the rate of graft failure, primary or secondary,[168] and that sequential administration of different growth factors, that is, GM-CSF followed by G-CSF, offered no advantage over GM-CSF alone in accelerating hematopoiesis or preventing lethal complications in patients with poor graft function after transplantation.

Because of the potential for enhancing antimicrobial function with GM-CSF, it is not known whether the routine use of small doses of GM-CSF post bone marrow transplantation is indicated. On the basis of theoretic considerations, in situations where the neutrophils have recovered but the patient remains infected and severely immunecompromised, due to graft-versus-host-disease or the therapy thereof, the use of GM-CSF may help prevent, or be an adjunct to the treatment of, fungal or other opportunistic infection. However, there are no prospective studies to date confirming such a benefit.

Mobilization of Peripheral Blood Progenitor Cells

For the successful mobilization of progenitor cells of peripheral blood for clinical use, several approaches have been used:

General Guidelines for Mobilization of Peripheral Blood Stem Cells (PBSC)

- Both G-CSF and GM-CSF mobilize PBSC.
- There is a dose response effect for both G-CSF and GM-CSF in PBSC mobilization.
- Combinations of cytokines and chemotherapy mobilize more PBSC than cytokines alone.
- Patients who have received no or minimal prior chemotherapy have a greater than 90% likelihood of achieving an adequate collection of PBSC with cytokine/chemotherapy combinations.
- Patients who have received more than 6 months of alkylating agent therapy, fludarabine or radiation therapy have only a 70% chance of obtaining adequate number of PBSC (>1.5 × 10^6 CD34 cells/kg) using standard technique.
- For heavily pretreated patients, in whom there is a significant risk of nonmobilization using standard techniques, use of an early-acting cytokine such as stem cell factor (SCF) or flt3 ligand (Flt3 L) together with a late-acting cytokine (G-CSF or GM-CSF) is likely to significantly enhance the rate of PBSC mobilization and enable the transplant to take place.

Reproduced with permission from Stiff PJ: Peripheral blood stem cell mobilization: Contemporary issues and early studies using Flt3 ligand. In Rowe JM, Lazarus HM, Carella AM (eds.): Handbook of Bone Marrow Transplantation. London, Martin Dunitz, 2000, p 22.

1. Collecting cells during the recovery following intensive myelosuppressive chemotherapy;
2. Following the administration of growth factors, G-CSF or GM-CSF; and
3. Using the combination of hematopoietic growth factors and myelosuppressive chemotherapy.

In practice, progenitor cell grafts are most efficiently collected following the administration of the combination of chemotherapy and growth factors although there is a significant proportion of patients in whom an adequate number of progenitor cells can be collected following the use of growth factors alone. Current understanding of peripheral blood stem cell mobilization is outline in the box below.[171–174]

Although the rate of engraftment using mobilized peripheral blood stem cells is more rapid than following the use of immobilized bone marrow stem cells,[175–178] the published data suggest that there is no fundamental difference in the rate of engraftment between mobilized peripheral blood stem cells or mobilized cells obtained from the bone marrow. In practice, mobilization of peripheral blood stem cells has become commonplace and is easily performed in the outpatient settings. The vast majority of autologous transplants are performed in this manner and an increasing number of allogeneic stem cell transplants are performed using this approach. Some countries prohibit the use of growth factors to healthy children who act as donors; however, the evolving data suggest that the risks, if any, are minimal.

Recently there have been several reports on the efficacious use of a single dose of pegfilgrastim as an alternative to daily injections of cytokines for mobilization.[179,180] This may ease the burden on patients but more mature data are awaited before this becomes standard of care for mobilization.

Myelodysplasia

The administration of the myeloid growth factors, GM-CSF and G-CSF, have also been reported to be occasionally beneficial in increasing the neutrophil count and function in patients with myelo-

dysplasia.[181–185] The initial concerns about the safety of using growth factors known to stimulate leukemic blast cell proliferation have been previously discussed. Clinical data, however, perhaps surprisingly, have demonstrated that stimulation of leukemia does not appear to be of major concern in patients with myelodysplasia.[186] Most studies have not shown an uncontrolled proliferation of leukemic blasts or significant negative effects on survival beyond the expected rate of transformation to frank AML associated with GM-CSF or G-CSF administration. Although most studies have shown a small, but often significant, effect on neutrophil production, the biological significance of this is not always clear as the clinical response of a patient has often not been described in detail.

MDS is a disease of older adults, and conventional therapy is usually unsatisfactory. There is evidence that more than 90% of patients have an increase in their neutrophil count in response to cytokines.

It appears that GM-CSF and G-CSF have the capacity to effect a modest increase in mature myeloid elements. The clinical effects of these cytokines are clearly limited, but in a palliative clinical setting they may be important adjuncts to the supportive care of patients with MDS.

Chemotherapy-Induced Neutropenia

The routine use of growth factors for the primary prophylaxis of neutropenia following chemotherapy for solid tumors or lymphoma is not supported by prospective data.[105–107] Several randomized studies using GM-CSF or G-CSF have been conducted to evaluate the role of primary prophylaxis in patients with lymphoma undergoing induction chemotherapy.[187–189] None of these studies showed a clear benefit in terms of tumor response or survival, although meta-analyses did report a reduction in the incidence of neutropenia and infections.[190,191] The original guidelines published by the American Society of Clinical Oncology suggested that cytokines should only be offered when a therapeutic regimen has an expected rate of febrile neutropenia of at least 40%.[104,105] A subsequent recent update has modified this to an expected rate of febrile neutropenia of at least 20%.[106] A similar recommendation appears in the published guidelines of the National Comprehensive Cancer Network.[107]

Once a patient has developed febrile neutropenia following a course of chemotherapy, it is common practice to administer growth factors in future cycles as secondary prophylaxis. There are clear advantages in maintaining dose intensity and, thus, although convincing prospective data are lacking, such a practice seems reasonable. Growth factors are also used routinely as an adjunct to the therapy of febrile neutropenia following chemotherapy for patients with solid tumors or lymphomas. In most cases, no more than a few days of growth factor administration are required.

An alternative to the administration of daily growth factor has been development of pegfilgrastim, which is a pegylated recombinant G-CSF designed specifically for sustained duration of action and requiring only a single injection per each cycle of chemotherapy.[192,193] Administration of pegfilgrastim as opposed to daily growth factor injections reduces the burden on the patients and may affect the quality of life and compliance of the patient. Typically, pegfilgrastim produces a rapid rise in the absolute neutrophil count with a more sustained duration of response than achieved with daily courses of growth factor.[194] Randomized studies have established the efficacy and safety of pegfilgrastim in chemotherapy-induced neutropenia following treatment of breast cancer,[195] lung cancer,[196] lymphoma,[197] and Hodgkin lymphoma.[198]

Aplastic Anemia

Although often used empirically, there are scanty data supporting the use of myeloid growth factors in acquired aplastic anemia. Nonrandomized data suggest that the degree of response to cytokines is likely to be most pronounced in the less severe forms of aplastic anemia—when its use is less critically needed.[199] There are some data that cytokines may be useful as an adjunct to the therapy of severe bacterial or fungal infections, although they do not appear to be of benefit as prophylaxis for infections in patients with acquired aplastic anemia.[200]

A lingering concern in the use of cytokines for patients with acquired aplastic anemia has been the potential role of cytokines in promoting the development of MDS and AML. The initial concern was first reported from Japan in 1997[201] demonstrating an incidence of more than 40% of MDS in children with acquired aplastic anemia receiving cytokines. Although these data could not be confirmed in a subsequent Italian study,[202] the issue remains unresolved. A recent survey performed by the European Group for Blood and Marrow Transplantation included 840 patients. Among the 43% of patients who received first-line therapy with cytokines, the incidence of MDS/AML was 10.9% compared with 5.8% among patients who did not receive cytokines with their primary therapy.[203] At this time, the retrospective nature of this analysis of registry data does not permit a definitive conclusion on this issue.

In contrast to acquired aplastic anemia there are considerable data supporting the use of myeloid growth factors in patients with congenital aplastic anemias, including Kostmann syndrome, Fanconi anemia, Pearson syndrome, and Shwachman–Diamond syndrome.[199]

Although the outlook for those patients has improved dramatically following the use of myeloid growth,[204] the Severe Chronic Neutropenia International Registry has reported on the increased risk of MDS or AML developing in those patients receiving cytokines.[205] The precise relationship between the duration or dose of cytokine therapy and the risk of development of MDS/AML has not been established.[206]

The recent report from the Severe Chronic Neutropenia International Registry documented a cumulative incidence after 10 years of 21% of patients developing MDS or AML after therapy with G-CSF and 8% of patients having mortality due to sepsis. However, in less responsive patients with congenital neutropenia, who required higher doses of G-CSF (greater than 8 μg/kg/day), 40% developed MDS or AML and 14% died from sepsis, as compared with 11% and 4%, respectively, for the more responsive patients who also received lower doses of G-CSF.[207]

THROMBOPOIETIC GROWTH FACTOR

Thrombopoietin (TPO) is a naturally occurring glycosylated peptide that stimulates the differentiation of bone marrow stem cells into megakaryocyte progenitor cells, induces the expression of megakaryocyte differentiation markers, promotes megakaryocyte proliferation and polyploidization and, ultimately, increases the number of platelets in the circulation.[9,208–212] It also primes platelets to aggregate in response to otherwise subthreshold levels of thrombin, collagen, or diphosphate. In addition to stimulating megakaryocyte production, TPO is essential for the survival and expansion of hematopoietic stem cells.

Two recombinant thrombopoietins have been extensively studied and demonstrated some clinical activity. One is the full thrombopoietin molecule[213] and the other is a truncated form of the protein produced in *Escherichia coli* and modified with polyethylene glycol to provide stability in vivo.[213,214] The latter agent is known as megakaryocyte growth and development factor (MGDF).[213]

Early clinical trials of these two forms of the recombinant protein—the full-length molecule, recombinant human thrombopoietin, rHuTPO, and the truncated molecule, MGDF—have demonstrated a dose-dependent increase in circulating platelet counts when given to healthy donors.[215,216] Administration of both agents after chemotherapy has enhanced platelet recovery, reducing the degree of thrombocytopenia after moderately myelosuppressive regimens.[217–219] Their use following more intensified chemotherapy regimens (induction for acute leukemia, high-dose therapy for transplantation), given in multiple doses, has generally failed to reduce the severity of throm-

bocytopenia or the need for platelet transfusion.[218,219] TPO can also increase the number of hematopoietic stem cells mobilized with G-CSF[220] and improve the amount of platelets derived from plateletpheresis, if administered pre-pheresis to platelet donors.[213,221,222]

An emerging potential indication for TPO is idiopathic thrombocytopenic purpura. Despite the abundant number of megakaryocytes observed in patient bone marrow, endogenous levels of TPO in these patients are low and the response rate to the thrombopoietin receptor agonist AMG531 (a peptide mimetic TPO), in patients with refractory idiopathic thrombocytopenic purpura, is around 60% to 80%.[223]

Unfortunately, administration of MGDF to healthy donors was reported to be unsafe, inducing the development of severe thrombocytopenia is some of the healthy donors receiving TPO. Antibodies produced by the donors against unrecognized epitopes on the MGDF-truncated product cross-reacted against endogenous TPO, resulting in thrombocytopenia. This side effect led to the abandonment of the use of MGDF and encouraged investigators to currently search for peptide and nonpeptide mimetics that bind and stimulate the thrombopoietin receptor on hematopoietic cells.

IL-3, IL-6, and IL-11 are potent stimulators of platelet production. However, IL-3 and IL-6 are too toxic for routine clinical use. On the other hand, the use of IL-11 is far less toxic and, in fact, has been approved by the FDA for the prevention of chemotherapy-induced thrombocytopenia.[224] IL-11 is a thrombopoietic growth factor directly stimulating the proliferation of the hematopoietic stem cells and megakaryocyte progenitor cells and induces megakaryocyte maturation resulting in increased platelet production.[224]

On the basis of two randomized double-blind placebo-controlled trials,[225,226] the current indication for IL-11 is for the prevention of severe thrombocytopenia and the reduction of platelet transfusions following myelosuppressive chemotherapy in patients with non-myeloid malignancies who are at high risk for developing severe thrombocytopenia.[227] However, despite some encouraging reports, suggesting IL-11 to be able to reduce platelet transfusion requirements,[227] its use has been modest owing to side effects, including edema, dyspnea, pleural effusions, and in some patients, atrial arrhythmias, papilledema, and periosteal bone formation.[227,228]

At the current time there are insufficient data to support the use of IL-11 following intensive chemotherapy for AML or bone marrow transplantation.[229,230] Several prospective randomized trials, though small, have compared IL-11 with placebo, following high-dose chemotherapy and autologous stem cell transplantation. There was a tendency for reduction in platelet transfusion requirements in the IL-11 group; however, the median time to platelet transfusion independence was similar.[230]

Although these thrombopoietic growth factors are of great potential theoretic value, a clinical role similar to the myeloid growth factors or erythropoietin has not been established for them.

CHAPTER 59

PATHOBIOLOGY OF ACUTE MYELOID LEUKEMIA

Gerlinde Wernig and D. Gary Gilliland

INTRODUCTION

Acute myeloid leukemia (AML) is a complex disease with considerable phenotypic and genotypic heterogeneity. There are more than 100 recurring cytogenetic abnormalities observed in AML and numerous point mutations. AML is challenging from a clinical perspective as well as from a genetic perspective. Most adults who develop AML will die of their disease or complications related to therapy. Furthermore, patients with AML are still treated with the same empirically derived cytotoxic chemotherapy today, comprising anthracycline and cytosine arabinoside, as was used two decades ago. There is clearly a compelling need to develop more effective and less toxic therapies for this disease.

How can we approach the development of molecularly targeted therapies against the backdrop of almost overwhelming genetic diversity? First, because there are a limited number of AML phenotypes, many of the observed mutations and gene rearrangements associated with AML must target similar transcriptional and/or signal transduction targets. Second, there are several mutations that occur at relatively high frequencies, such as FLT3 mutations, that are attractive targets for therapeutic intervention. This chapter provides a general overview of our current understanding of the genetics of AML and the therapeutic implications.

ETIOLOGY

Most cases of AML are sporadic, characterized by acquisition of somatic mutations in hematopoietic progenitors that confer a proliferative and/or survival advantage, impair hematopoietic differentiation, and confer properties of limitless self-renewal. It is usually not possible to identify a cause for development of AML, either as an inherited predisposition to disease or as a consequence of environmental exposure. However, analysis of rare heritable cases of AML and of cases related to exposure to environmental agents including chemotherapy and ionizing radiation have provided valuable clues to the etiology of AML.

Environmental Exposures

Exposure to a variety of environmental agents has been implicated in the pathogenesis of AML. Ionizing radiation and alkylating agents induce DNA, usually by inducing double-strand breaks that may result in point mutations, genomic deletions, or the chromosomal translocations associated with hematopoietic stem cell transformation.[1] For example, an increased incidence of AML has been noted in survivors of atomic bomb explosions, with a risk that is proportional to the degree of radiation exposure.

Chemical exposure to organic solvents such as benzene and occupational exposure to petroleum products have been associated with a higher risk of developing AML[1]; however, case–control studies of leukemia have demonstrated only a slight increase in risk of disease for persons with occupational or chemical exposures. Except for special groups exposed to high levels of benzene or radiation, the reported risks associated with occupational and chemical exposure have generally been less than twofold, making these exposures of questionable pathogenetic significance in a disease with a yearly incidence on the order of 1/100,000. The presence of RAS mutations in patients with AML has been associated with specific occupational exposure to chemicals, suggesting that these exposures may induce genetic damage that may culminate in acute leukemia.[2]

Therapy-Related Leukemia

Ionizing radiation used in the treatment of malignancies such as Hodgkin lymphoma has also been linked to the development of AML, although the risk appears to be quite low when radiation alone is used as treatment, and is related to the age of the patient and doses of more than 2000 cGy.[3] Whether irradiation adds to the risk of therapy-related AML associated with chemotherapy remains controversial. Although some studies suggest that the risk of development of AML is significantly increased when the two modalities are combined, other studies have demonstrated that the combination of high-dose radiation therapy confined to small volumes and chemotherapy did not significantly increase the leukemogenic risk.

The development of AML after chemotherapy administered for a variety of other malignancies, ranging from Hodgkin lymphoma to breast cancer, is a devastating complication of curative treatment strategies.[3] Leukemia develops after a latency period of varying length, which suggests that the initial mutations resulting in clonal hematopoiesis may occur without any obvious hematologic change (no dysplasia or cytopenia). The subsequent acquisition of a variety of additional genetic lesions may be essential for the development of a preleukemia (myelodysplasia) or overt leukemia. Clonal chromosomal abnormalities have been reported in the majority of cases of therapy-related AML. The most frequently reported abnormalities involve complete loss or interstitial deletions of the long arm of chromosome 5 or 7 (or both). Typically these leukemias develop after alkylating agent-induced damage a median of 3 to 5 years after therapy for the primary malignancy and are associated with an antecedent myelodysplastic disorder.[4] A second group of therapy-related leukemias is associated with rearrangements of the MLL gene in chromosome band 11q23.[5] 11q23-associated AML often develops after treatment with drugs that target DNA-topoisomerase II (eg, epipodophyllotoxins, anthracyclines), with a very short latency of 12 to 18 months after treatment, and is not typically associated with an antecedent myelodysplastic syndrome.[6] Of concern are recent reports of the development of myelodysplastic syndrome and AML after dose-intensive therapy with (and without) autologous stem cell and hematopoietic growth factor support for the treatment of Hodgkin and non-Hodgkin lymphoma and breast cancer.[7,8] The identification of an increasing incidence of therapy-related AML consequent on attempts to improve cure rates for other malignancies emphasizes the importance of understanding the underlying pathogenetic mechanisms.

The genetic damage induced by chemotherapeutic agents can result in clonal proliferation, which may be an essential early step in leukemogenesis, occurring before the development of clinical abnormalities. Clonal hematopoiesis has been demonstrated in clinically asymptomatic patients who received prior cytotoxic chemotherapy for a variety of non-Hodgkin lymphomas.[9] Recently it has also been shown that sequential X-linked clonality assays may help predict

subsequent evolution to frank myelodysplasia or AML.[10,11] The specific genetic events induced by chemotherapeutic agents remain unknown; nevertheless, the resultant clonal proliferation and observed cytogenetic abnormalities provide a valuable model for multistep leukemogenesis.

Antecedent Hematologic Disorders That Predispose to Leukemia

Several hematologic disorders increase the risk of development of acute myeloid leukemia. Patients with myelodysplastic syndrome have a relatively high risk of progression to AML of approximately 30% over the lifetime of the affected individual. The risk is lower among patients with myeloproliferative diseases such polycythemia vera, essential thrombocythemia, and myeloid metaplasia with myelofibrosis. Paroxysmal nocturnal hemaglobinuria patients also have a low, but increased, risk for development of leukemia.

Inherited Predisposition to Leukemia

Familial leukemia may occur in the context of a clinical syndrome in which it is one component of the overall disease, or as an isolated leukemia-predisposition trait that is not specifically associated with comorbid conditions.[12] Syndromes associated with an increased risk of leukemia include a rare constitutional trisomy 8 syndrome associated with a characteristic facial and skeletal muscle dysmorphism and an increased risk of hematologic disorders, including aplastic anemia, myelodysplasia, and acute and chronic myeloid leukemia[13]; and Down syndrome, trisomy 21, in which there is a 10- to 18-fold increased risk for leukemia. In individuals with Down syndrome who are less than 3 years old, the leukemia is most frequently AML, of the FAB M7 subtype; after age 3, the development of ALL is more common. Analysis of atypical Down karyotypes in individuals who have progressed to AML has suggested that the 21q22.3 locus that includes the AML1 gene may be important. In has also recently been demonstrated that patients with Down syndrome who develop AML may have acquired loss-of-function mutations involving the hematopoietic transcription factor GATA-1.[14]

Defective DNA repair syndromes are also associated with a high incidence of hematologic malignancies, including AML. These heritable disorders include Bloom syndrome, in which AML, ALL, lymphoma, or other malignancies occur in approximately 25% of affected individuals[15]; Fanconi anemia, in which approximately 50% of patients develop AML or myelodysplasia by the age of 40[16]; neurofibromatosis that results from loss-of-function mutations in the neurofibromin (NF-1) tumor suppressor gene on chromosome 17q11.2 and is associated with the development of juvenile CML, ALL, lymphomas, and a disproportionately high rate of myelodysplastic syndrome evolving into AML in young patients[17]; Li-Fraumeni syndrome, an autosomal dominant disorder caused by mutations of the p53 tumor suppressor genes and is associated with the development of multiple tumor types including leukemia[12]; and Wiskott–Aldrich syndrome, an X-linked immunodeficiency syndrome caused by mutations in the WASP gene and is associated with the occasional development of lymphomas, AML, and ALL.[18] Other syndromes associated with a high risk of developing AML include Kostmann infantile genetic agranulocytosis, an autosomal recessive disorder that has been associated with mutations in the G-CSF receptor on chromosome 1p35-p34.3,[19,20] and the Blackfan–Diamond syndrome, consisting of congenital hypoplastic anemia and growth retardation.[21]

There have also been reported cases of familial leukemias not associated with any defined syndrome. For example, several families have an autosomal recessive pattern of inheritance of childhood-onset myelodysplasia associated with monosomy 7 and evolution to AML.[22] Autosomal dominant patterns of inheritance of leukemia have also been reported, with a variety of morphologic and cytogenetic subtypes.[12,23] These include the familial platelet disorder with propensity to develop AML (FPD/AML syndrome) that is due to inherited loss-of-function mutations in AML1.[24,25]

Although the environmental and hereditary conditions described above serve as excellent models for obtaining insights into the molecular pathogenesis of AML, it must be emphasized that the vast majority of patients with de novo AML show no evidence of any of these risk factors, and the etiologic factors contributing to the development of AML in the majority of affected individuals is poorly understood.

THE LEUKEMIC STEM CELL

What is the target cell for transformation in leukemia? It has recently been appreciated that the hierarchical organization of normal hematopoiesis that includes a small fraction of stem cells with self-renewal capacity, and larger numbers of committed progenitors that lack these properties, also applies to leukemia, and in all likelihood to other cancers.[26,27] That is, only a small fraction of leukemic blasts that are observed clinically have the capacity to self-renew. These observations are important because they suggest that this small subpopulation may be the most important to target therapeutically and also may be the most appropriate cell type in which to monitor response to therapy.

Several lines of evidence indicate that leukemic cells with self-renewal properties, or "leukemic stem cells," exist among the $CD34^+/CD38^-$ population in humans. Perhaps the most compelling evidence in support of the $CD34^+/CD38^-$ (multipotent) stem cell as the target for leukemic transformation in AML comes from recent studies in which purified AML subpopulations were transplanted into mice with severe combined immunodeficiency disease (SCID).[28] These experiments defined a SCID mouse leukemia-initiating cell (SL-IC) in the bone marrow of patients with AML. SL-ICs comprise approximately 1 in 105 AML cells and can repopulate immune-deficient mice with leukemic cells that are phenotypically identical to those of the AML patient from which they were derived.[28] In several AML patient samples studied, the SL-ICs resided in the most primitive compartment of cells—those that are $CD34^+/CD38^-$. $CD34^+/CD38^-$ cells purified from normal marrow give rise to mixed-lineage granulocytic–erythroid–megakaryocytic colonies in culture and can repopulate immune-deficient mice with normal cells. These experiments indicate that the SL-ICs share an immunophenotype expressed by normal multilineage stem cells and that the target for leukemic transformation may reside in this primitive pluripotent population of cells rather than in a lineage-restricted cell.

Using nonobese diabetic mice with SCID (NOD–SCID), a modified SCID mouse,[29] it has been shown recently that in AML patient samples, the SL-ICs reside only in the $CD34^+/CD38^-$ fraction and not in the $CD34^+/CD38^+$ fraction.[26] The SL-IC phenotype was consistent regardless of the FAB subtype (M1, M2, M4, M5), lineage markers, or percentage of leukemic blast cells expressing the CD34 antigen. The SL-ICs also demonstrated self-renewal capacity, a requirement for maintenance of the leukemic clone, assessed by their ability to be serially transplanted into secondary recipient mice. The uniformity of the leukemic stem cell phenotype, together with the observation that normal stem cell repopulating cells are also found in the $CD34^+/CD38^-$ fraction, has suggested the hypothesis that the leukemia-initiating transformation- and progression-associated genetic events always occur in primitive cells and not in committed progenitors.

However, recent data shed interesting new light on these observations. Expression of certain leukemia oncogenes in committed hematopoietic progenitors that are destined to apoptotic cell death can confer properties of self-renewal to these cells. For example, transduction of the MLL–ENL fusion gene into purified common myeloid progenitors (CMP) or granulocyte–monocyte progenitors (GMP) that lack the potential for self-renewal confers properties of leukemia stem cells. These include the ability to serially replate in methylcellulose cultures, and to engender an AML phenotype that can be

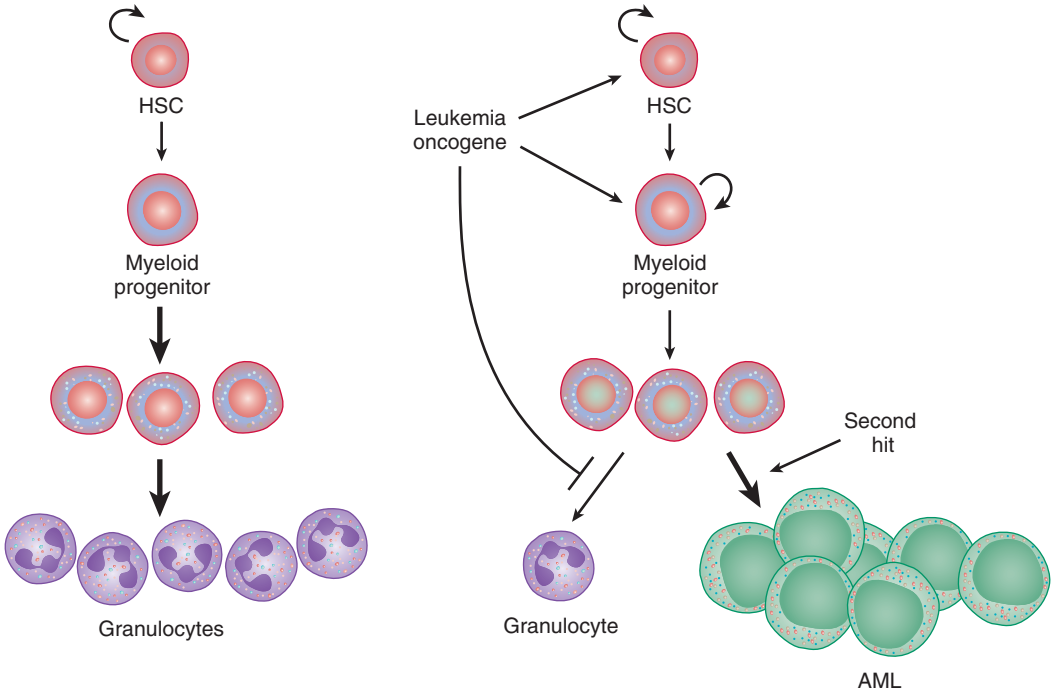

Figure 59–1 The leukemic stem cell. It has been hypothesized that there is a hierarchical development in leukemic cells as in normal hematopoietic cells in which only a small population of early hematopoietic progenitors have self-renewal capacity, as depicted on the left panel. Data derived from injection of human leukemic cells into NOD–SCID mice indicate that among leukemic populations, there is also only a small fraction of cells that have self-renewal capacity, and these have been termed leukemia stem cells (*left panel*). It has recently been shown in murine model systems that expression of certain leukemia oncogenes, such as MLL–ENL, can convert a hematopoietic stem cell that has intrinsic self-renewal capacity, or even a committed hematopoietic progenitor that has no capacity for self-renewal, into a cell that has properties of a leukemic stem cell. Subsequent mutations in this population, such as FLT3 mutations, would confer additional proliferative and survival advantage to these cells. These data indicate that although leukemia-associated mutations may occur in the self-renewing hematopoietic stem cell, they may also occur in committed progenitors and activate transcriptional programs that confer properties of self-renewal (*right panel*).

serially transplanted into secondary recipient mice.[30] The leukemias are immunophenotypically identical, regardless of whether the starting cell population is HSC, CMP, or GMP. These data suggest that certain leukemia oncogenes, such as the MLL–ENL fusion gene, can commandeer programs of self-renewal in committed progenitors and enforce phenotypic expression of markers associated with the hematopoietic stem cell (Fig. 59–1). There are several caveats, including the possibility that retroviral transduction contributes to the phenotype as a consequence of insertional mutagenesis and that this is a mouse model system, and mice may be different from humans in this regard. Nonetheless, these findings provide strategies for understanding the programs that control self-renewal. These may not only be valid targets for therapeutic intervention but may provide insights into approaches to confer properties of self-renewal to adult somatic cells for therapeutic benefit, such as tissue regeneration.

GENE REARRANGEMENTS AND MUTATIONS IN ACUTE MYELOID LEUKEMIA

Most cases of AML can be attributed to acquired somatic mutations that occur in hematopoietic progenitors. Many AML disease alleles were identified by molecular cloning of recurring chromosomal translocations that often pinpoint the genomic location of leukemogenic fusion genes. As detailed in the following sections, examples include fusions involving core binding factor, retinoic acid receptor-alpha, HOX family members, the MLL gene, and transcriptional coactivators such as CBP, MOZ, and TIF2. More recently, it has been appreciated that point mutations also contribute to a significant proportion of cases, including activating mutations in receptor tyrosine kinases such as FLT3 and KIT, and in RAS family members. In addition, loss of function point mutations have been identified in hematopoietic transcription factors such as AML1 (RUNX1), C/EBPalpha, and GATA-1. Most recently, mutations that result in aberrant localization of the nucleophosphim (NPM) have been identified and causally implicated in the pathogenesis of AML—in fact these appear to be the most frequent genetic alterations in AML and are associated with a favorable prognosis.

Chromosomal Translocations

Chromosome translocations result in aberrant expression of an otherwise normal gene because of juxtaposition to active promoter/enhance elements, or can result in expression of fusion genes (Fig. 59–2).[31] In AML, the majority of chromosome translocations result in the generation of chimeric fusion genes (Table 59–1). As detailed in the next section, characterization of the genes involved in these translocations has provided important insights into pathobiology of AML, and has also identified a spectrum of genes that are important in normal hematopoietic development. There are more than one hundred recurring chromosomal translocations observed in hematological malignancies, but many fewer clinical phenotypes. This observation suggests that despite genomic diversity of translocations, some of the resultant fusion genes must target similar signal transduction and/or transcriptional pathways in leukemia.

Core Binding Factor

More than a dozen different chromosomal translocations in AML target Core Binding Factor (CBF). The members of the CBF group function as heterodimeric complexes to regulate diverse target genes

involved in differentiation in many tissues (Fig. 59–3).[32] CBF factors consist of an α-subunit that binds DNA, and a β-subunit (CBFβ) that does not bind DNA directly but enhances transcriptional activation of target genes as a heterodimer with the α-subunit. Three α-subunits have been identified, designated RUNX1, RUNX2, and RUNX3 according to their homology to *Drosophila melanogaster* runt gene.[33] RUNX1 is expressed in hematopoietic cells and is the target of translocations in AML, and will herein be referred to as AML1, based on its cloning as a fusion gene associated with AML and the t(8;21). CBF is an important regulator of normal hematopoietic development, and transactivates a spectrum of genes that are important for both myeloid and lymphoid development.[32] Perhaps the most convincing evidence for the importance of CBF in hematopoietic development is the observation that homozygous loss of function of AML1 or CBFβ in knockout mice results in a complete lack of definitive hematopoiesis.[34–36]

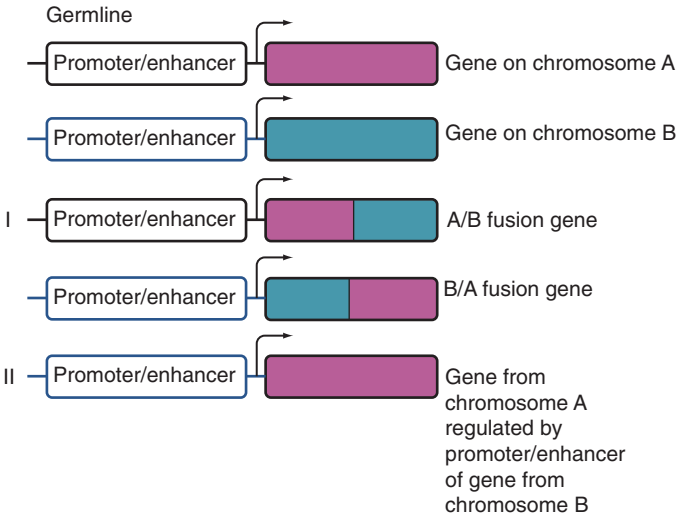

Figure 59–2 Molecular consequences of chromosome translocations. In (I), the chromosomal breakpoints occur within the transcription units, leading to the formation of chimeric genes and thus to the expression of fusion proteins. In (II), an intact transcription unit is juxtaposed to regulatory elements from a gene on another chromosome, resulting in aberrant expression of an otherwise normal gene.

AML1–ETO in the t(8;21)(q22;q22)

The t(8;21)(q22;q22) translocation is associated with the M2 subtype of AML. The clinical and morphologic correlations of this subtype of AML include a high incidence of development of extramedullary collections of leukemic blasts known as granulocytic sarcomas. The blasts have a characteristic morphology, including prominent Auer rods, salmon-colored granules, and large cytoplasmic granules and vacuoles. When the characteristic histologic appearance of these cells is identified in AML blasts that do not contain a t(8;21), the AML1–ETO fusion can often be identified by PCR, indicating that formation of the molecular fusion is responsible for the specific morphologic and clinical features of this subtype of AML.[37]

AML1–ETO is a transcriptional repressor that aberrantly recruits the nuclear corepressor complex, including histone deacetylase (HD) to CBF sites (see Fig. 59–3). AML1–ETO and other CBF fusions each appear to function as dominant negative inhibitors of the native CBF. Convincing evidence for dominant negative activity of AML1–ETO includes the observation that the expression of AML1–ETO from the endogenous Aml1 promoter in knockin mice results in an embryonic lethal phenotype that is identical to the $Aml1^{-/-}$ phenotype, despite the fact that there is a residual normal allele of Aml1 present in these animals.[38,39]

Because the AML1–ETO knockin has an embryonic lethal phenotype, it was not possible to characterize the effects of expression in adult hematopoietic cells. To circumvent embryonic lethality, a conditional allele was generated that allowed for normal development, followed by expression in the hematopoietic compartment. Expression of AML1–ETO appears to confer a subtle proliferative or survival advantage, in that these cells increase with time in the bone marrow. In addition, AML1–ETO appears to confer certain properties of self-renewal, such as the ability to serially replate in methylcellulose cultures. However, these animals do not develop AML unless chemical mutagens such as ethyl-nitrosourea are used, indicating that AML1–ETO expression alone is not sufficient to cause AML.[40]

CBFβ–MYH11 in the inv(16)(p13q22) and the t(16;16)(p13;q22)

The inv(16)(p13q22) and the t(16;16)(p13;q22) are observed primarily in the M4Eo subtype of AML. These patients, similar to those

Table 59–1 Correlation Between Morphologic Subtypes of Acute Myeloid Leukemia (AML) and Recurring Chromosomal Translocation

FAB Subtype	Cytogenetic Aberration	Molecular Aberration
M0, M1, and ALL	t(10:11)	*CALM-AF10*
M1	Trisomy 11	Partial duplication of *MLL*
M2	t(8;21)	*AML1-ETO*

MDS, T-AML, CML	t(3;21)	*AML 1-EAP/MDS1/EVI1*

ALL, acute lymphocytic leukemia; CML, chronic myelomonocytic leukemia; FAB, French-American-British (Cooperative Group); T-AML, T-cell acute myeloid leukemia.

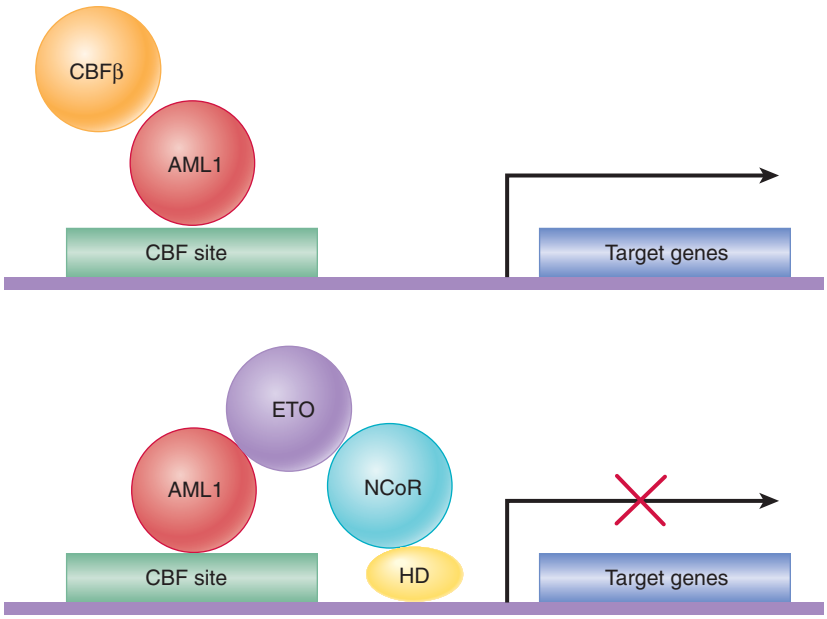

Figure 59–3 Core binding factor (CBF) and leukemia. Core binding factor is a heterodimeric transcription factor containing an AML1 and a CBFβ subunit. AML1 directly contacts DNA, and its transactivation potential is enhanced by binding to CBFβ, which does not contact DNA. Core binding factor fusions, including AML1–ETO (as depicted), CBFβ–MYH11, and TEL–AML1 act as dominant negative inhibitors of CBF through aberrant recruitment of the nuclear corepressor complex, including histone deacetylase. Histone deacetylase inhibitors are currently being explored as therapeutic agents for acute myeloid leukemia (AML) in clinical trials.

with the t(8;21), have a relatively good prognosis and a high likelihood of responding to regimens that include high-dose cytosine arabinoside.[41] The β-subunit of CBF, located at 16q22, is disrupted as a result of either this chromosomal inversion or a translocation leading to the formation of a fusion transcript with the gene for smooth muscle myosin heavy chain, MYH11, located at 16p13.[42] The CBFβ–MYH11 chimeric protein contains nearly all of CBFβ, including the heterodimerization domain for AML1, fused to the C-terminal sequences of MYH11, including its coiled-coil dimerization motif. The chimeric CBFβ–MYH11 protein thus retains its ability to bind to AML1 and is also capable of forming high-molecular-weight multimers through the coiled-coil domain of MYH11. Like AML1–ETO, the CBFβ–MYH11 fusion is a dominant negative inhibitor of transactivation mediated by CBF.[32]

Further support for the hypothesis that the CBFβ–MYH11 fusion is a dominant negative inhibitor of CBF includes the observation that mice that express the CBFβ–MYH11 allele from the endogenous promoter have a similar phenotype to that observed with the AML1–ETO fusion.[35] These mice exhibit phenotype nearly identical to either the $Aml1^{-/-}$ or $Cbf\beta^{-/-}$ mice, with midgestation embryonic lethality, absence of fetal liver hematopoiesis, and central nervous system hemorrhage. The chimeric mice generated from embryonic stem cells containing CBFβ–MYH11 do not develop leukemia unless chemical mutagens are employed.[43] Thus, like AML1–ETO, expression of CBFβ–MYH11 is not sufficient to cause AML.

Translocations Involving the Retinoic Acid Receptor-α Locus

One of the remarkable successes in molecularly targeted therapy of AML over the past decade has been the use of all-trans-retinoic acid (ATRA) to induce complete responses in patients with acute promyelocytic leukemia (APL). This empiric observation fueled efforts to clone the t(15;17)(q22;q22) breakpoint, with a focus on the retinoic acid receptor alpha locus on 17q22. The consequence of the translocation is fusion of the retinoic acid receptor α (RARα) gene on chromosome 17 to a novel partner on chromosome 15, PML (promyelocytic leukemia).[42–44] Two reciprocal fusion RNA species are produced as a consequence of the translocation, RARα–PML and PML–RARα. The PML–RARα fusion protein contains the zinc finger of PML fused to the DNA- and protein-binding domains of RARα. Several other chromosomal translocations associated with an APL phenotype have been cloned and characterized. Each of these targets the RARα locus, with fusion to various partners that include PLZF and NPM. The best studied of these is the PLZF–RARα fusion that also aberrantly recruits the nuclear corepressor complex. However, in contrast with the PML–RARα fusion, ATRA is not able to relieve corepression mediated by the PLZF–RARα fusion, and thus is not effective in patients that harbor the t(11;17) associated with this fusion gene.[44]

The PML–RARα and PLZF–RARα fusion proteins are dominant negative inhibitors of retinoid induced transactivation (Fig. 59–4).[45] In addition to interfering with normal RARα interacting proteins, such as RXRα, the PML–RARα fusion also interferes with the function of the native PML protein, which is thought to function as a tumor suppressor gene on the basis of analysis of mice that are deficient in Pml.[46] The PML protein is a component of a novel nuclear structure referred to by several names, including PML oncogenic domains, nuclear bodies, or nuclear domain 10.[47,48] This nuclear structure was initially discovered by immunohistochemical analysis of the targets of autoantibodies obtained from patients with primary biliary cirrhosis. The Sp100 protein was the first component of this structure to be identified. Type I and II interferons induce the expression of both PML and Sp100. Infection of cells with adenovirus or herpesvirus leads to the delocalization of Sp100 and PML. In APL cells, the integrity of the nuclear body is disrupted and a microspeckled distribution of PML–RARα is observed. Treatment of APL cells with ATRA causes the nuclear bodies to regenerate, with proper relocalization of PML. Recently, arsenic trioxide has also been found to target PML and PML–RARα to nuclear bodies and to induce degradation of these proteins.[49] Thus, the restoration of nuclear body structures by either ATRA or arsenic trioxide correlates with the ability of these agents to induce remission of APL.

The dominant interfering activities of the PML–RARα fusion protein results in a phenotypic block in differentiation at the promyelocyte stage of development. The clinical response of these patients to ATRA, as discussed in more detail below, is explained by the ability of this retinoid to bind to the PML–RARα fusion protein and reverse repression of target genes required for normal hematopoietic development. The ability of the PML–RARα fusion protein to repress transcription is due in part to the aberrant recruitment of the nuclear corepressor complex, including histone deacetylase,[50–52] suggesting that pharmacologic agents that inhibit histone deacetylases may be useful in the therapy of APL.[53–55]

Murine models of APL, like those for CBF mutations associated with leukemia, indicate that multiple mutations are required for the APL phenotype. Expression of PML–RARα in transgenic mice from promoters that direct expression to the promyelocyte compartment,

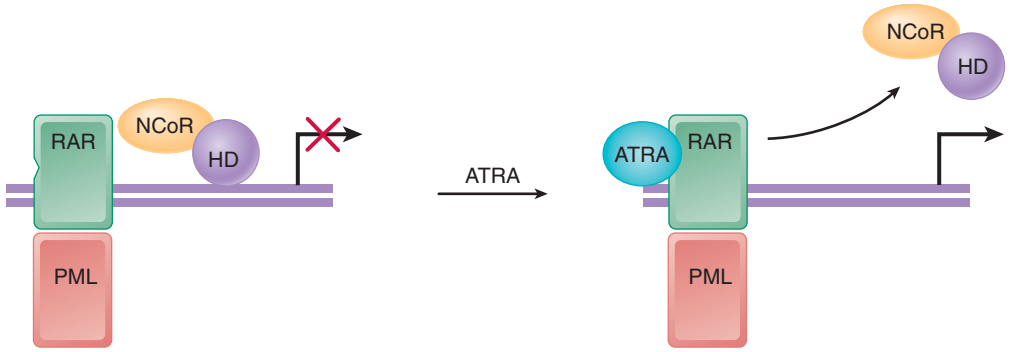

Figure 59–4 The PML–RARα fusion in acute promyelocytic leukemia. PML–RARα is a dominant negative inhibitor of transactivation mediated by retinoic acid receptor family members such as RXRα. As for the core binding factor fusions, dominant negative inhibition can be attributed to aberrant recruitment of the nuclear corepressor complex. All-trans-retinoic acid (ATRA) induces complete remission in the majority of cases of acute promyelocytic leukemia (APL) by inducing release of corepression, allowing for terminal differentiation and apoptosis of leukemic cells.

such as cathepsin G or MRP8, result in an APL-like phenotype.[56–58] However, there is approximately a 6-month lag prior to the development of leukemia, incomplete penetrance of approximately 15% to 30%, and acquired karyotypic abnormalities, all suggesting that second mutations are required for induction of leukemia. Coexpression of both the PML–RARα and RARα–PML under the cathepsin G promoter results in increased penetrance, but prolonged latency and acquisition of cytogenetic abnormalities, still supporting the need to additional mutation.[59] In at least some cases, activating mutations in FLT3, as discussed below, may be the additional mutation required. ATRA is efficacious in these animals, and the model has allowed for preclinical testing of novel agents currently in clinical trials, such as arsenic trioxide.[60]

MLL Gene Rearrangements in Leukemia

Translocations involving chromosome band 11q23 occur frequently in both AML and ALL and have several unique features in comparison with other subtypes of leukemia. There are at least 30 different partner chromosomes involved in recurring reciprocal 11q23 translocations.[5] This exceeds the number of known translocations affecting the immunoglobulin loci, suggesting that the 11q23 breakpoint region may contain genomically unstable sequences that lead to chromosomal recombination events. Translocations involving 11q23 are the single most common cytogenetic abnormality in infants with acute leukemia, regardless of phenotype, occurring in approximately 70% to 80% of these cases. 11q23 translocations are also observed frequently in therapy-related leukemias in patients who have previously been treated with chemotherapy drugs that inhibit topoisomerase II, especially the epipodophyllotoxins.

The chromosomal partners in 11q23 translocations are usually lineage specific. In AML, the t(9;11)(p22;q23), the t(11;19)(q23;p13.1), and the t(6;11)(q27;q23) are the most common, and in ALL, the t(4;11)(q21;q23) and the t(11;19)(q23;p13.3) predominate. The MLL gene was isolated from the 11q23 breakpoint by several groups and is referred to by other names, including HRX, ALL-1, and Htrx.[61–64] 11q23 translocations have been observed in several FAB subtypes but occur most commonly in the M4 myelomonocytic and M5 monoblastic leukemias. Myeloid leukemias with 11q23 translocations often coexpress lymphoid markers, whereas 11q23 lymphoid leukemias often express myeloid or monocytoid markers in addition to B-cell markers. These observations suggest that rearrangement of MLL may affect a pluripotent stem cell or, alternatively, that disruption of MLL may affect a common differentiation pathway shared by lymphoid and myeloid progenitor cells.

MLL encodes a large protein, with a predicted molecular weight of 430 kd, that contains two regions of extensive homology to the Drosophila trithorax gene.[65] The regions that are conserved with trithorax include a series of Cys4–His–Cys3 zinc fingers in the middle portion of the protein that have been referred to as PHD or LAP domains.[66,67] The C terminus of MLL contains a conserved motif, named the SET domain, because it is present in several proteins, including Su(var)3–9, enhancer of zeste, and trithorax.[68] At the N terminus of MLL, there are three AT-hook motifs similar to those present in the HMG-I(Y) proteins that bind to AT-rich sequences in the minor groove of DNA. There is also a region of homology to mammalian DNA methyltransferases. Neither the AT hooks nor the DNA methyltransferase domain is present in trithorax. The MLL protein also contains transcriptional activation and repression domains. In Drosophila, trithorax is essential to maintain the proper expression of homeotic genes but not to initiate their expression. Targeted disruption of Mll in mice causes lethality at embryonic day 10.5.[69] Mll heterozygous mice also exhibited a phenotype with growth retardation, bidirectional homeotic transformations of the axial skeleton, and sternal malformations. In the Mll homozygous deficient mice, expression of Hoxa-7 and Hoxc-9 was abolished, whereas in Mll heterozygous mice, the anterior boundaries of expression of these genes were shifted posteriorly. These findings indicate that MLL is a positive regulator of Hox gene expression.

A broad spectrum of MLL partner genes have been cloned at 11q23 partner chromosomal breakpoints. These include AF4 in the t(4;11)(q21;q23), ENL in the t(11;19)(q23;p13.3), ELL in the t(11;19)(q23;p13.1), AF9 in the t(9;11)(p22;q23), AF6 in the t(6;11)(q27;q23), AF1p in the t(1;11)(p32;q23), AF1q in the t(1;11)(q21;q23), AF-X in the t(X;11)(q13;q23), AF10 in the t(10;11)(p12;q23), AF17 in the t(11;17)(q23;q21), EEN in the t(11;19)(q23;p13), and CBP in the t(11;16)(q23;p13.3). Two MLL partner genes are involved in other chromosome translocations as well. For example, AF10 is fused to the CALM gene in the t(10;11)(p13;q14), and CBP fuses to the MOZ gene in the t(8;16)(p11;p13). The functions of most MLL partner genes are not yet known. Although no consistent homologies or motifs among the partner gene sequences have been identified that might explain how their fusion to MLL results in leukemia, certain partner genes have similar features (Fig. 59–5). For example, ENL and AF9 contain transcriptional activation domains and share extensive homology at their C termini. AF10 and AF17 contain leucine zipper and zinc finger motifs and also share extensive homology with each other. In addition, AFX and AF6q21 contain forkhead domains and also share other regions of homology. Three MLL partner genes have well-characterized functions. ELL has been shown to function as an RNA polymerase II transcriptional elongation factor. It serves to increase the catalytic rate of RNA polymerase II by suppressing transient pausing by the polymerase along the DNA template. CBP and p300 are transcriptional coactivators that mediate interactions between multiple transcription factors and the basal transcriptional machinery. The pattern of protein–protein interactions of MLL partner genes may provide insight into the nature of the aberrant functions of MLL fusion proteins in leukemia.

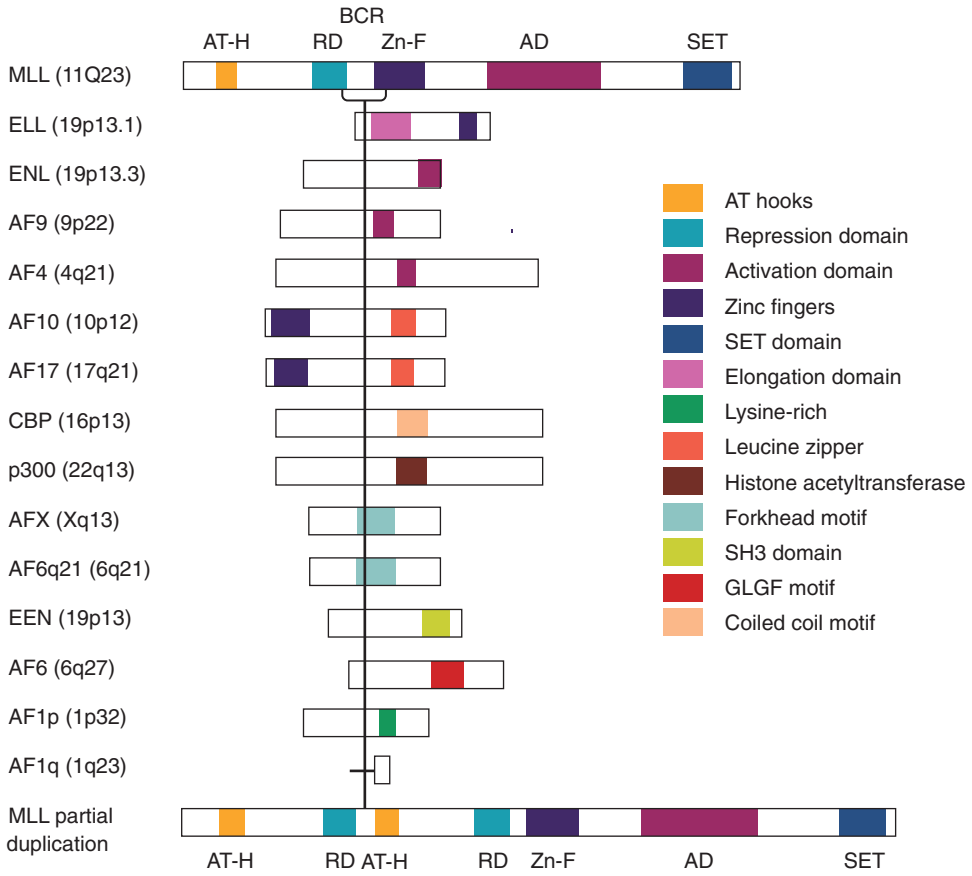

Figure 59–5 Motifs in MLL partner genes. The partner genes can be grouped into several classes that share common motifs. AT-H, AT hooks; RD, repression domain; Zn-F, zinc fingers; AD, activating domain.

In a subset of patients with AML and either trisomy 11 or a normal karyotype, a unique pattern of rearrangement of the MLL gene has been observed. As in the translocations that affect MLL, a fusion occurs involving one of the exons in its breakpoint cluster region. However, rather than fusing to a partner gene, the fusion is to 5′ sequences from MLL itself.[70,71] For example, the structure of the partial duplication might contain MLL exons 1 to 7 fused to exon 2 through the 3′ end of the gene. The largest duplication identified contains exons 2 to 9, and the smallest, exons 4 to 6. The region of the duplication contains the AT hooks, methyltransferase, and repression domains of MLL. In several cases, the 5′ and 3′ genomic breaks within MLL occur at similar points within Alu repetitive sequences, suggesting that partial duplications may be generated as a result of homologous recombination. In contrast to the reciprocal translocations involving MLL, the partial duplications of MLL appear to occur primarily in older patients and are infrequent in childhood and therapy-related leukemias. The morphology of the leukemias also differs in that the partial duplication patients usually are classified as FAB-M1 or -M2, rather than the M4 or M5 typically observed in cases with MLL translocations. These findings suggest that the critical transforming event may be related to rearrangement of MLL itself, as opposed to contributions from the respective fusion partners.

In support of this hypothesis, it has been reported that the MLL gene product is a propeptide that is cleaved by a novel protease, taspase 1. There appears to be aberrant regulation of HOX gene expression by noncleaved MLL, and it has been suggested that the MLL fusion genes and the MLL partial tandem duplications are surrogates for the noncleaved MLL protein.[72] This is an attractive hypothesis, in that it explains the remarkable lack of similarity between the multitude of MLL fusion partners in structure and function, and suggests that a cardinal transforming event that is related to dysregulated HOX gene expression, with MLL fusion proteins as noncleavable surrogates of the native MLL.[72,73] The fusion partners might then contribute to lineage specificity or other phenotypic aspects of transformation related to MLL gene rearrangements.

The t(4;11)(q21;q23) may also be observed in AML, particularly in infants and children.[74] This translocation was originally described in association with ALL, but later studies documented the myeloid or hybrid nature of blasts in some of the patients. New insights into pathogenesis of infant acute leukemia associated with the t(4;11) MLL–AF4 fusion have been gained from analysis of global patterns of gene expression.[74] These analyses indicate that infant leukemia with the MLL–AF4 fusion represents a distinct subclass of leukemia that can be readily delineated from AML or ALL by gene expression profiles. These data, and the target genes that are overexpressed in infant leukemia with the MLL–AF4 fusion such as FLT3, suggest novel approaches to therapy of this subtype of leukemia.

Two different strategies have been used to generate mouse models of 11q23 leukemias. To create an Mll–AF9 knockin mouse, the AF9 cDNA was targeted into the murine Mll genomic locus by homologous recombination in embryonic stem cells.[75] The chimeric mice generated from these embryonic stem cells all developed AML within 6 to 9 months. Chimeric mice that expressed only the N-terminal sequences of Mll did not develop leukemia. In addition, retroviral transduction of bone marrow has been used to express another 11q23 fusion gene, MLL–ENL, in hematopoietic cells.[76] In serial replating assays on methylcellulose, the MLL–ENL-transduced cells could be immortalized, whereas constructs containing either N-terminal MLL, ENL alone, or vector controls could not maintain proliferative capacity beyond three passages. After transplantation of MLL–ENL-transduced bone marrow, syngeneic recipient mice developed AML.

Homeotic Genes in Acute Myeloid Leukemia: HOX and CDX Family Members

Regulation of expression of the large family of HOX paralogs is important in patterning in vertebrate development, and also plays a critical role in normal hematopoietic development (reviewed in refer-

ence 77). HOX genes targeted by chromosomal translocations include the NUP98–HOXA9 and NUP98–HOXD13 fusions, associated with t(7;11) and t(2;11), respectively.[78,79] HOX gene expression is tightly regulated during hematopoietic development. HOXA9, for example, is expressed in early hematopoietic progenitor cells, but is downregulated during hematopoietic differentiation and is undetectable in terminally differentiated cells. It has been suggested that unregulated overexpression of the HOXA9 moiety from the constitutively active NUP98 promoter may result in aberrant differentiation. Experimental support for this hypothesis includes the observation that the NUP98–HOXA9 fusion protein can transform 3T3 fibroblasts, an activity that requires the HOXA9 DNA-binding domain.[80]

NUP98 is a component of the nuclear pore complex, and is constitutively and ubiquitously expressed. However, several lines of evidence suggest that NUP98 contributes more than a constitutively activated promoter to the transforming properties of the NUP98–HOXA9 fusion. For example, NUP98 motifs known as FG repeats are essential for transformation in fibroblasts, and may serve to recruit transcriptional coactivators such as CBP/p300 to HOXA9 DNA-binding sites.[80] In murine models of leukemia, overexpression of HOXA9 alone is not sufficient to cause AML, but coexpression of HOXA9 with transcriptional cofactors such as MEIS1 results in efficient induction of AML.[81] Thus, the NUP98 moiety in the context of the NUP98–HOXA9 fusion may serve multiple functions including provision of an active promoter, and recruitment of transcriptional coactivators such as CBP/p300 that subserve the function of other cofactors such as MEIS1. Epidemiologic evidence that the NUP98 contributes to leukemogenesis includes the observation that there are now a spectrum of fusion proteins that involve components of the nuclear pore that are targeted by chromosomal translocations in acute leukemias. These include NUP98 and NUP214 fused to a diverse group if partners include HOX family members, HOXA9 and HOXD13; and the DDX10, PMX1, and DEK genes, respectively.

It has been hypothesized that dysregulated HOX gene expression may be important in leukemias that do not directly target HOX family members. Several proteins that are upstream of HOX expression have been implicated in AML as fusion genes associated with AML. The most frequent of these are MLL gene rearrangements (see Fig. 59–5). As described above, more than 40 chromosomal translocations target MLL and result in fusions of MLL with a broad spectrum of partners. However, a common biological feature of all of these may be the ability to dysregulate HOX gene expression during hematopoietic development in that HOX genes have been shown to be direct targets of various MLL fusions.[82]

In addition, t(12;13) associated with AML results in the expression of high levels of CDX2 from the TEL locus.[83,84] CDX2 is a homeotic protein that regulates expression of HOX family members in the colonic epithelium. As in hematopoietic development, HOX gene expression is highest in colonic stem cells in the colonic crypts, and is downregulated with maturation to epithelial cells. It is thus plausible that high levels of expression of CDX2 dysregulate HOX expression in hematopoietic progenitors and result in leukemia. Evidence to support this includes the ability of CDX2 to induce leukemia in murine retroviral transduction models.[84] Although CDX2 is not normally expressed in hematopoietic cells, a family member, CDX4, has recently been cloned and appears to play a similar role in hematopoietic development as CDX2 does in the gut. Of note, CDX4 in hematopoietic cells appears to either be downstream or epistatic with MLL in the regulation of HOX gene expression.[85]

Taken together, these data indicate that the NUP98–HOXA9 fusion transforms hematopoietic progenitors in part through dysregulated overexpression of HOX family members, and by transactivation mediated through the NUP98 transactivation domain that recruits CBP. Recent evidence indicates, however, that like the other gene rearrangements involving hematopoietic transcription factors, expression of NUP98–HOXA9 alone is not sufficient to cause leukemia. In murine bone marrow transplant models, NUP98–HOXA9 induces AML only after markedly prolonged latencies indicative of a requirement for second mutation.[86]

Transcriptional Regulatory Proteins in Chromosomal Translocations

The recruitment of transcriptional coactivators and corepressors by transcription factors involved in leukemia suggests a critical role for these proteins in leukemogenesis. In keeping with the recurring theme that the diverse and numerous chromosomal translocations in leukemia may share targets and functional activity, there are chromosomal translocations that involve proteins that modulate and facilitate regulated gene expression.

Several fusion genes associated with leukemia involve transcriptional coactivators. These include the MLL–CBP, MLL–p300, MOZ–CBP,[87–89] and MOZ–TIF2[90,91] fusions that incorporate transcriptional coactivators CBP, p300, and TIF2. Although TIF2 itself is not known to have histone acetylase transferase activity, a hallmark of the coactivators CBP and p300, it has a well-characterized CBP interaction domain that may serve to recruit CBP into a complex with MOZ or TIF2. The transcriptional activation and transformation properties of these large fusion proteins are not well understood. One hypothesis is that the fusions have dominant negative activity for CBP and p300, or that the translocation leads to simple loss of function of CBP expressed from one allele. In support of this hypothesis, loss of a single allele of CBP or p300 in the human Rubenstein–Taybi syndrome increases predisposition to malignancies, including colon cancer. However, recent data also support the hypothesis that MOZ–TIF2 may represent a gain of function for CBP based on mutational analysis in cell culture and murine models of leukemia.[92] It has been demonstrated that MOZ nucleosome-binding activity and TIF2–CBP interactions are required for leukemogenesis, whereas MOZ histone acetyl transferase activity is not. These data suggest that the leukemogenicity of the fusion is based on recruitment of CBP to MOZ nucleosome-binding sites.[92]

The t(1;22) Translocation Associated With Infant Acute Megakaryoblastic Leukemia

Megakaryoblastic leukemias have proven challenging to study. Until recently little was understood about the molecular pathobiology of these diseases, in part due to the challenges of collecting clinical material for analysis in the context of severe bone marrow fibrosis. GATA-1 truncation mutations had been demonstrated in Down syndrome-associated AMKL, but these hypomorphic alleles are not observed in sporadic cases of AMKL.[93] However, new insights into non-Down syndrome AMKL have been obtained through the cloning of the t(1;22) that is associated with the majority of non-Down infant AMKL.[94,95] The consequence of t(1;22) in infant AMKL is expression of an aberrant OTT1–MAL fusion protein in the hematopoietic compartment. OTT1 (RBM15) contains three amino-terminal RNA recognition motifs, as well as motifs conserved in evolution through Drosophila, including a Spen paralog and an ortholog C terminal. Ott1 deletion in mice has identified multiple roles in hematopoietic development including effects on megakaryocyte growth.[96] The MAL (MKL1) gene is ubiquitously expressed and has functional motifs that include a coiled-coil dimerization motif and a proline-rich transcriptional activation domain. MLK1 is a Rho–GTPase-regulated cofactor for serum response factor.[97] Although these genes have certain functions that might be ascribed to leukemogenesis, the role of the fusion gene and its respective wildtype counterpart alleles in the development of leukemia is not known.

POINT MUTATIONS IN ACUTE MYELOID LEUKEMIA

Activating Mutations in RAS Family Members

Oncogenic RAS mutations are associated with AML and myelodysplastic syndrome (MDS), typically at codons 12, 13, or 61 or N- or K-RAS. The reported incidence varies widely between studies from 25% to 44% (reviewed in reference 98). One carefully conducted

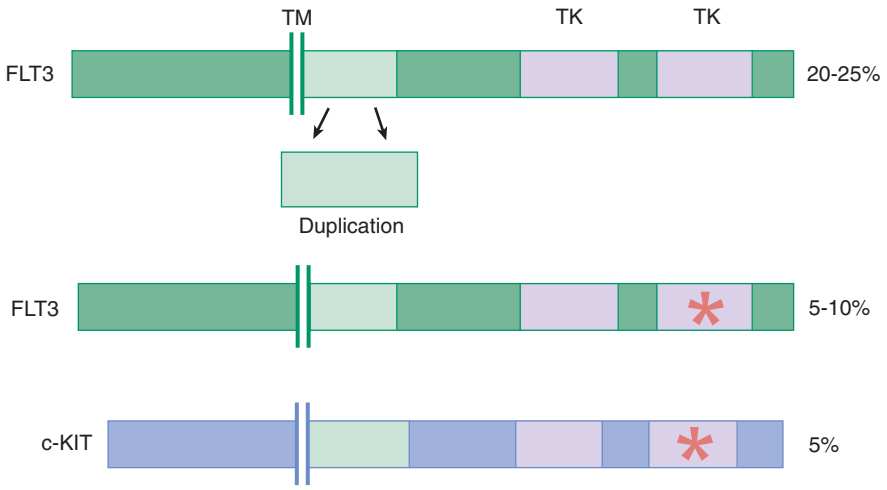

Figure 59–6 Activating mutations in FLT3 and KIT in AML. Approximately 20% to 25% of cases of AML have internal tandem duplication (ITD) mutations that occur in the juxtamembrane (JM) domain of FLT3, and may range in size from a few to more than 50 amino acids. The ITD disrupts an autoinhibitory structure in the JM domain and results in constitutive kinase activation in the absence of ligand. These mutations confer a proliferative and survival advantage to leukemic cells. Activation loop mutations occur in FLT3 and in KIT at a frequency of approximately 5% each, and also result in constitutive activation of these receptor tyrosine kinases.

cooperative group trial in which mutant RAS alleles were assessed by direct sequencing reported an 18% incidence of N- or K-RAS mutations, and that RAS mutations conferred a poor prognosis.[99] Considerable effort has been devoted to develop small molecule inhibitors of RAS activation, with a focus on prenylation inhibitors including farnesyl transferase and geranyl-geranylation inhibitors that preclude appropriate targeting of activated RAS to the plasma membrane.[100,101] Prenyltransferases have activity in AML, though responses do not correlate with the presence of activating mutations in RAS, [100,101] or even with inhibition of the target farnesyl transferase itself. There are several possible interpretations of these observations, including the possibility that RAS is activated by mechanisms other than intrinsic point mutations (such as constitutively activated tyrosine kinases like FLT3), or that other proteins that are targets of prenylation are important in leukemia pathogenesis, or that farnesyl transferase inhibitors target an as yet unidentified target.

Mutations That Constitutively Activate Receptor Tyrosine Kinases

Acquired activation loop and juxtamembrane mutations that result in constitutive activation of FLT3 and c-KIT have been identified in a significant proportion of AML cases. These findings may have important therapeutic implications with the recent demonstration of the efficacy of molecular targeting of the ABL kinase in BCR- and ABL-positive CML and CML blast crisis with imatinib (Gleevec).[102,103] FLT3 is the most commonly mutated gene in human AML, occurring in approximately 30% to 35% of cases of AML.[104,105] In 20% to 25% of cases, there are internal tandem duplications (ITDs) of the juxtamembrane domain that result in constitutive activation of FLT3 (Fig. 59–6). The ITDs may range in size from a few to more than 50 amino acids and are always in frame. Because of the extensive variability in size and exact position of the repeats within the juxtamembrane domain, it has been hypothesized that these are loss-of-function domains that impair an autoinhibitory domain, resulting in constitutive kinase activation in the absence of ligand. In support of this hypothesis, the crystallographic structure of FLT3 demonstrates a 7-amino acid extension of the juxtamembrane domain that intercalates into the catalytic domain, thereby precluding kinase activation.[106] It is likely that ITD mutations in this region would disrupt structure of the autoinhibitory domain resulting in kinase activation. In an additional 5% to 10% of cases there are so-called activating loop mutations that occur near position D835 in the tyrosine kinase.[107,108] Several large studies have confirmed the frequency of these mutations in both adult and pediatric AML populations, and that mutations in FLT3 appear to confer a poor prognosis.[109–111]

FLT3 mutations may occur in conjunction with known gene rearrangements such as AML1–ETO, PML–RARα, CBFβ–MYH11, or MLL. Analogous activating loop mutations at position D816 have also been reported in C-KIT in approximately 5% of cases of acute myeloid leukemia. These data suggest that constitutive activation of tyrosine kinases may play an important role in the pathogenesis of acute leukemia as well as in chronic myeloid leukemia. FLT3, KIT, and RAS mutations, as discussed below, form a complementation group in that these rarely overlap in the same patient, and each results in constitutive activation of signal transduction pathways in leukemic cells. However, they collectively account for only approximately 50% of cases, suggesting that other mutations that activate signal transduction pathways may be present in the remainder of cases of AML.

Loss-of-Function Point Mutations in AML1, C/EBPα, and GATA-1

As described above, AML1 is a frequent target of translocations in human leukemias. In addition to frequent involvement of AML1 as a consequence of chromosomal translocations, it has recently been determined that loss-of-function mutations in AML1 are responsible for the inherited leukemia syndrome FPD/AML (familial platelet disorder with propensity to develop acute myelogenous leukemia.[24,25] In addition, approximately 3% to 5% of sporadic cases of AML harbor loss-of-function mutations in AML1,[25,112] with a higher frequency in M0 AML (25%) and in AML or MDS with trisomy 21.

C/EBPα is a hematopoietic transcription factor that is required for normal myeloid lineage development. Because many translocations associated with acute myeloid leukemia phenotypes result in loss of function of hematopoietic transcription factors, it has been hypothesized that C/EBPα may also be a target for loss-of-function mutations in human leukemia. In fact, it has recently been reported that point mutations that result in expression of a mutant C/EBPα protein has dominant negative activity for wildtype C/EBPα in a fraction of M2 AML cases.[113] Thus, these mutations would be predicted to impair hematopoietic differentiation. Recent data indicate that C/EBPα mutations confer a favorable prognosis.[114]

GATA-1 mutations are associated with a subset of acute megakaryoblastic leukemias (FAB M7), in particular leukemias arising in patients with Down syndrome (constitutional trisomy 21). These mutations appear to result in loss of function or dysregulation of GATA-1 and are thought to contribute to leukemogenesis.[14] The mechanism through which hypomorphic alleles of GATA-1 contribute to leukemogenesis in the context of +21 is not known. GATA-1 mutations thus far have only been associated with Down syndrome,

and have not been observed in other infant acute megakaryoblastic leukemias, including those with the t(1;22) described above.

Nucleophosmin 1 Point Mutations in Acute Myeloid Leukemia

A series of fascinating mutations in the nucleophosmin 1 (NPM1) have recently been discovered that appear to be the most prevalent mutations in AML, exceeding even that of the FLT3 mutations. These mutations are of particular interest because they occur in a gene that might not be suspected as an oncogenic allele. Available evidence indicates that a spectrum of mutations in NPM1 in AML patients results in its mislocalization from the nucleus to the cytoplasm. NPM1 is thought to be involved in the regulation of diverse cellular processes, including regulation of the p53–ARF pathways through sequestration of ARF, ribosome biogenesis as an RNA-binding protein, and duplication of centrosomes during mitosis. NPM1 had been previously identified in acute leukemias as a translocation fusion partner with RAR and MLF as well as with ALK in anaplastic large-cell lymphoma. However, recent data indicate that NPM1 mutations occur in 25% to 30% of adult AML. These cases of AML have acquired somatic mutations in exon 12 that engender a novel nuclear export motif, resulting in constitutive cytoplasmic localization that is readily apparent by cellular fluorescence in situ hybridization.[115] The mechanism by which mutated NPM1 causes leukemia is not fully understood, although cytoplasmic localization of NPM1 is thought to be intrinsic to its transforming potential.[116] NPM1 mutations are found more frequently in normal karyotype AML, accounting for approximately 50% to 60% of cases. Furthermore, these NPM1 mutant cases are more likely to have concurrent FLT3–ITD mutations as well, in consonance with multihit pathogenesis of AML (discussed below). Among AML patients with normal cytogenetics, the presence of cytoplasmic NPM1 in the absence of the FLT3–ITD is associated with a more favorable prognosis.[116]

LOSS OF GENETIC MATERIAL IN ACUTE MYELOID LEUKEMIA: THE MODEST ROLE OF TUMOR SUPPRESSOR GENES

In contrast with solid tumors, mutations resulting in the loss of function of tumor suppressor genes are relatively uncommon in leukemia. However, several of the known tumor suppressor genes have been well characterized in myeloid leukemias, such as the association of p53 mutations with progression to blast crisis in CML.[117–119] In AML, p53 mutations occur less frequently. Only approximately 7% of cases have known p53 mutations at the time of diagnosis. The incidence of p53 abnormalities may be slightly higher in patients with AML evolving from a prior myelodysplastic syndrome and in cases with 11q23 translocations.[119,120] The p16INK4 gene is another critical cell-cycle regulatory gene that has been shown to be inactivated by a variety of mechanisms in a number of tumors, including frequent deletion in ALL but only very rarely in AML.[121] As noted above, patients with neurofibromatosis and mutations of the NF1 tumor suppressor gene have a high rate of developing neoplasms, including progression of myelodysplastic syndrome to AML, although these might be most appropriately viewed as mutations that result in activation of signal transduction pathways, and are thus more analogous to oncogenic RAS or tyrosine kinase mutations.[17,122] The Wilms tumor suppressor gene, WT1, has been found to be overexpressed in the leukemic blasts of approximately 75% of cases of newly diagnosed AML.[123,124] The WT1 gene, located in the 11p13 region, encodes a transcription factor normally expressed in a time- and tissue-dependent manner, mainly in the kidneys and gonads,[125,126] although it is also expressed in normal $CD34^+/CD38^-$ hematopoietic progenitor cells.[127] In AML, high WT1 levels at diagnosis correlate with lower remission rates and higher overall survival rates.[123,124]

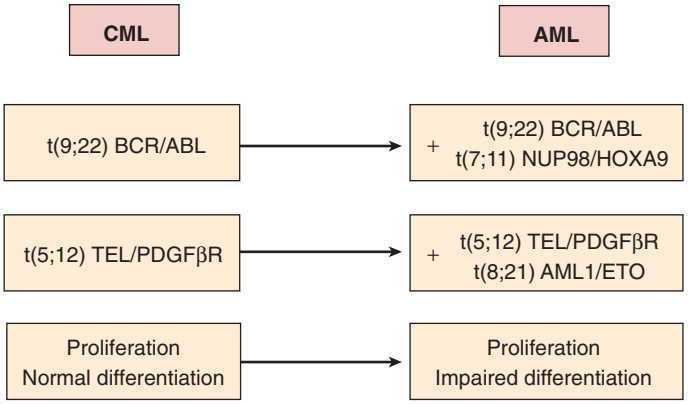

Figure 59–7 Disease progression in CML: Multistep pathogenesis of AML. There are clues to multistep pathogenesis of AML that can be derived from analysis of informative cases of disease progression in CML. Some cases of BCR–ABL positive CML, for example, progress to AML (CML blast crisis) with acquisition of a t(7;11) that results in expression of the NUP98–HOXA9 fusion. Similarly, progression of chronic myelomonocytic leukemia associated with the TEL–PDGFβR fusion may be associated with acquisition of the t(8;21) translocation associated with expression of the AML1–ETO fusion. These data suggest a model of AML in which there are cooperating mutations that confer a proliferative and survival advantage without affecting differentiation, such as BCR–ABL or TEL–PDGFβR; and those that contribute to impaired hematopoietic differentiation such as the AML1–ETO or NUP98–HOXA9 fusions.

A Role for Haploinsufficiency in Pathogenesis of Myelodysplastic Syndrome and Acute Myeloid Leukemia

Certain genetic alterations that result in loss of genetic material are specific to AML. These include loss of the long arms of chromosomes 5, 7, and 20, which occurs commonly in therapy-related AML and AML associated with prior myelodysplastic syndrome, and is associated with a poor prognosis.[3,4,128] These deletion events are discussed in detail elsewhere in this textbook. Despite decades of intensive effort, and the availability of the complete human genome sequence, classical tumor suppressor genes have not been identified in these intervals. Although it is possible that genes will be identified whose homozygous loss of function contributes to the leukemic phenotype, it seems increasingly likely that haploid dosage of one or more genes may be the critical genetic lesion. In support of this hypothesis, several genes, such as p27Kip1, have tumor suppressor activity at haploid gene dosage,[129] and haploinsufficiency of the hematopoietic transcription factor AML1 has been implicated in a familial leukemia syndrome.[24]

COOPERATING MUTATIONS: MULTISTEP PATHOGENESIS OF ACUTE MYELOID LEUKEMIA

More than one mutation is necessary for the development of acute myeloid leukemia. For example, there is evidence for acquisition of additional cytogenetic abnormalities with disease progression from CML to AML (ie, CML blast crisis). Disease progression in BCR- or ABL-positive CML include acquisition of t(3;21) AML1–EVI1, t(8;21) AML1–ETO, or t(7;11) NUP98–HOXA9 gene rearrangements (Fig. 59–7). Progression of chronic myelomonocytic leukemia to AML in a patient with the TEL–PDGFβR gene rearrangement was associated with acquisition of a t(8;21) AML1–ETO gene rearrangement.[130] Furthermore, expression of the AML1–ETO or CBFβ–MYH11 fusion proteins in murine models is not sufficient

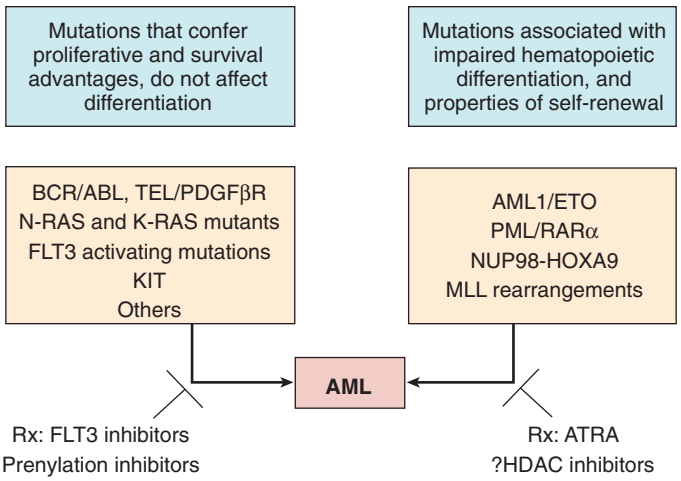

Figure 59–8 A model for cooperating mutations in AML. There are two broad complementation groups in AML. One group, characterized by activating mutations in signal transduction pathways, included oncogenic RAS, FLT3, or KIT mutations. These can be considered as complementation groups because they do not occur together in the same patient with leukemia, and thereby may subserve redundant functions that confer proliferative and survival advantage to hematopoietic progenitors. A second complementation group, exemplified by core binding factor fusions, or RARα fusions, are associated with impaired hematopoietic differentiation and may confer certain properties of self-renewal. These are also mutually exclusive in leukemias, indicating that they may also subserve an overlapping function in AML. When expressed together, components of these two complementation groups result in a phenotype of AML characterized by enhanced proliferative and survival advantage of leukemic blasts, impaired differentiation, and limitless self-renewal capacity.

to cause AML.[40,43] Chemical mutagens must be utilized in these contexts to generate second mutations that cause the AML phenotype. Lastly, transgenic mice that express the PML–RARα fusion protein develop AML only after a long latency of 3 to 6 months, with incomplete penetrance, indicating a need for a second mutation.[56–58]

The genetic epidemiology of AML provides important clues to the nature of the collaborating mutations (Fig. 59–8). There is one broad complementation group in AML that is composed of mutations that activate signal transduction pathways. These include activating mutations in FLT3, RAS, and KIT, and more rarely the BCR–ABL and TEL–PDGFβR fusion associated with disease progression in CML. These can be viewed as a complementation group because although they are collectively present in approximately 50% of cases of AML, they rarely if ever occur together in the same patient.

A second complementation group, typified by translocations involving hematopoietic transcription factors, includes AML1–ETO, CBFβ–SMMHC, PML–RARα, NUP98–HOXA9, MLL gene rearrangements and MOZ–TIF2. These mutations form a complementation group in that they are never observed together in the same leukemia. In general, this second class of mutations impairs hematopoietic differentiation and may confer properties of self-renewal to the leukemic stem cell, but is not sufficient to cause leukemia when expressed alone (see above). However, one mutation from each of these complementation groups is often coexistent in the same leukemia. For example, activating mutations in FLT3 and RAS have been observed in association with virtually all of the fusion genes in the second class described above.[131]

There is also support for the hypothesis of collaborating classes of leukemia oncogenes derived from analysis of genotypes of CML patients who progress to AML (also called CML blast crisis). Some cases of BCR- and ABL-positive CML progress to AML associated with acquisition of the t(7;11) translocation associated with expression of the NUP98–HOXA9 fusion gene discussed above. As another example, TEL–PDGFβR-positive chronic myelomonocytic leukemia may progress to AML associated with acquisition of the t(8;21) translocation associated with expression of the AML1–ETO fusion. These cases of disease progressions from CML to AML suggest the hypothesis that constitutively activated tyrosine kinases cooperate with mutations in hematopoietic transcription factors to cause the AML phenotype.

These findings suggest a hypothesis for pathogenesis of AML in which there are at least two broad classes of cooperating mutations.[131] One class, exemplified by activating mutations in FLT3 or RAS, confer proliferative and/or survival advantage to hematopoietic progenitors but do not affect differentiation. These mutations do not confer self-renewal capacity as assessed in part by the ability to serially replate in culture, or to serially transplant disease in murine models.[132,133] A second class of mutations, exemplified by AML1–ETO, CBFβ–SMMHC, PML–RARα, NUP98–HOXA9, MLL gene rearrangements, and MOZ–TIF2 serve primarily to impair hematopoietic differentiation and confer properties of self-renewal. Together these cooperating mutations induce the AML phenotype characterized by enhanced proliferative and survival advantage, impaired differentiation, and limitless self-renewal capacity. There is experimental evidence to support this model of cooperativity in murine models between BCR–ABL and NUP98–HOXA9,[86] TEL–PDGFβR and AML1–ETO,[134] and FLT3–ITD and PML–RARα.[135] These findings have important therapeutic implications, in that it may be possible to target both classes of mutations. For example, in acute promyelocytic leukemia with activating mutations in FLT3, it may be possible to target FLT3 with small-molecule inhibitors, and PML–RARα with ATRA (see Chapter 60, Fig. 60–2).[136] However, it is important to note that AML, as for other cancers, is likely the cause of multiple mutations. Although this "two-hit" paradigm provides a rationale for targeted therapeutic approaches to treatment of AML, it is likely that additional alleles are required for development of AML—and that these must be identified and studied in detail with attention to novel potential therapies.

CHAPTER 60

CLINICAL MANIFESTATIONS OF ACUTE MYELOID LEUKEMIA

Kenneth B. Miller and German Pihan

Acute myeloid leukemia (AML) is not a single disease but a heterogeneous group of neoplastic disorders characterized by the proliferation and accumulation of immature hematopoietic cells in the bone marrow and blood. These malignant cells gradually replace and inhibit the growth and maturation of normal erythroid, myeloid, and megakaryocytic precursors.

The clinical evaluation and prognosis of patients with AML has changed dramatically over the last decade. The initial evaluation of a patient with acute leukemia should be directed at defining the factors that are important in assessing the long-term prognosis and planning treatment. Molecular, cytogenetic, and immunologic studies have contributed to our understanding of the pathogenesis and prognosis of the AMLs. The initial evaluation should address the patient's history of possible exposure to known or suspected environmental or occupational leukemogenic agents. A personal or family history of prior illnesses that predisposes the patient to development of AML is important in planning treatment. The new classification system for AML attempts to incorporate in the final diagnosis the patient's prior exposures to leukemogenic agents with the morphology and the molecular and cytogenetic markers.

HISTORY

In 1827 Velpeau reported the first accurate description of a case of leukemia. The patient was a 63-year-old florist who developed an illness characterized by fever, weakness, urinary stones, and massive hepatosplenomegaly. Velpeau reported that the blood of this patient was "like gruel." He speculated that the appearance of the blood was due to white corpuscles and that the unique appearance was not the result of an infection.

In 1845 Bennett, a brilliant and controversial pathologist from Edinburgh, reported a series of patients who died with enlarged spleens and changes in the "color and consistency of their blood."[1] Although he found no infectious etiology for the peculiar appearance of the blood, he attributed these changes to the presence of "purulent material" in the blood and introduced the term *leucocythemia*. Virchow, the noted German pathologist, reported a similar case. Virchow commented on the reversal of the normal ratio of pigmented red to colorless white cells in his patient but did not attribute these changes to an infection. Unsure of the etiology of his finding, he was content to simply describe his observations and used the descriptive name "white blood" and named the disorder *leukemia*, derived from the Greek meaning "white blood."[2]

In 1877 Ehrlich developed aniline-based stains for use on air-dried films of blood and described the appearance of normal and abnormal white blood cells (WBCs). In 1889 Ebstein introduced the term *acute leukemia* to describe a rapidly fatal illness that failed to respond to available therapy.[3] In 1869 Neumann first suggested that the WBCs were made in the bone marrow and not the spleen and proposed term the *myeloid*, meaning marrow-derived. In 1879 Mosler described the aspiration of bone marrow as a means to diagnose leukemia.[4] In 1900 Naegeli described the myeloblast and divided the leukemias into either myelocytic or lymphocytic.[5]

The development of cytogenetic, immunologic, molecular, and biochemical markers has helped to further define the lineage of the leukemic cell and to classify the leukemias. Effective therapy and advances in supportive care have changed the approach to the patient with AML from a disease that was uniformly and rapidly fatal to one that responds to chemotherapy and is potentially curable. The new classification of AML now attempts to incorporate clinically and biologically important disease characteristics to better define prognosis and plan treatment of this heterogeneous group of disorders.

ETIOLOGY

Approximately 8000 new cases of AML occur per year, and the incidence has remained stable over the last decade. AML represent approximately 1.2% of all cancer deaths in the United States.[6,7] AML is a disease of adults. The median age at diagnosis is 65 years, and the incidence increases with age (Fig. 60–1). AML represents approximately 90% of all acute leukemias in adults but accounts for only 13% of leukemia cases in children younger than 10 years. In children younger than 15 years, acute lymphoblastic leukemia (ALL) is approximately five times more common than AML.[8] The incidence of AML rises rapidly after age 50 years. The age-specific incidence is 3.5:100,000, 15:100,000, and 22:100,000 in individuals 50, 70, and 80 years, respectively. The incidence of secondary AML (therapy-related AML [t-AML]) appears to be increasing, currently accounting for 10% to 20% of all cases of AML in adults.[9] Drugs, genetic factors, and environmental and occupational exposures are implicated as possible leukemogenic agents in both children and adults (Table 60–1).[8–10] Leukemogenesis is a multistep process that requires the susceptibility of a hematopoietic progenitor cells to inductive agents at multiple stages. The different subtypes of AML may have distinct causal mechanisms, suggesting a functional link between a particular molecular abnormality or mutation and the causal agent.[11] No one factor has been shown to cause leukemia in all individuals exposed.

Evidence supporting a genetic predisposition for leukemia has come from epidemiologic and family studies.[12] The highest incidences of AML in adults are found in North America, western Europe, and Oceania; the lowest incidences are found in Asia and Latin America.[13,14] Acute promyelocytic leukemia (APL) is more common among populations of Latino or Hispanic background.[15,16] Moreover, APL in patients originating in Latin America and southern Europe is associated with an increased frequency of the breakpoint in the promyelocytic leukemia gene *(PML)* at intron 6 representing the breakpoint cluster region 1 (BCR1). This higher rate of BCR1 APL subtype in Latin Americans is, in part, genetically determined and may be related to the American Indian forebears who immigrated to the Americas from eastern Asia approximately 12,000 years ago.[15,17] Individuals with APL have a significant greater body mass index than do patients with other types of AML.[18] This observation may be explained by the involvement of the retinoic acid receptor α *(RARA)* gene in the regulation of both hematopoiesis and adipogenesis. APL presenting as a secondary or treatment-related leukemia also has unique clinical and epidemiologic features. The secondary APLs are more often associated with a prior exposure to an anthracycline, and the breakpoint in the *PML* gene is different from de novo APL.[19] The highest incidence of secondary APL was in women with breast or ovarian cancer. Patients with breast cancer may have an increased risk for APL that is further increased by administration of anthracycline chemotherapy.[20]

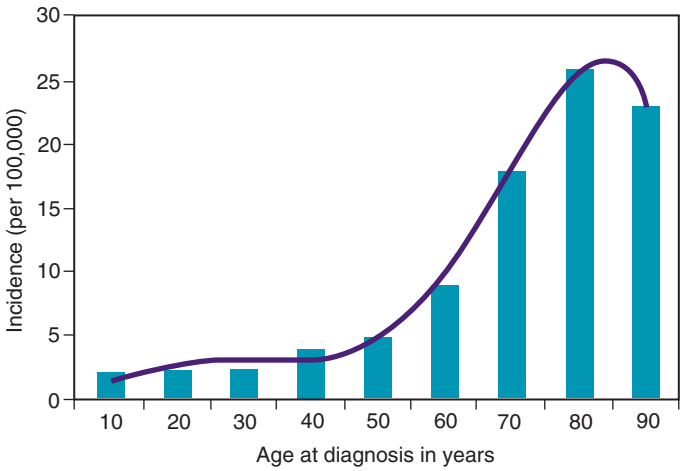

Figure 60–1 Age-specific incidence of acute myeloid leukemia in the United States.

Table 60–1. Risk Factors for Development of Acute Myeloid Leukemia

Genetic Disorders
Down syndrome
Bloom syndrome
Klinefelter syndrome
Patau syndrome
Ataxia-telangiectasia
Neurofibromatosis
Shwachman syndrome
Kostmann syndrome
Fanconi anemia
Li-Fraumeni syndrome
von Recklinghausen disease
Congenital neurofibromatosis
Familial platelet disorder syndrome
Acquired Disorders
Myeloproliferative disorders
Myelodysplastic syndromes
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria
Multiple myeloma
Nonseminomatous mediastinal germ cell tumors
Physical and Chemical Exposure
Benzene
Cigarettes
Embalming fluid (ethylene oxide)
Thorotrast
Radiation (therapeutic and nontherapeutic)
Chemotherapy

Genetic Factors

Multiple cases of both acute lymphoblastic leukemia (ALL) and AML occurring within the same family have been reported.[21,22] The concordance of each of the leukemia subtypes in families is more common than would be expected based on chance alone.[22] Reports of familial leukemia suggest that highly penetrant mutations in leukemia-susceptible genes could be a common mechanism of inherited AML.[23,24]

For all types of AML, a threefold increase in leukemia incidence is observed among first-degree relatives of patients with acute leukemia.[25] Monozygotic twins have an increased concordance for childhood leukemia. If one twin develops leukemia before age 6 years, the second twin has up to 25% risk of developing leukemia.[26] The clinical presentation of AML in monozygotic twins is atypical. The leukemia usually occurs before age 2 years; it occurs in both twins in close succession, typically in the same year; and it is of the same morphologic and cytogenetic subtype.[27] These results suggest a single cell origin of the AML occurring simultaneously in both twins or more likely a single leukemogenic event occurring in utero affecting both twins as a result of shared placental fetal circulation.[22,28,29] No similar excess of leukemia has been observed in nonidentical twins. Moreover, adult twin studies do not demonstrate such a high concordance for acute leukemia.[30]

The existence of a genetic predisposition to development of AML is suggested by the increased leukemia incidence associated with a number of congenital disorders. In Down syndrome (DS; trisomy 21), the incidence of acute leukemia before age 4 to 5 years is 150 times that of the general population, and the incidence of megakaryoblastic leukemia is 500 times higher than expected.[31–33] Moreover, families with a DS child may have be an increased incidence of acute leukemias in the genetically normal parents and siblings.[25,34,35] These reports of familial clustering of DS and leukemia have led to speculations that an inherited mutation in a group of mutator genes subsequently could induce karyotype instability that results in an increased risk for developing leukemia.[36] The AML in DS, classified as myeloid leukemia of Down syndrome (ML-DS), is associated with mutations in exon 2 of the transcription factor GATA1, which is acquired in utero.[37] The GATA1 mutation appears to be unique to DS and is detectable in virtually all cases of ML-DS.

The risk of childhood AML appears to increase with increasing maternal age.[38–40] The risk of childhood leukemia also is higher in children born to mothers who smoke and higher in children of women with a history of multiple miscarriages.[41] Moreover, in a case-control study, paternal preconception smoking was associated with an increased incidence of AML in the children.[42] Mothers of children with AML diagnosed before age 2 age had a fivefold increase in previous fetal loss and a 12-fold increase in two or more fetal losses.[24]

Disorders associated with chromosomal instability and increased chromosome breakage, including Fanconi anemia, ataxia telangiectasia, Bloom syndrome, and Kostmann syndrome, are associated with an increased incidence of AML.[43–45] The genetic disorders presumably give rise to a cellular environment that results in chromosomal instability, hypersensitivity to DNA damage, and increased susceptibility to mutations.[43] von Recklinghausen disease (congenital neurofibromatosis) is associated with an increased incidence of childhood AML.[44] Klinefelter syndrome (XXY) and Patau syndrome (trisomy 13) have been associated with an increased incidence of AML.[41]

Family studies suggest that the increased incidence of AML is part of a multistep process originating in leukemia-susceptible genes.[46,47] The initial molecular events leading to AML may not be localized to the cytogenetic deletions and translocations noted in the leukemic cell but rather predispose the cell to acquire the observed secondary mutations and cytogenetic translocations.[23] Hematopoietic transcription factors are frequent targets for leukemia-associated gene rearrangements.[48] The *AML1* (acute myeloid leukemia 1) gene, located on chromosome 21q22, is also called *RUNX1* (Runt-related protein 1) or *CBFA* (core-binding factor-α). RUNX1 is a highly conserved transcription factor that is critical for normal hematopoiesis. Mutations in the gene encoding AML1/RUNX1 have been in identified in families with an autosomal dominant syndrome called *familial platelet disorder*, members of which have a propensity to develop familial platelet disorder AML.[40] Mutations in the *AML1* gene may result in defective DNA binding, which leads to secondary karyotypic abnormalities that result in the development of AML. Although *AML1* mutations are present in the germline of these families, affected individuals do not develop AML until later in life. Mutations of *CEBPA*, the gene that encodes the granulocytic differentiation factor CCAAT/enhancer binding protein (C/EBP) α, has been shown to be the primary events in some forms of familial leukemia.[47] The factors responsible for the additional mutations necessary for the development of AML are not known.

Exposure History

Exposure to ionizing radiation and a number of chemicals has been linked to the development of acute leukemia. The evidence linking radiation exposure and leukemia comes in part from the long-term followup of survivors of the atomic bomb explosions in Hiroshima and Nagasaki.[49–52] The latency time from exposure to the development of leukemia was between 5 and 21 years, and the risk was related to age at the time of exposure and to radiation dose.[51] The development of leukemia was predictable and dose related. In Hiroshima, individuals had a 30-fold increased incidence of both AML and chronic myelogenous leukemia (CML). The highest rates were observed in persons younger than 10 years or older than 50 years at the time of exposure. In Nagasaki, where victims were exposed to a higher amount of gamma radiation, the incidence of AML was even greater.[53]

Exposure to even moderate doses of radiation is associated with an increased risk for developing AML. Workers at radium plants and military personnel exposed to ionizing radiation during nuclear test explosions have a higher than expected incidence of AML.[54,55] Patients who received low doses of radiation for treatment of benign disorders, such as ankylosing spondylitis,[56,57] menorrhagia,[58] tinea capitis,[59] benign thymic enlargement,[59] and rheumatoid arthritis,[60] develop AML at a greater than expected rate. Exposure to thorotrast, a colloidal suspension of thorium dioxide used widely in the 1940s as a radiographic contrast medium, has been associated with an increased risk of AML, specifically the acute erythroleukemia subtype.[61] The principal thorium isotope is ^{232}Th, which on decay exposes the individual to chronic low-dose α particles. The thorotrast-associated leukemia occurred 10 to 30 years after exposure. The genetic events resulting in the increased incidence of AML in individuals exposed to low doses of radiation are unclear but may be related to somatic point mutations of the *AML1* gene.[62]

Exposure to extremely-low-frequency electromagnetic fields generated by high-voltage power lines has been reported to be associated with an increased incidence of acute leukemia, but this association remains controversial and unproven.[63] It is unclear from the reported cohort and case-control studies whether exposure to electromagnetic radiation generated from wiring and power lines is physiologically, clinically, or epidemiologically important.[64,65]

Chronic exposure to a number of chemicals has been associated with the development of acute leukemia. Benzene is the best studied and has been the most widely used chemical leukemogenic agent.[66–69] Leather and rubber industry workers chronically exposed to benzene and benzene derivatives have a significantly increased incidence of AML.[70] Case-control studies have found that truck drivers, filling station attendants, workers in petroleum and gas plants, and painters have an increased incidence of AML, which perhaps is related to their chronic exposure to benzene and other hydrocarbons.[71–74] Persons exposed to embalming fluid, ethylene oxides, and herbicides may be at increased risk for acute leukemia.[75] Workers exposed to organic solvents used in the processing of medical radiographs and the manufacturing of electrical wiring may have an increased incidence of AML.[76] The interpretation of many of these case–control studies has been challenged, and the overall risk of leukemia for individuals exposed remains controversial. Cigarette smokers and individuals chronically exposed to cigarette smoke appear to be at increased risk for developing AML.[77,78] Heavy cigarette smoking is associated with the development of clonal, nonrandom, cytogenetic abnormalities.[79] Cigarette smoke contains measurable quantities of benzene, and metabolites of benzene are found in the urine of chronic cigarette smokers.[80,81]

Therapy-Related Acute Myeloid Leukemia

An increased incidence of acute leukemia has been reported in patients who received chemotherapy for a number of malignant and nonmalignant disorders (Table 60–2). Most commonly these secondary t-AMLs occur after administration of either alkylating agents or topoisomerase II inhibitors.[9,82] Estimating the risk of developing AML after chemotherapy is confounded by the frequent use of combination therapy; an increased risk of leukemia may be part of the natural history of various treated disorders. The combination of chemotherapy and radiation therapy further increases the risk of developing leukemia.[9,83]

Table 60–2 Drugs Associated with Increased Risks of Myelodysplastic Syndrome and Acute Myeloid Leukemia

Alkylating Agents	
Mechlorethamine	Cyclophosphamide
Ifosfamide	Busulfan
Melphalan	Chlorambucil
Carmustine	Lomustine
Cisplatin	Carboplatin
Topoisomerase II Inhibitors	
Etoposide	Teniposide
Doxorubicin	Daunorubicin
4-Epidoxorubicin	Mitoxantrone
Other Agents	
Procarbazine	Hydroxyurea[a]
Fludarabine[a]	Paclitaxel[a]
Docetaxel[a]	Irinotecan[a]
Methoxypsoralen[a]	Chloroquine[a]
Chloramphenicol[a]	Topotecan[a]

[a]Association is unclear and based on a limited number of case reports.

The t-AMLs are associated with clonal cytogenetic abnormalities, a defined clinical course, and a poor response to standard treatments. The risk of developing t-AML is proportional to the age of the patient, the cumulative dose of the administered alkylating agent, and the underlying disease. In Hodgkin lymphoma, the cumulative risk of developing AML after treatment with alkylating agents increases steadily 1 year after start of treatment and reaches a peak of 13% at 7 years.[84,85] The incidence of AML in patients treated with the mechlorethamine-Oncovin [vincristine]-procarbazine-prednisone (MOPP) regimen containing the alkylating agent mechlorethamine is 3%, 4%, and 7% at 3, 5, and 7 years, respectively. This is in contrast to a less than 1% incidence of AML in patients treated with a regimen that does not include alkylating agents or with radiation therapy alone. AML occurs after autologous bone marrow and stem cell transplants. The actuarial risk for secondary AML after chemoradiation therapy and autologous transplantation for Hodgkin lymphomas is between 6.8% and 18% at 10 years after transplant and is determined in part by the type and intensity of the pretransplant chemotherapy with alkylating agents.[86–88] Patients older than 40 years at the time of transplant who received prior radiation therapy or four or more chemotherapy regimens and required more than 5 days of apheresis to harvest sufficient cells and receive total body irradiation as part of the preparative regimen were at highest risk for developing AML.[89,90]

An increased incidence of leukemia has been reported in patients receiving alkylating agents for malignant and nonmalignant disorders.[91,92] Therapy-related leukemias now represent between 10% and 20% of all cases of AML. The t-AMLs are clinically and prognostically different from AML that occurs de novo. The t-AMLs are divided into two distinct types based on the type of agents administered.[19,83,93] The *alkylating agent–associated t-AMLs* usually are preceded by a variable period of myelodysplasia characterized by anemia, neutropenia, or thrombocytopenia. Clonal, nonrandom, cytogenetic abnormalities involving chromosomes 7, 5, and 8 in addition to other complex abnormalities occur in 50% to 90% of patients.[94] This pattern reflects the multistep process of alkylating agent–induced leukemia, which likely involves DNA damage-induced genomic instability and mitotic recombination with gain of oncogenes and

loss of tumor suppressor genes.[94] These t-AMLs are associated with an overall poor prognosis.

A clinically and cytogenetically distinct group of secondary leukemias has been reported in individuals who have received a topoisomerase II inhibitor.[95,96] This group includes the epipodophyllotoxins etoposide and teniposide and the anthracyclines daunomycin, mitoxantrone, and doxorubicin. The topoisomerase II inhibitors cause DNA damage via the intranuclear enzyme topoisomerase II. In contrast to alkylating agent–related AML, the *topoisomerase II–related t-AMLs* typically lack a preceding myelodysplastic phase and are characterized by a shorter latency of onset, generally less than 2 to 3 years.[97–99] These topoisomerase II–related t-AMLs are associated with chromosomal rearrangement involving chromosomes 3, 11, and 21 and characterized by a balanced translocation involving bands 11q23. They typically lack numerical chromosome abnormalities or complex karyotypes, a feature that may reflect the mechanism of topoisomerase II–induced genetic damage, which includes DNA cleavage at hotspots follow by illegitimate recombination.[100–102] The mixed lineage or myeloid–lymphoid leukemia *(MLL)* gene located on chromosome 11 band q23 is the most frequent site of the leukemogenic translocation induced by topoisomerase II inhibitors.[94] The treatment outcome for these patients is much worse than for patients with de novo AML having similar clinical and cytogenetic abnormalities. Secondary acute promyelocytic leukemia (t-APL) usually is associated with exposure to an anthracycline (mitoxantrone) and less often VP-16.[18] Unlike other t-AMLs, t-APL does not have a different prognosis from the de novo APL.[18]

In patients treated with adjuvant chemotherapy for breast cancer, the risk of developing AML/myelodysplastic syndrome (MDS) is related to the dose of both epirubicin (a topoisomerase II inhibitor) and cyclophosphamide (Cytoxan). The incidence of AML/MDS was 0.37% compared with 4.97% for the low and high doses of epirubicin and cyclophosphamide, respectively. Moreover, the risk for secondary AML/MDS may be more closely related with the dose intensity of the treatment than with the cumulative dose and may be independently correlated with the granulocyte colony stimulating factor (G-CSF) dose used.[103] The association between use of G-CSF and development of AML/MDS remains controversial. In a retrospective analysis, use of G-CSF after immunosuppressive therapy for severe aplastic anemia was associated with an increased incidence of AML/MDS: 10.9% versus 5.8% in patients who did or did not receive G-CSF, respectively.[104] A similar increased risk of AML/MDS after immunosuppressive therapy was noted in patients treated with G-CSF for severe congenital neutropenia.[105] The role of colony-stimulating factors in the development of MDS/AML in high-risk patients is unclear and may be confounded by other factors such as age and prior treatments.[106]

In children with ALL, the incidence of t-AML after exposure to one of the epipodophyllotoxins is approximately 5%.[98] However, in children with a T-cell ALL who received a topoisomerase II inhibitor, the incidence of t-AML is 19%. Cytogenetic studies suggest that the second leukemogenic event occurs in a normal hematopoietic progenitor and not in the initial ALL leukemic cell. The outcome for these children treated with standard cytotoxic chemotherapy is poor. Cases of t-AML with inv^{16} or t(8;21) occurring after therapy with a topoisomerase II inhibitor have been reported.[107,108] These leukemias are associated with rearrangements of the CBF genes *AML1/CBFA* at 21q22 and *CBFB* at 16q22.[107,108] As with other secondary leukemias, a genetic predisposition for AML has been proposed.[109] Individual differences in DNA stability and repair as well as variations in metabolism of chemotherapy may be important contributing factors. Polymorphism of the glutathione transferase gene *GSTP1* and the NAD(P)H:quinone oxidoreductase NQ01 is overrepresented in some patients with t-AML.[109,110]

Drugs other than the cytotoxic agents reported to be associated with development of acute leukemia include chloramphenicol,[111] phenylbutazone,[112] chloroquine,[113] and methoxypsoralen.[114] The strength of these associations remains unclear.

Certain acquired diseases are associated with transformation to AML. Patients with one of the myeloproliferative disorders, including polycythemia vera, essential thrombocythemia, chronic idiopathic myeloid metaplasia, and myelofibrosis, have an increased incidence of leukemic transformation. In patients with polycythemia vera, the incidence of AML is only approximately 1% for those treated only with periodic phlebotomies.[115] However, addition of chemotherapy or radiation therapy significantly increases the incidence of AML.[92,116–118] The incidence of AML appears to be related to the intensity and duration of the alkylating agent therapy. The relative risk for AML was 4 to 10 times greater for patients treated with daily continuous alkylating agents versus administration of intermittent pulse treatment.[116] Aplastic anemia is associated with late development of acute leukemia.[119] In patients with aplastic anemia treated successfully with antithymocyte globulin, 26% developed AML or one of the MDSs after 8 years. The risk for AML appears higher in patients with aplastic anemia occurring after irradiation or chemical exposure.[120] AML occurs in patients with paroxysmal nocturnal hemoglobinuria and appears to involve the same clone from which the abnormal erythrocytes are derived.[121] Multiple myeloma is associated with the development of AML.[122] The association between AML, multiple myeloma, and administration of multiple alkylating drugs is well documented, but AML can occur in patients with myeloma who have not received prior chemotherapy or radiation therapy.[123]

Primary nonseminomatous mediastinal germ cell tumors are associated with development of the acute megakaryocytic subtype of AML.[124] The secondary leukemias may be associated with the primary germ cell tumor and not result from the chemotherapy administered.[125] A number of AML subtypes are characterized by mutations that confer a proliferative or survival advantage to hematopoietic progenitors without altering differentiation. Mutations of members of the *RAS*, *FLT-3*, *KIT*, and other hematopoietic signaling molecules may play an important role in the proliferation and response to treatment. These factors must work in concert with additional acquired genetic lesions to affect both differentiation and proliferations resulting in AML. FLT-3 is a receptor tyrosine kinase and is important in hematopoietic stem cell survival and proliferation.[126] FLT-3 is mutated in approximately 25% to 30% of AMLs either by internal tandem duplications (ITDs) of the juxtamembrane domain or by point mutations of the kinase domain. It is one of the most frequent somatic alterations in AML. Both types of mutations activate FLT-3. Mutations in FLT-3 are associated with a poor prognosis. AML with *FLT-3*/ITD mutation is associated with a very poor prognosis that is independent of other prognostic factors.[127] However, the prognosis is partly dependent on the ratio of mutant to wild-type *FLT-3* as well as the size of the ITD. Larger ITDs appear to have a poorer prognosis.[128]

CLINICAL MANIFESTATIONS

The presenting signs and symptoms of AML are nonspecific and are related to decreased production of normal hematopoietic cells and invasion of other organs by the leukemic cells. Patients usually complain of a brief viral-like illness characterized by fatigue and malaise or may present with a progressive skin infection after a minor abrasion. Although anorexia is common, weight loss is unusual, generally reflecting the acute onset of the disease. Diffuse bone tenderness involving the long bones, ribs, and sternum is the initial clinical manifestation in 25% of patients. Joint pain and swelling, localized to large joints, may antedate other symptoms by weeks. The bone pain, which can be severe, is caused by expansion of the intramedullary space or direct involvement of the periosteum by the leukemic cells.

Findings on physical examination relate to the interference with normal hematopoiesis by the leukemic cells. Typically, in AML all three cell lines are affected. Anemia results in pallor and cardiovascular symptoms. Thrombocytopenia produces hemostatic defects, which result in petechiae and ecchymosis. Oozing from the gums, epistaxis, and excess bleeding after dental procedures or minor trauma are common initial manifestations. Petechiae are most prominent in the lower extremities and may appear suddenly after minor physical

activity. Splenomegaly occurs in up to 50% of patients with AML, but the splenic enlargement usually is modest and rarely extends more than 5 cm below the left costal margin. A very large spleen suggests that the leukemia has evolved from an preexisting chronic myeloproliferative disorder. Lymphadenopathy is rare in AML, in contrast to ALL, in which lymphadenopathy may be a prominent presenting finding. Involvement of the thymus or hilar nodes is very uncommon in AML. Skin involvement (leukemia cutis) occurs in approximately 10% of patients and usually presents as violaceous, raised, nontender plaques or nodules, which on biopsy are found to be infiltrated with myeloblasts (Fig. 60–1). Diffuse involvement of the skin may be seen. Biopsy may reveal prominent diffuse infiltrate involving the deep dermal surface but preservation of the superficial dermis (Fig. 60–2). Skin involvement is more common with the monocytic leukemic subtypes.[129] Sweet syndrome (acute neutrophilic dermatosis) is a cutaneous paraneoplastic syndrome that is associated with AML and other hematologic disorders.[130] It is characterized by fever and tender red plaques and nodules usually on the extremities. Sweet syndrome may precede the diagnosis of AML by several months (Fig. 60–3). Sweet syndrome is more common in the monocytic leukemias. The histologic finding in Sweet syndrome consists of a dense infiltrate primarily composed of mature neutrophils located predominantly in the mid and upper dermis.[131] Sweet syndrome may be associated with leukemia cutis. Skin lesions reveal the presence of leukemia cutis, with abnormal mature neutrophils and blast forms.[132] The pathogenesis of Sweet syndrome in AML is unknown. It has been postulated that leukemia-related growth factors (interleukin [IL]-1, IL-6, or G-CSF) directly or indirectly stimulate epidermal or dermal cells, which inducing the local accumulation of neutrophils. In some patients the neutrophils appear to be clonal and are derived from the leukemic cell, possibly as a result of chemotherapy-induced differentiation.[133] Sweet syndrome may occur in patients with normal, low, or elevated white blood counts. Similar lesions have been noted in patients with inflammatory diseases and associated with use of G-CSF.[133] Systemic steroids are the treatment of choice for leukemia associated Sweet syndrome and usually result in prompt improvement and resolution of the clinical symptoms and lesions.[134]

Myeloid granulocytic sarcomas (chloromas) are collections of blasts in extramedullary sites, which may present as isolated subcutaneous masses and may be confused with a primary or metastatic carcinoma.[135,136] The term *chloromas* is derived from the greenish appearance on sectioning, which is secondary to the presence of myeloperoxidase (MPO) granules in the myeloblasts. Myeloid sarcomas may precede the development of AML and are more common in the undifferentiated and minimally differentiated AML subtypes.[137] The presence of extramedullary leukemia is associated with a generally poorer response to treatment and shorter overall survival.[138] However, the presence of extramedullary disease may be a biologic marker for other adverse prognostic factors and therefore not an independent predictor of response.[139] Gingival hyperplasia caused by

Figure 60–4 Gingival infiltration in a patient with myelomonocytic leukemia.

leukemic infiltration is more frequent in the monocytic leukemias (Fig. 60–4) but may occur in all the leukemic subtypes. The patient initially may present to a dentist complaining of painful gums, rapidly progressive gingival disease, and gum bleeding after dental brushing.

Central and Peripheral Nervous System Manifestations

Central nervous system (CNS) involvement in AML is an uncommon presenting finding. From 5% to 7% of all patients have asymptomatic CNS involvement as determined by positive cerebrospinal fluid cytology.[140] Magnetic resonance imaging is the imaging study of choice to detect meningeal involvement in suspected cases of CNS leukemia.[141] The finding of asymptomatic CNS disease does not alone appear to predict a poor prognosis.[142] Patients at highest risk for developing CNS leukemia include those with a high circulating blast count, elevated lactate dehydrogenase activity, and one of the monocytic leukemic subtypes.[143,144] Of note is the very high frequency of CNS involvement, up to 35%, in AML with increased eosinophils [M4Eo variant in the French-American-British (FAB) classification; AML with abnormal bone marrow eosinophils and inv[16] (p13;q22) in the World Health Organization (WHO) classification], which is associated with inversion of chromosome 16. Leptomeningeal leukemia and intracerebral myeloid sarcomas occur frequently in this otherwise prognostically favorable subtype.[145] Unless signs of overt CNS involvement requiring therapy is evident, it is preferable to defer a lumbar puncture until the peripheral blasts have been cleared with chemotherapy in order to prevent accidental contamination of the spinal fluid with leukemic cells.[89,146] AML may recur in the CNS without evidence of systemic disease. Effective treatment of the CNS disease with either intrathecal chemotherapy and/or radiation therapy does not appear to prevent the subsequent development of recurrence in the bone marrow. Recurrence in the CNS has been associated with an overall poor prognosis.[147]

The majority of patients with leukemic involvement of the CNS are asymptomatic; however, some patients present with meningeal signs and symptoms associated with increased intracranial pressure. In these patients a lumbar puncture is required and typically reveals an elevated opening pressure with increased protein level and low glucose concentration in the cerebrospinal fluid. The cell count may be low; therefore, a cytocentrifuge preparation of the cerebrospinal fluid is required to detect the presence of leukemic cells. Cranial nerve palsies secondary to leukemic infiltration of the nerve sheath occur but are rare in AML. The fifth and seventh cranial nerves are most frequently involved.[148–150] Patients may present with sudden onset of facial muscle weakness, which rapidly progresses to paralysis. Optic nerve infiltration can result in papilledema, eye pain, blurred vision, or sudden onset of unilateral blindness. Retinopathy can occur and result in progressive impairment of vision.[149] Cranial nerve involvement can occur in the absence of overt CNS disease, and in these cases the cerebrospinal fluid may be negative for leukemic cells.[150] Magnetic resonance imaging of the affected nerve root may demonstrate thickening of the nerve sheath, which is suggestive of leukemic involvement. The affected cranial nerve roots should be irradiated as soon as possible after onset of symptoms to prevent permanent loss of function.[149] Patients presenting with neurologic findings and greater than 50,000/μL circulating leukemic cells are at high risk for a major CNS event and require emergency intervention to rapidly lower the blast count. The high number of circulating blasts increases the blood viscosity and is associated with small-vessel leukoblastic emboli, resulting in leukostasis in the cerebral vessels.[151] The leukemic blasts can infiltrate the arteriolar endothelial walls and cause secondary hemorrhage. Suspected or developing CNS leukostasis requires emergency efforts to rapidly lower the blast count and maintain the platelet count greater than 25,000/μL.[151–153] The combination of hyperleukocytosis and thrombocytopenia is associated with an increased risk for CNS hemorrhage.[152] Patients may complain of diffuse headaches and fatigue, which rapidly progress to confusion and coma. Leukostatic hemorrhage clinically resembles a major cerebrovascular accident (Fig. 60–5). Adhesion and aggregation of leukemic cells as well as local anatomic factors appear to play a role in development of CNS leukostasis.[153] Leukostasis is more intensive in the white matter and leptomeninges, with involvement of medium-sized vessels. The risk of CNS leukostasis rapidly increases when the blast count (blasts plus promyelocytes) is greater than 50,000/μL.[154] Patients with hyperleukocytosis generally should not receive red cells in order to avoid a further increase in blood viscosity. Despite most efforts to rapidly lower the white blood count and the blood viscosity, the prognosis for patients with CNS leukostasis remains very poor.[153]

Figure 60–5 Head computed tomographic scan of a patient presenting with a white blood cell count of 100,000/mm^3 and massive intracranial hemorrhage secondary to leukostasis.

Metabolic and Electrolyte Abnormalities

Metabolic and electrolyte derangements are common in patients with AML due to either leukemic organ infiltration or the effects of the cytotoxic chemotherapy and concomitant medications.[155] Hyperuricemia is the most frequent leukemia-related biochemical abnormality. It results from increased turnover of the proliferating leukemic clone and subsequent purine catabolism. Hyperuricemia and hyperuricuria can develop before therapy is started. Typically, however, the uric acid level rises rapidly once therapy is initiated as a result of release of intracellular nucleic acids by lysis of large numbers of cells. Urate crystals can precipitate in the renal tubules and ureters, causing acute renal failure. To prevent the development of urate nephropathy, all patients should receive intravenous hydration and should be started on allopurinol before chemotherapy is started. Allopurinol, by inhibiting xanthine oxidase, causes an increase in urine xanthine levels and can produce xanthine crystalluria. Xanthine nephrolithiasis and xanthine nephropathy resulting in acute renal failure, which is a rare complication associated with administration of allopurinol and chemotherapy-induced tumor lysis.[156] It is important to maintain adequate hydration as well as to administer allopurinol before and during induction chemotherapy. Alternatively, rasburicase, an analogue of urate oxidase that converts uric acid to allantois, which is five times more soluble than uric acid, is given intravenously and is not associated with elevated xanthine levels.[157] Rarely, leukemic cells produce an obstructive uropathy as a result of direct infiltration of the prostate gland.[158] Direct bilateral cortical, medullary, and interstitial kidney involvement with myeloblasts may rarely result in renal failure.[159,160] However, in AML, in contrast to ALL, kidney infiltration with blasts is uncommon.

Hypokalemia is a common finding in patients with AML.[155,161] The hypokalemia, which can be profound and require large doses of intravenous potassium, is most pronounced in the myelomonocytic and monocytic leukemias.[162] Ineffective myelopoiesis or destruction of the leukemic cells with therapy causes release of large amounts of lysozyme from the leukemic blasts. This enzyme is toxic to renal tubular cells, resulting in proximal renal tubular dysfunction and leading to renal potassium wasting. In most cases, however, lysozyme-induced tubular damage is not the sole mechanism of the hypokalemia.[163] Attempts to directly correlate elevated serum and urinary lysozyme levels with the leukemic subtype and the development of hypokalemia and the renal tubular defect have produced conflicting results.[164,165] Hypokalemia also may be induced by potassium entry into the metabolically active leukemic cell, which has higher sodium/potassium adenosine triphosphatase activity.[161] Leukemic cells can synthesize other factors, such as renin-like activity that may contribute to the development hypokalemia.[166] Renal potassium wasting with inappropriate kaliuresis is associated with hypomagnesemia.[155] Antibiotics and chemotherapy-induced nephropathy, diarrhea and vomiting contribute to the development of hypomagnesemia and hypokalemia during and prior to induction therapy. Hyperkalemia is a rare finding in patients with AML unless renal failure or a tumor lysis syndrome develops. Pseudohyperkalemia may occur in patients with hyperleukocytosis due to lysis of the leukemic cells and release of intracellular K^+ in collection vials in the laboratory.[167]

Hypercalcemia has been reported in association with AML.[168] The mechanism is unclear but may be related to the release of parathyroid hormone (PTH) or PTH-like fragments produced by leukemic cells.[169] The hypercalcemia may be caused by direct bone involvement or stimulation of osteoclasts and the development of lytic bone lesions.[170,171] In these instances, the blood calcium level parallels the activity of disease. Hypocalcemia presumably as a result of release by leukemic cells of factors that result in accelerated bone formation has been reported. The hypocalcemia is associated with hypoalbuminemia in many patients. The most common cause of the hypocalcemia is the coexisting hypomagnesemia, which impairs release of PTH and induces resistance to PTH.[155] The hypocalcemia can be profound, and patients can present with tetany and potentially fatal cardiac arrhythmias. The hyperphosphatemia and hyperphosphaturia associated with underlying renal insufficiency also can contribute to the hypocalcemia.

Rapid lysis of leukemic cells can acutely precipitate a number of serious metabolic problems due to release of intracellular phosphate, potassium, and urate. Tumor lysis syndrome is characterized by rapid development of hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia.[172,173] The consequences of tumor lysis syndrome are directly related to metabolic abnormalities: hyperuricemia produces urate nephropathy and acute renal failure; hyperkalemia is associated with potentially lethal cardiac arrhythmias; and hyperphosphatemia causes reciprocal depression of serum calcium level and progressive renal insufficiency, with further reduction of excretion of potassium and phosphate. Hypocalcemia, a result of hyperphosphatemia, can cause tetany, cardiac arrhythmias, and muscle cramps. The tumor lysis syndrome is rare in patients with AML. Tumor lysis is more common in patients who present with an elevated WBC count and elevated serum creatinine, uric acid, and lactate dehydrogenase (LDH) levels.[174,175] It is important to recognize patients at risk for this syndrome and to address and correct metabolic and electrolyte abnormalities before starting therapy. Allopurinol and intravenous hydration should be started before beginning chemotherapy. Renal function can rapidly deteriorate, and patients should be monitored daily to correct developing electrolyte abnormalities. Dialysis may be required and should be considered early in the course to prevent the complications of rapidly rising serum potassium, phosphate, and uric acid levels.[176] In the majority of patients, recovery of renal function after tumor lysis occurs early, and most patients can be supported through the relatively brief period of renal insufficiency.[177] Even with careful attention to electrolyte levels and use of intensive hydration, patients still may develop tumor lysis syndrome and acute renal failure. In the majority of patients with AML, development of renal insufficiency is associated with acute tubular necrosis, sepsis, and use of nephrotoxic drugs.[177] Use of nephrotoxic antibiotics and other medications is a frequent contributing factor to the development of renal failure during induction therapy.

Lactic acidosis has been associated with AML.[178] The etiology of this metabolic acidosis is unclear but may be the result of anaerobic glycolysis by the leukemia cells. When lactic acidosis occurs, it usually is associated with a very high or rapidly rising blast count, extramedullary disease, and leukostasis. The lactic acidosis parallels disease activity in these cases and improves with treatment of the leukemia.[179]

A spuriously low serum glucose level, potassium level, and arterial oxygen saturation can occur in the presence of high numbers of circulating blasts.[180] These spuriously low values reflect use by the leukemic blasts of glucose, potassium, and oxygen and typically reflect a delay in processing of the test sample. A spurious elevation of blood potassium levels may occur with hyperleukocytosis as a result of release of potassium from leukocytes undergoing lysis during clotting or as a result of prolonged storage of the sample before analysis.[167] If a spuriously elevated potassium or low glucose level is suspected, serum electrolyte studies should be repeated with an anticoagulated blood sample that is rapidly analyzed to prevent in vitro lysis of leukemic blasts.[161,180,181]

Specific Organ Involvement

Cardiorespiratory symptoms are common findings at presentation and during therapy in patients with acute leukemia. In the first week after treatment is started, infection and pulmonary hemorrhage associated with diffuse alveolar damage and/or infection contributed to the majority of early deaths in AML.[182,183] Pneumonia is the most common pulmonary problem. At presentation or early in the treatment course, gram-positive and gram-negative bacteria are the major pathogens. Patients who are neutropenic have an increased risk for pulmonary infection with fungi or other opportunistic organisms. Pulmonary leukostasis is a serious potential problem in patients who present with a blast count greater than 50,000/μL.[153,184] In this setting, leukocyte thrombi and plugging of pulmonary microvascular

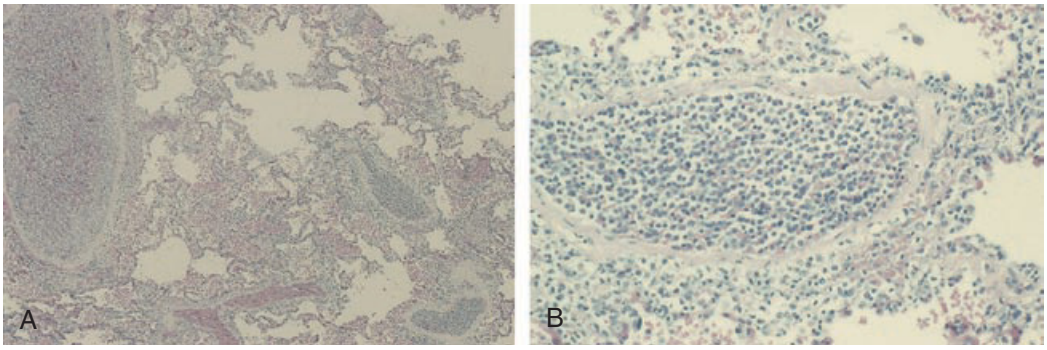

Figure 60–6 A, Pulmonary leukostasis with diffuse involvement of small and large vessels. **B,** Pulmonary leukostasis with involvement of a small pulmonary vessel. The vessel is occluded by aggregates of monoblasts.

Figure 60–7 Chest radiograph showing pulmonary leukostasis in a patient with monoblastic leukemia and a white blood cell count of 150,000/mm^3.

channels lead to vascular rupture and infiltration of the lung parenchyma (Fig. 60–6). Leukemia-associated acute respiratory failure may be due to pulmonary hemorrhage or to direct damage of the pulmonary endothelium from the lysed leukemic blasts.[185] Patients may note sudden onset of shortness of breath and progressive dyspnea. On physical examination they are tachypneic, with diffuse bilateral rales. Chest radiograph usually shows a diffuse interstitial infiltrate (Fig. 60–7). Fever is common. Hypercapnia, hypoxemia, and progressive respiratory acidosis are signs of a very poor prognosis.[186] Pulmonary leukostasis and the hyperleukocytosis syndrome are more common in patients with one of the monocytic subtypes and the microgranular variant of APL.[153] Hyperleukocytosis, defined as a blast count greater than 50,000/μL, increases the risk of fatal pulmonary and CNS leukostasis and should be considered a medical emergency. Measures to prevent or treat suspected pulmonary leukostasis should be directed at rapidly lowering the WBC count, correct any underlying coagulopathy, and avoiding measures that increase the blood viscosity.[187,188] Emergency treatment should include use of hydroxyurea and platelet transfusions to maintain the platelet count greater than 20,000/μL.[188] Transfusion of packed red cells should be avoided unless necessary for the clinical condition of the patient because a low hemoglobin level is a major determinant for preventing leukostasis in hyperleukocytosis.[153,187] Leukapheresis should be performed to rapidly lower the blast count in patients who present with greater than 50,000/μL myeloblasts or when early signs of leukostasis are present.[189]

The mechanism of hyperleukocytosis syndrome is not clear. Leukostasis is the clinical manifestation of hyperleukocytosis and results in microcirculatory dysfunction and sludging of leukemic cells in the capillary vessel. The interaction of intercellular adhesion molecule 1 (ICAM-1) and lymphocyte function-associated antigen 1 (LFA-1) appears to play a critical role in the adhesion and migration of AML and is responsible for the vascular disruption and distribution of blast cells.[190] The vascular disruption and bleeding in leukostasis appear to be result from interaction of the leukemic cell and the vascular endothelial surface. The interaction of the leukemic cell and the vascular endothelial appears to be critical in causing leukostasis. The absolute white blood count may be less important for the development of leukostasis than the presence of adhesion molecules displayed by the leukemic cell and their chemotactic response to local cytokines in the vascular microenvironment. Dexamethasone in vitro inhibits upregulation of adhesion molecules such a L-selectin and IL-8 receptor on myeloid leukemic cells and may have a role in treating the leukostasis.[153] Pulmonary hemorrhage and leukostasis may mimic the signs and symptoms of a bacterial or fungal pneumonia. Pulmonary hemorrhage may be diffuse, involving both lungs, or localized to a single segment or lobe. Patients typically complain of sudden onset of shortness of breath. Hemoptysis may occur, and hypoxemia and hypercapnia are common. Hyperleukocytosis can be associated with a spurious hypoxemia because of the metabolic requirements of the high blast count.[191] The prognosis for patients who develop pulmonary leukostasis is very poor, even with the rapid lowering of WBC count and initiation of chemotherapy. The presentation may be similar to other forms of noncardiogenic pulmonary edema that can occur during treatment of AML.[192] Physical examination may reveal few objective pulmonary findings, although chest radiograph typically reveals an interstitial pattern in the area of the hemorrhage.

Cardiovascular abnormalities usually result from derangements in metabolic, electrolyte, and pulmonary function. Leukemic infiltration of the heart or great vessels is rare, but leukemic involvement of the conduction system, pericardium, and myocardium as well as involvement of the arterial endothelial wall with monoblasts and subsequent formation and rupture of an aortic aneurysm have been reported.[193] Chemotherapy-related toxicities produce the majority of cardiovascular problems in patients with AML. The cardiotoxicity of the anthracyclines is dose related, and these agents act synergistically with other cardiotoxic agents. Left and right ventricular ejection fractions should be measured in all patients who have received a known cardiotoxic drug or who have a history of cardiac disease before they are given an anthracycline. Anthracycline cardiotoxicity is a multifactorial process and is related to oxidative stress and myocyte induction of apoptosis. Whether the therapeutic effects of the anthracyclines are different from the cardiotoxicity is unclear.[194] An echocardiogram may be more helpful in assessing wall-motion abnormalities. However, a pretherapy "baseline" ejection fraction or echocardiogram is not warranted for all patients before starting induction therapy. Unless the patient has known or suspected cardiac disease that would alter the chemotherapy regimen, treatment need not be delayed pending the result of ejection fraction. Patients who develop progressive cardiorespiratory failure and require intubation and respiratory support continue to have a grave prognosis.[195]

Gastrointestinal abnormalities are frequent in AML patients. Dysphagia is common and usually results from oral or pharyngeal infections, mucosal involvement with leukemia, or chemotherapy-induced mucositis. Oral candidiasis is a common presenting finding and may involve the tongue and/or the soft or hard palate. Esophageal candidiasis can produce substernal pain and a midepigastric "burning" sensation. Dysphagia is common with oral and esophageal candidiasis. The clinical appearance of oral and esophageal candidiasis may be deceptive, and mixed fungal and viral infections are common.[196] Leukemic involvement of the gingiva can occur in any of the AML subtypes. Gingival hypertrophy is most frequent in the well-differentiated monocytic types. Gastrointestinal involvement with AML is rare, but granulocytic sarcomas (chloromas) can form in the esophagus or small intestine and lead to obstructive symptoms.[197,198]

The anal and perirectal areas are important potential sources of infection in neutropenic patients. Patients initially may complain only of pain on defecation and diffuse anal tenderness without signs of infection or cellulitis. Perirectal abscesses usually are due to gram-negative bacteria and in the setting of granulocytopenia can rapidly progress to perirectal cellulitis and septicemia. Although routine digital rectal examinations are generally avoided in patients who are granulocytopenic, the perirectal area can be examined when a local infection is suspected.

Patients should be instructed on the importance of perirectal hygiene. Constipation should be avoided to prevent small mucosal tears. Agents that cause diarrhea should be carefully monitored, and use of harsh laxatives or agents that cause prolonged diarrhea should be avoided. Use of contrast agents that are cathartics must be critically evaluated before their routine use in patients with AML. The perirectal and oral areas are two important portals for infection.

Use of more intensive chemotherapy regimens and broad-spectrum antibiotics has resulted in an increased incidence of gastrointestinal complications.[199] Typhlitis, derived from the Greek word meaning *cecum*, is a fulminant necrotizing colitis related to granulocytopenia and cytotoxic therapy. It occurs in up to 10% of patients with leukemia who are undergoing intensive therapy.[200] Patients present with sudden onset of abdominal pain, fever, and a distended and tense abdomen. Bowel sounds are decreased, and abdominal radiographs are nonspecific, usually revealing an incomplete small bowel obstruction, a questionable right lower quadrant mass, pneumatosis, or no appreciable abnormality. Computed tomographic scanning frequently shows an edematous right colon with spiculation of the pericolic fat and subcutaneous edema. The clinical presentation frequently mimics that of acute appendicitis. The diagnosis of typhlitis usually is made based on clinical findings. Computed tomographic scan may be helpful in differentiating appendicitis from other causes of abdominal pain and fever.[201] The pathogenesis of neutropenic colitis is multifactorial and related to the chemotherapy administered and local mucosal damage. The cecum is the most common site because of limited vasculature and distensibility. The factors implicated in the pathogenesis of neutropenic colitis include a direct toxic effect of chemotherapy, local bacterial invasion, intramural hemorrhage, and leukemic infiltration of the bowel wall.[199] Treatment of typhlitis is controversial, and for many patients the prognosis is poor. Medical management includes bowel rest, broad-spectrum antibiotics directed at bowel pathogens including anaerobes and fungi, intravenous fluid replacement, total parenteral nutrition, and transfusion support.[202] Surgical intervention, usually a hemicolectomy, should be reserved for patients with localizing peritoneal signs suggesting an abscess or clear evidence of bowel perforation, as well as for those who do not respond to medical therapy. Patients who are neutropenic and thrombocytopenic can tolerate an exploratory laparotomy, but their postoperative course is more complicated.[203] The morbidity and mortality of surgery must be carefully weighed against the risk of medical therapy and support therapy in the individual patient. A majority of patients with typhlitis can be managed medically with intensive supportive therapy and antibiotics; only a minority of patients require surgical intervention.[199]

DIAGNOSIS

General Approach to Diagnosis of Acute Myeloid Leukemia

Advances in the understanding of the molecular and genetics of myeloid stem cell disorders have helped in defining clinically and biologically important subtypes of AML.[204–208] This expanding spectrum of AMLs coupled with efforts to institute risk-adapted therapy for these disorders[209,210] requires a comprehensive, yet algorithmic, approach to the diagnosis and classification of AML (see box on Stepwise Algorithm for Diagnosis and Classification of Acute Myelogenous Leukemia Using Cytomorphology, Cytochemistry, Immunophenotyping, Cytogenetics, and Molecular Cytogenetics).[211,212] Collection of adequate samples for cytomorphologic, immunophenotypic, cytogenetic, and molecular studies as well as timely exchange of information among the clinician, pathologist, and cytogeneticist are necessary for the diagnosis and classification of AML.

In many cases diagnosis is possible based on examination of the peripheral blood smear. However, a bone marrow aspirate should be performed to confirm the leukemia subtype and obtain marrow for cytogenetic and immunophenotypic studies. Air-dried marrow smears freshly prepared at the bedside from the aspirated marrow are stained with Wright-Giemsa or May-Grünwald-Giemsa to allow for detailed study of qualitative cytomorphology. Although a core biopsy is not required to make the diagnosis of acute leukemia,[213] a bone marrow core biopsy and touch preparation should be performed on all patients because the aspirate and core biopsy assess different aspects of normal and neoplastic hematopoiesis. A biopsy is particularly important when the marrow cannot be aspirated ("dry tap"). Under these circumstances, the marrow imprints or touch preparations may prove useful for determining cell lineage and performing cytochemical staining. The bone marrow biopsy is routinely stained with hematoxylin-eosin and/or Giemsa stain; it also can be stained by immunohistochemical methods if needed.

Immunophenotyping is best accomplished by multiparameter flow cytometry on aspirated marrow. When an aspirate cannot be obtained, flow cytometric studies can be performed with cells dissociated from a core biopsy.[214] Cytogenetic studies are important prognostic indicators and should be performed on all patients at the time of initial bone marrow biopsy. Samples for cytogenetics must be collected in heparin tubes because ethylenediaminetetraacetic acid (EDTA) interferes with cell growth. Conversely, samples for cytomorphology should be collected in EDTA tubes because heparin interferes with metachromatic stains. Cell suspensions from marrow collected in EDTA should be cryopreserved for possible molecular studies.[213] Cytogenetic, molecular, cytochemical, and immunophenotypic studies are important in diagnosing AML and defining major subtypes of AML in the FAB and WHO classifications. Cytogenetic analysis is performed on Giemsa-banded karyotypes and requires viable dividing cells. Cytogenetic analysis for a complete karyotype can take up to 2 weeks. The introduction and widespread use of fluorescent in situ hybridization (FISH) on interphase nuclei, although not supplanting standard cytogenetics, can provide additional information and is rapidly becoming more available.[215,216] Unlike cytogenetics, FISH analysis requires the clinician to direct the cytogeneticist to search for specific abnormalities. For instance, in suspected cases of APL, FISH analysis of interphase nuclei can rapidly detect the 15:17 translocation. FISH studies do not require dividing cells and therefore can be performed on peripheral blood samples. Test results are generally available in 24 to 72 hours. FISH analysis also can identify cryptic, structural, and numerical abnormalities that can be missed by conventional cytogenetic studies.[217] FISH analysis can help increase the yield of conventional cytogenetic analysis and is a useful adjunct to conventional cytogenetics.

Gene expression profiling using microarray technology to generate gene expression profiles in AML is an area of active research.[218,219] The amplification and hybridization of small amounts of RNA allow for gene expression profiling in AML and have identified potentially

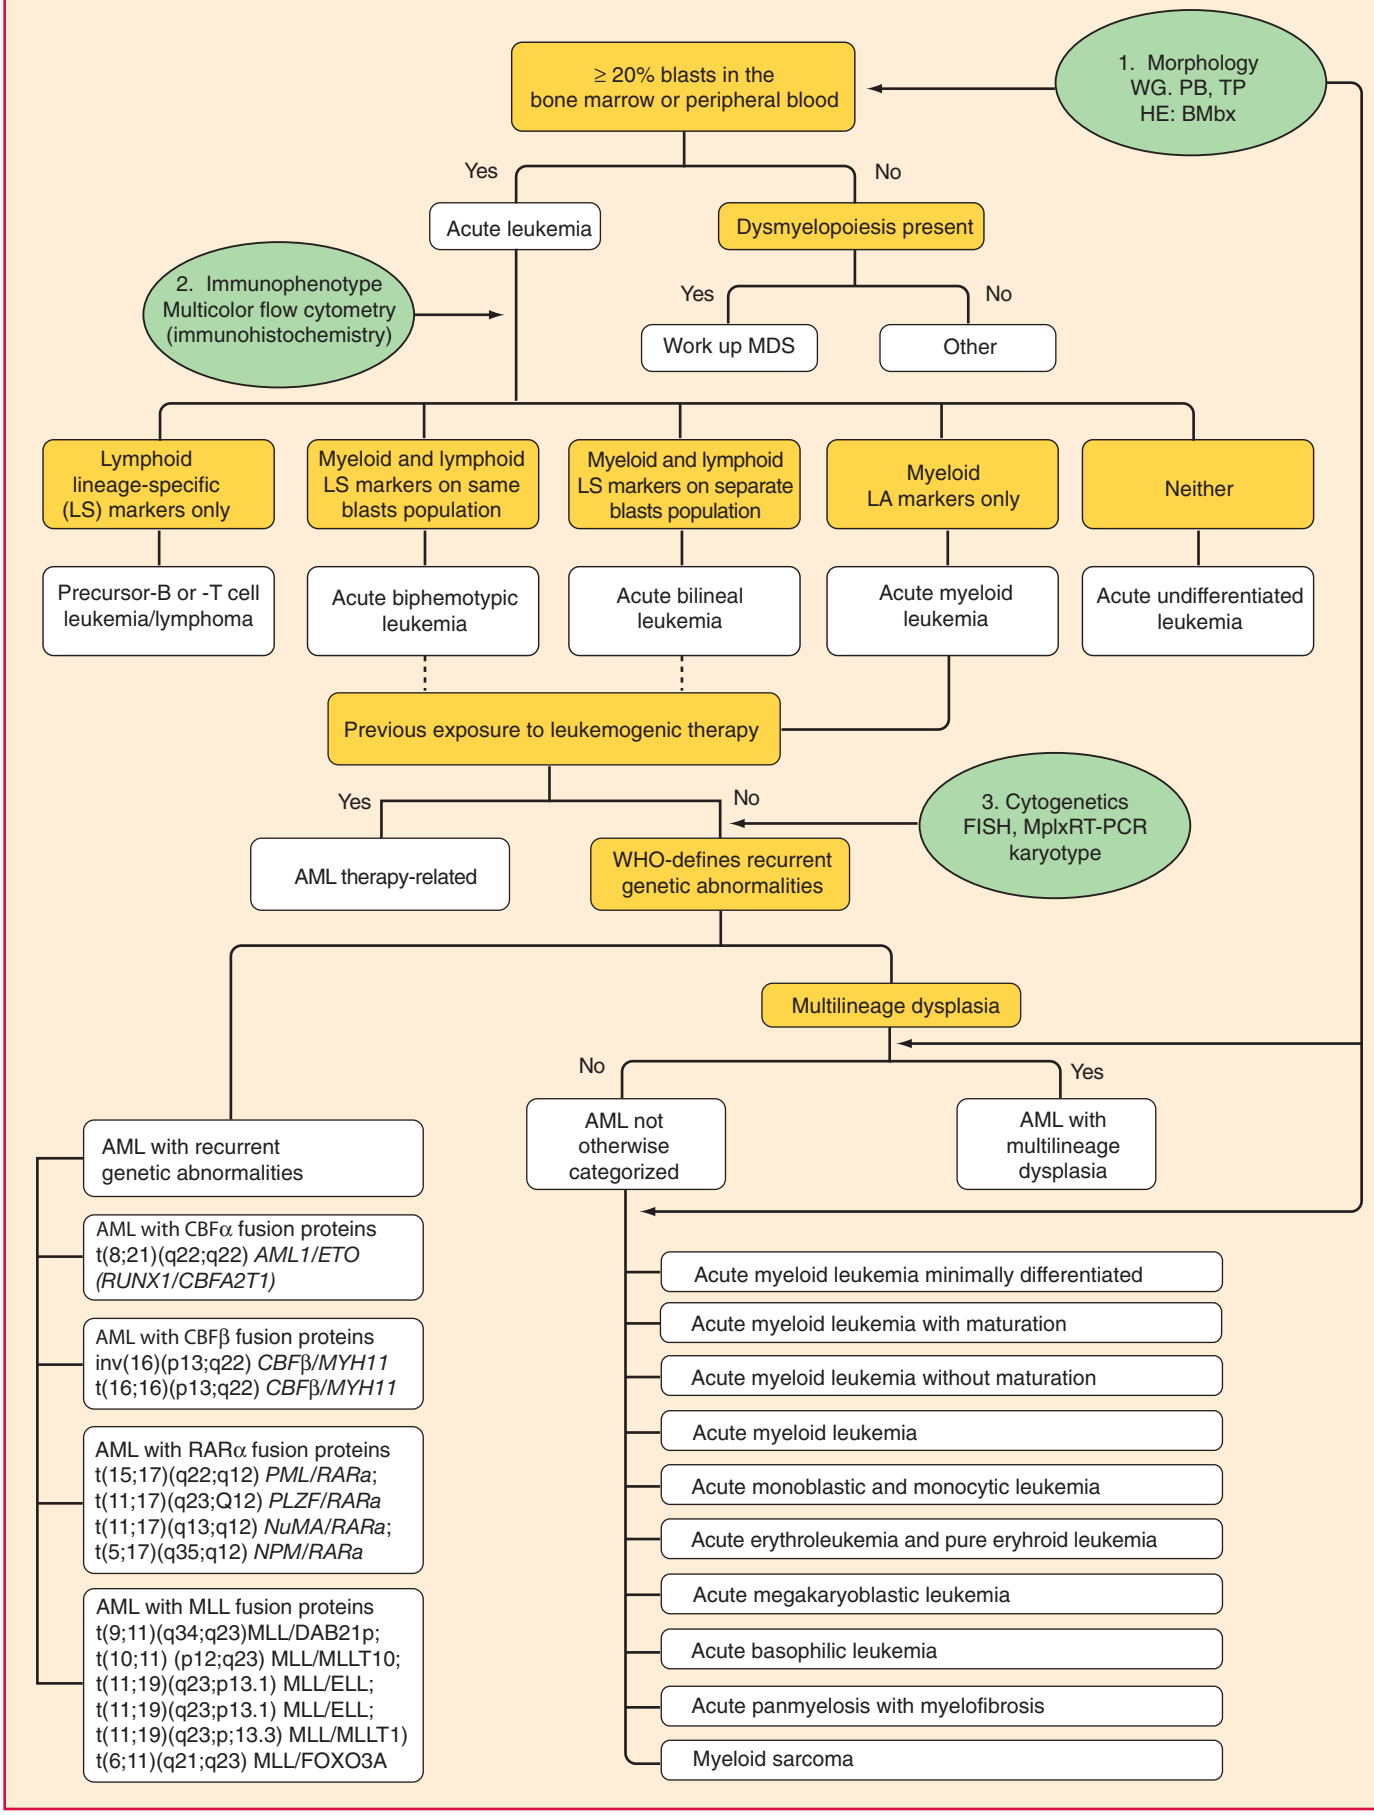
important differences in subtypes and biology not defined by traditional morphology or cytogenetics. Microarrays may be able to replace some existing genetic tests as well as add a new method for evaluating genomic abnormalities in AML. Newer high-content "tiled arrays" or single nucleotide polymorphism arrays can successfully identify common and specific somatic DNA lesions in AML as well as pinpoint small deletions or amplifications of chromosome segments. Global profiling of CpG methylation and chromatin post-translational modification (chromatin code) are capable of uncovering epigenetic changes in AML.[220,221] Combined, these technologies promise to define and map relevant genomic lesions, transcriptional signatures, and epigenetic changes that currently are not defined by traditional morphology or cytogenetics.[208]

Morphology in Diagnosis of Acute Myeloid Leukemia

Microscopic examination of a properly prepared and stained bone marrow or peripheral blood smear remains the cornerstone of AML diagnosis. Morphologic findings can direct the appropriate selection of additional diagnostic tests. The bone marrow aspirate should be evaluated for cellularity, number and morphology of megakaryocytes, myeloid/erythroid ratio (M:E), cellular maturation, and presence of dysplasia or asynchronous maturation. The blast percentage should be determined on a 500-cell differential of the bone marrow aspirate. The original FAB classification recognized three types of myeloblasts: I, II, and III (Table 60–3).[222] Type I blasts lack granules, have fine chromatin, a high nucleocytoplasmic ratio, and prominent nucleoli, and lack Auer rods. Type II blasts have a slightly more basophilic cytoplasm with few azurophilic granules (up to 20) and nuclear features similar to type I blasts except for a lower nucleocytoplasmic ratio. Type III blasts have a variable number of granules (>20) and basophilic cytoplasm with numerous azurophilic granules. The differences in blast types are determined by nuclear features and cytoplasm granules. Importantly, blasts lack a visible Golgi zone.[223] Myeloid precursors are classified as promyelocytes when they have moderately basophilic cytoplasm with numerous azurophilic granules and eccentric nuclei, largely resulting from an incipient Golgi apparatus. It is the absence of Golgi apparatus and not the paucity of granules that is the common cytologic denominator of myeloblasts. For diagnostic purposes, only type I and type II blasts should be reflected in the marrow cell differential count. Pre–B-cell ALL and some forms of natural killer cell leukemia may contain azurophilic cytoplasmic granules resembling those of myeloblasts. Subtle morphologic differences may not be sufficient to make the distinction, and immunophenotyping is necessary to confirm the lineage. Iron stores should be assessed with Prussian blue stain and the presence or absence of ringed sideroblasts specifically noted. Evaluation of the cellularity of a bone marrow aspirate is a qualitative assessment and may reflect the number of spicules obtained, slide preparation technique, and volume of diluting blood. Despite these limitations, the cellularity of a bone marrow aspirate should be noted. Marrow aspirate cellularity is grouped into five broad categories ranging from 0

Table 60–3 Type Blasts in Acute Myeloid Leukemia

Myeloblast	Features
Type I	Agranular basophilic cytoplasm, nucleus with fine chromatin, high nuclear/cytoplasmic ratio, two to four distinct nucleoli
Type II	Granulated basophilic cytoplasm with few (≤20) azurophilic granules, nuclear features similar to those of type I blasts but lower nuclear-to-cytoplasmic ratio
Type III	Heavily granulated basophilic cytoplasm with numerous (>20) azurophilic granules, nuclear features similar to those of type I blasts



Stepwise Algorithm for Diagnosis and Classification of Acute Myelogenous Leukemia Using Cytomorphology, Cytochemistry, Immunophenotyping, Cytogenetics, and Molecular Cytogenetics

The criteria are based on Wright-Giemsa–stained blood and marrow smears and biopsy. The percentage of blast cells separates acute myeloid leukemia (AML) from myelodysplastic syndrome (MDS). The World Health Organization (WHO) classification defines AML as greater than 20% blasts in the marrow or blood. The next step is to define the blast population by immunophenotyping and/or immunohistochemistry. The initial evaluation separates AML from ALL. A history of exposure to prior cytoxic chemotherapy or agents associated with AML defines the leukemia as *therapy-related acute myeloid leukemia* (t-AML). The WHO recognizes the unique clinical and biologic features of the therapy-related leukemias (t-AML). This subtype results from prior exposure to cytotoxic chemotherapy and/or radiation therapy. A majority of patients will have clonal cytogenetic abnormalities and now account for more than 40% of all patients with AML. The WHO recognizes two types of t-AML based on the type of prior exposure or treatment: alkylating agent–related AML and topoisomerase II inhibitor–related AML. The WHO classification defines major subgroups of AML that manifest recurring cytogenetic abnormalities. As a group, these AMLs have chromosomal translocations that result in the production of chimeric proteins, which are pivotal in the leukemogenic process. The genetic abnormalities define a specific biology, clinical course, and prognosis and therefore are important to classify them separately. In this group of patients, the diagnosis is defined by the cytogenetic abnormality independent of the percentage of blasts. There are four recurrent translocations in this group. The diagnosis is defined by the cytogenetic abnormalities and is not dependent on the number of blasts: (a) AML with t(8;21)(q22;q22), (AML1/ETO) (RUNX/CBFA2T1); (b) AML with abnormal bone marrow eosinophils and inv^{16}(p13;q22) or t(16;16)(p13;q22), (CBFB/MYH11); (c) acute promyelocytic leukemia: AML with t(15;17)(q22;q21)(PML/RARA) or t(11;17)(q23;q12) (PLZF/RARA) or t(5;17)(q23;q12)(NPM/RARA), or t(11;17)(q13;q12) (NuMA/RARA); and (d) AML with 11q23 (MLL) abnormalities. If multilineage dysplasia is present, then the leukemia is classified as *acute leukemia with multilineage dysplasia*.

AML with multilineage dysplasia is characterized by the presence of 20% or more blasts in the marrow and dysplasia in at least 50% of the cells of at least two of the three main hemopoietic lines. The leukemia may occur de novo or after a preceding myelodysplastic, myeloproliferative, or overlap myelodysplastic/myeloproliferative syndrome unrelated to prior exposure to chemotherapy. If such a syndrome preceded the development of acute leukemia, the AML is best designated as AML "evolving from a myelodysplastic syndrome." When a leukemia fails to satisfy the cytogenetic, morphologic, or clinical criteria for the newly defined subgroups, it is classified as AML not otherwise categorized. The *not otherwise categorized* designation essentially applies the original FAB classification with some modifications, namely, acute promyelocytic leukemia (M3) is no longer included; a pure erythroleukemia has been distinguished from erythroleukemia, acute erythroid/myeloid type; and acute basophilic leukemia (very rare) has been added, as is a rare entity termed acute panmyelosis with myelofibrosis and the solid tumor myeloid sarcoma.

CD, cluster designation; MPO, myeloperoxidase; NEC, nonerythroid cells; NSE, nonspecific esterase; PAS, periodic acid–Schiff; SBB, Sudan black B; TdT, terminal deoxynucleotidyl transferase; TNC, total nucleated cells.

Stepwise Algorithm for Diagnosis and Classification of Acute Myelogenous Leukemia Using Cytomorphology, Cytochemistry, Immunophenotyping, Cytogenetics, and Molecular Cytogenetics—cont'd

to +4 (aplastic, hypocellular, normal cellular, hypercellular, and intensely hypercellular).

The initial bone marrow in AML typically is hypercellular, with absent or decreased megakaryocytes. However, elderly patients or those with secondary or treatment-related AML may have a normal cellular or hypocellular bone marrow aspitrate.[224] Dysplastic myeloid and erythroid maturation may be noted. Myeloid precursors may be morphologically bizarre with asynchronous granulation. The prognostic significance of dysplasia by itself in de novo AML is controversial.[225,226] In addition, prominent dysplasia may suggest prior exposure to hematotoxins or may suggest that the patient's leukemia evolved from a prior MDS or is secondary to prior cytotoxic chemotherapy. Therefore, the presence or absence of dysplasia must be considered in the context of other defined prognostic indicators.[227]

Auer rods (or bodies), which are reddish rod-like filaments of aggregated primary granules, may be present in leukemic cells. These bodies (or rods), first described by Joseph Auer, are derived from incorporation of primary azurophilic granules into autophagic vacuoles. The term *phi body* has also been used to describe small spindle-shaped bodies not easily visualized by Giemsa stains. Phi bodies are best visualized by peroxidase reaction and may constitute a precursor of Auer rods. Cells containing multiple Auer bodies, sometimes referred to as *faggot cells* (from the term meaning "bundle of sticks"), are typical but not restricted to APL. They are faintly birefringent in polarized light. Ultrastructurally they have a defined three-dimensional crystal structure with a characteristic periodicity of 6 to 13 nm, which is different for each of the leukemic subtypes.[228] Auer rods are found in approximately 30% to 50% of newly diagnosed patients with AML and in a greater proportion (60%–70%) with use of cytochemical stains.[229] The myeloblasts in AML with (t8;21)(q22;q22) characteristically have thin and elongated Auer rods, which is a useful feature for recognizing this generally favorable subtype. The remission rate and duration of remission may be higher in patients whose leukemic cells demonstrate Auer rods.[230]

Hematoxylin-eosin stain of the bone marrow biopsy sample of undifferentiated immature AMLs typically exhibits a blue (basophilic) color due to close apposition of blasts with scant cytoplasm and basophilic stained nuclei. In contrast, biopsy samples of the more differentiated AMLs typically show a pale to orange (amphophilic to acidophilic) tinge due to the presence of blasts with more abundant cytoplasm. Monoblasts and promonocytes usually exhibit folded/convoluted nuclei and may contain prominent acidophilic nucleoli. Occasionally the marrow is hypocellular or contains clusters of blasts amidst more maturing myeloid progeny. Some of these cases may represent a diagnostic challenge. In cases with extensive fibrosis, as in some forms of megakaryoblastic leukemia and AML developing in the background of a chronic myeloproliferative disorder, the combination of morphology and immunocytochemistry on the core biopsy may be the only way to establish the diagnosis.

Cytochemistry in Diagnosis of Acute Myeloid Leukemia

Myeloid cells exhibit characteristic staining profiles for esterase, MPO, and periodic acid–Schiff (PAS) reagent (Table 60–4 and Fig. 60–8).[231] MPO and the specific esterase chloroacetate esterase (CAE) are markers for granulocytic differentiation, whereas the "nonspecific" esterases stain monocytic precursors. MPO is one of the most specific markers for the granulocytic lineage and is present in both primary and secondary granules. MPO is positive in myeloblasts, and activity increases as myeloblasts mature into promyelocytes. Auer rods are intensely positive for MPO, as are granules of eosinophils. Lymphoblasts and megakaryoblasts are MPO negative. Sudan black B (SBB) has a reactivity profile similar to that of MPO but is less specific for the myeloid lineage, occasionally staining diffusely the cytoplasm of lymphoblasts. MPO reactivity in 3% or more blasts is the criterion for classifying a leukemia as AML. MPO is negative in AML with minimal differentiation, acute monoblastic leukemia, and acute megakaryoblastic leukemia, which does contain platelet peroxidase but is demonstrable only by electron microscopy. PAS is positive in differentiated granulocytes and megakaryocytes, variably stains monocytes, and is negative in normal erythroid precursors. It weakly

Table 60–4 Cytochemical Stains Used for Diagnosis and Classification of Acute Leukemia

Cytochemical Stain	Specificity
Myeloperoxidase (MPO)	Stains primary and secondary granules of cells of myeloid/neutrophil lineage, eosinophil granules (granules appear solid), granules of monocytes, Auer rods Granules of normal mature basophils do not stain
Sudan black B (SBB)	Stains primary and secondary granules of cells of myeloid/ neutrophil lineage similar to MPO Eosinophil granules, granules of monocytes, Auer rods are positive Basophil granules usually are negative but sometimes show metachromatic staining (red/purple)
Naphthol AS-D chloracetate esterase ("specific" esterase)	Stains neutrophil and mast cell granules Auer rods usually are negative except in acute myeloid leukemia associated with granules), some T and B lymphocytes Abnormal eosinophils are positive
α-Naphthyl acetate esterase ("nonspecific" esterase)	Monocytes and macrophages, megakaryocytes, platelets, most T lymphocytes, some T lymphoblasts (focal)
α-Naphthyl butyrate esterase ("nonspecific" esterase)	Monocytes and macrophages Variable staining of T lymphocytes
Periodic acid–Schiff (PAS)	Neutrophil lineage (granular, increasing with maturation), leukemic promyelocytes (diffuse cytoplasmic), eosinophil cytoplasm but not granules, basophil cytoplasm (blocks), monocytes (diffuse plus granules), megakaryocytes, platelets (diffuse plus granules), erythroblasts positive in block-like pattern Negative in normal erythroid precursors
Acid phosphatase	Neutrophils, most T lymphocytes, T lymphoblasts (focal) Variable staining of eosinophils, monocytes, platelets Strong staining of macrophages, plasma cells, megakaryocytes, some leukemic megakaryoblasts
Toluidine blue	Metachromatic granules in basophils, mast cells
Perls stain, Prussian blue stain	Hemosiderin, and iron in erythroblasts, macrophages occasionally, plasma cells

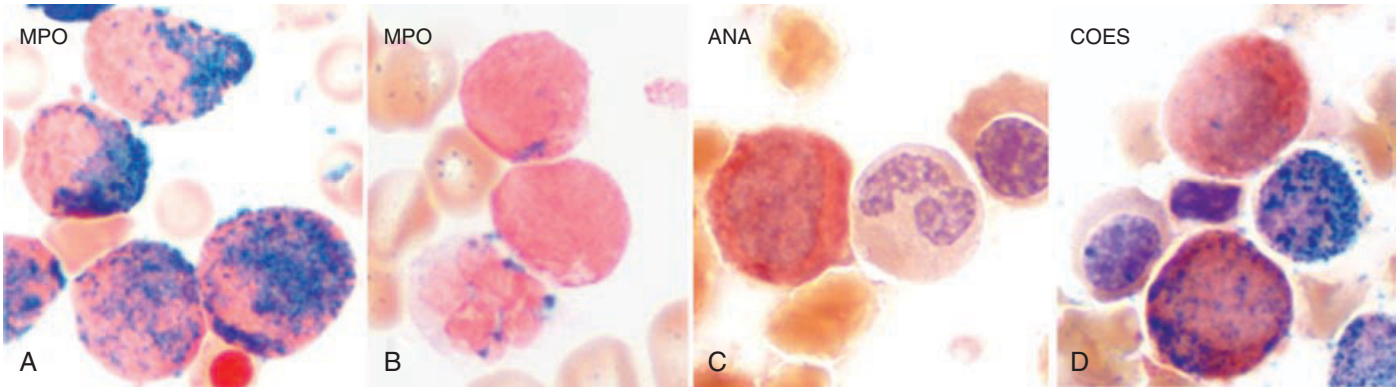


Figure 60–8 Cytochemistries: myeloperoxidase (MPO), α-naphthyl acetate esterase (ANA), and combined esterase (COES) reactions. The MPO reaction is easily performed, can be done in less than a few minutes, and provides important initial information about the lineage of the blasts, particularly in cases where morphology is difficult. In many laboratories the MPO reaction is routinely performed for all new acute leukemias. The MPO reaction should be interpreted in the blastic population and expressed as a percent of blasts that are positive. **A,** Positive MPO reaction is strong. **B,** Reaction is weak and seen in only some blasts. A counterstain would have obscured the weak reaction product. A weak MPO reaction is not uncommon in cases of acute myeloid leukemia associated with myelodysplasia (as in **B**). The neutrophils in such cases are only weakly positive (bottom cell, **B**). The ANA-reaction is a nonspecific esterase reaction positive in most monocytic cells (**C,** orange–brown cell on left compared to negative neutrophil, and erythroid cell, middle and right). The ANA reaction is interpreted as positive cells as a percent of nonerythroid elements. A significant monocytic component usually is defined as 20% or greater of the nonerythroid elements and usually is required to make a diagnosis of acute myelomonocytic leukemia. Of note, in some cases of acute myeloid leukemia with inv^{16} (i.e., acute myelomonocytic leukemia with abnormal eosinophils), the monocytes are ANA negative. A COES reaction uses another nonspecific esterase reaction for monocytes, α-naphthyl butyrate esterase (ANB) together with the specific esterase chloroacetate esterase (CAE) for granulocytes. The combination allows simultaneous evaluation of granulocytes (blue reaction product) and monocytes (orange–brown reaction product). **D,** Acute myelomonocytic leukemia. Monocyte (top), granulocyte (right), and myelomonocytic hybrid cell that exhibits both orange–brown and blue reaction products (bottom).

stains the cytoplasm of the majority of AML blasts in a diffuse pattern. It is most useful in the diagnosis of pure erythroid leukemia, where it intensely stains the cytoplasm of erythroblasts in a "block positivity pattern," a finding that is very useful in recognizing this form of erythroid leukemia.

Multiparametric Immunophenotyping in Diagnosis of Acute Myeloid Leukemia

The availability of well-characterized antibodies classified under the uniform terminology of *clusters of differentiation* (CD) has expanded the application of flow cytometry and made phenotyping of AML more precise, reproducible, and comprehensive. Immunophenotyping now is routinely used to distinguish AML from ALL and for lineage assignment. Individual cells can be stained with multiple antibodies directly labeled with various fluorophores. Several "gating" strategies specifically identify blast cells by combining side (orthogonal) scatter and CD45 staining (Fig. 60–9).[232] This strategy identifies blasts by cytoplasm complexity (granularity) on the side scatter channel Y-axis and "brightness" of staining with CD45 on the X-axis, creating specific zones or "gates" of the most common morphologic variants of AML blasts. This strategy permits the gating of even a small group of blasts in a background of numerous more mature cells. Immunophenotyping has been most useful in distinguishing between AML and lymphoid leukemias and in defining hybrid or biphenotypic leukemias (Table 60–5). Certain immunophenotypic profiles are strongly suggestive of the underlying cytogenetic abnormality (Table 60–6). The expression of a number of antibodies correlates relatively well with morphologic classification. Expression of CD34 and CD117 is common in undifferentiated or minimally differentiated AML, whereas strong expression of CD33 and loss of HLA-DR are characteristic of APL. However, the overall expression of surface antigens on myeloblasts does not entirely agree with either morphology or cytochemical staining.[233,234] Use of multiple monoclonal antibodies has identified certain phenotypic groups that may be clinically important, such as the association of AML with t(8;21) with the B-cell surface antigen CD19 and CD79a.[235] The majority of myeloid

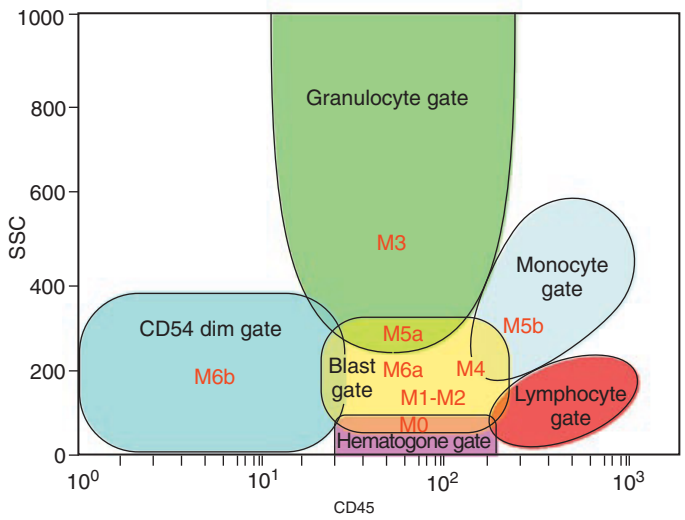

Figure 60–9 Side scatter versus CD45 flow cytometry ploy with approximate areas of "gates" where myeloblasts of the FAB acute myeloid leukemia subtypes usually are positioned. Gates are named according to the predominant normal peripheral blood cell population that normally inhabits them. Side scatter is a measure of "cytoplasm granularity," and CD45 represents the log of the intensity of staining with a common leukocyte antigen antibody.

blast cells express differentiation markers asynchronously, and the unusual coexpression of differentiation antigens is common. Myeloblasts also frequently express lymphoid associated antigens, most frequently CD2, CD7, and CD19.[236,237] CD19 is present in up to 34% of newly diagnosed AMLs.[236] The prognostic significance of this phenotypic heterogeneity is unclear, but it is not associated with a uniformly adverse prognosis. Use of immunophenotyping is particularly important for identification of AML with minimal differentiation, erythroid leukemias, and megakaryoblastic leukemia.[238] Immunophenotyping may be helpful for detecting minimal residual

Table 60–5 Monoclonal Antibodies Commonly Used for Immunophenotyping of Acute Myeloid Leukemia

	Flow Cytometry (Blood/Bone Marrow)	Immunohistochemistry (Core Biopsy)
Precursor antigen	CD45, TdT, CD34, HLA-DR	CD34, CD34, TdT
B lineage	CD19, CD20, CD22, CD79a, CD10	CD20, CD79a
T lineage	CD2, CD3, CD5, CD7	CD3, CD5, CD7
Myeloid lineage	CD13, CD33, CD117, CD15	Myeloperoxidase, CD117, CD15
Monocytic-monocytic	CD14, CD4, CD11b, CD11c, CD64, CD36	Lysozyme, CD68
Erythroid	Glycophorin A	Glycophorin A, hemoglobin A
Megakaryocytic	CD41, CD42, CD61 (cytoplasmic)	von Willebrand factor, factor VIII

disease following treatment. Flow cytometry is routinely performed at the time of diagnosis; however, it should not replace standard differential cell counting to diagnosis leukemia and evaluate response to treatment.[213]

Classification of Acute Myeloid Leukemia

The classification and diagnosis of AML (Table 60–7) has evolved from the primarily morphologic and cytochemical system proposed by the FAB Cooperative Group in 1976[222,223,239] to the current WHO classification, which explicitly includes clinical information, cytogenetics, and/or molecular abnormalities (Table 60–8). The FAB classification attempted to define relatively homogeneous morphologic categories. The FAB classified the acute leukemias according to the resemblance of the predominant leukemic cell type to a normal differentiating hematopoietic precursor cell.[240] The FAB group divided the myeloid leukemias into eight broad categories based on morphology, cytochemical staining, and immunologic phenotype of the predominant cell type, based on a Wright-Giemsa–stained blood and marrow smear or biopsy. In an attempt to incorporate relevant cytogenetic and clinical features into the classification of AML, the WHO developed a new classification of AML. The WHO-proposed classification retains much of the content of the FAB classification but defines unique clinical and biologically important subgroups by incorporating cytogenetics, adding the morphologic finding of multilineage dysplasia, and incorporating certain clinical data into the definition of four unique subgroups (Table 60–8).[241,242] The WHO classification also attempts to formally address the relationship of AML to MDS and the importance of multilineage dysplasia.[240,242] A fundamental change introduced by the WHO classification reduces the defining blast threshold for the diagnosis of AML from 30% blasts to 20% blasts in the marrow or blood. This new defining threshold eliminates the FAB-MDS subtype refractory anemia with excess blasts in transformation (RAEB-T). In addition, cases with certain recurring cytogenetic abnormalities are defined as AML regardless of the percent blasts in the blood or bone marrow. The WHO classification defines four major subgroups of AML that manifest recurring cytogenetic abnormalities. When a leukemic cell fails to satisfy the cytogenetic, morphologic, or clinical criteria for the newly defined subgroups, it is classified as AML not otherwise categorized. The *not otherwise categorized* designation essentially applies the

Table 60–7 Summary of Diagnostic Features of AML in the FAB Classification

FAB Subtype (%)	Diagnostic Features
AML-M0 (3%–5%)	≥30% blasts; >3% blasts reactive to MPO, SBB, or NSE; immunophenotyping $CD33^+$, $CD13^+$, may be $CD34^+$, TdT^+
AML-M1 (15%–20%)	≥30% blasts; ≥3% blasts reactive to MPO or SBB; <10% of marrow nucleated cells are promyelocytes or more mature neutrophils
AML-M2 (25%–30%)	≥30% blasts; ≥3% blasts reactive for MPO or SBB; ≥10% of marrow nucleated cells are promyelocytes or more mature neutrophils; t(8:21) chromosome abnormality
AML-M3 (10%–15%)	≥30% blasts and abnormal promyelocytes; intense MPO and SBB reactivity; promyelocytes and blasts with multiple Auer rods (faggot cells); t(15:17) cytogenetic abnormality
AML-M4 (20%–30%)	≥30% myeloblasts, monoblasts, and promonocytes; ≥20% monocytic cells in marrow; ≤5 × 10^9/L monocytic cells in blood: ≥20% neutrophils and precursors in marrow; monocytic cells reactive for NSE; abnormal eosinophils in M4 with associated inv(16) chromosome abnormality
AML-M5a (2%–7%)	≥80% monocytic cells; monoblasts ≥80% of monocytic cells; monoblasts and promonocytes NSE positive; monoblasts usually MPO and SBB negative
AML-M5b (2%–5%)	≥80% monocytic cells; monoblasts ≥80% of monocytic cells; promonocytes predominate; monoblasts and promonocytes NSE positive; promonocytes may have scattered MPO- and SBB-positive granules
AML-M6 (3%–5%)	≥50% erythroid precursors: ≥30% of nonerythroid precursors are myeloblasts; Auer rods may be present in myeloblasts; dysplastic erythroid precursors frequently are PAS positive
AML-M7 (3%–5%)	≥30% blasts; ≥50% cells megakaryoblasts by morphology or electron microscopy; immunophenotyping $CD41^+$, $CD61^+$

AML, acute myeloid leukemia; CD, cluster designation; FAB, French-American-British; MPO, myeloperoxidase; NSE, nonspecific esterase; PAS, periodic acid–Schiff; SBB, Sudan black B; TdT, terminal deoxynucleotidyl transferase. (Percent of all AML)

original FAB classification with some modifications, namely, APL (M3 and M3 variant) is no longer included as a separate subtype but is placed with the group AML with recurrent genetic abnormalities, which is defined by cytogenetics and not morphology, percent blasts, or immunophenotyping. Pure erythroleukemia has been distinguished from erythroleukemia, acute erythroid/myeloid type; acute basophilic leukemia (very rare) has been added, as is a rare entity termed *acute panmyelosis with myelofibrosis* and the solid tumor myeloid sarcoma. The WHO classification now is widely accepted by most cooperative groups and is replacing the FAB classification of AML. It is expected that the WHO classification will continue to evolve as new biologic markers become available. The new WHO classification requires greater interexchange among the pathologist, clinician, and cytogeneticist for the diagnosis and classification of AML.

When evaluating a patient with acute leukemia, the most important initial morphologic distinction is between AML and ALL or one of the MDSs. The prognosis and therapeutic strategies remain very different for patients with these disorders. In most cases the morphologic, cytochemical, and immunophenotyping analyses will define the appropriate lineage and diagnosis. The MDSs are most frequently confused with acute erythroid leukemia or hypoplastic AML.[243] In cases where nucleated erythroid cells constitute greater than 50% of all bone marrow nucleated marrow cells, the diagnosis may be difficult. In these cases, if the combined number of blasts, type I, and II is less than 20% of the nonerythroid elements (excluding lymphocytes and plasma cells), the case is classified as MDS. If the nucleated red cells comprise less than 50% of bone marrow cells, the percent of blasts is calculated as the percent of all nucleated cells (excluding lymphocytes and plasma cells). In many cases, the difference between an MDS and AML is a difficult diagnostic problem. The AMLs with no or minimal differentiation, the monoblastic leukemias without differentiation, and some of the acute megakaryocytic leukemias (AMKLs) can be difficult to differentiate from ALL by morphology or cytochemical stain alone. In these instances, immunophenotypic studies with lineage-specific monoclonal antibodies are critical.

Subtypes of Acute Myeloid Leukemia According to World Health Organization Classification (see Table 60–7)

The WHO classification explicitly defines AML subtypes with recurrent genetic abnormalities. As a group, these AMLs are relatively common and have chromosomal translocations that result in the production of chimeric proteins, which are pivotal in the leukemogenic process. These genetic abnormalities define a specific biology, clinical course, and prognosis, so classifying them separately is important. In this group of cases, the diagnosis is defined by the cytogenetic abnormalities and is not dependent on the number of blasts in either the bone marrow or blood.

Acute Myeloid Leukemia with Recurrent Genetic Abnormalities

The WHO incorporates a new approach to AML with this subclassification of AML. As a group, AMLs with recurrent genetic abnormalities are frequent and exhibit characteristic morphologic, immunophenotypic, genetic, and clinical features. Their clinical course is well defined, and their prognosis, except for those with involvement of the *MLL* gene, is generally favorable.[207,244] This subtype includes patients with AML associated with abnormalities of the CBFs. The CBFs are a group of heterodimeric transcriptional factors essential for normal hematopoiesis. The CBF-associated AMLs include the leukemias with t(8;21) and inv^{16}. The chimeric CBFs resulting from these genomic rearrangements interfere with the normal CBF transcriptional complex, leading to transcriptional repression of CBF-responsive genes and inhibition of normal myeloid differentiation.[125] CBF leukemias generally occur in younger patients (median age 39 years), with a slight male predominance. They respond to standard induction therapy.[245] The complete remission (CR) rate is 87% with both t(8;21) and inv^{16}, and the CBF-associated AMLs have a generally favorable prognosis. However, as with the other AML subtypes, other prognostic factors affect the response to treatment and overall survival. Older age, presence of blasts with additional complex cytogenetic abnormalities, and presence of *KIT* mutations are associated with a worse prognosis.[246] Patients who present with a higher blast count at diagnosis have a shorter overall survival and a poor response to treatment. In this subtype, the overall survival was improved for younger patients who received a more intensive treatment regimen that contained either high doses of cytarabine or a stem cell transplant.[247,248]

Table 60–8 Relationship between the WHO and the FAB classifications of Acute Myeloid Leukemia
World Health Organization (WHO) Classifications of Acute Myeloid Leukemia

WHO subtype	FAB subtype equivalent	WHO to FAB
Acute myeloid leukemia with recurrent genetic abnormalities		
- Acute myeloid leukemia with CBFα fusions – t(8;21)		M2
- Acute myeloid leukemia with CBFβ fusions – inv(16)		M4eo
- Acute myeloid leukemia with RARα fusions – t(15;17)		M3, M3v
- Acute myeloid leukemia with 11q23 translocations – MLL		M5a, M1, M0
Acute myeloid leukemia with multilineage dysplasia		
Acute myeloid leukemia, therapy related		M5, M1, M2, M0
Acute myeloid leukemia not otherwise categorized		
- Acute myeloblastic leukemia, minimally differentiated	Acute myeloblastic leukemia, minimally differentiated (M0)	M0
- Acute myeloblastic leukemia, without maturation	Acute myeloblastic leukemia, without maturation (M1)	M1
- Acute myeloblastic leukemia, with maturation	Acute myeloblastic leukemia, with maturation (M2)	M2
	Acute promyelocytic leukemia, hypergranular (M3)	M3
	Acute promyelocytic leukemia, hypogranular (M3v)	M3v
- Acute myelomonocytic leukemia	Acute myelomonocytic leukemia (M4)	M4
	Acute myelomonocytic leukemia, with eosinophilia	M4eo
- Acute monoblastic leukemia and monocytic leukemia	Acute monoblastic leukemia (M5a)	M5a
	Acute promonocytic Leukemia (M5b)	M5b
- Acute erythroleukemia (erythromyeloid)	Acute Erythroleukemia (M6a)	M6a
- Pure erythroid Leukemia	Acute Erythroleukemia (M6b)	M6b
- Acute Megakaryoblastic leukemia	Acute Megakaryoblastic leukemia (M7)	M7
- Acute basophilic leukemia		-
- Acute panmyelosis with myelofibrosis		M7
- Myeloid sarcoma		-
Acute myeloid leukemia of ambiguous lineage		
- Unifferentiated acute leukemia		
- Bilineal acute leukemia		
- Biphenotypic acute leukemia		

Acute Myeloid Leukemia with t(8;21)(q22;q22), (AML1/ETO) (RUNX/CBFA2T1) (Core-Binding Factor Acute Myeloid Leukemia) (Fig. 60–10) (8;21) (10%–30% of Acute Myeloid Leukemia; M2 by FAB Classification)

AML with t(8;21)(q22;q22) is one of the most common subtypes of AML.[249–251] It occurs most frequently in younger adults and less frequently in elderly patients. Most cases are de novo AML, but the frequency is also increased after administration of topoisomerase II inhibitors.[252] Extramedullary disease and splenomegaly are noted in 20% and 25% of patients, respectively.[227] Patients with t(8;21)(q22;q22) generally respond to standard remission induction standard chemotherapy and have a favorable prognosis.[248] Morphologically the blasts demonstrate evidence of maturation to and beyond the promyelocyte. The blasts may exhibit nuclear clefting with large ill-defined nucleoli. Auer rods are common and typically are thin and elongated. Most of the cells have a basophilic cytoplasm with small azurophilic granules. In a minority of cases, blasts, promyelocytes, and myelocytes exhibit prominent basophilic granules (pseudo–Chédiak-Higashi granules). Increased marrow eosinophils and/or basophils are not infrequent, but monocytes and promonocytes are generally not increased. Prominent dysplastic features in the neutrophils are common. Dysplastic erythroid or megakaryocytic precursors are rare. The neutrophilic dysplastic features are not associated with a poorer response to therapy or change in the otherwise favorable prognosis of this subtype. Myeloblasts are strongly positive for MPO and SBB, often with a "clumpy" cytoplasmic pattern. CAE is positive as well, reflecting maturation beyond myeloblasts.

Immunophenotype. Blasts in most cases of AML with t(8;21)(q22;q22) exhibit characteristic immunophenotype. Blasts express the stem cell markers CD34 and CD117 and the myeloid markers CD13 and CD33. Blasts are HLA-DR$^+$ and CD11b$^-$ and CD15$^-$, although the latter two are also strongly expressed by the maturing neutrophilic component. CD14 and CD64, two monocytic markers, usually are negative. The blasts characteristically coexpress lymphoid markers including CD19, occasionally CD56, but only rarely CD2 or CD7.

Cytogenetics and Genetics. In the majority of cases, t(8;21)(q22;q22) is present on standard GTG-banded karyotypes. In a minority of patients, t(8;21)(q22;q22) is not detectable by conventional cytogenetics. These patients harbor either complex karyotypes or cryptic translocations that can be detected by FISH analysis using RUNX and CBFA2T1 nucleic acid probes. Frequent secondary cytogenetic abnormalities in t(8;21) AML are loss of a sex chromosome, loss of part or all of chromosome 9q, trisomy 8, and trisomy 4.[245,247,253] These additional cytogenetic abnormalities, when adjusted for age and white blood count, are not associated with a worse prognosis.[245,247] However, the presence of additional complex cytogenetic abnormalities is associated with poorer overall survival.[245,247]

Acute Myeloid Leukemia with Abnormal Bone Marrow Eosinophils and inv^{16} (p13;q22) or t(16;16)(p13;q22), (CBFB/MYH11) (Fig. 60–11) (5%–10% of AMLs; M4Eo by FAB Classification)

AML with inv^{16} has differentiating characteristics of both neutrophils and monocytes. A distinguishing morphologic feature is the presence of abnormal eosinophil precursors in the bone marrow. Patients with *CBFB/MYH11* fusion genes often present with a high WBC count (range 30,000–100,000/μL) and hepatosplenomegaly.[254] Extramedullary disease, gingival hypertrophy, leukemia cutis, and meningeal leukemia are more common in this subtype than in the less well-differentiated myeloid leukemias. Extramedullary disease (myeloid sarcomas) may be present at the time of diagnosis or may be the

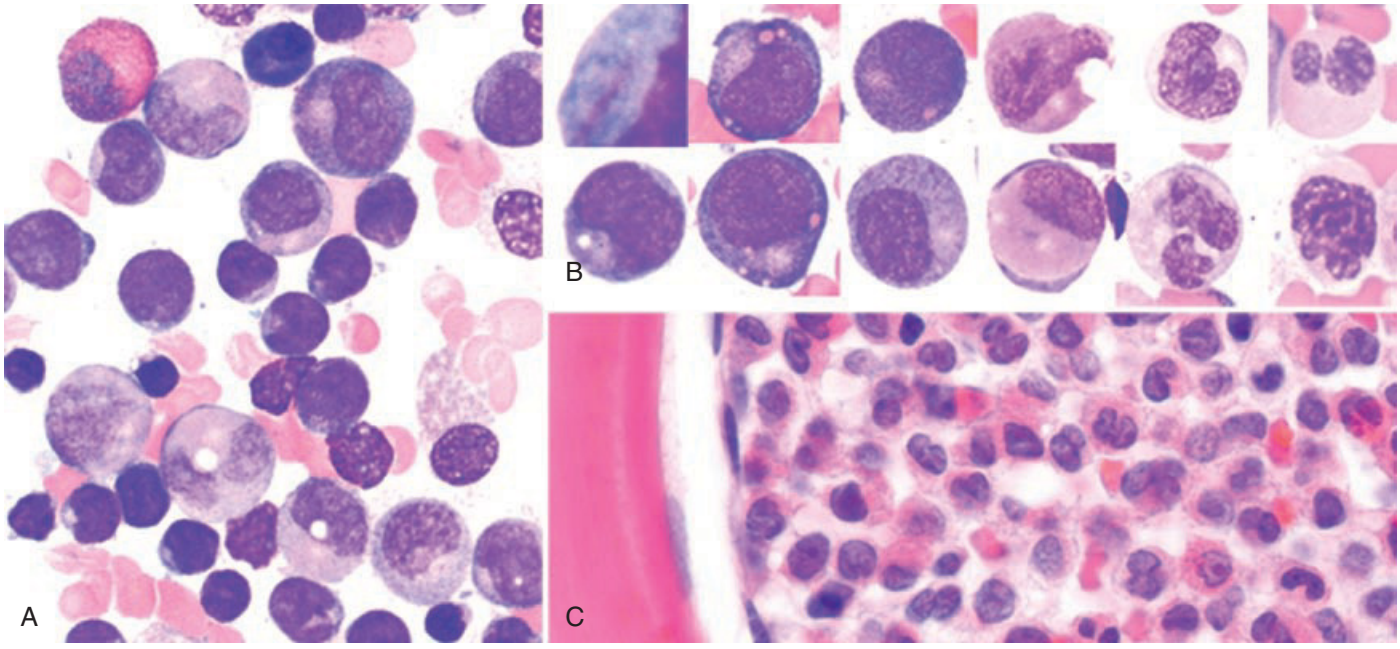

Figure 60–10 Acute myeloid leukemia with t(8;21)(q22;q22), *(AML/ETO)*. **A,** Low-power, Wright-stained bone marrow aspirate smear showing increased blasts associated with differentiating myeloid cells. **B,** Details illustrating some of the features associated with the leukemia. They include blasts with long thin Auer rods (top left), immature cells with abnormal eosinophilic globules (top and bottom, second from left), abnormal salmon-colored granulation in the maturing cells, sometimes associated with a basophilic periphery (top and bottom, fourth from left), and slightly abnormal features in the mature neutrophils (far right). Pseudo–Chédiak-Higashi granules were not seen in this case. **C,** Biopsy shows the significant degree of maturation that is sometimes seen. In some cases the blast count is less than 20%, but the diagnosis of acute myeloid leukemia still can be made with the cytogenetic finding of t(8;21).

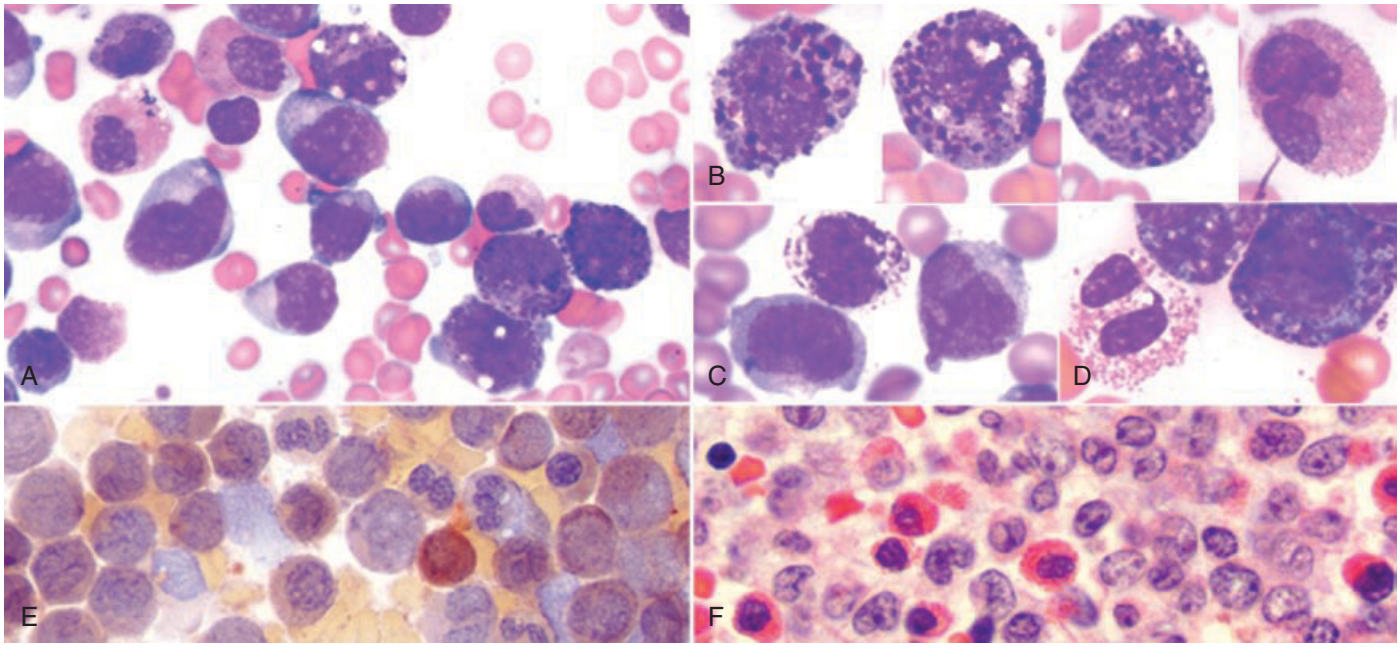

Figure 60–11 Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16)(p13;q22) or t(16;16)(p13;q22), *(CBFB/MYH11)*. **A,** Low-power, Wright-stained bone marrow aspirate showing blasts, monocytic cells, granulocytic cells, and abnormal eosinophils. **B,** Features of the abnormal eosinophils in three abnormal eosinophils (left three cells). Note the abnormal basophilic granules in the eosinophilic myelocytes. These granules are large, tend to cluster or coalesce, and are interspersed among the large eosinophilic granules, which are more difficult to see. As the eosinophils mature, the abnormal basophilic granules are less prominent and sometimes disappear (far right). A common misconception is that the basophilic granules are the granules of basophils and that the abnormal eosinophils are "hybrid cells." This is not true. **C,** Basophil in the same case (top cell) shown for comparison. **D,** Some cells from a case of reactive eosinophilia also shown for comparison. Immature eosinophils (cell to the right) have primary blue granules. However, they usually are less prominent and less atypical than the basophilic granules of the abnormal eosinophils. Of note, the monocytes in cases of acute myeloid leukemia with inv(16) or t(16;16) sometimes are ANA-reaction negative. **E,** ANA reaction. **F,** Abnormal eosinophils cannot be recognized in hematoxylin and eosin-stained sections of the biopsy sample.

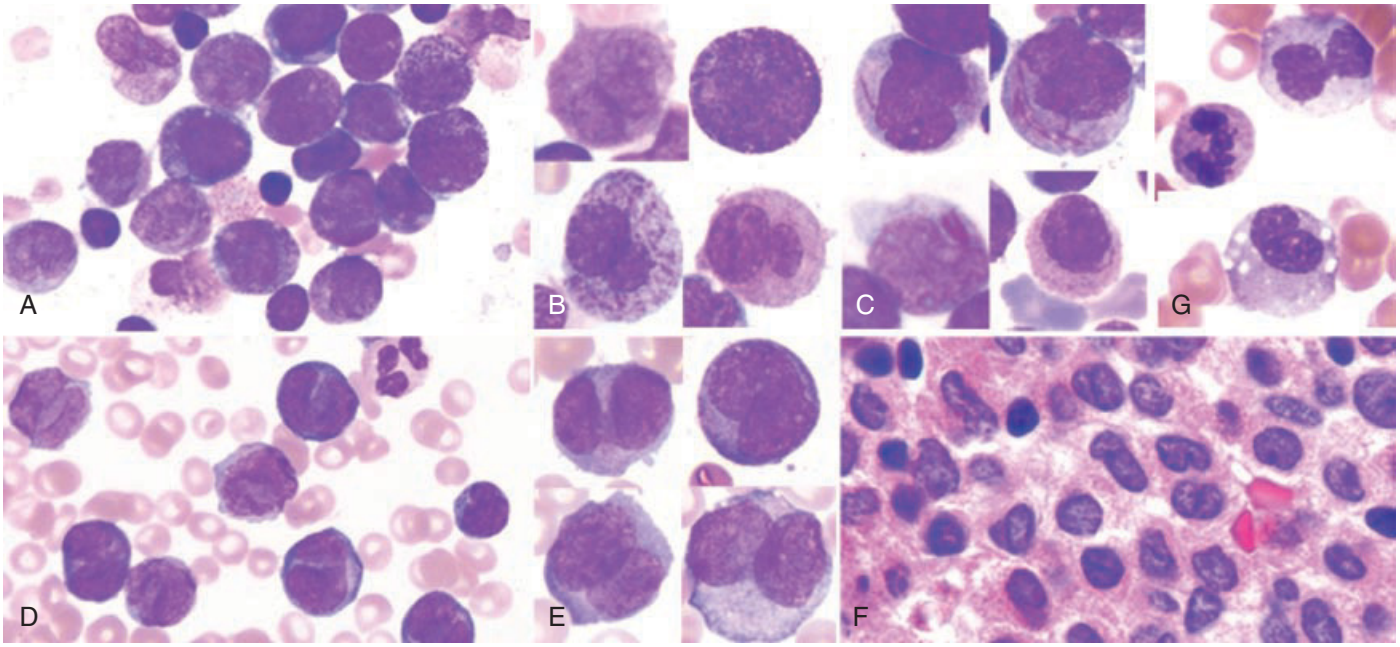

Figure 60–12 Acute promyelocytic leukemia (APL), acute myeloid leukemia with t(15;17)(q22;q21) *(PML/RARA)*. **A–C,** APL. **D, E,** Hypogranular or microgranular subtype. **F,** Bone marrow biopsy. **G,** APL cells maturing after all-*trans* retinoic acid (ATRA) therapy. In the typical granular type of APL **(A)**, the abnormal promyelocytes can exhibit variable morphologic features. Even within the same case, the granules can range from coarse, dark, and dense to fine and dust-like **(B)**. The nuclei in the abnormal promyelocytes frequently exhibit a bilobed, dumbbell, or reniform shape. This is a diagnostically important feature, which can be difficult to recognize beneath the granules **(B)**. Auer rods can be single, multiple, coalesced into Auer bodies, or even present in maturing cells **(C)**. The microgranular type usually presents with an elevated white blood cell count **(D)**. Although granules cannot be readily appreciated at the light microscope **(E)**, granules can be demonstrated by electron microscopy. The abnormal nuclear shapes (bilobed, dumbbell, and reniform) can be easily appreciated **(E)**. Bone core biopsy typically reveals sheets of cells with abundant granular cytoplasm. After ATRA therapy, the abnormal promyelocytes mature to abnormal neutrophils (**G**, top and bottom right, vs normal neutrophil, left). These can be seen for weeks after therapy and do not signify a failed response to the differentiating agent.

first evidence of a relapse.[254] The peripheral blood typically has myeloblasts and increased monocytes, but abnormal-appearing eosinophils frequently are absent. Patients with *CBFB/MYH11* AML have a favorable overall prognosis. The bone marrow has morphologically and cytochemically abnormal eosinophil precursors that are part of the leukemic clone.[255] In addition to eosinophilic secondary granules, eosinophil myelocytes and metamyelocytes exhibit characteristic cytoplasmic basophilic granules, which are numerous and are larger than the usual primary granules of promyelocytes. Less than 20% blasts may be present in the bone marrow, but patients with this characteristic cytogenetic abnormality still should be diagnosed with AML *CBFB/MYH11*. Auer rods are frequently present but only in myeloblasts or rarely in mature neutrophils, but not in monoblasts or promonocytes. Some cases do not present with abnormal eosinophils in the bone marrow or blood. These atypical cases morphologically resemble acute myelomonocytic leukemia (AMML), acute monoblastic leukemia, or AML with or without maturation. Cytochemical stains are helpful in identifying the monocytic and granulocytic cells in the peripheral blood and bone marrow. Myeloblasts typically stain with MPO and SBB. CAE is present in the more mature granulocyte precursors and, unlike in normal eosinophils, is present in abnormal eosinophils. Monoblasts usually are negative or only weakly positive for nonspecific esterases. Serum and urinary lysozyme levels, reflecting the monocytic component, frequently are elevated. The eosinophilic secondary granules stain positive with SBB, CAE, and nonspecific esterases, which is typical of granulocytic but not eosinophilic precursors. The hybrid morphologic and histochemical features of monocytes, eosinophils, and granulocytes in these cells result from abnormal differentiation of a primitive uncommitted leukemic cell.

Immunophenotype. Blasts typically are positive for panmyeloid antigens CD13 and CD33 but also for a variable number of monocytic markers, including CD14, CD11c, CD64, and CD4. CD34 and CD117 usually are positive. Blasts may also express the T-cell antigen CD2 but usually are negative for CD7. Dim or absent expression of CD33 in cells expressing high levels of CD34 and CD13 is relatively specific for *CBFB/MYH11* AML.[256–258]

Cytogenetics and Genetics. All patients with AML with abnormal marrow eosinophils have either a pericentric inversion of chromosome 16 or a balanced translocation between chromosome 16 homologues that transpose bands p13 and q22, leading to fusion of genes *CBFB* and *MYH11*.[254,259] The most common secondary chromosomal abnormalities in the typical *CBFB/MYH11 AML* are trisomy 22, trisomy 8, and 7q–. *KIT* mutations occur in up to one third of AML with *CBFB/MYH11* and are associated with a shorter disease-free response.[260,261]

Acute Promyelocytic Leukemia: Acute Myeloid Leukemia with t(15;17)(q22;q21) (PML/RARA) or t(11;17)(q23;q12) (PLZF/RARA) or t(5;17)(q23;q12) (NPM/RARA), or t(11;17)(q13;q12) (NuMA/RARA) (Fig. 60–12) (5%–10% of Acute Myeloid Leukemia; FAB M3, M3v by FAB Classification)

APL is characterized by distinctive morphology, younger patient age at presentation, associated coagulopathy, and unique response to treatment with all-*trans* retinoic acid (ATRA). In APL,

t(15;17)(q22;q21) results in fusion of the *RARA* gene on chromosome 17 with the *PML* gene on chromosome 15. RARA is a member of the nuclear steroid hormone receptor family and is important in the regulation of cellular differentiation. Normally, RARA heterodimers bind to promoter retinoic acid response elements (RARE) and recruit chromatin repressors, shutting down transcription. Upon binding to retinoic acid, RARA releases repressors and recruits transcriptional activators, reestablishing gene expression. PML/RARA retains RARE binding function and binds chromatin repressor more strongly.[262] Treatment of patients with APL with ATRA results in differentiation of leukemic cells, with approximately 70% to 85% of patients attaining CR.[263] APL has two morphologic variants: a "typical" or hypergranular variant found in 75% of cases and a less frequent microgranular (hypogranular) variant.[264] These two variants differ in clinical presentation, prognosis, and morphologic features.[263,265–269] The typical APL is hypergranular. Patients present with a low WBC count (3000–15,000/μL); a majority present with WBC count less than 5000/μL. Patients with microgranular APL typically present with a higher WBC count (range 50,000–200,000/μL). Leukostasis and fatal CNS or pulmonary hemorrhage are more common in patients with the microgranular variant.[270] The clinical features of APL depend to some extent on the type of fusion transcript resulting from the translocation.[271] APL with PLZF/RARA: t(11;17) or NPM/RARA: t(5;17) usually present with leukocytosis, which can be as high as that seen in the microgranular variant. APL with PLZF/RARA is resistant to therapy with ATRA as well as with arsenic trioxide.[272,273]

Patients with APL often present with thrombocytopenia, prolongation of prothrombin time and partial thromboplastin time, increased levels of fibrin degradation products, and hypofibrinogenemia. The coagulation disorder in APL results from at least three distinct mechanisms: disseminated intravascular coagulation, fibrinolysis, and proteolysis.[272] Disseminated intravascular coagulation is attributed to the spontaneous or chemotherapy-associated release of a tissue factor with procoagulant activity present in the granules of the leukemic promyelocytes. However, the bleeding disorder, cannot always be related solely to disseminated intravascular coagulation. Many patients have signs of primary fibrinolysis. The promyelocytic leukemic cell has both strong procoagulant activity on its cell membrane and proteolytic activity in the cytoplasmic granules, a combination that is unique to the leukemic promyelocyte and may explain the severe coagulopathy seen in some patients. Enhanced fibrinolysis is suggested by the increase in fibrin/fibrinogen degradation products, reduced α_2-antiplasmin levels, and normal antithrombin III and protein C levels present in all patients at diagnosis and up to initiation of therapy. Plasma from patients with APL has a plasminogen activator of tissue origin. APL cell express high levels of annexin II on their cell surface.[274] Annexin II is a fibrinolytic protein that increases the efficiency of plasmin formation.

Proteolysis is due to release from the leukemic cells of lysosomal neutrophilic enzymes, human leukocyte elastase, cathepsin G, and proteinase 3, all of which can cleave fibrinogen.[275] Leukemic promyelocytes also express high levels of tissue factor, a membrane glycoprotein that functions as a receptor for factor VII and as a site of activation of factor VII to VIIa. Tissue factor is an initiator of coagulation in normal tissues and may be a cellular activator of the coagulation system in malignant diseases.[276] The coagulopathy is present at diagnosis in 80% to 90% of cases and is exacerbated by cytotoxic chemotherapy. Treatment of bleeding disorders in patients with APL is controversial. Supportive therapy with fresh frozen plasma, fibrinogen, and platelets should be given until the coagulopathy resolves.[263] Use of ATRA with or without chemotherapy has changed the prognosis, course, and management of APL. The bleeding and clotting problems generally respond promptly to treatment with retinoic acid.

The microgranular variant occurs in approximately 20% of cases. It typically presents with a very elevated WBC count (frequently >100,000/μL), and the cells have minimal rather than excessive cytoplasmic granulation.[264] Patients have the typical t(15;17) of the "standard" hypergranular promyelocytic leukemia. The microgranular form can be confused morphologically with a monocytic leukemia. A minority of patients with the microgranular variant present with hyperbasophilic cytoplasm and cytoplasmic projections that may resemble megakaryoblasts. In the microgranular variant, the appearance of blasts in the peripheral blood and bone marrow may be very different.

The promyelocytes of hypergranular APL are larger than normal promyelocytes, and the nucleus varies from folded to reniform to bilobed. Granules may be so numerous that they obscure the nuclear outline. Auer rods may be so numerous as to form Auer bundles *(faggot cells)*.[222,277] Promyelocytes are strongly positive for SBB, MPO, and CAE.[277] Patients with the microgranular variant of APL present with abnormal promyelocytes devoid of normal primary azurophilic granules, and Auer rods are rare.[278] The cytoplasm may appear transparent and devoid of granules, or they may appear dusty, sometimes with large clusters of dust-like granules polarized within the cytoplasm. Electron microscopic studies demonstrate that the promyelocytes of microgranular APL have numerous granules smaller than 250 nm, which is below the limit of resolution of ordinary light microscopy.[279] The nucleus is irregular, folded or bilobed with delicate chromatin and inconspicuous nucleoli. As in the hypergranular form, the abnormal promyelocytes of microgranular APL are strongly reactive for MPO and CAE. The morphologic features of APL with the variant translocations may differ from those of typical APL.[280] For instance, APL with NPM/RARA generally lacks Auer rods, whereas APL with PLZF/RARA exhibit round nuclei, more condensed chromatin, and abundant cytoplasm that is less basophilic, suggesting that cells are arrested at the promyelocyte/myelocyte stage rather than the promyelocyte stage, as is typical of APL.[280] Additionally, Pelger-Huet–like cells are frequent in PLZF/RARAAPL.[280]

Immunophenotype. Both hypergranular and microgranular APL with PML/RARA fusion have characteristic immunophenotypes.[281,282] Cells strongly express CD33, lack or weakly express HLA-DR, are $CD34^-$, and frequently coexpress CD2 and CD9. The cells can express variable amounts of CD13, whereas more mature myeloid and monocytic markers, such as CD11b, CD14, and CD15, are expressed weakly or not at all.[281,282] The phenotype of the microgranular variant of APL is similar to that of the hypergranular form but may be $CD34^+$ and $CD2^+$ and express greater amounts of CD45.[283,284] CD56 expression is both variants correlates with lower CR rate and shorter overall survival.[280,285,286]

Cytogenetics and Genetics. t(15;17)(q22;q21) is present in 85% of APLs patients with PML/RARA. The remainder of cases have a cryptic PML/RARA (4%), have complex translocations masking t(15;17) (2%), or are cytogenetic failures.[287,288] FISH is useful for demonstrating cryptic or complex translocations. t(15;17) can rarely not be detected by FISH because of small insertion events that may be missed by large locus-specific FISH probes.[289] PML/RARA–negative APLs result from t(11;17)(q23;q12) due to PLZF/RARA fusion (0.8%), t(5;17)(q23;q12) leading to NPM/RARA fusion (0.2%), or t(11;17)(q13;q12) resulting in NuMA/RARA fusion (<0.1%). RARA fusions not involving PML account for only 2% of all cases of APL.[288] Secondary chromosome abnormalities present at diagnosis do not confer a poor prognosis.[290,291]

Acute Myeloid Leukemia with 11q23 (Mixed Lineage Leukemia) Abnormalities (Fig. 60–13) (5%–10% of Acute Myeloid Leukemias; FAB M5 by FAB Classification)

Acute leukemias with abnormalities of the *MLL* gene (also known as HRX or ALL-1) are clinically and biologically heterogeneous. MLL leukemias include AMLs, ALLs, and leukemias of ambiguous phenotype.[292–294] Although the majority of AMLs with *MLL* abnormalities are therapy-related leukemias and are associated with prior exposure to topoisomerase II inhibitors, a subgroup of de novo AMLs presents with the *MLL* abnormality.[295] In infants with AML it is the most

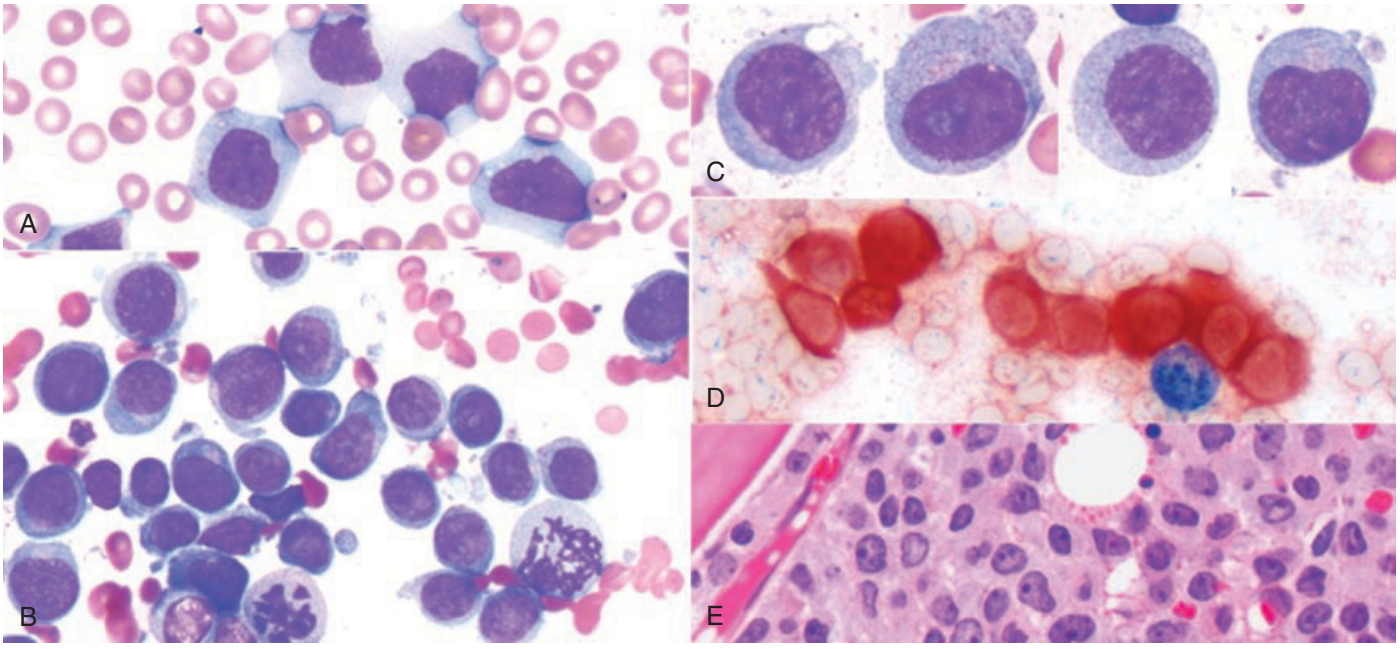

Figure 60–13 Acute monoblastic leukemia with t(9;11)((q31;q23), (*MLL* rearrangement). Case of acute monoblastic leukemia with t(9;11). **A,** Cases typically present with high counts due to circulating monoblasts. **B,** Bone marrow aspirate is packed with monoblasts and shows few granulocytic elements. **D,** Absence of a granulocytic component can be illustrated with the combined esterase reaction. Most cells show the α-naphthyl butyrate reaction product (orange–brown). Only rare granulocytes show the blue reaction product from the chloroacetate esterase reaction. **E,** The biopsy sample usually is packed with sheets of monoblasts with fine nuclear chromatin and abundant pink cytoplasm.

common cytogenetic abnormality, whether lymphoid, myeloid, or biphenotypic.[296–299] De novo AMLs involving the *MLL* gene present with high blood and marrow blast counts as well as higher platelet counts than typically seen in t-AML.[295] Hepatosplenomegaly and extramedullary disease are common. Patients with de novo AMLs with *MLL* translocations appear to have a better overall survival than those with t-AML/t-MDS, whether treated with conventional chemotherapy or marrow transplantation.[295] In infants, however, AML with *MLL* translocations is associated with a high blast count at presentation, hepatosplenomegaly, CNS involvement, and overall poor prognosis.[299] The blasts in de novo AML with *MLL* abnormalities resemble monoblasts. They are large and contain abundant cytoplasm that varies from pale to basophilic. Although primary granules often are present, they usually are small and inconspicuous. A minority of cases have blasts that resemble those of AML with or without maturation.

Immunophenotype. No immunophenotypic features are specific for AML with *MLL* translocation. Noninfant MLL leukemia with monoblastic morphology lacks CD34 and expresses markers of the monocytic lineage, including CD4, CD11b, CD11c, and CD36 but not CD14 or CD56. De novo AML with partial tandem duplication usually is $CD11c^{+}$.[300]

Cytogenetics and Genetics. The most common abnormalities of the *MLL* gene in de novo AML with karyotypic abnormalities of 11q23 are the reciprocal translocations t(9;11)(q34;q23), t(10;11)(p12;q23), t(11;19)(q23;p13.1), and t(11;19)(q23;p13.3) and in infants t(9;11)(q34;q23) and t(10;11)(p12;q23).[99,293,295,301–303] Additional 51 *MLL* partner genes have been characterized.[292]

Acute Myeloid Leukemias with "Disease-Defining Genetic Abnormalities" Not Included in the Current World Health Organization Classification

Not included in the current WHO classification are a number of other AMLs with recurrent genetic abnormalities. These abnormalities include translocations involving the genes *FGFR1*, *NUP98*, *MYST3 (MOZ)*, and *EVI1* and AML with t(6;9)(p23;q34), t(8;16) associated with hemophagocytosis. Leukemias with normal karyotypes and gene mutations, such as *NPM1*, *CEBPA*, and *RUNX (CBFA)*, currently are not addressed in the WHO classification (Table 60–9).

Acute Leukemia with Multilineage Dysplasia (Fig. 60–14)

AML with multilineage dysplasia is characterized by the presence of 20% or more blasts in the marrow and dysplasia in at least 50% of the cells belonging to at least two hematopoietic cell lines. This leukemia may occur de novo or after a preceding myelodysplastic/myeloproliferative or overlap myelodysplastic/myeloproliferative syndrome. The leukemia that occurs with a documented preceding MDS is best designated AML "evolving from a myelodysplastic syndrome." This type of AML occurs primarily in older individuals and often presents with pancytopenia. The incidence of this form of leukemia increases with age and shares cytogenetic, clinical, and biologic features with MDS. The prognosis with current AML therapy is very poor. MDS-related AMLs appear to differ biologically from de novo leukemias. The WHO emphasizes the background multilineage dysplasia and a documented history of MDS.

Morphology. Dysgranulopoiesis is characterized by neutrophils with hypogranular cytoplasm, hyposegmented nuclei (pseudo–Pelger-Huet anomaly), or multisegmented nuclei. Dyserythropoiesis is characterized by megaloblastic nuclei, with nuclear-to-cytoplasm asynchrony, nuclear fragments, or bizarre nuclei. Dysmegakaryopoiesis includes micromegakaryocytes and mononuclear or large multilobed megakaryocytes. The bone marrow may be hypocellular, normal cellular, or hypercellular.

Immunophenotype. Myeloblasts express lymphoid and/or myeloid markers. The blasts usually express CD34 and coexpress the myeloid markers CD13 and CD33 and the lymphoid marker CD7 or CD56.

Table 60–9 Genetically Defined Leukemias Not Included in the World Health Organization Classification

CURRENT AND PROPOSED MOLECULARLY DEFINED AML TYPES				
AML type[1]	HUGO[2] Gene Name	Karyotype[3]	Genotype[4]	Morphology/immunophenotype/clinical features[5]
Core binding factor (CBF) AML group	*RUNX1*	t(8;21)(q22;q22)	*RUNX1-RUNX1T1* fusion gene	AML with differentiation; coarse 1° granules, dysgranulopoiesis; favorable prognosis
•[6]	•	t(3;21)(q26;q22)	*RUNX1-EVI1* fusion gene	MDS > AML; acute megakaryoblastic leukemia; dysmyelopoiesis, ↓ platelets
•	•	t(1;21)(q36;q22)	*RUNX1-PRDM16* fusion gene	MDS > AML with minimal differentiation; AML w/o diff and AML differentiation
•	•	Normal	Acquired *RUNX1* point mutations	Up to 30% of AML with minimal differentiation; some AMKL; ~20% with FLT3 mutations
•	•	Normal	Germline monoalleic *RUNX1* point mutations	Familial platelet disorder with predisposition for acute myelogenous leukemia (FPD/AML).
•	*CBFB*	inv(16)(p13q22) t(16;16)(p13;q22)	*CBFB-MYH11* fusion gene	Acute myelomonocytic leukemia with abnormal eosinophils; extramedullary involvement (CNS, skin, spleen, liver); favorable prognosis
Retinoic acid receptor alpha (RARA) AML group	*RARA*	t(15;17)(q22;q12)	*PML-RARA* fusion gene	APL hypergranular (Auer rods, faggot cells) and microgranular variant (invisible granules); coagulopathy; ATRA sensitive; favorable prognosis
•	•	t(11;17)(q23;q12)	*PLZF-RARA* fusion gene	APL hypergranular with frequent mononuclear Pelger-Huet cells and absent binucleate promyelocytes; coagulopathy; ATRA resistent
•	•	t(11;17)(q13;q12)	*NuMA-RARA* fusion gene	APL hypergranular with bilobed and faggot cells; coagulopathy; ATRA sensitive
•	•	t(5;17)(q35;q12)	*NPM1-RARA* fusion gene	APL hypergranular with bilobed cells but absent Auer rods; coagulopathy; ATRA sensitive
MLL (mixed linage leukemia gene) AML group[7]	*MLL*	t(9;11)(p22;q23)	*MLL-MLLT3* fusion gene	De novo or therapy related (topo II inhibitors only) acute monoblastic/monocytic leukemia; CD34-; CD117-; poor prognosis
•	•	t(6;11)(q27;q23)	*MLL-MLLT4* fusion gene	•
•	•	t(10;11)(p12;q23)	*MLL-MLLT10* fusion gene	•
•	•	t(11;19)(q23;p13.1)	*MLL-ELL* fusion gene	•
EVI1 AML group	*PRMD3 (EVI1)*	inv(3)(q21q26) t(3;3)(q21;q26)	*EVI1::RPN1; RPN1_E::EVI1* enhancer effect	AML with multilineage dysplasia; therapy related AML ↑ platelet; trilineage dysplasia; prominent dysmegakaryopoiesis; poor prognosis
•	•	t(3;12)(q26;p13)	*ETV6-EVI1* fusion gene	•
•	*PRDM16 (MEL1)*	t(1;3)(p36;q21)	*RPN1_E::MEL1* enhancer effect	•
MYST AML group	*MYST3 (MOZ)*	t(8;16)(p11;p13)	*MYST3-CREBBP* fusion gene	De novo and therapy related acute monoblastic/monocytic or myelomonocytic leukemia; Erythrophagocytosis MPO+ NSE+ CD34– CD117– CD56+; poor prognosis
•	•	t(8;22)(p11;q13)	*MYST3-EP300* fusion gene	•
•	•	inv(8)(p11;q13)	*MYST3-NCOA2* fusion gene	•
